Familial hypertriglyceridemia is an autosomal dominant disorder that is characterized by overproduction of hepatic VLDL. The exact defect or mutation is unknown. Secondary factors that increase VLDL, such as diabetes, alcohol ingestion, and estrogen therapy, appear to exacerbate this condition. Low HDL associated with familial hypertriglyceridemia is related to increased catabolism. Individuals with this condition have hypertriglyceridemia (200 to 500 mg/dL) and low HDL-cholesterol (<35 mg/dL) at presentation. This diagnosis is considered in individuals who have a family and personal history of hypertriglyceridemia, CHD, and normal LDL levels. Cloudy infranatant after overnight refrigeration of plasma identifies a disorder of VLDL metabolism. Treatment starts with management of secondary factors that may exacerbate the condition. Dietary fat restriction (<10% of calories) and drug therapy with fish oil, niacin, and fibric acid derivatives should be initiated if target goals are not achieved.

For a deeper discussion on this topic, please see Chapter 195, “Disorders of Lipid Metabolism,” in *Goldman-Cecil Medicine*, 26th Edition.

Women's Health Topics

Vidya Gopinath, Yael Tarshish, Kelly McGarry

INTRODUCTION

The field of women's health grew out of the recognition that certain medical conditions are unique to women. Sex- and gender-specific differences exist in disease manifestation and management. Sex differences are defined as variations between males and females due to the specific composition and expression of their chromosomes. Gender differences are derived from sociocultural origins. For instance, women are disproportionately affected by poverty, intimate partner violence (IPV), unstable housing, substance use disorders, lack of transportation, lack of insurance, and the necessity of finding child care, all of which pose barriers to care and thereby influence their health. Variations in health outcomes between men and women are related to a complex interplay among lifestyle, environmental, behavioral, molecular, and cellular differences.

Women's health as a specialty focuses on conditions unique to women, diseases that disproportionately affect women, present differently or are managed in ways that are specific to women. Diagnoses unique to women include polycystic ovarian syndrome, menstrual irregularities, and endometriosis. Conditions that disproportionately affect women include breast cancer, osteoporosis, lupus, hypothyroidism, and urinary incontinence. Women have an increased susceptibility for developing certain conditions. For example, a woman who smokes the same number of cigarettes as a man is 20% to 70% more likely to develop lung cancer. Women are also more susceptible to alcohol-induced liver disease. Among individuals who consume 28 to 41 alcoholic beverages per week, the relative risk of alcohol-induced cirrhosis is 17.0 in women and 7.0 in men. During unprotected intercourse, women are 10 times more likely to contract human immunodeficiency virus (HIV) than men. The field of women's health has become more robust and includes practitioners from a multitude of disciplines: obstetrician-gynecologists, general internists, subspecialty internists, family medicine, emergency medicine, radiologists, and surgeons. Pharmacokinetics and pharmacodynamics of numerous drugs have sex-specific differences that are being discovered and require further study. The National Institutes of Health has made significant progress in the inclusion of women in clinical trials; they were historically excluded for numerous reasons including concerns about hormonal fluctuations affecting the data and teratogenic effects in women who were or could become pregnant. In 1977, the US Food and Drug Administration (FDA) recommended excluding women with "childbearing potential" from phase 1 and early phase 2 clinical studies. There is now growing recognition of the need for research studies to fully analyze sex-specific differences and include individuals of both sexes.

The seeds of this disparity in research and representation stem in part from the fact that women have been underrepresented in the

field of medicine. In 1849, Elizabeth Blackwell earned the first medical degree granted to an American woman, but the advancement of female physicians has been gradual. In 1950, only 6% of practicing physicians were female. Currently, female physicians make up 36% of the workforce. In 2017, for the first time, the number of women enrolling in US medical schools exceeded the number of men, with females representing 50.7% of the 21,338 new enrollees, compared with 49.8% in 2016. Given these statistics, women will have an expanding impact on shaping the profession and the world of health care.

In this chapter, we focus on medical issues unique to women and highlight what is known about sex and gender differences in common diseases. Although "females" and "women" are often used interchangeably, we recognize that biological sex and gender are not synonymous. We aim to be inclusive of sexual minorities and recognize that some topics may be relevant only to biological females or women who choose to have sexual relationships with males. For more detailed discussions of specific topics, please refer to the appropriate chapters in this edition of *Cecil Essentials of Medicine* and the 26th edition of *Goldman-Cecil Medicine*.

THE MENSTRUAL CYCLE

The menstrual cycle is a complex hormonal process resulting in the release of a single oocyte, an immature ovum or egg. The menstrual cycle consists of two phases, the follicular phase and the luteal phase. The follicular phase begins with the first day of menses. Several follicles grow until a single dominant follicle is selected. Meanwhile, the uterine endometrium gradually thickens. The follicular phase ends the day prior to the luteal hormone (LH) surge that marks the first day of the luteal phase. The LH surge initiates the release of the follicle from the ovary to travel down the fallopian tube to the uterine cavity. The luteal phase ends when either the oocyte becomes fertilized and implants in the endometrium or without fertilization, when levels of estradiol and progesterone decline. Without high levels of estradiol or progesterone, endometrial blood supply decreases, which then leads to sloughing of the endometrial lining and thus marks the onset of menses. The physiologic changes that define the menstrual cycle, including variations in hormones, the uterine lining, and morning basal body temperature, are graphically represented in Fig. 72.1. The average adult menstrual cycle is 28 to 35 days. Variability in length of cycle is common during adolescence; between ages 20 to 40 years old, women tend to have consistent cycle lengths.

Menstrual disorders are common and categorized as amenorrhea or abnormal uterine bleeding. Amenorrhea is defined as the lack of menses in a sexually mature female. It is further delineated as primary

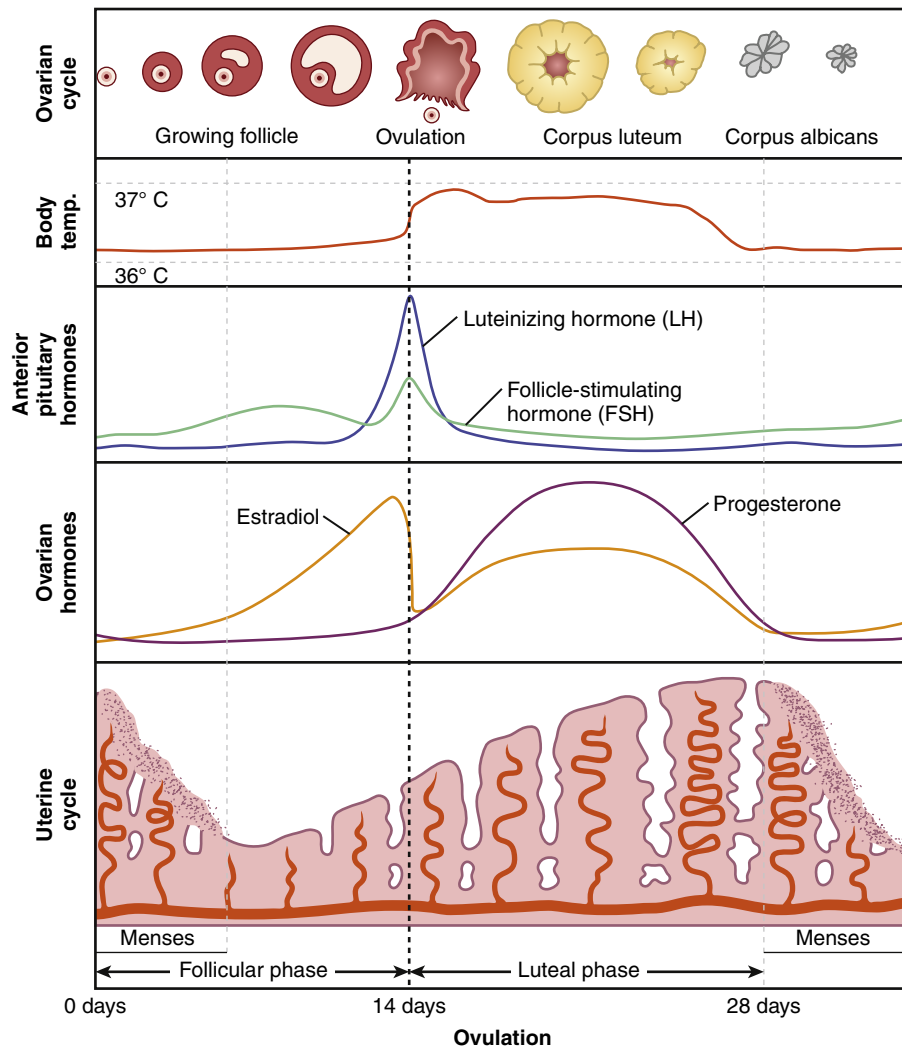

Fig. 72.1 The physiologic changes that define the menstrual cycle.

or secondary amenorrhea. These abnormalities may indicate problems related to the reproductive system or may be an early sign of an important underlying systemic illness. A pregnancy test must always be done to exclude pregnancy in cases of amenorrhea along with a thorough history and physical exam.

Primary Amenorrhea

Primary amenorrhea is most often caused by genetic or anatomic abnormalities. It is defined as the lack of menarche by age 15 or 16 despite normal sexual development or the lack of menarche by age 13 or 14 in the absence of sexual development. Breast development, the presence of a uterus, and levels of LH, follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and prolactin are important factors in determining the cause of primary amenorrhea. Work-up may include karyotyping and pelvic or brain imaging. The most common cause of primary amenorrhea is gonadal dysgenesis, which is found in Turner syndrome. The second most common cause is müllerian agenesis, a congenital malformation resulting in lack of uterine development and vaginal hypoplasia. If the uterus is present, an outflow tract obstruction such as an imperforate hymen or a transverse vaginal septum may be identified. FSH and LH levels can differentiate between functional hypothalamic amenorrhea and primary ovarian insufficiency.

Secondary Amenorrhea

Secondary amenorrhea is the absence of menses for 3 months in women with regular menses or 6 months in women with irregular menses outside of the setting of pregnancy or lactation. Oligomenorrhea occurs when menses are irregular or infrequent, with a cycle length usually greater than 35 to 40 days or fewer than nine menstrual cycles in 12 months, and it is often associated with chronic anovulation or oligo-ovulation. The most common cause of secondary amenorrhea is pregnancy. Lactation causes amenorrhea for up to 6 months in women who are exclusively breast-feeding. Prolonged amenorrhea can follow cessation of some hormonal contraceptives, especially depot medroxyprogesterone acetate (DMPA). Menopause should be suspected in a woman older than 45 years of age.

Amenorrhea and oligomenorrhea may be caused by pathologic changes at any point in the endometrial-ovarian-pituitary-hypothalamic axis. The differential diagnosis for other causes of secondary amenorrhea is broad. Most cases are associated with polycystic ovary syndrome (PCOS), hypothalamic amenorrhea, hyperprolactinemia or primary ovarian insufficiency.

PCOS and hyperandrogenism are associated with hirsutism, acne, and history of irregular menses. Hypothalamic amenorrhea can be functionally caused by stress, change in weight, diet or exercise or an eating disorder. Headaches and visual field deficits are concerning for hypothalamic-pituitary disease; galactorrhea indicates

hyperprolactinemia. Evidence of ovarian insufficiency includes symptoms of estrogen deficiency such as hot flashes, vaginal dryness, and decreased libido. Initial labs include FSH, TSH, prolactin, and possibly total testosterone. Pituitary MRI, progesterin withdrawal test, and hysteroscopy may be a part of the work-up if initial tests are unrevealing.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) affects approximately one third of women at some point in their life. Terms such as menorrhagia and metrorrhagia were updated in 2011 by the International Federation of Gynecology and Obstetrics. Instead they recommend use of the terms heavy menstrual bleeding (HMB), which is defined as ovulatory bleeding for more than 8 days or interfering with quality of life, and abnormal uterine bleeding with ovulatory dysfunction (AUB-O), which is defined as irregular bleeding.

In the PALM-COEIN classification, the etiology of HMB and AUB-O is divided into structural and nonstructural causes. The four main structural causes are polyp, adenomyosis, leiomyoma, and malignancy or hyperplasia. The five nonstructural causes are coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, and not yet classified.

Key elements of the history include details about bleeding, including the onset, duration, pattern, and quantity of bleeding. This history and information about breast tenderness and cramping prior to onset of bleeding can establish evidence of ovulatory cycles. The evaluation should also confirm the source of bleeding as uterine and not gastrointestinal, urinary, or vulvar. Pregnancy must be ruled out in all patients including those who are using contraception or deny being sexually active.

Evaluation includes a pelvic exam with a vaginal speculum and bimanual exam to characterize the uterus. Pap smear and cervical cultures should be obtained to assess for cervical disease or infection. Laboratory testing should include a complete blood count (CBC), thyroid studies, and serum ferritin. It may also include coagulation studies because a significant fraction (5% to 32%) of women with heavy menstrual bleeding have an underlying bleeding disorder.

Endometrial sampling should be performed for women age 45 or older and for women younger than 45 years of age who are at risk for endometrial hyperplasia or endometrial cancer (i.e., women with obesity or a history of chronic anovulation, failed medical therapy or persistent symptoms). For women with suspected structural abnormalities, a transvaginal ultrasound study should be pursued.

Management of abnormal bleeding depends on the underlying pathology identified and the degree of anemia caused by the bleeding. Hemodynamically unstable women may require uterine curettage or intravenous estrogen. For hemodynamically stable women, control of bleeding is usually achieved through a combination of estrogen and progesterin preparations, usually in the form of oral contraceptive pills. In women with a contraindication to estrogen, levonorgestrel-releasing intrauterine devices (IUDs) and high-dose oral progestins can be used. Irregular bleeding often continues with hormonal management but declines over time. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used by women who do not require contraception, because NSAIDs have been shown to decrease bleeding. Standard iron supplementation is recommended for patients with resultant anemia or iron deficiency. Surgical options include less-invasive treatments like endometrial ablation and uterine artery ablation as well as definitive therapy with hysterectomy. These are usually reserved for women who have failed other treatments, decline long-term medical therapy, and do not desire future pregnancy.

CONTRACEPTION

Approximately 62% of reproductive-age women in the United States are using some form of contraception and 99% of women who have

ever been sexually active with men have used a form of contraception in their lifetime. However, nearly half of pregnancies in the United States are unintended. When helping patients choose a contraceptive method, several important variables should be considered. Patient preference and likelihood of adherence to a given method are important components to consider in selecting a mode of contraception. Efficacy depends on appropriate use. Patients' past experiences with different forms of contraception and personal preferences help to predict how well they will adhere to current regimens. Observational studies have demonstrated patient-provider relationships are important in family planning care.

Obtaining a thorough personal and family medical history is important to determine what methods are appropriate for a patient. Certain medical issues can make a choice too risky for one patient but provide a health benefit for another. For example, oral contraceptives that increase the risk of thrombosis are contraindicated for a patient with a strong family history of venous thrombosis, but they could correct anemia in a patient with menorrhagia. The patient's sexual history and assessment of the risk for sexually transmitted infections (STIs) play a role in contraceptive choice and education about the use of barrier methods.

Methods of Contraception

Barrier methods include the diaphragm, cervical cap, male condom, and female condom. These methods do not disrupt fertility beyond their moment of use. The diaphragm and cervical cap need to be fitted by a medical professional and therefore require a prescription. With each sexual encounter spermicide must be applied and the device needs to be left in 6 to 8 hours after intercourse to be efficacious. The male condom can be purchased over the counter and is among the most cost-effective options. It has the added benefit of reducing the transmission of STIs. Prevention of conception and STI transmission depends on correct and consistent use: the male condom must be used during the entire sexual act. The female condom is also over the counter and protects against transmission of STIs, though there are less data on decreased STI transmission compared to male condoms.

Combination hormonal contraceptives are the most common form of hormonal birth control. They typically contain a low dose of estrogen ($\leq 35 \mu\text{g}$) and one of several progestins. Delivery methods include pills, patches, and intravaginal rings. These methods carry similar contraindications and have the same contraceptive mechanism: prevention of ovulation. Combined oral contraceptives (COCs) are classified as either monophasic, which release a constant hormone dose throughout the menstrual cycle, or multiphasic, which contain variable levels of hormones to be taken over the course of the month. Monophasic COCs are preferred because they have been more extensively studied, may be associated with improved mood variability compared to multiphasic formulations in susceptible women, and are simpler to use. No clear benefit has been demonstrated for multiphasic COCs. Continuous or extended cycle COCs allow for less frequent withdrawal bleeding and more control over timing of withdrawal bleeding, though this can be associated with more unpredictable bleeding. After cessation of combination hormonal contraceptives, menses typically return in 1 month. Fertility and menses are expected in all women within 90 days of stopping the medication.

The transdermal patch is applied weekly for 3 weeks per month followed by a week without the patch in order to allow for withdrawal bleeding. The patch is applied to a different site on the body each time. It delivers a higher average dose of estrogen but lower peak doses. One key difference between COCs and the patch is that the latter bypasses hepatic first pass metabolism; thus, the patch has fewer drug interactions and requires lower peak hormonal doses in order to be effective

as compared to COCs. Return to fertility can occur immediately after patch discontinuation because exogenous hormones reach very low levels within 3 days.

The ring is inserted vaginally and left in place for 3 weeks and then removed for 1 week to allow for withdrawal bleeding. Extended ring regimens are possible whereby a new ring is inserted the same day as the prior one is removed. This can be done every 3 weeks for up to a year to delay withdrawal bleeding, though it is associated with spotting. The patch and the ring are reasonable options for patients concerned with taking a daily medication.

Contraindications to combination hormonal contraception are related to the estrogen component. Contraindications include a personal history of a thromboembolic event or known thrombogenic mutation, cerebrovascular accident (CVA), coronary artery disease (CAD), uncontrolled hypertension, migraine with aura, smoking after age 35, breast cancer, estrogen-dependent neoplasms, undiagnosed abnormal vaginal bleeding, liver tumors, and pregnancy. There is no evidence that COCs cause weight gain. Upon initiation, some patients report breast tenderness, nausea, and bloating. Most symptoms go away quickly with continued use. Irregular bleeding typically resolves within 3 months. If COCs are started more than 5 days since onset of menses, back-up contraception is recommended for 7 days.

Potential noncontraceptive benefits of combination oral contraceptives include regulation of menstrual flow and improvement in ovarian cyst recurrence, endometriosis, chronic pelvic pain, acne, polycystic ovarian syndrome, hyperandrogenism, and mittelschmerz (i.e., midcycle pain). Long-term use of combination oral contraceptives has been associated with a reduced lifetime risk of endometrial and ovarian cancers. Bone density is higher in perimenopausal women who used COCs compared to women who did not.

Progesterone-only contraceptives are an option for women intolerant of estrogen or at increased risk for thromboembolic events. They can be taken continuously without a hormone-free interval. Contraindications include active CAD, breast cancer, hepatic tumor, and phlebitis. They are slightly less efficacious than the combination pills, and women may experience breakthrough bleeding. They have a short duration of action and half-life so they must be taken at the same time each day. Back-up contraception is required if a dose is taken more than 3 hours late. Upon cessation, the return of fertility is rapid. Compared to COCs, ovulation is not consistently suppressed.

DMPA is a progesterone-only injection administered every 12 weeks. Major side effects include irregular bleeding (which resolves over time) and amenorrhea (50% at 1 year). Weight gain, hair changes, and acne are possible side effects. The FDA issued a black box warning that DMPA may decrease bone density, especially in adolescents and perimenopausal women. This possible association between DMPA use and fracture risk remains controversial without definitive data; however, a retrospective cohort study found no significant fracture risk difference. Return to fertility can be delayed and is dependent on body weight: women with lower body weights conceive sooner after discontinuation as compared to women with higher body weight. If conception is desired within 1 to 2 years of initiating a contraceptive method, DMPA is not recommended.

The IUD can be a great option for women who do not desire pregnancy in the next 5 to 10 years. Worldwide, it is the most widely used method of reversible contraception. Two types of IUDs are available in the United States, and both are as effective as sterilization. The copper IUD can be left in 10 years. There are four progesterone-emitting IUDs available in the United States and they can be left in from 3 to 5 years depending on the formulation. The copper IUD can be associated with heavier menstrual bleeding and cramps. The progesterone IUD

may initially have breakthrough bleeding, but almost one half of users become amenorrheic. Return of fertility is rapid after removal of IUD.

The progesterone contraceptive subdermal implant was originally marketed as Implanon and is now Nexplanon. Unlike Implanon, Nexplanon is radiopaque. It is a 40-mm progesterone rod that is implanted under the skin of the upper arm and is highly effective for 3 years. It can be placed in outpatient offices and is helpful in reducing dysmenorrhea, but it is associated with irregular menses.

Postcoital emergency contraception (EC) can be achieved with one or several hormonal options or with placement of a copper IUD. EC is not considered an abortifacient. It functions to either disrupt ovulation or prevent fertilization. The copper IUD is the most effective option and can be used within 5 days of unprotected intercourse. Hormonal oral contraceptives can be used in a specifically formulated EC dose (Plan B) or off-label with a regimen of COCs. The recommendation is for use of Plan B within 72 hours of unprotected intercourse. It is available without a prescription. Efficacy of hormonal contraception decreases with increasing body mass index (BMI) above 25 kg/m². The only absolute contraindication to EC is pregnancy.

INFERTILITY

According to the Centers for Disease Control (CDC), 12% of US women have trouble conceiving. However, infertility is a unique medical condition in that it involves a couple rather than an individual. Infertility is a failure to conceive after 1 year of regular intercourse without contraception in women under age 35 or 6 months in women 35 years and older. The term fecundability is the probability of achieving pregnancy in one menstrual cycle. Impaired fecundity describes women who have difficulty getting pregnant or carrying a pregnancy to term. It is unclear if the prevalence of infertility has changed or if the heightened awareness of infertility is due to the combination of factors such as deferment of pregnancy to later in life, technological advances, and increase in awareness of infertility. Causes of infertility are likely varied among different demographic and socioeconomic groups.

Infertility may be caused by female factors, male factors or both. Approximately 20% to 30% of couples experience unexplained infertility. History should focus on menstrual and contraceptive history, surgeries, sexual dysfunction, medications, and family history of early menopause or reproductive issues. The physical exam should include a thyroid, breast and pelvic exam. The most common female cause is a problem involving ovulation (20% to 35%), followed by tubal disease (20% to 25%) and uterine factors (5% to 15%). Ovulatory dysfunction can be evaluated from patient report, but up to one third of women with normal menses are anovulatory; therefore, objective measures can be used to confirm ovulation with progesterone and LH levels, evaluation of cervical mucus and basal body temperature. Testing also typically includes TSH, FSH, and prolactin levels in women with irregular menses. Initial male evaluation includes semen analysis and a reproductive history. Further testing is performed by reproductive specialists and may include evaluation of ovarian reserve through a transvaginal ultrasound and hysterosalpingography to visualize the uterus and fallopian tubes and ensure tubal patency. The diagnosis of infertility is associated with significant stress for most couples and a provider's awareness can help to mitigate its effects.

PREGNANCY COMPLICATIONS AND RISK OF FUTURE DISEASES

During pregnancy, a woman is typically primarily cared for by her obstetrics provider. However, women with complex medical conditions or pregnancy complications may require a maternal fetal

medicine (MFM) specialist or an obstetric medicine specialist to participate in their care. MFM is a specialty in obstetrics and gynecology that manages high-risk pregnancies as well as unexpected complications in pregnancy such as a trauma to the mother, early labor, and bleeding. Obstetric medicine is a specialty of internal medicine that manages medical problems in pregnancy such as hypertension, kidney disease, thyroid disease, diabetes mellitus, and heart disease.

Pregnancy can be associated with exacerbations of chronic illnesses, unmasking a new illness or predicting future disease. An understanding of the long-term consequences of certain complications in pregnancy can smooth the transition back to primary care.

Gestational diabetes affects 4% to 8% of pregnancies in the United States. All pregnant women receiving routine obstetric care are screened for gestational diabetes. Women with a history of gestational diabetes are at increased risk for diabetes later in life. They should be screened 6 to 12 weeks postpartum with an oral glucose tolerance test and diagnosed with nonpregnancy diagnostic criteria for diabetes. They should have lifelong screening at least every 3 years.

Women whose pregnancies were complicated by a gestational hypertensive disorder, such as preeclampsia or gestational hypertension, are at increased risk for subsequent essential hypertension. A history of preeclampsia is associated with twice the risk of heart disease and stroke and four times the risk of hypertension. Currently, there are no additional screening or preventive interventions recommended for these women.

MENOPAUSE

Menopause is defined as the absence of a menstrual period for 12 consecutive months or the cessation of the menstrual cycle due to oophorectomy. The average age at menopause in the United States is 51 years, with a range of 40 to 58 years. Natural menopause prior to the age of 40 is considered premature ovarian failure. Menopause after the age of 55 is considered late menopause. The life expectancy of women in the United States is almost 80 years; therefore, many women spend at least one third of their lifetime in the postmenopausal period. Although symptoms such as hot flashes and vaginal dryness may develop during menopause, the process itself is a normal part of aging for women.

Transition From Perimenopause to Menopause

The transition to menopause can be erratic and prolonged over a 5- to 10-year period. It is characterized by ovarian and endocrine changes that ultimately result in the depletion of primordial oocyte stores and the cessation of ovarian estrogen production. An accelerated loss of follicles begins at about 37 years of age and is correlated with a small increase in FSH and a decrease in inhibin levels. As the FSH concentration increases, the follicular phase of the cycle decreases. One of the earliest clinical signs of the menopausal transition is shortening of the menstrual cycle from a mean length of 30 days in the early reproductive years to 25 days in the early menopausal transition.

Later in the menopausal transition, the few remaining follicles respond poorly to FSH, and anovulation may occur. Menstrual cycles may become erratic with prolonged periods of oligomenorrhea. Ovulation may still occur, and women in this time period are advised to continue effective contraception until 12 months of amenorrhea have occurred. Ultimately, when ovarian follicles are depleted, the ovary no longer secretes estradiol but continues to secrete androgens due to continued stimulation by LH.

Perimenopausal Symptoms

Menstrual irregularities are experienced by almost 75% of women and are usually the first change noticed by women entering the menopausal transition. Although changes in the menstrual flow are expected and

most women can be reassured, clinicians need to be aware of bleeding patterns that may represent underlying pathology and require evaluation.

Sleep disturbances in perimenopausal women are a well-documented phenomenon. Hot flashes can disturb sleep patterns and interfere with sleep quality, resulting in fatigue, irritability, and difficulty concentrating. Vaginal dryness and dyspareunia are common symptoms that can interfere with sexual function and increase the risk of urinary tract infections. Another genitourinary symptom that increases with age is urinary incontinence, which affects approximately 25% of postmenopausal women. The etiology is multifactorial. The endothelium of the bladder and urethra become more fragile and less elastic; urethral tone decreases with age. Uterine prolapse, cystoceles, rectoceles, and increasing BMI all increase the risk of urinary incontinence.

Change in mood is a common complaint during the menopausal transition, but a causative link between hormonal fluctuations and mood disturbances has not been established. Women who experience significant depression around menopause are more likely to have experienced depression earlier in their lives, particularly at times of hormonal change (e.g., postpartum depression, premenstrual dysphoric disorder [PMDD]). Mood issues during the perimenopausal transition should be approached in the same manner as at other ages.

In addition to mood symptoms, many women in perimenopause complain of difficulties with concentration and memory. A large multisite, multiethnic cohort study, the Study of Women's Health Across the Nation (SWAN), demonstrated that women had a small, transient decline in cognitive abilities during perimenopause. However, anxiety and depression also had independent negative effects on cognition. Most epidemiologic studies do not demonstrate an increased risk of depression or a decline in cognitive skills during the menopausal transition.

Hot flashes or vasomotor symptoms are the hallmark symptom of menopause. In the United States, up to 75% of women who experience a natural menopause and 90% of women who experience surgical menopause have vasomotor symptoms. Hot flashes may occur a few times per year or several times each day; 10% to 15% of women have hot flashes that are very frequent or severe. For most women, vasomotor symptoms are self-limited, lasting on average 1 to 2 years; however, up to 25% of women may have symptoms for longer than 5 years.

The exact cause of a hot flash is not understood, although it is related to a disturbance of hypothalamic thermoregulation. A hot flash consists of a sudden onset of a warm sensation over the face and upper body that ranges from mild to markedly uncomfortable. This may be accompanied by significant perspiration and typically lasts 2 to 4 minutes. It can be followed by chills. There are racial and ethnic differences in reported hot flashes, with African American women experiencing higher rates compared with white women and Hispanic and Asian women experiencing lower rates. Frequency of hot flashes is also affected by smoking, obesity, and stress.

In the 1950s, the use of estrogen to relieve hot flashes became widespread. In 1975, a study published in the *New England Journal of Medicine* showed that women who used estrogen for more than 7 years had a 14-fold increase in uterine cancer. Subsequent research determined that the increased risk of endometrial hyperplasia and uterine cancer is reduced to essentially zero when concurrent low-dose progestin is continued for 12 to 13 days per month. Women on estrogen with an intact uterus must use progestin therapy to prevent endometrial hyperplasia and cancer.

Menopausal hormone therapy (MHT) is the use of estrogen or combined estrogen and progestin for women with an intact uterus. MHT remains the most effective treatment of menopausal vasomotor symptoms. It is also FDA approved for the treatment of urogenital

atrophy and the prevention of osteoporosis. Evidence suggests that ultra-low-dose estrogen is sufficient to prevent bone loss. Although not FDA approved for treatment of osteoporosis, there is some research supporting its use in preventing fractures and increasing bone density.

Early epidemiologic studies demonstrated a decrease in coronary heart disease (CHD) events in women on MHT. However, the opposite conclusion was found in dedicated randomized trials. One large study demonstrated an overall null effect but an increased number of CHD events in the first year of treatment. Another large randomized controlled trial to evaluate MHT was stopped early because there was more harm than benefit with the treatment intervention. Therefore, menopausal hormone therapy is not recommended for primary prevention of CHD or chronic disease.

Postmenopausal Therapy

Hormone Therapy

Estrogen and estrogen-progestin therapy are appropriate and the most effective treatment for moderate to severe vasomotor symptoms. If hormone therapy is initiated, the lowest dose needed to treat the symptoms should be used and usually for short-term use. Women with a uterus require progesterone and estrogen. Combination MHT is recommended for 3 to 5 years total if initiated and limited by the increased risk of breast cancer. Estrogen-only therapy has a more favorable risk profile and can be used for 7 years in women without a uterus. Oral contraceptives can be used for management of menopausal symptoms for women who require contraception until age 51. The estrogen dose in oral contraceptives is 4 to 7 times higher than in MHT, and thus the use of COCs confers an unnecessary risk to postmenopausal women. One recommendation on determining ability to transition from oral contraception to MHT is to check FSH levels at age 50 to evaluate for menopause. Estrogen administration can be oral, transdermal, or topical. There are some minor differences in their risk profile. For example, transdermal estrogen is associated with decreases in blood pressure compared to oral administration. When administered transdermally, estrogen bypasses liver metabolism resulting in decreased angiotensin production thereby lowering blood pressure. MHT needs to be tapered when stopping because abrupt cessation could cause a recurrence of symptoms.

For women who have primarily vaginal symptoms such as vaginal dryness or urogenital atrophy, referred to as “genitourinary symptoms of menopause,” estrogen can be used transvaginally. Transvaginal estrogen can be high dose, in which case it has the risk profile of systemic oral or transdermal MHT. Low-dose transvaginal estrogen does not require progesterone in women who have a uterus and does not confer the same risks as systemic estrogen. For example, the low-dose estrogen ring releases 7.5 mcg of estradiol daily compared to the high dose ring that releases 50 to 100 mcg daily and is considered systemic estrogen.

Nonhormonal Therapies

During the 1990s, newer antidepressants that affect serotonin and/or norepinephrine (SSRIs and SNRIs) were observed to improve hot flashes. Randomized controlled trials studying the effects of SSRIs and SNRIs on vasomotor symptoms have demonstrated varied efficacy, but a large meta-analysis and systemic review found all SSRIs were more effective than placebo; escitalopram was found to be the most effective. However, the only FDA-approved nonhormonal treatment for hot flashes is paroxetine.

Gabapentin and pregabalin have also been demonstrated to decrease intensity and frequency of hot flashes. One study found the efficacy of gabapentin to be comparable to SSRIs. Clonidine is another nonhormonal option but is considered second line because it

is typically poorly tolerated due to dizziness and dry mouth. In practice, the SSRIs/SNRIs and gabapentin/pregabalin are commonly used off-label given demonstrated efficacy.

Complementary Therapy

As many as 75% of menopausal women have used some form of alternative or complementary treatment to relieve menopausal symptoms. Behavioral options such as dressing in layers, regular exercise, stress reduction techniques, and avoidance of known triggers are safe and may be helpful for many women. Cognitive behavioral therapy has also been demonstrated to be modestly effective. Some of the more common herbal remedies for menopausal symptoms include isoflavones and phytoestrogens (e.g., soy, chickpeas, red clover) and black cohosh. None of these therapies has been shown to decrease hot flashes beyond placebo.

BREAST PAIN, DISCHARGE, AND MASSES

Breast pain, masses, and nipple discharge are common symptoms that providers face when taking care of female patients. Women who present with breast symptoms often fear that any abnormality indicates the presence of malignancy. Although it is essential to keep breast cancer on the differential diagnosis throughout the clinical evaluation, most breast-related complaints are not manifestations of cancer. For example, in recent studies, breast pain was a presenting symptom in close to 6% of women who had breast cancer, whereas 70% of women report breast pain over the course of their lifetime.

Mastalgia

Breast pain can originate from the breast tissue itself, which is termed “true mastalgia,” or appear as referred pain from the chest wall. Chest wall pain is often isolated to the medial or lateral side of the breast. Intercostal nerves originating from T3 to T5 innervate the breast and nipple. Any irritation along their course can lead to pain experienced in the breast. Causes of nerve irritation include cervical and thoracic spondylosis, lung disease, and gallstones.

True mastalgia is often classified as cyclical or non-cyclical pain. Etiologies of non-cyclical pain include trauma, mastitis, superficial thrombophlebitis, cysts or tumors. Cyclical breast pain is the most common type of breast pain and is hormone dependent. The onset of pain occurs during the weeks before menstruation, and the start of menstruation marks resolution. A unifying etiology of cyclical breast pain remains unclear. Studies demonstrate that progesterone, prolactin, ratio of fatty acids, and type of estrogen receptors may play a role. The presence of breast pain in women on hormone replacement therapy suggests that hormones have a causative impact; however, hormone manipulation rather than concentration of estrogen appears to influence the occurrence of pain. Amount of caffeine intake has not been shown to have any impact on developing mastalgia, despite popular belief.

Evaluation of mastalgia often consists of age-appropriate breast cancer screening. Focal pain and pain that is progressively worsening may warrant further imaging. Unfortunately, obtaining a history of symptoms that follow a cyclical versus non-cyclical pattern has not proven to help differentiate between etiologies of pain.

Research shows that most women presenting with mastalgia respond well to reassurance. Adjustments in type of brassiere or additional breast support during the night can improve pain levels. Treatments with proven effectiveness for cyclical pain include danazol, tamoxifen, progestogen, and progesterone, as well as non-hormone-based therapies including selective serotonin reuptake inhibitors and the fruit extract *agnus castus*. Use of therapies such as danazol and

tamoxifen are limited by side effects of the medications. NSAIDs and steroid injections have been effective in managing chest wall pain.

Nipple Discharge

Based on history and examination, nipple discharge can be classified into three categories to guide evaluation and management. If the discharge is serous, sanguineous, or serosanguineous, spontaneously occurring, unilateral, originating from a single duct, and found to be reproducible on examination, then a mammogram and ultrasound are recommended for women over 30. An ultrasound is recommended as initial evaluation for women under 30. If the discharge is milky and bilateral, then a pregnancy test followed by a work-up for galactorrhea should be initiated. Work-up includes measuring TSH and prolactin levels. In women over 40, if the discharge is nonspontaneous, originates from multiple ducts, and cannot be characterized as serous, sanguineous, or serosanguineous, a diagnostic mammography plus ultrasonography is recommended. For women younger than 40, observation and education around avoiding nipple manipulation is appropriate. In summary, nipple discharge suggestive of malignancy occurs without provocation, is persistent, unilateral, presents in an older patient, is of serous, sanguineous, or serosanguineous quality or is associated with a mass or lump.

Breast Masses

There are four categories of breast masses: abscesses, benign masses, benign tumors, and cancer. Benign masses are further subdivided into categories of nonproliferative (i.e., cyst), proliferative without atypia (i.e., fibroadenoma), and atypical hyperplasia, which guide further evaluation and predict risk of becoming malignant. Cancerous masses are typically painless, occur in older women, and do not vary by menstrual cycle. Although breast cancers have characteristically been described as hard and immobile with irregular borders, no self or clinical examination finding reliably distinguishes between a benign and cancerous mass.

For women over 30, any palpable mass requires a diagnostic mammogram. Further diagnostic evaluation depends on a combination of radiographic qualities (i.e., solid vs. fluid filled) classified according to the Breast Imaging Reporting Data System (BI-RADS) and level of clinical suspicion. For example, if a mass gets a BI-RADS classification of 1, then an ultrasound is recommended. If it gets a BI-RADS classification of 4, then a tissue biopsy follows. For masses rated as BI-RADS 1 to 3, ultrasound findings in combination with clinical suspicion guide further evaluation versus observation. For women under 30, if clinical suspicion for malignancy is low, then a mass can be observed for several menstrual cycles. If clinical suspicion is high, then an ultrasound is the first line of imaging. BI-RADS from the ultrasound reading guides additional testing. If biopsies prove negative for malignancy or imaging determines that the mass is a cyst, masses are surgically removed and cysts aspirated only if the patient is symptomatic.

Breast Cancer Screening

Breast cancer is the most common type of cancer in women. Despite significant prevalence, it has a high survival rate of close to 90% at 5 years, which is attributed to early detection and effective treatment. Individuals are considered high risk for breast cancer if they have a personal history of breast cancer, a previous diagnosis of a high-risk breast lesion, a genetic mutation associated with risk for developing breast cancer, or if they have received radiation therapy to the chest. Although other risk factors such as early menarche, late menopausal onset, oral contraceptive or menopausal hormone therapy, increased breast density on mammography, and family member with a history of breast cancer have been identified, they do not change an individual's

categorization as average or high risk according to most guidelines. Screening consists of a mammogram for average-risk patients and an MRI in addition to mammography for high-risk patients. Different medical societies and international health organizations offer different guidelines regarding the appropriate age to begin screening for breast cancer in average risk women. These guidelines shift based on the results of risk-benefit models and the current data available. Current recommendations from US Preventive Services Task Force (USPSTF) are for screening average-risk women at age 50 and continuing every 2 years until age 75 years. Shared decision making around starting screening between age 40 and 49 should take place between the patient and provider. The American College of Obstetrics and Gynecology, in contrast, recommends that screening should start at age 40. Harms from screening mammography include false-positive results that could lead to overdiagnosis and overtreatment. Self-exams and breast exams as part of a routine physical for the purpose of screening are no longer recommended by most medical societies.

CERVICAL CANCER SCREENING

Cervical cancer screening is an important example of success in preventative medicine over the second half of the last century: mortality rates decreased by 50% between 1975 and 2008. In women found to have cervical cancer, 50% percent of them had not undergone screening in the preceding 3 to 5 years. The success of screening rests on the fact that cervical cancer progresses slowly.

Infections with high-risk strains of HPV (16 and 18) are responsible for approximately 70% of cervical cancer cases. Peak incidence of HPV infection occurs among women younger than 25 years of age, but most of these infections are transient. Approximately 10% of women remain HPV positive 5 years after infection. Current guidelines recommend Papanicolaou (Pap) tests with cytology starting at age 21 to be repeated every 3 years if normal. At age 30, both cytology and HPV co-testing can be sent and if both are negative, then testing can be spaced to every 5 years until age 65. A Pap test obtains cervical cells that are analyzed for the presence of abnormal cells to identify squamous intraepithelial lesions (SIL). SIL identified in the cytological report mandates a cervical biopsy via colposcopy. Biopsy results are graded in terms of cervical intraepithelial lesion (CIN) 1, 2 or 3. Depending on grade, they are treated and then monitored for possible progression into cancer according to a different algorithm of surveillance than normal screening. In addition, recommendations for screening differ for women who have had diethylstilbestrol (DES) exposure in utero or for women who are immunocompromised. The CDC recommends vaccination for HPV starting at age 11 and 12 (see *CDC Vaccines and Preventable Diseases* for full recommendations).

OSTEOPOROSIS

Eighty percent of the ten million Americans with osteoporosis are women. The risk of osteoporosis increases with age. Estrogen is protective of bones and many women experience significant bone density loss in the 5 to 7 years after menopause. Approximately one in two women over the age of 50 will experience a bone fracture due to osteoporosis. These fractures are associated with significant morbidity and mortality both directly and indirectly related to the fracture, including acute myocardial infarction, pulmonary embolus, loss of independence, decreased quality of life, and multiple hospitalizations. Twenty-one percent to 30% of patients with a hip fracture die within 1 year.

The USPSTF recommends screening for osteoporosis in average risk white women age 65 and older with bone density evaluation. The most common method of bone density evaluation is dual-energy

x-ray absorptiometry (DXA) of the hip and lumbar spine. Several risk assessment tools exist to evaluate a woman's risk of osteoporosis. The most commonly used is the FRAX tool. Risk factors for osteoporosis include a family history of hip fracture, smoking, long-term steroid use, and low body weight. Women younger than age 65 with at least one risk factor should have their osteoporosis risk assessed and then have bone density evaluation if their risk equals that of a 65-year-old white woman without risk factors. The recommendation is based on the risk of osteoporosis in white women because they have been historically the population studied. Ethnic background affects risk and management of osteoporosis, and racial minorities are diagnosed and treated less frequently. Women found to have osteoporosis who are treated have a moderate reduction in osteoporotic fracture. Treatment options include bisphosphonates, estrogen, and raloxifene. Individuals with osteopenia and osteoporosis are recommended to have adequate calcium and vitamin D intake through diet and/or supplements.

INTIMATE PARTNER VIOLENCE

IPV is a preventable public health problem that affects 1 in 4 American women during their lifetime. Nearly half of female homicide victims in the United States are killed by a current or former male intimate partner. IPV is any behavior that causes physical, sexual or psychological harm by a current or former intimate partner or spouse. There are numerous health consequences beyond the direct effects of IPV such as depression, anxiety disorders, chronic pain, and posttraumatic stress disorder (PTSD). Even when historical or physical examination clues are evident, IPV often remains undiagnosed by providers.

The USPSTF recommends that clinicians screen for IPV in women of childbearing age and refer women who screen positive to support services. The strongest evidence supporting screening is in women who are pregnant or postpartum, but the recommendation is to screen all women of childbearing age. There are several screening instruments to detect IPV. When screening for and discussing IPV, the clinician must be nonjudgmental, compassionate, and ensure confidentiality. Clinicians should normalize the screening interview with an explanation of IPV as an important health issue.

Identified risk factors for IPV victimization include younger age, female sex, lower SES, and a family history or personal history of violence. Suspicion for IPV should increase when there is a history of frequent emergency room visits, delay in seeking treatment, an inconsistent explanation of injuries, missed appointments, repeated abortions, late initiation of prenatal care or medication noncompliance. If a patient appears with an inappropriate affect, overly attentive or verbally abusive partner, apparent social isolation, and reluctance to undress or difficulty with examination of genitals or rectum, providers should further evaluate for IPV. Patients who are experiencing IPV present with a diverse range of complaints that include somatic and psychological symptoms as well as sexually transmitted infections. Women who screen positive for IPV should be evaluated for their risk of immediate harm. They should be provided with information about safety planning and a list of local and national resources.

OBESITY, METABOLIC SYNDROME, AND POLYCYSTIC OVARY SYNDROME

Obesity/Metabolic Syndrome

Rates of obesity (BMI >30) have increased in recent decades, yielding a rate of 40% in US adults in 2016. Overall, obesity appears to affect men and women equally, although the distribution by income varies by sex. Women in the lowest socioeconomic group have the highest rates of

obesity. Men in the highest and lowest socioeconomic groups had a higher rate of obesity compared to the middle-income group. Obesity increases the risk for many diseases. In women, central obesity (waist-hip ratio >0.9) predicts the risk of CAD. The risk of many cancers (e.g., endometrial cancer, breast cancer, kidney cancer, ovarian cancer) is increased for obese individuals. Obesity has specific implications for women during pregnancy, increasing the risk of numerous pregnancy-related complications, including gestational diabetes mellitus, fetal macrosomia, hypertension, shoulder dystocia, and cesarean delivery, and contributes to postpartum complications such as thrombosis and infection. Obesity is also associated with irregular menses and higher rates of anovulation.

The risk of cardiovascular disease related to the metabolic syndrome appears to have a stronger correlation in women. There are several definitions of the metabolic syndrome. The most commonly used defines metabolic syndrome as the presence of three or more of five risk factors that increase the chance of developing heart disease or stroke: central obesity, elevated triglyceride levels, low levels of high-density lipoprotein (HDL) cholesterol, hypertension, and impaired fasting glucose values. Women with the metabolic syndrome should be monitored and counseled about their increased risk of cardiovascular events and overt diabetes mellitus.

Polycystic Ovary Syndrome

PCOS is a complex endocrine disorder without a known etiology that affects approximately 5% to 10% of women worldwide. The key diagnostic criteria are androgen excess, ovulatory dysfunction and/or polycystic ovaries. The most commonly used diagnostic criteria is the Rotterdam 2003 criteria which requires two out of three of the above criteria. Risk factors for PCOS include first-degree relatives with PCOS, diabetes mellitus, obesity, and certain ethnic groups such as Mexican Americans. Reproductive and metabolic effects include anovulation, infertility, acne, hirsutism, obesity, nonalcoholic fatty liver disease, and metabolic syndrome. Increased insulin resistance is a significant consequence of the syndrome, increasing the risk of type 2 diabetes, particularly in obese women. Therefore, women with a diagnosis of PCOS require screening for diabetes.

Management of PCOS is primarily symptom based. For women who are overweight or obese, lifestyle modifications are recommended. COCs are the first line in PCOS to regulate menses and decrease hyperandrogenism in women not attempting to conceive. After COCs, second-line treatment for hyperandrogenism is an antiandrogen such as spironolactone or finasteride. Insulin sensitivity can be increased with metformin and thiazolidinediones. Metformin also regulates menses. These medications are contraindicated during pregnancy, and an effective form of contraception is required because these medications are teratogenic. Women with PCOS often struggle to conceive. Ovulation-inducing medications such as clomiphene citrate or letrozole are frequently required. Women with PCOS are at increased risk for endometrial and ovarian cancers. COCs decrease risk for endometrial hyperplasia and may decrease risk of endometrial cancer.

FIBROMYALGIA

The prevalence of fibromyalgia ranges from 2% to 8% depending on the diagnostic criteria used. Historically, the diagnosis of fibromyalgia has been significantly more common in women. Original diagnostic criteria involved the quantity of tender points present on exam. Either women were likely to report more tender points or the symptom manifestation between women and men differed, which led to a disproportionate number of women with the condition as compared to

men. With the change in diagnostic criteria, however, the disease has a smaller female to male ratio at 2:1. Since 2011, diagnosis has been determined by a symptom survey. Because of the vague set of symptoms and lack of laboratory findings, it has been a complicated and controversial diagnosis that continues to evolve.

Fibromyalgia is characterized by persistent pain, sleep disturbance, and fatigue lasting more than 3 months. The pain state is thought to be driven by how the central nervous system interprets peripheral nociceptive input. The central nervous system magnifies a given signal based on the levels of neurotransmitters, which then intensifies the pain response. The centralized pain phenomenon can be associated with other chronic pain states that have similar pathophysiology involving a specific organ system, such as chronic headaches, dysmenorrhea, irritable bowel syndrome, interstitial cystitis, or endometriosis. In addition, 10% to 30% of rheumatologic conditions are thought to have fibromyalgia as an associated diagnosis. The etiology is likely multifactorial, involving the influence of the environment, infection, and genetic predisposition.

Physical exam without any findings other than diffuse tenderness to palpation is characteristic. Treatment recommendations involve an integrated approach including both pharmacologic and nonpharmacologic modalities. Studies show that gabapentinoids, serotonin norepinephrine reuptake inhibitors, and gamma-hydroxybutyrate have efficacy in addressing symptoms of fibromyalgia. Choice of medication should be driven by predominant symptom, but multiple agents from different classes can be used for a synergistic effect. General patient-centered education, exercise, cognitive behavioral therapy, as well as some complementary and alternative medicine therapies such as tai chi, yoga, acupuncture, and trigger point injections, have been shown to be effective in increasing functionality. Setting expectations around the fact that fibromyalgia is a chronic disease that needs to be managed is an important part of the clinical care of these patients.

INTERSTITIAL CYSTITIS/HYPERSENSITIVE BLADDER

Interstitial cystitis, bladder pain syndrome, hypersensitive bladder, or painful bladder syndrome is a diagnosis that has evolved, changed names, and included different criteria for diagnosis over time. Based on literature from the Society for Urodynamics and Female Urology (SUFU), which was adapted by the American Urological Association, the current definition of interstitial cystitis is: "an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks' duration, in the absence of infection or other identifiable causes." Interstitial cystitis disproportionately affects women, with studies reporting ratios ranging from 2:1 to 8:1. It most often presents in the fourth decade of life. Quality-of-life scores demonstrate a significant negative impact on functioning. Diagnosis involves ruling out infection or other physiologic causes of symptoms. No lab test aids in the diagnosis of the disease; however, antinuclear antibodies are often present and can confound the diagnosis. Based on symptoms and risk factors different imaging modalities may be employed.

The exact etiology remains unknown. Possibilities include epithelial dysfunction, neurogenic inflammation on the level of the urothelium, and mast cell activation leading to a heightened pain response. Theories involving central amplification of a pain signal, similar to the pathophysiology used to explain pain in fibromyalgia, have been applied to interstitial cystitis. Hunner lesion interstitial cystitis is defined by the presence of well-circumscribed reddened mucosal areas with small vessels radiating towards a central scar visualized on cystoscopy. This form of the disease most often occurs in older patients and presents

with more severe symptoms and fewer associated other chronic pain conditions. Treatment involves an elimination diet geared towards decreasing foods with high acid and potassium content. Fulguration and electrocautery can be performed by a urologist.

Patients without identifiable lesions are more likely to have dyspareunia, vulvodynia, and bowel symptoms in addition to having more comorbid conditions. Guidelines for treatment involve starting with conservative options and progressing to more aggressive measures only in the case that initial treatments fail. Treatment often begins with diet modifications. Other nonpharmacologic approaches include pelvic floor physical therapy, cognitive behavioral therapy, and complementary therapy such as acupuncture and massage. Tricyclic antidepressants and antihistamines have led to a decrease in symptoms and an increase in functional status. Intravesical injections of BOTOX and combinations of dimethyl sulfoxide, heparin, or lidocaine, as well as nerve blocks and neuromodulators have been shown to be effective.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

HIV demands special attention in women's health care due to both epidemiologic and pathophysiologic factors. In the United States, only 7% of people with known HIV infections were women when the epidemic began; however, women now account for 25% of the population of people living with HIV, with women representing 20% of new infections in 2017. There is a higher incidence in rates of infection in African American women, which points to an inequality in education regarding HIV transmission and access to care. Heterosexual sexual encounters cause most HIV infections in women. Unprotected vaginal sex is a much higher risk for women than for men, and unprotected anal sex carries higher risk than unprotected vaginal sex.

The virus itself has a different physiologic impact on women: women typically have lower viral loads than men despite the same level of CD4 counts. Yet the rates of disease progression and opportunistic infections are similar for men and women. Awareness of gynecologic infections as initial manifestations of HIV/AIDS is important when treating women. Counseling for women of childbearing age around risk for vertical transmission and infection through breast milk are important considerations.

Although antiretroviral therapy and follow-up monitoring are similar for men and women with HIV/AIDS, general primary care for women with HIV requires special considerations. Risk for cervical abnormalities and cervical cancer is related to the degree of immunosuppression, age, and co-infection with high-risk HPV genotypes (16, 18, 52, and 58). Women with HIV infection are more likely to progress more rapidly to cervical cancer. The CDC recommends two cervical cytology screens at 6-month intervals in the first year after an HIV diagnosis and then annually. If there are three normal screens, then testing can be every 3 years. For more detail see the HIV opportunistic infection guidelines at CDC.gov. Vulvar and perianal intraepithelial neoplasia are more common in women with HIV than HIV-seronegative women, therefore any lesions present need careful evaluation.

EATING DISORDERS

Eating disorders are disturbances to a person's eating behaviors that result in significant health or psychosocial impairment. They often involve having a distorted body image. Common eating disorders include binge eating disorder, bulimia nervosa, and anorexia nervosa. Median age of onset is between 18 and 21 years old. The lifetime prevalence of binge eating disorder, bulimia nervosa, and anorexia nervosa are 2.8%, 1.0%, and 0.6%, respectively. Rates of eating disorders are

increasing, and white females tend to be disproportionately affected. According to the National Institute of Mental Health, the prevalence of eating disorders ranges between 2 to 5 times higher in women than in men. In contrast, some studies based on clinical practice have found a 20- to 30-fold higher prevalence in women. There is a high comorbidity with other mental disorders, primarily anxiety disorders. Physicians who care for adolescents should monitor weight and BMI and screen for alterations in body image and behaviors that suggest disordered eating. A number of screening instruments are available. Somatic symptoms are common and include dyspnea, chest pain, headache, and gastrointestinal problems. Self-induced vomiting is associated with erosion of dental enamel, parotid gland swelling, scarring or calluses on the dorsum of the hand, and esophageal complications such as Mallory-Weiss syndrome. Individuals with eating disorders should be evaluated for severe medical complications that require hospitalization. Unstable vital signs, moderate to severe refeeding syndrome and dehydration are indications for hospitalization for medical stabilization. Long-term treatment of anorexia may require inpatient hospitalization if there is minimal response to outpatient treatment or weight remains under 70% to 75% of ideal body weight. Management of eating disorders often requires a multidisciplinary approach with a primary care physician, psychologist, and nutritionist. Treatment for binge eating disorder is typically CBT. Treatment for bulimia includes a combination of pharmacotherapy, of which fluoxetine is first line, and psychotherapy. Treatment for anorexia is nutritional rehab and psychotherapy. If individuals fail to respond to outpatient treatment, they may require inpatient treatment for closer monitoring and more intensive treatment.

CARDIOVASCULAR DISEASE

CAD remains the leading cause of death for both women and men; however, significant sex and gender differences in the epidemiology, pathophysiology, and clinical manifestations of cardiovascular disease exist. Women with ischemic heart disease are more likely than men to experience atypical symptoms, such as fatigue, abdominal pain, indigestion, nausea and vomiting, and shortness of breath. These non-classic symptoms may partially explain why women tend to seek health care later than men. Even when women seek health care, they have a longer time to diagnosis and a longer time to medical intervention than men. Women are also more likely to have sudden cardiac death at presentation. They are less likely to receive proven effective therapies, such as β -blockers, aspirin, thrombolytics, and statins, and they are less often referred for invasive testing and coronary artery bypass grafting (CABG). Women are also more likely to die after a myocardial infarction and CABG compared with men. Inequalities are at play in the management of heart disease along racial lines: African American women are offered reperfusion therapy and coronary angiography at lower rates, and in-hospital mortality rates are higher compared with those of white women.

Women who present with acute coronary syndrome more frequently have coronary arteries absent of thrombus, but with distal emboli. This points to pathophysiologic differences in ischemic heart disease based on sex. Vasoreactivity and endothelial dysfunction are more common in women, which is demonstrated in the phenomenon of spontaneous coronary artery dissection, an underdiagnosed cause of acute coronary syndromes (ACS) seen in women between the ages of 45 and 60 and associated with pregnancy and the postpartum period. Takotsubo syndrome (stress cardiomyopathy) represents an estimated 8% of ACS cases in women, whereas it is the cause of less than 1% of ACS cases in men. Women with ischemic heart disease tend to present with ACS an average of 7 to 10 years later than men. The predominance

of disease in women post menopause suggests the protective role of higher estrogen states. Estrogen enhances HDL cholesterol and influences atherosclerotic plaque progression and regression. Estrogen may also be beneficial due to its vasodilatory, anti-inflammatory, and anti-oxidative properties.

Much of the evidence used to guide the treatment of coronary disease in women is based on trials that predominantly enrolled men. The studied treatments and interventions may not induce the same benefit and may even cause harm. For example, due to the tendency for women to have smaller arteries and fewer lesions, initial noninvasive tests have a higher likelihood of producing false-positive results that lead to invasive testing for evaluation of obstructive CAD.

PRECONCEPTION COUNSELING AND PRE-PREGNANCY CARE

Preconception counseling involves a combination of taking a thorough social, family, and medical history to assess potential risks to the mother and potential fetus and offering guidance around maintaining a healthy lifestyle, nutritional supplementation, and avoidance of potential toxins. The first step of a visit involves assessing desire of the patient to become pregnant, discussing what factors are influencing her decision, and offering contraception if pregnancy is not wanted. Women with a personal or family history of genetic disorders may benefit from formal genetic counseling. During a preconception visit, blood work is assessed and immunizations can be administered.

All prescribed and over-the-counter medications and herbal supplements need review to identify potential teratogens. Medications not considered necessary for the well-being of the mother should be stopped. This is not always possible or indicated for women treated for chronic medical conditions where the risk in stopping the medication outweighs the potential harm to the fetus. All women planning pregnancy or capable of becoming pregnant should be advised to take a daily multivitamin with folic acid (400 μg) to reduce the risks of neural tube defects and other congenital anomalies, including cardiovascular defects, urinary defects, and cleft lip.

Medical conditions known to increase the risk of adverse pregnancy outcomes for women and their offspring include obesity, diabetes, thyroid disease, seizure disorders, hypertension, rheumatoid arthritis, chronic renal disease, thrombophilias, asthma, and cardiovascular disease. Preconception care of these conditions can improve pregnancy outcomes. Patients usually are referred to high-risk pregnancy care for evaluation. Addressing obesity prior to pregnancy is important because although higher BMIs lead to adverse outcomes for both the woman and baby, weight loss should not occur during pregnancy.

Approximately 1% of pregnancies in the United States are complicated by pregestational diabetes. Gestational diabetes (GDM) occurs in approximately 7% of pregnancies. GDM has a high recurrence rate (30% to 80%) in subsequent pregnancies and a significantly increased risk for future development of type 2 diabetes. In women with pregestational diabetes and GDM, adequate control of diabetes reduces the risk of congenital malformations. Goal for HbA_{1C} prior to conception is less than 6.5%.

Hyperthyroidism and overt hypothyroidism occur in approximately 0.2% and 2.5% of all pregnancies, respectively. Adequate treatment of thyroid illness improves pregnancy outcomes. Approximately 70% to 80% of women with rheumatoid arthritis experience remission of disease during pregnancy, although the remaining women have active or worsening disease in pregnancy. Women with systemic lupus erythematosus (SLE) often experience exacerbations in pregnancy. SLE increases the risk of adverse fetal outcomes, including spontaneous abortion, fetal growth restriction, and preterm birth. Maternal

mortality is associated with conditions such as pulmonary hypertension (especially Eisenmenger's syndrome), congenital heart disease with hypoxia and poor functional class, and arrhythmias.

Assessing for substance use and providing support around abstinence from tobacco, alcohol, and other illicit substances is important in addressing fertility concerns, for the general well-being of the woman, and for the development of the fetus. Routine laboratory evaluation includes rubella titer, varicella titer (in women with a negative history of varicella), hepatitis B surface antigen, and a complete blood count to assess for hemoglobinopathy. Women should receive screening for HIV, chlamydia, and syphilis.

Immunity to measles, mumps, rubella, tetanus, diphtheria, poliomyelitis, and varicella should be ensured through vaccination. Women should receive influenza vaccine in pregnancy due to the increased risk of complications from influenza infection. Ideally, women should receive all indicated vaccinations at least 1 month before conception. Live vaccines (e.g., rubella) should not be given during pregnancy.

PERINATAL DEPRESSION

Depression during pregnancy and in the postpartum period is a significant and common occurrence for childbearing women. Although more efforts to understand the cause, impact, and adequate management are emerging, stigma and underdiagnosis have led to missed opportunities to provide women with appropriate care. Defining and categorizing the specific type of depression particular to this period varies, thereby making it more challenging to study, recognize, and treat. Perinatal depression as delineated by ACOG is defined as major or minor episodes of depression that occur during pregnancy or within the first 12 months after delivery. The DSM-V, however, defines postpartum depression (PPD) as the onset of depressive symptoms within the first 4 weeks of delivery. Studies show that 33% of women with PPD had symptoms during pregnancy, whereas 27% had symptoms pre-pregnancy. In 2016, USPSTF issued a recommendation for routine depression screening in the general adult population and specifically including pregnant and postpartum women, which highlights perinatal depression as a condition worthy of attention but at the same time does not clearly delineate it from other types of depression.

Changes in sleep, appetite, and libido directly caused by responsibilities associated with caring for a newborn may complicate evaluation of postpartum depression based on symptomatology. Postpartum, 50% of women experience a change in mood, called "postpartum blues," marked by intensified emotions that are transient, lasting for the first few weeks after birth. Postpartum blues can develop into PPD. Anxiety or obsessions regarding the health and safety of the baby are common in the postpartum period; the degree to which these thoughts and feelings lead to a debilitating state varies and thereby drives the diagnosis of the psychological condition of PPD. Studies of PPD have found that 20% of women with this diagnosis have suicidal thoughts. Risk factors for PPD include depression and anxiety during pregnancy, traumatic birth experience, previous history of depression, and complications in the health of the infant.

Pathophysiology is multifactorial, likely including genetic, hormonal, immune, and social influences. Although changes in hormones have been assumed to be at the center of PPD, studies have failed to demonstrate a clear association between reproductive levels in women with PPD. Management should be driven by severity of symptoms. First steps involve providing support around self-care and psychosocial needs, which includes encouraging exercise and sleep. In moderate cases, cognitive behavioral therapy and the addition of an SSRI is recommended. In severe cases, additional classes of antidepressants are added, if a switch in SSRI does not yield improvement. ECT

is recommended when suicidality and/or psychosis are present. The FDA has recently approved a treatment for severe postpartum depression that consists of an intravenous formulation of allopregnanolone, a steroid that works on GABA receptors. However, applicability only to women with severe symptoms and cost limit current use of this medication.

SEXUAL DYSFUNCTION

Sexual dysfunction is a term that describes a range of sexual health-related concerns that cause personal distress. The etiology is often multifactorial with psychological, sociocultural, biologic, and physiologic components. It is experienced by approximately 40% of women in the United States. Women around menopause, between the ages of 45 and 65, are most commonly affected. It is often underdiagnosed and undertreated. Numerous medical conditions can impact sexual function due to changes in desire, arousal, orgasm or the presence of pain. Aging itself is associated with decreased libido and sexual responsiveness. The decline in estrogen during menopause causes thinning of the vaginal epithelium, decreased vaginal elasticity, and decreased lubrication. Medications are also implicated in sexual dysfunction, most commonly SSRIs. Evaluation includes a thorough medical and sexual history and the physical exam should also include testing for STIs. Management depends on the etiology but is frequently multifactorial. Some treatment options include pelvic physical therapy, psychotherapy or sex therapy, and mindfulness-based interventions. Pharmacologic options are limited but there are two recently FDA-approved medications. Flibanserin is a daily oral medication approved for premenopausal women with low sexual desire; however, its use is limited by a black box warning, an interaction with alcohol, and significant nausea and dizziness. Bremelanotide, a subcutaneous injection administered as needed prior to sexual activity, was approved in June 2019 for premenopausal women with low sexual desire. Hormone therapies such as systemic estrogen and testosterone have been used off label. Systemic estrogen was not found to improve sexual dysfunction in postmenopausal women in the Women's Health Initiative. Testosterone has been found to improve sexual dysfunction in peri- and postmenopausal women in most studies. Testosterone is metabolized to estrogen, thus its use can be associated with abnormal uterine bleeding and breast symptoms.

PELVIC PAIN

Pelvic pain is characterized as acute or chronic, and both types are commonly encountered in primary care practice. Acute pelvic pain usually manifests over hours to days and may be gynecologic, gastrointestinal, or urologic in origin. Life-threatening conditions, including ruptured ectopic pregnancy and appendicitis, need to be ruled out. Gynecologic causes include complications of pregnancy, acute pelvic infection, and ovarian pathology, including cyst and torsion.

Chronic pelvic pain (CPP) is lower abdominal pain of at least 6 months' duration, and it is severe enough to cause functional impairment or require treatment. Approximately 10% of ambulatory gynecologic referrals are for CPP. The history obtained for evaluation of CPP should include characteristics of the pain; a thorough review of systems; prior medical, surgical, gynecologic, and obstetric history; and a thorough psychiatric and social history, including episodes of domestic violence as a child or an adult and periods of substance abuse.

The most common conditions associated with CPP are endometriosis, chronic pelvic inflammatory disease, interstitial cystitis, irritable bowel syndrome, pelvic floor myalgia, myofascial pain, and neuralgia.

Interstitial cystitis or painful bladder syndrome is a clinical diagnosis consisting of pain, pressure, or discomfort related to the bladder and associated with lower urinary tract symptoms lasting more than 6 weeks and occurring in the absence of infection or other identifiable causes. Mental health issues, including substance abuse, somatization, depression, and physical or sexual abuse, can also cause CPP and are important to identify so that women need not undergo unnecessary testing and interventions.

Physical examination should assess for focal areas of pain, scars, hernias, or masses in the abdomen, and a pelvic examination should be performed. After the most likely diagnosis has been identified, an empirical, targeted treatment may be instituted and followed for efficacy. Further work-up should be considered if the patient does not respond or symptoms change. If empirical therapy and a thorough investigation do not yield a diagnosis, laparoscopy may be considered to identify pelvic pathology.

Any identified peripheral etiology to CPP should be treated; however, CPP of unclear etiology is common and does not have definitive treatment. Depending on the underlying cause, management strategies may include heat therapy (for musculoskeletal pain), counseling and psychiatric referral, gastrointestinal referral, medications (e.g., gabapentin for neuropathic pain, NSAIDs, hormonal contraceptives), hysterectomy, and nerve transection procedures. Multidisciplinary approaches, including medications and interventions that address dietary and psychosocial factors, may be superior to medical treatment alone.

GENDER AND FEMALE SEXUAL MINORITIES

The health care needs of female sexual and gender minorities have significant overlap with the general population but require specific attention and sensitivity given significant barriers to care and differences in both sexual health concerns and certain medical issues. Females who have sex with females come from diverse racial, ethnic, and socioeconomic backgrounds and may choose to identify as lesbian, gay, or bisexual or transgender. Gender minorities, such as individuals who identify as transgender or genderqueer, identify and/or express a different gender than the gender traditionally associated with their assigned sex at birth. Gender and sexual minorities are significantly more likely than heterosexual women to experience implicit and explicit discrimination during health care visits. Many providers do not take a sexual history or inquire about sexual orientation. Health care providers may inadvertently assume heterosexuality and communicate heterosexist attitudes, making it more difficult for patients to disclose their sexual orientation. A lack of cultural competency means that providers do not understand appropriate terminology around gender identity and sexual orientation, which can create further challenges in provider-patient relationships.

Rates of STIs between females who have sex with females are not well studied; however, the assumption that there is lower risk for STIs through female-female sex as compared to heterosexual intercourse is not based in adequate research. Female-female sex allows for transmission of infection through vaginal fluids, menstrual blood, mucosal contact, and via sex toys. Dental dams, condoms, or latex sheet provide a barrier for transmission of bacterial and viral infections. Using condoms on sex toys and cleaning sex toys between use can decrease the spread of infection. Lubrication can also decrease infection transmission by preventing breakdown and bleeding of mucosal areas. Rates of bacterial vaginosis are higher in females who have sex with females, which has suggested transmissibility of bacterial vaginosis and that it should be classified as an STI.

Sexual minorities should receive the same age-appropriate preventative health care and cancer screenings as heterosexual women. For transgender individuals, the decision as to whether to screen for breast cancer or cervical cancer should be based on current anatomy and risk as opposed to gender identity of the individual. Recognition that the individual's relationship to the organ in need of cancer screening may be dysphoric for the individual should inform how screenings are introduced and discussed during a clinic visit.

Sexual and gender minority stress as a result of prejudice and systemic discrimination has direct and indirect impacts on the health of individuals. Recent studies comparing the health and health risk factors between individuals who identified as lesbian, gay or bisexual (LGB) and heterosexual individuals demonstrate LGB persons have higher rates of psychological distress, heavy alcohol and tobacco use, obesity, cardiovascular disease, type 2 diabetes, and breast and gynecological cancers compared to heterosexual women. These differences are not explained by any innate biological differences between heterosexuals/cisgendered individuals and sexual/gender minorities but are felt to be heavily influenced by minority stress and decreased access of medical care. Lifetime rates of intimate personal violence are higher for lesbian, bisexual, and transgender peoples. Although the differences in health outcomes for sexual and gender minorities do not change screening recommendations, provider awareness is important in meeting the physical and emotional health needs of all patients.

Men's Health Topics

Niels V. Johnsen, Douglas F. Milam, Joseph A. Smith, Jr.

INTRODUCTION

Men's health has grown into a subspecialty field that includes primary care physicians, urologists, and endocrinologists, among others. Men's health needs and concerns are becoming more evident and often require the expertise of those with dedicated interest in men's health topics. This chapter aims to address benign disorders that are unique to men because they specifically involve the male genitalia and reproductive system. Male genitourinary malignancies and infertility are addressed in [Chapters 59 and 67](#).

TESTOSTERONE DEFICIENCY

Definition and Epidemiology

The prescribing and use of testosterone in the United States has risen dramatically in the past decade. However, many men continue to fail to receive treatment when appropriate due to lack of provider knowledge or unsupported clinical concerns, while others continue to receive testosterone despite the lack of a clear clinical indication. Furthermore, escalations in direct-to-consumer marketing and the rise of well-publicized centers dedicated solely to the management of men's health issues have further increased patient interest in and desire to receive testosterone therapy.

Previously referred to by a number of different terms, *testosterone deficiency* is the preferred terminology adopted by the American Urological Association (AUA) to describe the condition of low serum testosterone in men in conjunction with signs or symptoms associated with low serum testosterone levels. The true prevalence of testosterone deficiency is not known. Estimates range between 2% and 77% of the US male population. This wide variability in estimates stems from inconsistencies both in definitions of testosterone deficiency applied within the literature, as well as variabilities in the assays and cut-off values used to determine low serum testosterone levels.

Testosterone deficiency does not refer to a low serum testosterone level alone, but by definition requires additional clinical signs or symptoms associated with low serum testosterone. Previous recommendations have attempted to quantify a required number of associated symptoms or signs for diagnosis of testosterone deficiency in a patient with a low total serum testosterone; however, the current AUA guidelines simply state that patients must have at least one sign or symptom in addition to low serum testosterone levels for diagnosis. These include symptoms such as fatigue, depression, erectile dysfunction, cognitive dysfunction, decreased libido, and decreased endurance; as well as signs such as loss of body hair, weight gain, or loss of lean muscle mass. Unfortunately, while some signs and symptoms are more

suggestive of testosterone deficiency, many are nonspecific and can often be manifestations of other illnesses or disease states ([Table 73.1](#)). Thus, it is vital that clinicians have a thorough understanding of testosterone deficiency in order to ensure patients are both offered appropriate care when indicated and not offered care when not indicated.

Pathophysiology

Testosterone is produced primarily by the testicles as a result of stimulation by luteinizing hormone (LH) secreted from the anterior pituitary gland, which in turn is stimulated by the hypothalamus. This hypothalamic-pituitary-gonadal (HPG) axis can often be disrupted by aging, with multiple studies showing that the prevalence of testosterone deficiency increases significantly with advancing age. Disruptions in the HPG axis can occur at multiple points and lead to differing classifications of testosterone deficiency. *Primary hypogonadism* is a condition due to testicular failure, in which the testicles fail to produce adequate amounts of testosterone (and sperm) despite adequate stimulation by LH from the anterior pituitary. *Secondary hypogonadism*, on the other hand, is a low serum testosterone level as a result of failure of the pituitary to secrete sufficient amounts of LH. In this state, the Leydig cells of the testicle are not adequately stimulated and thus do not produce testosterone. *Secondary hypogonadism* can be the result of disease processes such as pituitary tumors, hemochromatosis, or obstructive sleep apnea.

As the predominant androgen in men, testosterone circulates within the bloodstream in four distinct forms. Approximately 44% of testosterone is tightly bound to sex hormone-binding globulin (SHBG) and represents the non-bioavailable component of serum testosterone. However, 50% is loosely bound to albumin, 4% loosely bound to corticotropin-binding globulin, and 2% freely circulating within the bloodstream, representing the bioavailable form of testosterone. The 2% of circulating testosterone that it is not bound to serum proteins, however, is the most biochemically active form of testosterone and referred to as free testosterone (FT).

Laboratory tests of total testosterone (TT) measure both the bound and unbound forms of testosterone. In patients with either borderline-low serum TT levels or in patients with low-normal TT levels with significant associated signs or symptoms, measurement of FT may be helpful in making a clinical diagnosis. Increased levels of SHBG in the serum can decrease the level of FT, as more testosterone becomes bound to SHBG. The level of SHBG may increase with smoking, excessive coffee consumption, age, and disease processes such as hepatitis and hyperthyroidism. Therefore, increased levels of SHBG can contribute to testosterone deficiency. Conversely, while obesity may

TABLE 73.1 Signs and Symptoms of Testosterone Deficiency

Specific Signs and Symptoms	Less Specific Signs and Symptoms
Reduced sexual desire (libido) and activity	Decreased energy and self-confidence
Decreased spontaneous erections	Feeling sad, depressed mood
Breast discomfort, gynecomastia	Poor concentration and memory
Less axillary and pubic hair and less shaving	Sleep disturbance and sleepiness
Very small or shrinking testes	Mild anemia (normochromic, normocytic)
Infertility and low sperm count	Reduced muscle bulk and strength
Height loss and low bone mineral density	Increased body fat and body mass index
Hot flashes and sweats	Diminished physical or work performance

decrease levels of SHBG, it too can contribute to testosterone deficiency through the peripheral conversion of testosterone into estrogen within adipose cells. Lastly, conditions such as extreme exercise, recreational drug use, nutritional deficiency, stress, use of certain medications, and acute illness can transiently lower serum testosterone.

Clinical Presentation

Low testosterone levels can affect a patient's general, sexual, physical, and psychological health. In [Table 73.1](#), these symptoms are grouped according to their specific relation to testosterone deficiency. Various studies have categorized and used the symptoms of testosterone deficiency in different ways. For example, one clinical trial looking at the incidence of testosterone deficiency defined the syndrome as the presence of 3 of 12 clinical symptoms combined with a low serum FT or TT level, whereas, in a similar trial, patients were considered to be testosterone deficient if they had a low TT and exhibited three specific sexual symptoms. Current guidelines state that clinicians should use these different symptomologies as a means to determine the appropriateness and potential benefit of checking a patient's serum testosterone level, while also noting that decreased libido is the most common presenting symptom.

Diagnosis

For several reasons, the diagnosis of testosterone deficiency is not straightforward. By the very simplest of definitions, diagnosis requires a low serum testosterone level on at least two separate occasions in conjunction with at least one clinical symptom. Most clinical guidelines suggest measuring an early morning TT in any adult man who has symptoms associated with testosterone deficiency and, if low, repeating a subsequent early morning test using the same assay to confirm low testosterone. An early morning blood draw is recommended given the diurnal variation in serum testosterone levels. According to the AUA, a serum TT level of less than 300 ng/dL serves as the appropriate threshold value for identifying testosterone deficiency. However, it should be noted that there is significant variability between different testosterone assays that may alter the range of normal for each particular test, so providers should be sure to evaluate their assay-specific ranges when making determinations for therapy. In highly symptomatic patients with borderline or normal TT, FT should be assessed; however, FT tests are not recommended initially due to higher variability, increased time, and increased costs. In addition, screening of asymptomatic men for low testosterone is not medically necessary or appropriate.

In men with borderline testosterone levels, repeat measurement of a morning testosterone level is warranted because there may be significant day-to-day and diurnal variability. Ideally, levels should be checked within 4 hours of waking (usually between 7 and 11 AM), when testosterone levels are highest. It is not necessary to fast before a testosterone laboratory test; however, in a study from 2013, there was

a 25% reduction in TT levels in healthy men 60 minutes after an oral glucose tolerance test. Strength training may also transiently decrease serum testosterone levels in healthy men (but typically not outside the normal range).

Testosterone levels should not be checked during acute or subacute illness. However, physicians should have a lower threshold to check the testosterone level in patients with chronic illnesses that are known to cause a symptomatically lower testosterone concentration, such as diabetes mellitus, chronic obstructive lung disease, inflammatory arthritic disease, renal disease, human immunodeficiency virus (HIV)-related disease, obesity, metabolic syndrome, and hemochromatosis. In fact, some have argued that patients who have a pituitary mass, HIV-associated weight loss, unexplained anemia, chronic narcotic use, or chronic steroid use should have their testosterone level checked regardless of symptoms.

In patients with a confirmed low TT in the presence of symptoms, LH levels should be checked to determine the etiology of testosterone deficiency and to rule out secondary hypogonadism. Testosterone-deficient patients with a low LH likely have a defect at the level of the hypothalamus or pituitary (hypogonadotropic hypogonadism), whereas those with elevated LH levels have a primary testicular defect (hypergonadotropic hypogonadism). There are a number of conditions that may cause hypogonadotropic hypogonadism, including Kallmann syndrome, pituitary tumors, infiltrative pituitary disorders such as hemochromatosis or sarcoidosis, hyperprolactinemia, and prior head trauma. Patients with this disorder warrant further investigation to determine the source of the testosterone deficiency, such as serum prolactin measurements or possible endocrine evaluation. Hypergonadotropic hypogonadism, on the other hand, may be the result of prior infection or trauma to the testes, autoimmune damage, or possibly Klinefelter's syndrome, which would prompt karyotyping for diagnosis.

Men over the age of 40 being considered for testosterone replacement should have their prostate-specific antigen (PSA) level measured and a digital rectal examination (DRE) performed to assess the prostate. If either is abnormal, referral to a urologist should be considered. [Table 73.2](#) provides helpful guidelines for evaluating possible testosterone deficiency. For patients with documented testosterone deficiency who are interested in future fertility, reproductive medicine evaluation should be performed because testosterone therapy markedly decreases sperm production. Return of normal spermatogenesis takes a variable amount of time, if at all.

Treatment

Testosterone therapy is recommended for men with confirmed testosterone deficiency on two separate tests who also have associated signs or symptoms of deficiency, or in the select cases mentioned above. The primary purpose of testosterone therapy is to provide symptom

TABLE 73.2 Testosterone Deficiency Diagnosis Do's and Don'ts

Do check total testosterone (TT) in every symptomatic adult male >40 yr
Do confirm low testosterone results with a second test
Do check in the morning
Do have a lower threshold to check testosterone in patients with certain chronic illnesses
Do consider measuring prolactin and LH level in patients with low testosterone
Do check hematocrit and PSA levels prior to initiating testosterone therapy
Don't check the testosterone level during acute or subacute illness
Don't start with measurement of free testosterone
Don't monitor testosterone treatment with measurements of free testosterone
Don't consider testosterone therapy in a patient trying to father a child

LH, Luteinizing hormone; PSA, prostate-specific antigen.

relief by returning patients to normal physiologic levels of testosterone. This, in turn, may improve symptoms such as erectile dysfunction, decreased libido, anemia, depressive mood, or low bone mineral density. However, the data are not as clear as to the benefits of testosterone therapy in improving cognitive function, fatigue, or metabolic syndrome measures. Patients should also be counseled that although the data on the cardiovascular risks or benefits of testosterone therapy are currently inconclusive, low testosterone is a known risk factor for cardiovascular disease. Clinicians should also obtain a baseline hematocrit, because polycythemia (hematocrit >52%) is known to occur significantly more frequently in men on testosterone therapy. This is especially true for men receiving intramuscular testosterone injections and those with hormone pellet implants. Polycythemia can often be addressed with dose adjustment, but it will occasionally require phlebotomy or hematology consultation.

There are numerous testosterone replacement formulations. In the United States, the most commonly used forms are testosterone enanthate or cypionate by intramuscular (IM) injection, transdermal testosterone patches, testosterone gels, and implantable timed-release pellets. The goal of therapy should be to achieve a serum TT level in the middle tertile of the reference range for the assay being used. Because of the frequency of significant skin irritation with the testosterone patch, many practitioners prefer one of the other modalities, usually based on patient preference. There is also the risk of transference with gel applications, particularly worrisome for those who come in contact with pregnant women or young children. For specifics on dosing and formulations, the AUA Guideline on Evaluation and Management of Testosterone Deficiency provides a comprehensive table with recommendations. In general though, daily gel applications mimic diurnal variation with early morning application, produce middle tertile testosterone levels, and have a relatively low rate of polycythemia. Intramuscular injection (often biweekly) does not produce diurnal variation, causes very high testosterone levels initially that often fall to subtherapeutic levels before the next injection, and is more likely to produce polycythemia than gel preparations. Pellets do not mimic diurnal variation, often produce polycythemia, but have the advantage of dosage intervals as long as 6 months.

Side Effects of Testosterone Therapy

Testosterone therapy causes decreased sperm production and usually decreased testicular volume, and it may cause acne, oily skin, and breast tenderness. Testosterone replacement is not a treatment for infertility and has, in fact, been investigated as a method of male contraception.

Patients who are interested in fathering children should not take testosterone and those with a desire for future fertility should be informed that the return of normal spermatogenesis after cessation of testosterone is variable. If necessary, human chorionic gonadotropin (HCG), selective estrogen receptor modulators (SERM), aromatase inhibitors, or a combination thereof may be administered for testosterone-deficient men wishing to preserve fertility.

In addition, as previously discussed, testosterone can increase hematocrit levels and cause life-threatening polycythemia. Generally, patients experience a rise over the first 6 months of treatment, with a plateau thereafter. If the hematocrit becomes significantly elevated, testosterone replacement should be suspended and only resumed at a modified dose after levels have normalized. Occasionally, patients require phlebotomy to avoid or treat dangerous polycythemia.

Testosterone therapy may worsen obstructive sleep apnea and congestive heart failure; therefore, patients in whom these conditions are untreated should not be started on testosterone therapy. Present data suggest that testosterone therapy does not worsen levels of high-density lipoproteins and there is no definitive evidence linking testosterone therapy to an increased risk of venothrombotic events.

Testosterone Therapy and the Prostate

It has previously been advocated that testosterone therapy should be avoided in men with a history of prostate cancer, given the known association of testosterone with prostate cancer pathophysiology. Although this topic remains controversial, a number of providers now treat patients with confirmed testosterone deficiency and a history of prostate cancer in select cases. The current AUA guidelines state that there is inadequate evidence to quantify the risk-benefit ratio of testosterone therapy in men with a history of prostate cancer. However, in patients with a history of prostatectomy with low-risk pathology, current studies show no increased risk of cancer recurrence with testosterone therapy. Similar results have been seen in low-risk prostate cancer patients treated with radiation. Patients with a history of high-risk cancer treated by radiation, however, have experienced increased rises in post-treatment PSA values and should be cautioned about the risks with testosterone therapy. These patients, as well as those with active or recurrent prostate cancer, who desire testosterone therapy should be referred to centers with experience and expertise in this clinical scenario.

Monitoring Testosterone Treatment

Patients on testosterone therapy should have regular laboratory testing to confirm that appropriate serum testosterone levels are being achieved. As stated previously, therapy should be targeted to achieving the middle tertile of normal on the particular testosterone assay being used. In general, patients using gels or patches, as well as intranasal formulations, should have levels checked within 4 weeks of initiation of treatment, and then every 6 to 12 months once on steady dosing. For patients on short-acting injectable formulations, it is generally recommended to check testosterone levels after four cycles and then every 6 to 12 months. For patients who achieve target testosterone levels for 3 to 6 months but still do not feel that their inciting symptoms have improved, testosterone therapy should likely be discontinued in all but select cases (for example, patients with prior documented bone mineral density loss).

ERECTILE DYSFUNCTION

Erectile dysfunction (ED) is defined as the inability to achieve and/or maintain an erection sufficient for satisfactory sexual performance and is known to affect some 150 million men worldwide. According to

the Massachusetts Male Aging Study, 52% of men older than 40 years of age are afflicted with some degree of ED, with the prevalence of ED tripling between the ages 40 and 70 years. By age 70 years, 15% of men will experience complete ED. While age and physical health are the most important predictors of the onset of ED, smoking remains one of the most important modifiable lifestyle factors impacting one's risk for ED.

Recently, many clinics that specifically treat ED and men's sexual health have opened across America, designed to meet a growing need for treatment of this condition. However, these clinics often charge out-of-pocket fees for treatments and medications that primary care physicians can provide and that are often covered by insurance. Therefore, it is more important than ever for primary care physicians to have a thorough understanding of this disease process and its management in order to provide appropriate and medically supervised care.

Mechanism of Erection

Afferent signals capable of initiating erection can originate within the brain, as with psychogenic stimulation, or as a result of peripheral tactile stimulation. While there is no discreet center for psychogenic erections, the temporal lobe appears to be important in this process. The pelvic plexus receives input from both the sympathetic and the parasympathetic nervous system and propagates these signals into the cavernous nerves of the penis. Sympathetic fibers involved originate in the thoracolumbar spinal cord, while parasympathetic fibers originate in the second through fourth sacral spinal cord segments (S2 through S4). Afferent somatic sensory signals are carried from the penis through the pudendal nerve to the S2 through S4 nerve roots. This information is then routed both to autonomic centers of the brain and to the spinal cord. Parasympathetic innervation is largely involved in achieving an erection (tumescence), whereas sympathetic, adrenergic innervation plays a vital role in the process of ending an erection (detumescence).

Sexual stimulation and the resultant propagation of efferent signaling through the pelvic plexus causes the release of nitric oxide (NO) by the cavernous nerves into the neuromuscular junction at the level of the smooth muscle of the corpora cavernosa of the penis (Fig. 73.1). NO subsequently activates guanylyl cyclase, which converts guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP). Protein kinase G is activated by cGMP and in turn activates several proteins that cause a decrease in the intracellular concentration of calcium ions (Ca^{2+}). Decreased Ca^{2+} concentration in the smooth muscle results in muscular relaxation, cavernosal artery dilation, increased blood flow, and subsequent tumescence. With the resultant cavernosal expansion from increased blood flow, venous sinuses that usually drain the penis are compressed and venous outflow from the penis is reduced, allowing for a persistent increased pressure within the penis and maintenance of the erection. At the end of erection, sympathetic nerves release norepinephrine, which ultimately results in smooth muscle contraction and detumescence. Similarly, phosphodiesterase type 5 (PDE5) works within the smooth muscle cells of the cavernosal tissue to degrade cGMP, ending the propagation of the signaling cascade for erection.

Causes of Erectile Dysfunction

Although often multifactorial in etiology, ED can be generally classified into two types: psychogenic ED and organic ED. Psychogenic ED was once thought to be the most common type of ED; however, advances in understanding of the mechanics and neurophysiology of erectile function have identified other more common causes. As a result, psychogenic ED is now thought to account for fewer than 15% of patients seen by ED specialists. Patients with psychogenic ED have otherwise intact vascular and neural physiology and are often able to

Fig. 73.1 Sexual stimulation causes the release of nitric oxide (NO) by the cavernous nerve into the neuromuscular junction. ATP, Adenosine triphosphate; cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; PDE5, phosphodiesterase type 5.

achieve erections either nocturnally or with self-stimulation, but continue to have difficulties with ED. This is most often related to issues such as depression, stress, anxiety or other psychiatric illness.

Organic ED represents the majority of ED seen clinically and can be classified as vasculogenic, neurogenic, endocrinologic or a combination thereof. For many patients, atherosclerotic arterial disease results in poor vascular inflow, impacting the ability to achieve an erection. Recent estimates suggest that atherosclerosis alone accounts for up to 60% of ED cases seen in men over the age of 60. Furthermore, a diagnosis of ED has been strongly associated with future cardiovascular disease in US men.

Cardiovascular Disease

In the United States, atherosclerotic vascular disease, hyperlipidemia, smoking, and hypertension are frequent causes of ED. These relationships are not surprising, as erection is achieved by a combination of relaxation of arteriolar smooth muscle and increased venous resistance of channels penetrating the wall of the corpora cavernosa. Cardiovascular disease may decrease erectile ability by decreasing blood flow to the penile arteries, mechanical obstruction of the vascular lumen, or, more commonly, due to the resultant endothelial dysfunction. Endothelial dysfunction is the most common cause of ED, in which there is an interruption of the neural control mechanism of vascular smooth muscle function due to a decreased ability of endothelial cells to release NO, leading to decreased blood flow and pressure in the corpora cavernosa. Given this close relationship between ED and cardiovascular disease, men presenting with ED should undergo appropriate cardiovascular risk factor evaluation and management. Men presenting with new onset ED in their forties are particularly at risk with an approximately 15 times increased risk of a myocardial event.

The principal blood vessels supplying the corpora cavernosa are the cavernosal arteries, which are terminal branches of the internal pudendal artery. Diseases of large and small arteries may decrease corporal blood pressure and lead to decreased penile lengthening and

TABLE 73.3 Frequency of Decreased Erectile Rigidity and Ejaculatory Dysfunction by Medication Class

Medication Class	Decreased Erectile Rigidity	Ejaculatory Dysfunction
β-Adrenergic antagonists	Common	Less common
Sympatholytics	Expected	Common

α ₂ -Agonists	Common	Less common
α ₁ -Antagonists	Uncommon	Less common ^a
Angiotensin-converting enzyme inhibitors	Uncommon	Uncommon
Diuretics	Less common	Uncommon
Antidepressants	Common ^b	Uncommon ^c
Antipsychotics	Common	Common
Anticholinergics	Less common	Uncommon

^aPatients are able to ejaculate, but retrograde ejaculation is seen in 5% to 30%.

^bUncommon with serotonin reuptake inhibitors.

^cDelayed or inhibited ejaculation with serotonin reuptake inhibitors.

rigidity. Veno-occlusive disease in the penis is also a significant cause of ED. In these patients, there is often appropriate arterial inflow but an impaired ability to prevent leakage of blood through the venous system out of the penis. As such, these patients often experience normal initial rigidity but quickly lose their erection before ejaculation occurs.

Neurogenic Erectile Dysfunction

Because the nervous system plays an integral role in the physiology of erection, any disease process that affects the brain, the spinal cord, or the peripheral nerves can cause ED. For example, dementia, Parkinson's disease, and stroke are diseases of the brain associated with ED. Patients with spinal cord injury commonly have ED. Because of an intact spinal reflex pathway, most patients with spinal cord injury respond to tactile sensation, but they usually require medical therapy to maintain the erection through intercourse. Iatrogenic injury to nerves during surgery (e.g., prostatectomy, rectal surgery) is also a common cause of neurogenic ED. Neurogenic ED due to decreases in penile tactile sensation can occur with increasing age.

Endocrine Disorders

Testosterone plays a permissive role in erectile function, and many endocrine disorders can directly or indirectly decrease plasma free or bound testosterone. However, while testosterone deficiency is an uncommon primary cause of ED as erectile ability is only partially androgen dependent, the current AUA guidelines do recommend checking a morning serum testosterone in men with ED to confirm that they are not testosterone deficient. Patients with testosterone deficiency typically have decreased or absent libido in addition to loss of erectile rigidity. If testosterone deficiency is confirmed on two separate morning testosterone tests, testosterone therapy should be offered. If erectile rigidity fails to improve with 3 to 6 months of testosterone therapy, testosterone supplementation should be discontinued. Testosterone therapy is not indicated for patients with normal circulating testosterone levels and ED.

The most common endocrine disorder affecting erectile ability is diabetes mellitus. In addition to causing atherosclerosis and microvascular disease, diabetes affects both the autonomic and the somatic nervous systems, including loss of function of long autonomic nerves. The loss of function of these long cholinergic neurons results in interruptions of the efferent arm of the erectile reflex arc. Diabetes also appears to produce dysfunction of the neuromuscular junction at the level of arterial smooth muscle in the penile corpora

cavernosa. Studies have indicated markedly decreased acetylcholine and NO concentrations in the trabeculae of the corpora cavernosa in diabetic patients. These findings probably represent a combination of neural loss and neuromuscular junction dysfunction. Other endocrine disorders, such as hypothyroidism, hyperthyroidism, and adrenal dysfunction, can also cause ED. Because of the uncommon occurrence of thyroid and adrenal disorders in patients presenting for treatment of ED, testing of those axes is not a part of the routine work-up of ED.

Medication-Induced Erectile Dysfunction

Many commonly prescribed medications can cause or contribute to decreased erectile function. Table 73.3 lists the major classes of medications implicated in ED and suggests how commonly these medications interfere with erectile function. Changing medications may restore erectile function in some patients. However, proceeding directly to treatment of ED is usually a better option in all but the most straightforward cases.

Medical and Surgical Therapies

Since the introduction of sildenafil in 1998, the Process of Care Model for the evaluation and treatment of ED has been adopted. This model targets the primary care provider as the initial source of care for patients with ED. Currently available therapies for ED include oral PDE5 inhibitors, intraurethral alprostadil, intracavernosal vasoactive injection therapy, vacuum constriction devices, and penile prosthesis implantation. Although a stepwise treatment approach starting with oral agents and progressing to more invasive therapeutic interventions has generally been advocated, many men's health specialists now advocate assessing each patient individually and ensuring that all options are discussed (Fig. 73.2). All patients who are candidates for oral medications should generally try these prior to more invasive procedures given their relative high success and low risk profile; however, all patients are not required to proceed incrementally up the chain of treatment measures, as long as they are fully informed of the available options. Informed patient decision making is critical to successful progression through the Process of Care pathway. Patient referral is primarily based on the need or desire for specialized diagnostic testing and management. Most importantly, all men with comorbidities known to negatively affect erectile function should be counseled that lifestyle modifications such as improved diet and physical activity may have a significant positive impact on their erectile function.

Fig. 73.2 A logical treatment algorithm for erectile dysfunction.

Oral Phosphodiesterase Type 5 Inhibitors

Current medical therapy is based on inhibition of PDE5, which degrades cGMP to inactive 5'-GMP, as shown in Fig. 73.1. Sildenafil, vardenafil, avanafil, and tadalafil all competitively inhibit PDE5 breakdown of cGMP. Use of a PDE5 inhibitor results in improved erectile rigidity even in patients with decreased NO or cGMP synthesis. However, not all patients respond to PDE5 inhibition. Adequate sexual stimulation and intact neural and vascular pathways are necessary to produce an adequate amount of NO and cGMP to increase deep penile artery blood flow. PDE5 inhibitors have been shown to be effective in men with vasculogenic, psychogenic, neurogenic, and mixed cases of ED. The overall response rate to PDE5 inhibitors is 70%.

Unless contraindicated, PDE5 inhibition should be considered first-line therapy for most men. The combination of PDE5 inhibitors and α -adrenergic receptor blockers (often used in men with lower urinary tract symptoms related to an enlarged prostate) can result in transient hypotension; however, in general it is safe to use selective α -blockers such as tamsulosin and alfuzosin with any PDE5 inhibitor, particularly once a patient is already established on therapy with the α -blocker. However, PDE5 inhibitors should not be used concurrently with nitrate medications due to the significant risk of a large (>25 mm Hg) synergistic drop in blood pressure. Periodic follow-up is necessary to determine therapeutic efficacy, assess for side effects related to PDE5 inhibition, and evaluate any changes in health status. Commonly reported side effects include headaches and flushing, while some patients have reported changes in vision due to unintended inhibition of PDE6 in the retina.

Alprostadil Intraurethral Drug Therapy

In patients for whom PDE5 inhibition is unsuccessful, one potential second-line medical treatment is intraurethral administration of prostaglandin E_1 (alprostadil). Alprostadil pellets are inserted directly into the urethra with the use of a pellet applicator and then diffuse into the surrounding tissue, initiating a second messenger cascade involving cAMP and inducing erection. This method of delivery assumes substantial venous communications between the corpus spongiosum surrounding the urethra and the corpus cavernosum and is effective in many patients who fail oral PDE5 inhibitor medications. A number of patients experience difficulty initiating this type of treatment due to discomfort or concerns in using the applicator, so it may be beneficial to administer the first dose in an office setting. To lubricate the urethra, patients should void prior to insertion of the pellet.

Up to one third of patients have normal, transient burning penile pain, and this should be discussed with the patient before treatment. Dizziness and presyncope are uncommon complications. Intraurethral alprostadil results in rapid onset erection after administration and has a minimal risk of priapism. It can be used with increased efficacy in

combination with PDE5 inhibitors. Transient burning pain in the sexual partner can occur and is caused by leakage of the medication from the urethra into the vagina. This method of achieving erection is also contraindicated in men having intercourse with a pregnant female, due to the above risks of transference. This can be managed by wearing a condom.

Intracavernosal Injection Therapy

Pharmacologic injection therapy involves the injection of vasodilator agents into the corpora cavernosa to produce erection by stimulating dilation of the corporal artery smooth muscle. More than 90% of patients with ED respond to this type of therapy. Commonly used agents, either alone or in combination, include alprostadil, papaverine, and phentolamine. As monotherapy, alprostadil is most commonly used. Of the three, only alprostadil has been evaluated in rigorous clinical trials and has specific marketing approval from the US Food and Drug Administration for the treatment of ED. Phentolamine is often used to potentiate the action of papaverine and can be used in combination with both alprostadil and papaverine. These vasoactive drugs can be formulated with different combinations of medications and concentrations to achieve increased efficacy and decreased side effects. *Bimix* and *trimix* are terms often used to refer to a combination of two or three of these medications, respectively.

The most common side effects of this type of treatment are bruising and penile pain (50%). Penile pain is more common in young patients and is usually worse with alprostadil. Therefore, a combination using lower-dose alprostadil or formulations of papaverine and phentolamine alone might be beneficial in younger patients. Other, more serious risks of injection therapy include priapism and corporal scarring. Priapism has been reported to occur in 1% to 4% of patients but is more commonly reported in patients with neurogenic ED, especially young men with spinal cord injury. Significant acquired penile curvature due to corporal scarring (Peyronie's disease) is seen uncommonly and usually follows several years of injection therapy. Penile curvature appears to be less common with the use of alprostadil than with papaverine. The most common problem with pharmacologic injection therapy, however, is continuation of treatment, as up to 50% to 60% of patients stop using the technique within 1 year due to poor tolerance and satisfaction.

As with intraurethral alprostadil, initial treatment should be performed under the supervision of a physician. The medication can be injected using a self-contained medication-syringe kit or a 29-gauge (5/8-inch) insulin syringe with medication drawn from a refrigerated vial. It is advisable to start with a small test dose and slowly titrate the dosage for desired effect over several weeks. The patient should not use the medication more than once in a 24-hour period and should be instructed to seek medical care promptly for prolonged erections lasting longer than 4 hours. Typically, administration of the test dose should be carried out in the morning, and the patient should be expected to stay in close proximity to the medical office to monitor for priapism. Should a patient develop priapism, it usually resolves without sequelae after intracavernosal injection of phenylephrine in a setting where blood pressure and heart rate can be continuously monitored. Formal guidelines for the treatment of priapism are available on the website of the AUA.

Vacuum Constriction Devices

Vacuum constriction devices enclose the penis in a plastic tube with an airtight seal at the penile base. Air is pumped out of the cylinder, creating a vacuum and pulling blood into the corporal bodies, leading to penile erection. A constriction band is then slid from the cylinder to the base of the penis to constrict venous outflow and maintain the erection. Simultaneous use of a vacuum device and a PDE5 inhibitor is safe

and has been shown to improve erectile rigidity and patient satisfaction with the vacuum device. Some of the common side effects that affect patient satisfaction with these devices are coldness, numbness, and bruising of the penis, as well as the cumbersome nature of the process.

Penile Prosthesis

A penile prosthesis is an either semirigid or inflatable device that is implanted into the penis in the operating room under general anesthesia. These devices allow for men to achieve rigid erections suitable for penetration and sexual function. In contemporary series, most patients prefer the inflatable devices over semirigid options because of the more natural erection when inflated and a fully flaccid penis when deflated. Although implantation of a penile prosthesis is more invasive than the other techniques, this device is the most effective long-term option for impotence treatment, with nearly 90% of patients and partners satisfied with the result.

Important interval improvements have been made in the design of implantable penile prostheses to make them more durable and resistant to infection. Improvements in the connections between tubing and corporal cylinders have cut the mechanical failure rate to less than 5% in 5 years. Components now also have special coatings that either contain antibiotics or absorb antibiotics applied topically at the time of implantation in order to decrease the risk of infection.

PEYRONIE'S DISEASE

Peyronie's disease (PD) is an acquired condition of the penis that involves fibrosis of the tunica albuginea, resulting in contracture and ultimately penile curvature and/or deformity. It may affect up to 6% of men in the United States. This disease can be quite debilitating to men for both psychological as well as functional reasons. Other than embarrassment related to the appearance of their penises, many men experience depression, relationship difficulties, and diminished quality of life, not to mention pain and difficulty in sexual activity, both for themselves and for their partners. There have been a number of significant advances over the past decade in the management of PD, progressing from a purely surgical disease process to one that now is often amenable to minimally invasive injection therapies.

Pathophysiology

PD is the result of fibrosis in the tunica albuginea of the penis and is believed to be secondary to repetitive microvascular trauma and buckling events over time. While some individuals will present with a clear history of a significant prior penile injury, most recall no inciting event. The natural history of PD itself is variable as well. Most men report a gradual worsening of curvature with associated penile pain for a number of months prior to presentation to a physician. For men who remain untreated for PD after presentation to a physician, approximately 12% will note improvement in their curvature over the ensuing year, while the remainder will either remain stable or worsen with time.

PD is defined temporally by *active* and *stable* phases of disease. The active phase is generally characterized by changes in the degree of curvature with time, as well as other degrees of penile modeling changes such as development of an "hourglass" appearance or induration. The prime characteristic of the active phase of disease, however, is the presence of pain, particularly with erection. The stable phase of disease is defined by at least 3 months of stable, unchanged curvature and/or other deformity. Pain with manipulation should be absent once a patient has reached the stable phase of the disease.

Differential Diagnosis

Acquired penile curvature due to PD may be difficult to differentiate from congenital penile curvature in some individuals, especially those

who become sexually active later in life. Patients with congenital curvature generally have lifelong ventral curvature and no palpable fibrotic plaque consistent with PD. Acute penile trauma may cause pain and/or induration that may be confused for the active phase of PD. Rarely, patients with acute penile fractures may develop PD later in life due to inappropriate collagen deposition following injury.

Evaluation

The most common presenting symptom for patients with PD is dorsal curvature (the penis curves up towards the abdomen) with a palpable fibrotic plaque on the dorsum of the penis. However, there is tremendous variation in the degree and extent of curvature that patients may develop, with many patients having ventral, lateral, or multiplanar, compound curvatures. Furthermore, many patients develop the previously mentioned "hourglass" appearance due to circumferential constriction of the tunica albuginea by fibrosis within the corpora cavernosa. PD has been shown to occur simultaneously in patients with Dupuytren contracture of the hands or Ledderhose disease of the plantar fascia, so patients should be appropriately evaluated for these diseases as well. While some patients will occasionally present with photographs of their erect penis for evaluation, providers should be comfortable inducing a pharmacologic erection to evaluate the degree, extent, and location of curvature in the office. Concomitant penile duplex ultrasonography may be useful to evaluate the vascular integrity of the penis, as well as for possible calcifications of the fibrotic plaque, but this is best performed by individuals specifically trained in this technique.

Measurements of penile length and specific notation on the location and size of the plaque are useful in determining treatment strategies. A thorough sexual history is similarly vital in the initial evaluation. The degree or extent of ED must be ascertained, as PD commonly coexists with ED and the presence of ED impacts potential treatment options. Treatment of penile curvature due to Peyronie's disease will not improve decreased penile rigidity. Similarly, a thorough history of the duration and stability of curvature, as well as the presence of pain with erections and/or intercourse, should be obtained in order to determine if a patient is in the active and stable phase of disease.

Treatment

Active Phase

Active phase disease represents an ongoing physiologic process in which collagen deposition is incomplete and variable. Many attempts have been made in the past to alter this process through the use of medications; however, no proven therapies have been found to be efficacious, other than simple nonsteroidal anti-inflammatory drugs (NSAIDs) for the pain associated with active disease. Surgical treatments for PD are not indicated during the active phase of the disease. Although a number of proposed oral therapies have been previously advocated with hopes of preventing or reversing curvature, there is currently insufficient evidence for their use. The most commonly used oral medication, vitamin E, has had a number of both observational and randomized control trials performed, all of which have failed to demonstrate efficacy in reducing curvature, pain or progression. The primary aim for management of patients in the active phase of disease is symptom control with NSAIDs.

Stable Phase

For patients in the stable phase of PD, in whom curvature has been stable for at least 3 months and there is no significant pain with erections, treatment is geared towards improving sexual function and quality of life. There is no urgent medical indication for intervening on PD in the absence of patient bother. Treatment decisions are based on patient

wishes and tailored according to degree of erectile function, tolerance of each intervention, and ability to undergo general anesthesia.

Intralesional injection therapy. There are currently two commonly used medications for PD that are directly injected into the fibrous plaque of patients and have been shown to be effective in improving curvature. Interferon- α was the first widely successful intralesional injection therapy used in PD patients. This medication functions by decreasing the rate of fibroblast proliferation within the tissues, thus decreasing the deposition of extracellular collagen. Interferon- α has been shown to have efficacy in improving both curvature and plaque size.

More recent, however, was the FDA approval of collagenase clostridium histolyticum (CCH) in 2013 for use in PD patients. This medication contains a collagenase enzyme that, when directly injected into Peyronie's lesions, enzymatically degrades interstitial collagen, improving curvature. The IMPRESS trial, which led to the FDA approval of CCH for PD patients, consisted of up to four 6-week cycles, with each cycle including two injections of CCH 24 to 72 hours apart. The treatment group, as compared to a saline control group, was found to fare significantly better, with a mean 34% improvement in curvature (17 degrees) in the treatment group as compared to 18% (9 degrees) in the control group. While this trial excluded individuals with curvatures of less than 30 degrees, as well as those with ventral curvatures and plaques, some providers have now extrapolated these data to treat individuals not initially eligible based on these inclusion criteria. Though no head-to-head trials have been conducted, CCH appears to be more effective at decreasing penile curvature than interferon- α .

While intralesional injection therapy is generally safe and minimally invasive, there are some associated risks. Patients who receive interferon- α are at significant risk of developing sinusitis, flulike symptoms, and penile swelling. CCH, on the other hand, has been associated with rare serious adverse events such as penile fracture, while the majority of patients developed mild adverse side effects such as pain, swelling, bruising, or painful erections. Lastly, patients may require up to 24 weeks of therapy to reach maximal improvement in curvature, which may dissuade some individuals.

Surgical therapy. The goal of surgical therapy for PD is to correct the penile deformity (curvature and/or hourglass) and allow the patient to return to satisfactory intercourse. For patients with PD who are either not interested in or not candidates for intralesional injection therapies there are three primary surgical options. The primary determinant of the surgical therapy offered is the degree of ED in the patient. Improvement of penile curvature in a patient who is otherwise unable to obtain a sufficient and satisfactory erection will improve that patient's quality of life. For patients with significant ED despite pharmacotherapy, placement of a penile prosthesis may be performed (as discussed previously), often with adjunct maneuvers discussed later to obtain straightening.

The most commonly performed procedure for men with PD is tunical plication. In this procedure, the convex side of the penis is shortened with placement of sutures directly in the tunica albuginea opposite the fibrous plaque on the contralateral side of the penis. This procedure may result in perceived penile shortening and is best reserved for men with sufficient preoperative stretched penile length, as well as for those with mild to moderate degrees of curvature. Plication techniques are unable to address hourglass or other indentation deformities but are unlikely to have any significant negative impact on erectile function.

An alternative approach, particularly for men with more significant curvatures or in those in whom a plication technique may have too significant of an impact on penile length, is plaque incision (or excision) and grafting. In this procedure, the PD plaque is identified and incised (or excised if extensively calcified). Incising the plaque relieves

TABLE 73.4 Symptoms of Lower Urinary Tract Syndrome

Overactive Bladder	Obstructive Voiding
Frequency	Hesitancy
Nocturia	Slow stream
Urgency	Stop-and-start voiding
Urge incontinence	Sensation of incomplete emptying

the tension that the fibrous plaque was applying to the penis causing it to curve, allowing it to return to its normal straight position without sacrificing length. The resultant defect in the tunica albuginea is then grafted using either autologous tissues (i.e., saphenous vein) or other graft materials (allograft, xenograft, or synthetic grafts have all been utilized). Importantly, this procedure can be used to correct hourglass and other indentation deformities that other techniques cannot. Although this procedure does maintain penile length, there are increased concerns related to postoperative ED, with up to 30% of men reporting new-onset or worsening ED after the procedure. However, overall, satisfaction and straightening rates are greater than 80% for both plication and grafting techniques.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is a nonmalignant enlargement of the prostate gland and is widely prevalent in the aging male patient. It is estimated that more than 90% of all men will develop histologic evidence of BPH during the course of their lifetime, with at least 50% of these men developing lower urinary tract symptoms (LUTS) that prompt them to seek medical care. Broadly speaking, LUTS can be divided into two groups: obstructive voiding symptoms and overactive bladder symptoms (Table 73.4).

Although most patients who seek medical care for BPH do so because of the associated LUTS, these same symptoms can also result from other illnesses such as diabetes mellitus, spine disease, Parkinson's disease, multiple sclerosis, and cerebrovascular disease (Fig. 73.3). It is important to evaluate all patients for these non-BPH-related conditions to ensure appropriate management is provided. It is also important to pay close attention to medication use, because a number of medications used in the elderly population can result in various urologic symptoms, including both obstructive and overactive bladder voiding symptoms. Lastly, BPH itself is a histologic diagnosis and does not in itself require intervention. Intervention is only indicated for individuals in which BPH is resulting in bothersome symptoms or complications related to impaired bladder emptying.

Pathophysiology

Prostate growth and the subsequent development of BPH occur under the influence of testosterone and the more metabolically active byproduct, dihydrotestosterone (DHT). Testosterone produced by the testes is converted to DHT by the action of the enzyme 5 α -reductase within the prostate itself. DHT is the major intracellular androgen within the prostate and is believed to be responsible for the development and maintenance of the hyperplastic cell growth characteristics of BPH.

BPH develops predominantly in the periurethral prostatic tissue, referred to as the *transition zone* (Fig. 73.4). Tissue growth in this area leads to the phenomenon of bladder outlet obstruction (BOO), which causes LUTS. BOO occurs as a result of two mechanisms: first, mechanical obstruction from increased tissue volume in the periurethral zone of the prostate and, second, dynamic obstruction caused by decreased bladder neck relaxation during voiding and increased

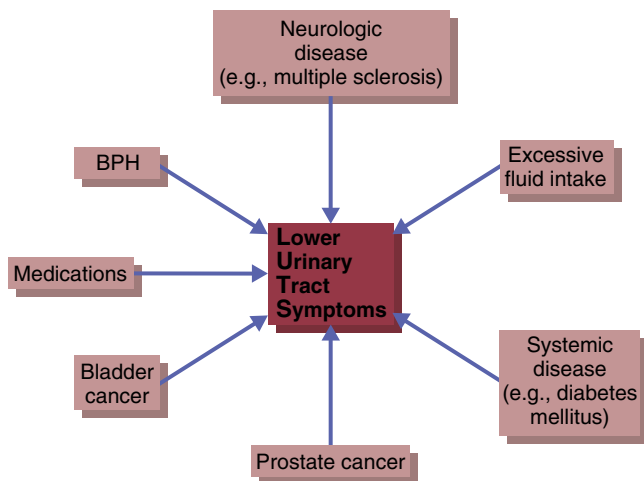

Fig. 73.3 Causes of lower urinary tract symptoms (LUTS). *BPH*, Benign prostatic hyperplasia.

smooth muscle tone in the bladder neck and prostate gland. Also important, but less well characterized, is the response of the detrusor muscle to the increase in outlet resistance provided by those two mechanisms. As bladder outlet resistance increases, the bladder responds by increasing the force of contraction. This added work results in physical and mechanical changes in bladder function over time and may contribute to the presence of overactive bladder symptomatology in patients with BOO.

Early in the course of BOO, the bladder is able to compensate to overcome the elevated outlet resistance; however, with persistent obstruction, the patient typically develops LUTS, particularly difficulty initiating the stream, weak stream, hesitancy, and intermittency. These symptoms frequently drive patients to seek medical care. Later during the course of the obstructive process, the bladder wall becomes thickened and loses compliance. The subsequent loss of compliance results in a decreased functional capacity of the bladder, which exacerbates the patient's overactive bladder symptoms such as urgency and frequency.

Diagnosis

The initial evaluation of a patient with LUTS suggestive of BPH should include a detailed medical history that focuses on the patient's urinary symptoms as well as the past medical history, including comorbid conditions and any previous surgical procedures, general health conditions, and history of alcohol and tobacco use. The assessment of symptoms can be facilitated with the use of the AUA Symptom Index (also known as the *International Prostate Symptom Score*, or IPSS). This is a self-administered, validated questionnaire consisting of seven questions related to the symptoms of BPH and BOO. The AUA Symptom Index classifies voiding symptoms as mild (0 to 7), moderate (8 to 19), or severe (20 to 35). Validated instruments such as the AUA Symptom Index are useful during the initial evaluation as an overall assessment of symptom severity and during follow-up visits to assess the effectiveness of any medical or surgical interventions.

A general physical examination should be performed that includes a DRE and a focused neurologic examination. Urinalysis, either by dipstick or by microscopic examination of urine sediment, is also mandatory to rule out hematuria and evidence of urinary tract infection. Glucosuria can be a significant finding, particularly if not previously identified, as this may indicate the presence of polyuria contributing to the patient's LUTS. The initial clinical practice guidelines for the diagnosis of BPH recommended a serum creatinine measurement to assess renal function in all patients with signs or symptoms suggestive

of BPH. However, this recommendation came under scrutiny because of its low yield for the detection of renal insufficiency secondary to obstructive uropathy. As such, serum creatinine measurement is no longer a routine part of the BPH work-up. According to the same clinical practice guidelines, PSA measurement is optional during the initial evaluation. PSA can function as a surrogate for prostate volume measurement in addition to being a screening test for prostate cancer. The Medical Therapy of Prostatic Symptoms (MTOPS) study, sponsored by the National Institutes of Health, demonstrated that PSA increases linearly with prostate volume and that a PSA level greater than 4 ng/mL conveys a 9% risk of requiring surgical therapy for benign disease over a 4.5-year period.

The following additional diagnostic tests should be considered when evaluating patients with BPH, specifically those in whom surgical therapy is being considered. Uroflowmetry is a noninvasive method of measuring urinary flow rate. The maximal urinary flow rate, Q_{max} , is considered the most useful measurement for identifying patients with BOO. However, a diminished Q_{max} alone is not diagnostic of BOO because patients with diminished flow rates may have such due to impaired bladder contraction rather than physical obstruction. Typical values range from 25 mL/second in a young man without BOO to 10 mL/second or slower in a man with significant BOO. Measurement of postvoid residual (PVR) urine may be accomplished by urethral catheterization or, preferably, by ultrasonography. Elevated PVR volumes indicate an increased risk for acute urinary retention and eventual need for surgical intervention. Elevated residuals, furthermore, put patients at risk for the formation of bladder stones, urinary tract infections, or renal deterioration with long-term retention. The MTOPS study demonstrated that 7% of men with PVR greater than 39 mL required surgical intervention over a 4.5-year period. Elevation of PVR to greater than 200 mL raises the question of functional impairment of the bladder and warrants further evaluation with urodynamic testing.

Routine evaluation of the upper urinary tracts (kidneys and ureters) with excretory urography or ultrasonography is not recommended for the average BPH patient unless there is concomitant urinary pathology (i.e., hematuria, urinary tract infection, renal insufficiency, a history of prior urologic surgery, or a history of nephrolithiasis). Likewise, transrectal ultrasonography (TRUS), CT or MRI imaging are not routinely recommended for medical therapy but should be considered in the preoperative assessment of prostate gland size prior to surgical intervention, as this may influence selection of technique.

Differential Diagnosis

A number of conditions can cause LUTS in the aging male. A DRE and PSA testing are helpful in distinguishing between BPH and prostate cancer, but neither is diagnostic. Early-stage prostate cancer is typically asymptomatic and patients can have both conditions concurrently. Although PSA testing is not sufficiently sensitive or specific to reliably differentiate BPH from prostate cancer, it is a useful tool to stratify a patient's risk for the presence of prostate cancer and assess the need for further prostate cancer evaluation. While controversy surrounding the use of PSA for prostate cancer screening persists, in general, patients between the ages of 40 and 55 at a higher risk for prostate cancer (i.e., African American men and/or those with a family history) and all men ages 55 to 69 should engage in shared decision making with their primary care providers to discuss the risks and benefits of prostate cancer screening and make an individualized decision on screening. Men with elevated PSAs or concerning DRE should be referred to a urologist for further evaluation and management.

Prostatitis is another condition that can cause LUTS. It may result from bacterial infection or from a nonbacterial inflammatory process, and the symptoms may substantially overlap those of BPH,

Fig. 73.4 Zonal anatomy of the prostate gland.

particularly in older men. Diabetes mellitus, neurologic diseases such as Parkinson's disease or cerebrovascular disease, and other conditions of the urinary tract, such as urethral strictures, may result in LUTS in patients with BPH. Finally, many medications, particularly those with significant anticholinergic side effects, can cause symptoms mimicking those associated with BPH.

Medical Management

Medical management is the preferred first-line treatment option for patients diagnosed with LUTS due to BPH, and most patients can be effectively managed with a minimum of side effects on medication alone. In general, medical management is initiated for patients with moderate to severe AUA symptom scores. However, in the absence of indications for surgery (refractory urinary retention, hydronephrosis with or without renal impairment, recurrent urinary tract infections, recurrent gross hematuria, or bladder calculi), the decision to embark on any course of therapy, medical or otherwise, is principally driven by the patient. Every patient has a different perception of his symptoms: nocturia twice nightly may be a minor nuisance for some but may represent a significant problem for others. There is no absolute AUA symptom score or other objective measure that dictates the need for initiation of therapy for symptomatic BPH. Each patient must be evaluated individually, and the treatment course must be tailored to the patient's individual situation.

α -Adrenergic Antagonists

α -Blockers are the most commonly prescribed medications for the treatment of LUTS associated with BPH. The bladder neck and prostate are richly innervated with α -adrenergic receptors, specifically α_{1a} -receptors, which constitute about 70% to 80% of the total number of α -receptors in these areas. α_{1b} -Receptors modulate vascular smooth muscle contraction and are located in the bladder neck and prostate to a lesser degree.

Doxazosin, terazosin, tamsulosin, and extended-release alfuzosin are long-acting α -receptor antagonists. These medications are typically administered once daily, usually at bedtime to minimize the potential side effect of orthostatic hypotension. They act through α_1 -receptors and can cause vasodilation resulting in transient hypotension and lightheadedness. Blood pressure reduction is greater in patients with a history of hypertension (average reduction, 10 to 15 mm Hg)

relative to normotensive patients (average reduction, 1 to 4 mm Hg). Overall, 10% to 20% of patients experience some (often transient) side effects from these medications, including dizziness, asthenia, headaches, peripheral edema, and nasal congestion. Dose titration is recommended for doxazosin and terazosin to minimize occurrence of adverse effects and optimize the therapeutic response. Maximal response is usually seen within 1 to 2 weeks with doxazosin and within 3 to 6 weeks with terazosin. Overall, these drugs reduce symptom scores by 40% to 50% and improve urinary flow rates by 40% to 50% in about 60% to 65% of patients treated.

Tamsulosin is a selective α_{1a} -receptor antagonist with a long half-life. It has a significantly lower degree of nonspecific α -receptor binding compared with other α -receptor antagonists. Therefore, side effects such as postural hypotension and dizziness are less commonly seen. This drug does not appreciably affect blood pressure in hypertensive or normotensive patients. Maximal response is usually seen within 1 to 2 weeks after the initiation of therapy.

One notable side effect of this class of medications reported in a significant proportion of individuals is retrograde ejaculation. In this condition, the ejaculate is propelled across the bladder neck into the bladder, rather than out the urethra, as a result of the increased relaxation of the prostate and bladder neck tissues. While not medically dangerous, this can be disconcerting to many men who are unaware of this potential side effect. Tamsulosin and silodosin have been shown to have the highest rates of retrograde ejaculation of the regularly prescribed α -blockers.

5 α -Reductase Inhibitors (Finasteride and Dutasteride)

Finasteride and dutasteride block the intracellular conversion of testosterone to DHT by inhibiting the action of the enzyme 5 α -reductase. This results in an approximate 18% to 25% reduction in prostate gland size over 6 to 12 months. It is most effective in reducing symptoms and preventing disease progression in patients with large prostate glands (>40 g), although recent evidence suggests that symptomatic improvement and stabilization of disease progression may occur in treated men with prostates as small as 30 g. 5 α -Reductase inhibition has also been shown to decrease the risk for urinary retention and subsequent surgical intervention, again predominantly in those patients with larger glands. Initial response is seen within 6 months, and maximal effect occurs 12 to 18 months after the initiation of therapy. Data from the MTOPS study demonstrated that combination therapy with

an α -blocker and a 5 α -reductase inhibitor was more effective than single-agent therapy alone in men with large prostates. As such, many men are placed on concomitant therapy.

It should be noted that finasteride and dutasteride have been found to reduce serum PSA by about 50%. This must be taken into consideration when interpreting PSA values for prostate cancer screening in men taking these agents. After 6 months of therapy, the effective PSA level in a patient taking finasteride or dutasteride may be calculated by doubling the measured PSA value. Free PSA (the percentage of non-protein-bound PSA) is also reduced by about 50%. Use of finasteride or dutasteride may result in sexual dysfunction, including decreased erectile rigidity, decreased libido, and decreased ejaculate volume. ED caused by 5 α -reductase inhibitor therapy is reversible and returns to baseline within 2 to 6 months after discontinuation of therapy.

Phosphodiesterase Type 5 Inhibitors

Although more often thought of as medications for the treatment of ED, sildenafil, vardenafil, and tadalafil have been shown to be efficacious in the treatment of urinary symptoms related to BPH. As previously discussed, these medications work by preventing the degradation of cGMP by PDE5. This results in lower intracellular calcium levels and, consequently, smooth muscle relaxation. This process works in the vasculature of the penis as well as the smooth muscle cells of the prostate, urethra, and bladder neck. A number of randomized, double-blind, placebo-controlled trials have shown significant improvements in LUTS in men treated with a once-daily regimen of one of these medications. Although it has not been conclusively shown that PDE5 inhibitors are more efficacious than α -blockers, it does appear that the combination of the two medications works better than either one of them alone. The common side effects of these medications are headache, nasal stuffiness, and facial flushing.

Anticholinergic Medications

For most men, symptoms of overactive bladder make up a large component of LUTS associated with BPH. As previously discussed, many men with long-standing BOO have symptoms of urgency, frequency, and nocturia. One of the best ways to treat these symptoms of overactive bladder is with the daily use of anticholinergic medications such as oxybutynin, tolterodine, or solifenacin. The use of anticholinergic medications in combination with α -blockers has been shown to result in greater improvement in LUTS, quality of life, and AUA symptom scores in men with symptoms of overactive bladder due to BPH than use of either agent in monotherapy. The typical side effects of this class of medications include dry mouth, constipation, nausea, and impaired cognition. The risk of urinary retention related to the use of these medications in men appears to be minimal.

Surgical Management

Minimally Invasive Therapy

Although transurethral resection of the prostate (TURP) remains the standard for surgical treatment of BPH, substantial effort has been devoted to the development of less invasive and less morbid methods of treating patients with symptomatic BPH. This has led to a number of minimally invasive therapies, primarily using various energy platforms to cause tissue destruction within the prostate. These office-based techniques are best reserved for patients with smaller prostates and may transiently increase bladder outlet obstruction for 1 to 2 weeks due to postprocedure swelling. Maximal tissue reduction and treatment effect generally occur within 12 weeks.

Water vapor thermal therapy and transurethral microwave thermotherapy (TUMT) are the most widely used minimally invasive methods of treating symptomatic BPH. With water vapor therapy a

hollow needle is placed in prostatic tissue under cystoscopic visualization which is used to inject steam. Surrounding tissue is immediately coagulated. Several puncture sites are chosen based on the prostatic anatomy. During TUMT, catheter-mounted transducers use microwave energy to heat prostatic tissue, resulting in coagulative necrosis and shrinkage of the prostate gland. The subsequent reduction in prostate transition zone volume results in an improvement in flow rates and symptom scores. Transurethral needle ablation (TUNA), which uses low-level radio frequency energy to effect similar changes within the prostate gland, is no longer recommended by the AUA guidelines. Water vapor thermal therapy and aquablation are both office-based procedures that have shown efficacy similar to TUMT in patients with prostates less than 80 g, although retreatment rates may be higher than with other interventions. Lastly, the prostatic urethral lift procedure, which involves the placement of permanent transprostatic implants to mechanically open the urethra and improve voiding, has been shown to be effective in men with small prostates and no appreciable median lobe.

The most common side effects of these treatments are temporary increases in overactive bladder symptoms, transient urinary retention, hematuria, and ejaculatory dysfunction. However, antegrade ejaculation is generally preserved in men undergoing both water vapor thermal therapy and the prostatic urethral lift procedures, so patients should be appropriately counseled. Late complications such as urethral strictures and ED have been reported but are significantly less common than with traditional surgical approaches. The major benefits of these less invasive therapies are the reduction in traditional surgical morbidities (e.g., bleeding) and risks associated with general or spinal anesthesia and decreased rates of long-term complications such as incontinence, ED, bladder neck contractures, and urethral strictures. Additionally, most of these procedures can be accomplished safely on an outpatient basis, either in the office or in an ambulatory surgical setting.

Success rates for minimally invasive therapies are intermediate between those achieved with medical management and those of traditional surgical therapy, with 65% to 75% of patients experiencing symptomatic improvement and improved flow rates. The long-term durability of these therapies appears to be good but is presently being evaluated.

Surgical Management

TURP remains the “gold standard” for the surgical management of symptomatic BPH. A TURP procedure involves removal of the transition zone of the prostate through the use of a scope passed through the urethra using a cutting electrocautery loop. The goals of the surgery are to reduce the transition zone prostate tissue to the level of the prostatic capsule and to create a smooth, open appearance of the prostatic urethra and bladder neck. Improvements in the conventional technique have included bipolar electrosurgical cutting, which allows the use of normal saline irrigation and eliminates the risks associated with the potential systemic absorption of hypotonic irrigation solutions.

Newer operating room-based therapies have evolved that produce end results similar to or better than those of TURP. Holmium laser enucleation (HoLEP) is a surgical technique performed by specially trained urologists, generally indicated for large size prostates (>80 g). In this procedure, the entirety of the prostatic adenoma is “enucleated” from the capsule of the prostate and then removed through the urethra after morcellation. Other procedures include various forms of vaporization of the transition zone tissue of the prostate. In contrast to the TURP and HoLEP, no pieces of prostate are removed with these procedures as the tissue is vaporized. The various vaporization procedures include potassium titanyl phosphate (KTP or GreenLight)

TABLE 73.5 Success in Medical Versus Surgical Management of Benign Prostatic Hyperplasia

Degree of Improvement	α_1 -Blockers	Finasteride	TURP	TUIP	Open Surgery
Symptoms (%)	48	31	82	73	79
Flow rate (%)	40-50	17	120	100	185
Mean probability (%) of achieving the stated improvements	74	67	88	80	98

TUIP, Transurethral incision of the prostate; TURP, transurethral resection of the prostate.

laser therapy, also called photovaporization of the prostate, and bipolar plasma vaporization of the prostate (button TURP). Rates of urinary incontinence, retrograde ejaculation, and urethral stricture are all higher after operating room procedures than after office-based therapies. Perioperative morbidity, including the need for blood transfusion, although substantially decreased by technical improvements, is likewise higher after TURP and similar procedures. However, standard electrosurgical resection of the prostate (TURP) is the most effective surgical treatment for symptomatic BPH short of enucleation. Success rates, as measured by improved symptom scores and increased urinary flow rates, are 80% to 90% after TURP.

Transurethral incision of the prostate (TUIP) is a more limited surgical procedure, although still performed under anesthesia in the operating room, that consists of incising the bladder neck and proximal prostatic urethra. This procedure is generally reserved for men with smaller prostates (<30 g) who have significant LUTS. Although it is more invasive than the heat-based therapies, success rates approach those of TURP in properly selected patients. Morbidity after TUIP is significantly less than after TURP, but long-term durability of symptom relief is less than that seen with TURP.

Surgical enucleation (simple prostatectomy) is reserved for patients with very large glands. Traditionally performed via an open lower abdominal incision, this procedure involves incision into the bladder neck or the capsule of the prostate and then removal of the prostatic adenoma from within the prostatic capsule. While success rates are high, the rate of complications such as bleeding and incontinence is higher than with any of the other traditional surgical approaches (Table 73.5). With advancements in robotic technology, this surgery is now being performed with a robot-assisted laparoscopic approach that has significantly reduced the associated morbidity. For many centers, robot-assisted simple prostatectomy or HoLEP remain the mainstay for management of very large symptomatic prostates.

Conclusion

The management of LUTS resulting from BPH has undergone a dramatic shift from principally a surgical approach to more of a medical one. This evolution of care, coupled with the aging of the U.S. population, has resulted in a shift of care for these patients from the urologist to the primary care physician. In the absence of severe LUTS or indications for early surgical intervention, the primary care physician can now successfully manage most cases of mild to moderate BPH. If there is no or minimal response to therapy, a variety of minimally invasive and surgical options are now available that are all highly successful.

BENIGN SCROTAL DISEASES

Benign masses of the scrotum are some of the most common complaints of men presenting to their primary care providers. While serious concerns such as testicular cancer or an incarcerated inguinal hernia must always be considered, the majority of these masses

are benign. A thorough clinical history and physical exam alone will likely lead one to the correct diagnosis; scrotal ultrasound can be used to confirm a diagnosis or aid in finding the diagnosis for those with equivocal exam findings.

Varicocele

A scrotal varicocele is an abnormal dilation of the veins of the pampiniform plexus that run along the spermatic cord and can be palpated as a “bag of worms” with or without having the patient performing the Valsalva maneuver while standing. When examining a patient for any scrotal pathology, it is important to have the patient stand. A clinical varicocele is one that can be palpated on physical examination. Because the occurrence of varicoceles increases with age, the prevalence in the literature is highly variable. The prevalence of a unilateral palpable left-sided varicocele is between 6.5% and 22%, and that of bilateral palpable varicoceles ranges from 10% to 20%. The prevalence of an isolated right-sided palpable varicocele is less than 1%. However, because of a very rare association of isolated right-sided varicocele with retroperitoneal malignancy, many clinicians perform axial imaging on patients with a unilateral right-sided varicocele. In general, a left-sided varicocele does not have clinical significance unless it can be palpated on physical examination. A varicocele that is incidentally found during ultrasonography of the scrotum and is not palpable on examination is considered a subclinical varicocele and typically does not warrant intervention.

Palpable and nonpalpable varicoceles are most commonly found incidentally and, in most cases, have no clinical significance. However, palpable varicoceles can cause ipsilateral testicular atrophy, discomfort, and/or affect semen parameters. Therefore, it is important for the clinician to compare the size of the testicles in patients who desire future fertility. If the physical examination is unclear, scrotal ultrasonography can be used to accurately measure the size of both testicles. Any patient who desires future children and has a size discrepancy greater than 20% should be monitored closely and possibly referred to a urologist. Although varicoceles are most commonly found incidentally, they may also be found during a work-up for male factor infertility, scrotal pain, or asymptomatic testicular atrophy.

The pathophysiology of varicoceles is poorly understood but involves dilation of the internal spermatic vein and transmission of increased hydrostatic pressure across dysfunctional venous valves. Stasis of blood in the venous system disturbs the countercurrent heat exchange that is responsible for maintaining testicular temperature and may result in testicular parenchymal damage and impaired spermatogenesis.

Varicoceles are the most common cause of both primary male infertility (patient has fathered no children) and secondary male infertility (patient has fathered at least one child), accounting for 33% of cases. However, most men with palpable varicoceles are able to father children without difficulty. In a man with infertility and a palpable varicocele, semen analysis commonly reveals a low sperm count and

abnormal sperm morphology and motility. After surgical correction of a varicocele in a patient with infertility, semen parameters improve in 60% to 80% and subsequent pregnancy rates range from 20% to 60%.

Providers often perform scrotal ultrasonography on any patient with chronic testicular pain to determine the source. Varicoceles are commonly found during this evaluation, but usually only palpable (clinical) varicoceles are considered as a source of pain. If a nonpalpable varicocele is found on an ultrasound examination, the patient should not be told that it is the cause of his pain. However, patients with palpable varicoceles and chronic testicular pain should be referred for treatment, as more than 80% of these men will have improvement in their pain after surgical correction.

Common operative techniques for treatment of a varicocele include high retroperitoneal ligation of the internal spermatic vein, microsurgical inguinal and subinguinal varicocelectomy, laparoscopic varicocelectomy, and gonadal vein embolization. The inguinal approach using microscopic magnification has the highest success and lowest complication and recurrence rates. The most common complication is hydrocele formation, whereas a rare complication is inadvertent ligation of the testicular artery resulting in testicular atrophy and loss. Surgical intervention for subclinical (nonpalpable) varicoceles is not indicated.

Spermatocele (Epididymal Cyst)

Spermatoceles and epididymal cysts are dilations of the tubes that connect the testicle to the epididymis (ductuli efferentes). Although they are technically synonymous, many clinicians refer to small lesions as epididymal cysts and larger ones as spermatoceles. These cystic lesions are very common and are found in 29% of asymptomatic men on ultrasonography. After a vasectomy, 35% of men develop a new small spermatocele, suggesting that distal obstruction of the vasa likely contributes to their development.

On physical examination, spermatoceles are somewhat mobile, firm masses that are separate and distinguishable from the smooth border of the testicle. It may be possible to transilluminate larger lesions, but this is rarely performed in practice. Spermatoceles are filled with a clear fluid that usually contains abundant amounts of sperm. If the lesion cannot be transilluminated, it is advisable to perform an ultrasound study of the scrotum to distinguish a spermatocele from a solid mass or from other testicular lesions. Of note, should a solid mass be identified on the epididymis on imaging, the vast majority of solid masses of the epididymis are benign. However, referral to a urologist for risk evaluation is prudent. Small spermatoceles and epididymal cysts normally have no clinical significance and are typically not the source of a patient's chronic testicular pain. They can be surgically removed if they are large or are causing discomfort for the patient.

Acute Epididymitis

Acute epididymitis is a clinical syndrome that may manifest with fever, acute scrotal pain, and impressive swelling and induration of the epididymis. Epididymitis is most often caused by retrograde bacterial spread from the bladder or urethra into the vasa and then into the epididymides. In men younger than 35 years of age, the most common causative agents are those organisms associated with sexually transmitted infections—namely, *Neisseria gonococcus* and *Chlamydia trachomatis*. In older men, acute epididymitis is usually caused by a coliform bacteria such as *Escherichia coli* and often occurs in association with other lower urinary tract infections or bladder outlet obstruction.

The most important consideration in diagnosing acute epididymitis is differentiating this disease from acute testicular torsion. Physical examination can be nonspecific, although focal epididymal swelling and tenderness are suggestive, and the presence of white cells and bacteria in the urine is indicative of an infectious etiology. Scrotal

ultrasonography with Doppler flow can be extremely helpful in differentiating acute epididymitis from torsion in difficult cases, as the epididymis will present with increased vascular flow (hyperemia) while torsion will show no or diminished flow within the testicle.

Patients with acute epididymitis have significant inflammation that can also involve the testicle (epididymo-orchitis). Patients with severe epididymitis involving the testicle are often systemically ill. In most instances, initial treatment should consist of antibiotics, nonsteroidal anti-inflammatory medications, and possibly oral narcotics. In some cases, broad-spectrum antibiotics or even hospital admission may be necessary. In general, patients younger than 35 years of age should be treated with ceftriaxone and doxycycline. Older patients are usually empirically treated with a fluoroquinolone for 2 to 4 weeks. Complications associated with acute epididymitis include abscess formation, reactive hydrocele formation, testicular infarction, infertility, and chronic epididymitis or orchalgia.

Hydrocele

A hydrocele is a sterile fluid collection located between the parietal and visceral layers of the tunica vaginalis of the scrotum. Noncommunicating hydroceles are commonly seen in adults and usually surround the testicle and spermatic cord. Communicating hydroceles are more common in children and actually represent indirect inguinal hernias. These communicating hydroceles contain only fluid and not bowel or fat because the opening into the peritoneal cavity is small. Communicating hydroceles can be distinguished from noncommunicating hydroceles on physical examination by gently pushing the fluid out of the scrotum and into the peritoneum, or by a history of fluctuation in size of the fluid collection throughout the day or with standing and lying down.

Patients with a noncommunicating hydrocele usually have complaints of heaviness in the scrotum, scrotal pain, or an enlarging scrotal mass. Usually the diagnosis is easily made based on the physical examination and transillumination of the scrotum. If the testis is not palpable, an ultrasound study may be performed to rule out a testicular tumor associated with a secondary or reactive hydrocele. Noncommunicating hydroceles are caused by increased secretion or decreased reabsorption of serous fluid by the tunica vaginalis. Infection, trauma, surgery, neoplastic disease, and lymphatic disease are causative in many adults, whereas the remainder of cases are idiopathic.

Asymptomatic hydroceles are benign and do not require treatment unless desired by the patient. Definitive treatment of symptomatic hydroceles requires surgical intervention. Although the recurrence rate is significantly higher with aspiration and sclerotherapy, this approach can be a good option in patients who are considered poor surgical candidates. Hydrocelectomy procedures involve drainage of the serous fluid with either excision of the redundant tunica vaginalis or plication of the sac without excision. After surgery, the rates of hydrocele recurrence and chronic pain are 9% and 1%, respectively.

Testicular Torsion

Testicular torsion is considered a true urologic emergency. The testicle receives its blood supply from the testicular artery (a branch of the aorta), the vasal artery (a branch of the inferior vesicle artery), and the cremasteric artery (a branch of the inferior epigastric artery). All three vessels are transmitted to the testicle through the spermatic cord. Torsion of the spermatic cord impairs arterial inflow as well as venous outflow. If detorsion is not performed within 6 to 8 hours, testicular infarction and hemorrhagic necrosis are likely to occur. Typically, patients are younger than 21 years of age, although testicular torsion can occur later in life. Delays in presentation and diagnosis are more

common in the adult patient population and are often related to patient and physician factors.

The characteristic signs and symptoms of acute testicular torsion are the acute onset of scrotal pain, swelling, nausea, vomiting, loss of normal rugae of the scrotal skin, absent cremasteric reflex, and a high-riding, rotated, tender testicle. The diagnosis of testicular torsion remains a clinical one; however, in equivocal cases, if ultrasound equipment is readily available and obtaining an ultrasound does not negatively affect the patient promptly proceeding to the operating room, scrotal ultrasonography may be performed prior to surgery. In many cases, surgical exploration is undertaken when the index of suspicion is high but imaging is not available. Doppler ultrasonography is extremely useful in differentiating testicular torsion from other causes of acute scrotum, such as acute epididymitis, torsion of the appendix testis, and trauma, as previously discussed.

It is possible to untwist testicular torsion by manual manipulation of the testicle through the scrotum in the emergency room or in a physician's office. After giving the patient parenteral narcotics, the testicle can be untwisted by gently pulling down on it and, usually, rotating it laterally (like opening a book). If this is successful, the testicle will uncoil like a spring and fall into its normal position, with immediate relief of the patient's pain. Even if the procedure is successful, patients should still be taken to the operating room for bilateral orchiopexy to prevent future occurrences.

Important surgical principles include surgical detorsion and assessment of testicular viability in the operating room. If the testis is determined to be viable, bilateral orchiopexy is performed using the technique of three-point fixation (sutures placed medially, laterally, and inferiorly). In the presence of infarction, orchiectomy is recommended. Orchiopexy of the contralateral testicle is always performed simultaneously. When diagnosis and surgery occur in a timely fashion, testicular salvage rates approach 70%. Delayed surgical therapy significantly decreases the salvage rate to approximately 40%.

Normal Physiology of Bone and Mineral Homeostasis

Clemens Bergwitz, John J. Wysolmerski

CALCIUM HOMEOSTASIS

Circulating free (or ionized) calcium concentrations are maintained within a narrow normal range by an intricate series of homeostatic mechanisms. Maintaining stable calcium levels is important for at least three reasons. First, calcium along with phosphorus forms *hydroxyapatite*, the major mineral contained within the skeleton. Hydroxyapatite provides structural integrity to bones and also provides a metabolic store of calcium to maintain circulating levels if calcium is not readily available from the environment. Reductions in the mineral content of the skeleton can impair its biomechanical integrity and result in fractures. Second, the circulating ionized calcium concentration influences membrane excitability in muscle and nervous tissue. An increase in serum calcium levels produces refractoriness to the stimulation of neurons and muscle cells, which could lead to muscular weakness and even coma. Conversely, a reduction in ionized calcium levels increases neuromuscular excitability, which can translate clinically into seizures or spontaneous muscle cramps and contractions referred to as *carpopedal spasm* or *tetany*. Finally, intracellular calcium contributes to a host of cellular functions, including enzymatic reactions, intracellular signaling, vesicular trafficking, and cytoskeletal organization to name a few. Therefore, all cells require a stable source of calcium in extracellular fluid for proper function. Physicians routinely use a variety of drugs that regulate channels and intracellular calcium concentrations to manipulate cellular function for the treatment of a wide variety of human diseases.

Total circulating calcium levels, which are customarily measured for diagnostic purposes, typically fall between 8.5 to 10.5 mg/dL (4 mg/dL = 1 mmol/L). Of this total value approximately 50% of calcium circulates as free or ionized calcium, 5% circulates as insoluble complexes such as calcium sulfate, phosphate, and citrate, and the remainder (45%) is bound to serum proteins, principally albumin. It is the free, ionized calcium that is important for physiologic processes or in pathophysiologic settings. While changes in the total calcium usually reflect changes in ionized calcium levels, in some instances, total serum calcium can change without a change in the ionized calcium level. For example, if the serum albumin level declines as a result of hepatic cirrhosis or the nephrotic syndrome, the total serum calcium also declines, but the ionized serum calcium concentration remains normal. Therefore, measuring the ionized serum calcium level directly or deriving it from formula 1 and 2 can be important clinically.

Formula 1 (Payne RB, Little AJ, Williams RB, Milner JR: Interpretation of serum calcium in patients with abnormal plasma proteins, *Br Med J* 4:643-646, 1973) is:

$$\text{Ca}_{\text{Ad}} \text{ (mmol/L)} = \text{Ca}_{\text{T}} \text{ (mmol/L)} + 0.025 (40 - \text{albumin, g/L})$$

Formula 2 (Pfitzenmeyer P, Martin I, d'Athis P, et al: A new formula for correction of total calcium level into ionized serum calcium values in very elderly hospitalized patients, *Arch Gerontol Geriatrics* 45:151-157, 2007) is:

$$\text{Ca}^{2+} \text{ (mmol/L)} = 0.188 - 0.00469 \text{ protein (g/L)} \\ + 0.0110 \text{ albumin (g/L)} + 0.401 \text{ Ca}_{\text{Ad}} \text{ (mmol/L)}$$

An overview of calcium economy is represented in [Fig. 74.1](#). As depicted, the circulating calcium level is influenced by a series of three major fluxes of calcium: (1) The net absorption of calcium from the diet in the gut, (2) the storage of calcium in and the liberation of calcium from the hydroxyapatite “warehouse” in the skeleton, and (3) the filtration and net excretion of calcium by the kidneys. Calcium homeostasis and disorders of calcium metabolism involve the hormonal regulation of fluxes between these three compartments.

Calcium Fluxes Into and Out of Extracellular Fluid Intestinal Calcium Absorption

The average dietary calcium intake for an adult is approximately 1000 mg per day. About 300 mg of the total is absorbed (i.e., unidirectional absorption is about 30%), principally within the duodenum and proximal jejunum. However, about 150 mg of calcium per day is secreted by the liver (in bile), the pancreas (in pancreatic secretions), and the intestinal glands into the gut lumen. Thus, net absorption (called *fractional absorption*) of calcium is approximately 15% of intake and about 85% of calcium entering the gut lumen will be excreted in the feces each day.

The efficiency of calcium absorption is regulated at the level of the small intestinal epithelial cell, the enterocyte, by the active form of vitamin D, 1,25-dihydroxyvitamin D (1,25(OH)₂D), also called *calcitriol*. Increases in 1,25(OH)₂D enhance calcium absorption, and decreases in 1,25(OH)₂D reduce absorption of dietary calcium. Dietary calcium absorption can be increased over the short term by increasing calcium intake or by increasing plasma 1,25(OH)₂D concentrations, or both. Pathologic increases in serum calcium (i.e., hypercalcemia) can be caused by increases in circulating 1,25(OH)₂D (e.g., in sarcoidosis) or by excessive calcium intake (i.e., milk-alkali syndrome). Conversely, hypocalcemia can result from a decline in 1,25(OH)₂D (e.g., chronic renal failure, hypoparathyroidism, vitamin D deficiency).

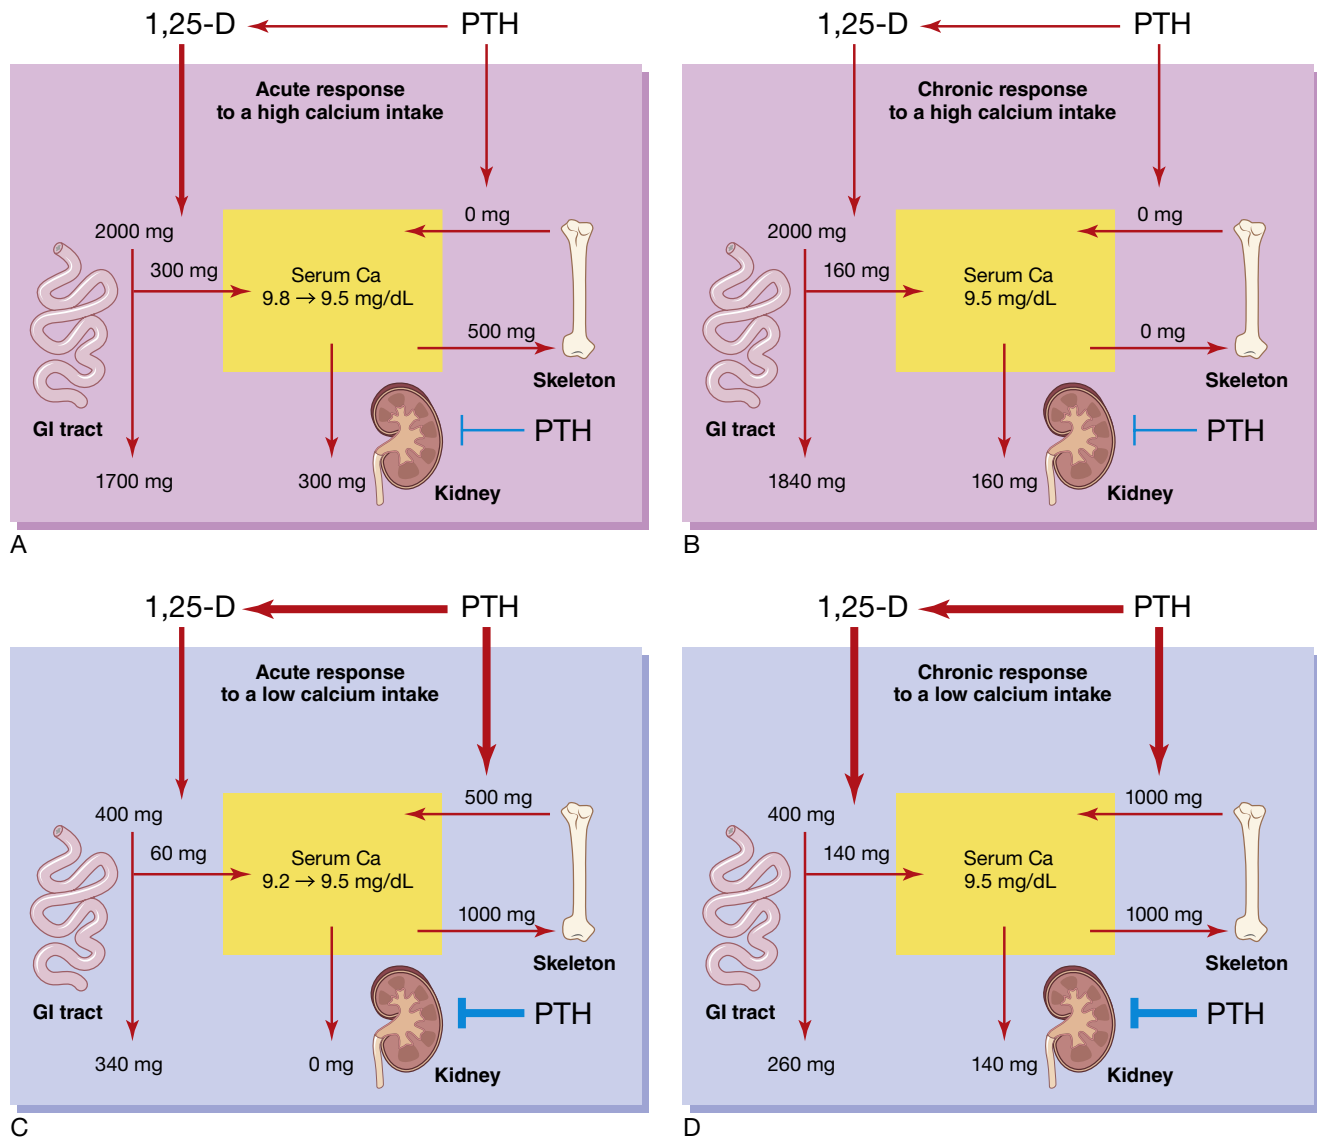

Fig. 74.1 Calcium homeostasis. (A) The acute response and (B) the chronic response to increases in calcium intake. (C) The acute response and (D) the chronic response to decreases in calcium intake. Details are provided in the text. *GI*, Gastrointestinal; *PTH*, parathyroid hormone; $1,25(OH)_2D$, 1,25-dihydroxycholecalciferol (calcitriol). SI conversion: 1 mg calcium = 0.4 mmol calcium.

Renal Calcium Handling

The filtered load of calcium by the kidneys is about 10,000 mg per day assuming a glomerular filtration rate (GFR) of 100 mL/min and serum calcium of 10 mg/dL, making the kidney the most important moment-to-moment regulator of the serum calcium concentration and, as a result, disordered renal calcium handling (e.g., thiazide diuretic use, hypoparathyroidism) can produce significant abnormalities in serum calcium homeostasis.

Of the 10,000 mg of calcium filtered at the glomerulus each day, about 9000 mg (90%) is reabsorbed *proximally* by the proximal convoluted tubule, the pars recta, and the thick ascending limb of Henle loop. This 90% is absorbed in conjunction/competition with sodium and chloride reabsorption and is not subject to regulation by parathyroid hormone (PTH). The remaining 10% (1000 mg) that arrives at the distal tubule is subject to regulation by PTH, which stimulates renal calcium reabsorption. The anticalciuric effect of PTH can be extremely efficient, and elevated PTH concentrations can essentially eliminate calcium

excretion into the urine. This action is a potent mechanism for retaining calcium under conditions of calcium deprivation (e.g., a low-calcium diet, vitamin D deficiency, intestinal malabsorption) and can contribute to hypercalcemia under pathologic conditions, as in primary hyperparathyroidism. The absence of PTH action, in turn, produces hypercalcemia and nephrolithiasis in hypoparathyroidism. Because of preserved PTH action at the distal tubules in pseudohypoparathyroidism, hypocalcemia characterizes this rare genetic condition, which is caused by end-organ resistance to PTH at the proximal tubules, leading to hypovitaminosis D and hypocalcemia despite often elevated PTH levels.

About 150 mg of calcium is excreted by the kidney in the final urine on a daily basis in a healthy individual. If the kidney filters 10,000 mg of calcium each day, and if 150 mg is excreted in the final urine, 9850 mg (98.5%) is reabsorbed at proximal and distal sites. Therefore, a healthy person is in zero calcium balance with respect to the outside world: intake (1000 mg/day) – output [(850 mg/day in feces) + (150 mg/day in urine)] = 0.

Fig. 74.2 Cellular components of bone remodeling. Bone remodeling is a continuous process that involves the activation of osteoclast precursors in the macrophage lineage (i.e., colony-forming units of granulocyte-macrophage progenitors [CFU-GM]) by RANKL that become actively resorbing osteoclasts, which tunnel into the bone surface to dig resorption lacunae. Bone resorption can be inhibited by bisphosphonates, which are toxic to osteoclasts, or by antibody drugs that inhibit RANKL, such as the decoy receptor osteoprotegerin (OPG). Osteoblast precursors in the fibroblast–bone marrow stromal cell lineage (CFU-F) then appear and become active at the sites of prior resorption, and they secrete new osteoid, which later mineralizes to fill the lacunae created by osteoclastic bone resorption. Both processes are stimulated by PTH, which inhibits the bone formation inhibitor sclerostin. PTH analogs and antibody drugs that inhibit sclerostin can be used to stimulate bone formation.

Skeletal Biology and Calcium Homeostasis

The skeleton contains about 1.2 kg of calcium in a male adult and 1.0 kg in a female adult. Most of this calcium is in the form of crystal hydroxyapatite, a calcium phosphate salt. Calcium contributes in an important way to the structural integrity of the skeleton and, in turn, the skeleton serves as a quantitatively large reservoir (i.e., a sink) for adding and removing calcium to and from the extracellular fluid (ECF) compartment at appropriate times.

The adult skeleton is composed of two types of bone: cortical (or lamellar) bone and trabecular (or cancellous) bone. Cortical bone predominates in the skull and the shafts of long bones, and trabecular bone predominates at other sites, such as the distal radius, the vertebral bodies, and the trochanters of the hip.

Bone is not an inert tissue; rather, it is continually turning over. The adult skeleton is completely remodeled every 3 to 10 years. Remodeling is perhaps best appreciated by recalling that orthopedic surgeons routinely and intentionally set fractures imperfectly, knowing that the normal processes of bone remodeling will restore the bone's original shape with the passage of time.

The cells that regulate bone turnover can be divided into those that remove old bone, those that provide new bone (Fig. 74.2) (see Chapter 76), and those that regulate these two processes. Cells that remove, or resorb, old bone are osteoclasts. These cells are large, metabolically active, multinucleated cells derived from the fusion of circulating macrophages. Following attachment to the surface of bone,

osteoclasts form a sealing zone over the bone surface into which they secrete protons (i.e., acid), proteases (e.g., collagenase), and proteoglycan-digesting enzymes (e.g., hyaluronidase). The acid solubilizes hydroxyapatite crystals, releasing calcium, and the enzymes digest bone proteins and proteoglycans (e.g., collagen, osteocalcin, osteopontin), which constitute the nonmineral, or osteoid, component of bone. Osteoclasts move along the surface of trabecular bone plates and drill tunnels in cortical bone, periodically releasing the digested contents within their sealed zones into the bone marrow space and thereby creating resorption pits, called Howship's lacunae, on the trabecular bone surface. The released calcium contributes to the ECF calcium pool, and the released proteolytic products, such as deoxy-pyridinoline cross-links (i.e., collagen fragments and hydroxyproline), can be used clinically as indices of bone resorption.

New bone formation is accomplished by osteoblasts, which are derived from marrow stromal cells or bone surface lining cells. Osteoblasts synthesize and secrete the components of the nonmineral phase of bone, called osteoid. The components are mostly proteins and include collagen, osteopontin, osteonectin, osteocalcin, proteoglycans, and a plethora of growth factors, including transforming growth factor- β and insulin-like growth factor-I. Osteoblasts also produce alkaline phosphatase, which inactivates the mineralization inhibitor pyrophosphate, and type 1 collagen, which forms cable-like structures in bone matrix, and they also facilitate the deposition of hydroxyapatite between these proteinaceous cables. Both the bone-specific

isoform of alkaline phosphatase and procollagen can be used clinically as indices of bone formation. Maintaining the correct balance between protein and mineral in bone provides the combination of compliance and toughness needed to withstand the biomechanical forces encountered by the skeleton.

In the past decade, attention has focused on a third, previously underappreciated bone cell type, the osteocyte. These cells are descendants of osteoblasts and are embedded into the mineralized phase of bone. Osteocytes physically connect with one another and to cells at the mineral surface through long dendritic processes. The dendritic processes extensively permeate the mineralized phase of bone through an elaborate canalicular network. Osteocytes serve a critical role in sensing biomechanical strain within bone, and through their cellular extensions to the bone surface, they communicate signals that attract, activate, or repress osteoclasts and osteoblasts. In this way, they determine which areas of the skeleton require new bone formation and which need to be targets of osteoclastic bone resorption, a critical function for proper structural remodeling of bone tissue.

Bone remodeling involves the coordinated removal of old bone through osteoclastic bone resorption stimulated by receptor activator of nuclear factor κ B ligand (RANKL) followed by the formation of new bone via osteoblastic bone formation. This process occurs in discrete locations called bone remodeling units, the locations of which, as described previously, are likely dictated by osteocytes. In adults, skeletal homeostasis requires the careful balancing of osteoclast and osteoblast activities so that the same amount of bone that is removed by osteoclasts is replaced by osteoblasts. This is accomplished by a complex, and only partly understood, three-way series of communications between osteoclasts, osteoblasts, and osteocytes, that are modulated by systemic hormones. Altering the relative activities of these cells can result in the net movement of calcium out of or into the skeleton on a physiologic basis but a prolonged imbalance of osteoclastic and osteoblastic activities can result in disease. For example, excessive bone remodeling leads to osteoporosis, while absent bone remodeling leads to adynamic bone disease, both conditions that can predispose to fractures. Bone remodeling is also exploited therapeutically. Anabolic agents for osteoporosis, such as sclerostin inhibitors or parathyroid hormone and parathyroid hormone-related protein analogues stimulate the activity of osteoblasts to produce new bone. In contrast, antiresorptive agents, such as estrogens, estrogen-like drugs, bisphosphonates, and RANKL inhibitors, reduce bone resorption to improve bone mass and bone mechanical properties.

Bone remodeling is important for systemic calcium homeostasis. Osteoclasts are mobilized to release calcium from the skeleton in times of need in order to maintain a normal serum calcium concentration and prevent hypocalcemia. Conversely, unmineralized osteoid produced by osteoblasts serves to deposit excess calcium to prevent hypercalcemia. Under normal circumstances, osteoclasts result in the release of about 500 mg of calcium per day from the skeleton to the ECF compartment. At the same time, osteoblasts produce osteoid that mineralizes at a rate such that about 500 mg of ECF calcium is deposited in the skeleton at new sites. From the perspective of the normal homeostatic fluxes shown in Fig. 74.1, the skeleton is in zero calcium balance with the ECF, and the whole organism is in zero calcium balance with the external environment.

Considering the complexity of this calcium homeostatic system and the importance of maintaining tight control of serum calcium levels, an obvious need exists for systemic regulation and integration of the calcium fluxes across the GI, skeletal, and renal compartments. The two key metabolic regulatory hormones that coordinate these activities are PTH and the active form of vitamin D, 1,25(OH)₂D.

Fig. 74.3 Calcium and phosphate homeostasis are co-regulated by parathyroid hormone (PTH). PTH is secreted as an 84-amino-acid protein, which is cleaved in the liver to derivative amino-terminal and carboxyl-terminal (C-term) forms. Actions of the amino-terminally intact forms of PTH are listed in Table 74.1. It stimulates synthesis of the active form of 1,25(OH)₂D, 1,25-dihydroxycholecalciferol, from its biologically inactive precursors, vitamin D₂ and D₃, which are either produced in the skin or absorbed from the diet in the gastrointestinal (GI) tract, and 25-hydroxylated in the liver and kidney. 1,25(OH)₂D stimulates absorption of calcium and phosphate from the diet in the GI tract. Different from PTH, fibroblast growth factor 23 (FGF23) stimulates renal phosphate excretion and inhibits the last step (1 α hydroxylation) of vitamin D activation. Although both PTH and FGF23 lower phosphate levels, PTH primarily responds to changes in circulating calcium levels, while FGF23 responds to alterations in phosphate levels. Their different actions on vitamin D synthesis reflect their different primary functions since PTH increases 1,25 vitamin D levels to help restore low calcium levels towards normal and FGF23 suppresses 1,25 vitamin D levels to help restore elevated phosphate levels towards normal.

Regulatory Hormones

Parathyroid Hormone

PTH is a peptide hormone produced by the four parathyroid glands (Fig. 74.3 and Table 74.1). These glands are located behind the normal thyroid lobes, with two on the right and two on the left. Through the calcium sensor—a G protein-coupled receptor for calcium that is located on the surface of the parathyroid cell—the serum ionized calcium concentration is continuously monitored. In this exquisitely sensitive system, minor (e.g., 0.1 mg/dL) reductions in serum ionized calcium lead to PTH secretion, and minor increments in serum calcium lead to suppression of PTH secretion.

PTH is secreted as an 84-amino-acid peptide hormone that is rapidly (half-life of about 3 to 5 minutes) cleaved by the Kupffer cells in the liver into an active amino-terminal form and an inactive carboxyl-terminal fragment. Continuous monitoring of the serum calcium concentration by the parathyroid glands, the immediate secretion of PTH in response

TABLE 74.1 Hormone Actions

Hormone	S-CA	U-CA	P-Pi	U-Pi	S-1,25(OH) ₂ D	S-Mg	U-Mg	Other
PTH	↑	↓	↓	↑	↑	=	=	Stimulates bone remodeling, induces hypotension
FGF23	=/↓	=/↓	↓	↑	↓	=	=	Inhibits growth plates resulting in short stature, causes left ventricular hypertrophy
1,25(OH) ₂ D	↑	↑	↑	↑	↓	=	=	Inhibits PTH secretion and stimulates FGF23 synthesis
EGF1	=/↓	=/↑	=	=	=/↓	↑	↓	

EGF1, Epidermal growth factor 1; FGF23, fibroblast growth factor 23; PTH, parathyroid hormone; 1,25(OH)₂D, 1,25-dihydroxy vitamin D.

to hypocalcemia, and the rapid clearance of PTH after secretion enable the parathyroid gland and PTH to regulate serum calcium rapidly and with remarkable precision.

PTH targets three organs, two directly and one indirectly. In the kidney, PTH stimulates calcium reabsorption in the distal tubule inhibiting urinary calcium excretion. PTH also inhibits phosphate and bicarbonate reabsorption by the proximal tubules, which induces phosphaturia and hypophosphatemia and proximal renal tubular acidosis, respectively. PTH also stimulates the production of the active form of vitamin D, 1,25(OH)₂D by the renal tubules. These actions of PTH on the kidney are rapid and direct.

The second PTH target is the skeleton. PTH can mobilize calcium immediately from the skeleton through the activity of osteoclasts and osteocytes, without activating bone formation, which is important for the rapid delivery of calcium to the ECF. If PTH is elevated over days to weeks, it also stimulates the activity of osteoblasts directly and through inhibition of sclerostin release by osteocytes to produce new bone. This type of prolonged elevation in PTH stimulates bone resorption in excess of bone formation to maintain a net release of skeletal calcium to the ECF, enabling the skeleton to help prevent hypocalcemia in states of nutritional calcium deficiency, malabsorption or vitamin D deficiency.

The third target organ is the intestine, which PTH affects indirectly. By increasing renal synthesis of 1,25(OH)₂D, PTH can lead to increased intestinal calcium absorption to supply more calcium to the ECF from the diet, a response that is not immediate but occurs over several days of PTH stimulation. Seen in concert, PTH is secreted in response to hypocalcemia, and the actions of PTH combine to restore a low serum calcium concentration to normal by preventing renal calcium losses, by releasing calcium from the skeleton, and by indirectly stimulating (through 1,25(OH)₂D) increases in intestinal calcium absorption.

Vitamin D

Vitamin D occurs in two forms: ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃) (Fig. 74.3 and Table 74.2). Both substances are inactive precursors. One (D₃) is derived principally from skin exposed to sunlight and the other (D₂) is derived from plant sterols in the diet. Either D₂, D₃ or both can be found in multivitamins and commercial dietary supplements.

Both precursors are constitutively converted to their respective 25-hydroxyvitamin D (25[OH]D) derivatives in the liver through the actions of the enzyme vitamin D 25-hydroxylase (CYP2R1). 25(OH)D is also called calcidiol and has 1000-fold lower affinity to the vitamin D receptor (VDR) when compared to 1,25(OH)₂D, but it is a helpful clinical laboratory measure of the vitamin D status (i.e., repletion or deficiency) of patients with hypocalcemia, osteomalacia or rickets, osteoporosis, intestinal malabsorption, and other similar conditions. Furthermore, severe liver disease such as cirrhosis prevents this 25-hydroxylation and leads to a vitamin D–deficiency syndrome called hepatic osteodystrophy.

25(OH)D is converted, or activated, in the renal proximal tubule by the enzyme 25-hydroxyvitamin D₃ 1 α -hydroxylase (CYP27B1) to the active form of the vitamin, 1,25(OH)₂D, which is also called calcitriol.

PTH increases 1,25(OH)₂D levels by stimulating its formation through the activity of CYP27B1 while also inhibiting its degradation through the activity of another enzyme, CYP24A1 (24-hydroxylase), which converts 1,25(OH)₂D to its inactive metabolite, 24,25(OH)₂D. The primary action of 1,25(OH)₂D is to regulate intestinal calcium absorption. PTH, through 1,25(OH)₂D, indirectly regulates calcium absorption from the diet by the intestine. The hypocalcemia of hypoparathyroidism is a result, in part, of inadequate intestinal calcium absorption. Conversely, hyperparathyroidism is associated with hypercalciuria and nephrolithiasis, both of which directly result from increases in circulating 1,25(OH)₂D levels. Therefore, measurement of 1,25(OH)₂D can be used as an index of parathyroid function and intestinal calcium absorption.

Because of some affinity to the vitamin D receptor, high doses of calcidiol can be used to treat hypoparathyroidism. However, 1 α -hydroxylated versions (i.e., hectoral), which can be 25-hydroxylated by CYP2R1 in the liver or calcitriol, have become standard of care for these disorders (see Table 74.2).

Calcitonin

Calcitonin is produced by the parafollicular or C cells of the thyroid gland in response to hypercalcemia. It was once viewed as an essential calcium-regulating hormone. Pharmacologic doses of calcitonin reduce serum calcium levels by inhibiting osteoclastic bone resorption, which is used in the emergency setting along with hydration to rapidly treat life-threatening hypercalcemia, but this effect wears off quickly due to tachyphylaxis (i.e., desensitization of osteoclasts). Little evidence exists that calcitonin has homeostatic relevance in humans, although it appears to contribute to the regulation of calcium and skeletal homeostasis during reproductive cycles in female rodents.

Integration of Calcium Homeostasis

Ingestion of a greater than normal dietary calcium load (see Fig. 74.1A) leads to a mild rise in the serum calcium level. The rise in calcium is sensed by the parathyroid glands that suppress PTH secretion causing a rapid and marked increase in renal calcium excretion by the distal tubule. It also immediately decreases osteoclastic activity, which slows continued bone resorption but allows continued calcium entry from the ECF into unmineralized osteoid. These two effects produce a rapid, short-term reduction in serum calcium to normal levels. However, if the high-calcium diet is maintained over the long term, these adaptations are insufficient. Continued renal calcium wasting leads to hypercalciuria (with nephrolithiasis and nephrocalcinosis), and unopposed osteoblastic bone formation leads to excessive skeletal mineralization (i.e., osteopetrosis).

Two additional responses (see Fig. 74.1B) are required to prevent the long-term adverse effects of a high-calcium diet. First, subacute or chronic suppression of PTH reduces circulating 1,25(OH)₂D. This reduces the efficiency of calcium absorption from the intestine, calcium entry into the ECF, and urinary calcium excretion. Second, a chronic decrement in PTH leads to a chronic decline in osteoblastic activity. No osteoid is formed, and the ability to deposit calcium into the skeleton is decreased.

TABLE 74.2 Phosphate and Vitamin D Metabolite Preparations

Phosphate Preparations	Phosphorus Content	Potassium (K) Content	Sodium (Na) Content
Neutra-Phos powder (for mixing with liquid)	250 mg/packet	270 mg	164 mg
Neutra-Phos-K powder (for mixing with liquid)	250 mg/packet	556 mg	0 mg
K-Phos Original tablet (to mix in liquid, acidifying)	114 mg/tablet	144 mg	0 mg
K-Phos MF tablet (mixing not required, acidifying)	126 mg	45 mg	67 mg
K-Phos #2 (double strength of K-Phos MF)	250 mg	90 mg	133 mg
K-Phos Neutral tablet (nonacidifying, mixing not required)	250 mg	45 mg	298 mg
Phospho-Soda solution (small doses may be given undiluted)	127 mg/mL	0 mg/mL	152 mg/mL
Joule's solution (prepared by compounding pharmacies)	30 mg/mL	0 mg/mL	17.5–20 mg/mL

Vitamin D and Related Agents	Available Preparations
Vitamin D	
Calciferol (Drisdol)	Solution: 8000 IU/mL Tablets: 25,000 and 50,000 IU
Dihydrotachysterol	
DHT (Hytakerol)	Solution: 0.2 mg/mL Tablets: 0.125, 0.2, and 0.4 mg
1,25 Dihydroxyvitamin D	
Calcitriol (Rocaltrol)	0.25 and 0.5 µg capsules and 1 µg/mL solution
Calcijex	Ampules for IV use containing 1 or 2 µg of drug per mL
1α-Hydroxyvitamin D	
Alfacalcidol	0.25, 0.5, and 1 µg capsules Oral solution (drops): 2 µg/mL Solution for IV use: 2 µg/mL
Vitamin D Analogues	
Paricalcitol (Zemlar)	1 and 2 mcg capsules 2 and 5 mcg/mL injectable solution
Doxercalciferol (Hectoral)	0.5, 1, and 2.5 µg capsules 2 mcg/mL injectable solution

SI conversion: 1 mg phosphorus = 0.32 mmol phosphorus, 1 µg vitamin D = 40 IU vitamin D.

From Carpenter TO, Imel EA, Holm IA, Jan de Beur SM, Insogna KL. A clinician's guide to X-linked hypophosphatemia. *J Bone Miner Res.* 2011 Jul;26(7):1381-8. <https://doi.org/10.1002/jbmr.340>. Epub 2011 May 2.

Conversely, during brief periods of dietary calcium deficiency (see Fig. 74.1C), as occurs between meals, the serum calcium level declines almost imperceptibly and PTH levels rise, which immediately reduces renal calcium excretion. At the same time, an acute activation of osteoclasts and osteocytes delivers skeletal calcium into the ECF. The combination of reduced urinary calcium loss and increased skeletal calcium efflux rapidly returns blood calcium to normal.

Over the longer term, the initial response is inadequate and leads to skeletal demineralization. A longer-term solution is required, and the adaptation is 2-fold (see Fig. 74.1D). First, a chronic low calcium intake, as may occur in a person with lactose intolerance, leads to a chronic elevation in PTH, and over a matter of days to weeks, this leads to an increase in the 1,25(OH)₂D level, which increases the efficiency of calcium absorption from the intestine (i.e., increase in the fractional absorption of calcium) to compensate for the reduction in dietary intake. Second, chronically elevated PTH leads to an increase in osteoblast activity to match the increased osteoclastic activity. In this steady-state adaptation to a low-calcium diet, PTH levels are elevated, and coupled increases in osteoclastic and osteoblastic activities take place (i.e., increased bone turnover), but net skeletal calcium losses are negligible or normal. These physiologic adaptations hold for mild reductions in dietary calcium but in cases of severe calcium restriction or malabsorption, chronic and more significant elevations in PTH can

lead to an imbalance of greater bone resorption than bone formation and chronic bone loss.

From an evolutionary standpoint, as life moved from a calcium-rich marine environment to a terrestrial setting in which calcium availability was unpredictable, a complex, elegant regulatory mechanism evolved that permitted survival without requiring intentional behavioral adaptations to the vagaries of calcium supply. As discussed in Chapter 75, disorders that cause hypercalcemia or hypocalcemia are always caused by abnormalities at the interfaces of the ECF with the intestine, kidney, and skeleton. The physician needs only to recall these homeostatic premises to dissect the pathophysiologic process with precision, enabling her or him to treat the underlying disorder effectively.

PHOSPHATE HOMEOSTASIS

Phosphorus is an inorganic element, abbreviated as *P* in physical chemistry literature. The biologically relevant molecule is the negatively charged, divalent phosphate ion (HPO₄²⁻), also referred to as inorganic phosphate (Pi). Phosphate is an important physiologic buffer, and at neutral pH in blood, it is apportioned between HPO₄²⁻ (divalent) and H₂PO₄⁻ (monovalent) species. Clinical laboratories use differing methods to measure either phosphate (colorimetric assays) or phosphorus (flame photometry), but phosphate measurements are converted to phosphorus (1 mg/

dL phosphate contains 0.32 mmol/L phosphate, which is equal to 0.32 mmol/L phosphorus). Physicians need to be aware that phosphorus preparations often list the mass of the phosphate salt, which includes oxygen, sodium, and potassium (see Table 74.2). Phosphorus content varies for the specific preparation being prescribed, which should be considered in consultation with the pharmacist and hospital formulary.

Pi participates in the regulation of an enormous number of biologic processes fundamental to life. They include being an integral component of the DNA double helix, shuttling oxygen from hemoglobin to cells and vice versa using 2,3-diphosphoglycerate (2,3-DPG), intracellular signaling through kinases that attach phosphate groups to other molecules, facilitating critical intracellular messenger systems such as cyclic monophosphate (cAMP) and inositol phosphates, maintaining basic intracellular redox status through the nicotinamide adenine dinucleotide phosphate (NADP-NADPH) system, and serving as the gateway to the glucose metabolic pathway through glucose 6-phosphate.

Most phosphorus is intracellular as Pi or organophosphate. In addition to its critical intracellular roles, Pi has a key extracellular role. The anion pairs with calcium in the hydroxyapatite crystal lattice that provides structural integrity to the skeleton (discussed earlier). As with calcium, phosphate is critical to skeletal strength, and disorders of phosphorus homeostasis, such as hypophosphatemic rickets, lead to pathologic skeletal fractures. The skeleton also serves as a major storage site for phosphate that is accessed in times of severe phosphate deficiency.

The broad intracellular roles for Pi have two corollaries. First, clinically significant intracellular Pi deficiency may exist without marked hypophosphatemia. Second, life-threatening Pi deficiency is often unrecognized because its manifestations (i.e., reduced levels of consciousness, hypotension, respirator dependence, and muscular weakness) are nonspecific but common in intensive care unit settings. Astute clinicians learn to recognize general debility as a potential sign of Pi deficiency. Pi repletion in this setting may produce dramatic results.

In contrast to regulation of the serum calcium concentration, which is very tight, the regulation of the serum phosphate concentration is relatively lax. Serum phosphate levels are maintained in a range between 2.5 and 4.5 mg/dL, which is broader than the range of normal calcium concentrations. Furthermore, the normal range of infants is higher, between 3.5 and 5.5 mg/dL, and decreases to the adult range in the first few years of life. Even so, the regulation of the extracellular Pi concentrations is no less important, because hypophosphatemia and hyperphosphatemia can both cause disease. Pi is abundant in most diets, and only 33% of intestinal Pi absorption is regulated, principally by 1,25(OH)₂D, while 67% occurs in an unregulated fashion. Conversely, its excretion is tightly regulated in the renal proximal tubules by PTH and fibroblast growth factor 23 (FGF23).

Fig. 74.4 outlines the main fluxes of phosphate that define the circulating level as well as overall phosphate economy. The box represents the ECF, and as with calcium, it has interfaces with the GI tract, kidney, and skeleton. Because most phosphate is contained within cells, the phosphate black box has a quantitatively significant interface with the intracellular compartment.

Intestinal Phosphate Absorption

A normal diet contains about 1200 to 1600 mg of phosphorus, and about two thirds of this amount, or 800 to 1200 mg, is absorbed each day. This fixed fractional absorption of about 67% occurs in the duodenum and jejunum. In the normal world of phosphate abundance, this intake is more than ample. Under conditions of dietary phosphorus deficiency, as occurs in chronic alcoholism, intensive care units, intestinal malabsorption, or phosphate-binding antacid use, failure of adequate phosphorus absorption presents a physiologic challenge for which no physiologic remedy exists.

Skeletal Phosphate Fluxes

As with calcium, osteoclastic bone resorption and osteoblastic new bone formation (see Fig. 74.2) lead to skeletal phosphate exit or entry, respectively. Under pathophysiologic conditions, skeletal phosphate fluxes may become important. For example, skeletal destruction in multiple myeloma or severe immobilization syndromes leads to hypercalcemia and hyperphosphatemia, which can cause nephrocalcinosis and renal failure. Conversely, osteoblastic metastases in prostate and breast cancers as well as the hungry bone syndrome after parathyroidectomy can cause clinically significant hypophosphatemia. Although phosphorus has been viewed as a passive passenger with calcium in the calcium regulatory process, recent insights suggest that FGF23, whose levels are determined by phosphate concentrations, stimulates bone matrix mineralization independently of calcium by suppressing osteopontin and by stimulating alkaline phosphatase activity.

Intracellular-Extracellular Phosphate Fluxes

Phosphate shuttles from extracellular to intracellular compartments. This issue becomes important in certain clinical situations. For example, in the setting of metabolic acidosis, phosphate leaves the intracellular compartment and may lead to hyperphosphatemia, whereas under conditions of alkalosis, serum phosphate concentrations decline, and hypophosphatemia develops as phosphate enters the intracellular compartment.

The intracellular phosphate level has important clinical implications, in part, in the settings of crush injury (i.e., rhabdomyolysis) and tumor lysis syndrome. In both conditions, large intracellular loads of phosphate are delivered into the ECF and result in hypocalcemia, seizures, nephrocalcinosis, and renal failure. Conversely, glucose shifts phosphate into cells as glucose 6-phosphate, and overzealous intravenous or oral caloric restitution in the undernourished patient can result in severe hypophosphatemia and sudden death.

Renal Phosphate Handling

The most important mechanism for maintaining a normal serum phosphorus concentration is the regulation of renal phosphorus excretion. As with calcium, phosphate is filtered by the glomerulus, and 90% is reabsorbed (i.e., tubular reabsorption of filtered phosphate [TRP]). The remaining 10% is excreted (i.e., fractional excretion of phosphorus [FE_{Pi}]). The FE_{Pi} can be calculated in a spot urine sample using formula 3:

$$FE_{Pi} = \left(\frac{\text{urine Pi [mg/dL]} / \text{urine creatinine [mg/dL]}}{\text{serum creatinine [mg/dL]} / \text{serum phosphorus [mg/dL]}} \right)$$

The TRP is simple to calculate using formula 4:

$$TRP = 1 - FE_{Pi} \text{ (expressed in \%, when multiplied by 100)}$$

The renal handling of phosphorus is best considered as a tubular maximum (T_m)-regulated process. The T_m/GFR is normally identical to a normal serum phosphorus concentration in blood, 2.5 to 4.5 mg/dL. If the serum phosphate concentration rises above this level, phosphaturia occurs, and as a result the serum phosphorus returns to the normal range. If the serum phosphate concentration declines below this level, filtered phosphate is entirely reabsorbed as TRP approaches 100%. Thus, the T_m/GFR can be considered as a dam in the phosphate reservoir, over which excess phosphate spills and whose level controls the concentration of serum phosphorus. The T_m/GFR is not fixed but can be moved upward or downward, depending on metabolic needs and prevailing metabolic conditions (described later).

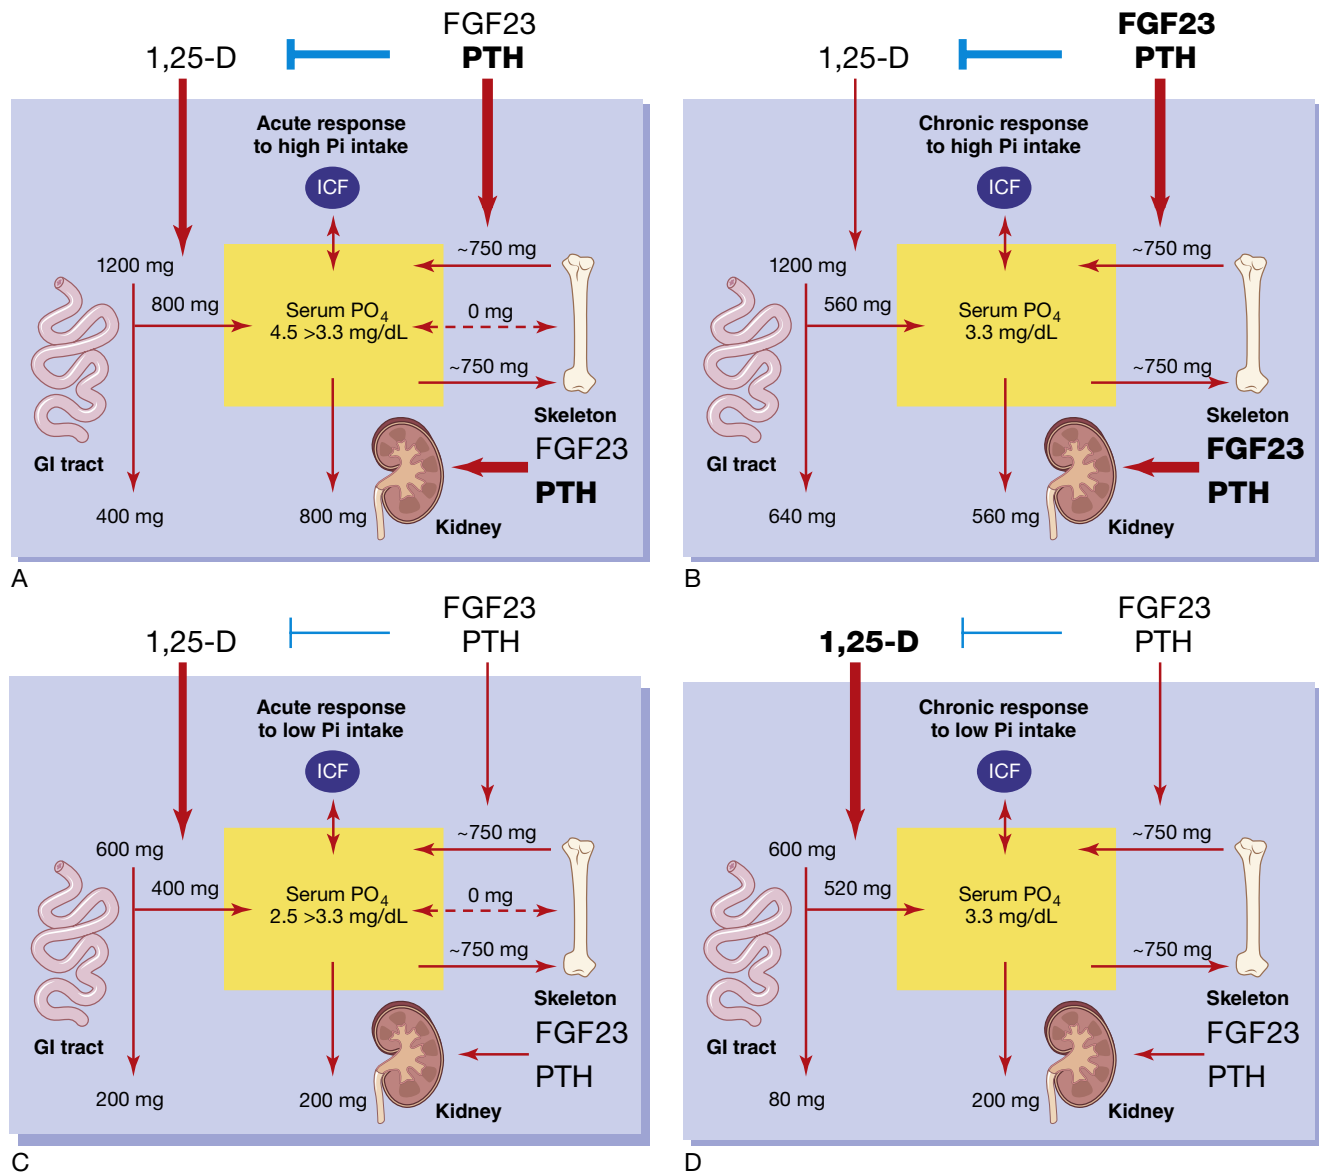

Fig. 74.4 Phosphate homeostasis. (A) The acute response and (B) the chronic response to increases in phosphate intake. (C) The acute response and (D) the chronic response to decreases in phosphate intake. Details are provided in the text. *FGF23*, Fibroblast growth factor 23; *GI*, gastrointestinal; *ICF*, intracellular fluid; *PTH*, parathyroid hormone; $1,25(\text{OH})_2\text{D}$, 1,25-dihydroxycholecalciferol (calcitriol). SI conversion: 1 mg phosphorus = 0.32 mmol phosphorus.

The TRP can be used to derive TmP/GFR from the nomogram of Bijvoet, which is shown in Fig. 74.5. Determining renal handling of Pi by calculation of TRP and deriving TmP/GFR proves enormously useful in clinical practice because it is the central starting point for determining whether hypophosphatemia is principally renal or nonrenal in origin.

Regulatory Hormones

Fibroblast Growth Factor

In addition to PTH, which has long been appreciated to be phosphaturic, experimental dietary phosphorus deprivation in laboratory animals and humans leads to a PTH-independent increase in the TmP/GFR , and high-phosphate feeding results in a PTH-independent decline in the TmP/GFR . Over the past two decades, the principal phosphaturic hormone or phosphatonin responsible for regulating renal phosphate handling was identified as fibroblast growth factor 23 (FGF23). FGF23 also affects calcium regulatory hormones; however, the principle regulator of FGF23 is phosphate, while the principle

regulator of PTH is calcium. FGF23 together with FGF19 and FG21 define a family of evolutionarily conserved endocrine fibroblast growth factors. FGF23 elicits its phosphaturic actions in the renal proximal and distal tubules by activation of a co-receptor complex composed of FGFR1c and alpha klotho (aKL). It also acts in an aKL-independent fashion to suppress CYP27B1 and stimulate CYP24A1, leading to inactivation of $1,25(\text{OH})_2\text{D}$. This requires two different receptors, FGFR3 and FGFR4. The net effect of these actions is a decrease of serum phosphorus. FGF23 also suppresses PTH, stimulates bone mineralization, and inhibits erythropoietin-mediated synthesis of red blood cells, which are less well-understood actions.

FGF23 is produced by osteoblasts and osteocytes. Its gene expression is stimulated by a number of factors including $1,25(\text{OH})_2\text{D}$ and bone matrix factors, for example phosphate-regulating neutral endopeptidase, X-linked (PHEX), the gene mutated in X-linked hypophosphatemia (XLH). Phosphate stimulates FGF23 secretion on the posttranslational level, presumably by increasing activity of the o-glycosylase, GALNT3, which prevents FGF23 inactivation. Mutations

Fig. 74.5 Nomogram shows the tubular maximum for the phosphorus glomerular filtration rate (TmP-GFR). It allows conversion of the fractional excretion of phosphorus (or its inverse, the tubular reabsorption of filtered phosphate [TRP]) into the TmP-GFR. The TRP is calculated, and a line is drawn (red arrow) extending from the serum phosphorus level (left vertical line), through the TRP (middle diagonal line), to the right vertical line, which represents the TmP/GFR. TmP values are provided in millimolar and milligram per deciliter units. TmP values below 1.0 mmol or 2.5 mg/dL are abnormal in the setting of hypophosphatemia and indicate renal phosphate wasting. C_{creat} , Creatinine concentration; C_{PO_4} , phosphate concentration.

in the o-glycosylation site of FGF23 stabilize and thereby increase its bioactivity and are responsible for autosomal dominant hypophosphatemic rickets (ADHR). FGF23 is also the factor responsible for most paraneoplastic hypophosphatemic syndromes, also referred to as tumor-induced osteomalacia (TIO).

MAGNESIUM HOMEOSTASIS

Magnesium is a divalent cation and its homeostasis parallels phosphorus homeostasis. Like Pi, magnesium is principally intracellular, with concentrations inside the cell that far exceed those outside the cell. Both substances govern key intracellular regulatory processes. In the case of magnesium, these processes include fundamental events such as DNA replication and transcription, translation of RNA, the use of adenosine triphosphate as an energy source, and regulated peptide hormone secretion.

Both substances are abundant inside all kinds of cells. Because they are well supplied in vegetarian and carnivorous diets, little evolutionary pressure exists to develop a complex regulatory network and, as with phosphate, serum magnesium concentrations are not tightly regulated. Because magnesium is principally intracellular, measurement of serum levels may provide false estimates of actual total body and intracellular magnesium status. Because magnesium is essential for fundamental processes such as gene transcription and cellular energy use, life-threatening magnesium deficiency is often unrecognized because its symptoms are nonspecific: weakness, respirator dependence, diffuse neurologic syndromes (including seizures), and cardiovascular collapse.

Magnesium has a molecular weight of 24 (1 mole = 24 g), and because it is divalent, one equivalent is 12 g. Blood magnesium

Fig. 74.6 Magnesium homeostasis. See Fig. 74.1 for nomenclature and the text for details.

measurements are often provided in milligrams per deciliter (mg/dL) or milliequivalents per liter (mEq/L); oral magnesium supplements are expressed in milligrams per tablet or milliequivalents per vial; and urinary magnesium excretion values are given in milliequivalents or milligrams per 24 hours. As with calcium and phosphate, it is helpful to examine daily magnesium fluxes. In Fig. 74.6, magnesium values are provided in milligram and milliequivalent units.

As with phosphorus, magnesium has quantitatively important interfaces with the intestine, skeleton, intracellular supplies, and kidney. At the level of the intestine, magnesium is widely available in normal diets and about one third of what is ingested is absorbed in a largely unregulated fashion. In normal circumstances, because dietary magnesium is abundant, magnesium deficiency does not occur. However, deficiency due to insufficient dietary absorption may occur with alcoholism, proton pump inhibitor or cyclosporin use, in intensive care unit settings in which adequate nutrition often is not provided, or with intestinal malabsorption.

Magnesium is incorporated into hydroxyapatite crystals in the skeleton as mineralization of osteoid occurs, and it is released by osteoclastic bone resorption (see Fig. 74.3). In quantitative terms, these fluxes are small.

Many instances of magnesium deficiency are caused by excessive renal losses. Functional examples include the magnesuria that accompanies saline infusions, aminoglycoside, diuretic, or alcohol use, and secondary hyperaldosteronism states such as cirrhosis and ascites. Genetic magnesium deficiency occurs as a result of mutations in claudin 16 and 19 (*CLCN16* and *CLCN19*), both of which encode for paracellular calcium and magnesium channels in the thick ascending limb, and transient receptor potential melastatin 6 (TRPM6) in the distal renal tubules. Gitelman-like hypomagnesemia occurs with several of the Bartter syndromes.

As with calcium and phosphorus, the fractional excretion of magnesium (FE_{Mg}) can be calculated, and it should be used as an index of whether the kidney is appropriately conserving magnesium in states of hypomagnesemia or whether renal magnesium wasting is the cause of the hypomagnesemia. The normal FE_{Mg} is 2% to 4%. Hypomagnesemic individuals have FE_{Mg} values below 1% to 2%.

Like phosphate, magnesium homeostasis can best be viewed as a renal Tm-regulated process (see “Renal Phosphate Handling”), with the renal Tm for magnesium set at a fixed level of about 2.2 mg/dL. In this scenario, abundant dietary magnesium exists, and excessive magnesium intake is managed by spillage of excess magnesium into urine when the Tm of 2.2 mg/dL is exceeded. Conversely, in settings

of dietary magnesium deficiency, which equate evolutionarily with caloric deficiency, short-term deficiency is prevented when serum levels fall below the renal T_m of 2.0 mg/dL.

Regulatory Hormones

The significance of hormonal regulators for magnesium homeostasis is currently unclear. Isolated recessive hypomagnesemia is caused by loss-of-function mutations in the epidermal growth factor gene (*EGF1*; see Table 74.1). EGF1 is magnesiotropic as it acts in an autocrine or paracrine fashion to stimulate expression of TRPM6 in the distal convoluted tubules of the kidneys, which increases Mg reabsorption from the urine. Its role as magnesiotropic hormone is further supported by the hypomagnesemia in cancer patients who are treated with the chimeric human/mouse anti-EGF antibody cetuximab or with inhibitors of the EGFR tyrosine kinase (i.e., erlotinib). Magnesium deficiency can result in parathyroid failure and therefore hypocalcemia due to its important role in peptide hormone secretion.

PROSPECTUS FOR THE FUTURE

Although it may seem that calcium, PTH, vitamin D, magnesium, and phosphorus homeostasis and skeletal biology are well understood,

many of the physiologic details described in this chapter have been elucidated only during the past 10 to 15 years, and new regulatory proteins (e.g., fibroblast growth factor 23, epidermal growth factor 1) and diseases continue to be identified. This area of research is dynamic, with many unanswered questions remaining.

Disorders of Serum Minerals

Emily M. Stein, Yi Liu, Elizabeth Shane

INTRODUCTION

This chapter will provide an overview of the metabolic disorders that can impact serum calcium, phosphorus, and magnesium. We will review those disorders that manifest in both excess and deficiency. Please refer to [Chapter 74](#) for descriptions of normal calcium, phosphorus, and magnesium metabolism. We will briefly review the pathophysiology of these disorders, the signs and symptoms, and strategies for treatment. When evaluating a patient, it is critical to consider the broad differential diagnosis for each metabolic abnormality. For all of the metabolic disturbances, the severity of presentation can vary dramatically depending not only on the magnitude of the abnormal value but also on the acuity with which it develops. Patients with chronic abnormalities may have very few symptoms, whereas those with more acute changes are more likely to be symptomatic. Even among patients who have multiple conditions that may result in metabolic disturbances, the most common diagnoses are still most likely. For example, a patient with a history of malignancy who develops hypercalcemia may have humoral hypercalcemia of malignancy, but primary hyperparathyroidism (HPT) should also be considered.

DISORDERS OF CALCIUM METABOLISM

Hypercalcemia

Pathophysiology

Serum calcium is tightly regulated by the movement of ionized calcium between the skeleton, intestines, kidney, and serum binding proteins. Hypercalcemia develops when there are abnormalities in the movement of calcium between the extracellular fluid (ECF) and one of these compartments or when there is abnormal binding of calcium to serum proteins. Hypercalcemia causes hyperpolarization of neuromuscular cell membranes, which become refractory to stimulation and can result in several symptoms, including neuropsychiatric disturbances, gastrointestinal abnormalities, renal dysfunction, musculoskeletal symptoms, and cardiovascular disease.

The physiologic black box described in [Chapter 74](#) should be considered when diagnosing or treating patients with hypercalcemia. Causes of hypercalcemia can be grouped into factitious disorders (e.g., abnormalities in serum proteins), parathyroid mediated, non-parathyroid mediated, medication related, and miscellaneous disorders. The differential diagnosis for hypercalcemia is outlined in [Table 75.1](#).

Symptoms and Signs

Calcium is included in the standard basic metabolic panel, and as a result asymptomatic hypercalcemia is often discovered by routine laboratory testing. Whether a patient develops symptoms depends on several factors, including the degree of hypercalcemia and the rapidity with which it develops. Typically, when absolute serum calcium is

above 13 mg/dL patients are symptomatic. A gradual increase in serum calcium, even into the severe range above 15 mg/dL, may cause fewer symptoms than a rapid rise to 13 mg/dL. The overall health status and age of the person with hypercalcemia influence the severity of symptoms. Symptoms can be most severe in elderly patients.

Hypercalcemia can cause smooth muscle hypoactivity, resulting in constipation and ileus. Pancreatitis and peptic ulcer, although less commonly seen, can occur in patients with severe hypercalcemia. Hypercalcemia is also associated with neurologic dysfunction, which can range in severity from mild confusion to coma. Renal impairment can result from hypercalcemia through several mechanisms. Hypercalcemia causes afferent arteriolar vasoconstriction and activation of the calcium receptor in the distal nephron, which reduces the glomerular filtration rate (GFR). It can also cause a form of nephrogenic diabetes insipidus with associated polydipsia and polyuria. As a result, the ECF volume is reduced and the GFR further lowered. Hypercalcemia can directly cause kidney damage through deposition of calcium phosphate crystals into the renal interstitium (i.e., nephrocalcinosis or interstitial nephritis) as well as into the urine leading to nephrolithiasis and obstructive uropathy. Hypercalcemia can have severe adverse effects on the heart, including arrhythmias. Abnormalities on electrocardiogram include shortening of the QTc interval, prolonged PR interval, widened QRS complex and bradycardia. ST elevations mimicking myocardial infarctions have also been reported. Muscular weakness is also frequently seen among hypercalcemia patients.

Differential Diagnosis

Hyperproteinemia. Approximately 50% of circulating calcium is bound to serum albumin and other proteins. Increases in serum proteins lead to an artifactual increase in total, but not ionized, serum calcium concentrations. This increase is commonly observed in settings of volume depletion and dehydration. Patients with hypercalcemia as a result of hyperproteinemia do not display signs or symptoms. Treatment should be avoided in this setting as it might actually result in hypocalcemia.

Parathyroid hormone–related hypercalcemia

Hyperparathyroidism. Both primary and tertiary hyperparathyroidism are characterized by hypercalcemia. Patients who have secondary hyperparathyroidism (SHPT) in response to other abnormalities, such as vitamin D deficiency, calcium deficiency, or chronic kidney disease, will have serum calcium values that are frankly low or in the low-normal range. However, it is important to note that these disorders can coexist. Full consideration of a patient's comorbidities and laboratory test results may be necessary for making the proper diagnosis or combination of diagnoses.

Primary hyperparathyroidism. Primary hyperparathyroidism (PHPT), due to overproduction of parathyroid hormone (PTH) from

TABLE 75.1 Disorders Associated With Hypercalcemia

PTH-Related Hypercalcemia	Non-PTH Mediated Hypercalcemia
Primary hyperparathyroidism	Malignancy-associated hypercalcemia
Tertiary hyperparathyroidism	Humoral hypercalcemia of malignancy
Familial hypocalciuric hypercalcemia or familial benign hypercalcemia	Hypercalcemia caused by 1,25-dihydroxyvitamin D ₃ (1,25[OH] ₂ D ₃)-secreting lymphomas
	Hypercalcemia caused by direct skeletal invasion
	Granulomatous disorders
	Sarcoid
	Berylliosis
	Foreign body
	Tuberculosis
	Coccidioidomycosis
	Blastomycosis
	Histoplasmosis
	Granulomatous leprosy
	Eosinophilic granuloma
	Histiocytosis
	Inflammatory bowel disease
	Endocrine disorders other than hyperparathyroidism
	Hyperthyroidism
	Pheochromocytoma
	Addisonian crisis
	Vasoactive intestinal peptide–producing tumor (VIPoma); watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome
	Milk-alkali syndrome
	Total parenteral nutrition (TPN)
	Calcium-containing TPN in patients with decreased glomerular filtration rate
	Chronic TPN in patients with short-bowel syndrome
	Immobilization plus high bone turnover (risk is particularly high in individuals with the following)
	Juvenile skeleton
	Paget's disease
	Myeloma and breast cancer with bone metastases
	Mild primary hyperparathyroidism
	Secondary hyperparathyroidism (e.g., from continuous ambulatory peritoneal dialysis)
	Medications
	Thiazides
	Aminophylline
	Lithium
	Estrogen/antiestrogen in breast cancer with bone metastases (estrogen flare)
	Vitamin D and derivatives (calcitriol, dihydrotachysterol)
	Vitamin A (including retinoic acid derivatives)
	Foscarnet
	Anabolic agents (teriparatide, abaloparatide)

abnormal parathyroid glands, is by far the most common cause of hypercalcemia among otherwise healthy outpatients. In approximately 85% of patients with HPT, a single parathyroid adenoma is responsible for excess PTH secretion, while in about 15% there is hyperplasia of

multiple glands. Rarely, HPT may result from parathyroid carcinoma. The diagnosis of HPT is relatively straightforward in patients who have hypercalcemia in the setting of a frankly elevated serum PTH. It is important to note, however, that in a patient with normal parathyroid gland function, PTH synthesis and secretion should be suppressed by hypercalcemia. Therefore, a PTH level within the normal range should be considered inappropriately high in the setting of hypercalcemia and may indicate underlying hyperparathyroidism. Concurrent vitamin D deficiency, which predisposes to hypocalcemia, can mask elevated calcium levels in patients with HPT; in such cases, hypercalcemia may become apparent only after vitamin D is repleted. Other typical biochemical features of HPT include hypophosphatemia, increased 1,25(OH)₂D and chloride levels, and a reduction in serum bicarbonate.

Many patients diagnosed with PHPT are asymptomatic and have serum calcium in the mildly elevated range. Because serum calcium is typically included in chemistry panels, this diagnosis is frequently made when hypercalcemia is found during routine laboratory testing. Less frequently, patients may present with symptoms including osteoporosis, bone pain, and nephrolithiasis. Kidney stones are most often comprised of calcium oxalate and, less commonly, calcium phosphate. Osteoporosis is common among patients with HPT. In the classic densitometric pattern of HPT, bone mineral density (BMD) is relatively preserved at the spine, lower at the hip, and particularly low at the 1/3 radius. This is because the 1/3 radius is a predominantly cortical site, which is susceptible to the effects of excess PTH. Though rarely seen today, severe HPT can cause the classic skeletal manifestations known as *osteitis fibrosa cystica* in which there are bone cysts and “brown tumors,” which are collections of osteoclasts intermixed with fibrous tissue and poorly mineralized woven bone (see [Chapter 76](#)). Some patients with HPT may develop renal disease as a result of the mechanisms described earlier.

Rarely, HPT can occur as part of one of the multiple endocrine neoplasia (MEN) syndromes. It is associated with pituitary and pancreatic neuroendocrine tumors (MEN 1) and with pheochromocytomas and medullary carcinoma of the thyroid (MEN 2).

Tertiary hyperparathyroidism. Tertiary HPT refers to HPT-associated hypercalcemia that occurs in the setting of prolonged stimulation of the parathyroid glands. Chronic hypocalcemic stimulation of the parathyroids eventually leads to hyperplasia. The abnormal glands stop responding appropriately to elevations in serum calcium, ultimately resulting in hypercalcemia. This is typically seen in patients with chronic renal failure and can be seen after renal transplantation.

Familial hypocalciuric hypercalcemia. Familial hypocalciuric hypercalcemia (FHH), or *familial benign hypercalcemia*, is an autosomal dominant genetic disorder caused by heterozygous inactivating mutations of the calcium sensing receptor. As a result of the defect, the parathyroid glands interpret normal serum calcium levels as low, increase PTH in response, and serum calcium rises. PTH in this disorder is in the high-normal to slightly high range. Hypercalcemia is typically mild, in the range of 11 to 12 mg/dL. Abnormal calcium receptors are also expressed in the kidney, leading to inappropriate renal conservation of calcium and hypocalciuria, further exacerbating hypercalcemia. With the exception of the hypocalciuria, patients with FHH have biochemical profiles similar to those with PHPT. However, affected individuals are asymptomatic and do not develop adverse sequelae from FHH. It is critical to distinguish the two disorders, particularly in patients being considered for parathyroidectomy, because patients with FHH do not require any intervention. In contrast to the mild presentation of heterozygous individuals, homozygous patients usually develop severe hypercalcemia in infancy, requiring urgent total parathyroidectomy.

Nonparathyroid hormone–mediated hypercalcemia

Malignancy-associated hypercalcemia. The most common cause of hypercalcemia among hospitalized patients is malignancy. Cancer may lead to hypercalcemia through several mechanisms, the majority of which are PTH independent. Hypercalcemia typically occurs in patients with end-stage malignancies and progresses rapidly. Approximately 50% of patients die within 30 days of developing malignancy-associated hypercalcemia (MAHC). Hypercalcemia usually occurs in patients with large tumor burdens but can also be seen in patients who have small neuroendocrine tumors, such as islet cell tumors and bronchial carcinoids. Tumors that commonly cause hypercalcemia include breast, renal, squamous cell, ovarian carcinomas, multiple myeloma, and lymphoma.

Humoral hypercalcemia of malignancy (HHM) results from excessive secretion of parathyroid hormone–related protein (PTHrP) by tumor cells. This is the most common cause of MAHC, accounting for approximately 80% of cases. PTHrP acts on the same receptor as PTH and can induce similar systemic effects. PTHrP mimics the actions of PTH on the kidney to promote calcium retention and on the skeleton to activate osteoclasts and induce bone resorption. PTHrP is typically produced at low levels in healthy individuals; however, excess levels can cause significant hypercalcemia. Patients with HHM have elevations in PTHrP and reductions in the levels of PTH, 1,25-dihydroxyvitamin D₃ (1,25[OH]₂D), and serum phosphorus (see Chapter 74). Tumors classically associated with HHM include squamous cell carcinomas (i.e., larynx, lung, cervix, and esophagus), renal, ovarian, and breast carcinomas. In HHM, hypercalcemia typically occurs in the absence of skeletal metastases. If tumor resection or ablation is possible, hypercalcemia will reverse.

Another etiology of MAHC is local tumor invasion of the skeleton, a process called *local osteolytic hypercalcemia* (LOH). LOH accounts for approximately 20% of patients with MAHC. In contrast to HHM, these patients often have extensive skeletal metastases. The primary tumor is most commonly breast cancer or a hematologic neoplasm such as multiple myeloma, leukemia, or lymphoma. Local factors secreted by tumors in the bone marrow induce osteoclastic bone resorption. These include PTHrP, macrophage inflammatory protein 1 α (MIP-1 α), receptor-activating nuclear factor- κ B ligand (RANKL), interleukin-6, and interleukin-1. Typically, patients with LOH have both hypercalcemia and hyperphosphatemia as a result of excess bone resorption. PTH, PTHrP and 1,25(OH)₂D levels are reduced, reflecting appropriate suppressive responses to hypercalcemia

A third, rare, form of MAHC is secretion of 1,25(OH)₂D by lymphomas and dysgerminomas. The increased 1,25(OH)₂D leads to intestinal calcium hyperabsorption as well as bone resorption. This condition is mechanistically similar to the hypercalcemia that occurs in granulomatous disease (see below).

Granulomatous diseases. Another type of PTH-independent hypercalcemia occurs in patients with granulomatous disease including sarcoidosis, tuberculosis, and fungal infections (see Table 75.1). The granulomas in these conditions contain the 1 α -hydroxylase enzyme and therefore have the ability to convert inactive 25-hydroxyvitamin D to its active metabolite, 1,25(OH)₂D. Hypercalcemia results from intestinal calcium hyperabsorption and to a lesser extent, 1,25(OH)₂D-induced bone resorption. As a result of increased 1 α -hydroxylase activity, patients with these disorders are susceptible to developing hypercalcemia when exposed to sunlight, ultraviolet radiation, or relatively trivial quantities of dietary vitamin D. The excess 1,25(OH)₂D results in an elevated serum phosphorus and suppression of endogenous PTH. The combined hypercalcemia and hyperphosphatemia can result in nephrocalcinosis and renal failure.

Other endocrine disorders. Although HPT is most common, other endocrine disorders can cause hypercalcemia as well. Hyperthyroidism can cause mild hypercalcemia through an increase in bone resorption driven by elevated thyroid hormone. This can occur in up to half of patients with this disorder. Serum calcium in these patients is usually below 11 mg/dL.

Hypercalcemia can also be seen in patients with pheochromocytoma. In patients with pheochromocytoma as part of MEN 2, hypercalcemia can result directly from PHPT, which is also part of this syndrome. In other patients, hypercalcemia is due to PTHrP secretion by the pheochromocytoma. Hypercalcemia has also been reported in patients with hypoadrenalism and those with VIPomas, a type of islet cell tumor.

Milk-Alkali syndrome. As reviewed in Chapter 74, absorption of calcium from the diet is usually well regulated. However, ingestion of very large quantities of calcium, particularly from supplements, can exceed the regulatory ability of this system and result in hypercalcemia. This can occur in patients ingesting large quantities of calcium carbonate or other calcium-containing antacids for peptic ulcer disease. This condition, known as milk-alkali syndrome, consists of the triad of hypercalcemia, metabolic alkalosis, and acute kidney injury. Severe hypercalcemia is common and may lead to renal failure. Calcium intake in patients with milk-alkali syndrome typically exceeds 4 g/day and can be in the 10- to 20-g/day range.

Parenteral nutrition. Patients receiving both enteric and parenteral nutrition can develop hypercalcemia. Hypercaloric enteric feeding regimens may contain large quantities of calcium, which can lead to a form of milk-alkali syndrome. Patients with renal impairment are at particular risk for developing hypercalcemia in this setting. Hypercalcemia has also been described in patients treated with total parenteral nutrition (TPN). In some cases, hypercalcemia results from large amounts of calcium, vitamin D, or aluminum in the TPN solution. Often patients who develop hypercalcemia have short-bowel syndrome and are on long-term TPN.

Immobilization. Hypercalcemia can occur in the setting of immobilization. Immobilization activates osteoclast mediated bone resorption and inhibits osteoblast activity, uncoupling bone turnover. As a result, there is substantial, rapid movement of calcium from the skeleton into the ECF. This condition is associated with hypercalciuria and calcium nephrolithiasis. It can result in severe skeletal demineralization if untreated. Typically, for immobilization-related hypercalcemia to occur, patients must be completely immobilized for weeks and have a concurrent underlying predisposition to hypercalcemia because of high bone turnover. This condition is most commonly seen in young adults or children, patients with HPT, Paget's disease, skeletal metastases or multiple myeloma. The most effective treatment for immobilization-related hypercalcemia is resumption of active weight bearing. Hydration and antiresorptive medications, if hypercalcemia is severe, can be used to lower serum calcium as well.

Medications. Drugs that may cause hypercalcemia include thiazide diuretics, lithium, aminophylline, theophylline, vitamins D and A, foscarnet, and osteoanabolic agents like teriparatide and abaloparatide.

Treatment of Hypercalcemia

Patients with mild, asymptomatic hypercalcemia may not require immediate treatment. For severe (Ca >14 mg/dL) or symptomatic hypercalcemia, the initial treatment includes intravenous hydration, calcitonin, and antiresorptive agents like bisphosphonates or denosumab. Volume expansion with isotonic saline is usually initiated first. Loop diuretics should be avoided unless patients have volume overload or heart failure. Subcutaneous calcitonin, which has a rapid onset of action, is usually administered in addition to fluids for the first

48 hours. However, because tachyphylaxis develops rapidly to calcitonin therapy, it should be discontinued after 24 to 48 hours. Concurrent use of intravenous bisphosphonates, preferably zoledronic acid, is often needed, particularly in patients with hypercalcemia of malignancy. Denosumab is an alternative option for patients who are refractory to bisphosphonates or have renal dysfunction that precludes bisphosphonate use. These medications have a slower onset of action, so it is important to treat concurrently with fluids and calcitonin when rapid correction of the calcium is required. Cinacalcet, a calcimimetic agent typically used in patients with secondary HPT from chronic kidney disease (CKD), can also be used to treat severe hypercalcemia from tertiary HPT or due to parathyroid carcinoma. Glucocorticoids are the preferred treatment for hypercalcemia due to overproduction of 1,25-vitamin D related to granulomatous disease or lymphomas. In cases of severe hypercalcemia that are refractory to medical treatment, or in patients with advanced CKD, dialysis against a low or zero calcium bath can be performed.

Therapy for hypercalcemia should ultimately be directed at reversing the underlying pathophysiologic abnormality. Patients with symptomatic primary HPT should undergo parathyroidectomy. For asymptomatic patients with PHPT, indications for surgery include osteoporosis, kidney stones, reduced renal function, and a serum calcium concentration greater than 1 mg/dL above normal. Other patients may be monitored conservatively. In patients who are unwilling or unable to undergo surgery, medical management of hypercalcemia may be attempted using bisphosphonates. As above, familial hypocalciuric hypercalcemia does not require treatment.

Treatment of hypercalcemia related to granulomatous diseases focuses on correcting the underlying disorder. Measures include a low dietary calcium intake, low vitamin D intake, limiting sun exposure, and hydration. If hypercalcemia is severe, glucocorticoids can be used.

Disorders associated with increased intestinal calcium absorption (e.g., sarcoid, milk-alkali syndrome, 1,25[OH]₂D₃-secreting lymphomas) should be treated by having patients limit intake of both calcium and vitamin D. Medications that induce hypercalcemia should be discontinued.

Hypocalcemia

Pathophysiology

Hypocalcemia can be caused by several mechanisms. Apparent hypocalcemia can result from a reduction in serum proteins that bind calcium, typically albumin. In these patients, ionized calcium and calcium corrected for albumin will be normal. Increased serum phosphate can cause hypocalcemia via an increase in the calcium-phosphate solubility product. Increased renal calcium excretion or a reduction in intestinal calcium absorption can cause hypocalcemia. Hypocalcemia can also result from loss of calcium from the ECF into the skeleton, which can occur in the setting of some malignancies, after parathyroidectomy (hungry bone syndrome), or with certain medications, including bisphosphonates, denosumab, chelating agents, and foscanet. Many disorders that cause severe hypocalcemia do so by impacting several of these processes simultaneously. In order to provide effective treatment, all of the mechanisms through which a disorder is causing hypocalcemia should be considered and addressed. Hypocalcemia leads to a reduction in the potential difference across cell membranes, producing hyperexcitability in neuromuscular cells which can spontaneously fire (see [Chapter 74](#)).

Symptoms and Signs

The seminal signs of hypocalcemia on physical exam relate to neuromuscular hyperexcitability. Hypocalcemia can cause paresthesias, seizures, and skeletal muscle contractions (i.e., carpal spasm, pedal spasm, or tetany). The *Trousseau sign* describes spontaneous contraction of

the forearm muscles in response to inflation of a blood pressure cuff around the upper arm to above systolic pressure. The *Chvostek sign* describes twitching of the facial muscles that is elicited by gentle tapping of the facial nerve as it exits the parotid gland. On an electrocardiogram, hypocalcemia can manifest as a prolonged QTc interval. Patients with hypocalcemia may also have more general symptoms such as fatigue, weakness, and abdominal pain. As with hypercalcemia, the severity of symptoms will relate to both the severity and chronicity of hypocalcemia.

Differential Diagnosis

Disorders that may lead to hypocalcemia are summarized in the following sections and [Table 75.2](#).

Hypoalbuminemia. The majority of serum calcium is bound to albumin. Low serum albumin will lead to a low measured total calcium although ionized values will be normal. This is commonly seen in patients with cirrhosis, nephrotic syndrome, malnutrition, and severe burns. The formula commonly used to correct serum calcium for low serum albumin levels is: corrected calcium = measured total calcium + (0.8 × [4.0 – measured albumin]). This formula should be used to confirm the presence of hypocalcemia.

Hypoparathyroidism. In hypoparathyroidism, low levels of parathyroid hormone result in hypocalcemia through decreased intestinal calcium absorption and reduced calcium reabsorption in the distal renal tubule. Hypoparathyroidism most commonly occurs as a complication of neck surgery or as a consequence of autoimmune disease. Postoperative hypoparathyroidism typically occurs after thyroid, parathyroid, or laryngeal surgery. Autoimmune hypoparathyroidism can occur as a single entity or as part of autoimmune polyglandular syndrome, where it can be associated with primary adrenal insufficiency (Addison's disease), type 1 diabetes, autoimmune thyroid disease, vitiligo, and mucocutaneous candidiasis. Other less common causes of hypoparathyroidism include congenital hypoparathyroidism as part of DiGeorge syndrome, isolated parathyroid failure, or genetic mutations. Rarely, infiltrative conditions including sarcoidosis, hemochromatosis, HIV, and malignancy (i.e., breast cancer) can cause hypoparathyroidism.

The diagnosis of hypoparathyroidism is made by finding an inappropriately low serum PTH in a patient with hypocalcemia. The phosphorus concentration is usually high normal or frankly elevated, and plasma 1,25(OH)₂D concentrations are reduced. Prolonged hypoparathyroidism may be associated with asymptomatic basal ganglia calcification on computed tomography scans and plain radiographs of the skull.

Treatment for hypoparathyroidism has historically been directed at increasing intestinal calcium absorption through the use of large doses of calcium (up to 6 to 8 g of elemental calcium per day) along with active vitamin D (1,25[OH]₂D) in doses of 0.25 to 1.0 µg/day. With this regimen it is possible to induce sufficient intestinal calcium hyperabsorption to overwhelm the ability of the kidney to excrete it. However, this treatment can exacerbate hypercalciuria leading to nephrocalcinosis and nephrolithiasis, making it critical to monitor 24-hour urinary calcium. Thiazide diuretics can be used as adjunctive treatment to stimulate renal calcium reabsorption, reduce hypercalciuria, and raise serum calcium. Treatment should be aimed at maintaining serum calcium concentration in the low-normal range.

The approval of recombinant PTH 1-84 by the FDA for chronic hypoparathyroidism has provided an important option for treatment that lowers the risk of some of the adverse effects of high dose calcium and calcitriol.

Pseudohypoparathyroidism. In the group of disorders known as pseudohypoparathyroidism, patients are resistant to the actions of PTH. In these disorders, resistance may result from several different inactivating mutations in the signal-transducing protein G_{sα}. The most

TABLE 75.2 Differential Diagnosis of Hypocalcemia

Hypoparathyroidism	Hypoalbuminemia
Surgical	Sepsis
Idiopathic and autoimmune	Hypermagnesemia and hypomagnesemia
Infiltrative diseases	Rapid bone formation
Wilson's disease (copper)	Hungry bone syndrome after parathyroidectomy or thyroidectomy
Hemochromatosis	Osteoblastic metastases
Sarcoidosis	Vitamin D therapy of osteomalacia, rickets
Metastatic (breast) cancer	Hyperphosphatemia
Congenital	Crush injury, rhabdomyolysis
Isolated, sporadic	Renal failure
DiGeorge syndrome	Tumor lysis
Infant of mother with hyperparathyroidism	Excessive phosphate (PO ₄) administration (PO, IV, PR)
Hereditary	Medications
X-linked	Mithramycin, plicamycin
Parathyroid gland calcium receptor (Gα11 subunit)-activating mutations	Bisphosphonates
Parathyroid hormone (PTH) signal peptide mutation	Denosumab
<i>GCM2</i> (formerly <i>GCMB</i>) mutation	Calcitonin
Pseudohypoparathyroidism	Fluoride
Type Ia: multiple hormone resistance, Albright hereditary osteodystrophy	Ethylenediaminetetraacetic acid (EDTA)
Type Ib: PTH resistance without other abnormalities	Citrate
Type Ic: specific PTH resistance, resulting from defect in catalytic subunit of PTH-receptor complex	Intravenous contrast
Type II: specific PTH resistance, postreceptor defect of adenyl cyclase, undefined	Foscarnet
Vitamin D disorders	Cisplatin
Absent ultraviolet exposure	Pancreatitis
Vitamin D deficiency	Hypoalbuminemia
Fat malabsorption	Hypomagnesemia
Vitamin D-dependent rickets, renal 1α-hydroxylase deficiency, 1,25-dihydroxyvitamin D-receptor defects	Calcium soap formation
Chronic renal failure	
Hepatic failure	

common form of pseudohypoparathyroidism, Type Ia, also known as *Albright hereditary osteodystrophy*, is associated with resistance to multiple hormones and has a classic phenotype: short stature, shortened fourth and fifth metacarpals and metatarsals, obesity, mental retardation, subcutaneous calcifications, and café au lait spots. Laboratory studies in these patients demonstrate hypocalcemia and hyperphosphatemia similar to hypoparathyroidism. However, PTH levels are paradoxically elevated. Treatment involves supplementation with calcium and active vitamin D analogs.

Vitamin D deficiency. Sufficient vitamin D is necessary for maintenance of serum calcium. Active vitamin D, 1,25(OH)₂D, is required for intestinal calcium absorption. In order to maintain sufficient vitamin D levels, individuals must have adequate intake of vitamin D from diet and supplements or sufficient sunlight exposure for cutaneous manufacture of vitamin D. As calcium and vitamin D are absorbed from the small intestine, patients with inflammatory gastrointestinal disease, including celiac disease or short-bowel syndrome, or prior upper intestinal surgery are at risk for vitamin D deficiency and hypocalcemia. Patients with hepatic disease commonly have vitamin D deficiency, due in part to impaired 25-hydroxylation. Because the majority of conversion of 25-hydroxyvitamin D to 1,25(OH)₂D occurs in the kidney (see [Chapter 74](#)), patients with reduced kidney function often have low 1,25(OH)₂D, which can cause reduced intestinal absorption of vitamin D and hypocalcemia. Severe vitamin D deficiency can result in osteomalacia or rickets (see [Chapter 76](#)). Certain genetic syndromes affecting vitamin D conversion or causing vitamin D resistance can result in severe hypocalcemia.

Long-term, high-dose treatment with older antiseizure medications such as phenytoin or phenobarbital or their derivatives may lead to hypocalcemia and osteomalacia.

Sepsis. Sepsis from both gram-positive and gram-negative organisms has been associated with hypocalcemia. The mechanisms for this are poorly understood. Although hypocalcemia occurring in the setting of sepsis is typically mild, its presence is associated with a poor prognosis.

Magnesium disorders. Hypocalcemia can result from low magnesium levels. This occurs most commonly in patients with alcoholism, malnutrition, intestinal malabsorption, and cisplatin-based chemotherapy. Magnesium deficiency causes a form of functional hypoparathyroidism that is due to decreased PTH secretion and resistance to PTH at the kidney and skeleton. These abnormalities can be quickly reversed with magnesium replacement. Paradoxically, in rare instances, hypermagnesemia can cause hypocalcemia. Magnesium, like calcium, is a divalent cation. In very high concentrations, it can mimic the actions of calcium and suppress PTH, causing hypoparathyroidism and hypocalcemia.

Hyperphosphatemia. Phosphate binds calcium avidly and therefore, excess can cause hypocalcemia. This can be seen in disorders that cause severe hyperphosphatemia including rhabdomyolysis (e.g., crush injuries), renal failure, and tumor lysis syndrome. Severe hyperphosphatemia can also be caused by ingestion of large amounts of phosphate-containing purgatives in preparation for colonoscopy, inadvertent perforation of the rectum during the administration of phosphate enemas, and administration of large doses of intravenous

phosphate. In these examples, the onset of hyperphosphatemia is acute, and hypocalcemia is immediate and severe. Seizures can occur as the earliest manifestation. Treatment involves reducing the serum phosphorus level. Intravenous calcium should not be given to hyperphosphatemic patients because calcium-phosphate salts can precipitate into soft tissues.

Recalcification and rapid bone formation. Increased rates of skeletal mineralization that exceed the rate of bone resorption lead to net calcium entry into the skeleton and can cause hypocalcemia. This classically occurs in patients with hyperparathyroidism following parathyroidectomy, a situation known as “hungry bone syndrome.” In these patients, preoperative rates of bone turnover are very high but formation and resorption are coupled. Postoperatively, as PTH acutely drops, so do rates of osteoclastic bone resorption. However, an elevated rate of bone remineralization continues. As a result of this imbalance, there is a net influx of calcium and phosphorus into the skeleton. This disorder can persist for weeks after surgery and may require very high doses of calcium and vitamin D metabolites to treat. Hypocalcemia from rapid skeletal uptake can also occur in the setting of extensive osteoblastic bone metastases, most commonly observed in prostate or breast cancer.

Pancreatitis. In patients with pancreatitis, fatty acid soaps are formed by lipases released from the inflamed pancreas. The free lipases then autodigest omental and retroperitoneal fat into negatively charged ions that tightly bind calcium in the ECF, resulting in hypocalcemia. The hypocalcemia is reversible by calcium infusion and self-terminates when pancreatitis improves. The development of hypocalcemia in patients with pancreatitis is a poor prognostic sign.

Medications. Several medications can cause hypocalcemia, including those used to treat hypercalcemia and osteoporosis such as bisphosphonates, denosumab, and cinacalcet. Fluoride compounds (e.g., anesthetic gas), chelating agents such as ethylenediaminetetraacetic acid (EDTA) and citrate in stored blood products, radiographic intravenous contrast agents, the antiviral drug foscarnet, and chemotherapy including cisplatin, 5-fluorouracil, and leucovorin can all cause hypocalcemia. Patients with undiagnosed vitamin D deficiency may be particularly susceptible to developing hypocalcemia when they receive one of these medications.

DISORDERS OF PHOSPHATE METABOLISM

Hyperphosphatemia

Pathophysiology

Phosphate plays a key role in many ubiquitous cellular processes, including DNA synthesis and replication, energy generation and use, oxygen uptake and delivery by erythrocytes, and maintenance of the redox state (see Chapter 74). Hyperphosphatemia can develop due to one of three mechanisms: decreased renal excretion, increased phosphate load in the acute setting, and redistribution to the extracellular space. Chronic hyperphosphatemia can lead to soft tissue calcifications. Most diets naturally contain substantial quantities of phosphate, which is cleared by the kidney. However, as GFR declines below 20 to 30 mg/dL, the renal capacity to excrete phosphate diminishes. Patients with stage 4 and 5 CKD (GFR below 30 mL/min) often have some degree of hyperphosphatemia. As detailed above, excess phosphate will avidly bind calcium, and can cause hypocalcemia.

Symptoms and Signs

Hyperphosphatemia is usually identified incidentally on routine blood tests. There are no specific symptoms or signs.

Differential Diagnosis

The differential diagnosis of hyperphosphatemia is detailed in the following sections and in Table 75.3.

TABLE 75.3 Causes of Hyperphosphatemia

Artifactual
Hemolysis
Increased gastrointestinal intake
Rectal enemas
Oral Phospho-Soda purgatives
Gastrointestinal bleeding
Large phosphate loads
K-Phos
Blood transfusions
Redistribution to the extracellular space
Tumor lysis syndrome
Rhabdomyolysis (crush injury)
Hemolysis
Reduced renal clearance
Chronic or acute renal failure
Hypoparathyroidism
Acromegaly
Tumoral calcinosis

Pseudohyperphosphatemia. Hyperphosphatemia may occur artifactually as a result of hemolysis of red blood cells in blood collection tubes. This effect is also commonly seen with potassium, another ion with high intracellular concentrations. Hemolysis should be considered as a cause when unexplained hyperphosphatemia and hyperkalemia occur concurrently. In this circumstance, a new blood sample should be obtained and the levels repeated.

Reduced renal clearance. Renal clearance of phosphate is the main mechanism for maintaining phosphate homeostasis. Acute and chronic kidney disease can cause hyperphosphatemia. Parathyroid hormone promotes phosphate excretion in the proximal nephron. Therefore, patients who have hypoparathyroidism tend to have high-normal or frankly elevated serum phosphate values.

In *tumoral calcinosis*, the ability of the kidney to clear phosphate is defective, either because of genetic mutations in proteins involved in renal phosphate clearance or from advanced CKD. This reduced clearance leads to chronic hyperphosphatemia and the accumulation of calcium-phosphate salts around large joints of the appendicular skeleton. Children and adolescents have higher serum phosphate concentrations than adults and are more prone to this condition.

Increased gastrointestinal intake. Hyperphosphatemia can occur in the setting of excess oral phosphate loads. This most commonly occurs in patients using phosphate-containing purgatives as preparation for colonoscopy. Inadvertent perforation of the rectum during the administration of a Phospho-Soda enema, with delivery of large amounts of phosphate directly into the peritoneal cavity, can also cause hyperphosphatemia. Bleeding from the upper GI tract can also lead to delivery of a large GI phosphate load that is absorbed systemically, therefore leading to hyperphosphatemia.

Systemic phosphate loads. A large phosphate load delivered into the ECF through intravenous medications, or endogenous sources such as muscle or tumor necrosis, can result in hyperphosphatemia. Hyperphosphatemia is often seen in patients who receive large doses of potassium phosphate for hypokalemia (see Chapter 74).

Redistribution to the extracellular space. Hyperphosphatemia may result from the rapid destruction of large amounts of tissue. In tumor lysis syndrome, large tumors respond to chemotherapy with massive cell death and can release substantial amounts of phosphate. This is commonly seen with treatment of Burkitt lymphoma. In acute rhabdomyolysis, phosphate is released from damaged skeletal muscle.

In severe hemolysis, phosphate stored in red blood cells is released and moves to the extracellular space. In each of these conditions, renal impairment is also common and the excess phosphate combined with worsening renal dysfunction can result in progressive renal failure, severe hypocalcemia, seizures, and even death.

Hypophosphatemia

Symptoms and Signs

Because phosphate plays such a ubiquitous and critical role in cellular processes, low phosphate levels can be life threatening. Hypophosphatemia can result in generalized, nonspecific symptoms and signs ranging from generalized weakness and malaise, to hypotension, respiratory failure, congestive heart failure, and coma. Hypophosphatemia often occurs in critically ill patients. These patients are at high risk because of limited oral nutrition, as well as exposure to intravenous diuretics and saline infusions that accelerate renal phosphate losses. With correction of serum phosphate, patients can have complete recovery of mental status and respiratory capacity.

Chronic hypophosphatemia leads to defects in skeletal mineralization, a phenomenon called *rickets* in children or *osteomalacia* in adults. These syndromes produce weakness, bone pain, bowing of the long bones, and fractures or pseudofractures (see Chapter 76). Hypophosphatemia can go unnoticed if phosphate is not routinely checked because symptoms are nonspecific. Under-mineralization can cause low bone mineral density and patients with osteomalacia may be mistaken for having osteoporosis if not properly identified. This is a critical distinction because osteoporosis treatment can actually exacerbate the underlying mineralization disorder. As with acute hypophosphatemia in critically ill patients, patients with chronic hypophosphatemia will dramatically improve with correction of phosphate. Bone pain resolves and wheelchair-bound patients can regain full ambulatory ability.

Differential Diagnosis

Hypophosphatemia can result from excessive renal phosphate loss, decreased intestinal absorption, or intracellular shifts of phosphate from the ECF (Table 75.4). Once a low serum phosphate has been found, urine collection for measurement of the maximum tubular reabsorption of phosphate (TmP) can help to identify the cause (see Chapter 74). In the setting of a low serum phosphate, renal reabsorption should be high as a compensatory response. A low TmP in a patient with hypophosphatemia is therefore indicative of a renal deficit.

Excessive renal phosphate losses. Patients with hypophosphatemia resulting from renal losses will have a low TmP. Inappropriately increased renal phosphate excretion may be due to the presence of a circulating factor versus an intrinsic defect in renal phosphate reabsorption. PTH is phosphaturic, and HPT can cause hypophosphatemia in patients with normal renal function. Hypophosphatemia can be seen in patients with PHPT and in SHPT due to vitamin D deficiency and calcium malabsorption. Vitamin D deficiency can lead to decreased gastrointestinal calcium absorption and secondary HPT, resulting in increased urinary phosphate excretion. A low serum phosphate level may be the first clue to severe vitamin D deficiency. PTHrP is also phosphaturic, and as a result, patients with humoral hypercalcemia of malignancy are commonly hypophosphatemic.

Certain genetic disorders may lead to severe renal phosphate wasting (see Chapter 76). Most of these genetic disorders result in elevated levels of fibroblast growth factor 23 (FGF23), a circulating protein that both inhibits intestinal phosphate absorption and decreases renal phosphate reabsorption, resulting in hypophosphatemia. These disorders include X-linked hypophosphatemia (XLH), also called *vitamin*

TABLE 75.4 Causes of Hypophosphatemia

Inadequate phosphate (PO ₄) intake
Starvation
Malabsorption
PO ₄ -binding antacid use
Alcoholism
Renal PO ₄ losses
Primary, secondary, or tertiary hyperparathyroidism
Humoral hypercalcemia of malignancy (parathyroid hormone–related protein)
Diuretics, calcitonin
X-linked hypophosphatemic rickets
Autosomal dominant hypophosphatemic rickets
Oncogenic osteomalacia
Fanconi syndrome
Alcoholism
Excessive skeletal mineralization
Hungry bone syndrome after parathyroidectomy
Osteoblastic metastases
Healing osteomalacia, rickets
PO ₄ shift into extracellular fluid
Recovery from metabolic acidosis
Respiratory alkalosis
Starvation refeeding, intravenous glucose

D-resistant rickets, in which there is an inactivating mutation in the enzyme PHEX that regulates FGF23. In autosomal dominant hypophosphatemic rickets (ADHR), there are mutations in FGF23 that disrupt its breakdown. Oncogenic osteomalacia or *tumor-induced osteomalacia* is an acquired renal phosphate-wasting syndrome. In this disorder, mesenchymal tumors secrete excess amounts of FGF23. Acquired or inherited diffuse proximal renal tubular disorders, such as Fanconi syndrome, may lead to hypophosphatemia as a result of renal phosphate wasting.

Thiazide and loop diuretics are potent phosphaturic agents, and their use without phosphate replacement therapy can lead to hypophosphatemia. Excessive ethanol can also have this effect. Tenofovir, an antiretroviral medication that is increasingly used for the treatment and prevention of HIV infection, can also induce renal phosphate wasting. In some cases, tenofovir can cause Fanconi syndrome, with renal loss of glucose, uric acid, amino acids, and bicarbonate in addition to phosphate. As a result of significant phosphate loss, these patients can present with bone pain, weakness, and fractures because of skeletal demineralization and osteomalacia.

Decreased intestinal absorption. Hypophosphatemia that results from inadequate phosphate intake will be associated with a high TmP. Because most foods are rich in phosphate, it is rare for an individual with a normal diet to develop phosphate deficiency. However, deficiency can occur in settings of severe caloric deprivation, such as anorexia nervosa, prisoner-of-war camps, prolonged critical illness, malabsorption syndromes, and chronic alcoholism. In the first three disorders, caloric intake is low and little phosphate is consumed. Conversely, in alcoholism, overall caloric intake may be high but is primarily derived from alcohol, which does not contain phosphate. The use of phosphate-binding antacids such as aluminum hydroxide gels may lead to severe phosphate deficiency, hypophosphatemia, and osteomalacia.

Intracellular phosphate shift. Phosphate can be shifted from serum into the intracellular compartment as a result of increased formation of phosphorylated carbohydrate compounds. Insulin increases the rate of glucose uptake into cells and its subsequent phosphorylation to

glucose-6-phosphate. Patients with diabetic ketoacidosis require phosphate repletion to avoid hypophosphatemia. In the setting of significantly depleted phosphate reserves, rapid consumption of oral carbohydrates or parenteral glucose can precipitate profound hypophosphatemia and sudden death due to respiratory or circulatory failure.

Increased bone mineralization rates may result in large amounts of phosphate entering the skeleton and hypophosphatemia. One example is the hungry bone syndrome that occurs after parathyroidectomy when there is an acute drop in PTH and in bone resorption (see section on hypocalcemia). Hypophosphatemia as a result of increased skeletal uptake can also be seen in patients with osteoblastic metastases and after treatment of vitamin D–deficient rickets or osteomalacia from vitamin D deficiency.

Treatment

Oral phosphate replacement is the optimal method for correction of hypophosphatemia. Phosphate is usually provided in two to four divided doses of 2000 to 4000 mg/day. Doses greater than 1000 to 2000 mg/day can cause diarrhea and other gastrointestinal side effects, particularly at initiation. Gradual increases in doses may be helpful for minimizing GI effects. Intravenous phosphate should be given only to patients for whom oral administration is not an option. Intravenous dosages up to 500 to 800 mg/day may be required. Frequent monitoring of serum phosphate, calcium, and creatinine levels is necessary. Burosumab, a monoclonal antibody to FGF23, was recently approved by the FDA to treat XLH.

DISORDERS OF MAGNESIUM METABOLISM

Hypermagnesemia

Symptoms and Signs

Clinically significant hypermagnesemia is uncommon. The most common symptom is drowsiness. On exam, patients have hyporeflexia and if untreated, eventual neuromuscular, respiratory, and cardiovascular collapse. Hypermagnesemia can also lead to hypocalcemia through effects on PTH (see “Hypocalcemia” section).

Differential Diagnosis

Hypermagnesemia is typically encountered in two settings: patients with severe renal failure who receive magnesium-containing antacids and in women who receive large doses of intravenous magnesium sulfate for eclampsia or preeclampsia (Table 75.5). Mild hypermagnesemia is common in patients on dialysis, but severe hypermagnesemia occurs only in the settings of renal failure accompanied by parenteral or oral magnesium salt administration, such as the use of magnesium-containing antacids or phosphate binders. In women being treated for eclampsia, hypermagnesemia occurs but is rarely severe, as patients are typically closely monitored by labs and physical exam.

Hypomagnesemia

Symptoms and Signs

Hypomagnesemia is common, particularly among critically ill patients in the ICU setting. As with hypophosphatemia, it is not always detected. Magnesium is key to many biologic processes, and hypomagnesemia may cause hypocalcemia, seizures, and paresthesias as well as many neuromuscular, cardiovascular, and respiratory symptoms.

Differential Diagnosis

The differential diagnosis of hypomagnesemia is reviewed in the following sections and in Table 75.5.

Inadequate intake. Inadequate intake of magnesium is common among alcoholics and other malnourished individuals. It may occur as

TABLE 75.5 Causes of Hypermagnesemia and Hypomagnesemia

Hypermagnesemia
Renal failure accompanied by magnesium antacid use
Parenteral magnesium sulfate administration for eclampsia
Hypomagnesemia
Inadequate intake
Starvation
Malabsorption
Alcoholism
Vomiting, nasogastric suction
Excessive renal losses
Diuretics
Saline infusion
Secondary aldosteronism
Cirrhosis
Congestive heart failure
Osmotic diuresis, hyperglycemia
Cisplatin, aminoglycoside antibiotics, amphotericin
Hypokalemia
Hypercalcemia, hypercalciuria
Proximal tubular diseases
Genetic defects

part of an intestinal malabsorption syndrome and in association with continuous vomiting or nasogastric suctioning.

Excessive renal losses. Excessive renal losses of magnesium are common in clinical practice. Thiazide and loop diuretics cause renal magnesium losses, and saline infusions can have a similar effect. Aldosterone can induce renal magnesium loss. This can be seen in patients with primary hyperaldosteronism and more commonly in the secondary hyperaldosteronism from cirrhosis, volume depletion, and congestive heart failure. Osmotic diuresis can cause renal magnesium loss as well, which is commonly seen in patients with poorly controlled diabetes mellitus. Certain nephrotoxic drugs such as cisplatin, aminoglycoside antibiotics, and amphotericin induce proximal renal tubular injury and severe renal magnesium wasting. Hypokalemia, hypercalcemia, and hypercalciuria can also lead to increased renal magnesium excretion. In diseases that lead to proximal tubular injury, such as Fanconi syndrome and interstitial nephritis, magnesium wasting can occur.

Treatment

Magnesium can be replaced intramuscularly or intravenously. A typical treatment regimen is 24 to 48 mEq (3 to 6 g) of magnesium sulfate given over 24 hours. Oral magnesium salts such as magnesium oxide are also available; however, oral dosing is limited to mild cases requiring low doses because of the cathartic effects of high doses of oral magnesium.

Metabolic Bone Diseases

Marcella D. Walker, Thomas J. Weber

INTRODUCTION

Metabolic bone disease (MBD) is an umbrella term that describes a heterogeneous group of skeletal disorders due to focal or diffuse alterations in bone remodeling and/or mineralization, often with associated abnormalities in mineral metabolism. Bone mineral density (BMD) is usually affected, although in some cases is normal. Etiology varies by disorder but includes metabolic, pathophysiologic, nutritional, genetic, toxic, infectious, and other causes. This family of disorders encompasses common conditions such as osteoporosis (see [Chapter 77](#)), less common conditions such as osteomalacia, as well as rare disorders including osteopetrosis. This chapter provides an overview with a focus on the more common diseases ([Table 76.1](#)). Normal skeletal homeostasis and histopathology are reviewed in [Chapter 74](#) and [Fig. 76.1A](#).

The clinical presentation of MBD is variable, ranging from asymptomatic incidental findings on laboratory tests, or radiographs, to disabling bone pain, muscle weakness, skeletal deformity, and fractures. Common laboratory and radiologic tests are useful in the evaluation of MBD and can often be diagnostic ([Table 76.2](#) and [76.3](#)). The “gold standard” for assessing both static and dynamic bone metabolism, although rarely required based on clinical history, remains tetracycline-labeled undecalcified bone biopsy of the anterior iliac crest. Bone biopsy allows assessment of osteoclast and osteoblast activity as well as osteoid mineralization. Undecalcified sections (see [Fig. 76.1A to F](#)) are necessary because the acid-mediated decalcification performed during routine pathology removes calcium and cannot distinguish between mineralized mature bone and unmineralized osteoid that may be normal or pathologic. Because tetracycline is incorporated into hydroxyapatite crystals as osteoid mineralizes and fluoresces under fluorescence microscopy, administration to patients before biopsy allows evaluation of the rates and effectiveness of bone formation and mineralization (see [Fig. 76.1B and F](#)).

PAGET'S DISEASE OF BONE

Paget's disease, or *osteitis deformans*, is the second most common MBD after osteoporosis, affecting 2% to 3% of adults over age 55 years in the United States. Incidence varies geographically and by race/ethnicity (most frequent in those of European descent) and may be declining. Paget's disease is usually a focal disorder of bone remodeling, in contrast to many others, such as osteoporosis, that affect the entire skeleton. Paget's disease may be *monostotic* or *polyostotic* (affecting one vs. multiple bones). Original lesions may expand, but new lesions rarely develop. It may involve any skeletal site, but the pelvis, vertebrae, skull, femur, and tibia are most commonly affected.

Paget's disease is characterized by an increase in bone resorption by abnormal osteoclasts, followed by rapid formation of poorly organized,

structurally weak “woven” bone (see [Fig. 76.1C](#)). The markedly increased osteoblast activity accounts for the typical sclerotic lesions observed on plain radiographs ([Fig. 76.2A to C](#)), the increased uptake of radionuclide on bone scan (see [Fig. 76.2D](#)), and the concomitant increase in serum levels of alkaline phosphatase, the latter of which is a protein byproduct of bone formation and the biochemical hallmark of Paget's disease. The pathogenesis of Paget's disease is unknown, but both genetic variants and viruses may contribute. Up to 30% with Paget's have a familial history and several genes have been implicated, including *SQSTM1*, *ZNF687*, *CSF-1*, *RANK*, and *PML* among others. Evidence suggests Paget's disease may result from chronic paramyxovirus infection with measles, respiratory syncytial virus or canine distemper virus.

Most patients are asymptomatic and diagnosed incidentally, either by increased serum alkaline phosphatase level on routine testing or on radiographs obtained for other reasons. Depending on the location and extent of lesions, however, patients may have bone pain, skeletal deformities including long bone bowing, fractures, osteoarthritis, and signs of nerve compression (e.g., deafness, spinal stenosis). Rare sequelae include hypercalcemia (in immobilized patients) and high-output cardiac failure. Because pagetic lesions are highly vascular, the skin over affected bones may be warm. The most feared (rare) complication is development of osteosarcoma in a pagetic lesion (<1%).

Paget's disease is typically diagnosed using biochemical markers of bone turnover and radiologic studies. In most patients, elevated total serum alkaline phosphatase is an adequate and sensitive indicator of disease activity. However, the serum level of bone-specific alkaline phosphatase may be a more sensitive indicator in those with low disease activity or if hepatic-derived alkaline phosphatase levels are low. A bone scan at diagnosis defines the location and extent of pagetic lesions (see [Fig. 76.2D](#)). Radiographs of the affected areas can confirm Paget's disease and are useful for evaluating complications and local disease progression (see [Fig. 76.2A to C](#)).

Therapeutic goals include relief of symptoms and prevention of complications. Indications for treatment include alleviating symptoms (e.g., bone pain, headache, neurologic complications), decreasing blood flow preoperatively to minimize bleeding during elective surgery involving a pagetic site, managing hypercalcemia, and preventing future complications of progressive local disease (bowing of the long bones, hearing loss due to temporal bone involvement, and neurologic complications from foramen magnum or vertebral involvement). Moderate quality evidence exists only for pain reduction with bisphosphonate therapy.

Treatment of Paget's disease involves a combination of non-pharmacologic (i.e., physical therapy) and pharmacologic therapy, including antiresorptive agents and analgesics. Bisphosphonates, the mainstay of treatment, decrease bone resorption at pagetic sites by

Gaucher's disease
Hemolytic diseases (e.g., thalassemia, sickle cell anemia)

inhibiting osteoclasts. Intravenous zoledronic acid is the first-line treatment and leads to more rapid and sustained normalization of alkaline phosphatase than oral bisphosphonates. Surgery may be needed for an impending or complete fracture through pagetic bone, realignment of arthritic joints, and total joint arthroplasty in affected hips or knees.

OSTEOMALACIA AND RICKETS

Although common in the United States and throughout the world, osteomalacia and rickets are often underappreciated and overlooked. Osteomalacia and rickets are essentially the same disorders, but by definition, rickets occurs in children with open growth plates (i.e., epiphyses), and osteomalacia occurs in adults who are skeletally mature. The fundamental abnormality in these disorders is an inability to mineralize (i.e., form hydroxyapatite crystals) osteoid, the precursor to mineralized bone. Although osteoid is produced, there is a defect in the mineralization process. This results in the accumulation of characteristic thick osteoid seams on bone biopsy (see [Fig. 76.1E and F](#)) and a reduction in the bone mineral content that renders it mechanically inferior, leading to stress or pseudofractures, frank fractures, bowing of the long bones, and other skeletal deformities ([Fig. 76.3A to C](#)).

Mineralization disorders are due to disturbances in vitamin D, calcium, phosphorus or inhibitors of mineralization/matrix development. Vitamin D deficiency (low 25-hydroxyvitamin D level) is

the most common cause of rickets and osteomalacia and is usually due to poor intake or malabsorption, but impaired hepatic production, excessive renal loss, and accelerated catabolism of vitamin D can occur in advanced liver disease, nephrotic syndrome, and with anticonvulsant use, respectively. Mutations in P450 enzymes regulating vitamin D metabolism (1 α -hydroxylase and 25-hydroxylase) and the vitamin D receptor (VDR) are much rarer causes of rickets and osteomalacia.

Hypophosphatemic disorders are less frequent causes of osteomalacia, but often present with more severe symptoms. These conditions include inherited or acquired disorders, like X-linked hypophosphatemic rickets (XLH) and tumor-induced osteomalacia, respectively, due to altered metabolism or over-production of a “phosphatonin” protein, fibroblast growth factor 23 (FGF23), as well as other renal phosphate-wasting conditions such as Fanconi syndrome.

Toxins interfering with mineralization, including aluminum, fluoride, and heavy metals (e.g., cadmium), can also cause osteomalacia. In addition, because calcium salts are acid soluble, chronic metabolic acidoses can result in osteomalacia or rickets. Mutations in tissue nonspecific alkaline phosphatase (TNSALP) result in skeletal over-accumulation of the naturally occurring mineralization inhibitor, pyrophosphate, causing hypophosphatasia (HPP). HPP, which is life-threatening in neonates due to respiratory failure from lack of rib mineralization, presents less severely in adults with bone pain, lower extremity stress fractures, and dental disease/tooth loss, though it can be a source of significant morbidity. Finally, osteomalacia is rarely due to inherent defects in bone matrix, such as in type VI *osteogenesis imperfecta* (OI).

In children, rickets presents with decreased longitudinal growth, widening of the long bone metaphyses (wrists, tibias), and bowing but may also include dental and other skeletal sequelae (i.e., rachitic rosary from enlargement of the costochondral junctions). In adults, osteomalacia presents with bone pain, proximal muscle weakness, fractures, and difficulty walking. The diagnosis of osteomalacia is suggested by the above symptoms and signs. Biochemistries, particularly serum phosphorus, vitamin D (25-hydroxyvitamin D₃ and 1,25[OH]₂D₃), parathyroid hormone (PTH), and alkaline phosphatase reflect the underlying pathobiology. Inappropriate phosphaturia with a low tubular maximum for phosphorus or glomerular filtration rate, measured with a fasting 2-hour urine phosphorus and creatinine (see [Chapter 75](#)), typifies renal phosphate-wasting disorders.

The characteristic radiologic signs of osteomalacia are stress fractures, also known as Looser's zones or Milkman's pseudofractures, primarily in weight-bearing bones. They can be identified by plain radiographs, but computed tomography (CT), MR or whole body bone scintigraphy may be required ([Fig. 76.3C](#)).

BMD, measured by dual-energy x-ray absorptiometry or DXA, is usually low, although often is erroneously assumed to be due to osteoporosis. Given this, and that some osteoporosis treatments (i.e., bisphosphonates) can worsen osteomalacia, the physician should review the list in [Table 76.1](#) and exclude alternative mineralization disorders prior to recommending conventional osteoporosis treatments. Finally, although the diagnosis of osteomalacia can often be made clinically, definitive diagnosis in uncertain cases relies on tetracycline-labeled undecalcified bone biopsy, which quantitates the degree of mineralization defect (see [Fig. 76.1E and F](#)).

Treatment of rickets or osteomalacia is dependent on underlying etiology. Ergocalciferol or cholecalciferol with supplemental calcium leads to fracture healing and reduced pain in severe vitamin D deficiency. Oral phosphorous salts and activated vitamin D

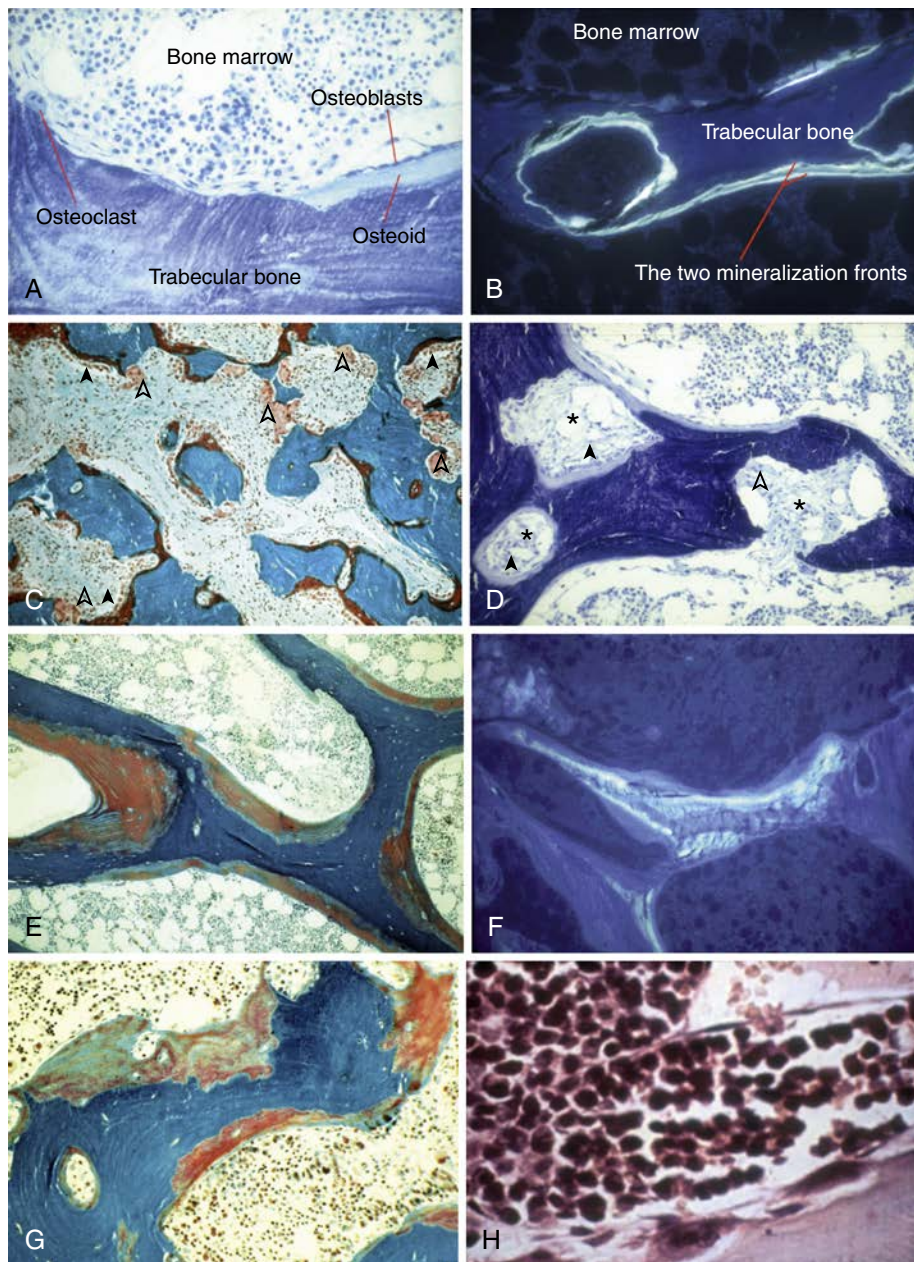

Fig. 76.1 (A) Normal bone histology, showing a normal bone-remodeling unit as seen in an undecalcified human anterior iliac crest biopsy. On the left, a multinucleated osteoclast has moved across the mineralized trabecular bone surface over the previous week or two, resorbing (removing) old bone. On the extreme right, the bone surface is covered by osteoid secreted by the overlying osteoblasts. In between the osteoclast- and osteoblast-covered surfaces of the trabecular bone are a large number of flat, fibroblastoid cells referred to as *lining cells*. No osteocytes are visible in this section. (B) Tetracycline labeling of a bone biopsy from a patient with hyperparathyroid bone disease. Notice the bright yellow parallel lines on the trabecular bone surface. These lines represent the two sets of tetracycline labeling, which occurred 14 days apart. From these sets, the mineralization rate can be described in micrometers (microns) per day, the so-called *mineral apposition rate*, and it is increased dramatically in this example, as is typical of hyperparathyroid bone disease. Contrast with example F, which has no tetracycline labeling. (C) Paget's disease. Enormous and abundant highly multinucleated osteoclasts (*open arrowheads*) are resorbing trabecular bone, and a comparably enormous number of osteoblasts (*closed arrowheads*) are making new but disorganized bone. The marrow space is replaced by fibrous cells. (D) Primary hyperparathyroidism has the classic features of osteitis fibrosa cystica. Far more osteoid and osteoblasts (*closed arrowheads*) and osteoclasts (*open arrowhead*) exist than in the normal example (A). Three large microcysts (*asterisks*) have been created by aggressive osteoclastic bone resorption. These microcysts account for the *cystica* component of osteitis fibrosa cystica. The marrow space, particularly within the microcysts, is filled with fibroblasts, which make up the *fibrosa* component of osteitis fibrosa cystica. (E) Osteomalacia or rickets. Notice the abundant quantities of partially and chaotically mineralized osteoid (*orange*). These seams are the thick osteoid seams and represent osteoid that has been produced by osteoblasts but that cannot mineralize, which is the signature defect in osteomalacia and rickets. (F) Tetracycline labeling reveals a complete absence of mineralization, diagnostic of osteomalacia or rickets. Compare with example B. (G) Renal osteodystrophy. This photomicrograph of a biopsy from a patient on dialysis demonstrates many of the classic features of renal osteodystrophy, including evidence of aggressive osteoclastic bone resorption (i.e., numerous osteoclastic lacunae on the bone surface compared with the smooth surfaces in example A) and abundant, partially and chaotically mineralized areas of osteoid (*orange*). (H) Infiltrative bone disease as exemplified by multiple myeloma. The bone marrow is replaced by plasma cells, and two large osteoclasts in lacunae are actively resorbing the trabecular bone surface.

analogues, such as calcitriol, improve osteomalacia in hypophosphatemic rickets, although targeted reduction of FGF23 levels with a monoclonal antibody also improves bone pain and fracture healing in XLH. Treatment of children with HPP using recombinant TNSALP can be life-saving and markedly reduces pain and disability. Identification and withdrawal of drugs/toxins causing inhibition of mineralization generally improves osteomalacic symptoms. Treatment of these diseases is gratifying because the responses are often dramatic with restoration of normal function in patients who were severely disabled.

HYPERPARATHYROID BONE DISEASE

Hyperparathyroid bone disease can be a major cause of skeletal morbidity, though the clinical presentation varies widely, depending on the nature and severity of the underlying parathyroid disorder. Patients with primary hyperparathyroidism (PHPT), characterized by elevated serum calcium and PTH levels from a parathyroid adenoma or hyperplasia, typically have no symptoms related to accelerated bone remodeling from excess PTH. However, in many patients, osteopenia or osteoporosis can be detected by DXA, which often shows bone loss at the cortical-rich proximal one third radius and proximal femur and

sparing of the cancellous-rich lumbar spine. Fracture risk, particularly risk for vertebral fractures, is also increased in PHPT, but many vertebral fractures are clinically occult (i.e., only identified by spine imaging).

Secondary hyperparathyroidism (SHPT), which is a physiologic PTH elevation occurring in response to hypocalcemia and/or 25-hydroxyvitamin D₃ deficiency, is also associated with bone loss from cortical-rich sites. SHPT is almost always present in advanced chronic kidney disease (CKD) as a result of chronic hypocalcemia, hyperphosphatemia, and low calcitriol (1,25[OH]₂D₃) levels, as well as in malabsorptive states such as gastric bypass. Tertiary hyperparathyroidism is characterized by hypercalcemia and elevated PTH resulting from long-standing SHPT, usually from end-stage renal disease (ESRD; see Chapter 30). In tertiary hyperparathyroidism, chronic parathyroid stimulation results in hyperplasia or adenomas and autonomous gland function.

In patients with chronically, markedly elevated PTH levels, severe hyperparathyroid bone disease, known as *osteitis fibrosa cystica* (OFC), may develop. OFC was common among patients with PHPT in the United States before the onset of routine biochemical screening that began in the 1970s but occurs in fewer than 2% of patients today. OFC remains frequent in regions of the world where calcium is not routinely measured. Today, OFC is typically seen in the context of severe, prolonged, and uncontrolled secondary and tertiary hyperparathyroidism (from ESRD) and parathyroid carcinoma. OFC, a *high turnover* skeletal disease, is characterized by coupled increases in osteoclastic bone resorption and osteoblastic osteoid synthesis, accelerated rates of bone mineralization accompanied by microcysts in the cortex and trabeculae (the *cystica* of OFC), and increased numbers of fibroblasts and marrow stroma (the *fibrosa* of OFC) (see Fig. 76.1B and D). Levels of markers of bone formation (i.e., alkaline phosphatase and osteocalcin) and resorption (i.e., N-terminal and C-terminal telopeptides) are usually increased, reflecting the bone histology. The radiologic hallmarks of OFC are salt-and-pepper demineralization of the calvarium, resorption of the tufts of the terminal phalanges and distal clavicles, subperiosteal resorption of the radial aspect of the cortex of the second phalanges (Fig. 76.4), and Brown tumors (i.e., collections of osteoclasts that produce gross lytic lesions) of the pelvis and long bones. Patients with OFC may have bone pain or fractures.

The treatment involves normalizing or lowering elevated PTH concentrations. In patients with OFC, curative parathyroidectomy normalizes biochemistries and leads to resolution of the radiologic

Paget's disease	Normal	Normal	Normal or high	Dependent on intake; Often low	Normal	High
Primary/hyperparathyroidism	High	Low or low normal	High	Dependent on intake; Often low	High or high normal	High or high normal

signs. In hyperparathyroid patients without OFC but with osteopenia or osteoporosis, BMD typically increases robustly after parathyroidectomy, particularly in the lumbar spine. If the hypercalcemia is mild and BMD is normal, no treatment may be required. Medical therapy with cinacalcet, a *calcimimetic* (mimics the action of calcium at the calcium-sensing receptor) can be used to lower PTH levels in those with parathyroid carcinoma who have failed surgical resection and patients with severe hypercalcemia due to primary or tertiary hyperparathyroidism who are not surgical candidates. Hypocalcemia may occasionally occur after parathyroidectomy in patients with more severe disease, a condition known as *hungry bone syndrome* (see Chapter 75).

SHPT due to vitamin D deficiency is treated with oral vitamin D₃ (cholecalciferol) or D₂ (ergocalciferol). SHPT from ESRD can be treated with a combination of the active form of vitamin D (1,25[OH]₂D₃ [calcitriol] or analogues), calcium supplementation, phosphate binders, and cinacalcet, depending on the clinical situation.

Infrequently, parathyroidectomy is needed for severe hyperparathyroid bone disease related to SHPT.

RENAL OSTEODYSTROPHY

Renal osteodystrophy (ROD) refers to changes in bone turnover, mineralization, and morphology that occur in CKD. ROD is typically associated with abnormalities in serum calcium, phosphate, PTH, FGF23 or vitamin D metabolism and also may be accompanied by vascular and soft tissue calcification. The term *chronic kidney disease–mineral and bone disorder* (CKD-MBD) describes the systemic disorder encompassing both the mineral and bone metabolism abnormalities in CKD.

ROD may occur as early as stage 2 CKD and is prevalent among those with stage 4 to 5 CKD. Furthermore, even mild and moderate CKD confers an increased risk of fracture. The pathophysiology of ROD is complex and related to alterations in both hormonal and

Fig. 76.2 Typical radiologic abnormalities in Paget's disease. (A) Compare the normal skull (*top*) with the skull (*bottom*) with the classic cotton-wool appearance, an expanded calvarium, and osteosclerosis of the petrous bones. (B) Classic asymmetrical involvement of the pelvis with a mixture of lytic and blastic lesions. (C) Bowing deformity of the femur with a markedly thickened cortex. (D) A whole-body radionuclide scan demonstrates polyostotic Paget's disease.

Fig. 76.3 (A) A typical example of rickets, with bowing of the femurs and tibias, wrist enlargement due to metaphyseal flaring and rachitic rosary, and enlargement of the costochondral junctions of the ribs. (B) A skeletal radiograph of a child with rickets. The weight-bearing bones of the lower extremities are bowed, and the epiphyses are open, mottled, and overgrown. (C) Looser's zones or pseudofractures (*arrows*) are characteristic of osteomalacia or rickets. The closed epiphyses indicate the patient is an adult. This radiograph is diagnostic of osteomalacia.)

Fig. 76.4 Skeletal radiographic changes of hyperparathyroidism. (A) A hand film from a patient with primary hyperparathyroidism. The *arrow* indicates a typical giant cell tumor (brown tumor), which is a collection of osteoclasts that lead to macrocystic changes in bone. The *arrowhead* indicates the irregular radial surface of a phalanx resulting from subperiosteal bone resorption, which is typical of hyperparathyroidism. The brown tumor and the subperiosteal resorption refill and disappear when the offending parathyroid tumor or hyperplasia is resected. (B) Radiograph of a normal hand for comparison. No brown tumors are seen, and the phalangeal periosteal surfaces are smooth. (C) The classic salt-and-pepper appearance of the skull in hyperparathyroidism. The periosteal surfaces of the inner and outer cortices or tables of the calvarium are indistinct as a result of subperiosteal bone resorption. The lateral view of the calvarium is hazy and indistinct, showing micropunctations. (Courtesy J. Towers, MD, and D. Armfield, MD, University of Pittsburgh, Pittsburgh, Penn.)

mineral metabolism. In early CKD, reduced phosphorous excretion leads to increased production and circulating levels of FGF23. SHPT results from hypocalcemia due to hyperphosphatemia and its precipitation with phosphate into soft tissues as well as defective renal $1,25[\text{OH}]_2\text{D}_3$ production (see Chapters 30 and 75).

Several types of ROD can occur and are classified as high-turnover (OFC), low-turnover (adynamic bone disease or ABD), osteomalacia, or mixed ROD. Tetracycline-labeled transiliac bone biopsy is the only way to reliably distinguish which type of ROD is present, though levels of PTH and alkaline phosphatase may provide noninvasive guidance (typically high in OFC). OFC and osteomalacia were common in the past, but their prevalence has declined while that of ABD has increased. The reasons for this, and the exact mechanisms leading to development of one type of ROD versus another, are not entirely clear, but may be related to degree of PTH elevation and other pathogenic factors.

As noted previously, OFC is due to excessive PTH secretion that causes marked increases in bone turnover, demineralization, and fracture. OFC may respond dramatically to $1,25(\text{OH})_2\text{D}_3$, cinacalcet, or both. Intravenous etelcalcetide, a newer calcimimetic, may be more effective. In contrast, ABD is characterized by little or no osteoblastic or osteoclastic activity or osteoid on bone biopsy. The condition results from excessive treatment with $1,25[\text{OH}]_2\text{D}_3$ or calcium-phosphate binders that are believed to cause “over-suppression” of PTH, although other factors may contribute as well. Patients may have bone pain, fractures, hypercalcemia, and vascular calcification. Treatment centers on reducing the dose of active vitamin D analogs, cinacalcet or other measures. Though an intuitive choice of treatment, little data confirm that osteoanabolic agents, such as PTH analogues, are beneficial in the treatment of ABD.

Severe osteomalacia, now uncommon in CKD, is characterized by bone pain, low BMD, and thickened osteoid seams with a mineralization defect on bone biopsy (see Fig. 76.1E). A major contributor to osteomalacia in the past was aluminum bone deposition from now obsolete aluminum-containing phosphate binders. More subtle defects in mineralization can be seen, however, even in early CKD from increased phosphorous and FGF23. CKD-associated osteomalacia may respond to $1,25[\text{OH}]_2\text{D}_3$ replacement. Mixed ROD is much less common and can be characterized by either high- or low-turnover bone disease along with osteomalacia (see Fig. 76.1G).

TRANSPLANTATION OSTEOPOROSIS

Patients who have undergone organ transplantation often have osteoporosis and are at high risk for fracture. Post-transplant use of immunosuppressive drugs, particularly glucocorticoids, leads to rapid bone loss. Glucocorticoids increase bone resorption, reduce bone formation, decrease gastrointestinal calcium absorption, and increase renal calcium excretion, leading to marked bone loss, and often fracture, within 6 months of initiation. Tacrolimus and cyclosporine have also been associated with bone loss.

Decreased BMD may, however, be present before transplantation as a result of organ failure and its treatment, malnutrition or malabsorption, inactivity, or hypogonadism. For example, those with primary biliary cirrhosis have reduced osteoblast function and low-turnover osteoporosis due to cholestatic toxins. Patients with cystic fibrosis have calcium and vitamin D malabsorption, malnutrition, and low weight. In those with end-stage lung or cardiac disease, physical inactivity contributes. Patients with ESRD who undergo renal transplantation often have ROD. Screening of patients at risk for transplant osteoporosis is paramount. Pretransplant DXA, measurement of vitamin D, and spine imaging is recommended. Early intervention with osteoporosis

therapies in those at high risk for fracture or post-transplant bone loss may prevent post-transplant fractures.

GENETIC DISEASES

Monogenic disorders that lead to abnormal BMD (low or high) or focal skeletal disease are uncommon, but their discovery has advanced our understanding of basic skeletal biology and in turn led to the development of new therapeutic agents for osteoporosis.

The most common monogenic disorder causing low BMD is OI, the severity of which is dependent on the underlying gene involved. OI most often results from mutations in the genes for type I collagen, although defects in collagen processing and mineralization may also cause disease. Patients with OI generally have very low BMD with marked skeletal fragility and deformities but may also have involvement of collagen-containing tissues including the tendons, skin, eyes, and teeth (dentogenesis imperfecta). A much rarer but mechanistically important monogenic form of low BMD is the osteoporosis-pseudoglioma syndrome, characterized by autosomal dominant, severe osteoporosis with blindness. This disease results from inactivating mutations in the low-density lipoprotein receptor-related protein 5 gene (*LRP5*), which acts in the osteoblast WNT-signaling pathway to increase bone formation. A missense mutation in *WNT* has also been described in a family with early-onset osteoporosis.

In contrast, activating mutations in *LRP5* lead to an autosomal-dominant form of very high BMD. Mutations in the gene encoding an inhibitor of the WNT signaling pathway, sclerostin, also lead to increased bone formation and high bone mass phenotypes, such as Van Buchem disease and sclerosteosis. These latter discoveries have led to the development of a monoclonal antibody against sclerostin for the treatment of osteoporosis.

In contrast to the disorders that affect bone formation, osteopetrosis, or “marble bone disease,” refers to a group of disorders resulting from mutations that impair osteoclastic bone resorption. Although osteopetrosis is associated with increased skeletal mass, fracture risk is increased, presumably due to a change in material properties or “brittleness” that results in reduced bone strength. The clinical presentation is variable depending on the underlying genetic etiology, but the features may include skeletal deformity/short stature, recurrent and poorly healing fractures, macrocephaly, dental abnormalities, overgrowth of neural foramina with nerve paralysis, and impaired hematopoiesis due to bone overgrowth crowding out the bone marrow space. Radiographic findings are diagnostic and indicate generalized sclerosis, a “bone in bone” appearance (from remaining primary spongiosa or calcified cartilage), rugger-jersey vertebrae, flaring of the long bone metaphyses (Erlenmeyer flask deformity) and calvarial and basilar thickening (Fig. 76.5A to C). There is no established treatment for osteopetrosis.

Genetic bone diseases can also present with focal skeletal lesions. Fibrous dysplasia (FD) is a rare condition characterized by fibro-osseous lesions within the skeleton and sometimes extra-skeletal manifestations. It is due to activating mutations in the *GNAS* gene, encoding the alpha subunit of the stimulatory G protein involved in cyclic adenosine monophosphate (cAMP) production and signaling that causes abnormal differentiation of osteoblasts and osteocytes. Mutations occur post-zygotically and are not inherited, resulting in a somatic mosaicism, with the extent of disease dependent on the timing of the mutation in development. Abnormal osteoblasts secrete a disorganized fibrotic bone matrix resulting in irregular trabeculae enmeshed within a fibrous stroma of spindle-shaped cells, as well as cytokines that result in bone resorption within lesions. Abnormal bone mineralization also

Fig. 76.5 (A) Head/face CT from a patient with fibrous dysplasia indicating expansion of the right maxilla; the cortex is intact but there are multiple lucent and sclerotic areas and some areas of ground-glass appearance; there is narrowing of the right maxillary sinus. (B–D) indicate diagnostic radiographic findings in a patient with “adult” osteopetrosis. There is generalized sclerosis. (B) The calvarium is thickened due to osteopetrosis. (C) The typical “Rugger-Jersey” spine due to bands of calcified primary spongiosa. (D) Endobones (*arrow*) or a “bone in bone” appearance can be seen in the pelvis due to calcified cartilage deposited during endochondral bone formation.

occurs locally and sometimes systemically, related to over-production of FGF23.

FD can involve one (monostotic) or multiple (polyostotic) bones but can rarely affect the entire skeleton (pan osteotic). The presentation of FD varies from incidentally discovered asymptomatic radiographic findings to severe disability from fractures, pain, and skeletal deformity. FD most often affects the skull and femur, though the spine, ribs, and pelvis are commonly involved as well. Radiographically, FD lesions appear as expansile, deforming, medullary lesions with cortical thinning and overall “ground-glass” appearance (Fig. 76.5D) but can evolve over time and become sclerotic. Diagnosis is often made radiologically with plain films or CT. Bone biopsy is infrequently required. As in Paget’s disease, extent of disease is best assessed with technetium-99 scan. FD also may be associated with extra-skeletal features including café au lait spots and/or hyperfunctioning endocrinopathies (McCune-Albright syndrome), resulting from mutant progeny cells within extraskeletal tissues. Skeletal malignancies are a

rare complication of FD. Depending on the extent of disease, management may include analgesia, physical therapy, orthopedic surgery for proximal femur or spine disease, monitoring for cranial nerve deficits, treatment of endocrinopathies and mineral disturbances, and bisphosphonates, though there are limited data regarding efficacy of the latter.

ISCHEMIC AND INFILTRATIVE DISEASES

Bone disease may also develop from ischemia or infiltration of the skeleton. Ischemic injury may develop due to drugs/toxins (excess glucocorticoids/alcohol), hemoglobinopathies, glycogen storage disorders (e.g. Gaucher’s disease) and excess radiation, among other causes. Radiographs may show focal or diffuse changes in BMD, as well as bone collapse. In multiple myeloma, malignant infiltration of the bone marrow by plasma cells results in excessive osteoclast activation, severe osteoporosis, and commonly hypercalcemia (see Fig. 76.1H). Systemic mastocytosis, another lymphoproliferative disease that can

affect multiple organs including the skin (urticaria pigmentosa), liver, spleen, and lymph nodes, may cause focal osteolytic lesions as well as diffuse osteoporosis and fractures. These and other infiltrative disorders can lead to diffuse osteopenia, bone pain, and fractures, and should be considered in unexplained osteoporosis.

Osteoporosis

Susan L. Greenspan, Mary P. Kotlarczyk

INTRODUCTION

Osteoporosis, the most common disorder of bone and mineral metabolism, affects about 50% of women and 20% of men older than 50 years. The National Institutes of Health Consensus Development Panel on Osteoporosis Prevention defines osteoporosis as a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk of fracture. Bone strength has two major components: bone density and bone quality. Bone density reflects the peak adult bone mass and the amount of bone lost in adulthood. Bone quality is determined by bone architecture, bone geometry, bone turnover, mineralization, and damage accumulation (i.e., microfractures) (Fig. 77.1).

DEFINITION AND EPIDEMIOLOGY

In the United States, 2 million osteoporotic fractures occur each year. There are almost 300,000 hip fractures annually, which are associated with a mortality rate of more than 20% during the first year. The mortality rate is higher in men than in women. More than 40% of patients with hip fracture are unable to return to their previous ambulatory state, and about 20% of them are placed in long-term care facilities. When defined by bone mineral densitometry, 44 million Americans have low bone mass, and 10 million have osteoporosis. Although morbidity is less with vertebral fractures, the 5-year mortality rate is similar to that for hip fractures. Only one third of radiologically diagnosed vertebral fractures receive medical attention.

PATHOLOGY AND RISK FACTORS

Peak bone mass is determined primarily by genetic factors. Men have a higher bone mass than women, and African American and Hispanic individuals have a higher bone mass than white individuals. Other factors that contribute to the development of peak bone mass include nutrition and calcium intake, physical activity, timing of puberty, chronic illness, smoking, and use of medications that harm bone such as glucocorticoids.

The causes of bone loss in adults are multifactorial. The pattern of bone loss is different in women than in men, and bone loss is greater in sites rich in trabecular bone (e.g., spine) than cortical bone (e.g., femoral neck) (Fig. 77.2). Women lose significantly more trabecular bone than men. Estrogen deficiency during menopause contributes significantly to bone loss in women, and they may lose 1% to 5% of bone mass per year in the first few years after menopause. Women continue to lose bone mass throughout the remainder of their lives, with another acceleration of bone loss occurring after age 75 years. The mechanism of this accelerated loss in old age is not clear.

Multiple causes of secondary bone loss contribute to osteoporosis and fractures. Medications that commonly cause bone loss include

glucocorticoids, antiepileptic medications, excess thyroid hormone, heparin, androgen deprivation therapy, aromatase inhibitors, and depo-medroxyprogesterone. Endocrine diseases resulting in female or male hypogonadism also lead to bone loss. Hyperparathyroidism, hyperthyroidism, and hypercortisolism commonly cause bone loss, as can vitamin D deficiency. Gastrointestinal problems can contribute to decreased absorption of calcium and vitamin D (Table 77.1). Risk factors for falls (e.g., age, poor vision, previous falls, immobility, orthostatic hypotension, cognitive impairment, vitamin D insufficiency, poor balance, gait problems, weak muscles, sarcopenia) also contribute to fractures.

CLINICAL PRESENTATION

Unlike many other chronic diseases with multiple signs and symptoms, osteoporosis is considered a silent disease until fractures occur. Whereas 90% of hip fractures occur after a fall, two thirds of vertebral fractures are silent and occur with minimal stress, such as lifting, sneezing, and bending. An acute vertebral fracture may result in significant back pain that decreases gradually over several weeks with analgesics and physical therapy. Patients with significant vertebral osteoporosis may have height loss, kyphosis, and severe cervical lordosis, also known as a *dowager's hump*. Prolonged bisphosphonate use (>5 years) may result in an atypical femoral fracture, which may manifest as unilateral or bilateral thigh pain and result in a femoral shaft fracture with no or minimal trauma.

Bone Mineral Density and Other Bone Mass Assessments

In 1994, the World Health Organization (WHO) developed a classification system for osteoporosis and low bone mass based on data from white, postmenopausal women (Table 77.2). Osteoporosis is defined as a bone mineral density less than or equal to 2.5 standard deviations (SDs) below young adult peak bone mass (T-score ≤ -2.5 SD). Low bone mass (i.e., osteopenia) is defined as a bone mass measurement between 1.0 and 2.5 SDs below adult peak bone mass (T-score between -1.0 and -2.5 SD). Normal bone mineral density is defined as assessments at or above 1.0 SD below adult peak bone mass (T-score ≥ -1.0 SD).

The standard for assessing bone mineral density is dual-energy x-ray absorptiometry (DXA), which has excellent precision and accuracy. Measurements are made at the hip and spine, and in about 30% of cases, discordance is found between these measurements (Fig. 77.3). Classification should be made only if two or more vertebrae are available for analysis on spine images because of the high error rate when a single vertebra is assessed. Classification is based on the lowest value (i.e., total spine, total hip, or femoral neck).

In patients with hyperparathyroidism, in which cortical bone loss is often seen, forearm DXA using the one third distal radius site should

Fig. 77.1 Three-dimensional reconstruction by microcomputed tomography of a lumbar spine sample from a young adult normal woman and from a woman with postmenopausal osteoporosis. In the osteoporotic woman, bone mass is reduced and microarchitectural bone structure is deteriorated. Whereas the platelike structure in the normal case is very isotropic, the structure in the osteoporotic case shows preferential loss of horizontal struts; the plates have become rods that are thin and farther apart, and there is a concomitant loss of trabecular connectivity. These changes lead to a reduction in bone strength that is more than would be predicted by the decrease in bone mineral density. (From Riggs BL, Khosla S, Melton LJ 3rd: Sex steroids and the construction and conservation of the adult skeleton, *Endocr Rev* 23:279-302, 2002; Courtesy Ralph Mueller, PhD, Swiss Federal Institute of Technology [ETH] and University of Zurich, Switzerland.)

Fig. 77.2 Patterns of age-related bone loss in women and in men. *Dashed lines* represent trabecular bone, and *solid lines* represent cortical bone. The figure is based on multiple cross-sectional and longitudinal studies using dual-energy x-ray absorptiometry. *BMD*, Bone mineral density. (From Khosla S, Riggs BL: Pathophysiology of age-related bone loss and osteoporosis, *Endocrinol Metab Clin North Am* 34:1015-1030, 2005.)

also be assessed. Forearm assessments may be helpful in older patients who often have falsely elevated bone mineral density measurements at the spine as a result of atypical calcifications from degenerative joint disease, sclerosis, or aortic calcifications or in obese patients whose weight exceeds the table limit.

Bone mineral density can be measured by hip or spine quantitative computed tomography (QCT). However, less normative data are available for hip QCT, vertebral precision is inferior to that of DXA,

and radiation doses are significantly higher than those of DXA. Single-photon absorptiometry of the forearm and peripheral measures, such as heel ultrasound, have also been used to assess bone mass. However, the WHO classification should be used only with the central DXA measurements.

The National Osteoporosis Foundation (NOF) recommends obtaining a bone mineral density assessment in all women 65 years old or older, men aged 70 or older regardless of risk factors, and in adults

TABLE 77.1 Conditions, Diseases, and Medications That Cause or Contribute to Osteoporosis and Fractures**Lifestyle Factors**

Alcohol abuse

TABLE 77.2 World Health Organization Classification for Osteoporosis

Classification	Criteria for Bone Mineral Density
Normal	At or above -1.0 SD of young adult peak mean value
Low bone mass (osteopenia)	Between -1.0 and -2.5 SD of young adult peak mean value
Osteoporosis	At or below -2.5 SD of young adult peak mean value

SD, Standard deviation.

age 50 and older who have a fracture. They also suggest screening younger postmenopausal women and men age 50 to 69 with clinical risk factors for a fracture and adults with a condition or on a medication associated with low bone mass or bone loss (Table 77.3). This recommendation differs from 2018 US Preventive Services Task Force (USPSTF) guidelines that recommend screening women age 65 and older and younger women at risk (using screening tools) but did not endorse screening for men. The guidelines of the NOF concur with the Endocrine Society and International Society for Clinical Densitometry. Reference databases are available for white, African American, Asian and Hispanic men and women.

FRAX, a fracture risk assessment tool, predicts the 10-year risk for hip or any major osteoporotic fracture for women and men between 40 and 90 years of age. The FRAX for the individual patient incorporates femoral neck T-score, age, gender, height, weight, and specific risk factors, including history of adult fracture, parental hip fracture, current smoking, glucocorticoid use, rheumatoid arthritis, alcohol (three drinks or more per day), and secondary osteoporosis. The fracture risk prediction is specific for race and country and should be used for patients *not* on therapy.

Bone mineral density determined by DXA usually can be monitored after 2 years of therapy, depending on the site to be assessed and the type of therapy prescribed. For example, trabecular bone, which has greater surface area and is more metabolically active than cortical bone, is more likely to show improvements with stronger-acting antiresorptive agents. Changes in bone mass with potent antiresorptive therapy are more prominent in the spine compared with other areas. Seeing no changes in forearm bone mineral density over time is common despite good precision. Although the heel has a high percentage of trabecular bone, precision is poor, and monitoring should not be done at this site.

All patients with osteoporosis or low bone mass should have a work-up for secondary causes of bone loss. It should include a serum calcium level (corrected for albumin) to rule out hyperparathyroidism or malnutrition; a 25-hydroxyvitamin D level to assess for vitamin D deficiency or insufficiency; an alkaline phosphatase level to assess for Paget's disease, malignancy, cirrhosis, or vitamin D deficiency; liver and renal function tests to assess for abnormalities; a 24-hour urine calcium and creatinine assay to evaluate for hypercalciuria or malabsorption; a test for sprue in patients with anemia, malabsorption, or hypocalciuria; a thyrotropin level to rule out hyperthyroidism; and serum protein electrophoresis to rule out myeloma in older adults with anemia. Measurement of the parathyroid hormone (PTH) level often is needed to interpret the calcium and vitamin D levels. Total testosterone levels are recommended for men.

A more extensive work-up can be done in severe or unusual cases. A bone biopsy is rarely needed. Markers of bone turnover vary considerably in clinical practice, and these tests usually are reserved for research. However, they may be useful for assessing the rate of bone turnover after prolonged bisphosphonate use or a bisphosphonate holiday.

Radiography

Conventional radiographs and vertebral fracture assessment in adults age 50 and older can reveal a vertebral compression fracture that is diagnostic of osteoporosis (Fig. 77.4) even in the absence of a BMD. However, two thirds of vertebral compression fractures are asymptomatic. Low bone mass may not be evident on radiographs until 30% of the mass has been lost. When assessing bone mass, radiographs may be read inappropriately as a result of overpenetration or under penetration of the film. Radiographs therefore are a poor indicator of osteoporosis (with the exception of vertebral fractures), and the diagnosis is instead based on bone mineral densitometric results. A vertebral fracture assessment (VFA) can often be performed in tandem with a standard DXA and can identify vertebral compression fractures.

PREVENTION

General preventive measures for all patients include adequate calcium and vitamin D intake, exercise, and fall prevention techniques. The recommended daily allowance of calcium for adults, as reviewed by the Institute of Medicine, is 1200 mg for women 51 years or older and men 71 years or older and 1000 mg for men 50 to 70 years old. Calcium intake can be accomplished by dietary consumption, supplementation, or the combination of diet plus supplement. The supplements should be pure calcium carbonate or pure calcium citrate, taken in divided doses of approximately 500 to 600 mg twice daily. Calcium carbonate should be taken with meals for best absorption, whereas calcium citrate may be taken with or without food. Calcium supplements are available as tablets and in chewable and liquid forms. Foods such as orange juice, cereals, breads, and nutrition bars may be calcium fortified. There is no benefit to taking more than 1200 mg per day, and excess intake may increase the risk of kidney stones and cardiovascular disease (although data are controversial).

Vitamin D is important for calcium absorption and bone mineralization. Vitamin D has nonskeletal benefits and has been associated with improvement in muscle strength and prevention of falls. Vitamin D comes from two sources: diet and photosynthesis. Because dietary sources of vitamin D are limited only to certain foods (e.g., fortified milk, yogurt) and patients are often advised to avoid sun exposure for prevention of skin cancer and wrinkles, many studies have documented vitamin D deficiency and insufficiency in older adults. Older patients have a reduced ability to synthesize vitamin D in the skin. Low vitamin D levels can lead to secondary hyperparathyroidism.

Vitamin D can be taken in a multivitamin, in a calcium supplement, or in pure form and is available as cholecalciferol (D_3) or ergocalciferol (D_2). Based on data from noninstitutionalized patients without osteoporosis, the daily dose recommended by the Institute of Medicine is 600 IU per day for adults up to age 70 and 800 IU for those older than 70 years to achieve a 25-hydroxy vitamin D level of at least 20 ng/mL (50 nmol/L). However, the NOF suggests 800 to 1000 IU per day and a 25-hydroxy vitamin D level of at least 30 ng/mL for optimal calcium absorption. Elderly patients, those with malabsorption, and obese patients may need greater amounts of vitamin D. Older patients with severe vitamin D deficiency may be given 50,000 IU of vitamin D once per week for 3 months to bring serum vitamin D into the normal range to be followed by a maintenance dose of at least 1000 IU daily. The upper limit of vitamin D intake is 4000 IU/day. Activated vitamin D is rarely needed and should not be given on a regular basis for postmenopausal osteoporosis.

 Fracture risk: Increased

Fig. 77.3 (Left) This patient has a lumbar spine (L1 through L4) bone mineral density (BMD) of 0.794 g/cm² (white circle with cross on the graph) as measured by dual-energy x-ray absorptiometry (DXA) and a T-score of -2.3. The reference database graph displays age- and sex-matched mean BMD levels ±2 standard deviations (SDs) derived from a normative database from the manufacturer (Hologic, Inc., Bedford, Mass.). The T-score indicates the difference in SD between the patient's BMD and that of the predicted sex-matched mean peak of a young adult; the z-value is the difference in SD between the patient's BMD and the sex-, age-, and ethnicity-matched mean BMD. (Right) This patient has a total hip BMD of 0.807 g/cm² and a femoral neck BMD of 0.655 g/cm² (white circle with cross on the graph) as measured by DXA, a total hip T-score of -1.1, and a femoral neck T-score of -1.7. The reference database graph displays age- and sex-matched mean BMD levels ±2 SDs derived from the third National Health and Nutrition Examination Survey. The T-score indicates the difference in SD between the patient's BMD and the predicted sex-matched mean peak young adult BMD; the z-score is the difference in SD between the patient's BMD. The 10-year fracture risk (FRAX) is 15% for a major osteoporotic fracture and 1.6% for a hip fracture (including reported risk factors: previous fracture, BMI = 24.2, using a US Caucasian database). (Bone densitometry report for the Horizon bone densitometer, Bedford, Mass., Hologic, Inc.)

TABLE 77.3 National Osteoporosis Foundation Recommendations for Bone Mineral Density Testing

- Women age ≥ 65 yr and men ≥ 70 yr, regardless of clinical risk factors
- Younger postmenopausal women, women in the menopausal transition, and men age 50–69 yr with clinical risk factors for fracture
- Adults who have a fracture after age 50 yr
- Adults who have a condition (e.g., rheumatoid arthritis) or are taking a medication (e.g., glucocorticoids in a daily dose of ≥ 5 mg prednisone or equivalent for ≥ 3 mo) associated with low bone mass or bone loss

Fig. 77.4 Lateral spine radiograph demonstrates a thoracic anterior wedge compression fracture.

Weight-bearing exercise (walking, jogging, dancing, tai chi, etc.) is important for maintaining skeletal integrity. Study results are controversial concerning different types and durations of exercise by postmenopausal women and men. However, weight-bearing or resistance training exercises usually are suggested and have been shown to improve bone mass or maintain skeletal integrity. In patients with new vertebral fractures, physical therapy is important for improving posture and increasing the strength of back muscles.

Because 90% of hip fractures and a significant number of vertebral fractures occur following a fall, preventive measures are suggested for frail older patients at risk for falling. Fall-proofing the household includes installing grab bars in the bathroom and hand rails on stairways, avoiding loose throw rugs and cords, ensuring good lighting by the bedside, and moving objects within easy reach in the kitchen. Other fall prevention measures include eliminating medications that cause dizziness or postural hypotension (if possible), assessing the need for assistive devices (e.g., canes, walkers), and ensuring appropriate footwear and good vision. The benefits of hip protectors for hip fracture reduction are disappointing and controversial, and compliance with these products is often poor.

TREATMENT AND PROGNOSIS

The NOF developed treatment guidelines that incorporate a 10-year fracture risk prediction. The NOF suggests treatment for

TABLE 77.4 National Osteoporosis Foundation Guidelines for Treatment

- An adult hip or vertebral fragility fracture
- Osteoporosis by DXA T-score ≤ -2.5 SD for lumbar spine, total hip, or femoral neck after appropriate evaluation
- Low bone mass by DXA T-scores between -1.0 and -2.5 SD at the lumbar spine or femoral neck and a FRAX 10-year probability of a hip fracture $\geq 3\%$ or a 10-year probability of major osteoporosis-related fractures $\geq 20\%$.

DXA, Dual-energy x-ray absorptiometry; FRAX, fracture risk assessment tool; SD, standard deviation.

postmenopausal women and men 50 years old or older, as shown in Table 77.4. In addition, the National Bone Health Alliance (NBHA) group of experts published an expanded version that included a fourth criterion for treatment: fracture of proximal humerus, pelvis or wrist in the setting of osteopenia (T-score between -1.0 and -2.5).

Patients taking glucocorticoids can fracture despite having normal bone density. The American College of Rheumatology suggests that patients starting glucocorticoids who will be treated for 3 months or longer have a bone density test and start antiresorptive therapy if indicated according to their guidelines.

Bisphosphonates

Bisphosphonates are the mainstay of osteoporosis prevention and treatment. They inhibit the cholesterol synthesis pathway in osteoclasts, causing early apoptosis and inhibiting osteoclast migration and attachment. Unlike other agents, bisphosphonates are incorporated into bone, the half-life is long, and the agent may be recycled.

In the United States, the bisphosphonates alendronate, risedronate, ibandronate, and zoledronic acid have been approved for the prevention and treatment of osteoporosis. Alendronate can increase bone mass by about 8% at the spine and 4% at the hip over 3 years. This increase has been associated with an approximately 50% reduction in spine, hip, and forearm fractures (Table 77.5). Alendronate is prescribed at 35 mg once weekly for osteoporosis prevention and 70 mg once weekly for the treatment of osteoporosis. Alendronate has been approved for use in men and patients with glucocorticoid-induced osteoporosis.

Risedronate is approved for the prevention and treatment of osteoporosis at a dose of 35 mg per week or 150 mg per month or as a delayed dose after breakfast of 35 mg per week. Large-scale, multicenter studies have shown improvements in bone mass of about 6% to 7% at the spine and 3% at the hip over 3 years. These studies revealed approximately 50% reduction in vertebral fractures, 40% reduction in nonvertebral fractures, and 40% reduction in hip fractures (see Table 77.5). Risedronate is approved for the treatment of osteoporosis in men and for the prevention and treatment of patients with glucocorticoid-induced osteoporosis.

Oral ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. After 3 years of treatment, ibandronate increased bone density by 6.5% at the spine and 3.4% at the hip, and it reduced new vertebral fractures by approximately 60%. No reductions in nonvertebral or hip fractures occurred. Ibandronate is approved at an oral dose of 150 mg monthly and for treatment at an intravenous dose of 3 mg every 3 months.

Zoledronic acid is approved for the prevention and treatment of postmenopausal osteoporosis, osteoporosis in men, and steroid-induced bone loss. The 3-year pivotal trial demonstrated increases of 6.9% of bone density at the spine and 6.0% at the hip, and the drug reduced spinal fractures by 70%, nonvertebral fractures by 25%, and

hip fractures by 41%. Zoledronic acid is given at a dose of 5 mg intravenously once per year for treatment and 5 mg intravenously every 24 months for prevention.

There is not a simple guide for which bisphosphonate is chosen, since the order of medication selection is often determined by the cost of the medication and insurance consideration. Generally, alendronate is the most commonly used because it is usually the least expensive.

Because oral bisphosphonates are poorly absorbed, they must be taken first thing in the morning on an empty stomach with a full glass of water. Patients must wait 30 minutes (when taking alendronate and risedronate) to 60 minutes (when taking ibandronate) before eating and must not lie down. A delayed-release form of risedronate can be taken after breakfast.

Potential side effects of bisphosphonates include epigastric distress, heartburn, and esophagitis. Intravenous bisphosphonates have been associated with an influenza-like syndrome after infusion. Bisphosphonates can also cause arthralgias and myalgias. They are contraindicated in patients with renal insufficiency (i.e., estimated glomerular filtration rate of 30 to 35 mL/minute). Osteonecrosis of the jaw (ONJ) is a rare adverse event of abnormal bone growth in the jaw, which is more often associated with high-dose intravenous bisphosphonates in patients with cancer and poor oral hygiene. Atypical femoral shaft fractures (AFF) have been reported rarely after long-term use (>5 years of oral or >3 years intravenous) of bisphosphonates. These fractures may manifest with a prodrome of unilateral or bilateral thigh pain, and fractures may occur with minimal activity. These fractures are rare after osteoporosis treatment but common in cancer patients receiving frequent high doses intravenously.

Denosumab

The receptor activator of nuclear factor- κ B (RANK) and its ligand (RANKL) are mediators of osteoclast activity. Compared with placebo, denosumab, an antibody to RANKL, produced a relative increase in bone mineral density at the spine of 9.2% and hip of 6.0% over 3 years, and it reduced fractures by 68% at the spine, 40% at the hip, and 20% at nonvertebral sites. Denosumab is approved for postmenopausal women and men with osteoporosis, men with prostate cancer on androgen deprivation therapy, postmenopausal women with breast cancer on aromatase inhibitors, and men and women on glucocorticoids. It is given as a 60-mg subcutaneous injection every 6 months. Denosumab may cause hypocalcemia so calcium intake by diet or supplement is encouraged. It is rarely associated with a rash or skin infection and very rarely associated with ONJ or AFF. When therapy is stopped, bone loss and vertebral compression fractures can occur, especially in patients with a previous vertebral fracture. It is suggested patients switch to an oral or intravenous bisphosphonate. Following denosumab discontinuation, teriparatide (a recombinant version of human parathyroid hormone) treatment (see later) can lead to bone loss at some sites.

Estrogen Agonists-Antagonists

Estrogen agonists-antagonists were previously called selective estrogen receptor modulators (SERMs) because they have some estrogen-like and anti-estrogen-like benefits. Raloxifene is approved for the prevention and treatment of osteoporosis in women. The Multiple Outcomes of Raloxifene Evaluation (MORE) trial found that bone mass was increased by 4% at the spine and 2.5% at the femoral neck over 3 years. This increase was associated with an approximate 50% reduction in vertebral fractures. No reduction in nonvertebral or hip fractures was seen (see Table 77.5). Treatment was associated with improved lipid status, as shown by decreased total and low-density lipoprotein cholesterol.

Raloxifene is not associated with endometrial hyperplasia, and patients should not have bleeding or spotting. They do not have breast tenderness or swelling. Raloxifene reduces the risk for invasive breast cancer in postmenopausal women with osteoporosis and in women at high risk for invasive breast cancer. Patients have the same small risk of deep vein thrombosis or pulmonary embolus that is found with hormone therapy. Raloxifene does not relieve postmenopausal symptoms and may exacerbate hot flashes. Studies have not found a significant impact on cardiovascular disease. Raloxifene can be given with or without food in a daily oral dose of 60 mg per day.

Hormone Therapy

Investigators of the Women's Health Initiative, a large, randomized, placebo-controlled, multicenter trial evaluating estrogen therapy, reported a 34% reduction in hip and vertebral fractures after 5.2 years. In addition to improvements in bone mass, benefits include an improved lipid profile, decreased colon cancer incidence, and decreased menopausal symptoms. However, because of the potential risks of hormone therapy (i.e., cardiovascular events, breast cancer, deep vein thrombosis, pulmonary embolus, and gallbladder problems), it should be used only for prevention or management of menopausal symptoms, and other agents should be used for the treatment of osteoporosis. A combination of conjugated estrogen/bazedoxifene is also approved for prevention in postmenopausal osteoporosis and other menopausal symptoms (hot flashes).

Parathyroid Hormone

Recombinant human PTH (1-34), or teriparatide, is an osteoanabolic agent that increases spinal bone mineral density by 9.7% and hip bone mineral density by 2.6% in 18 months. It is associated with a 65% reduction in vertebral fractures and a 53% reduction in nonvertebral fractures. Teriparatide is taken for up to 2 years as a subcutaneous, 20- μ g daily dose for postmenopausal women and men at high risk for fracture including patients on glucocorticoids. Side effects include nausea, headache, and dizziness and may be associated with bone loss at some sites if initiated following denosumab discontinuation. After therapy, patients benefit from antiresorptive therapy to prevent bone loss. Recombinant human PTH (1-84) is approved for use in Europe.

Parathyroid Hormone-Related Peptide

Abaloparatide analog of PTHrP (1-34) is an osteoanabolic agent that increases spine bone density by 9.8% and hip bone density by 3.4% in approximately 12 months. The pivotal trial reported a reduction of vertebral fractures by 86% and nonvertebral fractures by 43%. It can be administered as a daily subcutaneous injection of 80 mg for up to 2 years for postmenopausal women. Side effects include nausea, headache, dizziness, and palpitations. A patch form is under investigation. Following therapy, an antiresorptive agent is recommended to prevent bone loss.

Romozosumab

Romozosumab is a monoclonal antibody to sclerostin that has a dual effect mechanism of action since it increases bone formation and decreases bone resorption. In pivotal trials compared to placebo, after 12 months romozosumab increased bone density by 13.7% at the spine and 6.2% at the hip and reduced vertebral fractures by 73% and hip fractures by 38%. It is approved for postmenopausal women with osteoporosis for 12 months as a subcutaneous monthly injection of 210 mg. It should be followed by an antiresorptive therapy to prevent bone loss. It is rarely associated with ONJ and AFF. In a study where romozosumab was compared to alendronate, there was an increased risk of

cardiovascular events and strokes, so it should be avoided in patients who have had these events in the preceding year.

Calcitonin

Calcitonin is a 32-amino-acid peptide produced by the parafollicular cells of the thyroid gland. The pivotal clinical treatment trial did not show significant changes in bone mineral density after 3 years. However, the 200 IU dose of nasal calcitonin was associated with a 50% reduction in vertebral fractures (see Table 77.5). No reduction in nonvertebral or hip fractures was found. There is a possible association with development of cancer. Calcitonin may reduce pain following an acute vertebral compression fracture.

Choice of Therapy and Sequential Versus Combination Therapy

The initial choice of medication and sequence of therapy is important and under investigation. Currently, conventional therapy starts with a single agent. The choice of therapy is usually driven by the insurance provider, and often an oral antiresorptive bisphosphonate such as alendronate is the least expensive and provides fracture risk reduction at key vertebral, nonvertebral, and hip sites. If a patient has a contraindication to an oral bisphosphonate such as GERD, an intravenous bisphosphonate such as zoledronic acid is often initiated.

The concept of “treat-to-target” is based on the premise that starting any therapy may not be sufficient to achieve an acceptable level of risk. For high-risk patients with severe osteoporosis, the initial choice of therapy may be based on using the most potent therapy first

(anabolic), followed by a less potent therapy (antiresorptive) to maintain skeletal integrity. Recent studies have demonstrated greater vertebral fracture risk reduction with an anabolic therapy compared to an antiresorptive therapy.

Combination therapy with an anabolic and potent antiresorptive (denosumab) has been shown to increase bone mineral density more than monotherapy, but fracture reduction studies are needed. Combination of two antiresorptive therapies are not indicated.

Duration of Treatment

Osteoporosis is a chronic disease and requires lifelong management and follow-up. It is recommended that patients be reevaluated after 5 years of oral or 3 years of intravenous bisphosphate therapy. If they are osteopenic and without fracture risk they can begin a bisphosphate holiday, but reevaluation is suggested in 1 to 2 years. If they still have osteoporosis, have fractured on therapy, or are still at risk for fracture, therapy can be continued but a change to an alternative agent should be considered. After 2 years of an anabolic therapy with teriparatide or abaloparatide or 1 year of romosozumab, an antiresorptive therapy is suggested. There is no limit to the duration for denosumab, but following discontinuation of therapy an alternative antiresorptive therapy should be considered to prevent bone loss.

Vertebroplasty and Kyphoplasty

Vertebroplasty involves injection of cement (i.e., polymethylmethacrylate) into a compressed vertebra to prevent the vertebral body from

further collapse. Kyphoplasty introduces a balloon into the vertebral body to expand it, followed by cement placement inside the vertebral body. This approach expands the vertebral body and may increase height. Some studies suggest a significant reduction in pain early on, but the long-term pain reduction may be similar to that of placebo. Ongoing studies are needed to determine whether differences in outcomes can be found between vertebroplasty and kyphoplasty. These procedures are recommended only for patients with significant pain from vertebral fractures and are not routinely performed in asymptomatic patients with vertebral osteoporosis.

Approach to the Patient With Rheumatic Disease

Niveditha Mohan

INTRODUCTION

Rheumatic diseases encompass a range of musculoskeletal and systemic disorders that involve the joints and periarticular tissues in addition to other organ systems in the body. Differentiating localized from systemic processes, executing logical diagnostic procedures, and embarking on appropriate therapeutic courses demand careful clinical evaluation. The medical history and physical examination are paramount in this process. Laboratory tests are more confirmatory than diagnostic. Confirmation or exclusion of systemic connective tissue disease on the basis of laboratory results is unreliable and therefore unwise.

MUSCULOSKELETAL HISTORY

A logical approach to musculoskeletal complaints is indispensable to arriving at the correct diagnosis. Features in the medical history that are useful for distinguishing different types of arthritis are listed in [Tables 78.1 and 78.2](#). The first step is to confirm that the complaint originates from the musculoskeletal system and is not referred pain caused by other organ system pathology (e.g., left shoulder pain due to cardiac disease). The next step is to define whether the problem is articular or extra-articular based on the history and clinical presentation.

Demographic data provide useful information. The age of the patient can point to a specific rheumatic disorder. The spondyloarthropathies are more commonly diagnosed in young men, systemic lupus erythematosus (SLE) in young women, gout in middle-aged men and postmenopausal women, and osteoarthritis in the older population. Asymmetrical pain and swelling in the knees have different connotations in a 70-year-old patient than in a 20-year-old patient.

Immune status may affect the diagnosis of rheumatic disease. Immunocompromised patients should be evaluated for infectious arthritis. Patients with human immunodeficiency virus (HIV) infection may have a severe form of Reiter syndrome or a sudden flare of psoriasis or psoriatic arthritis.

The patient's history provides the basis for differentiating inflammatory from noninflammatory arthropathies. Inflammatory arthritis is characterized by pain at rest, morning stiffness (typically greater than 60 minutes), gelling phenomenon (i.e., stiffening of joints after inactivity), and joint tenderness associated with other signs of inflammation such as swelling, erythema, and warmth. In osteoarthritis and nonarthritic musculoskeletal problems, pain usually does not occur at rest and is precipitated or worsened by activity. Some osteoarthritic joints are stiff initially but are improved with activity. The onset of

disease is abrupt in crystal-induced arthritis, less so in septic arthritis, and slow and insidious in most other disorders.

Patterns of joint involvement are typical of certain disorders: monoarthritis (one joint), as in septic or crystal-induced arthritis; pauciarthritis or oligoarthritis (two to four joints), as in Reiter syndrome or psoriatic arthritis; and polyarthritis (five or more joints), as in rheumatoid arthritis or SLE. Symmetry, migratory features, large versus small joint involvement, and axial versus appendicular locations are characteristic features of specific diseases and should be sought in the patient's history. Enthesopathy (i.e., disease at the attachment of tendons or ligaments to bone) can indicate a spondyloarthropathy.

Constitutional features such as fatigue, weight loss, and fever are seen in systemic autoimmune disease and infection but not in localized conditions. A thorough review of systems can provide clues to the primary diagnosis by defining associated systemic syndromes. Although there are many exceptions to these demographic and clinical generalizations, they provide helpful starting points when a patient is being evaluated for the first time.

PHYSICAL EXAMINATION

On physical examination, active and passive range of motion in all joints should be carefully assessed, and tenderness, swelling, warmth, erythema, deformity, and joint effusions should be evaluated ([Fig. 78.1](#)). Patients are frequently unaware of detectable joint abnormalities, including deformity and effusion, which are signs of joint disease. Reported pain may be referred from another site, which can be determined by examination. Pain in the knee is often a sign of hip disease and may be reproduced on examination of the hip. Palpable synovitis (i.e., thickening of the synovial membrane) is helpful in diagnosing inflammatory arthritides such as rheumatoid arthritis.

Different diseases have distinctive patterns of joint involvement, which provide critical diagnostic information. For example, prominent disease of distal interphalangeal joints is seen in psoriasis and inflammatory osteoarthritis. Wrist and metacarpophalangeal involvement are almost universal in rheumatoid arthritis but rare in osteoarthritis. Examination of the axial skeleton may reveal diminished lumbar flexion, decreased rotational motion of the spine, and decreased chest expansion, features of ankylosing spondylitis and other spondyloarthropathies. Patients may report symptoms in only a single joint, but finding additional affected joints on physical examination can change the entire evaluation.

Because rheumatic diseases may involve any organ system, a complete physical examination should be performed for all patients.

Alopecia and fundoscopic changes (in SLE), uveitis (in spondyloarthropathy and juvenile arthritis), conjunctivitis (in reactive arthritis), sicca symptoms (in Sjögren's syndrome), oral and other mucous membrane ulcers (in reactive arthritis, SLE, and Behçet syndrome), lymphadenopathy (in SLE and Sjögren's syndrome), and cutaneous lesions (in psoriasis, dermatomyositis, scleroderma, SLE, and vasculitides) should be considered. Recurrent otorhinolaryngologic complaints, such as sinusitis, should raise suspicion for granulomatosis with polyangiitis (i.e., Wegener's granulomatosis). Lesions of psoriasis in the scalp, umbilicus, and anal crease, thickening of the skin on the fingers in scleroderma, and mucous membrane ulcers are often overlooked.

The lung examination may find evidence of interstitial fibrosis (in scleroderma, SLE, rheumatoid arthritis, and myositis), and a cardiac evaluation may reveal aortic insufficiency (in SLE and spondyloarthropathy), pulmonary hypertension (in systemic sclerosis), or evidence of cardiomyopathy (in systemic sclerosis, myositis, and amyloidosis). Pleural and pericardial rubs may be detected in SLE. Hepatosplenomegaly (in SLE and rheumatoid arthritis) and abdominal distention (in scleroderma) are also valuable clinical clues.

Muscle examination may reveal weakness from myositis, neuropathy (in vasculitis and SLE) or myopathy (in steroid myopathy). A

complete neurologic examination may reveal carpal tunnel syndrome, peripheral neuropathy such as mononeuritis multiplex (i.e., asymmetrical sensory or motor neuropathy seen in many vasculitides), and central nervous system disease (in SLE and vasculitis). Recurrent miscarriages, livedo reticularis, Raynaud's phenomenon, and recurrent thrombotic events indicate antiphospholipid antibody syndrome.

The onset of systemic rheumatic diseases is usually insidious, and the clinical course is prolonged. However, presentation sometimes can be acute depending on the organ system involved. The initial evaluation must determine whether diagnosis and treatment of the patient's problem requires urgent attention. Infectious processes need immediate treatment. Acute joint inflammation, fever, and systemic signs such as chills, night sweats, and leukocytosis provide supporting evidence for infection. Gouty arthritis may share some or all of these clinical features, but its onset tends to be more abrupt. Inflammation extending beyond the margins of the joint is characteristic of septic arthritis and is otherwise seen only in crystal disease. Nonarticular processes such as cellulitis, septic bursitis, tenosynovitis, and phlebitis may mimic infectious arthritis. Analysis of synovial fluid is the key to diagnosis.

Acute nerve entrapment or spinal cord compression, tendon rupture, and fractures may occur in the absence of obvious trauma. Spinal cord compression may be the result of a herniated disk or vertebral subluxation. Tendon rupture may occur in inflammatory arthritides, particularly in the wrist of patients with rheumatoid arthritis. Pelvic and other insufficiency fractures may be seen in patients with osteoporosis or osteomalacia.

Patients with SLE or systemic vasculitis may have central or peripheral nervous system disease, including brain and peripheral nerve infarcts, glomerulonephritis, inflammatory or hemorrhagic lung disease, coronary artery involvement, intestinal infarcts, and digital infarcts. Threatened digit loss may also be seen in cases of scleroderma due to severe Raynaud's and vasculitis. Renal crisis may occur in scleroderma, with vasculopathy leading to renal infarcts, azotemia, microangiopathy, and severe hypertension. Acute blindness is a potential complication of giant cell arteritis, and the diagnosis requires urgent therapy even before confirmatory biopsy.

Acute inflammatory myositis should be promptly treated because it may progress rapidly and involve the respiratory musculature. In some cases, major organ involvement may be occult. When systemic disease is suggested, the patient's lungs and kidneys should be carefully evaluated.

TABLE 78.1 Clinical Features That Are Helpful in the Evaluation of Arthritis

Age, sex, ethnicity, family history
Pattern of joint involvement
Monoarticular, oligoarticular, polyarticular
Large versus small joints
Symmetry
Insidious versus rapid onset
Inflammatory versus noninflammatory pain (e.g., morning stiffness, gelling, night pain)
Constitutional symptoms and signs (e.g., fever, fatigue, weight loss)
Synovitis, bursitis, tendinitis
Involvement of other organ systems (e.g., rash, mucous membrane lesions, nail lesions)
Arthritis-associated diseases (e.g., psoriasis, inflammatory bowel disease)
Anemia, proteinuria, azotemia
Erosive joint disease

TABLE 78.2 Differentiating Features of Common Arthritides

Disease	Demographics	Joints Involved	Special Features	Laboratory Findings
Gout	Men, postmenopausal women	Monoarticular or oligoarticular	Podagra, rapid onset of attack, polyarticular gout, tophi	SF: Crystals, high WBC count, >80% PMNs
Septic arthritis	Any age	Usually large joints	Fever, chills	SF: High WBC count, >90% PMNs, culture
Osteoarthritis	Increases with age	Weight-bearing, hands		Noninflammatory SF
Rheumatoid arthritis	Any age, predominantly women ages 20–50 yr	Symmetrical, small joints disease	Rheumatoid nodules, extra-articular	SF: High WBC count, >70% PMNs
Reactive arthritis (Reiter syndrome)	Young males	Oligoarticular, asymmetrical	Urethritis, conjunctivitis, skin and mucous membranes	SF: Moderate WBC count, >50% PMNs
Spondyloarthropathy	Young to middle-aged men	Axial skeleton, pelvis (sacroiliac joints)	Uveitis, aortic insufficiency, enthesopathy	
Systemic lupus erythematosus	Women in childbearing years	Hands, knees	Nonerosive joint disease, autoantibodies, mostly mononuclear; multiorgan disease	SF: Low to moderate WBC count, almost 100% have antinuclear antibodies

PMNs, Neutrophils; SF, synovial fluid; WBC, white blood cell.

Fig. 78.1 Anatomic structures of the musculoskeletal system (*left*). Locations of musculoskeletal disease processes (*right*). (From Gordon DA: Approach to the patient with musculoskeletal disease. In Bennett JC, Plum F, editors: Cecil textbook of medicine, ed 20, Philadelphia, 1996, WB Saunders, p 1440.)

TABLE 78.3 Classification of Synovial Effusions by Synovial White Blood Cell Count

Group	Sample Diagnoses	Appearance	Synovial Fluid WBC Count (MM ³) ^a	PMN Cells (%)
Normal		Clear, pale yellow	0–200	<10
I. Noninflammatory	Osteoarthritis; trauma	Clear to slightly turbid	50–2000 (600)	<30
II. Mildly inflammatory	Systemic lupus erythematosus	Clear to slightly turbid	100–9000 (3000)	<20
III. Severely inflammatory (noninfectious)	Gout	Turbid	2000–160,000 (21,000)	≈70
	Pseudogout	Turbid	500–75,000 (14,000)	≈70
	Rheumatoid arthritis	Turbid	2000–80,000 (19,000)	≈70
IV. Severely inflammatory (infectious)	Bacterial infections	Very turbid	5000–250,000 (80,000)	≈90
	Tuberculosis	Turbid	2500–100,000 (20,000)	≈60

PMNs, Neutrophils; WBC, white blood cell.

^aRange, with mean values in parentheses.

LABORATORY TESTING

Synovial fluid analysis is an important part of the evaluation of arthritis (Table 78.3). It helps to distinguish between inflammatory and noninflammatory arthritis, and results can be diagnostic of infectious arthritis or crystal disease.

Synovial fluid consists of an ultrafiltrate of plasma plus hyaluronic acid that is secreted by synovial lining cells. Evaluation of synovial fluid should include a cell count and differential, examination for sodium urate and calcium phosphate dehydrate crystals, Gram stain, and culture. Synovial fluid glucose and protein levels are not useful tests. Synovial fluid examination should be performed for all acute arthritides and all situations in which joint infection is likely. It should be performed at least once to evaluate chronic inflammatory arthritis. Aspiration and analysis of fluid before therapy are essential for appropriate decision making.

Although autoantibodies are often considered the hallmark of rheumatic diseases, their utility in diagnosing individual patients is much less than commonly assumed. Although almost 95% of patients with SLE have antinuclear antibodies (ANAs), as do most patients with scleroderma and autoimmune myositis, the proportion of patients with other rheumatic diseases who have positive test results is much lower. Conversely, 15% to 25% of healthy persons have ANAs, sometimes in high titers, when commercial test kits are used. Older persons

and patients with nonrheumatic systemic diseases such as malignancies and nonrheumatic autoimmune diseases such as thyroiditis or hypothyroidism have even higher frequencies of ANAs.

The very low specificity of a positive ANA result in the absence of clinical findings for an autoimmune disorder precludes its use as a screening test for disease in the general population. Other autoantibodies may be more useful and are discussed in subsequent chapters.

Rheumatoid factor is found in approximately 80% of patients with rheumatoid arthritis but also found in other rheumatic diseases, chronic infection, neoplasia, and almost any disease state that can cause chronic hyperglobulinemia. Neither positive nor negative test results are diagnostic, and the results should be interpreted only in the clinical context. Although the specificity of the rheumatoid factor is low, it does predict more aggressive joint disease and extra-articular joint manifestations.

Antibodies to cyclic citrullinated peptides are helpful in diagnosing rheumatoid arthritis because they have a high specificity (>90%). Their sensitivity varies from about 50% to 75%. Antibody tests should be ordered and repeated only if they can help in making the diagnosis, assessing the prognosis, or altering the treatment plan.

Tests for acute phase proteins, C-reactive protein, and the erythrocyte sedimentation rate are nonspecific, but positive results suggest an inflammatory disease. In some cases, such as in patients with giant cell

arteritis and polymyalgia rheumatica, these tests may be useful for the diagnosis and monitoring the course of disease and therapy. Anemia may suggest chronic disease or hemolytic anemia. Leukopenia, especially lymphopenia, suggests SLE, and thrombocytosis indicates active inflammation. Leukocytosis may reflect inflammation or infection, and glucocorticoid therapy also elevates the neutrophil cell count by demarginalization. Urinalysis should always be performed in patients with systemic disease. Proteinuria, red blood cells, and casts should be considered evidence of occult renal disease. Laboratory tests should always be considered in the context of the clinical presentation.

IMAGING STUDIES

Radiographic studies often show changes characteristic of particular diseases. In patients with established rheumatoid arthritis, radiographs may demonstrate classically erosive disease of the small joints of the wrists, the ulnar styloid, the metacarpophalangeal and proximal interphalangeal joints, and the small joints in the foot. The erosions are bland and nonreactive. In contrast, erosive psoriatic arthritis causes a sclerotic reaction, and the patient may have characteristic telescoping of joints, also called *pencil-in-cup lesions*. Large erosions with overhanging sclerotic margins and even juxta-articular tophi may be seen in gout.

In ankylosing spondylitis, sacroiliitis is observed on pelvic radiograph films and has high diagnostic specificity. Syndesmophytes (i.e., calcification of the outer rim of the annulus fibrosus), bridging osteophytes, calcification of spinal ligaments, and a typical bamboo spine in the late stages are seen on lumbar and chest radiographs. Joint space narrowing, bony spurs, and sclerosis are seen in osteoarthritis. Chondrocalcinosis is a common finding. It may be asymptomatic or may lead to crystal arthritis (i.e., pseudogout). In acute arthritis, radiographs are much less helpful because bony changes take time to develop; only in septic joint disease is destruction observed in the early stages.

Imaging modalities such as magnetic resonance imaging (MRI), radionuclide scans, ultrasound, and computed tomography are often useful in assessing diseases of bones, joints, muscle, and soft tissues. Ultrasound may be used to detect synovial cysts, especially Baker cysts of the knee, and it is being used more frequently in the outpatient setting to guide procedures.

MRI is the procedure of choice for evaluating early avascular necrosis of bone, especially the hips, and for meniscal or rotator cuff disease.

MRI is preferred for evaluating intervertebral disk disease with radiculopathy and spinal stenosis, and it is useful for assessing solid lesions of bone and joints, including neoplastic lesions. The sensitivity of MRI for detecting edema (i.e., water) enables evaluation of infectious and noninfectious inflammatory muscle diseases. MRI is a sensitive but not a specific modality for evaluating osteomyelitis, properties shared with radionuclide imaging. MRI should not supplant clinical evaluation or plain radiography.

In many instances, diagnosis can be made with certainty only by pathologic examination of tissue. Muscle biopsy may be necessary to establish a diagnosis of inflammatory muscle disease, and nerve biopsy may be needed to detect vasculitis. Skin biopsy is useful in differentiating the many causes of rheumatologic skin disease. Renal biopsy is often needed for determination of the diagnosis, treatment, and prognosis.

SUMMARY

The evaluation of arthritis begins with a detailed history consisting of the location and pattern of joint involvement, differentiation of inflammatory from mechanical and other causes, and a thorough review of systems to determine the nonarticular systemic features. The patient's age and sex, family history, medication history, and coexisting medical conditions have a bearing on the diagnosis and treatment plan. Radiographic and laboratory studies, particularly synovial fluid analysis, provide confirmatory and sometimes diagnostic information.

For a deeper discussion of these topics, please see Chapter 241, "Approach to the Patient with Rheumatic Disease," in *Goldman-Cecil Medicine*, 26th Edition.

Rheumatoid Arthritis

Larry W. Moreland, Rayford R. June

DEFINITION

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disorder that is characterized by symmetrical joint pain and swelling, morning stiffness, and fatigue. RA has a variable disease course, often with periods of exacerbations and, less frequently, disease quiescence. Outcomes range from rarely seen remitting disease to severe disease that produces disability and, for some patients, premature death.

Without treatment, most patients have progressive joint damage and significant disability within a few years. Since the introduction of methotrexate in 1985 and tumor necrosis factor- α (TNF- α) inhibitors in the 1990s, there has been a change in the treatment paradigm; many conventional and biologic therapies are now available to effectively treat this previously debilitating chronic disease.

EPIDEMIOLOGY

RA is a worldwide problem with a prevalence in Europe and North America of 0.5% to 1% of the adult population and an annual incidence of 25 to 50/100,000. RA is at least twice as common in women as in men and has a higher prevalence in specific patient populations such as the Pima and Chippewa Native Americans, with a respective prevalence of 5.3% and 6.8%. The disease affects individuals at any age, but most common age of onset is between 50 and 60 years. RA is uncommon among men younger than 45 years of age, but the incidence rises steeply with increasing age. Poor prognostic factors include high disease activity with many joints involved, increased inflammatory markers, high titers of rheumatoid factor (RF) and/or cyclic citrullinated peptides (CCP) antibodies, tobacco use, and erosions on radiographs. With the advent of new therapies, disease severity has decreased over time with less marked radiographic damage and fewer major orthopedic surgeries including joint replacements. However, despite these advances, work-related disability rates remain high for patients with RA. Numerous studies have demonstrated increased mortality rates for patients with RA compared with the general population, with a relative risk of 1.3. The increased mortality rate is more pronounced in males than in females with RA and is attributed to infectious complications and cardiovascular disease.

ETIOLOGY AND GENETICS

The specific underlying cause of RA (i.e., triggers in the susceptible host) is unknown. As for most autoimmune diseases, RA is thought to result from a complex interaction of genetic and environmental factors. RA may consist of multiple environmental stimuli leading to a common clinical presentation. There is not a known single mechanism of initiation or perpetuation. Various environmental triggers such as smoking, obesity, silica exposure, mineral oil, and organic solvents

have been associated with the development of RA. Smoking has the most impact, particularly on CCP antibody-positive disease; CCP-positive disease has a more distinct presentation and epidemiology than CCP-negative disease.

An individual's genetic profile also plays a critical role in the susceptibility to and severity of RA. Supporting a genetic component, studies have revealed a 9% to 15% concordance in monozygotic twins that is approximately four times greater than the rate in dizygotic twins. RA is a polygenetic disease with over 100 susceptibility loci reported. The genes with the greatest impact lie in the class II major histocompatibility (MHC) locus, accounting for approximately 60% of the genetic risk for RA. A specific sequence on the HLA-DR haplotype involved in antigen recognition is called the *shared epitope*, which is strongly associated with severe RA and extra-articular manifestations. Multiple mutations in various alleles can then cause changes in the peptide binding groove leading to decreased self-tolerance. Although important, the shared epitope does not fully explain RA because it also occurs in only 25% to 35% of the white population whereas the chance of developing RA in shared-epitope carriers is only 1 in 25 (4%). Non-MHC and HLA genetic associations primarily involve pathways within CD4⁺ T cells and pathways affecting T- and B-cell interactions, cellular proliferation, and cytokine signaling pathways.

The interplay between environmental and genetic factors is most clearly seen with the increased risk of RA associated with smoking and the MHC class II loci. The exact association between the two is unclear, but research has shown that the bacteria in periodontal and mucosal lung disease, which are increased with smoking, can promote citrullination of bacteria leading to antibodies against multiple different citrullinated peptides. Anti-CCP antibodies are associated with aggressive disease.

For a deeper discussion of these topics, please see Chapter 248, "Rheumatoid Arthritis," in *Goldman-Cecil Medicine*, 26th Edition. ♦

PATHOLOGY AND PATHOGENESIS

RA is a heterogeneous disease with a complex pathogenesis. RA is a clinical diagnosis presenting as a single clinical phenotype, but the underlying pathogenic immunologic genotype is more often than not unique. Instead, several signaling pathways often lead to the same clinical presentation.

Synovial membrane inflammation characterizes RA. Specific processes that lead to this inflammation and cellular proliferation are loss of tolerance, cytokine production, and autoantibody production. Several cytokine signaling pathways are involved with the predominant cytokines interleukin-1 (IL-1), IL-6, TNF- α , and granulocyte-macrophage colony-stimulating factor (GM-CSF)

detected within the synovium and peripheral blood. As mentioned, in anti-CCP-positive disease, the initial site of inflammation may be in the periodontal mucosa and lung. Many advances have been made in understanding the cell-cell interactions and cytokine signaling, but little is known about the loss of tolerance and role of regulatory T cells in disease onset and propagation. Many insights into the pathogenesis of RA have resulted from analyzing the responses to cytokine inhibition (i.e., IL-1, TNF- α , and IL-6) and to specific T- and B-cell-directed therapies. For instance, TNF- α blockade therapies were initially developed for other diseases but then found to be very effective for RA.

The process of synovial inflammation and proliferation is initiated by an interaction between antigen-presenting cells (APCs) and CD4⁺ T cells. APCs display complexes of class II MHC molecules and peptide antigens that bind to specific receptors on the T cells. Clonal expansion of T-cell subsets occurs with an appropriate second signal, or co-stimulation, delivered by the APC to the T cell. Activated T_H1 and T_H17 T-cell subsets predominate in synovial tissues. These cell types stimulate synovial macrophages to secrete proinflammatory cytokines such as IL-1, TNF- α , GM-CSF, and IL-6 to activate inflammatory pathways.

In addition to cellular and cytokine processes, the humoral immune system is also involved in the pathogenesis of RA. The autoantibodies found most frequently in patients with RA are immunoglobulin M (IgM), RF, and anti-CCP. Positive RF and anti-CCP testing is associated with aggressive, erosive RA, and these autoantibodies are found in serum sometimes years before patients develop signs of RA. Although a causal link has not been confirmed, CCP antibodies, combined with genetic and environmental factors (e.g., smoking, periodontal disease),

are involved in the development of RA. It is not known yet how to prevent RA in people with high risk for developing it.

RA pathogenesis occurs in stages. In the induction phase, the anatomy of the synovial lining within the articular joint enables recruitment of inflammatory cells. Cigarette smoke, bacterial products, viral components, and other environmental stimuli may amplify this process and promote a dysregulated immune system. A genetic propensity for autoreactivity may initiate a then irreversible pathway to RA.

The destructive phase, which can be antigen dependent or independent, involves mesenchymal elements such as fibroblasts and synoviocytes. Bone erosions result from local differentiation and activation of osteoclasts, whereas cartilage damage appears to be caused by proteolytic enzymes produced by synoviocytes, macrophages, and synovial fluid neutrophils. Counter-regulatory mechanisms (e.g., soluble TNF- α receptors, suppressive cytokines through regulatory T cells, protease inhibitors, natural cytokine antagonists) are not produced in high enough levels, leading to a loss of tolerance.

Cytokines, which are hormone-like proteins that regulate many immune cell functions, have been implicated in synovial inflammation. The inflammatory milieu of the joint is dominated by proinflammatory factors produced by macrophages and fibroblasts, especially in the synovial intimal lining. In addition to the four cytokines mentioned previously (IL-1, IL-6, GM-CSF and TNF- α), many other cytokines and chemokines have been identified at the protein and mRNA level within the synovium.

Joint damage in RA results from proliferation of the synovial intimal layer forming a pannus that overgrows, invades, and destroys adjacent cartilage and bone (Fig. 79.1). Fibroblast-like synoviocytes

Fig. 79.1 Pathogenetic events in rheumatoid arthritis. The proliferative synovial pannus invades at the bone-cartilage interface. Interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α) activate synovial cells (SC) to produce prostaglandins and matrix metalloproteinases (MMPs). In the synovial fluid, polymorphonuclear leukocytes (PMN), activated by immune complexes and complement, produce mediators of inflammation and destruction. CD, Chondrocytes; MNC, mononuclear cell; OC, osteoclast.

and macrophages are the predominant cellular components of the invading pannus of the synovium. Extracellular matrix damage resulting from synovial expansion is caused by several families of enzymes, including serine proteases, cathepsins, and matrix metalloproteinases.

❖ For a deeper discussion of these topics, please see Chapter 248, “Rheumatoid Arthritis,” in *Goldman-Cecil Medicine*, 26th Edition.

CLINICAL PRESENTATION

Articular Manifestations

RA manifests with a symmetrical polyarthritis that typically starts with the small joints of the hands and feet and can progress to the synovium of the wrists, elbows, shoulders, knees, and ankles. Patients have an insidious onset of inflammatory symptoms, which are fatigue, pain, and stiffness that is worse with inactivity and is improved with movement. Prolonged morning stiffness, usually lasting more than 1 hour, is a classic feature of RA (Table 79.1). Often, warm water and heat will also relieve this stiffness. Any diarthrodial (synovial) joint may be involved, including the apophyseal (spinal), temporomandibular, and cricoarytenoid joints. Involved joints are swollen, warm, and tender, and they may have effusions. The synovium, which is normally a few cell layers thick, becomes palpable on examination (i.e., synovitis).

Without treatment, RA progresses in some patients to joint destruction and deformity. Erosive lesions of bone and cartilage often are visible radiographically at the margins of bone and cartilage, the sites of synovial attachment. Not all patients with RA have erosive disease, with only 40% of patients in many present-day studies having radiographic erosions. Tenosynovitis (i.e., inflammation of tendon sheaths) leads to tendon malalignment, stretching or shortening and exacerbates joint subluxation.

Joint deformities leading to functional disability occur in RA after long-standing joint disease. Common deformities are ulnar deviation at the metacarpophalangeal joints and volar subluxation at those joints and at the wrists. Flexion and extension contractures in the proximal and distal interphalangeal (PIP and DIP) joints of the fingers lead to the characteristic swan-neck deformity (i.e., flexion contracture at the DIP joint and hyperextension at the PIP joint) or boutonnière deformity (i.e., flexion contracture at the PIP and hyperextension at the DIP joint).

Synovitis at the wrists can lead to median nerve compression and carpal tunnel syndrome. Carpal tunnel syndrome can often be the first sign of RA. Rarely, long-standing cervical spine disease may lead to C1-C2 subluxation and life-threatening spinal cord compression. Rupture of synovial fluid from the knee into the calf (i.e., Baker cyst) may mimic deep vein thrombosis or imitate cellulitis.

Extra-articular Manifestations

RA is a systemic disease in which there can be multiple extra-articular manifestations, particularly in severe uncontrolled RA (Table 79.2).

TABLE 79.1 Clinical Characteristics of Rheumatoid Arthritis

Morning stiffness or gelling
Symmetrical joint swelling
Predilection for wrists and proximal interphalangeal, metacarpophalangeal, and metatarsophalangeal joints
Erosions of bone and cartilage
Joint subluxation and ulnar deviation
Inflammatory joint fluid
Carpal tunnel syndrome
Baker cyst

Constitutional symptoms are common with disease onset and flares; these symptoms include fatigue, low-grade fever, weight loss, and myalgia. Extra-articular manifestations are more common in RF-positive patients and some epidemiologic studies have shown a decrease in extra-articular manifestations associated with newer treatments and improved disease control.

The most common extra-articular manifestation of RA is rheumatoid nodules, which can occur in 30% to 40% of patients. These are grossly palpable nodules on the skin at pressure points along extensor surfaces, especially at the elbows. Rheumatoid nodules are associated with RF positivity and tobacco use and can also occur in the lungs, pleura, pericardium, sclerae, and other sites, including the heart in rare cases. In the eyes, RA commonly is associated with keratoconjunctivitis sicca with coexistent Sjögren’s syndrome and less often with scleritis and episcleritis.

Lung involvement in RA can present as interstitial lung disease and may include pleuropericarditis, producing inflammatory exudative pleural and pericardial effusions. The cardiovascular effects of RA can range from long-term inflammation leading to accelerated coronary artery disease to pericarditis to small and medium-sized vasculitis. The vasculitis of RA can produce cutaneous lesions (e.g., ulcers, skin necrosis) and mononeuritis multiplex.

RA patients often have common hematologic manifestations such as anemia of chronic disease and thrombocytosis with uncontrolled disease and early presentation. Patients with RA also have an increased incidence of lymphoma. Larger granular lymphocyte (LGL) leukemia is a specific form of chronic leukemia associated with RA. Often LGL can present as Felty syndrome (i.e., rheumatoid arthritis, splenomegaly, and neutropenia). This rare complication can be accompanied by leg ulcers and vasculitis.

Medication side effects should also be considered as extra-articular manifestations of RA. Rheumatoid nodules can be precipitated by methotrexate with a syndrome called methotrexate nodulosis and must be differentiated from uncontrolled RA. TNF- α inhibitors, the most common biologic agent for RA, are associated with skin psoriasis and can also cause drug induced lupus.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

RA is a clinical diagnosis based on a thorough history and physical examination. Classic symptoms include morning stiffness associated with synovitis of small joints in a symmetrical fashion. No single diagnostic test enables a diagnosis of RA to be made with certainty. Instead, the diagnosis depends on the accumulation of characteristic symptoms, signs, laboratory data, and radiologic findings. There are no diagnostic criteria for RA but rather a pattern of clinical features and laboratory tests that aid the clinician in making the diagnosis. Classification criteria are useful in guiding the clinical diagnosis of RA and also create clear guidelines for classifying patients in research studies. The RA classification criteria were updated in 2010 to include anti-CCP testing

TABLE 79.2 Extra-articular Features of Rheumatoid Arthritis

Rheumatoid nodules: subcutaneous, pulmonary, sclera
Interstitial lung disease
Vasculitis, especially skin and peripheral nerves
Pleuropericarditis
Scleritis and episcleritis
Leg ulcers
Felty syndrome

TABLE 79.3 2010 ACR/EULAR Classification Criteria for Rheumatoid Arthritis

For patients who have at least 1 joint with definite synovitis and for whom the synovitis is not better explained by another disease.

- A. Joint involvement (0–5 points)
 - 1 large joint (0)
 - 2–10 large joints (1)
 - 1–3 small joints (with or without involvement of large joints) (2)
 - 4–10 small joints (or without involvement of large joints) (3)
 - >10 joints (with involvement of at least 1 small joint) (5)
 - B. Serology (0–3 points)
 - Negative RF and negative anti-CCP (0)
 - Low-positive RF or low-positive anti-CCP (2)
 - High positive RF or high positive anti-CCP (3)
 - C. Acute phase reactants (0–1 points)
 - Normal CRP and normal ESR (0)
 - Abnormal CRP or abnormal ESR (1)
 - D. Duration of symptoms (0–1 points)
 - <6 weeks (0)
 - ≥6 weeks (1)
- A score of at least 6 of 10 points is needed for the classification of definite rheumatoid arthritis.

ACR, American College of Rheumatology; CCP, cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RF, rheumatoid factor. Aletaha D, Neogi T, Silman AJ, et al: 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative, *Arthritis Rheum* 62:2569-2581, 2010.

and were designed to capture early RA (Table 79.3). Multiple studies have shown that prompt diagnosis and treatment are important to prevent disease progression, joint deformities, and disability. With the advent of specific diagnostic testing such as CCP testing and incorporation into the new classification criteria for early RA, both clinical practice and research settings have seen significant advancements with earlier treatment for patients with subsequently improved outcomes.

The differential diagnosis for RA is broad and includes viral arthritis (e.g., parvovirus, rubella, hepatitis B and C), thyroid disorders, sarcoidosis, reactive arthritis, psoriatic arthritis, Sjögren's syndrome, systemic lupus erythematosus (SLE), bacterial endocarditis, rheumatic fever, calcium pyrophosphate disease (CPPD), chronic tophaceous gout, polymyalgia rheumatica, erosive osteoarthritis, and fibromyalgia syndrome. A history and physical examination, including a thorough review of systems, persistence over time (with 6 weeks being on the most recent classification criteria; see Table 79.3), and available diagnostic testing guide the clinician in making the diagnosis. Initial laboratory tests in the evaluation should include a complete blood count, comprehensive metabolic panel, erythrocyte sedimentation rate, C-reactive protein, uric acid, RF, anti-CCP, ANA by indirect immunofluorescence, and hepatitis B and C testing. Additional tests such as viral serologies and autoantibody testing should be guided by the clinical presentation.

RF is an antibody (typically IgM but also IgG or others) that binds to the Fc fragment of IgG. RF and IgG join to form immune complexes that are detectable in the serum of 70% to 80% of patients with RA over the course of the disease. However, RF is not specific for RA and frequently occurs in patients with SLE, Sjögren's syndrome, infective endocarditis, sarcoidosis, lung and liver diseases (including infections

such as hepatitis B and C), and also in healthy individuals. In an individual patient, the RF titer does not correlate with disease activity, but high titers are associated with severe erosive arthritis and extra-articular disease. The finding of RF in serum alone does not establish a diagnosis of RA, but it can help to confirm the clinical impression. RF does not need to be repeatedly tested once the diagnosis is made.

Anti-CCP antibodies are a more specific marker for RA than RF. Anti-CCP antibodies are antibodies directed at citrullinated peptides and can be tested with one diagnostic test. Anti-CCP antibodies in the presence of at least one swollen joint have a high specificity (>95%) for RA. Compared to RF, CCP antibodies have improved specificity (96% vs. 86%), with similar sensitivity (67% vs. 70%) for RA. These antibodies can be detected several years before the development of clinical RA, and they are associated with severe RA outcomes, including radiographic joint damage and a poor prognosis. Because of their specificity for RA, anti-CCP antibodies are useful in differentiating RA from other conditions positive for RF, including Sjögren's syndrome, infection, and hepatitis.

Acute phase reactants, such as the erythrocyte sedimentation rate and C-reactive protein, are usually elevated in active inflammation but are not sensitive or specific for the diagnosis of RA. These tests are useful for differentiating RA from noninflammatory conditions such as osteoarthritis or fibromyalgia. However, even when there is clear clinical evidence of joint inflammation, the values for acute phase reactants may be normal. Inflammation in RA often leads to anemia of chronic disease and thrombocytosis.

Synovial fluid analysis is usually not necessary when there is a clear chronic inflammatory polyarthritis. Arthrocentesis should be performed to rule out infection or crystalline arthropathy in monoarthritis if only a single joint is involved. Synovial fluid analysis is nonspecific but can support the diagnosis by showing inflammatory joint fluid with cell counts between 2000 and 100,000. Radiographs, although not part of the 2010 RA classification criteria, may show characteristic periarticular osteopenia, marginal joint bone erosions, and uniform joint space narrowing in a symmetrical distribution. Often radiographs will be normal in early RA but can serve as a baseline to assess disease progression over time.

For a deeper discussion of these topics, please see Chapter 242, "Laboratory Testing in the Rheumatic Diseases," Chapter 243, "Imaging Studies in the Rheumatic Diseases," Chapter 247, "Bursitis, Tendinitis, and Other Periarticular Disorders and Sports Medicine," and Chapter 248, "Rheumatoid Arthritis," in *Goldman-Cecil Medicine*, 26th Edition.

TREATMENT

The ultimate goals for managing RA are to reduce pain and discomfort, prevent joint deformities, and maintain normal physical and social function. Although there is no cure for RA, remission can be maintained in a subset of patients. Treatment begins with effective communication between the physician and patient regarding the nature of the disease and the goals of treatment.

Nonpharmacologic therapeutic options include reduction of joint stress, often through physical and occupational therapy. Local rest of an inflamed joint can reduce joint stress, as can weight reduction, splinting, and the use of walking aids. Vigorous activity should be avoided during disease flares. Full range of motion of joints, however, should be maintained by a graded exercise program to prevent contractures and muscle atrophy. Physical therapy improves muscle strength, decreases joint stress, and maintains joint mobility. Occupational therapy can provide various appliances to protect joints and make daily activities easier.

TABLE 79.4 Conventional Disease-Modifying Antirheumatic Drugs

Conventional Agents	Toxicities
Azathioprine	Infection, nausea, bone marrow suppression, fever, pancreatitis
Baricitinib, tofacitinib (targeted synthetic oral DMARD)	Infection rate similar to biologic DMARDs; bone marrow and hepatic toxicity, hyperlipidemia, contraindicated with biologics
Hydroxychloroquine	Retinal toxicity, requires ophthalmologic monitoring
Leflunomide	Bone marrow and hepatic toxicity; cholestyramine washout if toxic; contraindicated in pregnancy
Methotrexate ^a	Oral ulcers, nausea, bone marrow suppression, pneumonitis; contraindicated in pregnancy and severe coexistent lung disease; hepatotoxicity
Sulfasalazine	Nausea, bone marrow suppression

DMARDs, Disease-modifying antirheumatic drugs.

^aInitial recommended DMARD in moderate to severe RA.

Pharmacologic Approach

Studies have revealed that disease-modifying antirheumatic drug (DMARD) therapy early in the course of RA slows disease progression more effectively than delayed therapy. Early RA is currently defined as within 6 months of diagnosis and established RA as greater than 6 months. A targeted approach at the extent of disease activity should be used to minimize joint inflammation. Effective treatment with DMARDs can improve signs, symptoms, and radiographic progression, even in long-standing disease. The inflammation of RA should be controlled as completely as possible, as soon as possible, and for as long as possible. Conventional DMARDs and biologic DMARDs prevent disease progression and disability.

Disease Activity

Establishing a diagnosis of RA enables the clinician to determine treatment and also counsel the patient regarding future disease course, need for treatment, and prognosis. Intensity of treatment is guided by the extent of disease activity. As mentioned, RA involves the diarthrodial joints but the exact pattern of joint involvement is patient specific. More joints involved means worse disease and is associated with worse outcomes of disease. Disease activity can be defined by multiple different disease activity tools that combine input from physical exam with counting the number of swollen and tender joints, patient input on their global assessment of RA disease activity, not just pain, and laboratory tests showing evidence of inflammation, most commonly by ESR and CRP. The goal of treatment should be absence of joint inflammation. When the diagnosis is made, the patient should be treated in consultation with a rheumatologist, if available, to use specialized disease activity measurements with a goal to minimize joint inflammation towards remission or low disease activity. These disease activity measures include the DAS28 (disease activity measuring involvement of 28 joints), ESR/CRP, CDAI (Clinical Disease Activity Index), SDAI (Simple Disease Activity Score), RAPID3 (Disease Activity Score developed from short and simple questionnaire), and PASDAS (PAS Disease Activity Score based on a weighted index that includes 7 components).

Conventional Disease-Modifying Antirheumatic Drugs

Many DMARDs are available for treating RA. All conventional DMARDs have a slow onset, taking 1 to 6 months to become fully

TABLE 79.5 Biologic Disease-Modifying Antirheumatic Drugs

Biologic Agent	Targeted Mechanism
Adalimumab, certolizumab, etanercept, golimumab, infliximab	Cytokine directed, anti-TNF- α
Anakinra	Cytokine directed, anti-IL-1
Sarilumab, tocilizumab	Cytokine directed, anti-IL-6
Abatacept	T-cell directed, inhibits co-stimulation
Rituximab	B-cell directed, anti-CD20

IL, interleukin; TNF, tumor necrosis factor.

effective, and they need close monitoring for toxicity (Table 79.4). Once the diagnosis of RA is made, a DMARD should be initiated.

Methotrexate is universally used as the initial DMARD in patients with early RA because of its established efficacy and known toxicity profile (evidence from multiple randomized controlled trials). It can be administered once weekly by the oral or parenteral route. Known side effects to monitor for include oral ulcers, nausea, hepatotoxicity, cytopenias, and pneumonitis. If contraindications to methotrexate exist such as chronic liver disease or alcohol use in excess of two drinks per day for males or one per females, alternative conventional DMARDs such as sulfasalazine or hydroxychloroquine should be used in monotherapy. Early in the course of disease, NSAIDs and low-dose corticosteroids can be used for rapid control of inflammation in combination with DMARDs.

In cases of methotrexate failure or inadequate response with continued moderate to high disease activity, the subsequent choice of conventional and biologic DMARDs is not standardized and is instead based on clinical factors such as route of administration, side effects and risks of adverse events, cost, and patient and physician preference. Often combination therapy of multiple DMARDs is used for RA treatment. For patients with mild RA, hydroxychloroquine or sulfasalazine, or both, may be used as first-line drugs. Triple therapy, the combination of methotrexate, hydroxychloroquine, and sulfasalazine, was shown in two randomized, controlled trials to be noninferior to biologic TNF- α inhibitors. Tofacitinib and baricitinib are a new class of synthetic DMARDs that inhibit Janus kinase (JAK)s and reduce cytokine levels. JAK inhibitors are the one class of synthetic DMARDs that should not be used in combination with biologic DMARDs due to increased risk of infections.

Biologic DMARDs

Biologic DMARDs are targeted, immune-based therapies that were introduced in the 1990s with the initiation of cytokine-directed TNF- α inhibitors. Biologics are produced by living cells using recombinant DNA technology (Table 79.5). TNF- α inhibitors were the first of 10 biologic DMARDs approved by the U.S. Food and Drug Administration (FDA) for the treatment of RA (see Table 79.3). Five TNF- α -directed therapies are available. The TNF- α inhibitors are the most widely used biologic agents because of the rapid improvement they produce in patients resistant to methotrexate therapy. They are one class of the biologics recommended in addition to methotrexate after methotrexate failure.

Most biologic DMARDs are given by intravenous or subcutaneous injection and are quite expensive but very effective treatments. Biosimilars are biologic medications with a similar molecular structure to a sister biologic medication and that have no clinically meaningful differences from FDA-approved biologic DMARDs. Multiple biosimilars are available and more are in development as cheaper alternatives to

biologic DMARDs. Most biologics have an increased risk of infection, including risk of reactivation of tuberculosis. Other cytokine-directed therapies include the IL-6 receptor antagonists sarilumab and tocilizumab and the IL-1 receptor antagonist anakinra. Biologic DMARDs also include an inhibitor of T-cell co-stimulation, abatacept; and a B-cell-depleting agent, rituximab. All patients should be screened for tuberculosis within 12 months prior to starting the first biologic DMARD. Biologic DMARDs should not be used in combination with other biologics because of increased risk of atypical infections.

❖ For a deeper discussion of these topics, please see Chapter 33, “Biologic Agents and Signaling Inhibitors,” in *Goldman-Cecil Medicine*, 26th Edition.

Symptomatic Control and Bridging Therapy

DMARDs often take up to 1 to 6 months to produce low disease activity or remission. Consequently, nonsteroidal anti-inflammatory drugs (NSAIDs), which are not disease modifying, are frequently used early in the disease process for symptomatic control. NSAIDs can have significant side effects, including renal toxicity and increased risk of gastrointestinal bleeding; NSAIDs should be used with caution in patients with multiple medical comorbidities but are a standby for many patients with chronic disease.

Glucocorticoids remain important in the treatment of RA, especially for acute exacerbations of disease. These agents are used for RA in low to medium doses. Glucocorticoids are useful for brief exacerbations and decrease bone erosions, but the long-term side effects of glucocorticoids can be substantial; they should be used primarily in episodes of RA flares or high disease activity as bridging therapy for further DMARD effects. Side effects include osteoporosis, avascular necrosis of bone, obesity, hypertension, and glucose intolerance. Screening, prevention, and treatment for osteoporosis should be considered for all patients who receive long-term glucocorticoid therapy for prevention of glucocorticoid-induced osteoporosis. Intra-articular glucocorticoids are extremely effective treatment for exacerbations involving only a few joints.

❖ For a deeper discussion of these topics, please see Chapter 230, “Osteoporosis,” in *Goldman-Cecil Medicine*, 26th Edition.

Medical Care Specialized for Rheumatoid Arthritis

RA is a chronic disease that requires focused care for comorbidities. DMARDs themselves require frequent laboratory monitoring for toxicities, including bone marrow suppression, hepatotoxicity, and renal dysfunction.

Infection

All patients should be tested for hepatitis B and C prior to starting a DMARD or biologic. Patients should be tested for latent tuberculosis within the previous 12 months by either a purified protein derivative (PPD) or interferon- γ release assay (IGRA) before starting a biologic DMARD. Opportunistic infections can occur in patients receiving DMARDs and biologic therapies and should be considered in the clinical care if chronic cytopenias or respiratory disease. In the setting of acute infection, DMARDs and biologic therapies should be withheld.

Vaccinations

Vaccination status should be assessed by primary care and rheumatology in caring for patients with RA. Ideally, vaccinations should occur during quiescent disease and also prior to starting immunosuppressive therapy. Killed vaccines can be given to patients while on all immunosuppressive conventional and biologic therapy, but live vaccines should be avoided in patients on biologic therapy. Prophylactically, all RA patients should be vaccinated for pneumococcal, influenza, and hepatitis B infection if increased risk. Herpes zoster vaccine to prevent shingles

should be given to patients greater than 50 years old. If the live vaccine is used, this should be used prior to starting or while off biologic agents.

Osteoporosis

RA itself is a risk factor for osteoporosis, and combined with glucocorticoid use, it can lead to severe osteoporosis and subsequent morbidity. In every RA patient, bone health should be addressed to prevent development of osteoporosis. Bone health can be evaluated by periodic dual-energy x-ray absorptiometry (DXA), a risk assessment tool including coexistent tobacco use, family history of fractures, and ensuring adequate vitamin D supplementation. Routine strength training and aerobic exercise in moderation is recommended to improve bone health and ensure joint stabilization.

Cardiovascular

RA is a risk factor for cardiovascular disease due to chronic inflammation and should be monitored and managed. Lipid treatment recommendations do not currently differ from the routine non-RA patient populations. Hypertension, exacerbated by both pain and coexistent medications such as NSAIDs and glucocorticoids, should be monitored and treated according to current guidelines.

Perioperative

Caution should be taken preoperatively when the RA patient is being anesthetized to avoid C1-C2 subluxation and spinal cord compression. Flexion and extension radiographs of the cervical spine should be considered preoperatively for general anesthesia to assess for atlanto-occipital joint instability. Joint replacement surgery plays an important role for patients who have had severe, destructive joint disease, particularly in the knees and hips. Medications should be evaluated preoperatively with biologic DMARDs held one treatment cycle prior to starting. Methotrexate and conventional DMARDs can be continued through joint replacement surgery with improvement in both surgical and RA outcomes.

CONCLUSION AND PROGNOSIS

Although the underlying cause of RA is unknown, advances in cell biology, immunology, and molecular biology have led to dramatic therapeutic advancements for this disease. Conventional and biologic DMARDs improve short- and long-term outcomes. Bone erosions can occur within 1 to 2 years of disease onset, and early initiation of DMARDs is essential to prevent further morbidity.

RF and/or CCP positivity and extra-articular features are characteristic of severe disease. Tobacco use is the most significant environmental risk factor for RA and smoking cessation should be recommended to patients at risk for and with RA. The incidence of lymphoma and other malignancies is increased among patients with RA, and the overall mortality rate is increased by coexisting cardiovascular disease and infection.

Although up to 15% of patients can go into drug-free remission, long-term disability is still significant for most patients. Fifty percent of patients with RA are not working in their original occupation after 10 years, approximately 10 times the rate in the normal population. Most patients fall between these disease extremes with various levels of functional impairment. Some have a waxing and waning course over a period of years, with acute episodes of single- or multiple-joint exacerbations.

Future developments in RA therapy will include guidelines about when to institute and withdraw biologic DMARDs, novel targeted biologic agents, when to use biosimilars, and personalized approaches based on an understanding of individual disease pathogenesis and disease activity.

Spondyloarthritis

Douglas W. Lienesch

DEFINITION

Spondyloarthritis is a form of inflammatory joint disease characterized by inflammation of the axial skeleton (spine and sacroiliac joints) and/or the peripheral joints, often associated with inflammation of the eye, gastrointestinal tract, genitourinary system, and skin. *Axial spondyloarthritis* is the term used when the spine is the site of inflammation, and *peripheral spondyloarthritis* indicates inflammation of the joints and periarticular tissues in the extremities.

The cardinal clinical feature of spondyloarthritis is inflammation of the sacroiliac joints (i.e., sacroiliitis) and the spine (i.e., spondylitis). Inflammation of tendon insertion sites (i.e., enthesitis), inflammation of entire digits (i.e., dactylitis), and inflammation of one to four lower extremity joints (i.e., oligoarthritis) are extraspinal skeletal findings. A positive family history, eye inflammation (i.e., anterior uveitis or conjunctivitis), and the absence of rheumatoid factor and subcutaneous nodules are common.

Spondyloarthritis may be further subcategorized based on other clinical features. Patients with axial spondyloarthritis with typical radiographic features including sacroiliac joint erosions, spinal syndesmophytes, and ankylosis of the joints have *ankylosing spondylitis*. In the absence of these radiographic changes, *nonradiographic axial spondyloarthritis* may be present if there are typical symptoms accompanied by magnetic resonance imaging inflammatory signs at the sacroiliac joint or spine. Axial or peripheral inflammatory joint disease in the setting of psoriasis or inflammatory bowel disease (IBD) is termed *psoriatic arthritis* or *IBD-related spondyloarthritis*, respectively. *Reactive arthritis* refers to spondyloarthritis with onset within a few weeks of certain types of infection.

Spondyloarthritis is strongly associated with human leukocyte antigen B27 (HLA-B27), a specific allele of the B locus of the HLA-encoding class I major histocompatibility complex genes. The frequency of HLA-B27 among white individuals is approximately 8%. However, up to 90% of white patients with ankylosing spondylitis and 80% of white patients with reactive arthritis or juvenile spondyloarthritis are HLA-B27 positive, and these percentages are even higher among patients with uveitis. The rate of HLA-B27 positivity among patients with inflammatory bowel disease or psoriasis with peripheral arthritis is not markedly increased unless they have spondylitis, in which case the frequency of HLA-B27 is 50%. The frequency of HLA-B27 varies widely among other ethnic groups and accounts for the broad variation of the prevalence of ankylosing spondylitis in different populations.

Ankylosing spondylitis is much more common among adolescent boys and young men, but this finding may reflect underdiagnosis in women, in whom disease manifestations may be milder than they are in men. Reactive arthritis is more common among men when it follows genitourinary *Chlamydia trachomatis* infection, but the sex distribution is even among patients after dysentery. Inflammatory arthritis

including spondylitis affects approximately 5% to 8% of patients with psoriasis and 10% to 25% of patients with ulcerative colitis or Crohn's disease. Men and women are affected equally. The prevalence of spondyloarthritis, particularly psoriatic and reactive arthritis, is increased in populations with high human immunodeficiency virus (HIV) infection rates.

PATHOLOGY

Although the strong association of HLA-B27 with spondyloarthritis is well established, a specific role in the pathogenesis of these disorders has not been elucidated. Animal models in which rodents transgenic for HLA-B27 develop inflammatory abnormalities strikingly similar to those seen in HLA-B27-associated human diseases provide compelling indirect evidence for a pathogenic role. When raised in a germ-free environment, these animals remain disease free, suggesting a key additional environmental factor.

In addition to the strong genetic links for the risk of spondyloarthritis, important associations exist between specific bacterial agents and disease pathogenesis. Genitourinary infection with *C. trachomatis* or diarrheal illness with *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* species can induce reactive arthritis. Several additional infectious agents are less commonly implicated. They appear to trigger an inflammatory response, possibly as a result of persistence of bacterial antigens, or cause an aberrant immunologic response to infection that results in misfolding of HLA-B27 molecules in antigen-presenting cells, generating a persistent inflammatory reaction.

No one theory of pathogenesis of spondyloarthritis explains the clinical spectrum of these disorders, and more research is clearly needed to solidify an understanding of their origin. The complex role of the immune system in spondyloarthritis is highlighted by the observation that patients infected with HIV appear more likely to have severe disease, especially psoriatic arthritis. When HIV infection is treated with antiviral agents, the incidence of spondyloarthritis declines.

Although many of the cellular and molecular mechanisms of inflammatory joint disease have been elucidated, the pathophysiology of spondyloarthritis remains incompletely understood. Inflammation of the sacroiliac joints, spine, and entheses is a unique feature of these disorders. Pathophysiologic studies show that the inflammation originates at the interface of bone and cartilage in the sacroiliac joint and bone and fibrocartilage in the entheses. Macrophages and CD4⁺ and CD8⁺ T cells are present, and Th17 appears to play a critical role in the inflammatory process. Proinflammatory cytokines interleukin-17 (IL-17), interleukin-23 (IL-23), and tumor necrosis factor- α (TNF- α) are abundant.

Synovial tissue becomes inflamed, and osteoclasts are activated, leading to bone resorption, reminiscent of rheumatoid arthritis joint

inflammation. Unlike in rheumatoid arthritis, early bone resorption is followed by a secondary phase during which osteoblast activity predominates, leading to new bone formation in periarticular bone (i.e., hyperostosis) and around joints (i.e., osteophytosis) or vertebral bodies (i.e., syndesmophytes). Ultimately, bony fusion of joints (ankylosis) occurs. The relationship between these paradoxical phases of bone resorption and proliferation is an area of active investigation.

CLINICAL PRESENTATION

Common Clinical Features of Spondyloarthritis

All forms of spondyloarthritis have considerable clinical overlap with one another and are most easily considered as a group of related disorders. Table 80.1 outlines the clinical features of these disorders. The cardinal clinical features common to all of them are inflammatory spine pain and an asymmetrical, predominantly lower extremity inflammatory joint or tendon disease. Inflammatory spine pain should be suspected in young patients (<40 years) who have an insidious onset of chronic low back pain or buttock pain associated with prolonged morning stiffness and relieved by exercise.

The characteristic peripheral joint disease involves one to four joints, usually in the lower extremities, and may be associated with tendon insertion inflammation (i.e., enthesitis) or sausage digits (i.e., dactylitis). Symmetrical polyarthropathy involving the upper extremities and clinically similar to rheumatoid arthritis is seen in some forms of psoriatic or inflammatory bowel disease–related spondyloarthritis. Anterior uveitis, enthesitis, dactylitis, psoriatic skin or nail changes, inflammatory bowel disease, a family history of spondyloarthritis, or a history of preceding gastrointestinal or genitourinary infection suggests spondyloarthritis. Subcutaneous nodules, rheumatoid factor, and antinuclear antibodies are usually absent.

In a given patient, the clinical features of these disorders may accumulate over a prolonged period. Some patients do not initially demonstrate the typical findings of a specific disorder. They are considered to have undifferentiated spondyloarthritis. Early disease can be subcategorized as predominately axial spondyloarthritis or predominately peripheral spondyloarthritis, depending on the site of the dominant symptoms. Many patients later have clinical findings consistent with a specific subtype of spondyloarthritis.

Inflammatory spine pain is the cardinal feature of axial disease and results from inflammation in the sacroiliac joints and spinal elements.

Uncontrolled disease may lead to ankylosis (i.e., bony fusion) at sacroiliac joints and throughout the vertebral column, culminating in loss of spinal and costovertebral motion, deformity, and restrictive extrapulmonary physiology.

Enthesitis can occur in many different anatomic locations. They include spinous processes, costosternal junctions, ischial tuberosities, plantar aponeuroses, and Achilles tendons.

When peripheral arthritis of spondyloarthritis occurs, it frequently begins as an episodic, asymmetrical, oligoarticular process that often involves the lower extremities. The arthritis can progress and may become chronic and disabling. A unique feature of spondyloarthritis is the appearance of fusiform swelling of an entire finger or toe, referred to as *dactylitis* or *sausage digits*.

Anterior uveitis, or inflammation of the anterior chamber of the eye, is a common extra-articular manifestation of spondyloarthritis, especially among HLA-B27–positive patients. Acute bouts of uveitis are usually monocular, painful, and accompanied by eye redness and blurred vision. Recurrent attacks are common and can lead to blindness. Scleritis, episcleritis, and conjunctivitis are less commonly associated phenomena.

Spondyloarthritis may occasionally involve other organ systems and may cause significant morbidity and mortality. Aortitis, especially occurring in the ascending segment, can result in aortic insufficiency from aortic root dilation, aortic dissection, and cardiac conduction system abnormalities. Pulmonary fibrosis of the apical regions can occur, often in an insidious fashion. Spinal cord compression can result from atlantoaxial joint subluxation, cauda equina syndrome, or vertebral fractures. In rare cases, long-standing spondyloarthritis is associated with secondary amyloidosis.

Specific Clinical Features of Spondyloarthritis

Ankylosing Spondylitis

The cardinal clinical feature of ankylosing spondylitis is inflammatory spine pain. Over time, spine involvement ascends from the sacroiliac joints to involve all levels of the spine. Progressive loss of motion results from ankylosis of the vertebral column and apophyseal joints. Costovertebral involvement leads to decreased chest expansion and restrictive lung physiology.

Loss of mobility and secondary osteoporosis of the vertebral bodies increase the risk of traumatic spine fracture. Axial involvement of the shoulders and hips is common and associated with a worse prognosis.

Fig. 80.1 Reactive arthritis. (A) Keratoderma blennorrhagicum. Red to brown papules, vesicles, and pustules with central erosion show characteristic crusting and peripheral scaling on the dorsolateral and plantar foot. (B) Balanitis circinata. Moist, well-demarcated erosions with a slightly raised micropustular circinate border on the glans penis. (C) Bilateral conjunctivitis associated with anterior uveitis. (From Fitzpatrick TB, Johnson RA, Wolff K, et al: *Color atlas and synopsis of clinical dermatology*, ed 3, New York, 1983, McGraw-Hill, pp 393, 395.)

Peripheral oligoarthritis, enthesitis, and dactylitis are more common in females. Diagnosis requires demonstration of radiographic sacroiliitis (i.e., sacroiliac joint erosions, sclerosis, and ankylosis). Anterior uveitis is common. Aortitis, upper lobe pulmonary fibrosis, cauda equina syndrome, and amyloidosis are less common and seen in late disease.

Reactive Arthritis (Posturethral/Postdysenteric)

Among the unique clinical features of reactive arthritis are urethritis, conjunctivitis, and certain dermatologic problems (Fig. 80.1). The urethritis may result from the chlamydial infection that triggers the disease, or it may be a sterile inflammatory discharge seen in diarrhea-associated disease. Conjunctivitis may be mild in reactive arthritis and is distinct from uveitis.

Keratoderma blennorrhagicum is a distinct papulosquamous rash usually found on the palms or soles. Circinate balanitis is a rash that may appear on the penile glans or shaft of men with reactive arthritis. Nonpitting nail thickening and oral ulcers may also occur in patients with reactive arthritis. These lesions can be confused with similar findings in patients with psoriasis and inflammatory bowel disease, respectively.

Most cases are self-limited. Chronic or relapsing arthritis and chronic spondylitis are associated with HLA-B27 and *Chlamydia* infection.

Psoriatic Arthritis

Five identifiable clinical patterns of psoriatic arthritis are recognized: distal interphalangeal joint involvement with nail pitting; asymmetrical oligoarthropathy of large and small joints; arthritis mutilans, a severe, destructive arthritis; symmetrical polyarthritis, which is identical to rheumatoid arthritis; and predominately axial disease. These patterns are not exclusive, and clinical overlap is significant.

Spondylitis or sacroiliitis may occur along with any of the other patterns. The prevalence of HLA-B27 is increased among the patients with spondylitis or sacroiliitis but not among patients with the other patterns. Psoriatic skin or nail disease predates arthritis in most cases, but both may occur concomitantly, or joint disease may precede skin involvement. Rarely, joint disease is indistinguishable from psoriatic arthritis, which can occur in patients with a family history but no personal history of psoriatic skin disease.

Enteropathic Arthritis: Inflammatory Bowel Disease

Crohn's disease and ulcerative colitis (see Chapter 38) are frequently associated with inflammatory spine disease and peripheral arthritis.

The peripheral arthritis is typically nonerosive, oligoarticular, and episodic, and the degree of joint involvement fluctuates with gut activity. A more chronic, symmetrical polyarthritis may occur in patients with Crohn's disease.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of spondyloarthritis remains a clinical diagnosis made by identifying typical history and physical examination phenomena, analyzing selected laboratory tests, and using musculoskeletal imaging. The diagnosis is suggested by inflammatory spine pain or chronic lower extremity asymmetric inflammatory oligoarthritis in two to four joints. In this setting, features that increase the probability of spondyloarthritis include uveitis, psoriasis, enthesitis, dactylitis, inflammatory bowel disease, family history of spondylarthropathy, elevated C-reactive protein (CRP) level, HLA-B27, preceding gastrointestinal or genitourinary infection, and sacroiliitis on radiography, computed tomography (CT), or magnetic resonance imaging (MRI).

Differentiating spondyloarthritis from other inflammatory or degenerative joint or spine diseases can be challenging. Crystalline arthropathies can manifest with peripheral oligoarthritis, often in the lower extremities. However, the spine is rarely involved, and intracellular crystals can be demonstrated in the synovial fluid. Rheumatoid arthritis and other systemic autoimmune diseases usually manifest with symmetrical polyarthritis of the upper and lower extremities associated with abnormal serologies such as rheumatoid factors, anti-cyclic citrullinated peptide (CCP) antibodies, or antinuclear antibodies. Predominately axial spondyloarthritis must be differentiated from indolent infections of the sacroiliac joints, vertebrae, or intravertebral disks; degenerative disease of the spine and disks (i.e., spondylosis); and diffuse idiopathic skeletal hyperostosis (DISH).

The radiographic features of the spondyloarthritis are highly specific and, in the correct clinical setting, greatly increase the certainty of the diagnosis. Sacroiliitis is usually the earliest radiographic sign of spine disease and results in sclerosis and erosions of the sacroiliac joints with eventual bony fusion (Fig. 80.2A). Many radiographic changes result from chronic spondylitis, including ossification of the annulus fibrosus, calcification of spinal ligaments, bony sclerosis and squaring of vertebral bodies, and ankylosis of apophyseal joints. These changes can lead to vertebral fusion and a bamboo spine appearance (see Fig. 80.2B).

Fig. 80.2 (A) Bilaterally symmetrical sacroiliitis in ankylosing spondylitis. (B) Lumbar spondylitis in ankylosing spondylitis with symmetrical, marginal bridging syndesmophytes and calcification of the spinal ligament. (From Cush JJ, Lipsky PE: The spondyloarthropathies. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 2000, Saunders, pp 1499-1507.)

Radiographic findings progress over many years of illness and may not be apparent in early disease. However, during this preradiographic period, MRI demonstrates bone inflammation (i.e., osteitis) and erosion at the sacroiliac joints and vertebral bodies, and CT shows bony sclerosis and joint erosions.

Bone erosions, sclerosis, and new bone formation may occur at sites of enthesitis. Erosions at bone-cartilage interface (i.e., subchondral erosions), sclerosis, and bone proliferation are hallmarks of spondyloarthritis involving peripheral joints. In severe cases such as the arthritis mutilans form of psoriatic arthritis, total or subtotal bone resorption (i.e., osteolysis) of a phalange may occur.

TREATMENT

No cure has been found for any form of spondyloarthritis, but effective treatment for many of the manifestations is available. Patient education regarding the disease is essential and allows identification of affected family members and early detection of urgent clinical features such as uveitis. Physical therapy, including a daily stretching program, postural adjustments, and strengthening, helps to maintain proper bony alignment, reduce deformities, and maximize function, particularly for those with axial disease. Selective use of orthopedic surgery may be highly effective in correcting significant spinal deformities or instability.

Nonsteroidal anti-inflammatory drugs (NSAIDs) can provide significant relief of spinal pain and stiffness, and many patients take these drugs continually for years. No clear evidence indicates that systemic glucocorticoids benefit patients with spondyloarthritis, and these agents are usually avoided. Intra-articular glucocorticoid injection into the sacroiliac or other involved joints may provide temporary relief. Similarly, the role and efficacy of older immunosuppressive agents in the treatment of axial spondyloarthritis have not been established. In contrast, clinical trials have shown that the peripheral manifestations

of spondylarthritis improve with sulfasalazine and methotrexate. Apremilast, a phosphodiesterase-4 inhibitor, has shown efficacy in peripheral joint inflammation in patients with psoriatic arthritis.

TNF- α blockers (i.e., infliximab, etanercept, adalimumab, certolizumab, and golimumab) represent a substantial breakthrough in the treatment of spondyloarthritis. The efficacy of these agents is well established for patients with axial inflammation who do not satisfactorily or fully respond to NSAIDs and physical therapy. TNF- α blockers can significantly reduce pain, improve function, and improve quality of life. They may also prevent or slow disease progression and structural damage. The drugs are effective in psoriatic arthritis, suppress the skin and nail disease of psoriasis, and retard radiographic progression in the peripheral joints. Infliximab and adalimumab reduce gut inflammation in ulcerative colitis and Crohn's disease, with concomitant reduction in symptoms of joint and spine inflammation. Ustekinumab, an inhibitor of IL-23, has demonstrated efficacy in psoriasis and psoriatic arthritis, as well as the intestinal manifestations of IBD. Secukinumab and ixekizumab, IL-17 inhibitors, have clinical efficacy in psoriasis, peripheral and axial spondyloarthritis.

Flares of uveitis require care by an ophthalmologist experienced in treating inflammatory eye diseases. Topical or intraocular glucocorticoids may suffice, but systemic therapy with glucocorticoids or immunosuppressive medications may be necessary to control the inflammation and prevent permanent visual loss. Methotrexate is frequently employed and the TNF- α inhibitor adalimumab has proven efficacy.

Reactive arthritis is usually self-limited, and joint symptoms are managed with NSAIDs or intra-articular corticosteroid injections. When chronic arthritis or spondylitis develops, interventions are similar to those employed for other forms of spondyloarthritis. Evaluation and treatment of *C. trachomatis* and associated sexually transmitted diseases in patients with reactive arthritis and their sex partners are essential. Early treatment reduces the frequency of reactive arthritis.

Long-term antibiotics are ineffective for gastroenteritis-associated reactive arthritis. Clinical trials of long-term antibiotics for reactive arthritis after *C. trachomatis* infection have had mixed results, and this practice requires further study before it can be adopted.

SUMMARY

Disability due to spondyloarthritis varies according to the subtype and severity of the specific syndrome. Historically, patients with spondyloarthritis usually experienced a lesser degree of disability compared with those with rheumatoid arthritis. Some patients with reactive arthritis experience self-limited disease with no long-term sequelae. Alternatively, those with more severe disease can have deformation and destruction of the axial and peripheral joints, leading to severe disability. Serious and potentially fatal extraskeletal manifestations can manifest.

With the advent of effective immunosuppressant medications such as methotrexate and biologic agents (i.e., TNF- α , IL-17 and IL-23 inhibitors), patients with more severe manifestations have markedly improved symptom control and quality of life.

Systemic Lupus Erythematosus

Sonia Manocha, Tanmayee Bichile, Susan Manzi

DEFINITION AND EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune disease characterized by autoantibody production and immune complex deposition that can lead to organ inflammation and, if left untreated, organ damage. The cause of SLE is largely unknown. Clinical manifestations are heterogeneous, ranging from milder non-organ-threatening symptoms of fatigue or oral ulcerations to life-threatening organ involvement with nephritis and neurologic disease. Diagnosing SLE is often challenging due to its varied clinical presentation, and it can take up to several years and seeing multiple health care providers to accurately come to a diagnosis.

Incidence and Prevalence

New data regarding the incidence and prevalence of SLE in the United States have been derived from several lupus registries including Michigan, Georgia, California Lupus Surveillance Project (CLSP), Manhattan Lupus Surveillance Program (MLSP), CDC funded population-based registry, Minnesota, and a large national managed-care claims database. These lupus registries allowed for a comprehensive estimation of incidence and prevalence across various ethnicities, including African American, Caucasian, Alaskan Native/American Indian, Hispanic, and Asian populations.

There remains a female predominance in both incidence and prevalence of SLE. Overall, the incidence and prevalence of SLE ranges from 5.2 to 7.4 cases per 100,000 person years and 72.8 to 178 cases per 100,000 person years, respectively. There remains ethnic diversity with a higher incidence of SLE among non-white ethnic populations, with African Americans having the highest incidence and prevalence followed by Hispanic and Asian individuals.

During childbearing years, the female-to-male ratio of SLE prevalence is 10:1 to 15:1. This gender discrepancy also exists but is less distinct (2:1) in young children and older individuals, suggesting hormonal influences.

Mortality

Mortality rates due to SLE have waxed and waned over time. Initially, there was a decrease in mortality from 1968 to 1975 followed by a steady increase from 1975 to 1999. This increase was followed by a steady decrease in mortality after 1999. However, despite this sustained decrease, SLE mortality remains high compared with those without SLE. SLE mortality has a bimodal distribution, with infection and disease activity typically increasing mortality earlier in the course of disease and cardiovascular and renal disease increasing mortality later in the course of disease. Furthermore, a study of all-cause mortality utilizing Medicaid data found ethnic variability in SLE-related mortality showing Asians and Hispanics having lower mortality as compared with African Americans, Caucasians or Native Americans.

PATHOLOGY

Although SLE pathogenesis remains poorly understood, individuals who develop SLE likely have a genetic predisposition in the setting of immune system dysregulation, environmental triggers, and altered hormonal milieu. The genetic contribution to SLE is emphasized by the high concordance rate for monozygotic twins (>20%) and a lower concordance rate among other siblings (<5%). The search for genes involved in SLE pathogenesis is an active area of research. Genes coding for certain human leukocyte antigens, complement system components, immunoglobulin receptors, and various other proteins are being considered as candidate genes for SLE.

The many immune abnormalities in SLE implicate dysregulation of the humoral and cellular immune systems in the pathogenesis of the disease. Dysregulation leads to loss of self-tolerance and autoimmune destruction of healthy tissues, hallmarked by the production of autoantibodies and immune complexes. The heterogeneity of clinical manifestations of lupus and response to treatment is likely a result of the different genetic and molecular profiles of individual patients. This has led to the notion of lupus as a spectrum disorder that includes distinct phenotypes that require customized management strategies.

Various environmental triggers, including microorganisms and ultraviolet light exposure, may influence the development of SLE and lupus activity. The striking differences in SLE prevalence between genders and the effect of pregnancy on disease activity suggest a role for hormones in SLE pathogenesis.

CLINICAL PRESENTATION

SLE can affect virtually any organ system. Typically, patients experience fluctuating periods of increased disease activity, known as flares, alternating with periods of clinical quiescence. The frequency, intensity, and duration of flares are highly variable among patients, and when left untreated, may lead to irreversible organ damage.

A challenge with establishing a diagnosis of SLE has been to accurately estimate the onset of disease. Patients with SLE often have antibody positivity for many years prior to the onset of clinical symptoms. The type and severity of chief complaint in SLE depends on underlying organ involvement at the time of presentation, varying from vague constitutional symptoms to specific organ involvement such as seizures, glomerulonephritis, serositis, and thrombosis. In one study by Cervera and colleagues, most manifestations of SLE occurred in the first 5 years. Long-term prognosis in SLE varies greatly depending on whether patients are diagnosed early or late.

Constitutional Symptoms

Constitutional symptoms of SLE include fever, lymphadenopathy, weight loss, malaise, and fatigue. These are nonspecific and can be

related to other etiologies, and it is therefore imperative to be cognizant of infection in a patient with SLE presenting with fever. One way to distinguish a fever caused by infection versus a fever from SLE would be to evaluate serologic activity from lupus, especially complement levels, which are often elevated in the setting of infection because they are acute-phase reactants and decreased in the setting of active lupus.

Lymphadenopathy in lupus is often cervical and axillary and generally painful, soft, and mobile. Weight loss in SLE indicates an ongoing inflammatory state. Malaise and fatigue are among the most common but often difficult to treat presentations of SLE.

Mucocutaneous Manifestations

Skin manifestations of SLE are wide ranging and divided into categories including acute cutaneous lupus, subacute cutaneous lupus, and chronic cutaneous lupus. Acute cutaneous lupus includes a wide range of presentations. Many patients will present with a malar rash described as a butterfly rash with erythema and crusting that spares the nasolabial folds. Other presentations may include maculopapular rash, urticaria, bullous lupus and a toxic epidermal necrolysis (TEN)-like rash.

Subacute cutaneous lupus erythematosus (SCLE) typically presents as a psoriasiform or annular, polycyclic rash.

Chronic cutaneous lupus can cause disfigurement and scarring, with the most common form being discoid lupus. Other forms include lupus panniculitis (which is an inflammatory involvement of the subcutis and fat), tumid lupus, chilblains, lichen planus overlap, and mucosal lesions (oral, nasal, genital).

The majority of these rashes are photosensitive, which is an exaggerated response to ultraviolet (UV) light leading to symptoms of redness, itching or burning. Typically, skin manifestations of SLE occur within 24 to 48 hours after UV exposure.

Oral ulcerations occur in approximately 45% of SLE patients. Those involving the hard palate and buccal mucosa are more commonly associated with SLE. It is important to keep in mind that oral ulcers may also be seen in multiple other comorbid conditions such as acid reflux as well as herpetic infections.

Nonscarring alopecia involving the temporal area or diffuse thinning is another common cutaneous manifestation.

Musculoskeletal Manifestations

Arthritis is common in SLE. Usually this is an inflammatory, nonerosive arthritis. Some patients may develop deformities referred to as Jaccoud arthropathy. The hand in a patient with Jaccoud arthropathy looks similar to someone with rheumatoid arthritis except that the deformities are reducible (manually corrected) as opposed to fixed and imaging demonstrates absence of erosions.

Myalgia is another common manifestation of SLE, especially during periods of flares. Muscle weakness along with elevated CPK levels should raise suspicion of an underlying myopathy/myositis.

Hematologic Manifestations

Leukopenia (defined as white blood cell [WBC] count <4000 cells/mL), primarily lymphopenia, anemia, and thrombocytopenia, is common in SLE. Coombs positive autoimmune hemolytic anemia (AIHA) is one of the criteria for classification of SLE. Thrombocytopenia, which is an immune-mediated peripheral destruction disorder, may also be seen. Evans syndrome is rare in SLE and defined as AIHA and autoimmune thrombocytopenia. Thrombotic thrombocytopenic purpura (TTP) is also reported in SLE.

Cardiopulmonary Manifestations

Cardiac involvement in SLE is manifold. SLE can affect all parts of the cardiac system including the endocardium, myocardium, pericardium,

valves, conduction pathways, and the coronary arteries. Pericarditis is the most common of cardiac manifestations in SLE. Myocarditis is rare but can be fatal. Libman-Sacks endocarditis is valvular involvement in SLE described as sterile verrucous lesions typically seen on the left-sided heart valves. Cardiovascular disease in SLE is discussed separately.

Pulmonary manifestations in SLE can involve the pleura, parenchyma, and pulmonary vessels. Pleural involvement typically occurs with pleurisy and pleural effusions. Parenchymal involvement can present as acute lupus pneumonitis, interstitial lung disease, diffuse alveolar hemorrhage, and shrinking lung syndrome. Pulmonary vessel involvement typically presents as a pulmonary embolus often in the presence of antiphospholipid antibodies and pulmonary artery hypertension.

Gastrointestinal and Hepatic Manifestations

Gastrointestinal (GI) manifestations may be seen in about 50% of patients with SLE and are often difficult to diagnose. GI manifestations are often mild but may be life-threatening. Although acute abdominal pain in SLE is more commonly attributed to non-SLE etiologies, SLE-related causes of acute abdominal pain include pancreatitis, serositis, mesenteric vasculitis, and renal vein thrombosis. Lupus hepatitis is a controversial diagnosis. This has been described in the literature in SLE patients presenting with constitutional symptoms and elevated liver enzymes five times or greater the upper limit of normal. SLE patients with persistent elevations of LFTs without other symptoms should be further evaluated for autoimmune hepatitis (AIH) because this may be seen in association.

Renal Manifestations

Nephritis, which manifests with hematuria and proteinuria, is a major cause of morbidity and mortality for SLE patients. The International Society of Nephrology/Renal Pathology Society (ISN/RPS) revisited the 1982 World Health Organization classification of lupus nephritis (classes I through VI). ISN/RPS class IV (i.e., diffuse, proliferative) lupus nephritis is the most common form and has the worst prognosis, but it is also the most amenable to aggressive immunosuppressive therapy. See [Table 81.1](#) for more details.

Neuropsychiatric Manifestations

Neuropsychiatric manifestations of systemic lupus erythematosus (NPSLE) can vary from mild to severe and may be difficult to diagnose. NPSLE may involve any area of the nervous system with diffuse or focal involvement of the central nervous system (CNS) as well as involvement of the peripheral nervous system (PNS). Diffuse involvement may manifest as cognitive dysfunction, acute confusional state, headache, aseptic meningitis, and mood disorders. Focal involvement may present as cerebrovascular disease, myelopathy, movement disorders, demyelinating syndromes, and seizures.

Vascular Manifestations

More than 40% of SLE patients have Raynaud's phenomenon. This is typically described as cold sensitivity followed by biphasic or triphasic color changes with white discoloration followed by cyanosis and reactive hyperemia in the digits of hands and feet. Other areas affected by Raynaud's phenomenon include nose, earlobes, lips, and nipples.

Livedo reticularis is a netlike discoloration over arms or legs commonly seen in SLE. Livedo racemosa, which is a more severe form of livedo reticularis, can be seen in patients with SLE and Sneddon syndrome (ischemic cerebrovascular disease along with antiphospholipid antibodies [APLs]).

TABLE 81.1 International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 Classification of Lupus Nephritis

Class I	Minimal mesangial lupus nephritis Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence
Class II	Mesangial proliferative lupus nephritis Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy, but not by light microscopy
Class III	Focal lupus nephritis^a Active or inactive focal, segmental or global endo- or extracapillary glomerulonephritis involving 50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class III (A)	Active lesions: focal proliferative lupus nephritis
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis
Class IV	Diffuse lupus nephritis^b Active or inactive diffuse, segmental or global endo- or extracapillary glomerulonephritis involving 50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when 50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when 50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation.
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis
Class IV-G (A/C)	Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis
Class V	Membranous lupus nephritis Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class V lupus nephritis may occur in combination with class III or IV in which case both will be diagnosed Class V lupus nephritis show advanced sclerosis
Class VI	Advanced sclerosis lupus nephritis 90% of glomeruli globally sclerosed without residual activity

^aIndicate the proportion of glomeruli with active and with sclerotic lesions.

^bIndicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents. Indicate and grade (mild, moderate, severe) tubular atrophy, interstitial inflammation and fibrosis, severity of arteriosclerosis or other vascular lesions.

Data from Wallace D, Hahn BH: Pathogenesis of Lupus Nephritis. In Dubois' lupus erythematosus and related syndromes, ed 9, Philadelphia, 2019, Elsevier, pp 273.

Venous clots (e.g., pulmonary emboli, deep vein thrombosis) and arterial clots typically are seen in association with APLs and antiphospholipid syndrome. Leg ulcers, gangrene, thrombophlebitis, nail fold infarcts, cutaneous necrosis, and necrotizing purpura may also occur. Small vessel vasculopathy or vasculitis can be seen in lupus and may be a life-threatening manifestation.

Ocular Manifestations

Keratoconjunctivitis sicca from secondary Sjögren's syndrome is the most common ocular manifestation of SLE. Episcleritis, scleritis, uveitis, optic neuropathy, and retinal vasculitis can occur but are less frequent.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

SLE is a clinical diagnosis; no single test or feature is definitively diagnostic of the disease. SLE is typically suspected in patients presenting with clinical symptoms and exam findings suggesting a multisystem disease. Serologic testing is utilized to confirm the suspected diagnosis. It is important to note that many clinical manifestations and serologic tests that help to diagnose SLE can be seen in other diseases.

For example, arthralgias, myalgias, fevers, and rash are common presentations in many viral diseases that may also have a positive ANA. Anti-double-stranded DNA (anti-dsDNA) antibodies are reported in patients with hepatitis B and hepatitis C. Low complement levels could occur in patients with chronic liver disease or inherited complement deficiencies. Malignancy (lymphoma and other hematologic malignancies, solid organ cancer) is an important differential diagnosis to consider in an elderly patient with constitutional symptoms, lymphadenopathy, rash, arthralgias, myalgias and positive ANA.

Classification Criteria

Classification Criteria for SLE were designed to group similar patients for the purposes of research. There are several classification criteria currently used for SLE. The American College of Rheumatology (ACR) classification criteria for SLE were updated in 1997. Patients are considered to have SLE if they meet 4 of 11 criteria (Table 81.2).

The Systemic Lupus International Collaborating Clinics (SLICC) classification criteria were developed in 2012 to improve clinical relevance and incorporate new knowledge into the definition of SLE immunopathogenesis. Under the SLICC criteria, patients are classified to have lupus if they meet four criteria including at least one clinical and

TABLE 81.2 1997 American College of Rheumatology Criteria for Classification of Systemic Lupus Erythematosus^a

Criteria	Definitions
Malar rash	Fixed, flat or raised erythema is observed over the malar eminences, tending to spare the nasolabial folds.
Discoid rash	Erythematous, raised patches develop with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions.
Photosensitivity	Rash occurs as a result of unusual reaction to sunlight, determined by patient history or physician observation.
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, is observed by the physician.
Arthritis	Nonerosive arthritis involves two or more peripheral joints, characterized by tenderness, swelling, or effusion.
Serositis	a. Pleuritis: convincing history of pleuritic pain exists or rub is heard by a physician or pleural effusion is in evidence, <i>or</i> b. Pericarditis: documented by electrocardiogram or rub or evidence of pericardial effusion.
Renal disorder	a. Persistent proteinuria is >0.5 g/day or scored >3+ if quantitation is not performed, <i>or</i> b. Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed.
Neurologic disorder	a. Seizures: occurs in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance), <i>or</i> b. Psychosis: occurs in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance)
Hematologic disorder	a. Hemolytic anemia: develops with reticulocytosis, <i>or</i> b. Leukopenia: <4000/mm ³ is documented on two or more occasions, <i>or</i> c. Lymphopenia: <1500/mm ³ is documented on two or more occasions, <i>or</i> d. Thrombocytopenia: <100,000/mm ³ develops in the absence of offending drugs.
Immunologic disorder	a. Anti-double-stranded DNA: antibody to native DNA in abnormal titer, <i>or</i> b. Anti-Smith: presence of antibody to Smith nuclear antigen, <i>or</i> c. Positive finding of antiphospholipid antibodies is based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test.
ANA	An abnormal titer of antinuclear antibody is documented by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

^aThis classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a patient is classified as having definite SLE if any 4 or more of the 11 criteria are present (cumulative) during any interval of observation.

one immunologic finding. SLICC criteria also allow classification of a patient with SLE with only renal-limited disease (biopsy proven) in the presence of a positive ANA (Table 81.3).

The newest criteria from 2019 are a result of collaboration between ACR and European League against Rheumatism (EULAR) (Table 81.4). There are seven clinical and three immunologic domains. Each domain has several criteria, which are weighted. Within each domain, only the highest weighted criterion is counted towards the total score. Patients are classified to have SLE if there is a positive ANA of 1:80 or greater, at least one clinical criteria and a score of 10 or greater. These classification criteria are unique in the sense that they are the first weighted criteria for SLE. These criteria are combined with a comprehensive examination to help guide a diagnosis of SLE.

The hallmark of SLE is the presence of various autoantibodies that at times may be detected before the initial clinical presentation of SLE. The prevalence of these autoantibodies varies across different SLE patient cohorts and ethnic groups; however, more than 95% of patients with SLE will have a positive ANA, often with titers 1:160 or greater. The HEP-2 indirect immunofluorescence ANA test is the preferred assay over direct ELISA testing. Indirect immunofluorescence is reported in titers and patterns, with the most common pattern reported in SLE being homogenous (diffuse). ANA is not specific for the diagnosis of SLE, particularly in the presence of low titers and can often be seen in patients with normal ageing, viral infections, malignancies, and other connective tissue diseases.

Anti-dsDNA and anti-Smith antibodies are more specific for SLE. Anti-Ro antibodies are commonly found in SLE and are associated with subacute cutaneous lupus. Anti-Ro antibodies have implications during pregnancy with increased risk of neonatal lupus. Anti-U1-RNP is associated with increased risk of pulmonary hypertension

and is discussed further in the “Overlap Syndrome” section. Antihistone antibodies are generally associated with drug-induced lupus but can be seen in patients with idiopathic lupus (Table 81.5).

The complement system plays an integral role in immune activation in SLE. Low complements (low C3, C4, CH50) are often considered hallmarks of disease activity in SLE, in particular glomerular disease, making them a valuable tool for clinicians to monitor disease activity.

Drug-Induced Lupus

Many drugs have been associated with lupus-like symptoms and development of lupus-related antibodies. Drug-induced lupus generally affects older populations, and common causative medications include procainamide, isoniazid, hydralazine, propylthiouracil, TNF inhibitors, proton-pump inhibitors, minocycline, methyl dopa, levodopa, and interferon- α .

Clinical symptoms generally manifest as musculoskeletal, cutaneous, serous, and hematologic. Rarely, there may be renal or CNS involvement. The typical gender inequality in SLE is not represented in drug-induced lupus, but rather there seems to be a higher incidence in older men. Serologies often present include ANA and antihistone antibodies. The presence of anti-dsDNA antibodies is rare and is more commonly found in patients that were exposed to TNF inhibitor medications versus other medications.

In most cases, removal of the offending drug leads to improvement in symptoms. Depending on the severity of manifestations, glucocorticoids may also be helpful.

Neonatal Lupus

Neonatal lupus is a rare autoimmune disorder that develops in utero in which maternal anti-SSA/Ro and/or SSB/La antibodies cross the placenta and affect the fetus. This was first described in 1957 by G.R. Hogg

TABLE 81.3 Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria of Systemic Lupus Erythematosus

Clinical Criteria ^a	Examples
1. Acute cutaneous lupus	Bullous lupus Lupus malar rash (not malar discoid) Maculopapular lupus rash Photosensitive lupus rash (in the absence of dermatomyositis) Subacute cutaneous lupus Toxic epidermal necrolysis variant of SLE
2. Chronic cutaneous lupus	Classic discoid rash Localized (above the neck) Generalized (above and below the neck) Chilblains lupus Discoid lupus/lichen planus overlap Hypertrophic (verrucous) lupus Lupus erythematosus tumidus Lupus panniculitis (profundus) Mucosal lupus
3. Oral ulcers	Palate, buccal, tongue, <i>or</i> nasal ulcers (in the absence of other causes: vasculitis, Behçet's disease, infection, inflammatory bowel disease, reactive arthritis, and acidic foods)
4. Nonscarring alopecia	Diffuse thinning <i>or</i> hair fragility with visible broken hairs (in the absence of other causes: alopecia areata, drugs, iron deficiency, and androgenic alopecia)
5. Synovitis (≥2 joints)	Characterized by swelling <i>or</i> effusion <i>or</i> tenderness with ≥30 minutes of morning stiffness
6. Serositis	Typical pleurisy for >1 day <i>or</i> pleural effusions <i>or</i> pleural rub Typical pericardial pain for >1 day <i>or</i> pericardial effusion <i>or</i> pericardial rub <i>or</i> pericarditis by ECG (in the absence of other causes: infection, uremia, and Dressler pericarditis)
7. Renal	Urine protein/creatinine (<i>or</i> 24-hr protein) ≥500 mg of protein/24 hr <i>or</i> red blood cell casts
8. Neurologic	Acute confusional state (in the absence of other causes: toxic-metabolic, uremia, and drugs) Mononeuritis multiplex (in the absence of other known causes: primary vasculitis) Myelitis Peripheral or cranial neuropathy (in the absence of other known causes: primary vasculitis, infection, and diabetes mellitus) Psychosis Seizure
9. Hemolytic anemia	
10. Leukopenia	<4000 cells/mm ³ detected at least once (in the absence of other known causes: Felty syndrome, drugs, and portal hypertension)
11. <i>or</i> Lymphopenia	<1000 cells/mm ³ detected at least once (in the absence of other known causes: corticosteroids, drugs, and infection)
12. Thrombocytopenia	<100,000 cells/mm ³ detected at least once (in the absence of other known causes: drugs, portal hypertension, and thrombotic thrombocytopenic purpura)
Immunologic Criteria	
1. ANAs	Above laboratory reference range
2. Anti-double-stranded DNA	Above laboratory reference range, except ELISA: two times greater than laboratory reference range
3. Anti-Smith	
4. Antiphospholipid	Any of the following: lupus anticoagulant, false-positive RPR, medium- or high-titer anticardiolipin (IgA, IgG, or IgM), <i>or</i> anti-β ₂ glycoprotein I (IgA, IgG, or IgM)
5. Low complement	Low C3 Low C4 Low CH50
6. Direct Coombs test	In the absence of hemolytic anemia

ANAs, Antinuclear antibodies; ECG, electrocardiogram; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; RPR, rapid plasma reagin; SLE, systemic lupus erythematosus.

^aCriteria are cumulative. A patient is classified as having SLE using lupus nephritis as a stand-alone criterion (in the setting of ANAs or anti-dsDNA antibodies) *or* four criteria (with at least one of the clinical criteria and one of the immunologic criteria).

Modified from Petri M, Orbai AM, Alarcon GS, et al: Derivation and validation of Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus, *Arthritis Rheum* 64:2677-2686, 2012.

TABLE 81.4 2019 EULAR/ACR Criteria for Classification of SLE

Entry CriterionAntinuclear antibodies (ANA) at a titer of $\geq 1:80$ on HEp-2 cells or an equivalent positive test (ever)

↓

If absent, do not classify as SLE

If present, apply additive criteria

↓

Additive Criteria

Do not count a criterion if there is a more likely explanation than SLE

Occurrence of a criterion on at least one occasion is sufficient

SLE classification requires at least one clinical criterion and ≥ 10 points

Criteria need not occur simultaneously

Within each domain, only the highest weighted criterion is counted toward the total score^a

Clinical Domains and Criteria	Weight	Immunology Domains and Criteria	Weight
<i>Constitutional</i>		<i>Antiphospholipid antibodies</i>	
Fever	2	Anti-cardiolipin antibodies OR Anti- β_2 GPI antibodies OR Lupus anticoagulant	2
<i>Hematologic</i>		<i>Complement proteins</i>	
Leukopenia	3	Low C3 OR low C4	3
Thrombocytopenia	4	Low C3 AND low C4	4
Autoimmune hemolysis	4		
<i>Neuropsychiatric</i>		<i>SLE-specific antibodies</i>	
Delirium	2	Anti-dsDNA antibody ^b OR Anti-Smith antibody	6
Psychosis	3

in a full-term, 2-kg baby boy who had complete AV block and sub-endocardial fibrosis born to a mother with SLE. There is a 1% to 2% chance of having a child with neonatal lupus in mothers with anti-SSA/Ro or SSB/La antibodies. In women with a previous baby with neonatal lupus the risk of having a subsequent baby with cardiac involvement of neonatal lupus increases from 2% to 19%. The development of heart block is most common between 18 weeks' and 24 weeks' gestation in mothers with these antibodies; thus, screening with fetal heart tones and fetal echocardiography should begin at 16 weeks' gestation. If there are signs of heart block, the mother may be treated with fluorinated corticosteroids (i.e., dexamethasone or betamethasone). Many children with congenital heart block do not survive or have continued morbidities requiring pacemakers.

Other manifestations of neonatal SLE that are more common include rashes, cytopenias, and hepatosplenomegaly. These manifestations generally resolve after the baby begins to develop his or her own antibodies, at around 6 to 8 months. Although this is commonly a condition that is seen in children born to mothers with SLE, it may also be seen in other autoimmune conditions or in otherwise healthy mothers with SSA/Ro and/or SSB/La antibodies.

Overlap Syndrome

Some patients with clinical and laboratory features of two or more autoimmune diseases have an overlap syndrome. Mixed connective tissue disease is characterized by overlaps among SLE, scleroderma, and myositis with a high titer of anti-U1-RNP antibody levels. For

TABLE 81.5 Prevalence of Autoantibodies in Systemic Lupus Erythematosus

Target Autoantigen	Positive (%)
Nuclear antigens	>95
Double-stranded DNA	30–60
Smith	10–44

SSA/Ro	30–40
SSB/La	38
Phospholipids	16–60
Ribosomal P	5–10
Histone	21–90

Data from Wallace D, Hahn BH: Other Clinical laboratory tests in SLE. In Dubois' lupus erythematosus and related syndromes, ed 8, Philadelphia, 2013, Saunders, pp 526–531.

patients who have multiple autoimmune manifestations but do not meet the criteria of a specific autoimmune disease, the term *undifferentiated connective tissue disease* is used. In some instances, these patients may be early in their disease course and eventually develop a specific autoimmune disease.

TREATMENT

There is no known cure for SLE. Management can be challenging and is aimed at treating the underlying organ manifestations. Treatment is often multipronged with patient education; one or more medications including anti-inflammatories, antimalarials, glucocorticoids and immunosuppressive drugs; and management of other aspects such as fatigue, depression, and other psychosocial factors. General goals for treatment are to achieve low disease activity or remission and prevent flares with the least amount of glucocorticoid use possible. At this time, there are only four FDA-approved treatments for SLE: aspirin, glucocorticoids, hydroxychloroquine, and belimumab.

It is essential to establish the type of SLE and the extent of organ involvement prior to initiating treatment. This is important because prognosis of SLE varies based on the severity of disease at presentation.

Every patient with SLE should be educated on sun protection techniques and smoking cessation because both are important triggers of flares and ongoing disease activity. Sunscreen with at least SPF 30 and preferably one that blocks both UVA and UVB is recommended. Avoiding sun exposure during peak hours, typically midmorning to early evening, and use of long-sleeve shirts and wide-brimmed hats are advisable. Smoking not only increases all-cause mortality but also worsens SLE activity and may decrease efficacy of certain medications such as hydroxychloroquine.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used to treat certain manifestations of SLE including musculoskeletal symptoms, pericarditis, pleurisy, and fever. Typically, NSAIDs are used as short-term therapies. One should be cognizant of renal involvement prior to initiation and continuation of NSAIDs. Aspirin is often used in SLE patients with other cardiac risk factors to mitigate the increased risk of cardiovascular events. Aspirin is often used in patients with SLE who have high titer antiphospholipid antibodies without a history of thrombosis and in most pregnant women.

Glucocorticoids remain a very effective treatment modality in SLE. They are fast acting and halt ongoing inflammation in many organ systems, making them valuable during initial treatment and as bridge therapy for flares. Doses of glucocorticoids vary widely from oral low-dose

alternate-day regimen to very high doses of IV formulations. As a general rule, using the lowest effective dose for the shortest amount of time limits potential long-term side effects. Long-term use of moderate to high doses of glucocorticoids leads to a higher cumulative dose exposure over time and increased risk of toxicity. This includes obesity, diabetes mellitus, hypertension, hyperlipidemia, accelerated atherosclerosis, osteoporosis with increased risk of fracture, avascular necrosis, cataracts, glaucoma, and increased risk of infections. To avoid these toxicities, steroid-sparing immunomodulating or immunosuppressant agents are used.

Antimalarial agents are the cornerstone of therapy in SLE. Hydroxychloroquine is the most commonly used agent because it has less retinal toxicity compared to chloroquine. Quinacrine is an antimalarial agent with no retinal toxicity, but the oral formulation has to be compounded at a specialty pharmacy. Hydroxychloroquine is an immunomodulatory agent that is beneficial in treating cutaneous and musculoskeletal manifestations. It has also been shown to prevent organ flares, prevent organ damage, modulate risk factors for atherosclerosis and thrombosis, and prevent placental transfer of anti-Ro antibodies that cause congenital heart block and neonatal lupus. Newer guidelines for the screening and prevention of hydroxychloroquine retinopathy suggest use of 5 mg/kg/day or less and regular ophthalmologic monitoring. Ophthalmologic monitoring at baseline (within the first year) and then annually after 5 years (more frequent in high risk individuals) with a dilated eye exam, Humphrey visual field testing, and spectral domain optical coherence tomography (SD-OCT) is recommended to monitor for retinal toxicity. Risk for retinal toxicity is dose dependent and influenced by comorbidities.

Azathioprine (AZA), methotrexate (MTX), leflunomide (LEF), and mycophenolate mofetil (MMF) are immunosuppressive agents used in SLE. AZA is effective in treating a variety of manifestations including skin disease, musculoskeletal disease, and nephritis. It is safe during pregnancy and breast-feeding. Toxicity includes cytopenias, hepatotoxicity with transaminitis, and increased risk for infections. MTX is effective in treating cutaneous, arthritis, and serositis manifestations. MTX is teratogenic and should be discontinued 3 to 6 months prior to conception. Toxicity is similar to AZA. LEF works well for cutaneous and musculoskeletal manifestations. LEF is teratogenic and contraindicated in pregnancy and lactation. MMF has been used for more than 20 years for the treatment of lupus nephritis, but it is also effective for skin disease and serositis. MMF toxicity is primarily related to gastrointestinal intolerance, cytopenias, and infectious complications. Mycophenolic acid, which is an active form of MMF, has less gastrointestinal intolerance. MMF is teratogenic and contraindicated in both pregnancy and lactation.

In organ- or life-threatening SLE, the alkylating agent cyclophosphamide (CTX) is used. Scenarios where CTX is utilized include rapidly progressive glomerulonephritis, lupus cerebritis, and diffuse alveolar hemorrhage. However, it is associated with significant toxicity, particularly bone marrow suppression, hemorrhagic cystitis, gonadal toxicity, increased risk of infections, and certain malignancies. The use of lower doses of intravenous CTX has resulted in equal efficacy and fewer side effects and has replaced many of the older regimens.

Great potential and optimism exist for biologic immunomodulating agents that focus on various aspects of the immune system, including B cells, interactions between B and T cells, and cytokines. The most promising agents are those that target B cells, which produce autoantibodies. In 2011, belimumab, a monoclonal antibody that inhibits B-lymphocyte stimulator, was the first therapeutic agent approved for the treatment of SLE in more than 50 years (Table 81.6). There are a number of other potential biologic therapies for lupus in the pipeline and currently being tested in clinical trials.

TABLE 81.6 Treatment Options in Systemic Lupus Erythematosus

Medication	Mechanism of Action	Monitoring	Pregnancy Concern
NSAIDs	Inhibits cyclooxygenase, reducing prostaglandin and thromboxane synthesis	CBC and CMP, caution with renal disease	Caution in 1st trimester, avoid use in 3rd trimester
Glucocorticoids ^a	Inhibits multiple cytokines	Electrolytes, BP, blood sugar Caution with comorbid diabetes mellitus	May be used. Increased risk of low birth weight and premature birth.
Hydroxychloroquine ^a	Exact mechanism unknown. Inhibits TLR and various enzymes.	Ophthalmologic exam at baseline (within 6 months of starting), in 5 years then annually. If there are increased risk factors, every 6 months or annually.	Safe in pregnancy and lactation May decrease risk of neonatal lupus in mothers with anti-Ro or anti-La antibodies
Azathioprine	Inhibits T-lymphocytes	Check TPMT ^b prior to initiation CBC and CMP	May be used in pregnancy
Methotrexate	Inhibits dihydrofolate reductase and inhibits lymphocyte proliferation	Pregnancy test, hepatitis B and C serologies and CXR at baseline CBC and CMP Caution with renal disease, hepatitis or alcohol use	Teratogenic Avoid use in both men and women considering pregnancy
Leflunomide	Inhibits pyrimidine synthesis via dihydro-orotate dehydrogenase inhibition	Pregnancy test, TB test at baseline CBC and CMP	Teratogenic
Mycophenolate mofetil	Inhibits B and T lymphocyte proliferation	Pregnancy test at baseline CBC and CMP	Teratogenic
Belimumab ^a	Inhibits B lymphocyte stimulator (BLyS) binding to B cells which inhibits B-cell survival and decreased B-cell differentiation into immunoglobulin producing plasma cells	No routine testing	Avoid use during pregnancy and lactation Not enough data available
Cyclophosphamide	Alkylates and cross-links DNA	Creatinine at baseline CBC, UA and CMP May need to adjust dose in renal impairment	May cause gonadal failure Teratogenic Avoid use in pregnancy as well as lactation

^aDenotes medications that are FDA approved for the treatment of SLE.

^bTesting for thiopurine methyltransferase deficiency.

PROGNOSIS

Prognosis in SLE has improved with early diagnosis and advances in treatment. In 1955, 5-year survival of SLE was 55%, which improved to 64% to 87% in the 1980s, and most recently, it was reported at 95%. Survival rates are influenced by geographic location and ethnicity.

With improved mortality from lupus disease activity, the focus has been on prevention and management of comorbid conditions. Premature atherosclerotic heart disease, malignancy, bone health, and psychosocial well-being may be secondary to the inflammatory state seen in lupus or as a result of treatment.

SPECIAL CONSIDERATIONS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Pregnancy

Women with SLE have normal fertility but have higher rates of pregnancy loss (i.e., miscarriage and stillbirths) and preterm delivery (i.e., premature rupture of membranes, preeclampsia, and intrauterine growth restriction) than their healthy counterparts. Lupus activity preceding conception, especially nephritis, hypertension, and APS, are risk factors for pregnancy complications in SLE. Pregnancy itself may place women with SLE at a greater risk of a flare, particularly if the disease was active before conception.

With careful prenatal screening and planning, women with SLE can successfully have a healthy child. Prenatal monitoring of anti-SSA/

Ro and anti-SSB/La antibodies and APLs and pre-pregnancy consultation with an obstetrician caring for high-risk pregnancies are critical. Ideally, women with SLE should have clinical quiescence for 6 months prior to a planned pregnancy.

Hormone Therapy

Contraception plays an important role in pregnancy planning for women with lupus. Often it is important to avoid unintended pregnancy during periods of severe disease activity and fetal exposure to potentially teratogenic drugs.

Because SLE is more prevalent in women of childbearing ages there has been consideration of a hormonal role in pathogenesis. There have been concerns raised that estrogen-containing compounds could induce a flare. In the past, estrogen-containing contraceptives were considered relatively contraindicated. However, randomized controlled trials evaluating the rate of disease flares in women with SLE on estrogen-containing contraceptives found no significant difference in rates of serious flares. Still, as a general rule, women with SLE who have APLs should avoid contraception with estrogen-containing compounds due to increased risk of thrombotic events. More recently, intrauterine devices are becoming a recommended alternative, given the efficacy and safety profile.

The use of postmenopausal hormone replacement therapy for treating vasomotor symptoms in SLE should be restricted to patients with negative APLs and at the lowest dose and shortest duration.

TABLE 81.7 Revised Classification Criteria of Antiphospholipid Syndrome

Classification Criteria ^a	Definition
Clinical Criteria	
1. Vascular thrombosis	One or more clinical episodes of arterial, venous, or small vessel thrombosis in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity	a. One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks' gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus or b. One or more premature births of a morphologically normal neonate before 34 weeks' gestation because of (i) eclampsia or severe preeclampsia or (ii) recognized features of placental insufficiency or c. Three or more unexplained consecutive spontaneous abortions before 10 weeks' gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded
Laboratory Criteria	
1. Lupus anticoagulant	LAC detected in plasma on two or more occasions at least 12 weeks apart
2. Anticardiolipin antibody	The ACA antibody of IgG and/or IgM isotype in serum or plasma in medium or high titer (i.e., >40 GPL units, or >the 99th percentile) on two or more occasions at least 12 weeks apart, measured by a standardized ELISA
3. Anti- β_2 glycoprotein I antibody	β_2 GPI antibody of IgG and/or IgM isotype in serum or plasma (in titer >the 99th percentile), detected on two or more occasions at least 12 weeks apart, measured by a standardized ELISA

ACA, Anticardiolipin antibody; β_2 GPI, anti- β_2 glycoprotein I antibody; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; LAC, lupus anticoagulant.

^aAntiphospholipid antibody syndrome is diagnosed if at least one clinical criterion and one laboratory criterion are met.

Modified from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS), *J Thromb Haemost* 4:295-306, 2006.

Bone Health

Women with SLE have an increased risk for osteoporosis due to multiple factors. Some of these factors are more specific to SLE, such as chronic inflammation, renal disease, photosensitivity and avoidance of sun exposure, medication use (especially glucocorticoids), and premature ovarian failure, which may be due to SLE or the use of CTX. In addition, there are still the typical risk factors for osteoporosis such as smoking, alcohol use, family history, and low BMI. One challenging aspect in treating osteoporosis in young women with SLE is the use of bisphosphonates as these medications are not safe in pregnancy and may be present for years after discontinuation.

Cardiovascular Health

As survival and therapies for SLE have improved, and patients are living longer, cardiovascular disease (CVD) has emerged as a leading cause of morbidity and mortality. SLE patients are 5 to 10 times more likely than healthy individuals to have a coronary event. More striking, premenopausal women between 35 and 44 years of age are 50 times more likely than healthy women to have a myocardial infarction.

Autopsy series reveal atherosclerotic heart disease as the underlying mechanism of CVD in SLE. The cause of premature atherosclerosis in SLE is multifactorial and likely includes inflammatory mediators, SLE-related factors (e.g., premature menopause, corticosteroid therapy, disease activity), and traditional cardiovascular risk factors.

Although no firm cardiovascular management guidelines exist for SLE patients, the 2011 updated guidelines from the American Heart Association for prevention of CVD in women included (for the first time) autoimmune diseases (i.e., SLE and rheumatoid arthritis) in the increased-risk category. Physicians should consider premature

atherosclerotic CVD and aggressively evaluate SLE patients with typical and atypical cardiac symptoms, regardless of age and sex.

Secondary Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is a condition characterized by an increased risk of thrombosis and/or pregnancy loss in the setting of APLs. The term *lupus anticoagulant* is a misnomer because the in vitro anticoagulant effect reflects the prolonged activated partial thromboplastin time (aPTT), but the term does not indicate a diagnosis of SLE or an increased risk of bleeding. In fact, lupus anticoagulant is associated with an increased risk of thrombotic events.

If APS occurs in the absence of another autoimmune disease it is considered primary APS. When it occurs in the setting of SLE or another autoimmune disease it is considered secondary APS. Both primary and secondary APS have similar clinical manifestations and the treatment is also similar. Clinical manifestations of APS typically include increased risk for venous and arterial thrombosis, pregnancy complications, cerebrovascular and cardiovascular events, pulmonary hypertension, Libman-Sacks endocarditis, and neurologic complications.

Catastrophic APS (CAPS) is the most severe manifestation of APS, which affects multiple organs with microthromboses leading to rapid organ failure and potentially death. CAPS may be difficult to discern from sepsis or TTP.

For patients with presence of APS but no thrombotic events or pregnancy loss there is no indication for anticoagulation. If there is an episode of vascular thrombosis, treatment with lifelong anticoagulation is generally recommended. Warfarin remains the drug of choice for these patients despite the development of several other novel oral anticoagulants. Unfractionated and low-molecular-weight heparin are also effective anticoagulants for APS and are used for patients who suffer recurrent events while on warfarin therapy or patients who are or plan to become pregnant (Table 81.7).

Malignancy

Patients with SLE have an increased risk of solid organ cancers as well as lymphoma. A multicenter international cohort study by SLICC of more than 16,000 SLE patients reported an increased risk of malignancy compared with the general population. Most striking was a 4-fold increased risk of non-Hodgkin's lymphoma. Other hematologic, vulvar, lung, and thyroid cancers were also increased, whereas breast and endometrial cancers were observed less often in lupus. Malignancy risk appears to be highest early in the disease course, but risk remains elevated throughout a patient's lifespan. Although lymph node enlargement is a common manifestation of SLE, physicians must consider malignancy if the lymphadenopathy does not resolve with SLE treatment, is nontender or nonmobile, or if it occurs without other lupus symptoms.

Vaccines

Patients with SLE are at an increased risk of infection due to immune dysregulation in addition to the use of immunosuppressive medications. Vaccines play a vital role in prevention of infections. As a general rule, live attenuated vaccines are contraindicated in lupus patients on biologic therapy or high-dose immunosuppressive treatments with a few exceptions. Patients with SLE should receive pneumococcal vaccines (PCV 13 and 23) and annual influenza vaccine. Patients with SLE have a higher risk of HPV-related cancers, and younger individuals should receive the HPV vaccination to mitigate this risk. There is also an increased risk of latent varicella zoster reactivation. There is now an inactivated vaccine available for the use in immunocompromised individuals such as those with SLE. The long-term safety of this vaccine is still being evaluated.

Psychosocial Effects of Systemic Lupus Erythematosus

When deciding upon management of SLE one must take into consideration other factors that influence outcomes. There is an immune response to acute stress as well as physical and emotional trauma. Although commonly reported by patients, it has been difficult to demonstrate a causal relationship between stress and increased flares in clinical studies. Regardless, anxiety, depression, and social determinants of health can impact adherence to medications and treatment plans as well as overall quality of life and should be considered when caring for patients with lupus.

Fatigue

Fatigue is extremely common in SLE, affecting up to 80% of patients. The cause is often multifactorial, and it is essential to rule out reversible etiologies that may be contributing, such as thyroid disease, depression, non-restorative sleep, obstructive sleep apnea, deconditioning, poor nutrition, celiac disease and nutritional deficiencies, fibromyalgia, and medication side effects. It is often difficult to pinpoint the exact cause of fatigue, and this makes management challenging. Treatment requires addressing the underlying causes of fatigue as well as improving nutrition, sleep, and encouraging aerobic exercise.

Depression and Anxiety

Patients with SLE are at increased risk for depression and anxiety, which have been associated with worse outcomes and medication response. Management of depression and anxiety is essential to the overall treatment of patients with SLE. Along with pharmacologic modalities such as antidepressants and anxiolytics, nonpharmacologic interventions such as psychological counseling, biofeedback, and guided imagery should be incorporated into management of lupus when appropriate.

SUMMARY

Systemic lupus erythematosus is a chronic multisystem autoimmune disease characterized by periods of disease flares and quiescence,

and when left untreated it can lead to permanent organ damage and increased mortality. Diagnosis of SLE can be difficult and relies on a combination of clinical and laboratory factors. The Classification Criteria serve as a helpful reminder of common manifestations to aid in diagnosis. The heterogeneity of clinical manifestations of lupus has raised the concept of lupus as a spectrum disorder with different genetic and molecular profiles that define distinct phenotypes requiring customized management strategies.

Antimalarials remain the cornerstone of SLE treatment and have benefits beyond managing lupus disease activity. Immunosuppressive and biologic agents are available for manifestations that are not controlled by antimalarials. It is crucial to recognize the increased risk of comorbidities in lupus, including cardiovascular disease, malignancy, and bone loss. Addressing social determinants of health should be a part of the overall treatment plan in lupus. There is a pipeline of new agents currently being tested to improve management, morbidity, and mortality of patients with SLE.

Systemic Sclerosis

Anna Papazoglou, Robyn T. Domsic

INTRODUCTION

Systemic sclerosis (SSc) is a multisystem, autoimmune disease characterized by cutaneous and visceral fibrosis. The more common term for the disease, *scleroderma*, reflects this hallmark feature as it is derived from the Greek *scleros*, which means thick, and *derma*, which means skin. The pathology and damage from the disease reflects a complex interplay of vascular injury, immune system activation, and excessive fibrosis.

The disorder can range from a relatively benign condition to a rapidly progressive disease leading to significant morbidity or death. Although cutaneous manifestations are the most obvious features, visceral and vascular involvement can be severe and disabling. Monitoring for potential organ complications is essential in caring for SSc patients because early detection and treatment may minimize morbidity and mortality. There is ongoing research aiming to increase in-depth understanding of the complex mechanisms leading to SSc, which would facilitate the discovery of curative treatment.

EPIDEMIOLOGY

The annual US incidence of SSc is approximately 32 cases per million persons and the estimated prevalence is 254 cases per million persons. Incidence and prevalence vary somewhat throughout the world, and they typically are lower in Europe and Asia. SSc more commonly affects women, with a 3-5:1 female-to-male ratio. It occurs in individuals of all ages, from childhood to the elderly, but it most frequently affects those between the ages of 40 and 60 years. There are studies that indicate differences in the frequency and severity of SSc clinical manifestations as well as complications between men and women.

A familial pattern of inheritance is not as evident in SSc as in other connective tissue diseases, although first-degree relatives appear to be at somewhat increased risk. Twin studies have demonstrated only a 5% rate of concordance in monozygotic and dizygotic twins, implying that there are significant environmental contributions to its occurrence. Many patients with SSc, however, have family histories of other autoimmune diseases (e.g., thyroid disease, rheumatoid arthritis, systemic lupus erythematosus [SLE]). Genome-wide association studies have revealed a handful of genes associated with SSc that are shared with other diseases such as rheumatoid arthritis and SLE (e.g., major histocompatibility complex class I and II genes, *STAT4*, *IRF5*, *TNFSF4*, *IRF8*). These findings suggest a shared genetic predisposition to autoimmune conditions.

PATHOLOGY

The pathogenesis of SSc remains unclear. A combination of genetic and environmental factors results in complicated interaction of three clearly identified components, consisting of vascular abnormalities,

immunologic abnormalities and extracellular membrane abnormalities leading to tissue fibrosis, the hallmark of SSc (Fig. 82.1).

The initial event is postulated to be tissue injury including endothelial damage with subsequent endothelial cell activation and chemokine production as well as vascular injury. Vascular damage is characterized by vascular obliteration, defective vasculogenesis, and tissue hypoxia. Vascular changes are seen in the skin and may also occur in the pulmonary, cardiac, and renal blood vessels, affecting arteries, arterioles, and capillaries. True vasculitis is conspicuously absent. Early vascular involvement consists of an imbalance between vasodilatory and vasoconstrictive factors, endothelial cell activation with resultant leukocyte migration and smooth muscle cell proliferation.

Immune system activation is evident in several respects. The secretion of multiple chemokines leads to perpetuating cycles of inflammation and autoimmunity. SSc-associated autoantibodies are detected in more than 95% of patients with SSc. All 10 of the recognized SSc-associated autoantibodies are directed against distinct nuclear antigens. They are helpful in classifying patients, but their pathogenic role has not been clarified. There is evidence of T-cell activation, with a T_H2 -predominant cytokine profile. Elevated levels of interleukins (i.e., IL-1, IL-2, IL-2R, IL-4, IL-8, IL-13, and IL-17) and interferon have been reported. The role of T_H17 cells is not understood, but studies suggest that dysregulation of these proinflammatory T cells contributes to disease pathogenesis. In addition, there is increasing evidence of innate immune dysregulation in the setting of activated macrophages and altered expression and function of toll-like receptors.

The complex interplay between the chemokines produced by the inflammatory cells leads to activation of fibroblasts and presumed differentiation into myofibroblast. As such, there is overproduction of extracellular matrix, which results in progressively worsening fibrosis. Of note, fibroblasts are found in increased numbers in the skin and other tissues, and they develop an SSc phenotype when grown in vitro, producing an overabundance of collagen and living longer in tissue culture. Fibroblast persistence in culture suggests a perpetuated abnormality not requiring continued immune stimulation. Over the past decades, increasing evidence suggests that macrophages are important in the pathogenesis of systemic sclerosis through secretion of inflammatory cytokines; however, their exact role needs to be further clarified. Transforming growth factor β (TGF- β), specifically, is secreted by macrophages and has been found to have effect on the fibrotic mechanism through regulation of fibroblast function as well as various important processes in fibrosis.

CLINICAL PRESENTATION

Patients with SSc can have several clinical presentations, although Raynaud's phenomenon is the most common symptom (>95%). Distinctive phenotypes may manifest differently. SSc can have many

Fig. 82.1 Pathogenetic processes in systemic sclerosis. Vascular injury leads to intimal proliferation of endothelial cells (red) and smooth muscle cells (blue with black nuclei). Immune cells consisting of T cells (blue, small) and monocyte/macrophages (yellow with orange nuclei) are activated and home to sites in the dermis. Fibroblasts are activated to deposit increased amounts of interstitial matrix. *IL*, Interleukin; *PDGF*, platelet-derived growth factor; *TGF- β* , transforming growth factor- β .

internal organ manifestations, producing various clinical presentations and requiring tailored work-up protocols.

Classification by Cutaneous Features

Historically, SSc has been separated into two major clinical subsets defined by the degree and extent of skin involvement: limited cutaneous (lc) and diffuse cutaneous (dc) disease. Patients with lcSSc experience skin thickening limited to the distal extremities (i.e., below the elbows and knees) as well as the face. The dcSSc patients have similar distal changes in addition to involvement of the upper arms, thighs, or trunk at some time during the disease course. Few patients (<1%) have no skin thickening but have one or more typical SSc visceral manifestations. The term *scleroderma sine scleroderma* has been used to describe patients with minimal or no skin involvement whose clinical course resembles that of individuals with lcSSc.

The distinct cutaneous patterns are important, because patients with dcSSc are more likely to develop internal organ complications (e.g., renal crisis, cardiac involvement) early in their illness, whereas those with lcSSc can develop internal organ involvement at any point throughout their disease, even decades after the initial symptoms. Several classification criteria have been suggested that do not particularly assist in diagnosis of SSc but are rather intended primarily to help classify SSc patients for studies (Table 82.1). These clinical characteristics are derived from a long-standing registry at the University of Pittsburgh. Some patients with lcSSc or dcSSc may have typical features of another connective tissue disease (most commonly polymyositis, SLE, or rheumatoid arthritis-like features), and they are considered to have *SSc in overlap*.

Of note, as an attempt for early identification of individuals at risk for future development of SSc, the Very Early Diagnosis of Systemic Sclerosis (VEDOSS) approach has been considered recently as a potentially useful tool for predicting SSc disease development. Its role in clinical and research work at this time still requires better understanding. This approach, which includes patients with manifestations of Raynaud's phenomenon, puffy fingers, certain positive SSc antibodies, and reported

naifold capillaroscopy changes, may be helpful in identifying those at risk for developing established disease over shorter-term follow-up.

Serologic Classification

Serologic classification refers to SSc-associated serum autoantibodies. Patients with the same autoantibody tend to have a similar cutaneous pattern, natural history of disease, and risk of internal organ involvement.

Serologic classification can augment the clinical classification described previously. For example, 95% of patients with anticentromere antibody have lcSSc and are at increased risk for pulmonary hypertension during the course of the disease. Individuals with anti-topoisomerase I (i.e., anti-SCL70) or anti-RNA polymerase III antibody are more likely to have dcSSc. Those with anti-RNA polymerase III antibody have an increased risk of renal crisis, and those with anti-SCL70 have a higher frequency of interstitial lung disease.

The primary internal organ risks and cutaneous associations are depicted in Fig. 82.2, which illustrates the combined clinical-serologic classification of SSc. It is uncommon for patients to have more than one SSc autoantibody.

Raynaud's Phenomenon and Peripheral Vascular Involvement

Nearly all patients with SSc experience Raynaud's phenomenon during their disease course, often as the initial symptom. Raynaud's phenomenon is a triphasic vasospastic response to cold consisting of pallor (i.e., blanching) with or without cyanosis (i.e., bluish discoloration followed by reactive hyperemia manifested by erythema) with a characteristic distinct line of demarcation on the digits separating the affected from unaffected areas.

The onset of Raynaud's phenomenon can precede the development of skin changes by years in some patients. Beyond Raynaud's phenomenon, SSc patients can develop progressive peripheral vasculopathy. This may lead to loss of digital tip tissue with resulting digital pitting scars, ulcers, or gangrene (rare) that can lead to autoamputation. Digital tip ulcers occur more frequently in patients who are anticentromere or

TABLE 82.1 Manifestations of Systemic Sclerosis by Clinical Classification in the Pittsburgh Scleroderma Center Database

Manifestations	Diffuse (N = 1646)	Limited (N = 2124)
Cutaneous		
Puffy fingers	83%	80%
Skin induration, thickening	Widespread: trunk, face, extremities	Face, below the elbow and knee
Telangiectasias	62%	65%
Calcinosis	10%	13%
Peripheral Vascular		
Raynaud's phenomenon	95%	98%
Digital ulcerations	41%	37%
Pulmonary		
Interstitial lung disease	38%	34%
Pulmonary arterial hypertension	6%	18%
Cardiac		
Arrhythmias	12%	10%
Diastolic dysfunction	7%	9%
Myocarditis	3%	1%
Pericarditis	3%	2%
Renal		
Renal crisis	16%	3%
Gastrointestinal		
Esophageal hypomotility, reflux	84%	83%
Small intestine dysmotility	11%	8%
Malabsorption	5%	4%
Incontinence	3%	4%
Joint and Musculoskeletal		
Tendon friction rubs	51%	6%
Joint contractures	87%	37%
Myositis	6%	7%

Data from the University of Pittsburgh Scleroderma Databank, 1980-2018.

anti-topoisomerase I autoantibody positive. Lower extremity ulcerations in SSc patients have been increasingly reported in recent years.

Interstitial Lung Disease

Interstitial lung disease (ILD) can be one of the most serious complications of SSc and should be monitored for routinely, because it plays a major role in mortality and morbidity (see [Chapter 17](#)). The initial presentation is often a nonproductive cough and a gradual onset of dyspnea on exertion over several months to years. However, the onset can be abrupt.

High-resolution chest computed tomography (CT) typically shows bibasilar fibrotic changes, which can be progressive. Pulmonary function tests reveal reduced forced vital capacity (FVC). On pathologic

examination, the most frequently seen pattern is nonspecific interstitial pneumonitis (NSIP) or fibrosing NSIP. Patients with anti-SCL70 autoantibody and U11/U12 are at the highest risk for ILD.

Pulmonary Hypertension

SSc patients can develop pulmonary hypertension of three World Health Organization (WHO) classifications (see [Chapter 18](#) and [Chapter 12](#)). Pulmonary arterial hypertension (PAH, WHO group 1) is the most common, with an estimated 10% to 15% of patients in cohort studies developing PAH. It occurs most commonly in those with lcSSc. The clinical presentation includes rapidly progressive dyspnea occurring over several months. Pulmonary function tests reveal a reduced diffusion capacity for carbon monoxide (DLCO) out of proportion to any concomitant reduction in the FVC.

Less frequently, SSc patients develop pulmonary hypertension associated with ILD (WHO group 3) or pulmonary hypertension associated with left ventricular diastolic dysfunction from myocardial fibrosis or non-SSc-associated left ventricular disorders (WHO group 2). Screening for all types of pulmonary hypertension is performed by echocardiogram, and results should be confirmed by right heart cardiac catheterization.

Scleroderma Renal Crisis

Scleroderma renal crisis (SRC) manifests as the abrupt onset of accelerated arterial hypertension accompanied by a rise in serum creatinine levels and by microscopic hematuria and proteinuria on urinalysis. Microangiopathic hemolytic anemia and thrombocytopenia are common. Although once the major cause of mortality in SSc, SRC is now managed by aggressive blood pressure control with an angiotensin-converting enzyme (ACE) inhibitor, which should be maintained lifelong.

The typical setting for SRC is early dcSSc with a recent increase in skin thickening, palpable tendon friction rubs, and anti-RNA polymerase III antibody. During active, early dcSSc, patients should check their blood pressure once weekly and report a rise in systolic blood pressure of more than 20 mm Hg from baseline. Prednisone given at a dose of 15 mg daily or higher has been associated with the development of SRC and should be avoided in at-risk patients.

Cardiac Manifestations

In general, all cardiac structures may be affected with subsequent serious functional consequences. Underlying PAH contributes as well to cardiac manifestations of SSc. Patients with SSc have three primary types of cardiac involvement: pericarditis, myocarditis, and myocardial fibrosis. The latter can lead to congestive heart failure and arrhythmias due to fibrosis of the conduction system. These complications can be asymptomatic and underrecognized in SSc patients, but pathologic changes have been found in 70% of patients in older autopsy series. Later studies using cardiac magnetic resonance imaging (MRI) have supported the autopsy findings of subclinical cardiac involvement.

Diastolic dysfunction is becoming increasingly recognized as a complication of fibrosis and can be evaluated by echocardiogram during pulmonary hypertension screening. Many SSc deaths occur suddenly, possibly due to ventricular arrhythmias. It is prudent to obtain a resting electrocardiogram early in the disease course. Palpitations noticed by the patient should be addressed with a formal cardiac arrhythmia evaluation.

Gastrointestinal Tract Manifestations

At least one gastrointestinal manifestation will affect 80% or more of SSc patients, and all areas of the gastrointestinal tract may be affected. Gastrointestinal involvement is a significant cause of morbidity.

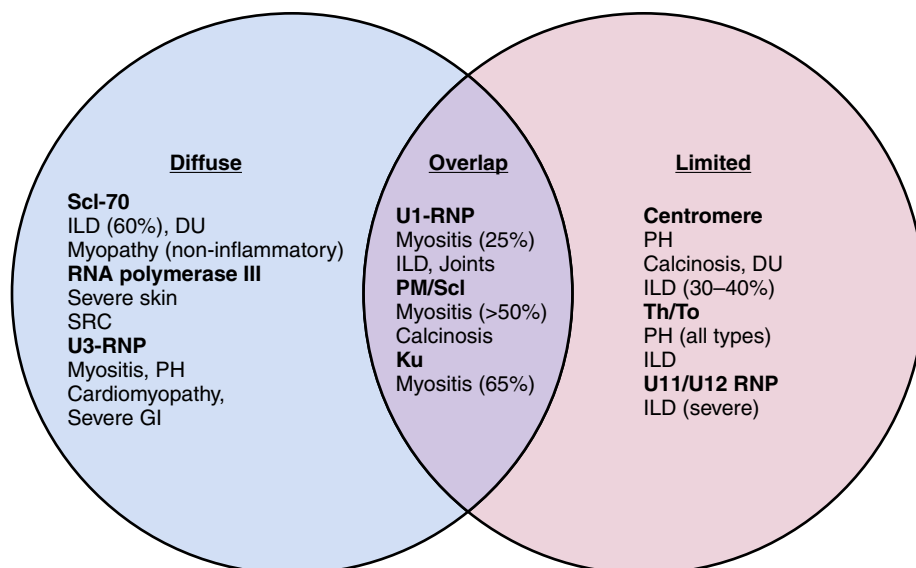

Fig. 82.2 Clinical-serologic classification of systemic sclerosis and antibody-associated internal organ manifestations. *Bold text* indicates an antibody; clinical manifestations listed below are associated with that antibody. *DU*, Digital ulcers; *ILD*, interstitial lung disease; *Ku*, 70/80-kD protein (XRCC6/XRCC5); *PH*, pulmonary hypertension; *PM*, polymyositis; *RNP*, ribonucleoprotein; *Scl*, sclerosis; *SRC*, scleroderma renal crisis.

When the esophagus is affected, patients experience heartburn and/or regurgitation due to a reduced lower esophageal sphincter pressure and distal dysphagia for solid foods due to esophageal dysmotility. The former can be determined by manometry. Less invasively, a barium swallow can reveal hypo- or aperistalsis to determine esophageal dysfunction. Neuropathic changes and fibrosis of the muscularis of the small intestine can lead to motor dysfunction and symptoms of postprandial abdominal distention. Small intestinal hypomotility may lead to bacterial overgrowth, causing bloating and diarrhea. When severe atony of the small intestine develops, patients occasionally develop a functional ileus or intestinal pseudo-obstruction. Parenteral nutrition may be necessary for severe malabsorption with accompanying weight loss and steatorrhea. Similar to the small bowel, the colon may develop impaired motor function leading to constipation and occasionally overflow diarrhea. Wide-mouthed diverticula on the antimesenteric border of the colon can be seen. The internal anal sphincter may become fibrotic, resulting in fecal incontinence.

Musculoskeletal Manifestations

Musculoskeletal manifestations are common. Tendons can become inflamed and fibrotic, particularly in early, diffuse disease. Palpable tendon or bursal friction rubs are virtually pathognomonic of SSc and often indicate progression to dcSSc before widespread skin thickening has occurred. Finger joint flexion contractures develop frequently within the first years of diffuse SSc. True arthritis with palpable synovitis should raise the question of an overlap condition or concomitant Sjögren's syndrome, because synovitis is not a typical feature of SSc.

Some patients develop a bland myopathy with nonprogressive, mild proximal muscle weakness and wasting. A few, particularly with features that overlap with other connective tissue diseases or mixed connective tissue disease, can develop true myositis, which can result in morbidity and disability.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Raynaud's phenomenon is prominent in the differential diagnosis for SSc. Features that identify Raynaud's patients who have or may later develop SSc or another connective tissue disease are abnormal nail fold

capillaries (i.e., megacapillaries, hemorrhages, neovascularization, and avascular areas), tissue loss at the tips of the fingers, and a positive anti-nuclear antibody (ANA) test result. None of these features is found in Raynaud's disease (i.e., primary Raynaud's phenomenon).

Mixed connective tissue disease (MCTD) is also on the differential for SSc. MCTD patients have features of two or more autoimmune diseases and are U1-RNP antibody positive. This most frequently includes SSc, polymyositis, and SLE. Patients with MCTD can develop any or all of the following SSc manifestations: Raynaud's phenomenon, puffy fingers, limited or diffuse skin thickening, myositis, ILD, PAH, and esophageal dysmotility.

Scleroderma mimics are sometimes difficult to distinguish from SSc (Table 82.2). They include eosinophilic fasciitis, the localized forms of scleroderma such as linear scleroderma (more frequently seen in children), and plaque or generalized morphea.

Nephrogenic systemic fibrosis is a complication of gadolinium administration for radiographic studies that occurs in the setting of renal failure. Nephrogenic systemic fibrosis manifests as symmetrical, bilateral, fibrotic, indurated papules, plaques, or subcutaneous nodules, which can be erythematous and occur on the lower legs or hands. The lesions are often preceded by edema and may initially be misdiagnosed as cellulitis. This diagnosis should be considered in patients being evaluated for a fibrotic disorder who have renal failure, regardless of the cause of renal disease.

Scleromyxedema and scleredema are cutaneous fibrotic disorders in which excessive mucin accumulation is found on skin biopsy. Scleromyxedema can mimic dcSSc on the physical examination or can manifest with multiple, firm, nodular skin lesions (i.e., papular mucinosis). A frequent association is a monoclonal gammopathy (i.e., immunoglobulin [IgG] paraprotein). Scleredema typically involves the nape of the neck and shoulders, sparing the distal extremities. All SSc mimics lack Raynaud's phenomenon, characteristic SSc internal organ involvement, and SSc-associated serum antibodies.

TREATMENT

No single efficacious therapy has been demonstrated in a randomized, placebo-controlled phase III study for SSc. Thus, patients must

TABLE 82.2 Scleroderma Mimics

Disorder	Distinguishing Features
Other Diseases	
Morphea	One or more discrete lesions; patchy or linear in distribution
Eosinophilic fasciitis	Finger flexures without sclerodactyly; characteristic groove sign when the arms are raised; puckering or dimpling of the upper arm and thigh skin; peripheral blood eosinophilia; fascia and deep subcutaneous fibrosis
Scleredema (Buschke disease)	Prominent involvement of neck, shoulders, and upper arms; hands spared; associated with diabetes
Scleromyxedema	Association with gammopathy; skin lichenoid and thickened but not tethered; may have Raynaud's phenomenon
Graft-versus-host disease	Skin changes similar to scleroderma; vasculopathy
Nephrogenic fibrosing dermopathy	Indurated plaques or nodules on the legs or arms, sparing the face; administration of gadolinium in the setting of renal dysfunction; often preceded by edema
Reactions to Environmental Agents and Drugs	
Bleomycin	Skin and lung fibrosis similar to scleroderma
L-Tryptophan (1980s)	Eosinophilia-myalgia syndrome from L-tryptophan contaminant or metabolite (first described in the 1980s); fever, eosinophilia, neurologic manifestations
Organic solvents (e.g., trichloroethylene)	Clinically indistinguishable from idiopathic systemic sclerosis
Pentazocine	Localized lesions at injection sites
Toxic oil syndrome	Contaminated rapeseed oil (Spanish epidemic in 1981); similar to eosinophilia myalgia syndrome
Vinyl chloride	Vascular lesions, acro-osteolysis, sclerodactyly, no visceral disease
Gadolinium	Nephrogenic fibrosing dermopathy

be appropriately monitored for visceral involvement to allow early identification and therapy targeted at specific organ complications. Consultation with a rheumatologist is helpful in this respect. Generally, patients with early diffuse or evolving diffuse scleroderma are likely to be considered for treatment with immunosuppression and treatment options specifically for those SSc patients with ILD include an anti-fibrotic agent. Given the lack of US Food and Drug Administration (FDA)- or EMA-approved therapy, SSc is an active area of therapeutic research; multiple international clinical trials are either ongoing or planned. Given this, patients should be considered for referral to a dedicated scleroderma center early in disease to have the advantage of these opportunities. Autologous stem cell transplant has been tested in the United States and Europe and has demonstrated an improvement in event-free and overall survival in patients with moderate to severe and early diffuse SSc. Treatment-related mortality must be weighed when considering stem cell therapy as an option, and we do not advise it for skin management alone.

With respect to evaluation and monitoring, all patients should undergo screening evaluation for ILD and pulmonary hypertension throughout the course of their disease. Current expert recommendations suggest that patients with early, diffuse disease should be monitored at least yearly for these complications. Patients with active dcSSc, particularly if they have tendon friction rubs, should undergo weekly blood pressure monitoring because the abrupt appearance of hypertension suggests SRC. Early dcSSc patients should also have skin thickness scores assessed for progression or regression of cutaneous disease. For dcSSc and lcSSc, initial esophageal motility studies should be considered, and further objective studies should be ordered on the basis of symptoms.

Education of patients and family members regarding the disease and an accurate prognosis based on disease subtype and stage can be helpful in management. Educational programs are available through foundations across the world. This includes the Scleroderma Foundation in the United States, Scleroderma Canada, Scleroderma and Raynaud's UK, Scleroderma Australia, and the World Scleroderma Foundation.

Raynaud's Phenomenon

Nonpharmacologic measures such as cold avoidance, warming measures, avoidance of vibratory tools, and smoking cessation are encouraged in all patients. Pharmacologic measures are recommended, because ongoing vascular injury may play a role in pathogenesis.

Calcium-channel blockers have been widely used for decades, and they are generally well tolerated by patients. Long-acting nifedipine is effective in more than one half of patients; other agents such as amlodipine are also frequently prescribed. The angiotensin-receptor blocker losartan reduced the severity and frequency of Raynaud's phenomenon attacks in a placebo-controlled trial. ACE inhibitors have not proved effective in several controlled trials. Phosphodiesterase-5 (PDE-5) inhibitors have been shown to improve Raynaud's phenomenon. Some studies have shown encouraging results with use of fluoxetine (selective serotonin reuptake inhibitor). The prostacyclin iloprost is used as a therapy for severe Raynaud's phenomenon and digital ischemia. The benefit of statin therapy for Raynaud's phenomenon has produced conflicting results, although it has benefits in endothelial dysfunction, which is a component of the vascular pathogenesis in SSc.

In patients with digital ulcerations, more aggressive therapy may be warranted. PDE-5 inhibitors have been helpful. Topical nitroglycerin as a paste, gel, or patch placed at the base of the fingers or over the dorsal wrist may be a useful adjunct. In randomized, placebo-controlled trials, bosentan, an endothelin receptor antagonist, prevented the formation of new digital ulcerations in patients with SSc and Raynaud's phenomenon, although it has not been approved by the FDA for this indication. Iloprost, an intravenous prostacyclin, has also been shown to reduce digital ulcerations and is frequently used in Europe, but it is not FDA-approved in the United States.

For patients with digital ulcers involving adjacent fingers, assessment of the ulnar and radial artery should be performed with arterial Doppler or angiography because larger arteries can become severely narrowed. Surgical interventions include sympathectomy of the digital, radial, or ulnar artery and venous bypass for ulnar or radial artery occlusion. Topical botulinum A injections are potentially helpful in

selected patients who are unable to tolerate other treatments. In SSc patients with recurrent digital ulcers or other thrombotic events, evaluation for a hypercoagulable state, particularly for lupus anticoagulant, should be performed. In this circumstance, aspirin or other anticoagulants are indicated.

Cutaneous Disease

No therapeutic agent has been found to achieve a clinically significant improvement in skin thickening as measured by the modified Rodnan skin score in a randomized, placebo-controlled trial for patients with dcSSc. The Rodnan skin score was developed by Dr. Gerald Rodnan at the University of Pittsburgh. It is calculated by estimating skin thickness on a scale of 0 to 3 in 17 skin areas. Negative findings in therapeutic trials have been attributed to the type of drugs chosen, the patient populations, and trial designs. In the past, considerable attention was given to methotrexate and D-penicillamine, but no trials demonstrate a clinically significant improvement in skin score. Case series with historical controls have suggested a benefit for mycophenolate mofetil, although it has not been studied in a randomized setting. Subset analysis from the Scleroderma Lung Study 2 suggested that both mycophenolate and cyclophosphamide therapy were associated with an improvement in the skin thickness of patients with dcSSc. More recently, two studies with tocilizumab failed to demonstrate a statistically significant improvement in skin score, although there was clinical improvement during the extended open label trial. Currently, mycophenolate mofetil and methotrexate are commonly used as first-line agents in dcSSc.

Scleroderma Renal Crisis

Early diagnosis and prompt initiation of ACE inhibitors are the keys to improved survival and outcomes of SRC. ACE inhibitors should be titrated to maintain a normal blood pressure, preferably less than 125/75 mm Hg, and lifelong treatment is recommended. Second-line agents to maintain blood pressure control include calcium-channel blockers (CCB). β -Blockers are relatively contraindicated because there is concern for worsening of Raynaud's phenomenon as well as for potential vascular complications.

Even if patients with SRC become dialysis dependent initially, some may experience a slow reversal of renal vascular damage if ACE inhibitor therapy is maintained. Because up to 50% of SRC patients can spontaneously come off dialysis, transplantation evaluation should be delayed until at least 2 years after SRC onset.

Interstitial Lung Disease

Early recognition of inflammatory ILD is important if treatment is to prevent progression to distortion of lung architecture and irreversible fibrosis. Controlled clinical trials support the potential benefit of mycophenolate mofetil, particularly with early detection of underlying ILD associated with SSc and initiation of treatment. Although the choice of mycophenolate mofetil has not been proven to be more effective compared to cyclophosphamide, there is overall better tolerance of the drug and a relatively safer side-effect profile. In addition, small trials have shown hopeful results in terms of using rituximab, an anti-CD20 monoclonal antibody, for fibrotic lung complications associated with underlying scleroderma. Two randomized controlled trials of tocilizumab revealed encouraging results regarding preservation of lung function. A recent trial of nintedanib in SSc-related ILD demonstrated that the annual rate of decline in FVC was lower with nintedanib than with placebo; nearly half the patients in this trial were taking background mycophenolate therapy. Lung transplantation can be considered for end-stage

ILD. In all settings, management of ILD should include management of esophageal disease.

Pulmonary Hypertension

Several agents have been approved for the treatment of PAH (see Chapter 18). Subset analyses of several placebo-controlled drug trials have shown improvement in established SSc or connective tissue disease-related PAH. They have included phosphodiesterase-5 inhibitors (e.g., sildenafil, tadalafil), endothelial receptor antagonists (e.g., bosentan, ambrisentan, macitentan), soluble guanylate cyclase inhibitors (riociguat), and prostacyclin analogues (e.g., treprostinil, epoprostenol, selexipag). There is growing interest in the potential benefit of immunosuppressive therapies for SSc-PAH in addition to vasodilators.

Theoretically, treatment of patients with early, less severe disease should improve outcomes. Because patients with SSc-related PAH have a worse prognosis than those with idiopathic PAH despite modern therapies, SSc patients with PAH should be recommended to a tertiary care facility with a dedicated pulmonary hypertension clinic.

Cardiac Manifestations

Combined corticosteroids and immunosuppression can be used for myocarditis. Conventional treatment is recommended for symptomatic pericarditis (see Chapter 10), arrhythmias (see Chapter 9), and diastolic heart failure (see Chapter 5).

Gastrointestinal Manifestations

Gastroesophageal reflux, which occurs in most SSc patients, can be treated with proton pump inhibitors and conservative measures, including elevation of the head of the bed and avoidance of alcohol and caffeine. If untreated, reflux esophagitis can progress to distal esophageal stricture formation.

Patients with severe esophageal, gastric, or small bowel dysmotility may improve with the use of prokinetic drugs such as metoclopramide, erythromycin, or octreotide. Rotating antibiotics may be of assistance for bacterial overgrowth. For advanced small bowel involvement with malabsorption, supplementation of iron, calcium, and fat-soluble vitamins may be required. Occasionally, total parental nutrition is necessary. Unexplained iron deficiency anemia in SSc patients suggests the possibility of gastric antral vascular ectasias (i.e., watermelon stomach), which are treated with laser photocoagulation as first-line therapy.

Skeletal Muscle, Joint, and Tendon Manifestations

Bland myopathy usually is nonprogressive and is treated with physical therapy. If there is evidence of myositis with elevated serum levels of muscle enzymes or abnormal electromyography or muscle biopsy, corticosteroids and immunosuppressive therapy (e.g., methotrexate, azathioprine) may be helpful.

Patients with lcSSc or dcSSc can develop contractures of the hands due to tendon involvement. Physical therapy with daily stretching exercises directed at the finger joints should be instituted as soon as possible to prevent further loss of finger motion.

For a deeper discussion of these topics, please see Chapter 251, "Systemic Sclerosis (Scleroderma)," in *Goldman-Cecil Medicine*, 26th Edition.

SPECIAL CONSIDERATIONS

Patients with SSc are at increased risk for development of cancer, particularly hematologic malignancies such as lymphoma as well as lung and breast cancer. There is ongoing research focused on understanding the exact pathogenetic mechanisms. Underlying inflammation is thought to play a major role. The existence of specific autoantibodies

in addition to the use of certain immunosuppressive agents also have been implicated in playing role. Pending clarification of the pathophysiology leading to malignancy, it is important to perform age-appropriate screening in SSc patients.

Systemic Vasculitis

Kimberly P. Liang, Kelly V. Liang

DEFINITION AND EPIDEMIOLOGY

The primary systemic vasculitides are inflammatory disorders of blood vessels that are characterized by immune-mediated injury leading to vessel necrosis, thrombosis, stenosis, or some combination of these. Vessels in any organ may be affected, but each vasculitis is characterized by different preferential vessel size or territory and tissue targeting. Although these disorders are rare, they may be organ- or life-threatening, so prompt diagnosis and treatment are necessary. The vasculitides are defined according to the 1990 American College of Rheumatology (ACR) classification criteria and the 1994 Chapel Hill Consensus Conference (revised in 2012) (CHCC) based on generally affected vessel size (small, medium, or large). Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAVs) have known associations with characteristic autoantibodies. Fig. 83.1 shows the major types of vasculitides. Although the ACR and CHCC definitions were not designed as diagnostic criteria, classification criteria such as these are important in clinical research study design, treatment, and prognosis. The ACR and the European League Against Rheumatism (EULAR) are currently in the process of refining diagnostic and classification criteria for primary vasculitides.

Determining the incidence and prevalence of each of the vasculitides is challenging given the rarity of the disorders, imperfect classification criteria and definitions for epidemiologic purposes, and some clinicopathologic overlaps that occur between certain types (e.g., AAVs).

Small Vessel Vasculitis

ANCA-Associated Vasculitides

Granulomatosis with polyangiitis (GPA; previously known as Wegener's granulomatosis), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA; previously known as Churg-Strauss syndrome), and renal-limited vasculitis (RLV) affect small and medium-sized blood vessels and may be associated with ANCA. Various studies have shown AAVs to have an incidence of approximately 10 to 20 per million. The peak age at onset is 65 to 74 years, with a female-to-male ratio of 1.5:1. EGPA is the least common of the AAVs, with an incidence of approximately 1.0 to 3.0 per million, and it also has a weaker association with ANCA than GPA and MPA.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is a small vessel vasculitis that occurs most frequently in young children, with a peak age at onset of 4 to 6 years, but can also occur in adults. HSP accounts for almost half of all cases of childhood vasculitis. In children younger than 17 years of age, the annual incidence of HSP is approximately 20 per 100,000. Males are more commonly affected than females (approximately 2:1), and HSP occurs more frequently during the winter and spring months.

Medium Vessel Vasculitis

Polyarteritis nodosa (PAN) is a medium vessel vasculitis that is characterized by arterial aneurysmal and stenotic lesions of muscular arteries, often located at segmental and branch points. In contrast to small vessel vasculitis, renal involvement in PAN is not characterized by glomerulonephritis but rather by aneurysms and stenoses of renal arteries that may result in hypertension or renal dysfunction or both. In addition, ANCAs are usually negative in PAN. PAN may occur either as a primary vasculitis or secondary to viral infections, mainly hepatitis B or C, or human immunodeficiency virus (HIV). Determining the incidence of this vasculitis is difficult, because PAN and MPA were not differentiated until 1994.

Kawasaki disease is a medium vessel vasculitis most often seen in boys younger than 5 years of age. It is the second most common vasculitis in childhood after HSP, accounting for about 23% of all childhood vasculitis cases. In the United States, the annual incidence in children younger than 5 years old is 20 per 100,000.

Large Vessel Vasculitis

Giant cell arteritis (GCA), also known as temporal arteritis, is the most common form of vasculitis in adults. It is a large vessel vasculitis that typically affects patients of Eastern European descent, with a mean age at onset of 70 to 75 years. It affects women more commonly than men (3:1). About 40% of patients with GCA have the related condition, polymyalgia rheumatica (PMR), which is characterized by subacute onset of aching and stiffness in the muscles of the neck, shoulder girdle, and hip girdle. However, only 10% to 25% of patients with PMR have or will develop GCA.

Takayasu's arteritis (TAK), or "pulseless disease," is a rare large vessel vasculitis that was initially identified in young women from East Asia but is now described worldwide. In adults, the female-to-male ratio is about 8:1, with an average age at diagnosis in the mid-20s.

PATHOLOGY

For most of the systemic vasculitides, the etiology and pathogenesis of disease are largely unknown. It has been proposed that a number of diverse mechanisms contribute to the development of vascular inflammation and subsequent injury on the background of genetic susceptibility (Fig. 83.2). Proposed triggers of disease include infection and environmental exposures (e.g., chemicals, pollutants). For most vasculitides, these associations remain speculative.

Humoral and cellular immune responses, cytokine release, chemokine activation, and immune complex deposition are important in disease pathogenesis. Normal protective and repair processes in the vessel can also contribute to injury and ischemia. For example, after injury, cellular migration and proliferation occurring as

Fig. 83.1 The vascular spectrum of the vasculitides. (From Jennette JC, Falk RJ, Bacon PA, et al: 2012 revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides. *Arthritis Rheum* 2013;65:1-11.)

part of vessel repair can result in intimal hyperplasia, and the pro-coagulant milieu that is protective against hemorrhage may lead to thrombosis and vessel occlusion. Impairment of blood flow in injured vessels results in tissue ischemia and damage. The degree of blood flow impairment varies along a broad spectrum of severity and may depend on the type of vasculitis as well as the size and location of the vessels involved.

Among the AAVs, the pathology of GPA is typically characterized by necrotizing granulomatous inflammation of small blood vessels supplying the upper and lower respiratory tract. In both GPA and MPA, renal pathology shows a pauci-immune necrotizing crescentic glomerulonephritis. In EGPA, there is a strong association with allergic and atopic disorders, including allergic rhinitis, nasal polyposis, and asthma. Approximately 70% of patients with EGPA have elevated levels of immunoglobulin E (IgE) and eosinophilia of peripheral blood and tissue. Small vessel histopathology typically reveals transmural eosinophilic infiltrates with scattered plasma cells and lymphocytes and extravascular granulomas.

The pathology of HSP is characterized by a leukocytoclastic vasculitis of small vessels with IgA deposition seen on immunofluorescence. Various infectious agents, including bacteria and viruses, have been reported as triggers for HSP.

The pathology of GCA and TAK are very similar histologically. In both, large vessels demonstrate a lymphoplasmacytic inflammatory infiltrate. Giant cells and granulomas may be seen in the media, and lumen-occlusive arteritis may occur from exuberant intimal hyperplasia. Additional pathologic features include proliferation of vascular smooth muscle cells and fragmentation of the internal elastic lamina.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical manifestations of the systemic vasculitides are diverse and differ not only among disorders but also among patients. Typical clinical manifestations associated with the size of the affected vessel are detailed in [Table 83.1](#). Fever, weight loss, malaise, anorexia, arthralgias, and myalgias may occur with all vasculitides.

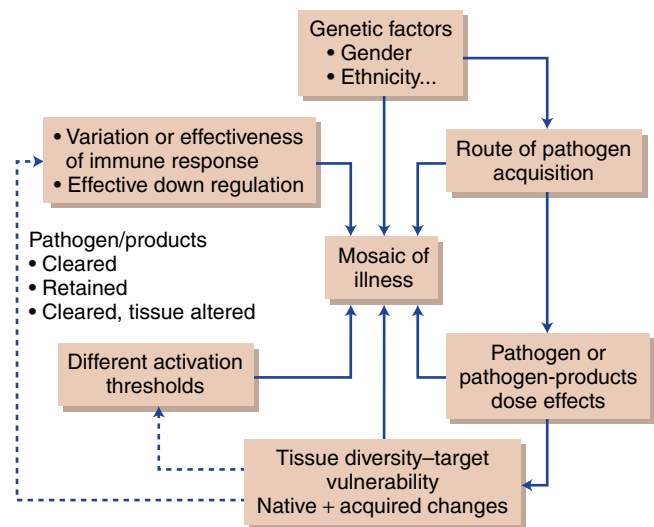

Fig. 83.2 Factors affecting disease vulnerability and expression.

Small Vessel Vasculitis

ANCA-Associated Vasculitides

GPA most commonly affects the sinuses and upper airway, the lungs, and the kidneys, although almost any organ system may be affected. Chronic refractory sinusitis, nasal crusting and ulcers, epistaxis, septal perforations, and otitis media are common presenting manifestations. Chronic nasal cartilaginous inflammation and destruction may lead to the characteristic “saddle nose” deformity. Lung involvement in GPA or MPA can include pulmonary nodules (often cavitory in GPA), infiltrates, or diffuse alveolar hemorrhage due to capillaritis. Importantly, life-threatening pulmonary hemorrhage may manifest simply as progressive acute dyspnea with hypoxia or respiratory failure, and not necessarily hemoptysis. Laryngotracheal disease may manifest as hoarseness or subglottic stenosis; orbital pseudotumors can also occur from GPA, and they may cause optic nerve compression, proptosis, and/or extraocular muscle palsies.

TABLE 83.1 Typical Clinical Features Based on Vessel Size^a

Large	Medium	Small
Limb claudication	Cutaneous nodules	Purpura
Asymmetrical blood pressures	Ulcers	Vesiculobullous lesions
Absence of pulses	Livedo reticularis	Alveolar hemorrhage
Bruits	Digital gangrene	Glomerulonephritis
Aortic dilatation	Mononeuritis multiplex	Mononeuritis multiplex
Aortic primary branch stenoses and/or aneurysms	Microaneurysms of mesenteric and/or renal branch arteries	Cutaneous extravascular necrotizing granulomas
		Splinter hemorrhages
		Scleritis, episcleritis, uveitis

^aConstitutional symptoms in all types are fever, weight loss, malaise, anorexia, arthralgias, and myalgias.

The renal manifestations in GPA, MPA, or RLV are those of nephritic syndrome, including acute renal failure, hematuria, hypertension, and subnephrotic proteinuria. Urine microscopy may reveal dysmorphic red blood cells. Renal biopsy reveals pauci-immune necrotizing crescentic glomerulonephritis. Additional organ manifestations that may occur in either GPA or MPA include neurologic, cutaneous, musculoskeletal, cardiovascular, and constitutional signs and symptoms. Patients may have subacute symptoms (weeks to months of sinusitis, arthralgias, and fatigue) or may exhibit acute “pulmonary-renal syndrome” with rapidly progressive glomerulonephritis and life-threatening alveolar hemorrhage with respiratory failure.

In EGPA, the clinical features comprise severe asthma, eosinophilia (>1500 cells/mL), and vasculitis involving two or more organs. Additional organ involvement in EGPA may include the nervous system, kidneys, skin, heart, and gastrointestinal tract. Sinus involvement in EGPA is typically not destructive as in GPA, and pulmonary infiltrates may be fleeting.

The diagnosis of any of the AAVs is most frequently established by tissue biopsy (e.g., kidney, lung, skin, sinus, nerve). ANCA testing plays an important diagnostic role in suspected small vessel vasculitis and is helpful in differentiating between GPA and MPA. Almost 90% of patients with renal disease have positive ANCA on testing. Most GPA patients have the cytoplasmic (cANCA) antiproteinase 3 (anti-PR3) type, whereas most MPA patients have the perinuclear (pANCA) antimyeloperoxidase (anti-MPO) type. The differential diagnosis for positive ANCA testing includes drug-induced effects, infections, and other autoimmune conditions. EGPA can be distinguished from other AAVs on the basis of a prior history of adult-onset asthma or allergic rhinitis and blood or tissue eosinophilia.

The differential diagnosis for any small vessel vasculitis includes infection, disorders of coagulation, drug toxicity, atherosclerotic and embolic disease, malignancy, and secondary vasculitides associated with other autoimmune diseases.

Henoch-Schönlein Purpura

Patients with HSP have lower extremity purpura, arthritis (typically of the large joints), abdominal pain, and renal disease at presentation (Fig. 83.3). In children, arthritis and abdominal pain affect about 75% of patients; the gastrointestinal manifestations may precede the purpura by up to 2 weeks and include hematochezia. The most common renal manifestation is microscopic hematuria with or without proteinuria.

Fig. 83.3 Palpable purpura on the lower extremities of a patient with small vessel vasculitis affecting the skin. These lesions are “palpable” because they are slightly raised (i.e., palpable even with the eyes closed), and they are typically nonblanching when palpated. (Modified from Molyneux ID, Moon T, Webb AK, Morice AH: Treatment of cystic fibrosis associated cutaneous vasculitis with chloroquine, *J Cystic Fibrosis* 9:439-441, 2010. Copyright 2010 European Cystic Fibrosis Society.)

The diagnosis of HSP is most often based on clinical and laboratory evidence, although skin or renal biopsy revealing IgA deposition may be helpful in solidifying the diagnosis. By classification criteria from the EULAR, patients with HSP must have purpura or petechiae with lower limb predominance and at least one of the following: arthritis or arthralgias; abdominal pain; histopathology demonstrating IgA deposition; and renal involvement. The differential for HSP includes other causes of abdominal pain, other causes of purpura in childhood, and hypersensitivity vasculitis. Hypersensitivity vasculitis is also a small vessel vasculitis that may occur in both children and adults and may be idiopathic or triggered by infections or drug exposures. It typically manifests as an isolated cutaneous leukocytoclastic (neutrophils and neutrophil debris in small vessels) vasculitis that is self-limited with treatment of the underlying cause (e.g., treatment of infection, discontinuation of drug culprit).

Medium Vessel Vasculitis

Polyarteritis Nodosa

The most common organ systems affected in PAN are the gastrointestinal, renal, and nervous systems. Mesenteric aneurysms or stenoses resulting in gut ischemia lead to symptoms of abdominal pain or “intestinal angina” (pain after eating). Renal artery aneurysms or stenoses result in hypertension or renal dysfunction, rather than glomerulonephritis as in MPA. Neurologic involvement may manifest as mononeuritis multiplex (painful asymmetrical sensory and motor peripheral neuropathy involving at least two separate nerve areas). Orchitis may be seen, manifesting as acute testicular pain. Anemia, elevated erythrocyte sedimentation rate or C-reactive protein or both, and hypertension (if renal artery involvement is present) are common. As in all vasculitides, constitutional symptoms may also be present.

The diagnosis of PAN is made based on angiographic or biopsy findings in the appropriate clinical setting. ANCAs typically are absent in PAN. A work-up for infection, including tests for hepatitis B and C and HIV, is warranted, given their known associations with PAN. The differential diagnosis includes MPA and mixed cryoglobulinemic vasculitis (defined by the presence of cryoglobulins in the blood). The latter vasculitis shares many clinical features with PAN, including

peripheral neuropathy, arthralgias, myalgias, purpura, and association with hepatitis C.

Kawasaki Disease

The clinical presentation of Kawasaki disease includes fever lasting longer than 5 days, conjunctival injection, oropharyngeal changes (strawberry tongue, mucous membrane desquamation), peripheral extremity changes (cutaneous desquamation), polymorphous rash, and cervical lymphadenopathy. Arthralgias, abdominal pain, hepatitis, aseptic meningitis, and uveitis have also been reported. Coronary artery aneurysms, one of the most serious complications of this vasculitis, appear within the first 4 weeks after onset of disease and are often detectable with echocardiography. Although areas of ectasia and small aneurysms may regress, larger aneurysms often persist and can result in coronary ischemia at any time after development, even into adulthood. Kawasaki disease is a triphasic disease, consisting of an acute febrile period lasting up to 14 days, a subacute phase of 2 to 4 weeks, and a convalescent phase that can last months to years. In the acute phase, the fever is persistent and high (>38.5° C) and is minimally responsive to antipyretics.

The differential diagnosis is wide and includes viral infections, toxin-mediated illnesses (e.g., toxic shock syndrome, scarlet fever), systemic juvenile idiopathic arthritis, hypersensitivity reactions, and drug reactions (e.g., Stevens-Johnson syndrome).

Large Vessel Vasculitis

Giant Cell Arteritis or Temporal Arteritis

At presentation, patients with GCA most commonly have new continuous headache, jaw claudication, visual disturbances (e.g., amaurosis fugax, diplopia), fatigue, and arthralgias. They are usually older than 50 years of age, have tender or thickened temporal arteries, and have an elevated erythrocyte sedimentation rate (>50 mm/hr by the Westergren method). Disease onset may be insidious or acute. Blindness due to anterior ischemic optic neuropathy occurs in 10% to 15% of patients with GCA and can occur at disease onset. Given the association between GCA and PMR, patients with PMR should be educated regarding signs and symptoms of GCA, and patients with GCA should be monitored for symptoms of PMR.

The diagnosis of GCA is often made by a biopsy of the superficial temporal artery. It is important to obtain a sufficient length of tissue (2 to 3 cm) because the vasculitis can have “skip lesions.”

Takayasu's Arteritis

The typical clinical manifestations of TAK include a systolic blood pressure difference of greater than 10 mm Hg between the arms, decreased brachial or radial artery pulses, bruits auscultated over the subclavian arteries or aorta, claudication of extremities, neck or jaw pain, headache, dizziness, hypertension, constitutional symptoms, arthralgias, and myalgias.

The diagnosis of TAK is often based on vascular imaging studies that demonstrate long, tapering stenotic lesions or aneurysmal lesions in the aorta and primary branches. The differential diagnosis includes syphilis, spondyloarthropathies, rheumatoid arthritis, inflammatory bowel disease, and connective tissue disorders. Vascular imaging studies including computed tomographic angiography and magnetic resonance angiography are typically performed for both diagnosis and disease surveillance.

TREATMENT AND PROGNOSIS

Small Vessel Vasculitis

ANCA-Associated Vasculitides

Glucocorticoids, often with other agents, are uniformly used to induce and maintain remission in AAV. They are typically initiated at a prednisone equivalent dose of 1 mg/kg/day with or without pulse

methylprednisolone (1 g IV daily × 3 days), followed by a gradual taper over approximately 6 to 12 months. In addition, the standard of care in both GPA and MPA has traditionally been cyclophosphamide, either oral or intravenous, for 3 to 6 months. This yields remission rates varying from 30% to 93% in GPA and from 75% to 89% in MPA.

Rituximab, an anti-CD20 chimeric monoclonal antibody that depletes B cells, was shown to be noninferior to cyclophosphamide in remission induction for AAV in several randomized controlled trials (RITUXVAS and RAVE trials).

Plasmapheresis, or plasma exchange therapy (PLEX), is often used in combination with remission induction therapy in patients with life-threatening disease such as alveolar hemorrhage, or rapidly progressive glomerulonephritis (pulmonary-renal syndrome). The MEPEX study was a randomized controlled trial comparing plasmapheresis with high-dose methylprednisolone for severe renal vasculitis. PLEX was shown to be superior to methylprednisolone in reducing the number of patients remaining dependent on dialysis. The PEXIVAS trial is an ongoing multicenter randomized trial evaluating adjunctive PLEX and two oral glucocorticoid regimens in severe AAV.

For limited (early) GPA, such as disease confined to the upper respiratory tract, methotrexate may be used for remission induction, rather than cyclophosphamide; this conclusion was supported by evidence in the NORAM trial. Trimethoprim-sulfamethoxazole was shown in two randomized controlled trials to be helpful in preventing relapses after remission induction in GPA.

For EGPA, mepolizumab, an anti-interleukin-5 monoclonal antibody, has recently been shown in a multicenter double-blind placebo-controlled trial to be superior to placebo in producing a higher proportion of patients in remission and longer duration of remission in those who were relapsing or refractory to standard therapy. Only 47% of those in the mepolizumab group relapsed, compared to 81% of those in the placebo group, over 52 weeks. Hence, mepolizumab is now being used as a steroid-sparing therapy in EGPA patients who are relapsing or refractory to standard therapy.

Remission maintenance therapies in AAV include methotrexate, azathioprine, mycophenolate mofetil, and rituximab (RTX). Because there are known risks of bladder cancer, hemorrhagic cystitis, and bone marrow suppression with cumulative use of cyclophosphamide, it no longer has a role in remission maintenance in AAV. The role of RTX in remission maintenance has recently shown strong evidence of efficacy based on the MAINRITSAN Trial. In this study, patients with newly diagnosed or relapsing GPA, MPA, or renal-limited ANCA-associated vasculitis (RLV) in complete remission were recruited after a cyclophosphamide-glucocorticoid regimen. Patients were randomly assigned to receive either 500 mg of RTX on days 0 and 14 and at months 6, 12, and 18 after study entry, or daily azathioprine until month 22. At month 28, major relapse had occurred in 29% in the azathioprine group and 5% in the RTX group. RTX is now also being used to maintain remission in AAV.

Although AAVs were once considered diseases with considerable mortality (80% at 2 years if left untreated), the prognosis has improved significantly over the last 30 years because of improved treatments. Patient survival is now reported to be as high as 45% to 91% at 5 years. Among AAV patients with renal involvement at presentation, 20% develop end-stage renal disease within 5 years.

Henoch-Schönlein Purpura

In mild cases, the therapy for HSP is simply supportive care (i.e., hydration and analgesics). However, glucocorticoids are commonly used to hasten the resolution of symptoms; early use of glucocorticoids has been associated with improved outcomes, especially when there is severe gastrointestinal involvement. In life-threatening cases

and in severe acute renal failure, additional immunosuppressive agents or plasmapheresis may be considered. The prognosis of HSP is generally good, with fewer than 1% of patients developing end-stage renal disease.

Medium Vessel Vasculitis

Polyarteritis Nodosa

Treatment of PAN includes glucocorticoids or nonsteroidal anti-inflammatory drugs (NSAIDs) or both. If disease is severe and persistent or relapsing, additional immunosuppressive agents are used, such as cyclophosphamide (especially for gastrointestinal or cardiac involvement), methotrexate, colchicine, or intravenous immunoglobulin (IVIG). In cases of PAN associated with hepatitis B or C, antiviral therapy is required not only for attaining control of the viral infection but also for treatment of the associated vasculitis itself. Corticosteroids and cyclophosphamide have improved patient outcomes, and the 1-year survival rate is now 85%. Prognosis is typically worse with more systemic complications such as renal or neurologic involvement.

Kawasaki Disease

Treatment of Kawasaki disease includes high-dose aspirin (30 to 100 mg/kg/day) for the first 48 hours, then 3 to 5 mg/kg/day. IVIG is standard therapy and has significantly decreased the incidence of coronary artery aneurysm complications in this disease. The initial IVIG dose is 2 g/kg within the first 10 days after presentation, with at least one repeat dose typically given if the first IVIG dose fails to improve the child's condition. The prognosis of Kawasaki disease, if promptly treated, is good; however, approximately 15% to 25% of patients develop coronary artery aneurysms that increase morbidity and mortality.

Large Vessel Vasculitis

Giant Cell Arteritis or Temporal Arteritis

Glucocorticoids are the cornerstone of therapy in GCA. To prevent vision loss, treatment should be instituted immediately (within 24 hours) if clinical suspicion for GCA is high or if visual disturbances are present. The initial dose of glucocorticoids is typically 1 mg/kg/day with a gradual taper. Most patients require a glucocorticoid treatment duration of 1 to 2 years, but it may be longer, especially in those with symptoms of PMR. In PMR without GCA, lower doses of glucocorticoids (10 to 20 mg/day of prednisone equivalent) are effective and provide prompt clinical response.

If patients experience relapse with glucocorticoid tapering, other immunosuppressive agents may be used. Methotrexate was shown in a meta-analysis of three randomized controlled trials to be a beneficial adjunctive agent in reducing risks of first and second relapses in GCA, with a significant decrease in the cumulative dose of glucocorticoids. Low-dose aspirin is an important adjunctive therapy in protecting against cranial ischemic events (level II evidence from two large retrospective studies). Recently, tocilizumab given subcutaneously weekly or every other week with a 26-week prednisone taper was found in a large 1-year randomized trial of GCA patients to result in more sustained glucocorticoid-free remission compared to either 26-week or 52-week prednisone tapering courses plus placebo. Hence, tocilizumab is now being used as an effective steroid-sparing agent to maintain remission in GCA.

Takayasu's Arteritis

Glucocorticoids are also the cornerstone of therapy for TAK; they are typically initiated at a dose of 0.5 to 1 mg/kg/day. Although most patients respond to the initial dose, relapses occur in more than 50% of patients during glucocorticoid tapering. Hence, steroid-sparing agents

are often used to aid in maintaining disease remission. The most commonly used steroid-sparing agents are methotrexate and azathioprine. In TAK, unlike in GCA and PMR, the tumor necrosis factor (TNF) inhibitors have shown promise in treating refractory disease. As in GCA, low-dose aspirin is believed to play a beneficial adjunctive role in preventing ischemic complications.

Revascularization interventions are often indicated in patients with TAK whose presenting symptoms include cerebrovascular disease, coronary artery disease, moderate to severe aortic regurgitation, renovascular hypertension, progressive limb claudication, or progressive aneurysm enlargement. Elective intervention should be performed when the disease is quiescent.

In both GCA and TAK, aortitis—a common manifestation of large vessel involvement—can lead to an increased risk of aortic aneurysm and subsequent dissection and rupture. In both GCA and TAK, disease flares occur in most patients, rendering them chronic, progressive, and relapsing conditions.

ADDITIONAL CONSIDERATIONS IN TREATMENT

Immunosuppressive therapy is associated with an increased risk of infection. Patients receiving combination therapy with moderate- to high-dose glucocorticoid (>20 mg/day of prednisone equivalents) and another immunosuppressive agent should also receive prophylaxis for *Pneumocystis jirovecii* pneumonia (previously known as PCP). Furthermore, infections can often mimic or result in flares of systemic vasculitis. Glucocorticoid therapy should never be discontinued abruptly, even in the setting of infection, because of the risk of adrenal crisis or disease relapse or both. In most cases, other immunosuppressive agents should be discontinued if infection is suspected or diagnosed.

Glucocorticoid therapy is a common cause of bone loss (osteopenia, osteoporosis). Because significant bone loss can occur even within the first 6 months of therapy, calcium and vitamin D supplementation should be initiated, and a baseline bone density study should be obtained. Consideration should be given to additional bone protection therapies (e.g., bisphosphonates). Methotrexate and cyclophosphamide are teratogenic, and cyclophosphamide may result in premature ovarian failure. These factors must be considered when choosing therapies for women of child-bearing age. Immunosuppressive agents also can be associated with bone marrow suppression and with additional long-term risks such as malignancy.

Crystal Arthropathies

Pooja Bhadbhade, Ghaith Noaiseh

GOUT

Gout is a disorder resulting from deposition of monosodium urate (MSU) monohydrate crystals in and around the tissues of joints causing attacks of acute inflammatory arthritis. Gout is associated with hyperuricemia, which is defined as a serum urate level greater than 6.8 mg/dL. The risk of gout is strongly associated with the degree of hyperuricemia. However, it is not a sufficient causative factor for the development of gout.

Typically, the disease presents as an acute and episodic monoarthritis affecting the lower extremities but can become recurrent, chronic, and deforming, affecting multiple joints. Tophi are a pathognomonic feature of gout resulting from accumulation of urate crystals in soft tissues or joints.

Epidemiology

In the United States, the prevalence of gout is 3.9%, affecting 8.3 million adults. The incidence rate ranges from 0.45 to 1 cases per 1000 person-years. There is a trend towards increasing incidence and prevalence, thought to be related to the aging population, increased use of certain medications such as diuretics, and the increasing frequency of risk factors for hyperuricemia including obesity, hypertension, renal disease, cardiovascular disease, and metabolic syndrome.

Men are three to six times more likely to have gout than women, but the sex disparity decreases with age due to loss of the uricosuric effect of estrogen after menopause. This also explains why gout is less common in premenopausal women.

Pathogenesis

Pathophysiology of Hyperuricemia

Uric acid is the end product of purine metabolism in humans. Unlike many other species, humans lack the enzyme uricase, which catalyzes the conversion of uric acid into allantoin, a very soluble metabolite. Most individuals maintain uric acid levels between 4 and 6.8 mg/dL and a total body uric acid pool of approximately 1000 mg. However, uric acid levels may increase, leading to supersaturation of urate in blood. MSU crystals form in some patients with serum uric acid levels greater than 6.8 mg/dL. Only about 20% of hyperuricemic patients develop gout during their lifetime. Factors controlling crystal formation are poorly understood, but urate solubility may be affected by temperature, pH, salt concentration, and cartilage matrix components. Urate crystallization is a critical step in the progression from asymptomatic hyperuricemia to clinical gout. Unlike soluble urate molecules, MSU crystals are a potent promoter of acute inflammation.

The total body uric acid pool depends on the balance between dietary intake, synthesis, and excretion. About two thirds of the daily excretion of uric acid occurs in the kidneys; the rest is eliminated by the gut. Renal underexcretion is the cause for approximately 90% of

hyperuricemia cases (Table 84.1). In the remaining 10%, hyperuricemia is caused by uric acid overproduction (>1000 mg in a 24-hour urine collection while on a standard Western diet) or by a combination of overproduction with renal underexcretion.

Fig. 84.1 summarizes the de novo biosynthesis and salvage pathways of purine metabolism. Abnormalities in the activities of key enzymes can lead to increased serum uric acid levels and development of gout. The de novo synthesis of purine is driven by the enzyme 5'-phosphoribosyl 1-pyrophosphate (PRPP) synthetase. In PRPP synthetase overactivity, overproduction of PRPP increases purine production. In salvage pathways, tissue-derived intermediate purine products (hypoxanthine, guanine, and adenine) are reutilized rather than undergoing further degradation to xanthine and uric acid. Deficiencies of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) activity result in impaired purine salvage and increased substrate for uric acid generation (Lysch-Nyhan syndrome and Kelley-Seegmiller syndrome). Overall, inborn errors of metabolism account for a small fraction of uric acid overproduction.

Most cases of uric acid overproduction result from increased reutilization of purine bases through salvage pathways (see Fig. 84.1). The purine precursors come from exogenous (dietary) sources or endogenous metabolism (synthesis and cell turnover). Purine-rich foods such as red meat, organ meats (e.g., sweetbreads, liver), seafood, high-fructose corn syrup-sweetened beverages, and alcohol comprise a significant portion of the daily purine load and can worsen hyperuricemia. On the other hand, consumption of low-fat dairy products is associated with reduced serum urate levels and may decrease the risk of gout.

A very small proportion of serum urate is bound to plasma proteins; therefore, urate is almost completely filtered in the glomeruli. Subsequent reabsorption and secretion are controlled by various organic acid transporters located on the luminal side of the proximal convoluted tubule epithelium. Only 10% of the initially filtered uric acid is eventually excreted in the urine.

In addition to the bidirectional transport of uric acid, organic acid transporters are also responsible for eliminating other organic acids and certain medications. The function of these transporters is affected by certain medications, including thiazides, low-dose aspirin, and cyclosporine, leading to decreased uric acid excretion and hyperuricemia. Conversely, medications such as probenecid and losartan, when excreted in the tubular lumen, exert their uricosuric effect by displacing uric acid from the transporter and increasing uric acid excretion. Certain genetic mutations affecting these transporters may lead to uric acid underexcretion. Renal insufficiency can cause hyperuricemia though decreased uric acid filtration.

Pathophysiology of Acute Gouty Attack

In some patients with prolonged hyperuricemia, tissue deposits of MSU crystals, called microtophi, form in the synovium and on the

surface of cartilage. During an acute attack, microtophi break apart, shedding a large number of MSU crystals into the joint space and activating synovial macrophages and fibroblasts that phagocytize the crystals. This, in turn, leads to the activation of a cytosolic multiprotein complex, the NALP3 (NACHT, LRR, and PYD domains-containing protein 3) inflammasome (Fig. 84.2). There is evidence that in acute gout, MSU crystals undergo phagocytosis, which activates the NLRP3 inflammasome, leading to the release of interleukin-1 β , which in turn induces further production of interleukin-1 β and other inflammatory mediators and activation of synovial lining cells and phagocytes.

MSU crystals undergo clearance by inflammatory cells that then undergo apoptosis. This, along with other mechanisms, eventually leads to resolution of the acute inflammatory process, typically after 10 to 14 days. Even after complete resolution of symptoms, a low-grade level of inflammation (intercritical inflammation) can persist in the otherwise asymptomatic joint. This inflammation may become clinically apparent in long-standing gout, contributing to development of tophi, chronic synovitis, cartilage loss, and bony erosions.

Clinical Features

Gout has three stages: asymptomatic hyperuricemia, acute intermittent gout, and chronic gout.

Acute Gouty Attacks

The classic picture of acute gout is rapid development of an inflammatory arthritis involving one or occasionally two joints. Severe pain, erythema, swelling, and exquisite tenderness typically occur. This clinical picture can be easily confused with that of septic arthritis or bacterial

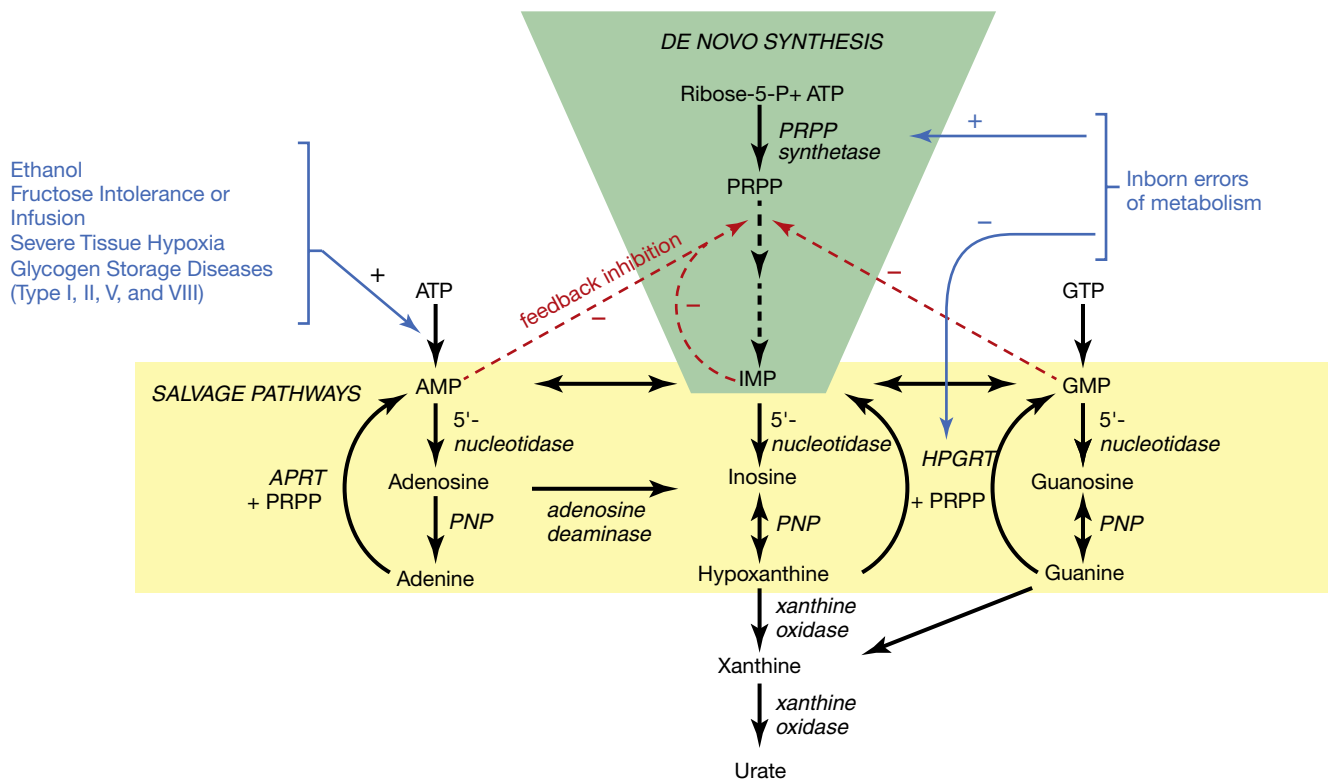

Fig. 84.1 The steps in the urate production pathways implicated in the pathogenesis of hyperuricemia and gout. *ADP*, Adenosine diphosphate; *APRT*, adenine phosphoribosyl transferase; *ATP*, adenosine triphosphate; *GMP*, guanosine monophosphate; *GTB*, guanosine triphosphate; *HPGRT*, hypoxanthine-guanine phosphoribosyl transferase; *IMP*, inosine monophosphate; *PNP*, purine nucleotide phosphorylase; *PRPP*, 5-ribosyl 1-pyrophosphate. (From Choi HK: Epidemiology, pathology, and pathogenesis, chap 12. In Stone JH, Crofford LJ, White PH, editors: Primer on the rheumatic diseases, ed 13, New York, 2008, Springer.)

cellulitis, because many patients can mount an intense systemic inflammatory response with fever, chills, and elevated inflammatory markers. The most commonly involved joints are the first metatarsophalangeal joint (podagra), followed by the joints of the ankle, midfoot, and knee. The pain intensifies over 8 to 24 hours. Acute attacks usually resolve, even without therapy, within 5 to 14 days. The clinical resolution is complete, and the patient is asymptomatic between attacks. Subsequently, involvement of the upper extremities can occur, affecting the small joints of the hands, wrists, and elbows.

Attack-provoking factors include use of diuretics, alcohol, surgery, trauma, and consumption of foods containing high purine levels. Each of these can cause fluctuation in serum urate levels. Initiation of urate-lowering therapy can trigger attacks in the early phase by the same mechanism.

Chronic Gout

This phase, called chronic gout (also referred to as *chronic tophaceous gout* or *chronic advanced gout*), typically develops 10 or more years after the onset of acute attacks. Transition to the chronic phase occurs if hyperuricemia is inadequately treated. During this transition, the intercritical periods are no longer free of pain. The involved joints become persistently uncomfortable and swollen, although the intensity of these symptoms is significantly less pronounced compared to acute attacks. On top of this persistent background pain, acute gouty attacks continue to occur, especially in the absence of therapy. Polyarticular involvement becomes much more frequent during this time, including joints of the upper limbs.

The pathognomonic feature of chronic gout is the *tophus*, a palpable collection of MSU crystals in soft tissue or joints. It is detected in about 75% of patients who have had gout for more than 20 years. The severity and duration of hyperuricemia determine the likelihood of tophus development. While tophi most often occur over the first metatarsophalangeal

joint, fingers, wrist, olecranon bursa, and helix of the ear, they can occur anywhere in the body. Infiltration of tophi into bone is thought to be the driving mechanism for bone erosion and joint damage in gout.

Diagnosis

The typical presentation of acute gouty arthritis in a characteristic joint distribution is strongly suggestive of the diagnosis, particularly if history of similar attacks that completely resolved is reported. However, detection of MSU crystals in the synovial fluid, bursa or tophus remains the diagnostic “gold standard.” Arthrocentesis is not only important to confirm clinical suspicion but also to rule out septic arthritis or other crystalline arthropathies. During acute attacks, intracellular, strongly negative birefringent, needle-shaped MSU crystals are typically identified by polarized compensated microscopy. MSU crystals can also be demonstrated in tophus aspiration (Fig. 84.3A).

Septic arthritis can coexist with urate crystals in the synovial fluid; Gram stain and culture should be performed and are necessary to exclude septic arthritis. Aspirated synovial fluid appears cloudy, and analysis shows inflammatory fluid (>2000 white blood cells per microliter), usually in the 10,000 to 100,000 white blood cells per microliter range. Serum uric acid is not a diagnostically reliable test during acute flares since serum urate level may be normal or even low. Laboratory testing may reveal leukocytosis and elevated inflammatory markers, both of which are nonspecific. Between attacks, MSU crystals can often be demonstrated in previously inflamed joints, providing support to the diagnosis.

Radiologic Features

During an acute attack, a plain radiograph may only show soft tissue swelling. In chronic advanced gout, well-defined, “punched out” juxta-articular erosions characterized by a sclerotic rim and overhanging

edges may be seen. The joint space is preserved until late in the course of the disease. Soft tissue masses may be detected in patients with tophi.

Dual-energy CT is a useful noninvasive imaging modality that can identify and color-code urate deposits in patients with gout. Ultrasound is a promising noninvasive tool in the diagnosis and management of gout.

Gout in Transplantation Patients

Hyperuricemia occurs much more frequently in transplantation patients using cyclosporine than in the normal population. Compared to patients with classic gout, transplant patients exhibit a significantly shorter period of asymptomatic hyperuricemia (0.5 to 4 years vs. 20 to 30 years), a shorter stage of acute intermittent gout (1 to 4 years vs. 10 to 15 years), and rapid development of tophi as early as 1 year after transplantation. Gouty attacks can be atypical and less severe, in part because of the concomitant use of prednisone.

Differential Diagnosis

Acute gouty arthropathy should be distinguished from septic arthritis and other crystal-induced arthropathies such as calcium pyrophosphate dihydrate (CPPD) deposition disease. The onset of acute CPPD arthropathy is usually less abrupt, and attacks tend to last longer, up to 1 month or more. Attacks occur more often in large joints such as the knee and wrist. Forms of spondyloarthropathies including reactive arthritis, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel-related arthritis can also present with monoarticular arthritis. In these disorders, synovial fluid is inflammatory, with a leukocyte count usually in the range of 10,000 to 50,000/ μ L, but crystals are absent and fluid culture is negative.

The diffuse and symmetric involvement of small joints in the hands and feet seen in chronic tophaceous gout can sometimes be confused with the symmetrical polyarthritis of rheumatoid arthritis and rheumatoid nodules. Aspiration of chronically inflamed joints or a tophus can help in distinguishing the two entities.

Treatment

Management strategies should focus on treating acute attacks, long-term management of hyperuricemia, patient education, and lifestyle modification.

Management of Acute Gouty Attack

Nonsteroidal anti-inflammatory drugs (NSAIDs) (such as naproxen and indomethacin) are typically used, and all seem to be equally

effective. A full dose should be immediately initiated. Therapy should be continued for 7 to 10 days to ensure complete resolution of symptoms. NSAIDs are inappropriate in patients with peptic ulcer disease, inflammatory bowel disease, or renal insufficiency, and they must be used with caution in patients at risk for cardiovascular events.

Oral colchicine can be effective if used within the first 24 to 48 hours of an acute attack. A commonly prescribed dose is 1.2 mg, followed by 0.6 mg 1 hour later in the first day, followed by dose tapering until the attack is resolved. Colchicine can cause nausea and diarrhea and therapy should be stopped if symptoms are severe. Use of intravenous colchicine is discouraged due to high risk of bone marrow suppression.

Intra-articular corticosteroid administration is a very effective therapy for patients with monoarticular or oligoarticular disease in whom other systemic therapies are contraindicated. Enteral or parenteral glucocorticosteroids are effective in patients with renal insufficiency, intolerance to NSAIDs or colchicine, or treatment resistance. This approach is usually reserved for polyarticular flares when intra-articular injection is not practical (i.e., too many involved joints). Prednisone, 30 to 50 mg daily, is commonly used.

Urate-lowering therapy (ULT) should *not* be interrupted during acute attacks. Prompt initiation of anti-inflammatory therapy at the onset of symptoms may shorten the duration of attacks.

Management of Intercritical and Chronic Gout

Urate-lowering therapy. The aim of chronic treatment is to prevent recurrent attacks and to minimize joint damage by depleting tophaceous deposits in joints and soft tissue. This is achieved by lowering uric acid level below 6 mg/dL. A target level of less than 5 mg/dL should be considered in patients with chronic tophaceous gout as this may result in a faster, more effective reduction in tophus size and flare frequency. Indications for ULT include two or more attacks in a single year, presence of tophi, chronic kidney disease CKD stage 2 or more, chronic gouty arthritis, or recurrent nephrolithiasis.

Three categories of urate-lowering therapies are available: uricostatic agents that decrease uric acid production, uricosuric agents that increase renal excretion of uric acid, and uricolytic agents that break up uric acid into other metabolites.

The optimal duration of ULT is not known, and lifelong therapy is usually recommended. ULT is typically started after resolution of an acute attack.

Uricostatic therapy. Allopurinol and febuxostat are xanthine oxidase inhibitors (XOI) that prevent urate formation. They are effective in managing gout in both overproducers and undersecretors of uric acid.

Allopurinol remains the first-line and most commonly used ULT agent, particularly in patients with chronic renal insufficiency, uric acid stones, or uric acid overproduction. If renal function is normal, a starting dose of 100 mg daily is recommended because higher doses may increase the risk of allopurinol-associated hypersensitivity, a potentially lethal complication. The risk of early flares may also be increased with higher doses. The dose should be titrated up by 100 mg increments every 2 to 5 weeks until the target uric acid level is reached. The maximal dose is 800 mg/day. Doses above 300 mg per day can be safely used in patients with renal impairment. Adverse events include rash (2%), hepatitis, vasculitis, eosinophilia, and bone marrow suppression.

Allopurinol-associated hypersensitivity is a serious side effect. Risk factors include concomitant use of thiazides and penicillin allergy. Fever, severe exfoliative dermatitis, eosinophilia, and hepatic and renal failure can occur. Febuxostat may be used in patients who do not achieve target uric acid levels despite adequate allopurinol dose titration or in patients with side effects to allopurinol.

Uricosuric therapy. Probenecid may be used as first-line ULT in uric acid undersecretors (<600 mg in a 24-hour urine collection) and in the setting of contraindication or intolerance to XOIs. Probenecid can be combined with an XOI to achieve target UA level, assuming adequate renal function. Probenecid is ineffective in patients with renal insufficiency (glomerular filtration rate <50 mL/minute) and is contraindicated in patients with nephrolithiasis. Patients should maintain high urine volume by drinking at least 1.5 L of fluid daily. Lesinurad is not used as monotherapy but can be combined with an XOI.

Uricosolytic therapy. Pegloticase (pegylated recombinant uricase), administered intravenously every 2 weeks, is used in cases refractory to conventional ULT. Rasburicase, another recombinant uricase, is used to prevent tumor lysis syndrome but has no role in the management of gout.

Future directions. As previously mentioned, IL-1 is a proinflammatory cytokine that has been shown to play an important role in pathogenesis of acute gouty attacks. As a result, IL-1 antagonists have been a target for recent drug therapies (see Fig. 84.2). These include anakinra, rilonacept, and canakinumab. Anakinra has been shown to be effective at treating acute flares, whereas rilonacept may be more effective in preventing gout flares due to its longer half-life. Canakinumab may be effective for both acute flares and flare prophylaxis when used with ULT. More formal clinical trials are needed comparing these therapies with conventional gout treatment.

Non-urate-lowering prophylactic therapy. Anti-inflammatory prophylaxis using low-dose colchicine or NSAIDs is usually recommended in conjunction with ULT to decrease the risk of flares that often accompany initiation of ULT. Prophylactic treatment is usually continued for 6 months after the serum uric acid goal is achieved.

Lifestyle modifications and education. A patient newly diagnosed with gout should be evaluated for potentially modifiable risk factors and associated illnesses such as obesity, hypertension, and hyperlipidemia. Decreased consumption of high-purine food (e.g., shellfish, liver, sweetbreads) and fructose-containing beverages, as well as reduced alcohol intake, should be recommended. Diuretics should be avoided, if possible.

Treatment of hyperuricemia in patients without gout. Allopurinol and rasburicase have been used for treatment and prevention of tumor lysis syndrome-associated hyperuricemia following chemotherapy. Otherwise, there is no evidence to support their use in asymptomatic hyperuricemia.

CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE

CPPD deposition disease is a clinically heterogeneous disorder that is characterized by the presence of intra-articular CPPD crystals. These crystals are deposited primarily in the cartilage, in the normally unmineralized pericellular matrix of hyaline and fibrocartilage. Calcification of the cartilage is promoted by alterations in the metabolism of inorganic pyrophosphate (PPi) and extracellular matrix leading to extracellular accumulation of PPi, which is necessary to the formation of CPPD crystals. Crystals are phagocytized by resident synovial macrophages, activating the intracellular NALP3 inflammasome complex and leading to recruitment and influx of neutrophils into the joint space.

CPPD deposition disease typically affects the elderly population. Up to 50% of individuals older than 85 years of age have radiographic evidence of CPPD crystal accumulation in cartilage (chondrocalcinosis), but most are asymptomatic. The most commonly involved joints are the knee menisci and the triangular fibrocartilage of the wrist. It is uncommon for CPPD deposition disease to affect patients younger than 50 years of age, unless the disease is familial or related to a metabolic abnormality (e.g., hyperparathyroidism, hemochromatosis).

CPPD deposition disease can present with acute CPPD crystal arthritis (pseudogout), chronic arthropathy with structural changes of osteoarthritis, or may be asymptomatic, presenting as an incidental finding of chondrocalcinosis on imaging. The most common clinical manifestation, occurring in more than 50% of patients, is a peculiar type of osteoarthritis called pseudo-osteoarthritis; it is a noninflammatory arthritis involving joints not typically affected by osteoarthritis, such as the wrist, shoulder, and metacarpophalangeal joints. A chronic symmetric polyarticular arthritis pattern resembling rheumatoid arthritis and a severe destructive arthropathy that mimics neuropathic arthritis on radiographs may be seen.

Acute pseudogout attacks may be precipitated by trauma, surgery (particularly parathyroidectomy for hyperparathyroidism), or severe medical illness. Administration of intra-articular viscosupplementation may also trigger a CPPD flare. Attacks are usually monoarticular or oligoarticular, similar to an acute gouty attack; if left untreated, they may last from a few days to a few months. The vigorous inflammatory response to CPPD crystals manifests as warmth, erythema, and swelling in and around the affected joint resembling acute gouty arthritis. Fever, elevated erythrocyte sedimentation rate, and leukocytosis can occur.

The diagnosis is confirmed by assessing synovial fluid for the presence of intracellular rod- or rhomboid-shaped crystals, which exhibit weakly positive birefringence when examined by compensated polarized light microscopy (see Fig. 84.3B). CPP crystals can be difficult to detect in some patients and are frequently missed in clinical specimens.

The presence of chondrocalcinosis (radio-dense deposits on radiographs) is highly suggestive of the diagnosis in the appropriate clinical context. Joint aspiration should always be performed to rule out septic arthritis. Importantly, joint infection can cause crystal shedding, leading to a concomitant crystal-related inflammation. Synovial fluid is inflammatory (>2000 white blood cells per microliter).

Therapy for CPPD deposition disease is indicated for symptomatic patients. There is no effective treatment to remove CPPD deposits from synovium or cartilage. Intra-articular glucocorticoid administration to the affected joints is effective. NSAIDs are also effective, but their potential toxicity in elderly patients may limit their use. Severe polyarticular attacks may require short courses of systemic corticosteroids.

In patients with frequent attacks, prophylactic daily low-dose colchicine may decrease the attack frequency.

APATITE-ASSOCIATED ARTHROPATHY

Abnormal accumulation of apatite (basic calcium phosphate, or BCP) may occur in hypercalcemic states and other illnesses. Unlike MSU or CPPD crystals, individual BCP crystals are not identifiable by polarized microscopy and can only be seen using electron microscopy. The most common presentation is calcific periarteritis, which typically occurs in the shoulder.

Milwaukee shoulder is an extremely destructive BCP-associated arthropathy that tends to affect elderly women. It is characterized by a large noninflammatory effusion (i.e., <2000 white blood cells per microliter) causing destruction of the rotator cuff and marked instability of the glenohumeral joint.

Other manifestations include acute reversible inflammatory arthropathies that resemble gout, referred to as *pseudo-pseudogout*, and ossifications along the anterolateral aspect of spinal vertebrae, termed *diffuse idiopathic skeletal hyperostosis* (DISH). Acute attacks of arthritis or bursitis may be self-limited. Intra-articular or periarticular injection of corticosteroids or the use of NSAIDs may shorten the duration and intensity of symptoms.

CALCIUM OXALATE DEPOSITION DISEASE

In calcium oxalate deposition disease, or oxalosis, calcium oxalate crystals are deposited in tissue. In primary oxalosis, a hereditary metabolic

disorder, this leads to nephrocalcinosis, renal failure, and early mortality. Secondary oxalosis complicates long-term hemo- and peritoneal dialysis; crystals are deposited in bone, cartilage, synovium, and periarticular tissue. Crystal shedding into the joint space may result in inflammatory arthritis of peripheral joints. Chondrocalcinosis or soft tissue calcifications can be seen on plain radiographs. The presence of strongly birefringent bipyramidal crystals in synovial fluid is characteristic. Treatment with NSAIDs, intra-articular corticosteroids, or colchicine usually results in moderate improvement.

Osteoarthritis

Joanne S. Cunha, Zuhal Arzomand, Philip Tsoukas

DEFINITION AND EPIDEMIOLOGY

Osteoarthritis, also known as degenerative joint disease, is the most common type of arthritis and musculoskeletal disease. It is a disease of synovial joints that encompasses the pathophysiologic changes that result from alterations in joint structure due to failed repair of joint damage and the individual's experience of illness, which is most often characterized by pain.

Osteoarthritis affects more than 300 million people worldwide. The prevalence of osteoarthritis continues to rise with the aging population, obesity epidemic, and increased numbers of joint injuries. Currently, more than 30 million adult Americans have some form of osteoarthritis.

The hands, knees, and hips are commonly affected joints in osteoarthritis. Hand and knee osteoarthritis is more common among women, especially after 50 years of age. Radiographic prevalence of osteoarthritis varies by the joint involved and often predates symptomatic osteoarthritis, with higher prevalence for knee and hand osteoarthritis than hip osteoarthritis.

Osteoarthritis is associated with major morbidity, reduced quality of life, and disability. There is increasing evidence of an association between osteoarthritis and cardiovascular disease. Osteoarthritis is one of the leading causes of long-term disability in the United States. Lower extremity osteoarthritis is the most common cause of difficulty with walking or climbing stairs, preventing an estimated 100,000 elderly Americans from independently walking from their bed to the bathroom.

Osteoarthritis has a large economic impact because of direct medical costs (e.g., physician visits, laboratory tests, medications, surgery) and indirect costs (e.g., lost wages, home care). With the aging of the US population, the burden of osteoarthritis is expected to increase in the coming years.

PATHOLOGIC FACTORS

The causes of osteoarthritis are complex and heterogeneous. Osteoarthritis may be classified as primary, or idiopathic, without a specific cause. Secondary osteoarthritis has an identifiable cause and is pathologically identical to primary osteoarthritis. Causes of secondary osteoarthritis include biomechanical factors, congenital or developmental deformities of the joint that alter its shape, traumatic events, metabolic disorders, and inflammatory conditions. Genetic predisposition, age, gender, and obesity are prominent risk factors as well.

The pathophysiology of osteoarthritis is not well understood. The cardinal feature in the pathogenesis of osteoarthritis is an imbalance between the destruction and repair of the joint tissues, with failure of the repair process and progressive loss of articular cartilage with associated remodeling of subchondral bone. In normal cartilage, there

is continuous extracellular matrix turnover with a balance between synthesis and degradation. In osteoarthritis, there is disproportion between these two processes, with an excess of matrix degradation that exceeds ongoing matrix synthesis. Excess degradation results from overproduction of catabolic factors such as proinflammatory cytokines and reactive oxygen species (Fig. 85.1).

Osteoarthritis is best defined as joint failure, a disease process that involves the total joint, including the subchondral bone, ligaments, joint capsule, synovial membrane, periarticular muscles, and articular cartilage. After bone trauma or repetitive injury, joint failure may result from joint instability caused by muscle weakness and ligamentous laxity, nerve injury and neuronal sensitization or hyperexcitability, or both.

Biomechanical contributors include repetitive or isolated joint trauma related to certain occupations or physical activities that involve repeated joint stress and predispose to early osteoarthritis. Altered joint shape may contribute to osteoarthritis through biomechanical factors, as may be seen with chronic patellar maltracking and the development of knee osteoarthritis and cam deformity or acetabular dysplasia in the development of hip osteoarthritis.

Obesity may contribute to osteoarthritis biomechanically or systemically through subacute or overt metabolic syndromes, both of which are associated with low-grade systemic inflammation. Age-related changes in habitus result in decreased muscle mass with a relative increase in visceral adiposity. This contributes to abnormal joint mechanics and low-grade systemic inflammation. Other age-related factors include changes in the extracellular matrix composition and structure leading to susceptibility for degeneration, mitochondrial dysfunction with increase in oxidative stress and promotion of catabolic activity, and chondrocyte dysfunction.

Inflammatory joint diseases, such as rheumatoid arthritis, may result in cartilage degradation and biomechanical effects that lead to secondary osteoarthritis. Crystal deposition diseases, osteonecrosis, Paget's disease, and metabolic disorders such as hemochromatosis, ochronosis, Wilson's disease, and Gaucher's disease are also associated with secondary osteoarthritis. High bone mineral density is associated with hip and knee involvement. Estrogen deficiency may be a risk factor for hip or knee disease, showcasing a hormonal influence. Candidate gene studies and genome-wide scans have identified several potential genetic markers. Patients often have a family history of osteoarthritis or joint replacement.

The destruction of the joint, including articular cartilage damage, osteophyte formation, and subchondral bone remodeling, is best viewed as joint failure and the final product of a variety of etiologic factors.

The earliest finding is fibrillation of the most superficial layer of the articular cartilage. Over time, disruption of the articular surface becomes deeper, with fibrillations extending to subchondral bone,

fragmentation of cartilage with release into the joint, matrix degradation, and eventually, complete loss of cartilage, leaving only exposed bone.

Early in the process, the cartilage matrix demonstrates increased water and decreased proteoglycan content, unlike the dehydration of cartilage that occurs with aging. The tidemark zone, separating the calcified cartilage from the radial zone, is invaded by capillaries. Chondrocytes initially are metabolically active and release a variety of cytokines and metalloproteinases, contributing to matrix degradation. In the later stages, this results in the penetration of fissures to the

subchondral bone and the release of fibrillated cartilage into the joint space.

An imbalance between tissue inhibitors of metalloproteinases and the production of metalloproteinases may be operative in osteoarthritis. Subchondral bone remodels and increases in density. Cystlike bone cavities containing myxoid, fibrous, or cartilaginous tissue may form. Osteophytes or bony proliferations at the margin of joints at the site of the bone-cartilage interface may form at capsule insertions. Osteophytes contribute to joint motion restriction and are thought to be the result of new bone formation in response to the degeneration

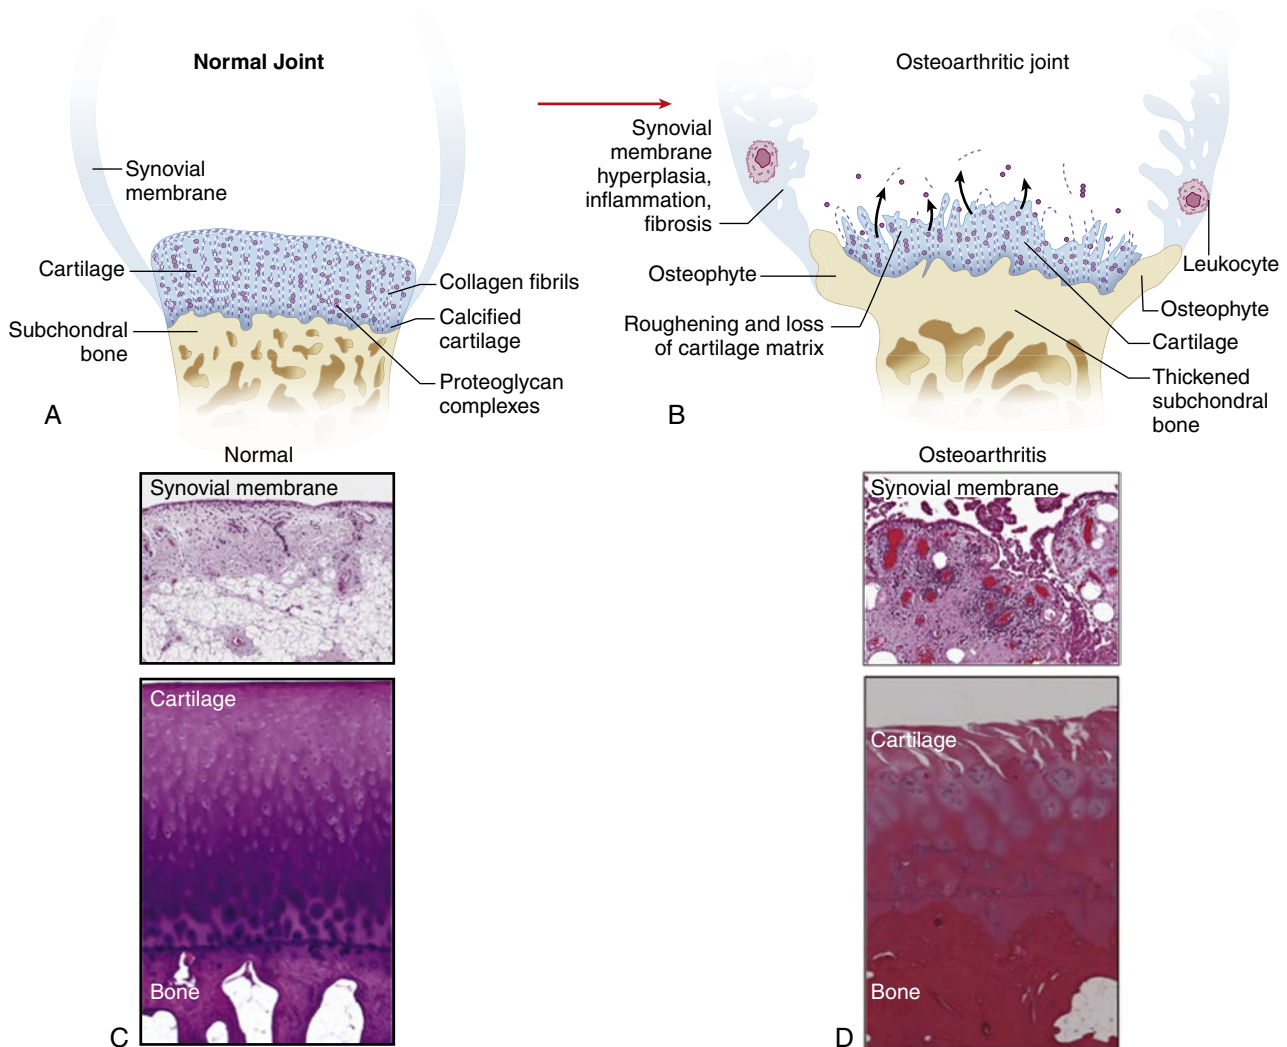

Fig. 85.1 Pathologic features of osteoarthritic joint tissues. (A) Features of a normal adult synovial joint. Healthy adult articular cartilage is characterized by a smooth surface and extracellular matrix (ECM) composed of a collagen type II fibrillar network and large proteoglycan complexes. The ECM is produced and maintained by the cellular components of cartilage, chondrocytes. The subchondral bone consists of a thin cortical layer and underlying trabecular bone. The synovial membrane lines the joint capsule and attaches at the cartilage-bone interface. In the normal state, it consists of a lining layer one or two cells thick, with underlying vascularized loose connective tissue. (B) Typical changes to tissues seen in osteoarthritis (OA). Enzymatic activities (ADAMTS4,5 and MMP-13 in particular) cleave proteoglycan and collagen components of the ECM, leading to loss of these molecules from the matrix. As the process advances, the articular cartilage thins and fibrillates, and eventually fissures down to the underlying bone are seen. Simultaneously, a remodeling response in the bone is observed. Thickening of the cortical subchondral bone layer occurs, and new bone growth at the margins appears as osteophytes. The synovial membrane changes observed in OA patients include lining layer hyperplasia, inflammation in the form of leukocyte infiltration, and fibrosis, which can be seen to varying degrees. Photomicrographs of human joint tissues showing these features are depicted in C (normal tissues) and D (OA tissues). (C and D, Courtesy Edward F. DiCarlo, MD, Hospital for Special Surgery, New York, NY.)

Fig. 85.1, cont'd (E and F) Radiographic features of osteoarthritic joint. Patient baseline (E) vs. 3 years later (F) showing typical features of OA progression including the development of medial joint space narrowing and osteophyte (spur outgrowth) at joint margins. The classical Kellgren and Lawrence grading system scores radiographs by five categories (scores 0–4) as follows: 0 = no osteoarthritis; 1 = small osteophyte of doubtful significance; 2 = definite osteophyte(s), possible joint space narrowing; 3 = multiple osteophytes, definite joint space narrowing, some subchondral sclerosis and possible deformity of bony ends; 4 = large osteophytes, marked narrowing of joint space, severe sclerosis of subchondral bone, and definite deformity of bone ends. (From Byers VV, Vincent TL: Osteoarthritis. In Goldman-Cecil Medicine, 26th edition, eds. Goldman L, Schafer AJ, Goldman-Cecil Medicine, 1698-1703.e2, Fig. 246-3.)

of articular cartilage, but the precise mechanism for their production remains unknown.

Several crystals have been identified in synovial fluid and other tissues from osteoarthritic joints, most notably calcium pyrophosphate dehydrate and hydroxyapatite. Although these crystals have potent inflammatory potential, their role in the pathogenesis of osteoarthritis remains unclear. Frequently, the crystals are asymptomatic and do not correlate with extent or severity of disease.

The diversity of risk factors predisposing to osteoarthritis suggests that many insults to the joints, including biomechanical trauma, chronic articular inflammation, and genetic and metabolic errors, can contribute to or trigger the cascade of events that results in the characteristic pathologic features described earlier. At some point, the cartilage degradation process becomes irreversible. With progressive changes in articular cartilage, joint mechanics become altered, perpetuating the degradative process.

CLINICAL PRESENTATION

Pain is the characteristic feature of osteoarthritis and the most common presenting symptom. Pain is usually worse with activity or weight bearing and better with rest. In later stages, pain may also occur at rest. Early in the disease course, pain tends to be transient, intermittent, and unpredictable. The pain may be characterized as severe, and its unpredictable nature is an extremely bothersome feature that limits activity and affects quality of life. With disease progression, pain tends to become constant but is reported to be less severe and have an aching quality. Other prominent symptoms, such as stiffness, gelling, fatigue, and sleep disturbance, often lead to functional limitation and disability.

Pain tends to be localized to the specific joint involved, but it may be referred to a more distant site. The cause of pain is unclear but is likely to be heterogeneous. Pain may result from interactions among structural pathology; the motor, sensory, and autonomic innervation of the joint; and pain signal processing at the spinal and cortical levels. Specific individual and environmental factors also may be important. A subset of patients may have neuropathic pain.

Patient-specific factors may modify pain reception and pain reporting. Patients' affective status, such as depression, anxiety, and anger, may influence the level of pain reported. Their cognitive status, including pain beliefs, expectations, and memories of past pain, and their communication skills may determine how pain is perceived and reported. Studies have shown that demographic factors such as age,

sex, socioeconomic status, race or ethnicity, and cultural background may affect pain reporting.

Patients may have stiffness, particularly after prolonged inactivity, but it is not a major feature of osteoarthritis and usually lasts for less than 30 minutes. Patients do not report systemic features such as fever.

Examination of an involved joint may reveal tenderness and bony enlargement. Joint effusion and soft tissue swelling may occur with knee involvement, but they tend to be intermittent. Persistent inflammation with joint warmth, erythema, effusion, and soft tissue swelling is usually not seen. Crepitus with movement, limitation of joint motion, and joint deformity, malalignment, and joint laxity or instability may be detected on evaluation. Joint deformity as manifested by lateral subluxation is fixed and not reducible. Muscle weakness and gait abnormalities may be seen.

Several subtypes of osteoarthritis have been identified. The nodal form involves the distal interphalangeal joints (DIPs), also known as Heberden nodes, and the proximal interphalangeal joints (PIPs), also known as Bouchard nodes. It is most common in middle-aged women, typically those with a strong family history among first-degree relatives. Erosive, inflammatory osteoarthritis is associated with prominent destructive changes, especially in the finger joints, and it is often quite symptomatic. Generalized osteoarthritis is characterized by involvement of the DIP, PIP, and first carpal-metacarpal joints, as well as the knees, feet, and hips.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of osteoarthritis is based on the signs and symptoms previously outlined. Although there are characteristic radiographic features, they are not necessary to make the clinical diagnosis. Imaging may be used to confirm the diagnosis and exclude other diseases, but radiographs are insensitive and may not show findings early in the disease course. Despite radiographic findings of osteoarthritis, pain may have other sources, such as bursitis, tendonitis, or referred pain. For example, hip disease may manifest as knee pain.

Osteoarthritis must be distinguished from inflammatory joint diseases such as rheumatoid arthritis and the spondyloarthropathies. This is accomplished by identifying the characteristic pattern of joint involvement and the nature of the individual joint deformity. Joints commonly involved in osteoarthritis include the DIPs, PIPs, first carpal-metacarpal, cervical and lumbar spine facet joints, hips, knees, and first metatarsophalangeal joints. Involvement of the metacarpal phalangeal joints (MCPs), wrist, elbows, shoulders, and ankles is

uncommon, except in the case of trauma, congenital disease, or coexisting endocrine or metabolic disease.

The characteristic radiographic features of osteoarthritis include joint space narrowing as a surrogate for cartilage loss; osteophytes and subchondral sclerosis as an indicator of new bone formation, which is characteristic of osteoarthritis; and subchondral cysts as a manifestation of myxoid or fibrous degeneration of subchondral bone. Bone attrition and subchondral bone remodeling may result in changes in bone shape. Magnetic resonance imaging (MRI) can demonstrate additional morphologic abnormalities, such as bone marrow lesions in subchondral bone, meniscal degeneration, and synovitis. Musculoskeletal ultrasonography is an alternative imaging modality used to identify osteoarthritic pathologic changes within the joint space, soft tissue, cartilage, and bone surfaces. Ultrasound can identify osteoarthritis features such as osteophytes, morphologic degeneration in cartilage, synovitis, and synovial fluid.

The pain and swelling of erosive hand osteoarthritis may suggest rheumatoid arthritis, although systemic inflammatory signs and other typical features of rheumatoid arthritis are absent. Patients with osteoarthritis typically have a negative rheumatoid factor, normal inflammatory markers such as erythrocyte sedimentation rate and *c*-reactive protein, normal complete blood count, and normal antinuclear antibody tests. Synovial fluid examination is typically noninflammatory with clear viscous fluid and normal white blood cell count. The prevalence of false-positive findings of rheumatoid factor and antinuclear antibody, sometimes in significant titers, is higher with increasing age. Osteoarthritis more commonly affects the distal small joints in the hands (DIPs > PIPs > MCPs and wrists), whereas rheumatoid arthritis more commonly affects proximal small joints in the hands (MCPs and wrists > PIPs > DIPs).

TREATMENT

The natural history of osteoarthritis includes periods of relative stability interspersed with rapid deterioration. Management should be individually tailored and may include a combination of nonpharmacologic, pharmacologic, and surgical approaches. The primary goal of treatment is to improve pain and function and reduce disability.

Patients should be educated regarding the objectives of treatment and the importance of lifestyle changes, exercise, pacing of activities, and other measures to unload the damaged joints. The initial focus should be on self-help and patient-driven treatments rather than on passive therapies. Patients should be encouraged to adhere to nonpharmacologic and pharmacologic therapies. Physical therapists may be helpful in providing instruction in appropriate exercises to reduce pain and preserve functional capacity. For knee and hip osteoarthritis, assistive devices such as walking aids may be useful. In patients with first carpometacarpal joint osteoarthritis, hand orthoses are recommended. Graded regular aerobic, aquatic exercise, muscle-strengthening, and range-of-motion exercises are beneficial. Tai chi has been shown to have beneficial effects not only in the treatment of knee and hip osteoarthritis, but also in improving quality of life and depression.

Overweight patients should be encouraged to lose weight. A combination of dietary weight loss in conjunction with exercise results in improvement of both pain and function compared to either intervention alone, though long-term weight management may be challenging for patients. A knee brace can reduce pain, improve stability, and diminish the risk of falling for patients with knee osteoarthritis and mild or moderate varus or valgus instability. Advice concerning appropriate footwear is also important. Spinal orthoses may provide benefit to patients with significant cervical or lumbar involvement. Local applications of heat, ultrasound, or transcutaneous electrical nerve

stimulation (TENS) may provide short-term benefit in these patients. In patients with knee and hip osteoarthritis, TENS is not recommended as there have been limited studies and lack of benefit. Acupuncture may also offer symptomatic benefit for patients with osteoarthritis, but its efficacy in knee, hip, and hand osteoarthritis is still debatable as studies have shown variable results.

Pharmacologic therapy provides symptomatic relief but does not alter the course of the disease. Pharmacologic therapy should therefore be selected based on its relative efficacy and safety. The use of concomitant medications in the setting of comorbidities should be taken into account.

Acetaminophen (up to 3 g/day with caution) may be an effective initial oral analgesic for mild to moderate pain, though it may not provide sufficient benefit on its own. In patients with symptomatic osteoarthritis, nonsteroidal anti-inflammatory drugs (NSAIDs) should be used at the lowest effective dose, although their long-term use should be avoided if possible. If patients are at risk for increased gastrointestinal toxicity, a cyclooxygenase-2 (COX2)-selective agent or a nonselective NSAID with co-prescription of a proton pump inhibitor or misoprostol for gastroprotection should be considered. All NSAIDs, including nonselective and COX2-selective agents, should be used with caution in patients with cardiovascular risk factors and chronic kidney disease. Topical NSAIDs and capsaicin may be effective alternatives to oral analgesic or anti-inflammatory agents in knee and hand osteoarthritis and may be used as adjunctive agents, particularly in elderly patients. If patients fail the aforementioned, find other therapies ineffective, and are not surgical candidates, then tramadol, a weak opioid receptor agonist, may also be used in these select cases. Non-tramadol opiates are discouraged as they pose risk for an increase of adverse effects that typically outweighs their benefits. In select patients that have exhausted other therapies and medications, non-tramadol opioids may be used for the shortest possible length of time, given the limited pain control with longer duration of these medications.

Despite the popularity of these products, meta-analyses have shown that oral glucosamine and chondroitin sulfate have limited benefit in patients with knee osteoarthritis and are currently not recommended in knee, hip or hand osteoarthritis.

Other agents, such as duloxetine, when compared to placebo, were shown to reduce pain and improve function in a meta-analysis. Duloxetine can be used in pain management and studies have shown efficacy in the treatment of osteoarthritis.

Occasional injection of intra-articular corticosteroids (usually no more than once every 4 months) may provide modest short-term symptomatic benefit with minimal toxicity, especially in the knee. Studies have shown that patients given more frequent corticosteroid injections (i.e., every 3 months) lose greater cartilage volume than those given a corticosteroid injection every 4 months, but the significance of this cartilage loss is unclear. Patients with moderate to severe pain and effusion or other local signs of inflammation may be more responsive to these injections. Intra-articular hyaluronate appears to have little or no benefit based on current evidence. Recent trials evaluated platelet-rich plasma injections and mesenchymal stem cell injections in osteoarthritis, but these are not currently recommended because there is a concern in the techniques used for these injections as well as the heterogeneity and lack of standardization of available preparations.

Surgical management includes total joint replacement, which is extremely effective in relieving pain, decreasing disability, and improving function. With improvements in surgical technique and technology, the indications for total joint replacement have expanded to include younger and older age groups. Other surgical options include osteotomy and uni-compartmental knee replacement.

Referral to an orthopedic surgeon should be considered in cases where other treatment options have been exhausted and quality of life is greatly reduced, including joint pain disrupting sleep, restriction of walking distance, and limiting participation in daily activities. Arthroscopy is not recommended for the management of knee osteoarthritis.

PROGNOSIS

Given the obesity epidemic and the marked contact loads that increased weight places on the knee, obesity is likely the most important modifiable risk factor for the development and progression of knee osteoarthritis. One kilogram of weight loss decreases the load on the knee by 4 kg. Varus and valgus malalignments have also been identified as important risk factors for the progression of knee osteoarthritis.

Nonarticular Soft Tissue Disorders

Niveditha Mohan

INTRODUCTION

The nonarticular soft tissue disorders account for most musculoskeletal complaints in the general population. These disorders include a large number of anatomically localized conditions (e.g., bursitis, tendinitis) and fibromyalgia syndrome, a generalized pain disorder. For most nonarticular soft tissue conditions, the etiologic factors and pathogenesis are poorly understood.

Once the location of the symptom is defined, (e.g., shoulder pain), the specific structure that is involved should be identified (e.g., supraspinatus tendon, subacromial bursa) using a careful history and physical examination. In the case of back pain, precise anatomic delineation of the structure involved (e.g., intervertebral disk, facet joint, ligament, paraspinal muscle) is more likely to require advanced imaging. When the patient complains of diffuse pain, it is imperative to evaluate for contribution of local pain that may be driving the diffuse pain, with a thorough physical examination.

EPIDEMIOLOGY

Precise data for prevalence or incidence of most nonarticular soft tissue syndromes are not available, but these conditions account for up to 30% of all outpatient visits. Fibromyalgia is considered to be the most common cause of generalized musculoskeletal pain in women between the ages of 20 and 55 years. The global mean prevalence is 2.7%.

ETIOLOGIC FACTORS AND PATHOGENESIS

The precise pathophysiology of most nonarticular soft tissue disorders remains unknown, although predisposing factors, such as trauma, overuse, repetitive activities (e.g., tennis elbow, lateral epicondylitis) or biomechanical factors (e.g., leg-length discrepancy in trochanteric bursitis), can be identified in many cases.

The term *tendinitis* implies tendon sheath inflammation, but small tendon tears, periostitis, and nerve entrapment have been proposed as potential mechanisms. Similarly, although the term *bursitis* implies bursal inflammation, demonstrable inflammation is difficult to find. In some cases (e.g., acute bursitis of the olecranon or prepatellar bursa), the mechanism is an acute inflammatory response to sodium urate crystals deposited in the soft tissue, an extra-articular manifestation of gout. The favorable response of tendinitis and bursitis to anti-inflammatory agents, including corticosteroids, supports the view that at least one component of these syndromes is the result of an inflammatory process.

Fibromyalgia is the current term for chronic widespread musculoskeletal pain for which no alternative cause can be identified. The underlying pathology is due to alterations in central nervous system

(CNS) function leading to augmented nociceptive (caused by pain) processing that leads to the development of CNS-mediated somatic symptoms of fatigue, sleep, memory and mood difficulties in addition to the chronic widespread pain. There may also be alterations in the immune system leading to an enhanced inflammatory state with emerging evidence that some of the pathobiology of fibromyalgia may involve altered nociceptor sensitivity. This disorder often begins in childhood or adolescence, and individuals who eventually go on to develop FM are more likely to experience headaches, dysmenorrhea, temporomandibular joint disorder, chronic fatigue, irritable bowel syndrome and other functional gastrointestinal tract disorders, interstitial cystitis/painful bladder syndrome, endometriosis, and other regional pain syndromes (especially back and neck pain).

CLINICAL PRESENTATION

Many of the soft tissue rheumatic syndromes involve bursae, tendons, ligaments, and muscles. Bursae are closed sacs lined with mesenchymal cells that are similar to synovial cells; the sacs are strategically located to facilitate tissue gliding. Subcutaneous bursae (e.g., olecranon, prepatellar) form after birth in response to normal external friction. Deep bursae (e.g., subacromial bursa) usually form before birth in response to movement between muscles and bones and may or may not communicate with adjacent joint cavities. Adventitious bursae (e.g., over the first metatarsal head) form in response to abnormal shearing stresses and are not uniformly found. Although most forms of bursitis involve isolated, local conditions, some may be the result of systemic conditions such as gout.

Tendinitis, bursitis, and myofascial disorders should be distinguished from articular disorders. In most cases, this can be accomplished by a careful examination of the involved structure ([Table 86.1](#)). General principles of the musculoskeletal examination are as follows:

1. Observation: If deformity or soft tissue swelling is detected, is it fusiform (i.e., surrounding the entire joint in a symmetrical fashion) or is it localized? Local rather than fusiform deformity distinguishes nonarticular disorders from articular disorders.
2. Palpation: Is tenderness localized or in a fusiform distribution? Is there an effusion? Local (not fusiform or joint line) tenderness distinguishes nonarticular disorders from articular disorders. An effusion typically indicates an articular disorder.
3. Assessing range of motion: The musculoskeletal examination includes the assessment of active range of motion (i.e., patient attempts to move the symptomatic structure) and passive range of motion (i.e., examiner moves the symptomatic structure). Articular disorders usually are characterized by equal impairment in active and passive movements as a result of the mechanical limitation

TABLE 86.1 Differentiating Nonarticular Soft Tissue Disorders From Articular Disease

Manifestation	Nonarticular Soft Tissue Disorders	Articular Disease
Limitation of motion	Active > passive	Active = passive
Crepitus of articular surfaces (structural damage)	0	+/0
Tenderness		
Synovial (fusiform pattern)	0	+
Local	+	0
Swelling		
Synovial (fusiform pattern)	0	+
Local	+/0	0

+, Present; 0, absent.

of joint motion resulting from proliferation of the synovial membrane, an effusion, or derangement of intra-articular structures. Impairment of active movement characterizes nonarticular disorders to a much greater degree than passive movement.

Clinical symptoms include pain, warmth, and swelling over the site of the bursa that are worse with activity and better with rest. Bursitis can be distinguished from tendinitis by the pain during active and passive range of movement; in tendinitis, pain is elicited only during active range of movement. However, for many patients there is concomitant bursitis and tendinitis.

Muscle sprains or strains are typically diagnosed based on a history of preceding activity causing the symptom along with pain and limitation of movement when the muscle is contracted against resistance. The clinical signs and symptoms of chronic myofascial pain are more nonspecific and characterized by a distribution that is frequently nonanatomic and associated with hyperalgesia in the involved area.

Fibromyalgia syndrome is characterized by widespread pain and a host of other symptoms, including insomnia, cognitive dysfunction, depression, anxiety, recurrent headaches, dizziness, fatigue, morning stiffness, extremity dysesthesia, irritable bowel syndrome, and irritable bladder syndrome.

DIAGNOSIS AND TREATMENT

Septic Bursitis

Superficial forms of bursitis, particularly olecranon bursitis and prepatellar and occasionally infrapatellar bursitis, are more frequently infected or involved with crystal deposition than are deep forms of bursitis, presumably due to direct extension of organisms through subcutaneous tissues. Most commonly, *Staphylococcus aureus* is isolated from infected superficial bursae. Septic bursitis should be suspected when there is cellulitis, erythema, fever, and peripheral leukocytosis.

Definitive diagnosis and exclusion of infection of subcutaneous bursae usually require aspiration of the distended bursa. The bursal fluid should be assessed for cell count, Gram stain, and culture and examined for crystals.

Nonseptic Bursitis

Nonseptic bursitis frequently appears as an overuse condition associated with sudden or unaccustomed repetitive activity of the associated extremity. The two most common types of bursitis are subacromial and trochanteric bursitis (Table 86.2).

Subacromial bursitis is the most common overall cause of shoulder pain over the lateral upper arm or deltoid muscle that is exacerbated

TABLE 86.2 Bursitis Syndromes

Location	Symptom	Finding
Subacromial	Shoulder pain	Tender subacromial space
Olecranon	Elbow pain	Tender olecranon swelling
Iliopectineal	Groin pain	Tender inguinal region
Trochanteric	Lateral hip pain	Tender at greater trochanter
Prepatellar	Anterior knee pain	Tender swelling over patella
Infrapatellar	Anterior knee pain	Tender swelling lateral or medial to patellar tendon
Anserine	Medial knee pain	Tender medioproximal tibia (below joint line of knee)
Ischiogluteal	Buttock pain	Tender ischial spine (at gluteal fold)
Retrocalcaneal	Heel pain	Tender swelling between Achilles tendon insertion and calcaneus
Calcaneal	Heel pain	Tender central heel pad

with abduction of the arm. It occurs as a result of compression of the inflamed rotator cuff tendon between the acromion and humeral head. Because the rotator cuff forms the floor of the subacromial bursa, bursitis in this location often results from tendinitis of the rotator cuff. Occasionally, subacromial bursitis or rotator cuff tendinitis results from osteophyte compression of the rotator cuff tendon originating from the acromioclavicular joint. The differential diagnosis includes tears of the rotator cuff, intra-articular pathologic mechanisms of the glenohumeral joint, bicipital tendinitis, cervical radiculopathy, and referred pain from the chest.

Trochanteric bursitis is the result of inflammation at the insertion of the gluteal muscles at the greater trochanter. It produces lateral thigh pain, which is often worse when the patient lies on the affected side. Women seem to be more prone to develop this condition, perhaps because of increased traction of the gluteal muscles as a result of the relatively broader female pelvis. Other potential risk factors include weight gain, local trauma, overuse activities such as jogging, and leg-length discrepancies (primarily on the side with the longer leg). These factors are thought to lead to increased tension of the gluteus maximus on the iliotibial band, producing bursal inflammation. The differential diagnosis of trochanteric bursitis includes lumbar radiculopathy (particularly of the L1 and L2 nerve roots), meralgia paresthetica (i.e., entrapment of the lateral cutaneous nerve of the thigh as it passes under the inguinal ligament), true hip joint disease, and intra-abdominal pathologic processes. Other bursitis syndromes are less common and listed in Table 86.2.

Septic bursitis is treated with a combination of serial aspirations of the infected bursa and antibiotics, initially directed against *S. aureus* and then adjusted depending on the results of bursal fluid cultures. Recurrent septic bursitis may need surgical excision of the bursa. The approach to nonseptic bursitis should include rest, local heat, and unless contraindicated by peptic ulcer disease, renal disease, or advanced age, nonsteroidal anti-inflammatory drugs (NSAIDs).

The most effective approach usually is local injection of a corticosteroid. Superficial bursae with obvious swelling should be aspirated before the corticosteroid is injected. For deep bursae, such as the subacromial or trochanteric bursae, aspiration yields little or no fluid, and direct injection of a corticosteroid without attempted aspiration is reasonable. Caution is advised in attempted aspiration or injection of the iliopsoas bursa, the ischiogluteal bursa, and the gastrocnemius-semimembranosus bursa (i.e., Baker cyst). These bursae lie close to important neural and vascular structures, and aspiration under ultrasound guidance is recommended.

TABLE 86.3 Tendinitis Syndromes

Location	Symptom	Finding
Extensor pollicis brevis and abductor pollicis longus (de Quervain tenosynovitis)	Wrist pain	Pain on ulnar deviation of the wrist, with the thumb grasped by the remaining four fingers (i.e., Finkelstein test)
Flexor tendons of fingers	Triggering or locking of fingers in flexion	Tender nodule on flexor tendon on palm over metacarpal joint
Medial epicondyle	Elbow pain	Tenderness of medial epicondyle
Lateral epicondyle	Elbow pain	Tenderness of lateral epicondyle
Bicipital tendon	Shoulder pain	Tenderness along bicipital groove
Patella	Knee pain	Tenderness at insertion of patellar tendon
Achilles	Heel pain	Tender Achilles tendon
Tibialis posterior	Medial ankle pain	Tenderness under medial malleolus with resisted inversion of ankle
Peroneal	Lateral midfoot or ankle pain	Tenderness under lateral malleolus with passive inversion

Tendinitis

Most tendinitis syndromes are the result of inflammation in the tendon sheath. Overuse with microscopic tearing of the tendon is the most common risk factor for tendinitis. Tendon compression by an osteophyte may occur, such as in the rotator cuff tendon compressed by an osteophyte originating from the acromioclavicular joint.

A common form of tendinitis is lateral epicondylitis, also known as *tennis elbow* (Table 86.3). This is a common overuse syndrome among tennis players, but it can be seen in many other settings requiring repetitive extension of the forearm (e.g., painting overhead). The diagnosis is confirmed by exclusion of elbow joint pathology and the finding of local tenderness at the lateral epicondyle, which is typically exacerbated by forearm extension against resistance. Enthesopathies such as Achilles tendinitis and peroneal and posterior tibial tendinitis may occur in the setting of an underlying seronegative arthropathy such as Reiter disease or psoriatic arthritis. A history and clinical evaluation for these disorders should be pursued for the appropriate patient.

Therapy for tendinitis—NSAIDs, local heat, and corticosteroid injection—is similar to that for bursitis. Rest, physical therapy, occupational therapy, and occasionally ergonomic modification are useful adjuncts. The goal of corticosteroid injection in tendinitis is to infiltrate the tendon sheath rather than the tendon itself because direct injection into a tendon may result in rupture of the tendon. Corticosteroid injection of the Achilles tendon should be avoided because of the propensity of this tendon to rupture. Surgical management of tendinitis is indicated only after failure of conservative treatment. For example, chronic impingement of the supraspinatus tendon that is refractory to conservative treatment may require subacromial decompression.

Fibromyalgia Syndrome

Descriptions of fibromyalgia syndrome exist far back in the medical literature, but it remains a diagnosis of exclusion due to the lack of objective diagnostic or pathologic findings. Fibromyalgia syndrome as

TABLE 86.4 2011 American College of Rheumatology Fibromyalgia Diagnostic Criteria Modification

Criteria
1. 0 to 19 pain locations on the widespread pain index (WPI)
2. 6 self-reported symptoms, including difficulty sleeping, fatigue, poor cognition, headache, depression and abdominal pain. 0–3 points for fatigue, cognition, and sleep; 1 point for abdominal pain, headache, and depression
3. Symptoms are present for at least 3 months
4. Exclusion of other explanation for the pain
Total score is calculated by adding WPI and self-reported symptom score; 12–13 is generally indicative of fibromyalgia. There has been a 2016 modification to this score to minimize misclassification of regional pain disorders.

Somatic symptoms may include muscle pain or weakness, irritable bowel syndrome, fatigue or tiredness, cognitive or memory problems, headache, numbness or tingling, dizziness, insomnia, depression, nervousness, seizures, abdominal pain or cramps (especially upper abdomen), constipation, diarrhea, nausea, vomiting, fever, dry mouth, itching, chest pain, wheezing, Raynaud's phenomenon, hives or welts, tinnitus, hearing difficulties, heartburn, oral ulcers, loss of or change in taste, dry eyes, blurred vision, shortness of breath, loss of appetite, rash, sun sensitivity, easy bruising, hair loss, frequent or painful urination, and bladder spasms.

defined by the American College of Rheumatology (ACR) 1990 definition for use in clinical trials is a chronic, widespread pain condition with characteristic tender points on physical examination, often associated with a constellation of symptoms such as fatigue, sleep disturbance, headache, irritable bowel syndrome, and mood disorders. In 2010, the ACR developed preliminary diagnostic criteria based only on symptoms because of well-documented issues with the tender point examination (Table 86.4). These criteria do not require a tender point examination, but they provide a scale for measuring the severity of symptoms that are characteristic of fibromyalgia and show good correlation with the 1990 ACR criteria.

The clinical presentation of fibromyalgia syndrome is an insidious onset of chronic, diffuse, poorly localized musculoskeletal pain, typically accompanied by fatigue and sleep disturbance. The physical examination reveals a normal musculoskeletal system, with no deformity or synovitis. However, widespread tenderness occurs, especially at tendon insertion sites, indicating a general reduction in the pain threshold.

Approximately one third of the patients identify antecedent trauma as a precipitant for their symptoms, one third of patients describe a viral prodrome, and one third have no clear precipitant. A variety of less typical presentations has been described, including a predominantly neuropathic presentation with paresthesias (i.e., numbness and tingling) in a nondermatomal distribution, an arthralgic rather than myalgic presentation, and an axial skeletal manifestation resembling degenerative disk disease. Many patients may have undergone invasive diagnostic tests and, in some cases, inappropriate procedures such as carpal tunnel release or cervical or lumbar laminectomies.

Conditions that should be considered in the differential diagnosis of fibromyalgia syndrome include polymyalgia rheumatica (in older patients), hypothyroidism, polymyositis, and early systemic lupus erythematosus or rheumatoid arthritis. However, symptoms are exhibited for many months or years without evidence of other signs or symptoms of an underlying connective tissue disease, making other possible diagnoses unlikely.

Results of laboratory and radiographic studies are usually normal for patients with fibromyalgia syndrome. Exclusion of other conditions, such as osteoarthritis, rheumatoid arthritis, and systemic lupus erythematosus, by radiography, erythrocyte sedimentation rate, assays for rheumatoid factor or antinuclear antibody, and other tests is no longer considered necessary for the diagnosis of fibromyalgia syndrome. Fibromyalgia should be diagnosed on the basis of positive criteria.

The treatment of fibromyalgia includes reassurance that the condition is not a progressive, crippling, or life-threatening entity. A combination of treatment options, including medication and physical measures, is helpful for most patients. Medications found to be helpful in short-term, double-blind, placebo-controlled trials include amitriptyline and cyclobenzaprine. Low doses of these medications (e.g., 10 to 30 mg of amitriptyline, 10 to 30 mg of cyclobenzaprine) are moderately effective and generally well tolerated. Studies have shown that newer antidepressants of the serotonin-norepinephrine reuptake inhibitor group (e.g., duloxetine, venlafaxine, bupropion) and $\alpha_2\delta$ ligands (e.g., gabapentin, pregabalin) are also effective, particularly in combination with low doses of tricyclic agents. There is currently significant interest among patients regarding the use of cannabinoids for the management

of chronic pain but very little data to support their use. However, there is evidence that chronic opioids are not indicated in these patients due to the high risk of dependence, tolerance, and possible worsening of hyperalgesia in these patients.

Patients should be encouraged to take an active role in the management of their condition. If possible, they should begin a progressive, low-level aerobic exercise program to improve muscular fitness and provide a sense of well-being. Cognitive behavioral therapy has been shown to improve function significantly. Adherence, compliance, and access to these modalities are limitations in patients. A combination approach is effective for most patients in alleviating symptoms, although a small minority of patients requires more intensive treatment strategies, such as psychiatric treatment or referral to a pain center.

Rheumatic Manifestations of Systemic Disorders and Sjögren's Syndrome

Andreea Coca, Ghaith Noaiseh

INTRODUCTION

Rheumatologic manifestations may herald a variety of systemic conditions, including malignancy, endocrinopathy, and hematologic disorders (Tables 87.1 and 87.2). Musculoskeletal symptoms can precede or follow the diagnosis of these diseases. Patients may complain of joint or muscle pain, joint swelling, rashes, and many other symptoms.

RHEUMATOLOGIC PARANEOPLASTIC MANIFESTATIONS

Cancer has a myriad of presentations, and paraneoplastic rheumatologic manifestations are not uncommon. They can vary from musculoskeletal conditions to vascular involvement (leukocytoclastic vasculitis), myositis, systemic lupus erythematosus (SLE)-like symptoms, and scleroderma. The pathophysiologic mechanisms of musculoskeletal symptoms in a patient with cancer are often unknown and remain speculative. The association is presumed if there is a close temporal relationship between the diagnosis of a malignancy and the onset of musculoskeletal symptoms or the rheumatic syndrome resolves after successful treatment of the malignancy. In many cases, however, the association may be coincidental.

Cancer may directly invade articular or periarticular structures and mimic rheumatic syndromes, as in chondrosarcoma, giant cell tumor, and osteogenic sarcoma. Musculoskeletal symptoms can occur as paraneoplastic phenomena without direct involvement by the tumor, as in dermatomyositis (DM) in patients with ovarian cancer.

The incidence of malignancy with rheumatic manifestations is unclear, but musculoskeletal symptoms occur more frequently with hematologic malignancies than with solid tumors. No single laboratory test can confirm the diagnosis of a rheumatic illness in a patient with cancer. All patients with rheumatologic syndromes should be evaluated with a thorough history, physical examination, and age-appropriate malignancy screening.

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy (HOA) is characterized by digital clubbing, periostitis of the long bones, and arthritis. Arthritis is most prominent in large joints, and periostitis develops mostly at the distal ends of the femur, tibia, and radius. The primary form of HOA (primary pachydermoperiostosis) is usually a self-limited disease of childhood. The secondary form may be generalized or localized and is mainly associated with lung cancer and suppurative lung disease.

HOA is also associated with cardiovascular disease (e.g., cyanotic congenital heart disease, infective endocarditis), hepatobiliary disorders (e.g., liver cirrhosis, primary biliary cirrhosis), and gastrointestinal disease (e.g., inflammatory bowel disease, celiac disease). Periostitis without digital clubbing can be seen in thyroid acropachy,

hypervitaminosis A, fluorosis, venous stasis, hyperphosphatemia, and sarcoidosis. Isolated chronic digital clubbing, which is mainly associated with pleuropulmonary disease, does not seem to cause HOA.

The pathogenesis of HOA remains elusive, although several possible mechanisms have been proposed, including platelet derived growth factor and vascular derived growth factor.

HOA is usually accompanied by bone and joint pain associated with periarticular periostitis. The pain is usually exacerbated by dependency and relieved with limb elevation. Typical signs of periostitis include periosteal new bone along the distal ends of long bones, which can be seen on plain radiographs. When periostitis is not obvious on plain radiography, a bone scan is useful to demonstrate early evidence of disease. Radiologic evaluation of the thorax is important because of the association between HOA and lung neoplasms.

In many cases, symptomatic management with nonsteroidal anti-inflammatory drugs or other analgesics while treating the underlying disorder provides significant relief of symptoms. In refractory cases, bisphosphonates such as pamidronate and zoledronic acid have been reported to be effective.

Rheumatoid Arthritis-like Polyarthriti

Inflammatory rheumatoid arthritis-like syndrome has been associated with solid neoplasms and hematologic malignancies. Clinical characteristics associated with this paraneoplastic syndrome include acute onset, asymmetrical disease frequently involving the lower extremities, synovitis in large joints that spares the wrists and hands without bony erosion, and negative results for rheumatoid factor and cyclic citrullinated peptide antibody. However, these features are not specific and may be confused with elder-onset rheumatoid arthritis, seronegative rheumatoid arthritis, spondyloarthritis, and remitting seronegative symmetrical synovitis with pitting edema (RS3PE).

Remitting Seronegative Symmetrical Synovitis With Pitting Edema

RS3PE manifests with sudden onset of polyarthriti, pitting edema, and prominent constitutional symptoms. More than one half of the RS3PE cases are associated with malignancy, including hematologic and solid tumors. The evaluation of the patient presenting with RS3PE should prompt an age-appropriate malignancy work-up.

Eosinophilic Fasciiti

Eosinophilic fasciiti can be easily mistaken for scleroderma, presenting with puffy skin, sometimes indurated, progressing towards significant subcutaneous thickening, with characteristic peripheral eosinophilia. It can be seen in the setting of a variety of hematologic malignant disorders.

Rheumatologic Complications of Checkpoint Inhibitor Immunotherapy

Immune checkpoint inhibitors (ICIs) are the most commonly used type of cancer immunotherapy. They work by blocking inhibitory molecules on the T cells, resulting in heightened T-cell mediated immune response against malignancy. Unfortunately, they have a variety of side effects, the musculoskeletal ones being among the predominant ones.

Inflammatory arthritis can present in a pattern similar to rheumatoid arthritis or a seronegative spondyloarthropathy. Joint damage can be severe and erosions are common. For the most part, the work-up is normal, although inflammatory markers can be elevated. Mild inflammatory arthritis responds to NSAIDs. In cases of severe arthritis, oral corticosteroids are warranted as well as anti-tumor necrosis factor (TNF) agents.

Sjögren's syndrome (SS)-like presentation manifests primarily with significant ocular and mucosal dryness. Most patients do not exhibit autoantibodies. The distinction from SS is based on minor salivary gland biopsy, which demonstrates a diffuse T cell lymphocytic infiltrate and acinar injury, a pattern distinct from SS.

Polymyalgia rheumatica and giant cell arthritis have been described following treatment with ICIs. PMR symptoms are typical, and temporal artery biopsy pathology is under distinguishable between users or nonusers of ICIs.

DM and polymyositis (PM) have also been described, with proximal muscle weakness, elevated muscle enzymes and pathognomonic abnormalities of the electromyography (EMG) and MRI images.

Monotherapy with oral steroids has generally been very effective.

Endocrine Disease	Musculoskeletal Manifestations
Diabetes mellitus	Carpal tunnel syndrome Charcot arthropathy Adhesive capsulitis Cheiroarthropathy Diabetic amyotrophy Diabetic muscle infarction
Hypothyroidism	Proximal myopathy Joint effusions Carpal tunnel syndrome Chondrocalcinosis
Hyperthyroidism	Myopathy Osteoporosis Thyroid acropachy
Hyperparathyroidism	Myopathy Erosive arthritis Chondrocalcinosis
Hypoparathyroidism	Muscle cramps Soft tissue calcifications Spondyloarthropathy
Acromegaly	Carpal tunnel syndrome Myopathy Raynaud's phenomenon Premature osteoarthritis
Cushing syndrome	Myopathy Osteoporosis Avascular necrosis

Immune checkpoint inhibitors can also modulate the underlying systemic autoimmune diseases. In patients with rheumatoid arthritis or psoriasis, up to 30% of them can flare during treatment. However, discontinuation of systemic immunosuppression is not recommended, and patients should continue the treatment.

**Systemic Autoimmune Diseases and Malignancy
Lupus-like Syndrome**

Antinuclear antibodies (ANAs) can be seen in patients with solid neoplasms (e.g., gastric, cervical, and breast carcinomas, testicular seminoma), lymphomas, or myelodysplastic disorders, but the significance of these autoantibodies is poorly understood. It is not clinically indicated to search for an underlying malignancy in a patient with typical SLE. However, lupus-like autoantibodies and unexplained Coombs-positive hemolytic anemia or thrombocytopenia without clinical signs of rheumatic disease warrant further investigation for an occult neoplasm.

Raynaud's Phenomenon and Scleroderma-like Syndrome

The sudden onset of Raynaud's phenomenon and scleroderma-like syndrome can herald an underlying tumor such as hematologic malignancies and carcinomas of the liver, ovary, testis, bladder, breast, or stomach. Scleroderma-like skin changes may also occur in patients with osteosclerotic myeloma with polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin abnormalities (i.e., POEMS syndrome) and in those with carcinoid tumors.

Characteristics that suggest secondary Raynaud's phenomenon include age at onset older than 50 years, symptom asymmetry, symptoms that persist year-round, and rapid digital ulceration and necrosis. Secondary Raynaud's is also suggested by scleroderma-like syndromes

in patients older than 50 years, rapid progression of skin sclerosis, or a poor response to therapy. The lack of Raynaud's phenomenon can be another distinguishing characteristic of paraneoplastic scleroderma-like syndrome because Raynaud's phenomenon occurs in approximately 95% of cases of systemic sclerosis.

Vasculitides

Vasculitis is rarely associated with malignancy and is most commonly seen in patients with lymphoproliferative disorders and myelodysplastic syndrome. Cutaneous leukocytoclastic vasculitis is the most common manifestation of paraneoplastic vasculitis. Although clinical presentations of paraneoplastic vasculitides are indistinguishable from those of the idiopathic condition, a chronic, relapsing disease with cytopenias and poor response to conventional treatment suggests a hidden malignancy.

Inflammatory Myopathies

The association between inflammatory myopathies and malignancies has been well established. DM and PM have an increased risk for malignancy, primarily solid tumors. Most malignancies are ovarian, lung, and stomach, primarily seen in the Western population. Differentiating between malignancy or not-malignancy-associated DM or PM can be very challenging, because CPK levels and muscle biopsy findings are similar. Immediately after diagnosis, all patients should undergo age-appropriate malignancy screening. This screening should be repeated every 3 to 5 years, regardless of disease activity. The suspicion for malignancy should be significantly increased in treatment-resistant myositis. The association of anti-P1 55/P1 40 antibodies has been described as highly predictive of cancer-associated DM.

Malignancies Associated With TNF Inhibitors

Adalimumab and etanercept have been on the market since the late 1990s and widely used in a variety of systemic and organ-specific autoimmune diseases. The most common malignancy reported was Hodgkin's and non-Hodgkin's lymphomas. There is an increased risk for nonmelanoma skin cancer but no evidence of other malignancies.

HEMATOLOGIC DISORDERS WITH RHEUMATIC MANIFESTATIONS

Hemophilia

Acute, painful hemophilic arthropathy of the knees, elbows, and ankles is the most common manifestation of hemophilia. Repeated episodes of hemarthrosis result in synovial proliferation and chronic inflammation, causing chronic hemophilic arthropathy. This is characterized by joint deformity, fibrous ankylosis, and osteophyte overgrowth. Radiography typically shows degenerative arthritis. Besides prompt administration of factor concentrate replacement, acute hemarthrosis must be treated conservatively with cold applications and joint immobilization followed by a structured physical therapy program. Aspiration (after factor replacement) is needed only if concomitant septic arthritis is suspected or the joint is very tense.

Sickle Cell Disease

Musculoskeletal complications of sickle cell disease include painful crises, arthropathy, dactylitis, osteonecrosis, and osteomyelitis. Sickle cell crisis is the most common musculoskeletal feature, and it can produce painful arthritis of the large joints and noninflammatory joint effusions adjacent to areas of bony crisis. Osteonecrosis of the femoral head, shoulder, and tibial plateau may result from repeated local bone ischemia or infarct.

Dactylitis manifesting as bilateral, painful, swollen hands or feet (i.e., hand-foot syndrome) may be the first manifestation of the disease in infants and young children. It can be associated with fever and leukocytosis, believed to be secondary to local bone marrow ischemia. Treatment is supportive. Increased risk of septic arthritis and osteomyelitis, most often due to *Salmonella* species, has been associated with hemoglobinopathies.

Endocrine Disorders

Endocrine diseases usually manifest with diffuse, poorly defined musculoskeletal symptoms and joint pain that is more often periarticular. Clinical suspicion of endocrinopathy is by far the most important diagnostic step. Routine clinical laboratory tests such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), ANA, rheumatoid factor, and uric acid level are usually not helpful. Radiographs often raise the suspicion of an endocrinopathy and are pathognomonic in advanced disease.

Diabetes

One of the most common musculoskeletal complications of diabetes is diabetic cheiroarthropathy (i.e., diabetic hand syndrome). It is characterized by insidious development of waxy thickening of the skin of the fingers and hands and by flexion contractures of the metacarpophalangeal joints and interphalangeal joints. Patients cannot press the palms together completely without a gap with the wrists fully flexed (i.e., prayer sign). Although this syndrome is associated with long duration of diabetes and poor glycemic control, it may develop before the onset of overt diabetes and mimic sclerodactyly.

Dupuytren contracture and stenosing flexor tenosynovitis (i.e., trigger finger) may be identified. People with diabetes are more prone to develop carpal tunnel syndrome. Diabetic periartthritis of the shoulders (i.e., adhesive capsulitis or frozen shoulder) is more common in patients with diabetes, especially in women with a long history of diabetes. Capsulitis is characterized by staged progression of pain and restriction of shoulder motion.

Patients with long-standing, poorly controlled diabetes may develop a painless, swollen, deformed joint known as a Charcot joint or neuropathic arthropathy. Tarsal, metatarsophalangeal, and tarsometatarsal joints are most commonly involved, and it can be confused with osteomyelitis on radiographs.

Diffuse idiopathic skeletal hyperostosis (DISH) is seen in up to 20% of diabetic patients, who are typically obese and older than 50 years. It is associated with neck and back stiffness rather than pain. Lateral radiographic views of the spine show four or more contiguously fused vertebrae, the result of flowing ossification of the anterior longitudinal ligament without involvement of apophyseal (facet) joints.

Diabetic amyotrophy (i.e., diabetic lumbosacral radiculoplexus neuropathy) is remarkable for acute or subacute onset of severe hip, buttock, or thigh pain followed by progressive weakness of the affected extremity. It occurs typically in older male patients who have relatively well-controlled diabetes.

Diabetic muscle infarction occurs in long-standing insulin-dependent diabetes. It presents with sudden onset of pain and swelling in the calf, mimicking deep venous thrombosis. CK levels might be elevated. A biopsy is often necessary to rule out other possible etiologies.

Thyroid Disease

Hypothyroidism is primarily associated with myxedematous arthropathy, primarily affecting the large joints with swelling and stiffness. Synovial fluid analysis reveals a noninflammatory fluid and radiographs are generally normal. Other common rheumatologic manifestations are carpal tunnel, nonspecific arthralgia, and a myositis-like picture with proximal muscle weakness and elevated CK.

Hyperthyroidism is associated with pain and proximal muscle weakness in up to 70% of hyperthyroid patients. Osteoporosis is likely the most common musculoskeletal manifestation of thyroid disease.

Thyroid acropachy is a rare manifestation of Graves' disease presenting with swelling of the hands, digital cramping, and periostitis. It is more likely to occur in patients already having other complications of Graves' disease, primarily ophthalmopathy.

Parathyroid Disease

The most common rheumatologic manifestations of primary hyperparathyroidism include pain, proximal muscle weakness, chondrocalcinosis, tendon ruptures, and osteoporosis. Long-standing uncontrolled hyperparathyroidism leads to osteitis fibrosa cystica, primarily seen in end-stage renal disease. Radiographs are characteristic, with subperiosteal resorption and resorption of the tuft of the distal phalanx. Occasionally, erosions can be seen, making it easy to confuse it with rheumatoid arthritis. Secondary hyperparathyroidism is the leading cause of renal osteodystrophy in chronic kidney disease.

Acromegaly

Acromegaly is often associated with joint pain, mostly secondary to degenerative disease affecting the weight-bearing joints, including the spine. Radiographs are characteristic and include periosteal apposition of tubular bones, deformation of the epiphysis, and chondrocalcinosis. In addition, acromegaly can also be associated with carpal tunnel and proximal muscle weakness. Overgrowth of cartilage initially produces joint space widening, but it may eventually lead to severe osteoarthritis with pain, limited range of motion, and deformity.

GASTROINTESTINAL DISEASES WITH RHEUMATIC MANIFESTATIONS

Whipple Disease

Whipple disease is a rare, multisystem disease that most often affects the gastrointestinal tract, caused by an infection with *Tropheryma whippelii*. Musculoskeletal symptoms can precede the diagnosis by years. Intermittent migratory oligoarthritis of large joints is typical, but some patients may have a florid polyarthritis. Synovial fluid is usually inflammatory with predominant mononuclear cells. Radiographs are often normal.

Hemochromatosis

Hemochromatosis is one of the most common genetic diseases among people of northern European ancestry, and it is frequently associated with osteoarthritis-like arthropathy, chondrocalcinosis, and osteoporosis. The second and third metacarpophalangeal joints of both hands are typically involved, and hook-like osteophytes on the radial side of the metacarpal are characteristic in radiographs, the "iron-fist" sign. Chondrocalcinosis of the wrist and knee is very common in patients with hemochromatosis. Acute attacks of pseudogout can be a predominant clinical manifestation. There is no effective treatment, and regular phlebotomies are not effective.

MISCELLANEOUS DISORDERS

Multiple Myeloma

Rheumatologic manifestations of multiple myeloma include bone pain resulting from lytic bone lesions, pathologic fractures, and osteoporosis. Thoracolumbar pain in the setting of hypercalcemia, renal insufficiency, and anemia suggest the possibility of multiple myeloma.

Multiple myeloma can manifest atypically and mimic specific autoimmune disorders such as SS and SLE.

Amyloidosis

Amyloidosis is a disorder of protein folding in which insoluble fibrillar proteins are deposited in the extracellular space in one or more organs, disrupting tissue structure and function. The clinical manifestations and prevalence depend on the type of amyloidosis. The amyloid protein can be identified as apple green birefringence on Congo red staining of an abdominal fat pad aspiration or rectal mucosal biopsy specimen.

Systemic light-chain (AL) amyloidosis is one of the most common forms of systemic amyloidosis. Amyloid proteins derived from monoclonal light chains can invade the synovium, producing rheumatoid arthritis-like symptoms. Joint stiffness is more pronounced in amyloid arthropathy, and deposition of amyloid protein at the glenohumeral joint produces enlargement of the anterior shoulder, called the *shoulder pad sign*. Amyloid deposition in the blood vessels can manifest as claudication and symptoms similar to those of temporal arteritis. Deposition in the muscles may also lead to weakness or pain, presenting with a myositis-like picture or muscle pseudohypertrophy.

Systemic AA amyloidosis (formerly known as secondary amyloidosis) can complicate any chronic inflammatory disorder. The most common rheumatologic diseases complicated by a systemic AA amyloidosis are rheumatoid arthritis, juvenile idiopathic arthritis and ankylosing spondylitis.

Human Immunodeficiency Virus Infection

There are a plethora of muscular skeletal manifestations associated with human immunodeficiency (HIV), either disease specific or secondary to highly active antiretroviral therapy (ART). They range from arthralgias and arthritis to inflammatory myositis, sarcoidosis, rheumatoid arthritis, SLE, SS, zidovudine-associated myopathy, osteopenia, osteomalacia, and osteomyelitis.

HIV-associated arthritis is seronegative polyarticular noninflammatory arthritis, primarily affecting the weight-bearing joints. It is a self-limiting condition, responding to conservative management. Rarely, it requires NSAIDs or low-dose corticosteroids for symptoms relief.

The incidence of reactive arthritis has been drastically reduced since introduction of ART. The presentation is classical, with enthesopathy, plantar fasciitis, dactylitis, and inflammatory synovial fluid. However, it can be associated with severe erosive arthritis, which is generally not seen in non-HIV-related reactive arthritis.

Muscle involvement in HIV is common. It can present with inflammatory or noninflammatory myopathy. Prior to ART, the patient was more likely to develop PM, nemaline rod (rod like structures in muscle cells) myopathy and HIV wasting syndrome. Posttreatment, mitochondrial myopathy and rhabdomyolysis are more commonly seen. The most common bone diseases seen in HIV patients are osteoporosis and avascular necrosis, especially in patients that have a very low CD4 count.

Sarcoidosis

Clinical features of sarcoidosis can mimic those of many acute and chronic rheumatic diseases. Acute sarcoidosis (also called Löfgren syndrome) manifests with fever, erythema nodosum, hilar lymphadenopathy, and acute polyarthritis, almost invariably involving the ankles and knees. The arthritis is usually self-limited and tends to be nondeforming and nonerosive.

Chronic sarcoid arthropathy is less common and usually associated with active multisystemic disease. Osseous involvement can be focal or

generalized and occurs in about 5% of patients with sarcoidosis. Bone cysts are usually asymptomatic, but they can manifest in the phalanges with sausage-like fingers or pseudoclubbing. Focal osteolytic changes can lead to pathologic fractures. Sarcoid muscle involvement is often asymptomatic, but it may manifest with proximal pain, progressive weakness, or atrophy

SJÖGREN'S SYNDROME

Definition and Epidemiology

SS is a chronic systemic autoimmune disease characterized by lymphocytic infiltration of salivary and lacrimal glands that leads to mucosal dryness and salivary gland enlargement, and by autoantibody production. Extra-glandular manifestations occur in 25% to 30% of patients and may occur as the presenting feature or during the evolution of the disease.

Prevalence is approximately 0.1% to 0.6% of the general population. SS is mostly a disease of middle-aged women, but it can affect people of all ages. The female-to-male ratio is at least 9:1. SS can occur as a primary disorder or can be associated with other autoimmune diseases such as rheumatoid arthritis and SLE.

Pathogenesis

The pathogenesis of SS is not fully understood. Autoimmune epithelitis is the most widely accepted model of autoimmunity in SS, in which the glandular epithelial cells (EC) act as a main orchestrator of the inflammatory response and not just an innocent bystander that is damaged by surrounding inflammation. In a genetically predisposed subject (e.g., HLA-DR3-DQ1-positive), outside triggers, such as sialotropic viruses or hormonal factors, activate EC, which then act as nonprofessional antigen presenting cells by expressing MHC I and II molecules and toll-like receptors, secreting cytokines and chemokines necessary to attract other inflammatory cells and activating both innate and adaptive immunity. Altogether, these steps promote a vicious cycle perpetuating immune system activation. Activated macrophages and dendritic cells produce type I interferon, leading to local tissue damage. Inflammatory milieu attracts and activates T and B lymphocytes to form lymphocytic foci. In fact, the presence of lymphocytic infiltration around the epithelial structures of salivary glands and other affected tissues is the histopathologic hallmark of SS.

Additionally, EC are among inflammatory cells that produce B-cell activating factor (BAFF or BLYS), a pivotal molecule that promotes B-cell maturation, proliferation, and survival. B-cell hyperactivity in SS is a key feature of the disease highlighted by presence of specific autoantibodies such as anti-Ro/SSA and anti-La/SSB antibodies, nonspecific hypergammaglobulinemia, presence of monoclonal gammopathy, and development of non-Hodgkin's lymphoma. Moreover, antibody production is essential for the formation of immune complexes (IC), which can lead to complement activation and tissue damage, or vasculitis, when deposited in the capillaries of certain organs such as the skin, kidneys, and peripheral nerves.

To summarize, immunopathogenesis of SS is thought to result from either lymphocytic infiltration of target tissue epithelia leading to progressive functional impairment or IC-mediated complement activation and tissue damage.

Clinical Presentation

Patients typically present with insidious onset of sicca syndrome (persistent dry eyes and dry mouth). Decreased tear flow leads to epithelial damage of cornea and conjunctiva, a condition known as keratoconjunctivitis sicca. Grittiness, foreign body sensation, photophobia, and formation of thick secretions in the inner canthus can occur. Untreated

cases can lead to corneal ulcerations, scarring, bacterial infections, and visual impairment.

Occasionally, patients may deny dry mouth but report difficulty swallowing dry food. Exam may reveal absence of a normal salivary pool under the tongue, dry and sticky mucosa, gingival recession, and dental caries. Atrophic oral candidiasis is a less recognized complication and usually presents with burning mouth syndrome and atrophied papillae on the tongue surface with or without angular cheilitis in the absence of classic whitish exudate. Upper respiratory tract involvement may lead to nasal dryness, recurrent nonallergic rhinitis and sinusitis, and dry cough. Vaginal dryness associated with dyspareunia and dry skin may also occur. Salivary gland enlargement is seen in about 30% to 40% of patients, classically presenting as painless unilateral or bilateral parotid gland enlargement, which spontaneously resolves 2 to 3 weeks later. Other common presentations include arthralgia, myalgia, fatigue, and malaise.

SS can overlap with several nonrheumatic autoimmune diseases, such as Hashimoto thyroiditis and celiac disease. In addition to SS-specific symptoms, patients may have a plethora of extraglandular manifestations, summarized in [Table 87.3](#).

Placental transmission of maternal anti-SSA/Ro and anti-SSB/La may lead to neonatal disease. Female patients with SS or SLE planning a family who have anti-Ro/La antibodies should be counselled about this risk to the neonate, which occurs in approximately 2% to 5% of cases.

Sjögren's Syndrome and Non-Hodgkin Lymphomas

Compared to the general population, SS patients have a 15- to 20-fold increased risk of developing lymphomas, usually mucosa-associated lymphoid tissue (MALT) B-cell lymphoma. Interestingly, lymphoma typically develops in organs where the disease is active, such as salivary glands. Persistent unilateral parotid gland enlargement in SS is alarming and requires additional work-up. Other risk factors associated with lymphoma development include palpable purpura, splenomegaly, lymphadenopathy, positive rheumatoid factor, positive serum cryoglobulins, C4 hypocomplementemia, lymphopenia, and monoclonal gammopathy. Patients who exhibit one or several risk factors need to be closely monitored.

Laboratory Findings

Antinuclear antibodies and rheumatoid factor are seen in up to 80% and 50% of cases, respectively. When present, patients may be erroneously diagnosed with SLE or RA. Anti-SSA/Ro, and anti-SSB/La antibodies are present in 60% to 80% and 30% to 40% of SS patients, respectively. Hypergammaglobulinemia, anemia of chronic disease, and elevated ESR (related to hypergammaglobulinemia) are commonly encountered. CRP is usually normal. Lymphopenia, neutropenia, and thrombocytopenia may also occur. Serum cryoglobulins and monoclonal gammopathy are present in 10% and 15%, respectively. Complement levels C3 and C4 may be decreased as markers of disease activity but low C4 may occasionally be congenital.

Diagnosis

In the clinically appropriate context, such as presence of sicca symptoms or an extraglandular manifestation, the diagnosis is made based on objective demonstration of glandular dysfunction *and* presence of autoimmunity as assessed by elevated serum anti SSA/Ro or a positive minor salivary gland biopsy. Importantly, absence of sicca symptoms does *not* rule out SS.

Various tests are used to assess for glandular dysfunction. To confirm keratoconjunctivitis sicca, the Schirmer test measures tear flow over a 5-minute period using standardized paper strips; 5 mm or less

TABLE 87.3 Systemic Manifestations of Sjögren's Syndrome

System	Clinical Manifestations
Constitutional	Fever Fatigue
Cutaneous	Purpura: hypergammaglobulinemic or cryoglobulinemia-associated leukocytoclastic vasculitis Annular erythema (photosensitive, indistinguishable from subacute cutaneous lupus erythematosus) Urticaria Xeroderma
Musculoskeletal	Arthralgia and myalgia Nonerosive arthritis (mimicking rheumatoid arthritis) Inflammatory myopathy
Pulmonary	Obstructive pattern on pulmonary function testing Interstitial lung disease (nonspecific, usual and lymphocytic interstitial pneumonia) Cryptogenic organizing pneumonia Bronchiectasis
Renal	Interstitial nephritis Renal tubular acidosis (typically type I, less commonly type II) Cryoglobulin-mediated membranoproliferative glomerulonephritis
Central nervous system	Multiple sclerosis-like syndrome Transverse myelitis Cognitive dysfunction
Peripheral nervous system	Axonal sensory polyneuropathy Sensorimotor polyneuropathy Small fiber neuropathy Autonomic neuropathy Ganglionopathy Chronic inflammatory demyelinating polyneuropathy Cranial neuropathies (usually trigeminal neuralgia) Mononeuritis multiplex (vasculitis-associated)
Hepatobiliary	Autoimmune cholangitis
Vascular	Raynaud's phenomenon (without digital tip ulcerations) Vasculitis (affecting small vessels, usually in skin, kidney, and nerves)
Reticuloendothelial	Lymphadenopathy Splenomegaly
Lymphoproliferative	Non-Hodgkin's lymphoma, usually marginal-zone histologic type, particularly mucosa-associated lymphoid tissue (MALT)-related lymphoma

of wetting confirms objective dryness. It is a simple test that can be performed routinely in the clinic. A normal Schirmer test does not rule out dry eyes. Slit-lamp examination of the ocular surface, using vital dye drops such as Lissamine green and fluorescein, assesses severity of ocular damage by staining devitalized spots. Unstimulated salivary flow can be measured by asking the patient to spit into a container for 5 to 15 minutes; a saliva flow rate of 0.1 mL/min or less confirms objective dryness. Diagnostic labial salivary gland biopsy is usually performed by harvesting four to six minor glands from the inner mucosa of the lower lip. The classical histological feature is

focal lymphocytic sialadenitis, which is foci of 50 or more lymphocytes clustered around normal appearing salivary tissue (periepithelial infiltrates) (Fig. 87.1).

Classification Criteria

2016 ACR/EULAR classification criteria are listed in Table 87.4. Although designed for research purposes and not considered diagnostic criteria, they can be helpful as a diagnostic framework in patients suspected to have SS. These classification criteria are applicable to any patient with at least one item of the following:

1. A symptom of ocular or oral dryness (persistent dry eyes >3 months, recurrent sensation of sand or gravel in the eyes, using tear substitutes >3 times daily, persistent dry mouth >3 months, or need to drink liquids to aid in swallowing dry food)
2. Suspicion of SS based on presence of a suggestive body organ involvement or abnormal laboratory testing as listed in the ESSDAI (European League Against Rheumatism SS Disease Activity Index) tool. Examples include prominent parotid swelling, recent diagnosis of axonal sensory polyneuropathy, significant neutropenia, hypergammaglobulinemia, and hypocomplementemia.

Objective dryness testing should be performed after holding anticholinergic medications for adequate period of time.

Exclusion criteria include history of head and neck radiation therapy, polymerase chain reaction (PCR)-confirmed active hepatitis C infection, AIDS, sarcoidosis, amyloidosis, graft-versus-host disease, and IgG4-related disease.

Differential Diagnosis

The differential diagnosis of SS includes etiologies that can cause sicca symptoms and or lacrimal/salivary gland enlargement. Numerous medications with anticholinergic properties, including over-the-counter products, may lead to dry eyes and mouth. Anxiety, depression or aging may also lead to sicca symptoms. Diffuse infiltrative lymphadenopathy syndrome associated with HIV and infiltrative diseases such as sarcoidosis can cause dry mouth and parotid swelling. IgG4-related disease is associated with sicca complaints and persistent lacrimal and salivary gland swelling. Sialadenosis (or sialosis) is a persistent, usually painless, bilateral swelling of parotid glands, associated with alcoholism, obesity, diabetes mellitus, chronic liver disease, and eating disorders. Histologic findings include fatty infiltrates and minimal inflammatory cells. Fibromyalgia syndrome may lead to sicca symptoms, along with fatigue and musculoskeletal pain.

Management

The goal of therapy in SS is to prevent complications and alleviate symptoms. Topical and systemic pharmacologic therapies can improve sicca symptoms, but therapeutic agents able to induce remission or alter the course of the disease are not yet available. Immunosuppressive medications are usually used in patients with severe systemic involvement. Treatment of sicca syndrome is summarized in Table 87.5.

Oral disease-modifying antirheumatic drugs (such as azathioprine and methotrexate) do not appear to be effective, although hydroxychloroquine is frequently used to treat arthralgia, rashes, and fatigue. Cyclophosphamide may be used with severe body organ involvement such as vasculitic neuropathies or glomerulonephritis. Currently, use of biologic therapies in SS is experimental; however, rituximab has been used in severe thrombocytopenia, interstitial lung disease, vasculitic neuropathies, and non-Hodgkin's lymphoma.

Fig. 87.1 (A) Low magnification. Cross-section of a labial minor salivary gland in SS patient revealing focal lymphocytic sialadenitis. Three lymphocytic foci, each (*triangles*) with >50 lymphocytes adjacent to normal-appearing glandular tissue. (B) High magnification. Several hundred lymphocytes forming a lymphocytic focus.

TABLE 87.4 2016 ACR/EULAR Classification Criteria of Primary Sjögren's Syndrome

Item	Score
Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥ 1 foci/4 mm ²	3
Positive anti-SSA/Ro	3
Ocular staining score ≥ 5 in any eye	1
Schirmer test ≤ 5 mm/5 min in any eye	1
Unstimulated salivary flow rate ≤ 0.1 mL/min	1

A score ≥ 4 points classifies a patient as having SS.

TABLE 87.5 Management of Sicca Syndrome in Patients With Sjögren's Syndrome

Treatment of dry eyes	<ul style="list-style-type: none"> Avoid dry environment Moisture chamber goggles/glasses Artificial tears (preservative free if used more than four times daily) Lubricating gels (at bedtime) Tear drainage duct plugging (reversible) or cautery (irreversible) Topical anti-inflammatory therapy (cyclosporine, lifitegrast, corticosteroids)
Treatment of dry mouth	<ul style="list-style-type: none"> Avoid or discontinue medications with anticholinergic properties, when possible Optimize oral hygiene (regular brushing, flossing) Sugar-free lozenges (to stimulate saliva) Artificial saliva Fluoride-based topical products Oral secretagogues (pilocarpine, cevimeline)

Host Defenses Against Infection

Richard Bungiro, Edward J. Wing

HOST VERSUS PATHOGEN: VICTORY, DEATH, OR COEXISTENCE

Many factors determine whether we coexist peacefully with our normal microbial flora and also whether we live or die in an environment filled with a wide spectrum of potentially pathogenic microbes. Factors such as age, nutritional status, underlying medical conditions (e.g., diabetes mellitus, chronic pulmonary disease), and the nature of the exposure (e.g., microbial virulence, inoculum size) may affect our response to infectious disease, with the outcome ultimately determined by our host defenses, which include anatomic (e.g., skin) and physiologic barriers (e.g., stomach acid), innate immune responses (e.g., phagocytes, microbial pattern receptors), and adaptive responses that include specific antibodies and cell-mediated immunity.

Humans are equipped with a multilayered host defense system to counter infectious organisms, and the interaction between a potential pathogen and a human can lead to one of three basic outcomes: death of the human host, elimination of the pathogen (with or without clinical symptoms), or an ongoing symbiotic relationship whose nature may change with time and under additional biologic pressures. For example, while some healthy humans are colonized by *Streptococcus pneumoniae*, pneumonia or meningitis may be caused by virulent strains, leading to death if the host's defenses cannot eliminate the pathogen in time. Most individuals exposed to *Mycobacterium tuberculosis* are asymptomatic because the adaptive immune response contains the organism in a live but nonreplicating (latent) state. Almost one third of the world's population is so infected, but only about 10% progress to active disease. Immunologic impairment (e.g., as a result of human immunodeficiency virus [HIV] infection) and factors such as age-associated immune senescence increase the risk of progressing from latent to active disease.

The asymptomatic nature of an infection should not automatically be equated with latency or dormancy of the pathogen. For example, chronic HIV infection was initially incorrectly characterized as having a prolonged latent or silent stage before the host developed immunodeficiency and opportunistic infections. However, most untreated HIV-infected individuals harbor actively replicating virus that kill CD4⁺ T lymphocytes on a daily basis, although the aggregate effects are not appreciated until CD4⁺ T lymphocyte levels are reduced to below 200 cells/mL, typically after 8 to 10 years of infection without antiretroviral treatment. Infected individuals are contagious to others despite their relatively asymptomatic state, thus treatment (when available) is recommended regardless of CD4⁺ T lymphocyte levels. Treatment halts viral immune destruction and reduces viral burden in blood and genital secretions, thus decreasing an infected individual's risk of transmitting HIV.

CATEGORIES OF HOST DEFENSES AND RISKS OF INFECTION

The relative importance of the innate and adaptive immune defenses is best illustrated by individuals who are deficient in a particular immunological component. For example, cancer chemotherapy may lead to the depletion of innate cells such as neutrophils, rendering the host more susceptible to bacterial and fungal infections. Congenital deficiency of immunoglobulins increases the risk of infections that are usually thwarted by antibody responses such as those associated with *Streptococcus pneumoniae* and *Haemophilus influenzae*. Pharmacologic inhibition of tumor necrosis factor- α (TNF- α) for the treatment of chronic inflammatory disease such as Crohn's or psoriasis increases the risk of developing active tuberculosis among those with latent infection. In 1981 astute clinicians, recognizing the increased incidence of an atypical pneumonia caused by *Pneumocystis jirovecii* (formerly *P. carinii*) among young men, sounded the alarm that a novel acquired immunodeficiency syndrome (eventually shown to primarily affect CD4⁺ T lymphocytes) had appeared that was later ascribed to HIV.

Host defenses to infection can be classified as nonimmunologic barriers, innate immunity, and specific or adaptive immunity. Immune defenses against microbial pathogens are composed of cells and molecules located in the blood, peripheral sites such as the skin and submucosal regions, and in secondary lymphoid tissues such as the lymph nodes, tonsils, spleen, and Peyer patches.

For a deeper discussion of these topics, please see Chapters 39 through 44 in Section VII, "Principles of Immunology and Inflammation," in *Goldman-Cecil Medicine*, 26th Edition. ❖

Nonimmunologic Host Defenses

Nonimmunologic host defenses include anatomic and physiologic barriers that prevent the entry of pathogens into the body. Injuries or devices that damage or bypass anatomic barriers frequently lead to infection. Examples include burns, intravenous catheters, intubation, urinary tract catheters, surgery, and trauma.

The respiratory tract defenses depend on mucus that entraps pathogens and on ciliary action and cough that continuously clear the mucus and organisms from the lungs and upper airways. Respiratory viruses, including influenza, may inhibit ciliary action or denude the mucous membrane completely, allowing bacteria to colonize and cause secondary infection. Stroke, medications, or other causes of reduced cough reflex may lead to poor clearance of secretions, mucus, and pathogens, leading to lung infection. Smoking and exposure to industrial toxins such as silica may similarly reduce lung host defenses, such as by reducing ciliary action and inhibiting alveolar macrophage function respectively. Alveolar macrophages located in the lung parenchyma play an essential role in the initial clearance and killing of pathogens.

Nonimmune gastrointestinal defenses include gastric acidity, which kills many microorganisms, and vomiting and diarrhea, which help to clear pathogens from the gut. Bacteria vary greatly in their susceptibility to gastrointestinal host defenses. For example, as few as 10 *Shigella* sp bacteria can cause infection, whereas 10^5 to 10^8 *Vibrio cholera* bacteria are required for infection.

The urinary tract is protected physically by regular urine flow, the acidity of the urine, and antimicrobial peptides. Conditions that interfere with these factors (e.g., prostatic hypertrophy, renal stones) may lead to stasis and infection. Mechanical injection of bacteria through the urethra into the bladder, as may occur in women during sexual intercourse, can lead to colonization of the bladder and infection. Urinary tract catheters bypass normal mechanical barriers allowing bacteria to enter the bladder retrograde resulting in urinary tract infections.

The normal microbiologic flora on the skin and in the respiratory and gastrointestinal tracts is an important component of host defenses. Normal flora compete with pathogens for nutrients and have antimicrobial activity of their own. To illustrate, certain commensal bacteria

of the skin secrete acid that prevents colonization by species more likely to cause disease. Disruption of the normal flora, such as by antibiotic treatment, allows opportunistic organisms such as *Clostridioides difficile* in the gut and *Candida* sp in the mouth or vagina to colonize and cause disease.

Organs that clear organisms from the bloodstream and lymph, including the liver, spleen, and lymph nodes, play an essential role after a pathogen has breached the primary anatomic barriers. Lack of a spleen increases a person's susceptibility to overwhelming sepsis caused by encapsulated bacteria including *S. pneumoniae*, *Neisseria meningitidis*, and *H. influenzae*. Cirrhosis of the liver allows portal vein blood to bypass the liver, increasing susceptibility to infection by gut flora.

Innate Immunity

Innate immunity refers to inborn resistance mechanisms that rapidly recognize pathogens and promote inflammation at the site of infection, thus comprising a critical first line of defense against pathogens. Fig. 88.1 compares the major features of innate and adaptive immunity.

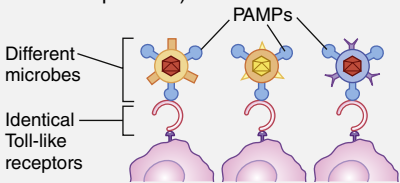

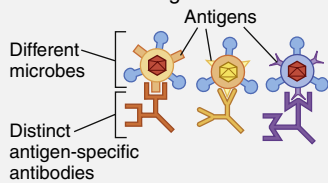

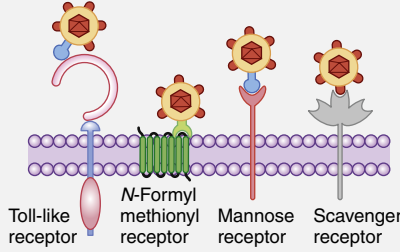

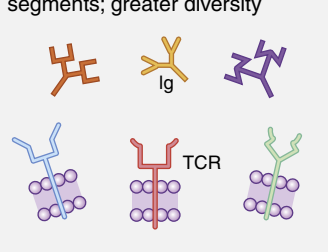

FEATURE	INNATE IMMUNITY	ADAPTIVE IMMUNITY
Specificity	For structures shared by classes of microbes (pathogen-associated molecular patterns) 	For structural detail of microbial molecules (antigens); may recognize nonmicrobial antigens 
Number of microbial molecules recognized	About 1,000 molecular patterns (estimated)	$>10^7$ antigens
Receptors	Encoded in germline; limited diversity (pattern recognition receptors) 	Encoded by genes produced by somatic recombination of gene segments; greater diversity 
Number and types of receptors	<100 different types of invariant receptors	Only 2 types of receptors (Ig and TCR), with millions of variations of each
Distribution of receptors	Nonclonal: identical receptors on all cells of the same lineage	Clonal: clones of lymphocytes with distinct specificities express different receptors
Genes encoding receptors	Germline encoded, in all cells	Formed by somatic recombination of gene segments only in B and T cells
Discrimination of self and nonself	Yes; healthy host cells are not recognized or they may express molecules that prevent innate immune reactions	Yes; based on elimination or inactivation of self-reactive lymphocytes; may be imperfect (hence the possibility of autoimmunity)

Fig. 88.1 Specificity and receptors of innate immunity and adaptive immunity. This summarizes the important features of the specificity and receptors of innate and adaptive immunity, with select examples illustrated. *Ig*, Immunoglobulin (antibody); *TCR*, T cell receptor. (From Abbas A K, Lichtman A H, Pillai S: Basic immunology: functions and disorders of the immune system, 6th ed. Philadelphia, Elsevier, 2018.)

The response of innate immunity is relatively nonspecific, invariant, rapid, and largely without memory. By contrast, adaptive immunity is highly specific and diverse but relatively slow during a primary infection, typically requiring days or even weeks to reach maximal activation. However, adaptive responses typically lead to the formation of durable memory that can be recalled upon secondary infection with a more rapid, robust response.

The molecules involved in innate immune responses include cytokines, chemokines, integrins, and pattern receptors. Cytokines are soluble proteins that have numerous functions, including promoting cellular growth and activation as well as regulating adaptive immune responses (Table 88.1). Their functions range from stimulating the production of and activating inflammatory cells, including neutrophils, macrophages, and eosinophils, to the direct antiviral action of interferons. Some activate endothelial cells and cause fever, whereas others regulate the inflammatory response.

Concentration gradients of chemokines in tissue attract leukocytes to areas of inflammation. Integrins on the surface of leukocytes allow adhesion to receptors on other types of cells such as vascular endothelium. This is the first step in recruiting and localizing leukocytes to areas of inflammation.

Pathogen pattern recognition receptors on phagocytes include toll-like receptors (TLRs), named for their homology to the toll molecule which was originally identified in the fruit fly, *Drosophila*; nucleotide oligomerization domain–like receptors (often abbreviated as Nod-like receptors, or NLRs); C-type lectin-like receptors (CLRs); and retinoic acid-inducible gene-I-like receptors (RLRs), which are intracellular receptors that detect viral RNA. TLRs, which recognize broad features of microbes such as the lipopolysaccharide (LPS) found in the cell wall of gram-negative bacteria, the peptidoglycan found in the cell walls of gram-positive bacteria, and the nucleic acids of viruses, have been studied extensively. TLRs are located on several immune cell types, including macrophages and dendritic cells. When a pathogen is detected by TLRs on the surface of a cell or associated with endosomes, signaling cascades are initiated that lead to the activation of nuclear transcription factors such as nuclear factor- κ B (NF- κ B). This stimulates the production of numerous cytokines important in the inflammatory response, including interleukin-1 (IL-1), IL-6, IL-10, IL-15, TNF- α , and growth factors (see Table 88.1). These cytokines amplify the inflammatory response by activating effector cells and by stimulating the production of many other inflammatory factors, including IL-2, interferons, C-reactive protein, complement components, and growth factors.

Complement factors are soluble proteins and enzymes that are produced as inactive precursors in the liver. Complement activation may occur as a result of antigen-antibody immune complex binding by factor C1 (the classical pathway), the binding of mannose-binding lectin (MBL) to microbial glycoproteins containing mannose (the lectin pathway), or the alternative pathway, which can be activated by bacterial cell wall components.

Regardless of how the complement system is activated, the cascade results in the production of C3 convertase, a protein that cleaves C3 into C3a and C3b fragments. This is followed by the production of a C5 convertase, which cleaves C5 into C5a and C5b. C3a and C5a, also known as anaphylatoxins, stimulate histamine release from mast cells leading to vasodilatation, increase vascular permeability and attract activated macrophages. C3b binds to the microbial surface and in conjunction with pathogen-specific immunoglobulin G (IgG) may stimulate phagocytosis. C5b serves as a nucleation point for the assembly of the membrane attack complex (MAC) that consists of C5b, C6, C7, C8 and multiple molecules of C9. MAC assembly results in pore formation that leads to bacterial lysis. Patients deficient in any of the

MAC components C5 to C9 appear to be particularly susceptible to organisms such as *Neisseria meningitidis* and *N. gonorrhoeae*. The complement system is regulated by numerous factors including soluble C1 inhibitor, which causes breakdown of the C1 complex, as well as the membrane-bound proteins decay-acceleration factor (DAF), which breaks down C3 convertases, and protectin, which inhibits MAC formation. These regulatory factors help to ensure that the complement system is not activated inappropriately against host cells.

The inflammatory response results in the classic clinical signs of inflammation, including erythema, pain, warmth, swelling, and loss of function. It can be initiated by microorganisms in tissue, tissue injury, or dysfunctional adaptive immunity (e.g., autoantibodies). The response includes inflammatory molecules as previously described and tissue and migrating leukocytes. Neutrophils are central to the clinical manifestations of inflammation in tissue, and patients with neutropenia or functional deficits in neutrophil function often lack the signs of inflammation at the site of serious infection.

Neutrophils are bone marrow–derived phagocytes whose production is greatly stimulated by infection through the action of macrophage-produced growth factors, including granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Neutrophils circulate in blood (where they are the most abundant white blood cell), are attracted to sites of inflammation, and are activated by chemotactic factors, including formyl peptides derived from bacteria, complement factors C3a and C5a, IL-8, interferon, and leukotrienes, particularly leukotriene B₄. Neutrophils migrate from the endovascular space into inflammatory tissue through an integrin-regulated process that includes receptors on neutrophils and vascular endothelial cells. Activated neutrophils then migrate using a chemoattractive (i.e., chemokine) gradient toward the site of inflammation.

Neutrophils are killing machines containing granules that have up to 100 different antimicrobial molecules. The contents of granules are released intracellularly into phagosomes after phagocytosis of a pathogen or released extracellularly in the vicinity of pathogens. Phagocytosis is greatly enhanced by opsonization (i.e., antibody and complement binding) of pathogens. The major microbicidal mechanism of neutrophils is the superoxide burst (i.e., production of superoxide anion catalyzed by NADPH oxidase) and then the dismutation to hydrogen peroxide (H₂O₂), which may in turn be converted to hypochlorous acid (HClO). Many other granule molecules, such as cathepsins, elastases, defensins, and collagenase contribute to the killing process. Similar mechanisms exist in other phagocytes such as macrophages. More recently it has been found that in addition to phagocytosis and degranulation, activated neutrophils produce neutrophil extracellular traps (NETs), which are webs of chromatin and proteases that can immobilize and kill pathogenic microbes.

Eosinophils, which are found more in tissue than the circulation, are primarily important in host defenses against multicellular parasites such as parasitic worms. Growth and differentiation of eosinophils is promoted by IL-5. Eosinophils are activated and recruited by a variety of mediators, including complement factors and leukotrienes. Eosinophil granules contain specific cationic proteins that are toxic to parasites. Eosinophils also play key roles in the pathogenesis of allergic reactions and diseases such as asthma.

Basophils in blood and mast cells in tissue contain granules with high concentrations of histamine and other inflammatory mediators. Basophils and mast cells express receptors for complement factors and others that bind immunoglobulin E (IgE) produced by B cells. They can be activated by complement factors C3a and C5a and by cross-linking of IgE by antigen on the surface of mast cells. Histamine is a short-acting, low-molecular-weight amine that acts through four

TABLE 88.1 Cytokines

Cytokine and Subunits	Principal Cell Source	Cytokine Receptor and Subunits ^a	Principal Cellular Targets and Biologic Effects
Type I Cytokine Family Members			
Interleukin-2 (IL-2)	T cells	CD25 (IL-2R α) CD122 (IL-2R β) CD132 (γ c)	T cells: proliferation and differentiation into effector and memory cells; promotes regulatory T cell development, survival, and function NK cells: proliferation, activation B cells: proliferation, antibody synthesis (in vitro)
Interleukin-3 (IL-3)	T cells	CD123 (IL-3R α) CD131 (β c)	Immature hematopoietic progenitors: induced maturation of all hematopoietic lineages
Interleukin-4 (IL-4)	CD4 ⁺ T cells (Th2, Tfh), mast cells	CD124 (IL-4R α) CD132 (γ c)	B cells: isotype switching to IgE T cells: Th2 differentiation, proliferation Macrophages: alternative activation and inhibition of IFN- γ -mediated classical activation
Interleukin-5 (IL-5)	CD4 ⁺ T cells (Th2), group 2 ILCs	CD125 (IL-5R α) CD131 (β c)	Eosinophils: activation, increased generation
Interleukin-6 (IL-6)	Macrophages, endothelial cells, T cells	CD126 (IL-6R α) CD130 (gp130)	Liver: synthesis of acute-phase protein B cells: proliferation of antibody-producing cells
Interleukin-7 (IL-7)	Fibroblasts, bone marrow stromal cells	CD127 (IL-7R) CD132 (γ c)	T cells: Th17 differentiation Immature lymphoid progenitors: proliferation of early T and B cell progenitors T lymphocytes: survival of naïve and memory cells
Interleukin-9 (IL-9)	CD4 ⁺ T cells	CD129 (IL-9R) CD132 (γ c)	Mast cells, B cells, T cells, and tissue cells: survival and activation
Interleukin-11 (IL-11)	Bone marrow stromal cells	IL-11R α CD130 (gp130)	Production of platelets
Interleukin-12 (IL-12): IL-12A (p35) IL-12B (p40)	Macrophages, dendritic cells	CD212 (IL-12R β 1) IL-12R β 2	T cells: Th1 differentiation NK cells and T cells: IFN- γ synthesis, increased cytotoxic activity
Interleukin-13 (IL-13)	CD4 ⁺ T cells (Th2), NKT cells, group 2 ILCs, mast cells	CD213a1 (IL-13R α 1) CD213a2 (IL-13R α 2) CD132 (γ c)	B cells: isotype switching to IgE Epithelial cells: increased mucus production Macrophages: alternative activation
Interleukin-15 (IL-15)	Macrophages, other cell types	IL-15R α CD122 (IL-2R β) CD132 (γ c)	NK cells: proliferation T cells: survival and proliferation of memory CD8 ⁺ cells
Interleukin-17A (IL-17A) Interleukin-17F (IL-17F)	CD4 ⁺ T cells (Th17), group 3 ILCs	CD217 (IL-17RA) IL-17RC	Epithelial cells, macrophages and other cell types: increased chemokine and cytokine production; GM-CSF and G-CSF production
Interleukin-21 (IL-21)	Th2 cells, Th17 cells, Tfh cells	CD360 (IL-21R) CD132 (γ c)	B cells: activation, proliferation, differentiation Tfh cells: development Th17 cells: increased generation
Interleukin-23 (IL-23): IL-23A (p19) IL-12B (p40)	Macrophages, dendritic cells	IL-23R CD212 (IL-12R β 1)	T cells: differentiation and expansion of Th17 cells
Interleukin-25 (IL-25; IL-17E)	T cells, mast cells, eosinophils, macrophages, mucosal epithelial cells	IL-17RB	T cells and various other cell types: expression of IL-4, IL-5, IL-13
Interleukin-27 (IL-27): IL-27 (p28) EBI3 (IL-27B)	Macrophages, dendritic cells	IL-27R α CD130 (gp130)	T cells: enhancement of Th1 differentiation; inhibition of Th17 differentiation NK cells: IFN- γ synthesis?

TABLE 88.1 Cytokines—cont'd

Cytokine and Subunits	Principal Cell Source	Cytokine Receptor and Subunits ^a	Principal Cellular Targets and Biologic Effects
Stem cell factor (c-Kit ligand)	Bone marrow stromal cells	CD117 (KIT)	Pluripotent hematopoietic stem cells: induced maturation of all hematopoietic lineages
Granulocyte-monocyte CSF (GM-CSF)	T cells, macrophages, endothelial cells, fibroblasts	CD116 (GM-CSFR α) CD131 (β c)	Immature and committed progenitors, mature macrophages: induced maturation of granulocytes and monocytes, macrophage activation
Monocyte CSF (M-CSF, CSF1)	Macrophages, endothelial cells, bone marrow cells, fibroblasts	CD115 (CSF1R)	Committed hematopoietic progenitors: induced maturation of monocytes
Granulocyte CSF (G-CSF, CSF3)	Macrophages, fibroblasts, endothelial cells	CD114 (CSF3R)	Committed hematopoietic progenitors: induced maturation of granulocytes
Thymic stromal lymphopoietin (TSLP)	Keratinocytes, bronchial epithelial cells, fibroblasts, smooth muscle cells, endothelial cells, mast cells, macrophages, granulocytes and dendritic cells	TSLP-receptor CD127 (IL-7R)	Dendritic cells: activation Eosinophils: activation Mast cells: cytokine production T cells: Th2 differentiation
Type II Cytokine Family Members			
IFN- α (multiple proteins)	Plasmacytoid dendritic cells, macrophages	IFNAR1 CD118 (IFNAR2)	All cells: antiviral state, increased class I MHC expression NK cells: activation
IFN- β	Fibroblasts, plasmacytoid dendritic cells	IFNAR1 CD118 (IFNAR2)	All cells: antiviral state, increased class I MHC expression NK cells: activation
Interferon- γ (IFN- γ)	T cells (Th1, CD8 ⁺ T cells), NK cells	CD119 (IFNGR1) IFNGR2	Macrophages: classical activation (increased microbicidal functions) B cells: isotype switching to opsonizing and complement-fixing IgG subclasses (established in mice) T cells: Th1 differentiation Various cells: increased expression of class I and class II MHC molecules, increased antigen processing and presentation to T cells
Interleukin-10 (IL-10)	Macrophages, T cells (mainly regulatory T cells)	CD210 (IL-10R α) IL-10R β	Macrophages, dendritic cells: inhibition of expression of IL-12, co-stimulators, and class II MHC
Interleukin-22 (IL-22)	Th17 cells	IL-22R α 1 <i>or</i> IL-22R α 2 IL-10R β 2	Epithelial cells: production of defensins, increased barrier function Hepatocytes: survival
Interleukin-26 (IL-26)	T cells, monocytes	IL-20R1/IL-10R2	Not established
Interferon- λ s (type III interferons)	Dendritic cells	IFNLR1 (IL-28R α) CD210B (IL-10R β 2)	Epithelial cells: antiviral state
Leukemia inhibitory factor (LIF)	Embryonic trophectoderm, bone marrow stromal cells	CD118 (LIFR) CD130 (gp130)	Stem cells: block in differentiation
Oncostatin M	Bone marrow stromal cells	OSMR CD130 (gp130)	Endothelial cells: regulation of hematopoietic cytokine production Cancer cells: inhibition of proliferation
TNF Superfamily Cytokines^b			
Tumor necrosis factor (TNF, TNFSF1)	Macrophages, NK cells, T cells	CD120a (TNFRSF1) <i>or</i> CD120b (TNFRSF2)	Endothelial cells: activation (inflammation, coagulation) Neutrophils: activation Hypothalamus: fever Muscle, fat: catabolism (cachexia)
Lymphotoxin- α (LT α , TNFSF1)	T cells, B cells	CD120a (TNFRSF1) <i>or</i> CD120b (TNFRSF2)	Same as TNF

TABLE 88.1 Cytokines—cont'd

Cytokine and Subunits	Principal Cell Source	Cytokine Receptor and Subunits ^a	Principal Cellular Targets and Biologic Effects
Lymphotoxin- $\alpha\beta$ (LT $\alpha\beta$)	T cells, NK cells, follicular B cells, lymphoid inducer cells	LT β R	Lymphoid tissue stromal cells and follicular dendritic cells: chemokine expression and lymphoid organogenesis
BAFF (CD257, TNFSF13B)	Dendritic cells, monocytes, follicular dendritic cells, B cells	BAFF-R (TNFRSF13C) <i>or</i> TACI (TNFRSF13B) <i>or</i> BCMA (TNFRSF17)	B cells: survival, proliferation
APRIL (CD256, TNFSF13)	T cells, dendritic cells, monocytes, follicular dendritic cells	TACI (TNFRSF13B) <i>or</i> BCMA (TNFRSF17)	B cells: survival, proliferation
Osteoprotegerin (OPG, TNFRSF11B)	Osteoblasts	RANKL	Osteoclast precursor cells: inhibits osteoclast differentiation
IL-1 Family Cytokines			
Interleukin-1 α (IL-1 α)	Macrophages, dendritic cells, fibroblasts, endothelial cells, keratinocytes, hepatocytes	CD121a (IL-1R1) IL-1RAP <i>or</i> CD121b (IL-1R2)	Endothelial cells: activation (inflammation, coagulation) Hypothalamus: fever
Interleukin-1 β (IL-1 β)	Macrophages, dendritic cells, fibroblasts, endothelial cells, keratinocyte	CD121a (IL-1R1) IL-1RAP <i>or</i> CD121b (IL-1R2)	Endothelial cells: activation (inflammation, coagulation) Hypothalamus: fever Liver: synthesis of acute-phase proteins T cells: Th17 differentiation
Interleukin-1 receptor antagonist (IL-1RA)	Macrophages	CD121a (IL-1R1) IL-1RAP	Various cells: competitive antagonist of IL-1
Interleukin-18 (IL-18)	Monocytes, macrophages, dendritic cells, Kupffer cells, keratinocytes, chondrocytes, synovial fibroblasts, osteoblasts	CD218a (IL-18R α) CD218b (IL-18R β)	NK cells and T cells: IFN- γ synthesis Monocytes: expression of GM-CSF, TNF, IL-1 β
Interleukin-33 (IL-33)	Endothelial cells, smooth muscle cells, keratinocytes, fibroblasts	ST2 (IL1RL1) IL-1 Receptor Accessory Protein (IL1RAP)	Neutrophils: activation, cytokine release T cells: Th2 development ILCs: activation of group 2 ILCs
Other Cytokines			
Transforming growth factor- β (TGF- β)	T cells (mainly Tregs), macrophages, other cell types	TGF- β R1 TGF- β R2 TGF- β R3	T cells: inhibition of proliferation and effector functions; differentiation of Th17 and Treg B cells: inhibition of proliferation; IgA production Macrophages: inhibition of activation; stimulation of angiogenic factors Fibroblasts: increased collagen synthesis

APRIL, A proliferation-inducing ligand; BAFF, B cell-activating factor belonging to the TNF family; BCMA, B cell maturation protein; CSF, colony-stimulating factor; IFN, interferon; IgE, immunoglobulin E; ILCs, innate lymphoid cells; MHC, major histocompatibility complex; NK cell, natural killer cell; NKT cell, natural killer T cell; OSMR, oncostatin M receptor; RANK, receptor activator for nuclear factor κ B ligand; RANKL, RANK ligand; TACI, transmembrane activator and calcium modulator and cyclophilin ligand interactor; Th, T helper; Tfh, T follicular helper; TNF, tumor necrosis factor; TNFSF, TNF superfamily; TNFRSF, TNF receptor superfamily; Treg, regulatory T cell.

^aMost cytokine receptors are dimers or trimers composed of different polypeptide chains, some of which are shared between receptors for different cytokines. The set of polypeptides that compose a functional receptor (cytokine binding plus signaling) for each cytokine is listed. The functions of each subunit polypeptide are not listed.

^bAll TNF superfamily (TNFSF) members are expressed as cell surface transmembrane proteins, but only the subsets that are predominantly active as proteolytically released soluble cytokines are listed in the table. Other TNFSF members that function predominantly in the membrane-bound form and are not, strictly speaking, cytokines are not listed in the table. These membrane-bound proteins and the TNFRSF receptors they bind to include OX40L (CD252, TNFSF4):OX40 (CD134, TNFRSF4); CD40L (CD154, TNFSF5):CD40 (TNFRSF5); FasL (CD178, TNFSF6):Fas (CD95, TNFRSF6); CD70 (TNFSF7):CD27 (TNFRSF27); CD153 (TNFSF8):CD30 (TNFRSF8); TRAIL (CD253, TNFSF10):TRAIL-R (TNFRSF10A-D); RANKL (TNFSF11):RANK (TNFRSF11); TWEAK (CD257, TNFSF12):TWEAKR (CD266, TNFRSF12); LIGHT (CD258, TNFSF14):HVEM (TNFRSF14); GITRL (TNFSF18):GITR (CD357 TNFRSF18); and 4-1BBL:4-1BB (CD137).

From Abbas A K, Lichtman A H, Pillai S: Basic immunology: functions and disorders of the immune system, 6th ed. Philadelphia, Elsevier, 2018.

different histamine receptors. Its actions include bronchoconstriction and bronchial smooth muscle contraction, itching, pain, vasodilation, and increased vascular permeability. Histamine also plays a role in gastric acid secretion, motion sickness, and sleep suppression. Commonly used antihistamines counter these effects.

Blood monocytes are produced in the bone marrow and circulate for several days in the blood. Some may migrate into tissues, where they may develop into macrophages that phagocytize pathogens and debris and kill microorganisms when activated by bacterial products such as lipopolysaccharide (LPS), interferon- γ , and other cytokines.

The properties and function of macrophages depend on the tissue. Alveolar macrophages in the lung are continuously exposed to airborne particles and pathogens, whereas microglia in the brain have a very different environment and function. Macrophages clear cellular debris after acute inflammation and thus are the custodians of peripheral tissue. Macrophages produce a variety of cytokines important in the inflammatory process, including IL-1, TNF- α , IL-6, IL-15, and leukocyte growth factors.

Fever during inflammation and infection results from cytokines such as IL-1 and TNF- α that are released by macrophages into the circulation. These molecules increase the level of prostaglandins in the hypothalamus, which elevates the normal temperature set point. This stimulates thermoregulatory mechanisms to elevate the core body temperature, which has antimicrobial effects.

Macrophages play a central role in granuloma formation. For example, macrophages are critical in controlling difficult-to-kill acid-fast mycobacteria such as *M. tuberculosis* or fungi by walling off viable organisms in granulomas. Macrophages also present antigen derived from microbial pathogens to T cells, helping to initiate the adaptive immune response.

Dendritic cells (DCs) are derived from myeloid or lymphocytic precursors. Dendritic cells of the myeloid lineage (also known as conventional DCs or cDCs) are found primarily in tissues where pathogens are likely to enter the body, such as the skin, gastrointestinal tract, spleen, and respiratory tract. These cells have branchlike cytoplasmic extensions (for which they are named), and they phagocytize pathogens in a manner similar to macrophages, then migrate to lymphoid organs where they interact with T cells. They are the major antigen-presenting cells (APCs) in the body and are critical for the initial activation of adaptive immune responses. Dendritic cells of the lymphoid lineage are known as plasmacytoid dendritic cells (pDCs). Like cDCs, pDCs may also present antigen to T cells; however, their major role is to produce copious amounts of interferon- α upon viral infection, providing a critical first line of defense.

Natural killer (NK) cells are large granular lymphocytes that kill abnormal cells, including virus-infected cells and certain tumor cells. NKs do not express immunoglobulins or T-cell receptors but rather employ a system of activating and inhibitory receptors to detect features of stressed cells such as reduction in the expression of major histocompatibility complex (MHC) molecules. Upon activation, NKs kill their targets by releasing granule contents that include the pore-forming protein perforin and various proteases known as granzymes, which may induce target cell death via lysis or apoptosis. NKs are part of the first line of defense against viral infections while adaptive immunity is developing. Patients with NK deficiencies have been shown to be highly susceptible to herpesvirus infection such as varicella-zoster virus.

Adaptive Immunity

The adaptive immune response is capable of producing exquisitely specific protective mechanisms against microbial pathogens (see Fig. 88.1). Adaptive responses to most protein-containing antigens produced by pathogens during a primary exposure leads to the

Fig. 88.2 Primary and secondary immune responses. The properties of memory and specificity can be demonstrated by repeated immunizations with defined antigens in animal experiments. Antigens X and Y induce the production of different antibodies (a reflection of specificity). The secondary response to antigen X is more rapid and larger than the primary response (illustrating memory) and is different from the primary response to antigen Y (again reflecting specificity). Antibody levels decline with time after each immunization. The level of antibody produced is shown as arbitrary values and varies with the type of antigen exposure. Only B cells are shown, but the same features are seen with T cell responses to antigens. The time after immunization may be 1 to 3 weeks for a primary response and 2 to 7 days for a secondary response, but the kinetics vary, depending on the antigen and the nature of immunization. (From Abbas A K, Lichtman A H, Pillai S: Basic immunology: functions and disorders of the immune system, 6th ed. Philadelphia, Elsevier, 2018.)

formation of memory B and T cells; secondary exposure to that antigen may recall the memory, leading to adaptive responses that are more rapid, of much greater magnitude, and of higher affinity than before (Fig. 88.2). The capacity of the adaptive immune system to protect against different pathogens is truly astounding. Through a process known as gene rearrangement it has been estimated that B cells can produce 10^{12} different immunoglobulin molecules and that T cells can have up to 10^{18} different T-cell receptors (TCRs) for specific antigens.

Antibodies and B Lymphocytes

Antibodies, also known as immunoglobulins (Igs), are variable glycoproteins produced by B cells that recognize specific structural motifs (epitopes) on the molecules (antigens) produced by microbial pathogens. In antimicrobial defense, binding of an antibody to a pathogen may inhibit (neutralize) the ability of the pathogen to infect a cell (e.g., influenza virus) or the ability of a toxin (e.g., tetanus toxin) to be effective; prompt phagocytosis by phagocytic cells such as neutrophils and macrophages (i.e., opsonization); activate the complement cascade; or kill an infected cell through the process known as antibody-dependent cellular cytotoxicity (ADCC), in which otherwise nonspecific immune cells such as neutrophils or macrophages are able to recognize antibodies bound to target cell surfaces and release cytolytic factors.

Antibody-mediated host defense occurs mainly in the extracellular space, as opposed to T cell-mediated host defenses that act primarily on intracellular pathogens (i.e., those that enter cells and survive intracellularly). The five major isotypes (also known as classes) of antibodies are summarized in Fig. 88.3 (note that IgG and IgA are further divided into subtypes). Effector functions mediated by antibodies include complement activation (IgM and IgG1/2/3),

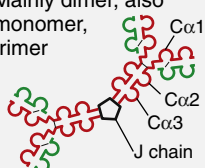

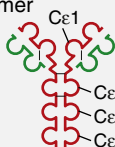

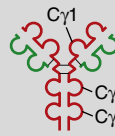

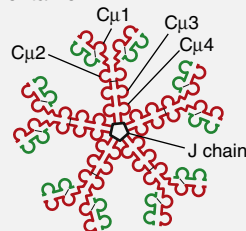

ISOTYPE OF ANTIBODY	SUBTYPES (H CHAIN)	PLASMA CONCENTRATION (mg/ml)	PLASMA HALF-LIFE (DAYS)	SECRETED FORM	FUNCTIONS
IgA	IgA 1,2 (α 1 or α 2)	3.5	6	Mainly dimer, also monomer, trimer 	Mucosal immunity
IgD	None (δ)	Trace	3	Monomer	Naive B cell antigen receptor
IgE	None (ϵ)	0.05	2	Monomer 	Defense against helminthic parasites, immediate hypersensitivity
IgG	IgG 1-4 (γ 1, γ 2, γ 3 or γ 4)	13.5	23	Monomer 	Opsonization, complement activation, antibody-dependent cell-mediated cytotoxicity, neonatal immunity, feedback inhibition of B cells
IgM	None (μ)	1.5	5	Pentamer 	Naive B cell antigen receptor (monomeric form), complement activation

Fig. 88.3 Features of the major isotypes (classes) of antibodies. This figure summarizes some important features of the major antibody isotypes of humans. Isotypes are classified on the basis of their heavy (H) chains; each isotype may contain either κ or λ light chain. The schematic diagrams illustrate the distinct shapes of the secreted forms of these antibodies. Note that IgA consists of two subclasses, called IgA1 and IgA2, and IgG consists of four subclasses, called IgG1, IgG2, IgG3, and IgG4. Most of the opsonizing and complement fixation functions of IgG are attributable to IgG1 and IgG3. The domains of the heavy chains in each isotype are labeled. The plasma concentrations and half-lives are average values in normal individuals. *Ig*, Immunoglobulin. (From Abbas A K, Lichtman A H, Pillai S: Basic immunology: functions and disorders of the immune system, 6th ed. Philadelphia, Elsevier, 2018.)

opsonization (IgG), neutralization (IgM, IgG, and IgA) and mast cell degranulation (IgE) which mediates type I hypersensitivity. IgG antibodies cross the placenta, providing protective immunity to newborns for months after birth. IgA molecules are secretory antibodies that act at mucosal surfaces and are the predominant antibody in external secretions such as mucus, saliva, and breast milk. IgE is responsible for allergic responses and host defenses against parasites. IgM (in monomeric form) and IgD are found on the surface of naïve B cells and function in the initial antigen-mediated activation of these cells.

The basic structural unit of an antibody is composed of two identical “heavy” (H) chains and two identical “light” (L) chains (Fig. 88.4). Each heavy and light chain has constant and variable regions, the latter mediating antigen specificity. The five major types of heavy chains are designated mu, delta, gamma, epsilon and alpha (μ , δ , γ , ϵ , and α) and define the antibody isotype (IgM, IgD, IgG, IgE and IgA). There are

two types of light chains, kappa and lambda (κ and λ), that may associate with any of the heavy chains. The antigen-binding site of each molecule is composed partly of the variable region of a heavy chain and partly of the variable region of a light chain. There are two such binding sites for each antibody monomer, although secreted antibodies may contain 2, 4, or 10 identical antigen binding sites depending on if they are secreted as a monomer (IgG, IgD, IgE), a dimer (IgA) or a pentamer (IgM) (see Fig. 88.3).

The B-cell receptor (BCR) is composed of the specific immunoglobulin produced by that B cell associated with signaling molecules on the cell surface. Naïve B cells simultaneously express BCRs that contain monomeric IgM or IgD, each with identical antigen specificity. When initially stimulated, B cells typically secrete pentameric IgM antibodies. Later in the immune response, a B cell may undergo a process that allows the isotype of immunoglobulin produced to switch (e.g., from IgM to IgG; see later).

Fig. 88.4 Structure of antibodies. Antibody molecules are composed of two heavy chains (red lines) and two light chains (blue lines) held together by disulfide bonds. The two heavy chains join to form a tail (Fc end), which can interact with receptors (FcR) on a variety of cells. The heavy and light chains contribute to the Fab end. At the 5' or amino-terminal end, these chains form two identical antigen-binding sites, much like two lobster claws. Near the hinge region of the antibody, there is a binding site for C1q, the first component of the complement cascade. (From Birdsall H: Adaptive immunity: antibodies and immunodeficiencies. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Saunders.)

The constant region of the two antibody heavy chains comprises the Fc portion, which can be bound by various Fc receptors (FcRs) on the surface of immune cells (Fig. 88.4), mediating effector functions such as opsonization, ADCC, and degranulation, depending on the isotype and cell type. Soluble complement factors may also bind the Fc portion of antibodies that have bound soluble or surface-associated antigens, activating the classic complement pathway.

Much as a child might produce a large number of unique structures from a small set of building blocks, using a relatively small amount of DNA humans can generate billions of different antibodies. The two major genetic strategies that allow humans to produce antibodies specific to virtually any antigen are known as immunoglobulin gene rearrangement and somatic hypermutation. Immunoglobulin gene rearrangement involves recombination of individual variable (V), diversity (D), and joining (J) gene segments to produce functional genes that encode the immunoglobulin light and heavy chains.

Humans have about 130 functional V segments distributed among the three immunoglobulin gene clusters (heavy chain, kappa light chain, and lambda light chain); each cluster contains four to six functional J segments, with the heavy chain cluster also containing about 25 functional D segments. During B-cell development proteins known as recombination activating genes 1 and 2 (RAG-1/2) mediate random recombination of V, D, and J segments on heavy chain alleles and V and J segments on light chain alleles in a stepwise process. The combinatorial diversity of V(D)J rearrangement is greatly augmented by flexible joining events that can lead to insertion or deletion of nucleotides at each junction. In this manner, an enormously diverse set of variable chains—perhaps as many as 10^{12} —may be assembled. Further genetic variation arises through a process known as somatic hypermutation, which occurs in proliferating B cells following activation by foreign antigen in lymphoid tissues.

The adaptive humoral response begins with recognition of foreign antigen by specific B cells in secondary lymphoid organs. Before activation, B cells express IgM and IgD with a particular specificity on their membranes; following binding of a protein antigen the B cells internalize and process the antigen, then present peptides derived from it to CD4⁺ helper T (Th) cells. Interaction with a Th that expresses a TCR specific for peptide derived from the foreign antigen allows a B cell to become activated, proliferate, and differentiate into antibody-secreting plasma cells or memory B cells. Proliferating B cells may begin to express antibody isotypes other than IgM and IgD (e.g., IgG, IgA, IgE) through a process known as isotype switching that is

driven by cytokines such as IL-4, IL-10, IL-5 and others produced by T cells. Isotype switching, which does not affect the specificity of the antibody, allows the host to take advantage of the various effector functions mediated by the different isotypes (e.g., complement fixation for IgM, opsonic activity for IgG). As mentioned previously, proliferating B cells may also undergo somatic hypermutation, a process by which point mutations are randomly inserted into the immunoglobulin DNA. While most such mutations are deleterious, those B cells bearing mutations that enhance antigen binding activity (affinity) are selected and expanded, leading to an overall increase in the quality of the antibody response over time—this is known as affinity maturation. Furthermore, T-cell interaction typically drives the generation of a pool of memory B cells that persist for the life of the individual. Such memory cells have the capacity to be reactivated upon subsequent exposure to foreign antigen, leading to secondary antibody responses that are faster, of greater magnitude, and of higher affinity than the primary response (see Fig. 88.2).

Although most protein antigens are said to be T-dependent (i.e., require Th cells for optimal B-cell activation), some antigens can stimulate B cells to proliferate and produce antibody directly without the presence of Th cells (T-independent). T-independent antigens include microbial-derived molecules such as LPS, which bind pattern receptors (e.g., TLRs) on B cells and may stimulate them without regard to antigen specificity. Others, such as microbial-derived polysaccharides that contain repeating epitopes, specifically engage B cells with sufficient strength to bypass the requirement for Th cell interaction. More commonly, however, B cells are stimulated through synergistic action with Th cells. Specific antigen is bound to the surface immunoglobulin of the B cell, triggering endocytosis, degradation of the antigen, and presentation of peptide fragments in association with MHC class II molecules on the cell surface. Th cells with TCRs specific for the MHC-peptide complex interact with the B cell; this interaction is stabilized and strengthened through cell adhesion molecules and costimulatory activation molecules such as CD28 on the T cell and B7-1/2 (also known as CD80/86) on the B cell. Th cells then produce costimulatory molecules such as CD40L (which engages CD40 on the B cell) and cytokines such as IL-4 that drive activation and antibody production by the B cells.

T Lymphocytes

T cell precursors are produced in the bone marrow and migrate to the thymus where they undergo development and selection. At the conclusion of their development most T lymphocytes express either

Fig. 88.5 Classes of lymphocytes. B lymphocytes recognize many different types of antigens and develop into antibody-secreting cells. Helper T lymphocytes recognize antigens on the surfaces of antigen-presenting cells and secrete cytokines, which stimulate different mechanisms of immunity and inflammation. Cytotoxic T lymphocytes recognize antigens on infected cells and kill these cells. Regulatory T cells suppress immune responses (e.g., to self antigens). (From Abbas A K, Lichtman A H, Pillai S: *Basic immunology: functions and disorders of the immune system*, 6th ed. Philadelphia, Elsevier, 2018.)

CD4 or CD8 molecules on their surface along with TCRs specific for a particular combination of antigenic peptide and self MHC. During development, the TCR is produced in a process involving V(D)J gene rearrangement mediated by RAG-1/2 in a manner broadly analogous to that of B cells. Most conventional T cells express TCRs that are a combination of alpha and beta TCR chains, each with constant and variable regions; others express TCRs consisting of gamma and delta TCR chains.

As maturation takes place in the thymus, T cells undergo selection processes that eliminate those whose TCRs have low affinity for self MHC (positive selection) or too high an affinity for self molecules (negative selection). The combination of positive and negative selection thus ensures that T-cell activation requires a combination of self MHC and foreign antigen. Naïve T cells, usually in regional lymph nodes or similar tissues such as Peyer patches in the gut, are sensitized by interaction with an APC such as a dendritic cell or memory B cell. The APC internalizes and processes microbial antigen and then presents peptides derived from that antigen to the associated T cell. Presentation of antigen occurs in association with MHC (also known as human leukocyte antigens, or HLA) class II molecules for CD4⁺ cells

or MHC class I molecules for CD8⁺ cells. CD4⁺ cells are called helper T cells (Th) and develop into Th1, Th2, and Th17 subsets. CD8⁺ cells are cytotoxic T cells (CTLs; see Fig. 88.5).

CD4⁺ T cells play a central role in the activation of B lymphocytes, other CD4⁺ T cells, CD8⁺ T cells, and phagocytic cells such as macrophages. CD4⁺ T cells orchestrate host defenses against pathogens that are initially acquired by phagocytic cells during phagocytosis or pinocytosis. Dendritic cells, for example, take up pathogens or antigens by phagocytosis or pinocytosis and then degrade them within phagosomes.

Antigenic peptides, which are produced by proteolytic degradation of protein antigens in phagolysosomes, bind noncovalently to a groove in MHC class II molecules. The complex is then transported to the cell surface for presentation to T cells expressing CD4 molecules on their surface. CD4⁺ T cells with specificity for the antigen then bind via their TCRs to the MHC class II/antigen complex on the surface of the APC. CD4 also associates with MHC II, stabilizing the interaction between T cell and APC. Accessory molecules, such as the adhesion molecule lymphocyte function-associated antigen 1 (LFA-1) on T cells, which interacts with intercellular adhesion molecule 1 (ICAM-1)

on the APC, are necessary to stabilize the interaction. Activating adhesion complexes such as CD28 on T cells and B7-1/2 (also known as CD80/86) on APCs are necessary for activation, proliferation, and activation of T cells. Following activation, T cell proliferation is driven by IL-2, which is produced by the activated T cell and stimulates it in an autocrine loop.

Activated CD4⁺ Th cells (initially called Th0 cells) can be driven by IL-12 and other cytokines to become Th1 cells or by IL-4 and IL-10 to become Th2 cells. Th17 cell differentiation is driven by transforming growth factor- β (TGF- β), IL-6, and IL-23. Th1 cells mediate host defenses against intracellular pathogens such as viruses, bacteria (e.g., *M. tuberculosis*) or parasites (e.g., *Toxoplasma gondii*). They do so by producing γ -interferon, which activates phagocytic cells such as macrophages that then destroy the invading intracellular pathogen, and IL-2, which activates CTLs to lyse infected cells.

Alternatively, activated CD4⁺ T cells can be driven by IL-4 to become Th2 cells that mediate processes such as antiparasitic immunity. Th2 cells stimulate B cells to produce antibodies against extracellular pathogens through the production of IL-4, and they stimulate proliferation of eosinophils for activity against parasites (e.g., worms) through the production of IL-5.

Th17 cells are stimulated by IL-23 and produce IL-17, which plays an important role in amplifying the inflammatory response by attracting neutrophils to sites of infection caused by extracellular bacteria and possibly fungi. The complexity of these CD4⁺ T-cell subsets is still being explored.

CD8⁺ T cells respond to pathogens that initially enter host cells directly, such as viruses. During intracellular replication, viral proteins are degraded in the cytosol by the immunoproteasome, a variant of the proteasome enzyme complex that is typically involved in cellular protein turnover. Resulting peptide chains of 8 to 10 amino acids are transported into the endoplasmic reticulum where they associate with newly synthesized MHC class I molecules and are routed via the Golgi complex to the cell surface. CD8⁺ CTLs may then bind to the presented MHC class I/antigen complex and lyse the infected cell through release of the pore-forming molecule perforin and apoptosis-inducing enzymes known as granzymes, or through ligation of Fas ligand on the CTL with Fas on the target cell, which also may induce apoptosis. CTLs are generated from naïve CTL precursors through specific association with a dendritic cell (DC) that has been “licensed” through interaction with a CD4⁺ Th1 cell. Interaction with the DC stimulates the production of IL-2 by the CD4⁺ Th1 cell and increases B7-1/2 (CD80/86) expression by the DC. The combination of antigen-specific signaling through the TCR, engagement of CD28 on the CD8⁺ cell by B7-1/2 on the DC, and Th1-derived IL-2 stimulates the CD8⁺ T cell to proliferate and differentiate into CTLs, which may then lyse infected target cells as described above.

In addition to effector T cells, populations of regulatory T cells modulate the immune response. Most regulatory T cells (Tregs) express CD4, CD25, and the FOXP3 transcription factor and help to temper immune responses, particularly those related to autoimmune diseases but also some infectious diseases.

HOST DEFENSE RESPONSE TO PATHOGENS

Humans are constantly exposed to microbial pathogens. Organisms such as *Streptococcus pneumoniae*, group A streptococci, and respiratory viruses may colonize the respiratory tract. *Staphylococcus aureus*, fungi, and many other organisms live on the skin. Thousands of microbial species have been identified in the gastrointestinal tract; most are benign, many are beneficial, and some are dangerous.

Host defenses need to react continuously and appropriately to breaches in nonimmunologic host defenses. For example, if a person suffers a puncture wound the skin barrier is breached, and pathogens may be inoculated into the subcutaneous tissues. This stimulates inflammatory responses in which cytokines stimulate the expression of adhesion molecules and chemokines on vascular endothelium. Neutrophils in the bloodstream then bind to the endothelium, traverse the vessel walls, and migrate into tissues, where they are attracted by a chemokine gradient to the site of tissue damage and infection.

A second process that breaches nonimmune host defenses results from infection by respiratory viruses. For example, influenza virus may compromise upper and lower respiratory host defenses by damaging the respiratory epithelium, inhibiting ciliary action and mucus production. Bacterial pathogens, most commonly *S. pneumoniae*, that colonize the respiratory tract in normal hosts may then colonize and invade the lower respiratory tract, leading to pneumonia. Organisms such as *M. tuberculosis* may evade upper respiratory and lower respiratory defenses and lodge in alveolar macrophages in the lung, where they can survive and multiply. Interference with alveolar macrophage function (e.g., silica exposure) may increase susceptibility to tuberculosis.

The innate immune system is critical during the early phases of infection. The response is rapid, albeit relatively nonspecific, and eliminates the pathogen or holds it in check until the adaptive immune system has time to respond. Phagocytes such as tissue macrophages patrol the periphery and detect pathogens through pattern receptors such as TLRs. This activates the phagocyte, induces phagocytosis and killing, and stimulates the production of cytokines and chemokines that initiate the inflammatory response and influence the development of the adaptive response.

Complement may be activated innately by pathogens through the alternative and lectin pathways and produce products to attract neutrophils, opsonize pathogens, lyse pathogens, and degranulate mast cells. Vasodilation results from histamine release, and circulating neutrophils are localized to the vascular endothelium nearest the site of invasion by integrins, pass through the vascular wall, and move down a chemokine gradient to the site of infection. Opsonization helps neutrophils, macrophages, and other immune cells ingest and kill the pathogen. These immediate inflammatory and innate immune responses are initiated immediately and increase over hours to days. These responses are highly effective, buying survival time for the host while more specific responses of the adaptive immune system develop.

Immature dendritic cells in peripheral tissues are sentinels for foreign molecules. Through pinocytosis and phagocytosis initiated by TLRs and other receptors, DCs detect pathogens; once they have acquired foreign antigen, DCs migrate to regional lymph nodes. There the DCs mature, process, and present antigen to T cells, initiating the specific adaptive immune response. The type of response depends on the type of pathogen. Intracellular pathogens such as *M. tuberculosis* stimulate a T cell-mediated response, whereas *S. pneumoniae* stimulates primarily a B-cell, antibody-mediated (humoral) response. Most infections produce components of cellular and humoral responses in various degrees that often act in concert. For example, influenza virus induces B-cell and T-cell responses; antibodies neutralize free virus and prevent further infection of respiratory epithelium and CTLs lyse infected epithelial cells.

Humoral Response

Early in infection, preexisting antibodies and complement factors react to pathogens directly and can initiate lysis, opsonization, and neutralization of pathogens. B cells may be activated by T cell-independent antigens or through interaction with CD4⁺ T cells for T cell-dependent antigens. B-cell populations proliferate and produce IgM antibodies

initially and then with isotype switching produce other types of antibodies, including IgG, IgE, and IgA. Antibodies acting in the extracellular space bind to pathogens or their products, potentially leading to neutralization, agglutination, opsonization, complement fixation, ADCC, and mast cell degranulation.

Cell-Mediated Response

Naïve T cells with specificity for the invading pathogen are activated, proliferate, and produce cytokines. CD4⁺ T cells produce cytokines that stimulate other T cells such as CTLs, enhance the overall inflammatory response, activate phagocytes for killing, and stimulate

antibody production. Previously sensitized memory CD4⁺ and CD8⁺ T cells may react rapidly with activation and proliferation on exposure to previously recognized pathogens.

Laboratory Diagnosis of Infectious Diseases

Kimberle Chapin

INTRODUCTION

The ability to rapidly and accurately diagnose pathogen-specific infectious diseases and resistance determinants has become the norm in medicine as a result of the continuous introduction of new technologies. In addition, companion diagnostics such as those that assess host-specific biomarker signatures in conjunction with software algorithms to clarify risk (e.g., likelihood of sepsis) or probable pathogen-specific group (e.g., viral vs. bacterial) add a personalized medicine component to infectious disease interpretation.

This chapter highlights significant components of testing for infectious diseases and trends in laboratory medicine and diagnostic technology that affect patient care. The 2018 American Society for Microbiology (ASM) and Infectious Disease Society of America (IDSA) guideline on use of the microbiology laboratory for the diagnosis of infectious diseases is a comprehensive resource summarizing laboratory diagnosis of infectious diseases by basic disease categories (e.g., respiratory, genital) focusing on best-use practice guidelines and containing numerous tables for rapid access of information. The document is well referenced and is updated on a regular basis. Other valued resources exist online for use with uncommonly encountered pathogens, such as the Centers for Disease Control and Prevention (CDC) DPDx (<https://www.cdc.gov/dpdx/index.html>) for parasitic infections that includes case studies and 360Dx (<https://www.360dx.com/>) that highlights new infectious diseases technologic advances that are important to track.

DIAGNOSTIC STEWARDSHIP

As infectious disease diagnostic tests and results have become available closer to the time of patient care, the basic concepts of optimal specimen acquisition, test selection, test performance parameters for a given patient population, and result interpretation by providers are admittedly more complex and somewhat overwhelming. Up to 70% of individual patient medical diagnoses are being made with the aid of a laboratory test result. Diagnostic stewardship, a process that promotes a team approach to optimizing microbiology test implementation, provider test choice and interpretation, along with assessment of outcomes to identify value of specific diagnostic tests for patient care have become requisite. For infectious diseases, this includes microbiology diagnostics that have been shown to affect directed patient care, morbidity, mortality, and health care costs. These are now published for a growing list of significant quality measures as shown in [Box 89.1](#).

SPECIMEN COLLECTION AND CANCELLATION OF INAPPROPRIATE SPECIMENS

Collection of the appropriate specimen and its preservation during transportation to a testing site are components of infectious disease

diagnosis that are often overlooked. As part of their accreditation and inspection process, laboratories have collection procedures and criteria for rejection of specimens that are deemed inappropriate to process. These evidence-based protocols ensure that results can be used reliably to treat patients and provide reasons for specimen requests not being performed. Examples include cancellation of a nonliquid stool for *Clostridioides difficile* toxin testing because it is inconsistent for a person with *C. difficile* infection (CDI) that produces watery diarrhea; urine specimens for culture received greater than 2 hours after collection and not refrigerated or in preservative, which allows overgrowth of bacteria and uninterpretable mixed organism results; and blood or genital specimens for molecular-based tests submitted in a device that does not preserve the nucleic acid target.

Liquid Media and Self-Collected Specimens

Specimen collection, including surgical tissue specimens, has recently become decentralized. However, the limitations for samples that require culture have been minimized by the use of flocked swabs placed directly into a liquid matrix that preserve both aerobic and anaerobic organisms and nucleic acid targets (e.g., E-swabs [Copan Diagnostics, Inc.]), and dry swabs for molecular analysis. In addition, patient-collected versus provider-collected specimens have been shown to yield equivalent or better test results, increase patient satisfaction, and encourage appropriate use of health care.

Provider Responsibility for Optimizing Results

All personnel (e.g., physicians, physician assistants, nurses, phlebotomists, patients) collecting specimens should be familiar with the appropriate collection devices, recommended collection techniques, testing requirements, including timeliness of transportation to the laboratory or need of fresh tissue (not in formalin) for culture, to ensure optimal identification of the pathogen.

If the practitioner requests a microbiology test not typically performed, such as anaerobic organisms from a cerebral spinal fluid (CSF) specimen, or a test without standardized interpretive criteria (e.g., antimicrobials not FDA-cleared), a call should be made to the laboratory.

RAPID AND/OR DIRECT FROM SPECIMEN DIAGNOSTIC METHODS

Rapid or *STAT* is no longer a term foreign to direct testing for infectious diseases and the microbiology laboratory. All major areas of diagnostic testing, including direct visualization of organisms in specimens, detection of organism-specific antigens, antibodies, proteins, and nucleic acids, as well as cell counts and biomarkers can be performed in 1 to 4 hours. Results are uploaded automatically upon completion into the electronic medical record (EMR) and are often

BOX 89.1 Infectious Disease Diagnostics Contributing to Patient Care Quality Measures

- *Clostridioides difficile* toxin molecular testing and infection control practices
- Rapid identification and susceptibility for identification and treatment of sepsis to reduce morbidity and mortality
- Presurgical testing for colonization with methicillin-resistant *Staphylococcus aureus* (MRSA) and *S. aureus* (MSSA), allowing presurgical decontamination and targeted antibiotic therapy in high-risk surgical procedures to reduce surgical site infections
- Rapid organism identification and resistance determinants to aid in successful anti-infective intervention and stewardship programs
- PCR technologies for common infections seen in urgent care settings (e.g., GAS and influenza), allowing appropriate therapy, decreasing wait times, and increasing patient satisfaction
- Multiplex syndromic panels and next-generation sequencing (NGS) allowing rapid identification of public health threats and implementation of risk reduction strategies in outbreak exposures (e.g., GI transmissible pathogens and emerging infections)

available during the time a practitioner is involved with the patient, allowing immediate treatment.

Table 89.1 lists common US Food and Drug Administration (FDA)–cleared or published direct testing methods used in laboratories for primary specimens. Examples include simple stains, such as the Gram stain, to complex nested–polymerase chain reaction (PCR) for syndromic conditions (e.g., infectious disease gastrointestinal panels) and reference tests such as next-generation sequencing (NGS) of cell free DNA.

Direct and *rapid* do not necessarily equate to high predictive values for a true positive or negative test result. Tests commonly used in the past because of ease of use and cost (e.g., viral antigens from throat swabs for influenza and India ink stain in CSF) are not recommended because false-negative and false-positive results, respectively, are common. As well, direct tests that add little value in clarifying the specific diagnosis, such as positive herpes simplex virus 1 and 2 (HSV1/2) antibody in a patient without a vesicle or positive PCR for *C. difficile* toxin in a patient without diarrhea, may in fact be harmful because of misinterpretation about significance.

DIRECT SMEAR INTERPRETATION

A direct smear interpretation can be exceedingly helpful in confirming a suspected infection (e.g., Gram stain of CSF for organisms consistent with pneumococcal meningitis, or fungal elements in tissue) and is performed typically within hours of receipt. Positive sterile specimen smears are reported as critical results. High sensitivity and specificity, however, often depend on specimens being collected appropriately (e.g., obtained before antibiotic administration), providing critical clinical information (e.g., immune status or travel) and experience of the person interpreting the smear.

Special Stains

Specialty staining for a variety of organisms, allowing valuable clinical information, is increasingly being sent off site from clinical care to reference laboratories for either staining or PCR. Most academic medical laboratories still maintain special stain capacity. Fluorescent staining with calcofluor (Fig. 89.1) and auramine have increased sensitivity for direct detection of fungal elements and acid-fast bacilli (AFB), respectively. Direct fluorescent antibody (DFA) staining for *Pneumocystis jirovecii*, more specific and rapid compared with staining of histologic tissue preparations, has some limitations in sensitivity such that

molecular detection is becoming more standard, but when positive, is exceedingly helpful for treatment. Likewise, direct smear interpretation for blood pathogens (e.g., *Babesia* and malaria) is very sensitive for acute disease, but outside of academic medical centers, is typically performed by molecular testing.

CULTURE WITH A BOOST

Despite advances in rapid direct and molecular diagnostics, culture is still a mainstay for infectious disease diagnosis of many specimen types (wounds, urine, blood, tissues), in part because technology to enhance rapid detection and identification of colony growth exist and are cost-effective. Specialized media, such as chromogenic media that are both differential (colony of interest appears a specific color because of added reagents) and selective (incorporated antibiotic allows only desired pathogen to grow), speed detection.

Blood and AFB specimens are incubated in continuously monitoring incubator cabinets that signal when a specimen is positive based on algorithmic growth curves. A positive specimen can be identified at any time of day, pulled and stained immediately after signaling positive, and tested for definitive identification and susceptibility. Many laboratories utilize automated instruments for streaking specimens onto culture plates, allowing consistency better than manual inoculation such that colonies are isolated better and susceptibility can be performed 1 to 2 days earlier. Likewise, incubators that are automated and perform time-lapsed photography on each plate, incorporating comparative differential analysis and artificial intelligence algorithms, can discard “no growth” plates within 24 hours compared to 2 to 5 days. Similarly, rapid identification and antimicrobial susceptibility performed by a combination of fluorescent tagged organisms with specific RNA probes and subsequent time-lapsed photography of organism growth in various antibiotic concentrations allows results 2 days soon than traditional techniques (Accelerate PhenoTest).

Matrix-Assisted Laser Desorption Ionization–Time of Flight Mass Spectrometry

Many laboratories still rely on automated systems that perform identification from organism growth by biochemical and enzymatic phenotypic methods as well as growth methods for determination of antimicrobial susceptibility. However, because these systems require additional growth for reactions to take place, organism identification is delayed another day and susceptibility an additional day. The increased use of matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) is a significant methodologic change that has become standard in many laboratories. This technique relies on the protein spectral analysis of the organism for identification, takes only minutes rather than days, and is very cost-effective. The technique is described in Fig. 89.2. Direct detection from positive blood broth, after a processing step, is also commonly used and allows a more inclusive organism range than molecular panels.

Table 89.2 lists the most common rapid identification methods used from positive broth cultures (e.g., blood) and from colony growth on a culture plate. Use of specific technologies is dependent on expertise in the laboratory, cost, test performance parameters and patient population.

Antibody and Antigen Tests From Blood and Body Fluids

Serology is valuable for confirmation of vaccination and/or response (e.g., rubella), often when a 4-fold rise in antibody titer is an optimal way to clarify if a disease is present, especially if IgM is nonspecific (e.g., *Bartonella*), or the primary technology for diagnosis (e.g., syphilis). Single antibody measurements are rarely helpful in clarifying the disease state (active or past infection) or the mode of transmission and often can be misinterpreted. (e.g., HSV 1/2 antibody).

TABLE 89.1 Common Methods of Direct Testing From Specimens

Test Methods ^a	Diagnostic Method	Analyte Detected
Smear stain preparations	Gram stain	Bacteria, fungal elements, including yeast and hyphae
	Fluorescence	DFA: <i>Pneumocystis jirovecii</i> , viruses ^b Auramine: mycobacteria Calcofluor: fungi
Antigen-antibody	Special: acid-fast (Kinyoun), partial acid-fast (PAF), India ink ^c	Smear use determined by laboratory and based on primary stained specimen ^d
	Wright stain	Leukocyte differentiation and count (e.g., <i>Plasmodium</i> , <i>Babesia</i>)
	Wright-Giemsa	
Molecular ^f	Latex agglutination	<i>Legionella</i> or <i>Streptococcus pneumoniae</i> urinary antigen
	Lateral flow antibody/antigen	Cryptococcal antigen in serum and CSF
	Serology for IgG, IgM, Western blot	GAS, RSV, influenza A or B, <i>Plasmodium</i>
Sequencing	Biomarkers	Multiple analytes; detection and/or confirmation of immune status and acute disease
	Hybridization and signal amplification	Single: Procalcitonin, ^e C-reactive protein
	Amplification of RNA or DNA, single analyte, small or large syndromic panels, direct from specimen or from blood, microbiome based and algorithmic interpreted	Combination: multiple biomarkers with algorithmic interpretation (e.g., viral vs. bacterial)
Next-generation sequencing (NGS)	Amplification with quantification of nucleic acids	Yeast, HPV, bacterial vaginosis or vaginitis
	Genotyping	Single analytes: Enterovirus, GAS, influenza, RSV; small bundle with ≤5 targets: sexually transmitted pathogens (GC, CT, TV, <i>Mycoplasma genitalium</i>)
Next-generation sequencing (NGS)	16S, 18S, ITS or metagenomic cell free DNA	Multiplex amplification with ≥5 targets: blood sepsis, respiratory, gastrointestinal, meningitis pathogens, microbiome based: vaginosis/vaginitis
		Chip array: Multiple targets, HPV, HCV genotyping
		HIV, HCV, HBV
		Genetic variants of e.g., HIV, HCV, HPV
		16S rDNA (prokaryotic); 18S rDNA (eukaryotic), ITS (nontranscribed region of fungal rDNA) targeted or metagenomics, can differentiate multiple species within one pathogen type/selected organism types or unbiased testing that allows discovery of new pathogens, respectively

CSF, Cerebrospinal fluid; CT, *Chlamydia trachomatis*; DFA, direct fluorescent antibody; DNA, deoxyribonucleic acid; FDA, US Food and Drug Administration; GAS, group A streptococci; GC, *Neisseria gonorrhoeae*; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; Ig, immunoglobulin; ITS, internal transcribed spacer; RNA, ribonucleic acid; RSV, respiratory syncytial virus; TV, *Trichomonas vaginalis*.

^aOne-hour, same-day testing.

^bDirect fluorescent antibody (DFA) is organism specific (e.g., *P. jirovecii*, varicella zoster, herpes simplex 1 or 2, cytomegalovirus), and better than histologic stains (e.g., silver stain) and Tzanck preparations (e.g., nucleated giant cells), which are not specific and can cause confusion by similar appearances for many infectious causes. Most DFA testing for viruses has been replaced with molecular technologies due to same-day turn-around time and increased sensitivity.

^cCryptococcal antigen from cerebrospinal fluid (CSF) or serum is the recommended test. India ink often yields false-positive results and is used by the laboratory for confirmation of suspected yeast in a Gram stain of CSF or patients positive by cryptococcal antigen.

^dFor example, partial acid-fast testing is performed if the Gram stain shows branching of gram-positive rods and *Nocardia* is suspected; acid-fast testing may be performed if the auramine-stained sample is positive.

^eProcalcitonin is a single biomarker used in clarifying bacterial sepsis. Newer combination biomarker tests along with machine learning algorithms suggest greater specificity and sensitivity for sepsis as well as clarifying viral or bacterial disease compared to PCT or traditional C-reactive protein.

^fCommon examples of pathogens are listed for each group, but many more analytes are available.

Cryptococcal antigen from cerebrospinal fluid and blood is the standard of care testing for detection of cryptococcal disease. Likewise, *Legionella* urinary antigen (*L. pneumophila* type 1) and *Histoplasma* urinary antigen are rapid and excellent tests for these conditions.

MOLECULAR DIAGNOSTICS

Use of molecular technology for infectious disease diagnosis is standard of care in microbiology because of ease of use (automation) and the tremendous clinical benefits to patient care (sensitive, specific, and rapid detection). Molecular assays may be performed in either microbiology or core laboratories with overlapping specialty

responsibilities (e.g., hematology, chemistry.) The basic categories are shown in Table 89.1.

FDA-cleared direct molecular tests include hybridization and amplification methods. The main difference between these methods is that with hybridization methods, the nucleic acid is not multiplied beyond what is already in the sample. For assays that target DNA, the sensitivity is limited because DNA exists as a single copy. For assays that target proteins or RNA, detection sensitivity is somewhat increased because these components are naturally amplified in the microbe. Familiar hybridization assays include fluorescent in situ hybridization (FISH) for targets in tissue and the protein nucleic acid (PNA) smear. Hybridization assay systems can increase their sensitivity by pairing with signal amplification, such as for human papillomavirus (i.e., Qiagen/Digene HPV test),

or multiple time point interpretations of probe signal uptake for rapid pathogen identification (i.e., Accelerate PhenoTest).

In contrast, amplification assays increase the original nucleic acid copy number through a variety of processes, including PCR, nested-PCR, transcription-mediated amplification (TMA), and

Fig. 89.1 Lactophenol cotton blue depicts fungal hyphae (rhizopus sp.) from a wound specimen.

isothermal loop amplification (LAMP). Real-time PCR refers to amplification and detection occurring simultaneously, enabling the analyte to be detected more quickly. Amplification assays can detect a single analyte (e.g., enterovirus from CSF) or a group of pathogens for a disease entity from a single specimen, such as sexually transmitted infections (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis*). They also allow quantification of the viral load for purposes of long-term treatment and assessment of clearance (i.e., human immunodeficiency virus (HIV), hepatitis B virus, and hepatitis C viral loads).

SYNDROMIC ASSAY PANELS

These assays detect a diverse set of pathogens most commonly associated with a specific syndromic condition as well as multiple resistance determinants, (e.g., acute respiratory disease, methicillin susceptibility genes for *S. aureus*). A single specimen aliquoted into a single cartridge is subsequently tested by amplification for multiple targets (multiplexing). FDA-cleared multiplex assays from 3 to 27 targets exist for respiratory syndromes, acute gastroenteritis, sepsis, STIs, bacterial vaginitis/vaginosis, and meningitis. Providers need to be aware of the syndromic panel in use because multiple manufacturers exist and the pathogens reported can vary widely (Fig. 89.3).

16S, 18S AND METAGENOMIC NEXT-GENERATION SEQUENCING FOR PATHOGEN DETECTION

16S and 18S sequencing for prokaryotic and eukaryotic organism identification are in general limited to specific groups of organisms and used in specialty laboratories. Metagenomic cell free DNA analysis is a hypothesis-free diagnostic approach that has the potential to detect nearly any organism from blood. Sequencing is helpful in patients that are immunocompromised, where uncommon pathogens ranging from

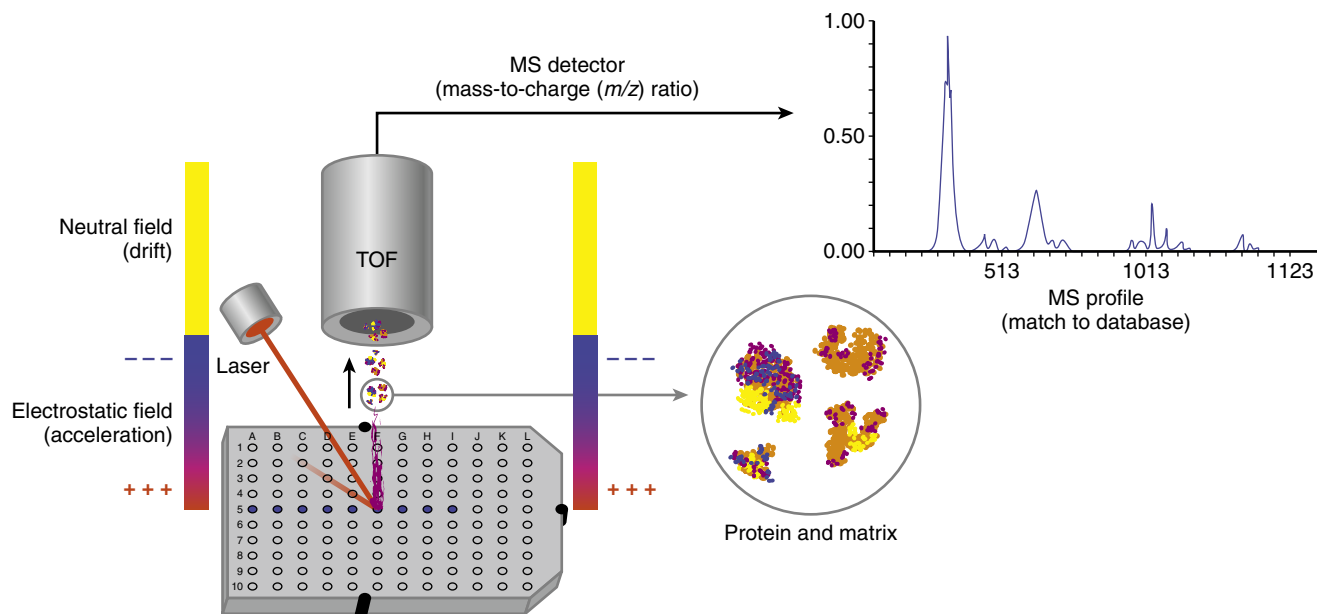

Fig. 89.2 Matrix-assisted laser desorption–time of flight mass spectrometry (MALDI-TOF MS). Bacterial or fungal growth is selected from a culture plate and applied directly onto a MALDI slide. Samples are overlaid with a matrix and dried. Samples are then bombarded by a laser, which results in sublimation and ionization of the sample and the matrix. The ions are separated based on their mass-to-charge ratio in a tube that measures the time it takes the ions to travel. A spectral representation of these ions is generated and analyzed by software that generates a profile that is subsequently compared with a database of reference MS spectra and matched, generating identification. The process takes only minutes. Although the instrumentation is expensive, the technology is US Food and Drug Administration cleared, and it yields rapid, robust, and reliable identification.

bacteria to viruses, fungi, and parasites may be present and potential infection is not being identified by other methods.

POINT-OF-CARE OR NEAR-PATIENT TESTING

Point-of-care (POC) or near-patient testing offers rapid results, typically while the patient is still in the clinical care setting, allowing directed treatment. This arena will continue to grow as patients shift into urgent care and home use venues. In addition, testing options will begin to replace less sensitive antigen tests with molecular-based tests that are more cost-effective (reducing duplicative testing and decreasing repeat visits) and have short turn-around times (minutes). They will also have an increasing menu outside of the usual urgent care pathogens of group A streptococci (GAS), influenza/RSV, and HIV tests to include other common acute care conditions such as sexually transmitted infections (STIs), bacterial vaginosis (BV), urinary tract pathogens, and biomarkers. The difference in testing diagnostics chosen to be performed in these settings (antigen, PCR, syndromic panel) will depend on the clinical severity of the patient. Urgent care assumes less severe disease and fast directed treatment, optimally with test results within an hour before the patient leaves, whereas emergency department providers may be assessing more critical patients, and testing helps decide admission or discharge to home.

Point-of-Care Testing in Resource-Poor Settings

Importantly, point-of-care testing (POCT) has become feasible for resource poor settings with battery-operated molecular systems or low cost microfluidic systems. Systems exist for diagnosis of tuberculosis and resistance determinants, HIV, human papillomavirus, and resistant STIs.

Point-of-Care Testing Quality Issues

Critically, because of cost, any test used in the POC setting should be reliable enough for the provider to have confidence in the directed treatment. Understanding the predictive values of tests being used, no matter the setting, is critical for interpretation of the result.

POCTs are dependent on the specimen type collected (e.g., nasopharyngeal swab is better than a throat swab for influenza A or B testing), the test analyte (e.g., GAS performance is more reliable than HIV oral testing), and the prevalence of disease at the time of testing as related to the technology of the diagnostic (e.g., influenza antigen-based vs. molecular).

For example, data from the novel H1N1 influenza outbreak demonstrated very poor sensitivity for rapid antigen tests (about 50%) compared with molecular tests. When a multiplex viral panel was used, other viral pathogens were identified as the cause of

Fig. 89.3 Graph shows results of the parasitic component of a multiplex gastrointestinal PCR panel that identifies pathogens in about 1 hour. Antigen tests are not sensitive and confirmatory parasitic smear or direct fluorescent antibody (DFA) testing takes days to weeks. Two cryptosporidium peaks associated with outbreaks in April 2018 and August 2019 at petting zoos allowed rapid response by the Department of Health, limiting exposures.

TABLE 89.2 Common Rapid Identification Methods From a Positive Culture Broth, Colony, or Tissue^a

Method	Organisms Detected	Time	Cost	Technical Expertise
PNA fluorescent smear	Bacteria, fungi (yeast)	2–4 hr	\$\$	++
Positive broth				
MALDI-TOF MS	Bacteria, fungi, mycobacteria	Minutes to 1 hr	\$	+
Colony or positive broth				
Hybridization probes	Bacteria, dimorphic fungi, mycobacteria	4–8 hr	\$\$\$	+++
Colony or positive broth				
Amplification ^b	Bacteria, viruses, mycobacteria, parasites	1–4 hr	\$\$ to \$\$\$\$	+ to +++
Next-generation sequencing, whole genome sequencing	Bacteria, fungi, mycobacteria, viruses, environmental	1–3 days	\$\$\$\$	+++ to ++++
Combination fluorescent rRNA probe and time-lapsed morphokinetic cellular analysis	Bacterial identification and rapid phenotypic susceptibility	2–8 hr	\$\$\$	++

MALDI-TOF, Matrix-assisted laser desorption ionization–time of flight mass spectrometry; PLC, high-pressure liquid chromatography; PNA, peptide nucleic acid; \$, relative cost; +, relative level of required expertise.

^aRapid methods require 2 to 24 hours. Methods presented are US Food and Drug Administration cleared or have had test performance validated in the clinical laboratory. Due to required technical expertise and cost, some of these assays may not be available in the routine laboratory, and providers should inquire about availability.

^bIncludes many different technologies, such as polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and isothermal loop amplification (LAMP).

influenza-like illness in more than 50% of patients admitted to hospitals. As a result, amplified testing assays for influenza, RSV, and GAS have been developed by manufacturers as Clinical Laboratory Improvement Amendment (CLIA)-waived tests for use in POC settings. Syndromic panel use in urgent care settings is unusual, but as more systems achieve CLIA-waived status, syndromic panel use will be more common. But urgent care clinics, especially those that serve patients within a specific health care system with more capacity for testing, will likely be able to incorporate greater POC testing, including receipt of self-collected patient specimens. Costs will be balanced by reducing the number of patients getting their care in costly emergency departments.

TRENDS IN THE DIAGNOSIS OF INFECTIOUS DISEASES

The most significant trend in diagnostics is that rapid change will continue as diagnostics grow to meet the changes in health care systems and the consumer. Relevant components are listed in [Box 89.2](#).

BOX 89.2 Trends in the Diagnosis of Infectious Diseases

- **Guidelines and evidence-based testing:** Continued development of evidence-based guidelines for both patient treatment and test reimbursement. Real-time use of diagnostic stewardship teams and health care system test order algorithms to guide appropriate test implementation, ordering, and interpretation.
- **Testing platforms:** Less reliance on traditional culture-based techniques with culture becoming increasingly automated at the front end (processing), aliquoting for MALDI-TOF identification, as well as the back-end components of reading and interpretation (machine algorithms).
- **Molecular technologies:** Wider availability and adoption of syndromic molecular panel assays as well as genetic resistance determinants due to speed and comprehensive menus. Accepted use of cell-free nucleic acid and next-generation sequencing (NGS) detection for low-yield pathogens (e.g., unusual or unexpected) and/or slow growing culture pathogens (e.g., fungi), especially in immunocompromised patients.
- **Antimicrobial resistance and stewardship:** Standardization of rapid phenotypic antimicrobial susceptibility, providing results 48 hours sooner compared to traditional culture susceptibility, aiding in antimicrobial stewardship initiatives.
- **Emerging infections:** Viruses, mycobacteria, mycology, and specialized pathogen culture and susceptibility will continue to move to specialty reference laboratories and public health until more rapid and user-friendly diagnostics are developed. Worldwide increase in fungal diseases will hasten fungal test development. Emergency use authorization (EUA) test systems will be sought by companies for emerging outbreak infections to aid in global strategizing.
- **Point-of-care testing:** Use of rapid and cost-effective molecular tests (microfluidic or similar), battery-operated (or similar), portable platforms developed for POC, including urgent care clinics and resource poor settings.

Fever and Febrile Syndromes

Maria D. Mileno

INTRODUCTION

Fever is one of the most common problems requiring medical evaluation. Fever is an elevation in core body temperature greater than normal daily variation, which is $37^{\circ}\text{C} \pm 0.4^{\circ}\text{C}$ ($98.6^{\circ}\text{F} \pm 0.7^{\circ}\text{F}$). Documentation of true fever can be important evidence of infectious processes that warrant investigation. Although fever is characteristic of most infections, it also occurs in noninfectious conditions such as autoimmune and inflammatory diseases, malignancy, and trauma.

This chapter reviews the pathogenesis of the febrile response, the approach to the acutely ill patient with fever, and fever of unknown origin. Fever can be associated with infections, such as those from animal exposures, or with common clinical scenarios in which it may occur as the sole complaint, manifest with rash, or develop with lymphadenopathy. A word of caution about the difference between true and factitious fever is offered at the end of the chapter.

PATHOGENESIS

Thermoregulation of core body temperature is one of the most important mechanisms in mammalian and human physiology. At core temperature the human body's systems work together at their optimum. The hypothalamic heat-regulating set point shifts in response to infection or inflammation mediated primarily by the host's monocytes and macrophages, which are activated as they encounter exogenous bacterial substances, toxins, or the cellular products of trauma.

Monocytes and macrophages produce small proteins called *cytokines*, such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). They are collectively known as *endogenous pyrogens* because they actively increase body temperature by increasing the hypothalamic set point, which is the normal temperature for the body that is controlled by the hypothalamus. IL-1 and other endogenous pyrogens are released by macrophages at the site of infection and travel through the bloodstream to the hypothalamus, where they elevate levels of prostaglandin E_2 (PGE_2). Elevated PGE_2 levels increase the set point, and thermoregulatory mechanisms raise the body's core temperature. IL-1 also induces production of PGE_2 in peripheral tissues, which causes the nonspecific myalgias and arthralgias that often accompany fever. Prostaglandin inhibitors such as aspirin or acetaminophen block prostaglandin synthesis and reduce elevated temperatures.

Thermoregulatory control is initiated through sensory neurons in the skin, abdomen, and spinal cord. Central nervous system (CNS) thermoreceptors sense and integrate temperature information. After the hypothalamic set point is raised, the firing rates of neurons in the vasomotor center are altered, causing peripheral vasoconstriction and producing a noticeable cold sensation in the hands and feet. Blood is shunted away from the periphery to the internal organs, and this process is sufficient to raise core body temperature by 1° to 2°C .

Other signaling mechanisms have roles in thermoregulation. The adipocyte-derived hormone leptin actively controls energy homeostasis, and thermogenesis in fat tissue contributes to increasing core temperature. Thermogenesis is important in fighting infection and in responding to cold-induced heat production. Fever has direct antimicrobial effects in some infections such as neurosyphilis and salmonellosis, and elevated temperature augments humoral and cellular immune responses. IL-1 acts independently on two physiologic systems: thermoregulation and iron metabolism. IL-1 can stimulate a wide range of host defenses to conduct a synergistic response to infection.

Fever also can have deleterious effects. It may lead to disorientation and confusion in persons with underlying brain disease and in healthy older individuals. Tachycardia can increase cardiopulmonary work, precipitating congestive heart failure or myocardial infarction in persons with significant cardiopulmonary disease. Fever should be controlled with antipyretics for comfort and to avoid compromising individuals with multiple medical problems. Acetaminophen is preferred for control of fever in children because of the risk of Reye's syndrome with salicylate use.

The terms *fever*, *hyperthermia*, and *hyperpyrexia* are not synonymous. Although most patients with elevated temperature have fever ($>38.3^{\circ}\text{C}$ or 100.9°F), some conditions can increase the body temperature by overriding or bypassing the normal homeostatic mechanism and may even produce body temperatures in excess of 41°C or 105.8°F (i.e., hyperthermia), which can be rapidly fatal and does not respond to antipyretics. Rapid cooling is critical to the patient's survival in hyperthermic conditions such as heat stroke. Even in otherwise healthy individuals, heat stroke can occur after vigorous exercise and prolonged exposure to high environmental temperatures and humidity. Heat stroke is marked by temperatures greater than 40.6°C (105.1°F), altered sensorium or coma, and cessation of sweating. Treatment includes covering the patient with wet compresses followed by intravenous infusion of fluids appropriate to correct fluid and electrolyte losses.

Severe hyperthermia may be a heritable reaction to anesthetics (i.e., malignant hyperthermia) or a response to phenothiazines (i.e., neuroleptic malignant syndrome). Serotonin syndrome, which often includes fever, is classically associated with the simultaneous administration of two serotonergic agents (e.g., selective serotonin reuptake inhibitors plus tramadol). It can also occur after initiation of a single serotonergic drug that increases the serotonin level of individuals who are particularly sensitive to serotonin. Occasionally, persons with CNS disorders such as paraplegia and persons with severe dermatologic conditions are unable to dissipate heat and can experience hyperthermia.

Hyperpyrexia is the term for extraordinarily high fever ($>41.5^{\circ}\text{C}$ or 106.7°F), which can occur in patients with severe infections but is most commonly observed in persons with CNS hemorrhages.

DIAGNOSTIC APPROACH TO THE ACUTELY ILL PATIENT WITH FEVER

Patterns of fever should be considered when assessing acutely ill, febrile persons. Evaluation includes determining the normal diurnal variation in body temperature, which often persists when patients have fever. Normally, body temperature peaks in the late afternoon or early evening.

Rigors (i.e., bed-shaking chills) often mark the onset of bacterial infection, typically bacteremia, although they may occur in other clinical situations, such as drug-induced fever or transfusion reactions. Wide swings in temperature may indicate an abscess. Malaria should be considered for anyone with fever who has visited or lived in malarious regions or who has relapsing fever accompanied by episodes of shaking chills and high fever separated by 1 to 3 days of normal body temperature and relative well-being. The timing of administration of anti-inflammatory drugs should be assessed because they may alter or blunt the febrile response. Most infectious diseases manifest with fever as an early finding and with subclinical and eventual clinical involvement of specific organ systems.

If fever occurs as the sole complaint or is associated with localized symptoms and signs, the diagnostic approach includes taking a thorough history, including an extensive review of systems, medical and surgical histories, and immunizations, including those from childhood. Antipyretics may be withheld to allow assessment of the fever trajectory. Elderly individuals, persons taking corticosteroids, and patients with chronic liver or renal disease may be less likely to mount a fever. All likely sources of disease, including travel, exposure to *Mycobacterium tuberculosis*, and occupational, hobby, animal, insect, and sexual contacts, should be assessed. Previous itineraries and activities, geographic risks of diseases, and the seasonality and incubation periods of possible disease exposures should be considered in returning travelers.

Viral Infection

Acute febrile illnesses in young healthy adults usually are caused by viral infections, which do not require precise diagnosis because they are self-limited and seldom have therapeutic options. Upper respiratory tract symptoms of rhinorrhea, sore throat, cough, and hoarseness most often result from rhinovirus, coronavirus, parainfluenza virus, and adenoviruses. Adenovirus outbreaks occur among persons living in close quarters such as military barracks or college dormitories. Respiratory syncytial virus, human metapneumovirus, and human bocavirus infections occur in similar conditions and sometimes manifest with pneumonia.

A coronavirus causes the potentially fatal upper respiratory viral infection called *Middle East respiratory syndrome* (MERS). It has caused pneumonia with acute respiratory distress syndrome (ARDS) and death in one half of infected individuals, and it is highly contagious. See Appendix for discussion of COVID-19.

Meningitis symptoms occur predominantly from enterovirus infections during summer months, although the symptom complex warrants urgent treatment of bacterial causes while the diagnostic process occurs. Febrile syndromes without meningitis are more common manifestations of enteroviral infections.

Arthropod-borne viruses such as California encephalitis virus; eastern, western, and Venezuelan equine encephalitis viruses; St. Louis encephalitis virus; and West Nile virus can produce self-limited febrile illnesses and encephalitis. Colorado tick fever is a biphasic illness seen after northwestern and southwestern tick exposures. It is characterized by high fevers and leukopenia. A deer tick virus—Powassan virus—has

been associated with numerous cases of fever and encephalitis in New England and the Upper Midwest.

Influenza causes sore throat, cough, myalgias, arthralgias, and headache in addition to fever, and it most often manifests in an epidemic pattern during winter months. It is unusual for fever to persist beyond 5 days in uncomplicated influenza. Prolonged fever in persons with diagnosed influenza warrants investigation and treatment of bacterial superinfection. The epidemics of avian influenza and H1N1 pandemic strains in recent years are sobering reminders that influenza viruses have a remarkable ability to mutate, producing new immune-resistant strains on a regular basis. Preventive yearly influenza vaccination is important.

Mononucleosis syndromes of fever with detectable lymph node enlargement typify infections with Epstein-Barr virus (EBV), cytomegalovirus (CMV), primary human immunodeficiency virus (HIV), and *Toxoplasma gondii* (i.e., toxoplasmosis). Other manifestations of these infections include abnormal liver function test results, respiratory tract symptoms, and neurologic symptoms. Diagnosis of acute HIV infection, which can produce a mononucleosis-like syndrome, is an urgent issue.

Bacterial Infections

Pathogenic bacteria can infect all body parts and can cause a spectrum of localized illness warranting antibiotic therapy. For example, *Staphylococcus aureus* may cause skin abscesses or cellulitis. Highly pathogenic organisms may colonize individuals who have had contact with the health care system. Most concerning is the event of bacteria entering the bloodstream. Obtaining timely blood cultures before administering the antibiotics indicated for presumed bacterial infections in persons with common clinical syndromes can help to identify bloodstream pathogens and define the required course of treatment.

Fever may be the predominant clinical manifestation of *S. aureus* illness. This organism and the methicillin-resistant form (i.e., MRSA) frequently cause sepsis without an obvious primary site of infection. It should be considered in patients undergoing intravenous therapy or hemodialysis and in those who use intravenous drugs or who have severe chronic dermatitis. Bacteremia with staphylococci may cause hematogenous seeding of bones leading to osteomyelitis and heart valves leading to endocarditis in individuals; the bacteremia may also reflect these underlying processes. Other common causes of bacteremia and their sources include *Streptococcus pneumoniae* (i.e., pneumonia), *Escherichia coli* (i.e., urinary tract and gastrointestinal sources), streptococci (i.e., skin), and anaerobes (i.e., gastrointestinal tract).

Listeria monocytogenes bacteremia is seen predominantly in persons with depressed cell-mediated immunity and pregnant women. Although bacteremia is the most common manifestation of listeriosis in these hosts, many with listeriosis may have meningitis and warrant lumbar puncture for cerebrospinal fluid culture. Most cases occur in individuals over age 50.

Typhoid and paratyphoid fever (i.e., enteric fever) are common in many low-income countries. Patients may have fever alone as the primary clinical manifestation. Travelers to six countries account for 80% of US cases: India, Mexico, Philippines, Pakistan, El Salvador, and Haiti. Fever with headache and an insidious onset with an unremarkable physical examination is common, although a faint and transient rash (i.e., rose spots) may appear by the second week of illness. Symptoms may include diarrhea, constipation, vague abdominal discomfort, and sometimes dry cough. Diagnosis depends on the culture of blood or stool.

Fever With Localized Symptoms and Signs

Localized bacterial infection can be apparent, as in cases of abscess, cellulitis, or otitis media, or can be clinically occult. It can develop as

TABLE 90.1 Infections Exhibiting Fever as the Sole or Dominant Feature

Infectious Agent or Source	Epidemiologic Exposure and History	Distinctive Clinical and Laboratory Findings
Viruses		
Rhinovirus, adenovirus, parainfluenza	None (adenovirus in epidemics)	Often URI symptoms; throat and rectal cultures; rapid viral antigen testing
Middle East respiratory syndrome (MERS)	Travel to Arabian Peninsula or contact from Middle East	Pneumonia with ARDS; viral antigen testing of sputum; PCR of normally sterile sites (CDC)
Enteroviruses (non-polioviruses: coxsackieviruses, echovirus)	Summer, epidemic	Occasionally aseptic meningitis, rash, pleurodynia, herpangina; serologic or nucleic acid testing (PCR)
Influenza	Winter, epidemic	Headache, myalgias, arthralgias; nasopharyngeal culture, rapid viral antigen testing
EBV, CMV	Close personal contact; blood or tissue exposure; occupational or perinatal exposure	Monospot test, EBV specific antibodies; EBV PCR in immunocompromised; CMV IgM shell vial assay; CMV antigenemia assay; CMV DNA of CSF; culture and histopathology of tissues
Colorado tick fever	Southwest and Northwest regions, tick exposure	Biphasic illness, leukopenia; blood, CSF cultures, serologic or PCR
Powassan virus	New England and Upper Midwest exposure	Altered mentation or encephalitis; serum and CSF IgM (CDC)
Bacteria		
<i>Staphylococcus aureus</i>	IV drug users, IV catheters, hemodialysis, dermatitis	Must exclude endocarditis; blood cultures
<i>Listeria monocytogenes</i>	Depressed cell-mediated immunity	Meningitis may also be present; blood, CSF cultures
<i>Salmonella typhi</i> , <i>Salmonella paratyphi</i>	Food or water contaminated by carrier or patient	Headache, myalgias, diarrhea, or constipation, transient rose spots; blood, marrow, or stool cultures
Streptococci	Valvular heart disease	Low-grade fever, fatigue; blood cultures
Animal Exposure		
<i>Coxiella burnetii</i> (Q fever)	Exposure to infected livestock, parturient animals	Headache, occasionally pneumonitis, hepatitis, culture-negative endocarditis; serologic testing
<i>Leptospira interrogans</i>	Water contaminated by urine From dogs, cats, rodents, small mammals	Headache, myalgias, conjunctival suffusion, biphasic illness, aseptic meningitis; serologic testing

ARDS, Acute respiratory disease syndrome; CDC, Centers for Disease Control and Prevention case definition; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; IgM, immunoglobulin M; IV, intravenous; PCR, polymerase chain reaction; URI, upper respiratory infection.

an undifferentiated febrile syndrome. Careful inspection of mucous membranes and conjunctiva may reveal petechiae, which are clues to meningococcemia or infective endocarditis. Finding heart murmurs in the setting of fever may suggest endocarditis and warrant additional blood cultures. Pulmonary signs in pneumonia include rales and evidence of consolidation, but persons with cryptococcosis, coccidioidomycosis, histoplasmosis, psittacosis, legionellosis, or pneumocystis pneumonia may show few signs. Pyelonephritis and renal abscesses can occur with few localizing signs.

These infections should be suspected based on exposure history and the host's immune status. It is important to assess the size of the liver, spleen, and lymph nodes, particularly in cases of viral infection. A swollen joint may indicate septic arthritis. A complete neurologic examination, including cranial nerves and testing for meningeal signs, may indicate CNS infection.

Malaria, bacterial sepsis, and bacterial infections of the lung, urinary tract, CNS, and intestines with resultant bacteremia warrant urgent initiation of empirical treatment while awaiting final identification and sensitivities. For febrile patients with features suggesting a bacterial infection, evaluation should include complete blood counts with differential and platelet counts, blood smears for those at risk for malaria or babesiosis, urinalysis, throat and blood cultures, and a chest radiograph.

Fevers with rash as a prominent feature warrant exclusion of life-threatening infectious diseases, including meningococcemia, toxic shock syndrome (TSS), and Rocky Mountain spotted fever (RMSF).

Characterization of the rash can help. Clues to some of the common infections exhibiting fever as the sole feature and those causing fever with rash are provided in Tables 90.1, 90.2, and 90.3. Tables 90.4 and 90.5 list common syndromes associated with imported fevers when assessing travelers.

FEVER OF UNKNOWN ORIGIN

Most febrile conditions resolve or are readily diagnosed and treated, but some fevers can persist and remain unexplained. Table 90.6 shows the most common causes of unexplained fevers.

The term *fever of unknown origin* (FUO) identifies a pattern of fever with temperatures greater than 38.3° C (101° F) on several occasions over more than 3 weeks after an initial diagnostic work-up for which the diagnosis remains uncertain. Verifying the presence or absence of fever is important; up to 35% of 347 patients admitted to the National Institutes of Health (NIH) for evaluation of prolonged fever were determined not to have significant fever or had fever of factitious origin. Cases of FUO are categorized as classic FUO, health care-associated FUO, neutropenic (immune-deficient) FUO, and HIV-related FUO. Each of these FUO subtypes can have unique causes.

Classic Fever of Unknown Origin

The most common causes of classic FUO are infections, malignancies, and noninfectious inflammatory disorders; miscellaneous causes and undiagnosed cases account for the remaining categories. Historically,

TABLE 90.2 Differential Diagnosis of Infectious Agents Producing Fever and Rash**Maculopapular, Erythematous Lesions**

Enterovirus

 Koplik spots: measles virus

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus.

infections have made up the largest category, representing 25% to 50% of cases. Abscesses, endocarditis, tuberculosis, complicated urinary tract infections, and biliary tract diseases have consistently been among the most important. Abscesses account for almost one third of infectious causes, and most are intra-abdominal or pelvic in origin. Perforation of a colonic diverticulum or appendicitis can sometimes lead to large, walled-off abdominal abscesses with few localizing signs.

During the past 50 years, the improvement of imaging studies and their greater accessibility have made abdominal or pelvic abscesses and malignancies more easily detected and less likely to be the cause of prolonged, undiagnosed fever. Malignant neoplasms can induce fever directly through the production and release of pyrogenic cytokines and

indirectly by undergoing spontaneous or induced necrosis or creating conditions conducive to secondary infections. Endovascular infections are usually detectable by blood cultures, although slow-growing or fastidious organisms may make detection difficult.

Infections, including tuberculosis, typhoid fever, malaria, and amebic liver abscesses, remain the most frequent causes of FUO in developing countries. The incidence of some FUOs varies according to geographic location. Classic FUO may occur as familial Mediterranean fever among Ashkenazi Jews; as Kikuchi disease, which is an unusual form of necrotizing lymphadenitis seen primarily in Japan; and as TNF receptor-associated periodic fever (TRAPS), formerly called familial Hibernian fever, which is an inherited periodic fever syndrome described originally in Ireland.

The proportion of FUOs due to noninfectious inflammatory diseases and undiagnosed conditions has risen. Of the connective tissue diseases, juvenile rheumatoid arthritis (i.e., Still disease), other variants of rheumatoid arthritis, and systemic lupus erythematosus predominate among younger patients. Temporal arteritis and polymyalgia rheumatica syndromes are more common among elderly patients.

Fever may be blunted or absent in up to one third of elderly individuals with serious conditions. Older people may more often have atypical clinical presentations of common infectious and noninfectious diseases. For example, elderly persons may have tuberculosis without cough or fever, infective endocarditis with fatigue and weight loss but without fever, and abdominal abscesses with little abdominal tenderness found on physical examination. Leukocytosis and increased band forms are more likely to be associated with a serious infection. HIV should be considered as a possible cause of FUO in older patients, although it is not usually suspected early in the course of FUO.

Fever in returned travelers is most often caused by common infections, such as malaria and respiratory or urinary tract infections. However, fever caused by dengue, typhoid fever, or amebic liver abscess is increasingly identified, especially among international travelers returning from the tropics. Katayama fever is a febrile syndrome occurring after exposure to fresh water schistosomes in endemic areas. It may resolve spontaneously or may require treatment with antiparasitic agents to prevent sequelae that carry severe morbidity. A travel history should be obtained, and it may redirect the entire work-up.

Health Care–Associated Fever of Unknown Origin

Some FUOs are associated with health care practices, including surgical procedures, urinary and respiratory tract instrumentation, intravascular devices, drug therapy, and immobilization. Quality control measures are set up to minimize and avoid bloodstream infections and decubitus ulcers. Drug-related fever, septic thrombophlebitis, recurrent pulmonary emboli, and *Clostridioides difficile* colitis must be considered in the work-up of hospitalized patients who develop fever greater than 38° C (100.4° F) for more than 3 days if it was not present on admission.

Immune Deficiency–Associated Fever of Unknown Origin

Immunosuppressed individuals have the highest incidence of FUO of any group of patients. Due to impaired immune responses, signs of inflammation other than fever are notoriously absent or diminished, producing atypical clinical manifestations and an absence of radiologic abnormalities for what otherwise would be readily diagnosed infections. In patients with impaired cell-mediated immunity, FUO often results from conditions other than pyrogenic bacterial infections (e.g., fungi, CMV).

Neutropenia is a dangerous condition that can be considered a subclass of immunodeficiency. Persons with profound neutropenia are at high risk for bacterial and fungal infections. Episodes of fever

TABLE 90.3 Fever and Rash in Viral Infection

Virus	Disease Features	Incubation and Early Symptoms
Coxsackie, ECHO virus	Maculopapular rubelliform, 1–3 mm, faint pink, begins on face, spreading to chest and extremities	Summertime No itching or lymphadenopathy
Measles	Herpetiform vesicular stomatitis with peripheral exanthema (papules and clear vesicles on an erythematous base), including palms and soles (hand, foot, and mouth disease) Erythematous, maculopapular rash begins on upper face and spreads down to involve extremities, including palms and soles. Koplik spots are blue-gray specks on a red base found on buccal mucosa near second molars. Atypical measles occurs in individuals who received killed vaccine and then are exposed to measles. The rash begins peripherally and is urticarial, vascular, or hemorrhagic.	Multiple cases in household or community-wide epidemic Mostly diseases of children Incubation period 10–14 days First, severe upper respiratory symptoms, coryza, cough, and conjunctivitis; then Koplik spots, then rash
Rubella	Maculopapular rash beginning on face and moving down; petechiae on soft palate	Incubation 12–23 days Adenopathy; posterior auricular, posterior cervical, and suboccipital
Varicella	Generalized vesicular eruption; pruritic lesions in different stages from erythematous macules to vesicles to crusted; spread from trunk centrifugally; zoster lesions are painful and often dermatomal	Incubation 14–15 days; late winter, early spring Herpes zoster is a reactivation, occurs any season
Herpes simplex virus	Oral primary: small vesicles on pharynx, oral mucosa that ulcerates; painful and tender Recurrent: vermilion border, one or few lesions, genital; may be asymptomatic or appear similar to oral lesions on genital mucosa	Incubation 2–12 days
Hepatitis B and C virus	Prodrome in one fifth; erythematous, maculopapular rash, urticaria Leukocytoclastic vasculitis occurs in hepatitis C	Arthralgias, arthritis; abnormal liver function test results; hepatitis B antigenemia
Epstein-Barr virus	Erythematous, maculopapular rash on trunk and proximal extremities Occasionally urticarial or hemorrhagic	Transiently occurs in 5–10% of patients during first week of illness
Human immunodeficiency virus	Maculopapular truncal rash may occur as early manifestation of infection	Associated fever, sore throat, and lymph node enlargement may persist for 2 or more weeks

TABLE 90.4 Common Syndromes and Diseases Associated With Fever in Returned Travelers

Sore Throat	Cough	Abdominal Pain	Arthralgia or Myalgia	Diarrhea
Bacterial pharyngitis	Amebiasis (hepatic)	Amebiasis (intestinal)	Arboviruses	Amebiasis (intestinal)
Diphtheria	Anthrax	Anthrax	Dengue	Anthrax
Infectious mononucleosis	Bacterial pneumonia	<i>Campylobacter enteritis</i>	Yellow fever	<i>Campylobacter enteritis</i>
HIV seroconversion	Filarial fever	Legionnaires disease	Babesiosis	HIV seroconversion
Lyme disease	TPE	Malaria	Bartonellosis	Legionnaires disease
Poliomyelitis	Histoplasmosis	Measles	Brucellosis	Malaria melioidosis
Psittacosis	Legionnaires disease	Melioidosis	Erythema nodosum leprosum	Plague
Tularemia	Leishmaniasis (visceral)	Plague	Hepatitis (viral)	Relapsing fever
Viral hemorrhagic fever (Lassa)	Loeffler syndrome	Relapsing fevers	Histoplasmosis	Salmonellosis
Nonspecific viral URTI	Malaria	Salmonellosis	HIV seroconversion	Schistosomiasis (acute)
	Measles	Schistosomiasis (acute)	Legionnaires disease	Shigellosis
	Melioidosis	Shigellosis	Leptospirosis	Typhoid in children
	Plague	Typhoid fever	Lyme disease	Viral hemorrhagic fevers
	Q fever	Viral hemorrhagic fevers	Malaria	Yersiniosis
	Relapsing fever	Yersiniosis	Plague	
	Schistosomiasis (acute)		Poliomyelitis	
	Toxocariasis		Q fever	
	Trichinosis		Relapsing fevers	
	Tuberculosis		Secondary syphilis	
	Tularemia		Toxoplasmosis	
	Typhoid and paratyphoid		Trichinosis	
	Typhus		Trypanosomiasis (African)	
	Viral hemorrhagic fevers		Tularemia	
	Nonspecific viral URTIs		Typhoid and paratyphoid

TABLE 90.5 Common Clinical Findings and Associated Infections After Tropical Travel

Clinical Findings	Infections
Fever and rash	Dengue, chikungunya, rickettsial infections, enteric fever (skin lesions may be sparse or absent), acute HIV infection, measles, acute schistosomiasis
Fever and abdominal pain	Enteric fever, amebic liver abscess
Undifferentiated fever and normal or low white blood cell count	Dengue, malaria, rickettsial infection, enteric fever, chikungunya
Fever and hemorrhage	Viral hemorrhagic fevers (dengue and others), meningococemia, leptospirosis, rickettsial infections
Fever and eosinophilia	Acute schistosomiasis; drug hypersensitivity reaction; fascioliasis and other parasitic infections (rare)
Fever and pulmonary infiltrates	Common bacterial and viral pathogens; legionellosis, acute schistosomiasis, Q fever, melioidosis
Fever and altered mental status	Cerebral malaria, viral or bacterial meningoencephalitis, African trypanosomiasis
Mononucleosis syndrome	Epstein-Barr virus, cytomegalovirus, toxoplasmosis, acute HIV infection
Fever persisting >2 weeks	Malaria, enteric fever, Epstein-Barr virus, cytomegalovirus, toxoplasmosis, acute HIV, acute schistosomiasis, brucellosis, tuberculosis, Q fever, visceral leishmaniasis (rare)
Fever with onset >6 weeks after travel	Vivax malaria, acute hepatitis (B, C, or E), tuberculosis, amebic liver abscess

HIV, Human immunodeficiency virus.

Modified from Centers for Disease Control and Prevention: CDC health information for international travel 2012, New York, 2012, Oxford University Press.

are common in patients with neutropenia. Many episodes are short lived because they respond quickly to treatment or are manifestations of rapidly fatal infections.

Bacteremia and sepsis can cause rapid deterioration in neutropenic patients, and empirical, broad-spectrum antibiotics should be administered promptly without waiting for the results of cultures. However, only about 35% of prolonged episodes of febrile neutropenia respond to broad-spectrum antibiotic therapy. If fevers persist after 3 days of treatment with broad-spectrum antibiotics, diagnostic tests to explore fungal causes should be considered along with empirical antifungal treatment.

Human Immunodeficiency Virus–Related Fever of Unknown Origin

The advent of highly active antiretroviral therapy (ART) with the achievable suppression of the HIV viral load has greatly reduced the frequency of FUO in HIV-infected patients. High vigilance is warranted to test for new HIV in a matter-of-fact manner in the primary care setting. The primary phase of HIV infection can be asymptomatic or sometimes be characterized by a mononucleosis-like illness in which fever is a prominent feature (see [Chapter 103](#)). After symptoms of the primary phase of HIV infection resolve, patients enter a long period of subclinical infection during which they are usually afebrile. In the later phases of untreated HIV infection, episodes of fever become common, often signifying a superimposed illness. Many of these are potentially devastating opportunistic infections, which tend to manifest in atypical fashion because of the severe immunodeficiency. Patients with untreated acquired immunodeficiency syndrome (AIDS) can have multiple infections simultaneously, which highlights the importance of treating and documenting adherence with ART. After initiating effective ART the HIV viral load is effectively suppressed and the frequency of FUO in HIV-infected patients falls markedly.

Approach to the Patient With Fever of Unknown Origin

Evaluation of a patient with FUO typically includes verification that the patient has fever, consideration of the fever pattern, a comprehensive history, repeated physical examinations, appropriate laboratory investigations, key imaging studies, and invasive diagnostic procedures. The physical examination should scrutinize the patient more closely than usual because key physical abnormalities in patients with FUO are subtle and require repeated examinations to be appreciated.

Work-up of a patient with an FUO should focus on the history, physical examination, and initial laboratory data. In place of rational diagnostic thinking, there is a temptation to order multiple comprehensive laboratory and imaging studies. Rather than leading to a diagnosis, this shotgun approach may result in enormous expense, false-positive results, and unnecessary additional investigations that may obfuscate the true diagnosis.

A fundamental principle in the management of classic FUO is that therapy should be withheld, whenever possible, until the cause of the fever has been determined, so that treatment can be tailored to a specific diagnosis. The exception is in the setting of the immunocompromised host because rapid empirical treatment is most often needed.

If fevers persist after an exhaustive work-up there may be a role for fluorodeoxyglucose positron emission tomography (18 FDG-PET/CT) imaging, if available. This allows enhancement of acute and chronic inflammatory processes by uptake of FDG in all activated leukocytes and provides the necessary spatial resolution that may substantially contribute to finding the cause of FUO. The radiation exposure and cost and the degree of incremental improvement in detection over other methods must be carefully considered.

Cardiac ECHO can be helpful if culture-negative endocarditis or atrial myxoma is suspected in patients with cardiac murmurs. The most invasive tests such as lymph node biopsies, bone marrow biopsies, and temporal artery biopsies should be undertaken only with strong clinical suspicion and based on physical findings or those found on imaging. Persons who reside in the southeastern part of the United States and immigrants from world regions endemic for *Strongyloides stercoralis* should have a *S. stercoralis* titre—whether or not they have a fever—to identify and eradicate risk for overwhelming strongyloidiasis.

SPECIFIC CONDITIONS AND EXPOSURES CAUSING FEVER

Fever After Animal Exposures

Q Fever

Q fever is a widespread zoonotic infection caused by the pathogen *Coxiella burnetii* that has acute and chronic manifestations. The primary source of infection is infected cattle, sheep, and goats. The organism can exist for months in soil and can become airborne. The onset of disease is typically abrupt, and high-grade fever (40° C or 104° F),

TABLE 90.6 Common Causes of Fever of Unknown Origin**Infections**

Abscesses
 Brucellosis
 Catheter infections
 Cytomegalovirus
 Coccidioidomycosis
 Histoplasmosis
 Human immunodeficiency virus (HIV) infection
 Infective endocarditis
 Intra-abdominal, subdiaphragmatic, and pelvic disease
 Liver and biliary tract disease
 Lyme disease
Mycobacterium tuberculosis
 Osteomyelitis
 Sinusitis
 Toxoplasmosis
 Urinary tract infection

Autoimmune Conditions

Adult Still disease
 Familial Mediterranean sarcoidosis
 Rheumatoid arthritis
 Systemic lupus erythematosus
 Temporal arteritis

Malignancy

Hepatocellular carcinoma
 Leukemia
 Metastatic cancers
 Pancreatic cancer
 Renal cell carcinoma

Miscellaneous Causes

Deep vein thrombosis, pulmonary embolism
 Hyperthyroidism
 Kikuchi disease
 Periodic fever (tumor necrosis factor receptor associated)

fatigue, headache, and myalgias are the most common symptoms. Acute Q fever is usually a mild disease that resolves spontaneously within 2 weeks. Q fever endocarditis usually occurs in patients with previous valvular damage or immunocompromise, and it is often the predominant manifestation of chronic infection.

An immunofluorescence assay is the reference method for the serodiagnosis of Q fever. Consideration of doxycycline therapy is warranted only for patients who are symptomatic.

Leptospirosis

Leptospirosis is a zoonotic infection with protean manifestations caused by the spirochete *Leptospira interrogans*. It is distributed worldwide, but most clinical cases occur in the tropics. The organism infects rodents, cattle, swine, dogs, horses, sheep, and goats, and it is shed in the urine. Humans most often become infected after exposure to environmental sources, such as contaminated water.

Leptospirosis may manifest as a subclinical illness followed by seroconversion, a self-limited systemic infection, or a severe, potentially fatal illness accompanied by multiorgan failure. Acute illness manifests with the abrupt onset of fever, rigors, myalgias, and headache in 75%

to 100% of patients. Conjunctival suffusion in a patient with a nonspecific febrile illness accompanied by lymphadenopathy, hepatomegaly, and splenomegaly points to a diagnosis of leptospirosis.

During the second phase of illness, fever is less pronounced, but headache and myalgias can be severe, and aseptic meningitis is an important manifestation. In some patients with leptospirosis, the clinical course may be complicated by jaundice (although liver failure is rare), renal failure, uveitis, hemorrhage, ARDS, myocarditis, and rhabdomyolysis (i.e., Weil syndrome).

Because the clinical features and routine laboratory findings of leptospirosis are not specific, a high index of suspicion must be maintained. The diagnosis is usually made by serologic testing for *L. interrogans*. Symptomatic individuals warrant treatment with doxycycline.

Brucellosis

Brucellosis is a zoonotic infection caused by *Brucella melitensis*. It is transmitted to humans by contact with fluids from infected animals (e.g., sheep, cattle, goats, pigs) or derived food products such as unpasteurized milk and cheese.

Clinical manifestations of brucellosis include fever, night sweats, malaise, anorexia, arthralgias, fatigue, weight loss, and depression. Patients may have fever and a multitude of complaints but no other objective findings. The onset of symptoms may be abrupt or insidious, developing over several days to weeks. The musculoskeletal and genitourinary systems are the most common sites of involvement. Neurobrucellosis, endocarditis, and hepatic abscesses occur in 1% to 2% of cases.

The diagnosis of brucellosis should be considered for an individual with otherwise unexplained fever and nonspecific complaints who has had a possible exposure. Ideally, the diagnosis is made by culture of the organism from blood or other sites, such as bone marrow. Serologic tests include tube agglutination and enzyme-linked immunosorbent assay (ELISA). For adults with nonfocal disease, treatment with doxycycline and rifampin is suggested.

Fever and Rash

The most concerning diseases associated with fever and rash are meningococemia, staphylococcal TSS, and RMSF.

Bacterial Meningitis

Neisseria meningitidis is the leading cause of bacterial meningitis in children and young adults in the United States. Recent experience in New York City identified HIV patients as being at increased risk for meningococcal disease.

Manifestations of meningococcal disease can range from transient fever and bacteremia to fulminant disease, with death ensuing within hours of the onset of clinical symptoms. Acute systemic meningococcal disease may manifest as one of three syndromes: meningitis alone, meningitis with accompanying meningococemia, and meningococemia without clinical evidence of meningitis.

The typical initial symptoms of meningitis due to *N. meningitidis* consists of the sudden onset of fever, nausea, vomiting, headache, decreased ability to concentrate, and myalgias in an otherwise healthy patient. A petechial rash appears as discrete lesions 1 to 2 mm in diameter, most frequently occurring on the trunk and lower portions of the body. More than 50% of patients have petechiae at clinical presentation. Petechiae can coalesce into larger purpuric and ecchymotic lesions.

Staphylococcal Toxic Shock Syndrome

S. aureus strains produce exotoxins that cause three syndromes: food poisoning, caused by ingestion of *S. aureus* enterotoxin; scalded skin syndrome, caused by exfoliative toxin; and TSS, caused by toxic shock syndrome toxin 1 (TSST-1) and other enterotoxins. About one half

of reported TSS cases are menstrual, associated with bacterial growth on highly absorbent tampons. Non-menstrual TSS has been associated with surgical and postpartum wound infections, mastitis, septorhinoplasty, sinusitis, osteomyelitis, arthritis, burns, cutaneous and subcutaneous lesions (especially of the extremities, perianal area, and axillae), and respiratory infections after influenza. Some MRSA strains can produce TSST-1, and patients infected with these strains may develop TSS.

The Centers for Disease Control and Prevention (CDC) case definition for a confirmed case includes several criteria. Patients must have fever greater than 38.9° C, hypotension, diffuse erythroderma, desquamation (unless the patient dies before desquamation can occur), and involvement of at least three organ systems. Although 80% to 90% of TSS patients have *S. aureus* isolated from mucosal or wound sites, the isolation of *S. aureus* is not required for the diagnosis of staphylococcal TSS.

Rickettsial Infections

RMSF is a potentially lethal but usually curable tick-borne disease. Most cases of RMSF occur in the spring and early summer in endemic areas, particularly in the south central and southeastern states, when outdoor activity is most common. The etiologic agent, *Rickettsia rickettsii*, is a gram-negative, obligate intracellular bacterium that is usually transmitted through a tick bite. Up to one third of patients with proven RMSF do not recall a recent tick bite or recent tick contact.

In the early phases of illness, most patients have nonspecific signs and symptoms such as fever, headache, malaise, myalgias, arthralgias, and nausea with or without vomiting. Most patients with RMSF develop a rash between the third and fifth days of illness. The rash typically begins with pink, blanching macules that evolve to a deep red color and then become hemorrhagic. The lesions begin at the wrists, forearms, and ankles and then spread to the arms, thighs, trunk, and face.

The diagnosis of RMSF is based on a constellation of symptoms and signs in an appropriate epidemiologic setting (e.g., endemic area in the spring or early summer). In later illness, the diagnosis can be made by skin biopsy and confirmed serologically.

Murine typhus is a worldwide illness caused by *Rickettsia typhi* organisms that are transmitted by fleas. It produces a moderately severe illness characterized by fever, rash, and headache. Disease in the United States has been reported in Texas and Southern California.

Rickettsia africae, the cause of African tick-bite fever, occurs in travelers returning from East Africa. It produces a large eschar with a febrile syndrome similar to RMSF. Rickettsial infections respond to treatment with doxycycline and warrant rapid initiation of treatment.

Lyme Disease

Lyme disease is a tick-borne illness caused by pathogenic species of the spirochete *Borrelia burgdorferi* in the United States. Other species in Europe and Asia can cause more aggressive presentations. Localized disease includes erythema migrans in 80% of patients and nonspecific findings that resemble a viral syndrome. Erythema migrans is an expanding macule that forms an annular lesion with a clearing middle.

Early disseminated Lyme disease with acute neurologic or cardiac involvement usually occurs weeks to several months after the tick bite and may be the first manifestation of the disease. Nonspecific symptoms (e.g., headache, fatigue, arthralgias) may persist for months after treatment of Lyme disease. There is no evidence that these persistent subjective complaints represent ongoing active infection. Co-infection with *Babesia* and *Ehrlichia* is common, and these infections should be considered in persons diagnosed with Lyme disease.

Human Ehrlichiosis

The principal vector of *Ehrlichia chaffeensis*, the agent that causes human monocytic ehrlichiosis (HME), is the Lone Star tick (*Amblyomma*

americanum). Patients typically have an acute illness that has an incubation period of 1 to 2 weeks. Most patients are febrile and have non-specific symptoms such as malaise, myalgia, headache, and chills.

One feature that may distinguish HME from human granulocytic anaplasmosis (HGA), another tick-borne illness caused by *Anaplasma phagocytophilum*, is a rash (macular, maculopapular, or petechial). This rash occurs in about 30% of patients with HME but is rare in patients with HGA.

The preferred and most widely available diagnostic method for ehrlichiosis is the indirect fluorescent antibody test. The diagnosis should be considered in all patients with Lyme disease or babesiosis. Treatment with doxycycline should be initiated for all patients suspected of having ehrlichiosis or anaplasmosis.

Viral Infections Associated With Rash

The typical manifestations of viral infections associated with rash may unequivocally establish the cause of a febrile syndrome. For example, varicella-zoster virus infection manifests with distinctive lesions of chickenpox or herpes zoster (i.e., shingles). The resurgence of measles mandates the ability to recognize its rash.

Acute onset of high fever characterizes viral hemorrhagic fevers, along with bleeding complications and high mortality rates in some cases. Arthropods often transmit viral infections, including dengue, which is one of the most common causes of fever in returned travelers.

Fever With Lymphadenopathy

Generalized and localized lymphadenopathy can be major manifestations of some infectious diseases, such as in mononucleosis syndromes, tuberculosis, HIV infection, and pyogenic infections.

Infectious mononucleosis is characterized by a triad of fever, tonsillar pharyngitis, and lymphadenopathy. EBV is a widely disseminated herpesvirus that is spread by intimate contact between susceptible persons and EBV shedders. Lymph node involvement in infectious mononucleosis is typically symmetrical and more commonly involves the posterior cervical than the anterior chains. The posterior cervical nodes are deep beneath the sternocleidomastoid muscles and must be carefully palpated. The nodes may be large and moderately tender. Lymphadenopathy may also become more generalized including enlargement of the spleen, which distinguishes infectious mononucleosis from other causes of pharyngitis.

Lymphadenopathy peaks in the first week and then gradually subsides over 2 to 3 weeks. Splenomegaly is seen in 50% of patients with infectious mononucleosis and usually begins to recede by the third week of the illness.

Patients with a clinical picture of infectious mononucleosis should have a white blood cell count with differential and a heterophile (Monospot) test. If the heterophile test result is positive, no further testing is necessary when the clinical scenario is compatible with typical infectious mononucleosis. If the heterophile test result is negative but there is still a strong clinical suspicion of EBV infection, the Monospot test can be repeated because results can be negative early in clinical illness.

If the clinical syndrome is prolonged or the patient does not have a classic EBV syndrome, immunoglobulin M (IgM) and immunoglobulin G (IgG) viral capsid antigen (VCA) and Epstein-Barr nuclear antigen (EBNA) antibodies should be measured. IgG EBNA detected within 4 weeks of symptom onset excludes acute primary EBV infection as an explanation and should prompt consideration of EBV-negative causes of mononucleosis.

Cytomegalovirus

The spectrum of human illness caused by CMV is diverse and mostly depends on the host. CMV infection in the immunocompetent host

usually is asymptomatic or may manifest as a mononucleosis-like syndrome. Transmission occurs through multiple routes.

The mononucleosis syndrome associated with CMV infection has been described as typhoidal because systemic symptoms and fever predominate, and signs of enlarged cervical nodes and splenomegaly are not as commonly seen as they are in EBV infection. Diarrhea, fever, fatigue, abdominal pain, and mildly abnormal liver enzymes are common findings. Immunocompromised patients, such as those who have received transplants, may have serious, life-threatening infections such as pneumonitis, hepatitis, colitis, and retinitis. Serology provides indirect evidence of recent CMV infection based on changes in antibody titers at different time points during the clinical illness. Serologies are also helpful in determining past exposure to CMV. This information is particularly relevant for monitoring immunosuppressed hosts at risk for CMV reactivation syndromes.

Primary Human Immunodeficiency Virus Infection

Most cases of new HIV infection are passed asymptotically, and routine testing of sexually active persons should be performed as part of good primary care. All patients with mononucleosis syndromes should undergo HIV testing. Published series consistently report that the most common findings of acute HIV are fever, generalized lymphadenopathy, sore throat, rash, myalgia or arthralgia, and headache when symptomatic.

Toxoplasmosis

Toxoplasmosis, an infection with a worldwide distribution, is caused by the intracellular protozoan parasite *T. gondii*. Humans can acquire *Toxoplasma* organisms through ingestion of contaminated meat, vertical transmission, blood transfusion, exposure to oocysts from cat feces, or organ transplantation.

Immunocompetent persons with primary infection are usually asymptomatic, but latent infection can persist for the life of the host. When symptomatic infection does occur, the most common manifestation is bilateral, symmetrical, nontender cervical adenopathy. Patients may have headache, fever, and fatigue. Symptoms usually resolve within several weeks. In AIDS patients or other immunocompromised hosts who have been previously infected, *T. gondii* infection may reactivate in the brain, causing abscesses and encephalitis.

Infections Causing Regional Lymphadenopathy

Scrofula (i.e., tuberculous cervical adenitis) develops in a subacute to chronic pattern. Low-grade fever is usually associated with a large mass of matted cervical lymph nodes. In children, *M. tuberculosis* is the etiologic agent, but in adults, *Mycobacterium avium* complex and *Mycobacterium scrofulaceum* are more commonly found. Surgical excision is the treatment of choice.

Cat-Scratch Disease

Cat-scratch disease, a condition caused by *Bartonella henselae*, is characterized by self-limited regional lymphadenopathy after a cat scratch or transmission from another vector. Other manifestations can include visceral organ, neurologic, and ocular involvement. In 85% to 90% of children, cat-scratch disease manifests as a localized cutaneous and lymph node disorder near the site of organism inoculation. In some individuals, the organisms disseminate and infect the liver, spleen, eye, bone, or CNS. Patients with localized disease usually have a self-limited illness, whereas those with disseminated disease can have life-threatening complications. *B. henselae* infection should be considered in the initial evaluation of FUO in children.

The diagnosis of cat-scratch disease is based on typical clinical findings (i.e., lymphadenopathy) associated with probable exposure

to cats or fleas. Laboratory testing that supports the diagnosis includes a positive *B. henselae* antibody titer or biopsy of a lymph node with a positive Warthin-Starry stain or polymerase chain reaction (PCR) analysis of tissue.

Pyogenic Infection

S. aureus and group A streptococcal (GAS) infections can produce acute, suppurative lymphadenitis. Enlarged and tender lymph nodes usually are found in the submandibular, cervical, axillary, or inguinal areas. Patients have fever and leukocytosis. Pyoderma, pharyngitis, and periodontal infections are usually the primary sites of infection. Management includes drainage and antibiotics.

Plague

Bubonic plague is a bacterial syndrome caused by *Yersinia pestis* that usually consists of fever, headache, and a large mat of inguinal, axillary, or cervical lymph nodes. Lymph nodes suppurate and drain spontaneously. The diagnosis should be considered for acutely ill patients in the southwestern United States with possible exposure to fleas and rodents. Gram-negative coccobacilli can be seen in lymph node aspirates. The characteristic safety-pin appearance of *Y. pestis* with dark blue staining of polar bodies is seen with Wayson stain.

Sexually Transmitted Diseases

Inguinal lymphadenopathy associated with sexually transmitted diseases can be unilateral or bilateral. In primary syphilis, enlarged nodes are discrete, firm, and nontender. Tender lymphadenopathies with matting are seen in lymphogranuloma venereum. The lymphadenopathy of chancroid is most often unilateral and manifests with pain and fused lymph nodes. Primary genital herpes infection also causes tender inguinal lymphadenopathy.

FACTITIOUS FEVER AND SELF-INDUCED ILLNESS

In most case series, factitious fever or self-induced illness is a relatively uncommon cause of FUO, but it may occur more often than generally appreciated. Patients with these conditions are often young women, and 50% have had training in some aspect of health care. They are often well educated, cooperative, articulate, and manipulative of family and caregivers. Patients can no longer manipulate thermometers because electronic or infrared thermometry is used, and causing factitious fever is difficult. Clues to the factitious fever diagnosis include absence of a toxic appearance despite high temperature readings, lack of tachycardia, and absent diurnal variation. Patients may appear well between episodes of fever.

Genuine fever can be induced if an individual injects or ingests pyrogenic substances such as bacterial suspensions, urine, or feces. Although intermittent polymicrobial bacteremia may suggest a diagnosis of intra-abdominal abscess, it represents self-induced infection. The discovery of needles and substances for injection in the patient's belongings may help in the diagnosis.

In most cases, a psychogenic basis for the behavior is assumed. However, one study with detailed psychological patient analyses found no evidence of major psychiatric diagnoses among individuals with self-induced or simulated illnesses. Munchausen syndrome and Munchausen by proxy are the most extreme forms of factitious fever. Patients often agree stoically to numerous highly invasive procedures to diagnose and treat themselves or their children (i.e., proxy). All of these individuals require objective but complete, tactful, and compassionate assessments and considerable psychiatric care.

Bacteremia and Sepsis

Russell J. McCulloh, Steven M. Opal

DEFINITION

Sepsis is a leading cause of morbidity and death among hospitalized patients. The disease process results from a complex interplay of host immune responses and infectious microorganisms. In 2016 an international panel of experts released an updated definition of sepsis, specifying it as life-threatening organ dysfunction caused by a dysregulated host response to infection. Manifestations can include fever, altered mental status, and abnormalities in inflammation and coagulation. Severe cases can progress to multiple organ system dysfunction followed by organ failure and death.

Diagnostic criteria for sepsis are provided in [Table 91.1](#). The term “severe sepsis,” once recognized as a separate entity defined by more severe organ dysfunction, is now synonymous with the current definition of sepsis and should no longer be used. Septic shock is a combination of sepsis and persistent hypotension and tissue hypoperfusion despite adequate fluid resuscitation or the need to use vasopressors to maintain a mean arterial pressure (MAP) at 65 mm Hg or greater and in addition an elevated serum lactate greater than 2 mmol/L. The continuum of disease manifestations from localized infection to multiorgan failure and refractory septic shock is depicted in [Fig. 91.1](#).

Sepsis is a situation in which the infection-induced systemic inflammatory and coagulopathic responses have become injurious to the host. Sepsis is an infectious process characterized by tissue injury from hypoperfusion and immune dysregulation. *Severe infection* should be used to describe an infection that is accompanied by systemic inflammation but without evidence of organ dysfunction remote from the site of infection (i.e., the former definition of sepsis). Whether these revised definitions can resolve the current confusion in terminology remains to be seen.

Understanding the pathophysiology of sepsis syndrome has proved helpful in differentiating and treating severe inflammatory processes that manifest with symptoms similar to sepsis, including pancreatitis, severe trauma, thermal burns, and certain toxin or environmental exposures. These processes can produce a systemic inflammatory response syndrome (SIRS), but they lack the component of infection needed to establish a diagnosis of sepsis. The remarkable clinical similarity between these severe “sterile” inflammations and septic shock reflects their molecular profiles. Identical signaling pathways for the immune response are activated by highly conserved pathogen-associated molecular patterns (PAMPs), which are molecular motifs recognized by cells of the host’s innate immune system. Damage-associated molecular patterns (DAMPs) are molecules released by injured host cells that act as endogenous danger signals to promote the inflammatory response (see “Pathophysiology of Septic Shock” later in this chapter).

EPIDEMIOLOGY

The worldwide incidence of sepsis is difficult to assess due to limited data from developing countries. In industrialized countries, reported rates of sepsis range from 22 to 300 cases per 100,000 people. Sepsis may account for up to 6% of adult deaths. In the United States, more than 750,000 cases of sepsis and 200,000 sepsis-related deaths occur annually. The risk of mortality depends on the severity of illness and multiple host factors (discussed later). Overall, estimates of death from sepsis range from 20% of mild to moderate cases to more than 60% of patients with septic shock.

The financial impact of sepsis cases is immense. Each episode of sepsis costs approximately \$50,000 in health care expenditures, for a total of more than \$24 billion dollars in 2016 in the United States alone.

Bacterial infections are the most common cause of sepsis. Bloodstream infections due to bacteria account for the largest proportion of hospitalizations. The rates are highest for premature infants, the advanced elderly (especially those older than 85 years of age), and patients with intravenous catheters, implanted devices, or severe medical morbidities such as severe burns or hematologic malignancies.

Pathogens most commonly identified in bloodstream infections include staphylococci (e.g., *Staphylococcus aureus*), group A streptococci, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa*. Immunocompromised patients and patients with long-term intravascular catheters are at increased risk for fungal bloodstream infections from *Candida* species, and some species may be resistant to commonly used antifungal medications. Given the broad variety of potential pathogens, clinicians face the dual challenges of an accurate and timely diagnosis and choice of appropriate empirical therapy.

Several epidemiologic factors can guide the clinician in cases of sepsis when a source has not been identified. [Table 91.2](#) lists microorganisms that are associated with certain host factors that predispose a patient to infection and sepsis. Host factors associated with worse outcomes include extremes of age, use of immunomodulating medications, and concomitant chronic medical conditions.

Several diagnostic and treatment factors are associated with severity of illness and clinical outcome. Delay in effective antimicrobial therapy correlates with worse outcomes. Infection with multidrug-resistant organisms may cause a delay in effective therapy, and for some organisms, particularly gram-negative enteric rods, the delay may be independently related to worse outcomes. Certain organisms (e.g., *P. aeruginosa*, *Staphylococcus aureus*) are more virulent. The primary infection site also is important; respiratory sites are the most common, and the central nervous system often is the most lethal site of infection. The number of organ systems involved plays a role, with mortality increasing as the number of dysfunctional organ systems increases.

TABLE 91.1 Diagnostic Criteria for Sepsis^a**General Criteria**

Life-threatening organ dysfunction caused by a dysregulated response to infection

Organ Dysfunction CriteriaChange in Sequential (Sepsis-related) Organ Failure Assessment (SOFA)^b score of ≥ 2 points. It can be used to measure the severity of organ dysfunction.**SOFA Scoring (Range 0–4 Per Category, 0–24 Total Score Range)**

Criterion	0	1	2	3	4
Respiration; P_{aO_2}/F_{iO_2} (torr)	>400	≤ 400	≤ 300	≤ 200 with respiratory support	≤ 100 with respiratory support
Platelets ($\times 10^3/\text{mm}^3$)	>150	≤ 150	≤ 100	≤ 50	≤ 20
Bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Glasgow Coma Scale	15	13–14	10–12	6–9	<6
Hypotension ^c	None	MAP <70 mm Hg	Dopamine ≤ 5 or dobutamine (or any dose of vasopressin)	Dopamine >5 or epi ≤ 0.1 or norepi ≤ 0.1 (or phenylephrine 100–300 mcg bolus)	Dopamine >15 or epi >0.1 or norepi >0.1 (or phenylephrine >300 mcg bolus)
Creatinine (mg/dL) or urine output (mL/day)	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 <500 mL/day	>5.0 <200 mL/day

Septic Shock Criteria

Vasopressor requirement to maintain a mean arterial pressure of 65 mm Hg or greater, AND

Hyperlactatemia (serum lactate >2 mmol/L [>18 mg/dL])

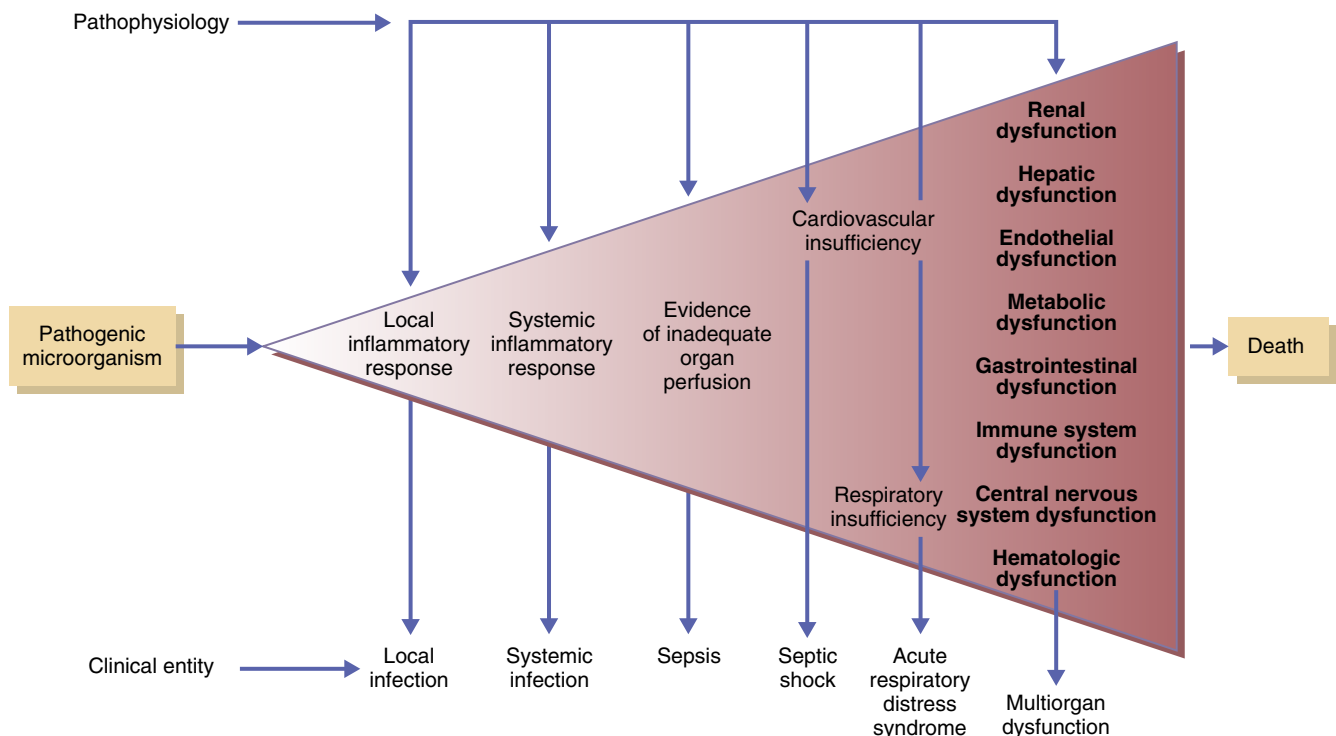

From Singer M, Deutschman CS, Seymour CW, et al: The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), JAMA 315(8):801-10, 2016.

F_{iO_2} , Fraction of inspired oxygen; *INR*, international normalized ratio; *MAP*, mean arterial pressure; P_{aO_2} , partial pressure of oxygen.

^aThe criteria include documented or suspected infection and some of the variables listed.

^bAssuming baseline SOFA of 0 in most cases.

^cAdrenergic agents must be administered for at least 1 hour to count; doses are in mcg/kg/min.

**Fig. 91.1** The spectrum of illness and nomenclature for sepsis pathophysiology.**PATHOLOGY AND IMMUNOPATHOGENESIS**

The pathologic findings of fatal septic shock are often rather bland on gross examination and even histologic examination of tissue samples.

The most common finding is increased tissue edema in the interstitial spaces and excess lung fluid and pleural fluid. Signs of hyaline membrane formation and fibrin deposition in the alveoli are common and

TABLE 91.2 Microorganisms Commonly Identified in Septic Patients Based on Host Factors

Host Factor	Organisms to Consider
Asplenia	Encapsulated organisms, particularly <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , <i>Capnocytophaga canimorsus</i>
Cirrhosis	<i>Vibrio</i> , <i>Salmonella</i> , and <i>Yersinia</i> species; encapsulated organisms, other gram-negative rods
Alcohol abuse	<i>Klebsiella</i> species, <i>S. pneumoniae</i>
Diabetes	<i>Mucormycosis</i> , <i>Pseudomonas</i> species, <i>Escherichia coli</i> , group B streptococci
Neutropenia	Enteric gram-negative rods, <i>Pseudomonas</i> , <i>Aspergillus</i> , <i>Candida</i> , <i>Mucor</i> species, <i>Staphylococcus aureus</i> , streptococcal species
T-cell dysfunction	<i>Listeria</i> , <i>Salmonella</i> , and <i>Mycobacterium</i> species, herpesviruses (including herpes simplex, cytomegalovirus, varicella-zoster virus)
Acquired immunodeficiency syndrome	<i>Salmonella</i> species, <i>S. aureus</i> , <i>Mycobacterium avium</i> complex, <i>S. pneumoniae</i> , group B streptococci

indicate the fibroproliferative stage of acute respiratory distress syndrome (ARDS). Occasionally, punctate or macroscopic evidence can be detected in the adrenal tissues. Diffuse petechiae in tissues and mucosal surfaces may indicate disseminated intravascular coagulation (DIC).

The kidneys usually appear normal, and necrosis of kidney tissues is distinctly uncommon. The term *acute tubular necrosis* is a misnomer, and the term *acute kidney injury* (AKI) is more appropriate for describing the functional and usually reversible loss of kidney function found in septic shock without accompanying evidence of glomerular or tubular necrosis.

An important finding at autopsy is identification of the infectious focus that caused septic shock. The focal infection that precipitated sepsis is readily identifiable in most deceased patients despite days to weeks of seemingly appropriate antimicrobial therapy directed against the pathogens. If careful histochemical studies are performed shortly after a patient succumbs to sepsis, excessive apoptosis (but not necrosis) of immune effector cells is identifiable in lung, spleen, lymph nodes, and hepatic tissues. Electron microscopy of tissues after death from sepsis often reveals loss of tight junctions along epithelial and endothelial surfaces. Electron microscopy also demonstrates diffuse mitochondrial swelling and degradation and clearance of intracellular organelles (i.e., autophagy).

PATHOPHYSIOLOGY OF SEPTIC SHOCK

The molecular mechanisms that underlie the basic pathophysiology of septic shock have been determined. Sepsis is triggered when a pathogen or cluster of pathogens breaches the epithelial barriers at a tissue site, evades clearance by humoral and cellular innate immune defenses, and causes an invasive infection. On entry into the host tissues, microbial pathogens are first sensed by myeloid cells of the innate immune system by pattern recognition receptors (e.g., toll-like receptors [TLRs]) on the cell surface and in endosomal compartments. TLRs detect highly conserved molecular motifs of microbes. Examples include lipopolysaccharide (LPS), the endotoxin produced by gram-negative bacteria; bacterial lipopeptides from gram-positive bacteria; β -glucans of the cell wall of fungi; viral RNA genomes and proteins; bacterial flagella; and DAMPs released from injured host cells, including intracellular structures such as histone proteins, mitochondrial DNA, and high-mobility group box 1 (Fig. 91.2).

TLRs and related intracellular pattern recognition receptors, including the inflammasome elements, retinoic acid-inducible gene 1 (*RIG1*)-like helicases, and cytoplasmic microbial TLR4, alert the host to infection. TLR4 is the long-sought-after LPS receptor of the human innate immune system. LPS is released from the cell membrane of gram-negative bacteria on their destruction. LPS is first bound to a

carrier protein, LPS-binding protein, and the LPS monomer is then delivered to a membrane-associated, multiligand, pattern recognition receptor, CD14. LPS monomers are then passed to a soluble protein (i.e., myeloid differentiation factor 2 [MD2]) and bind to the ectodomain of TLR4. After this LPS/MD2/TLR4 complex is completed and dimerized, intracellular signaling alerts the host to the invasive infectious challenge. The pathway induces a series of phosphorylation events of adaptor proteins and signaling molecules that terminate in the activation and translocation of transcriptional activating factors such as nuclear factor- κ B (NF- κ B) into the nucleus. The transcription factors bind to promoter sites of the acute phase protein network, resulting in an acute outpouring of inflammatory, host defense, and coagulation components.

Other TLRs, such as TLR5 (i.e., bacterial flagella) and the TLR2/TLR1 and TLR2/TLR6 heterodimers (i.e., bacterial lipopeptides, lipoteichoic acid, and other elements of bacteria and fungi), are expressed on the cell surface of immune effector cells that recognize different molecular patterns. Nucleic acid recognition-specific TLRs reside in endosomal vacuoles, where they detect microbial DNA (TLR9), single-stranded RNA (TLR7 and TLR8), and double-stranded RNA (TLR3).

An array of complement elements, cytokines, chemokines, prostanoids, vasoactive peptides, platelet-activating factor, and proteases are generated, resulting in activation of neutrophils, neutrophil extracellular traps (NETs), monocytes, macrophages, dendritic cells, lymphocytes, and endothelial cells in a combined effort to wall off the infectious process, clear the pathogens, and begin the process of tissue repair. This defense system efficiently clears pathogens from the host after local injury and the inevitable minor breaches of the epithelial barriers by microorganisms that occur over a lifetime.

If the inflammatory process is unchecked and accompanied by large numbers of pathogens or even a few highly virulent organisms (e.g., plague, tularemia, anthrax, and hemorrhagic fever viruses) to which the host has no preexisting immunity, a generalized, inflammatory, and injurious process known as *sepsis* evolves over a short time, and it can be deleterious or lethal to the host. The same inflammatory response that can be life-saving in localized infection can become life-threatening if it becomes sustained and generalized.

Endothelial membranes throughout the body are activated and become pro-adherent and pro-coagulant surfaces that promote neutrophil and platelet adherence. Neutrophils release proteases, cytokines, NETs, reactive oxygen radicals, and vasoactive prostanoids that damage endothelial cells and their function. Cytokine-inducible nitric oxide synthase is upregulated, resulting in massive generation of nitric oxide (NO). NO is a potent vasodilator, and in combination with other vasoactive peptides and phospholipid mediators, it promotes diffuse opening of capillary beds and increased permeability, with loss of

Fig. 91.2 Immunopathogenesis of sepsis. Early recognition of bloodstream infection begins with sensing by pattern recognition receptors: toll-like receptor 4 (TLR4); cluster determinant 14 (CD14); myeloid differentiation factor 2 (MD2) for gram-negative bacterial lipopolysaccharide and TLR2 for lipoteichoic acid and other elements from gram-positive bacteria. Engagement of the TLRs by their ligands signals transcription of the acute phase response genes by nuclear factor- κ B (NF- κ B). Septic shock is initiated by systemic release of an array of vasoactive mediators, including nitric oxide (NO) produced by cytokine-inducible NO synthase (iNOS).

intravascular fluids into the interstitial spaces. Reactive oxygen species combine with NO to generate highly injurious reactive nitrogen intermediates (e.g., peroxynitrite) that damage mitochondrial function and induce apoptosis. Systemic hypotension rapidly develops, and septic shock ensues. Immediate action by the clinician is mandatory to correct the hemodynamic status and resolve the underlying infection.

CLINICAL PRESENTATION

Despite the vast improvements in understanding the pathophysiologic basis of sepsis, clinical diagnosis remains limited to the medical history, symptomatic assessment, and nonspecific laboratory and hemodynamic criteria. Compounding the problem is the need for prompt institution of appropriate antimicrobial therapy, making early recognition of sepsis critically important. Patients with clinical findings as outlined in [Table 91.1](#) should undergo thorough and prompt evaluation for a possible infectious cause, including bacterial cultures of blood and (when indicated) other body fluids. Localizing signs and symptoms should prompt a thorough physical examination and directed imaging to identify a nidus of infection. Defects of natural defensive barriers, such as transcutaneous devices or intravascular catheters, should be assessed for infection and removed if suspected to be the origin of the septic process. To minimize the potential delay in prompt recognition and management of sepsis resulting from obtaining laboratory data, the Sepsis-3 recommendations included a bedside quick SOFA (qSOFA) scoring system. The qSOFA allows for repeated bedside evaluations of patients at risk for developing sepsis and relies on three clinical criteria, each worth 1 point: (a) Respiratory rate ≥ 22 /min or greater; (b) altered mentation; and (c) systolic blood pressure

less than 100 mm Hg. A qSOFA score of 2 or greater should prompt further investigation into infectious causes and organ dysfunction as well as initiation or escalation of therapy, as appropriate. Despite its clinical logic and its simplicity, the experience thus far with its predictive value has been mixed. General clinical presentation of sepsis varies widely. Many patients have fever or chills, but older patients and those on immunomodulating medications may not mount a fever. Hypothermia portends a worse prognosis or more severe illness. Tachypnea may be an indicator of respiratory compensation for underlying metabolic acidosis or the early signs and symptoms of ARDS.

Mental status changes can result from metabolic derangements caused by sepsis, hypoglycemia, the underlying infectious process, or concomitant hypotension. This symptom can be difficult to identify in the elderly patient with dementia, and caution should be exercised in the evaluation and treatment of the otherwise stable elderly patient with possible mental status changes.

Skin findings (e.g., cellulitis, abscess) can provide clues to the cause of sepsis and may indicate the state of peripheral systemic perfusion. Several microorganisms can cause specific skin manifestations in systemic infection. *S. aureus* and streptococci can cause diffuse erythroderma, bullous lesions, or generalized desquamation. Bacteremia caused by several gram-negative organisms, including *P. aeruginosa* and enteric organisms, can result in ecthyma gangrenosum, particularly in immunocompromised patients. These lesions are round and 1 to 15 cm in diameter, and they have a central area of necrosis and peripheral erythema. Infection with *Neisseria meningitidis* can result initially in lower extremity petechiae progressing to diffuse purpura, which likely portends septic shock and a high risk of death. A similar clinical presentation can be observed in other unusual infectious diseases, such as

overwhelming pneumococcal sepsis in the asplenic host or disseminated neisserial infections in patients with late complement deficiencies.

Hemodynamic instability, particularly hypotension with or without accompanying oliguria, is commonly associated with sepsis. Instability can result from poor cardiac output, intravascular fluid depletion, or low systemic vascular resistance. Hypotension can initially respond to intravenous fluid resuscitation, but in cases of severe sepsis and septic shock, it may require additional support with vasopressors. Intensive cardiac monitoring may be necessary to gauge the relative need for intravenous fluids or vasopressors after initial fluid resuscitation measures are attempted.

Patients in septic shock can be tachycardic and hypotensive. They may have relatively warm extremities (i.e., warm shock or distributive shock), or they may be peripherally vasoconstricted, with mottled and cool extremities (i.e., cold shock). Warm shock is the predominant finding in most adult patients at the onset of septic shock, with evidence of diffuse vasodilation, bounding pulses, and a compensatory high cardiac output despite evidence of diminished myocardial performance. Increased cardiac output is accomplished primarily by increased heart rate in an attempt to maintain blood pressure and perfuse vital organs. If shock is not promptly corrected, myocardial dysfunction ensues and cold shock evolves over the next several hours. Older patients with limited cardiac reserves tolerate shock poorly and are more likely to develop cold shock. Evidence of septic shock at presentation that is refractory to early resuscitation portends a poor prognosis, with mortality rates exceeding 70%.

Besides hypotension, oliguria can represent developing AKI. It can arise from a combination of the disease process, infecting organism, and medications. Inflammatory cytokines, microbial toxins, systemic hypotension, and iatrogenic renal injury from medications can result in AKI. Other causes of renal injury include interstitial injury from infection or medications and immune complex-mediated injury, as seen in cases of endocarditis.

Besides tachypnea, pulmonary symptoms seen in septic patients include marked hypoxia due to interstitial edema, inflammation, or hemodynamic instability. ARDS is defined as an arterial partial pressure of oxygen less than 50 mm Hg despite fractional inspired oxygen of greater than 50%, together with diffuse alveolar infiltrates and a pulmonary capillary wedge pressure of less than 18 mm Hg. ARDS occurs in up to 40% of septic patients. The diffuse pulmonary inflammation in ARDS results in increased pulmonary vascular permeability, which complicates fluid resuscitation efforts because excessive fluid can exacerbate pulmonary edema and hypoxia. Altered mental status and sepsis-related myopathy also result in airway compromise and weak respiratory effort, necessitating invasive ventilatory support.

Patients with sepsis can have marked hematologic changes. They may have neutrophilic leukocytosis, which is often accompanied by increased immature cell counts, or they can be markedly leukopenic (particularly lymphopenic), often in cases of severe septic shock. Transient neutropenia is often seen in the early phase of septic shock and results from activation and adherence of neutrophils along endothelial surfaces in the microcirculation. This is rapidly followed by prolonged neutrophilia as sepsis-induced inflammatory cytokines stimulate bone marrow synthesis of new white blood cells.

Thrombocytopenia and coagulopathy can occur, and patients have petechiae or purpura at presentation. Severe derangements in coagulation can produce DIC, which can lead to thrombin deposition throughout the microcirculation. Excessive activation and degradation of clotting factors can deplete coagulation factors, resulting in diffuse hemorrhage. Excessive mucosal bleeding around airway tubes and prolonged bleeding from venipuncture sites presage internal bleeding events. Massive gastrointestinal hemorrhage can occur, which can cause or exacerbate hypotension and shock.

Derangements in glucose homeostasis can be seen at presentation. This can take the form of hyperglycemia in diabetics receiving glucose-containing fluids or acute metabolic derangement due to infection. Hypoglycemia is more common in patients with underlying liver disease. Increased anaerobic metabolism due to poor tissue oxygenation and coupled with mitochondrial dysfunction and impaired hepatic clearance of lactic acid may result in increased serum lactate levels and metabolic acidosis.

DIAGNOSIS

Accurate diagnosis of sepsis relies on the history, physical examination, and general laboratory investigation. Diagnostic criteria for sepsis in adults based on the Sepsis-3 criteria are listed in [Table 91.1](#).

Accurate and timely identification of the underlying infectious cause is essential. For patients able to provide a history, an assessment of medical comorbidities, potential exposures, prior infections, and immune system abnormalities may help to guide empirical antimicrobial therapy and the laboratory investigation, particularly microbial cultures. Two sets of blood cultures drawn from a fresh venipuncture and from existing indwelling intravascular lines (before initiation of empirical antimicrobial therapy when possible) help to identify the causative organism in many cases. A recent study in over 3000 patients reinforces the value of obtaining diagnostic, pre-antibiotic treatment, blood cultures. The diagnostic yield was nearly 50% higher for blood cultures obtained in the pre-antibiotic treatment group compared to the post-antibiotic treatment blood cultures (sampled up to 120 minutes after the start of antibiotic therapy). Symptomatic assessment and physical examination should suggest a location of focal infection that can help to guide radiologic studies and interventions to drain pus.

Beyond microbial cultures, several other laboratory studies can help to define the severity of illness and provide baseline data for monitoring the response to therapy. Basic laboratory testing, including a complete blood count with differential, chemistries, and creatinine and aminotransferase levels, can help to identify significant organ dysfunction. Oxygen saturation by pulse oximetry should be measured promptly to identify gas exchange capacity and the need for ventilatory support. Coagulation studies should be obtained, particularly for patients with evidence of DIC and those who are thrombocytopenic. For patients with altered mental status or marked respiratory difficulty, arterial blood gas sampling can help define the underlying derangement and physiologic compensation and can indirectly gauge the severity of illness.

Levels of inflammatory markers, including C-reactive protein and procalcitonin, usually are elevated. An elevated procalcitonin level can help to differentiate septic shock from other causes of shock and provide some prognostic data and a measure of response to therapy. In cases of sepsis due to pneumonia, serial measurement of procalcitonin can help to guide the duration of antibiotic therapy.

Other testing should be directed toward identifying the potential cause. Patients with severe diarrhea should undergo testing for antibiotic-associated *Clostridioides difficile* infection. Imaging studies should focus on identifying infectious sources and facilitate drainage of fluid collections or abscesses. Computed tomography may be of use in such circumstances, although for the critically ill patient who is not stable for transport, bedside radiographic studies, especially ultrasound, should be considered.

Multiple tests of physiologic function and advanced microbiologic diagnostic tests are increasingly used in clinical practice. They include polymerase chain reaction (PCR)-based assays for identifying bacteria and viruses and various assays of inflammatory cytokines and other biomarkers alone and in combination as potential diagnostic and prognostic aids.

TABLE 91.3 Recommended Initial Management of Sepsis in Adults

- Start resuscitation immediately in patients with hypotension or serum lactate level >2 mmol/L.
- Obtain appropriate cultures before starting antibiotics if doing so does not significantly delay therapy.
- Evaluate for a focus of infection amenable to source control (e.g., abscess drainage).
- Remove intravascular catheters if potentially infected.
- Begin broad-spectrum antibiotics within the first hour of severe sepsis and septic shock. Initial antibiotic regimen is based on likely source of sepsis, likely pathogens, and local antibiotic susceptibility patterns of common pathogens.
- Begin fluid resuscitation using crystalloids as the first choice. If colloids are used, avoid starches and consider albumin in selected patients who have hypoalbuminemia or require large-volume fluid resuscitation.
- Give fluid challenge of up to 30 mL/kg of crystalloids over 15–30 min in septic patients with suspected volume depletion; larger volumes of fluids may be needed in some patients. The goals for resuscitation should be a central venous pressure of 8–12 mm Hg, a mean arterial pressure (MAP) \geq 65 mm Hg, and a superior vena cava oxygen saturation \geq 70% or mixed venous oxygen saturation \geq 65%.
- Maintain targeted MAP of \geq 65 mm Hg; if fluids are not effective in reestablishing adequate blood pressure, begin vasopressors. After hemodynamic parameters are stabilized, limit fluid therapy to prevent pulmonary fluid accumulation and exacerbation of hypoxemia.
- Use norepinephrine, centrally administered, as the vasopressor of choice. Epinephrine is the second choice, followed by vasopressin as salvage therapy. Dobutamine may be useful if an inotrope is needed. Avoid dopamine except for special situations (i.e., low risk of tachyarrhythmia and persistent bradycardia).
- Give red blood cells when the hemoglobin concentration decreases to <7 g/dL; target hemoglobin level is 7–9 g/dL.
- Target a tidal volume of 6 mL/kg in patients with acute respiratory distress syndrome.
- Give low-molecular-weight heparin or unfractionated heparin for deep vein thrombosis prophylaxis; use graduated pressure stockings or intermittent compression devices if heparin therapy is contraindicated.
- Provide stress ulcer prophylaxis using histamine H₂-blockers or a proton pump inhibitor.
- Provide expert supportive care; provide low-dose nutrition for the first week; consider stress-dose steroids if refractory septic shock occurs; maintain blood glucose in the 110–180 mg/dL range.

Data from Dellinger RP, Levy MM, et al: Surviving Sepsis Campaign: international guidelines for the management of severe sepsis and septic shock, 2012, Crit Care Med 41:580–637, 2013.

TABLE 91.4 Initial Antibiotic Recommendations for Adult Patients With Sepsis

Indication	Recommended Dosages ^a
Empirical coverage (source unknown)	Vancomycin 15 mg/kg q12h plus piperacillin-tazobactam ^b 3.375 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1.0 g IV q8h with or without an aminoglycoside (e.g., tobramycin 5 mg/kg IV q24) ^c
Community-acquired pneumonia (CAP)	Ceftriaxone 1 g IV q24h plus azithromycin 500 mg IV q24h or a fluoroquinolone (e.g., moxifloxacin 400 mg IV q24h or levofloxacin 750 mg IV q24h) ^d
Community-acquired urosepsis	Piperacillin-tazobactam 3.375 g IV q6h or ciprofloxacin 400 mg IV q12h
Meningitis	Vancomycin 15 mg/kg IV q6h plus ceftriaxone 2 g IV q12h plus dexamethasone 0.15 mg/kg IV q6h \times 2–4 days, preferably before antibiotics; add ampicillin 2 g IV q4h if listeria is suspected.
Nosocomial pneumonia	Vancomycin 15 mg/kg q12h plus piperacillin-tazobactam 4.5 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1 g IV q8h or cefepime 2 g IV q8h plus an aminoglycoside (e.g., amikacin 15 mg/kg IV q24h or tobramycin 5–7 mg/kg IV q24h) or levofloxacin 750 mg IV q24h. Some authorities substitute linezolid 600 mg IV q12h for vancomycin if MRSA is a significant concern or known to be the cause.
Neutropenia	Cefepime 2 g IV q8h; add vancomycin 15 mg/kg IV q12h if a central line is present and infection is a concern. Add antifungal coverage with caspofungin 70 mg IV \times 1, then 50 mg IV q24h if fever persists \geq 5 days. For suspected or proven invasive aspergillosis, voriconazole 6 mg/kg IV q12h \times 2, then 4 mg/kg IV q12h should be used.
Cellulitis and skin infections	Vancomycin 15 mg/kg IV q12h. Add piperacillin-tazobactam 3.375 g IV q6h in diabetics and immunocompromised patients. If necrotizing fasciitis is suspected, add clindamycin 900 mg IV; surgical debridement is crucial.

IV, Intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*.

^aAssumes normal renal function; dose adjustments are required with impaired creatinine clearance.

^bSubstitute aztreonam 2 g IV q8h if patient is allergic to penicillin.

^cMonitor drug levels of aminoglycosides (i.e., peak and trough).

^dSubstitute cefepime or a carbapenem and azithromycin \pm an aminoglycoside if the patient has severe CAP or health care–associated pneumonia.

TREATMENT

Septic shock is a medical emergency. Immediate attempts to reestablish physiologic hemodynamics, vital organ support, and oxygen delivery to tissues should accompany early diagnosis and treatment of infection. Patients should be transferred to the intensive care unit as soon as possible to receive optimal monitoring, hemodynamic support, and expert supportive care.

Early recognition, prompt resuscitation, and early institution of appropriate antimicrobial agents are the most important determinants of

a successful outcome. If appropriate, draining infectious foci (i.e., source control) should be done as soon as possible. Key elements of the 2016 Surviving Sepsis Campaign guidelines are summarized in Table 91.3.

An essential element in the treatment of sepsis is early administration of antibiotics active against the causative pathogen. Treatment is best given within 1 hour of the onset of septic shock, and an empirical, broad-spectrum antimicrobial regimen is usually employed until the results of cultures of blood and the site of infection become available. A suggested initial treatment regimen is provided in Table 91.4. Failing

to treat the causative pathogen until its identity and susceptibility profile become available days later is associated with adverse outcomes. After the pathogen is identified, de-escalation to the simplest monotherapy to which it is susceptible is important.

PROGNOSIS

Despite advances in clinical practice and treatment, sepsis mortality rates remain high, ranging from 20% to 30% among relatively healthy adults to more than 80% among the elderly, immunocompromised, and those with significant chronic medical comorbidities. Patients may experience significant weakness, wasting, and debilitation due to severe catabolism, poor nutrition, and prolonged hospitalization. Prolonged rehabilitation in a skilled facility after the initial hospitalization and additional home-based therapy may be required. Patients may have permanent disabilities, including impaired renal function or persistent debilitation from procedures required to treat the underlying infection.

Infections of the Central Nervous System

Su N. Aung, Allan R. Tunkel

INTRODUCTION

Infections of the central nervous system (CNS) can be caused by a number of pathogens, including viruses, bacteria, fungi, and parasites (i.e., protozoa and helminths). These infectious agents can penetrate the CNS by direct seeding or hematogenous spread and cause a constellation of symptoms. The clinical presentation of a CNS infection varies depending on the virulence of the offending pathogen, the location of the infection, and underlying host factors. CNS infections can impact structures contained in the cranium or spinal cord and may be associated with significant morbidity and mortality. This chapter focuses on meningitis, encephalitis, and focal intracranial and paraspinal infections, as well as prion diseases.

MENINGITIS

Definition

Meningitis, defined as inflammation of the leptomeninges that cover the brain and spinal cord, is identified by an abnormal increase in the number of white blood cells in cerebrospinal fluid (CSF). Inflammation can be caused by many infectious agents (i.e., bacteria, viruses, fungi, and parasites) and also can occur as a result of non-infectious conditions, including tumors or cysts, medications (e.g., nonsteroidal anti-inflammatory drugs, antimicrobial agents), systemic illnesses (e.g., systemic lupus erythematosus, Behçet disease, sarcoidosis), or neurologic procedures (e.g., neurosurgery, spinal anesthesia, intrathecal injections, retained devices).

The clinical presentation may be acute, subacute, or chronic based on the virulence of the infecting agent and patient characteristics. Acute meningitis is a syndrome characterized by the onset of symptoms within hours to several days, whereas chronic meningitis is usually characterized by abnormal clinical and CSF findings that persist for at least 4 weeks. Acute meningitis is most often caused by bacteria and viruses, whereas chronic meningitis is most often caused by spirochetes, mycobacteria, and fungi. The clinical presentation may also vary depending on the age of the patient, underlying health conditions, predisposing factors (e.g., head trauma, recent neurosurgery, presence of a CSF shunt or other retained devices), and immunosuppression.

Epidemiology and Etiology

Bacterial Meningitis

Bacterial meningitis is associated with high morbidity and mortality and requires prompt clinical recognition and treatment. Over 1.2 million cases of bacterial meningitis are diagnosed each year worldwide with incidence and mortality rates varying by region, pathogen, and

age. CSF findings commonly include pleocytosis (CSF white blood cell count in the hundreds to thousands range) usually associated with neutrophilic predominance, low glucose, and elevated protein.

Based on a prior surveillance study in the United States from 2003 to 2007, the most common pathogens causing bacterial meningitis were *Streptococcus pneumoniae* (58% of cases), *Streptococcus agalactiae* (18% of cases), *Neisseria meningitidis* (14% of cases), *H. influenzae* (7% of cases), and *Listeria monocytogenes* (3% of cases). Specific etiologic agents may be identified based on the patient's age and various risk factors (Table 92.1).

In the United States, *S. pneumoniae* is the most common etiologic agent of bacterial meningitis. The incidence has declined since the introduction of pneumococcal conjugate vaccines PCV7 and later PCV13, but mortality remains high, ranging from 18% to 26%. Among survivors, high rates of neurologic sequelae and systemic complications occur, especially in those over 60 years of age. Conditions associated with severe pneumococcal meningitis include asplenia or splenic dysfunction, multiple myeloma, hypogammaglobulinemia, alcoholism, malnutrition, chronic liver or kidney disease, and diabetes mellitus. Patients often have contiguous or distant foci of infection such as pneumonia, otitis media, mastoiditis, sinusitis, and endocarditis. Head trauma, with a CSF leak, is an important risk factor for recurrent pneumococcal meningitis.

The group B streptococcus (i.e., *S. agalactiae*) is a common etiologic agent of meningitis in neonates, with 52% of cases occurring during the first year of life. Mortality in the United States ranges from 7% to 27% with substantial long-term morbidity seen among survivors. Group B streptococcal meningitis can also occur in adults. Risk factors in adults include age older than 60 years, pregnancy or the postpartum state, diabetes mellitus, and other chronic diseases and immunosuppressed states but may also occur in adults without underlying conditions.

Neisseria meningitidis usually causes meningitis in children and young adults. Most cases in the United States are caused by serogroups B, C, and Y; serogroups A and W seldom occur in the United States. Patients with deficiencies in the terminal complement components (C5 to C8, and perhaps C9) and properdin are at increased risk for meningococcal infections, including meningitis with significantly higher rates of neurologic sequelae. Outbreaks of meningitis due to *N. meningitidis* may occur in persons living in close quarters, such as among household members, in daycare centers, college dormitories, and among the incarcerated. One outbreak of serogroup C disease was reported in New York City among men who have sex with men, and outbreaks caused by serogroup B have been reported at college campuses,

TABLE 92.1 Common Bacterial Pathogens and Factors Predisposing to Meningitis

Predisposing Factor	Bacterial Pathogens
Age	
<1 mo	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i>
1–23 mo	<i>S. agalactiae</i> , <i>E. coli</i> , <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i>
2–50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i>
>50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli
Immunocompromised state	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>)
Basilar skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β -hemolytic streptococci
Head trauma; post neurosurgery	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci (especially <i>Staphylococcus epidermidis</i>), aerobic gram-negative bacilli (including <i>P. aeruginosa</i>)

From Hasbun R, van de Beek D, Brouwer MC, Tunkel AR: Acute meningitis. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 9, Philadelphia, 2020, Saunders.

most recently at the Rutgers University, Columbia University, and University of California San Diego (Centers for Disease Control and Infection [CDC], May 2019). Risk is also increased in patients who are taking eculizumab (inhibits complement).

Prophylaxis is indicated for people in the same household, roommates, young adults exposed in dormitories, travelers who had direct contact with respiratory secretions from an index patient or was seated next to an index patient during a prolonged flight, and individuals who were exposed to oral secretions (e.g., intimate kissing, or health care workers who performed mouth-to-mouth resuscitation or endotracheal intubation on the index patient). Chemoprophylaxis should be administered as soon as possible if indications are met, ideally within 24 hours after identification of the index case, and is usually not beneficial beyond 14 days. Recommended antimicrobials for prophylaxis include rifampin, ciprofloxacin, and ceftriaxone. Currently, there are vaccines that cover serogroups A, C, W, Y (MenACWY) and serogroup B (MenB). Vaccination with the quadrivalent meningococcal vaccine against serogroups A, C, W, and Y is recommended for children ages 11 to 18 years of age and individuals 2 months or older with risk factors including anatomic or functional asplenia, persistent complement deficiency, HIV infection, individuals taking eculizumab, travelling to certain countries where vaccine is recommended (e.g., Saudi Arabia, Mecca, or Hajj), at-risk exposure during outbreaks, and microbiologists who work with the meningococcus bacteria. Two meningococcal B vaccines were approved in 2015 for persons aged 10 to 25 years; the recommendation from the Advisory Committee on Immunization Practices is that adolescents and young adults, ages 16 to 23 years, may be vaccinated for short-term protection against most strains of *N. meningitidis* serogroup B, but that the risk of infection in the United States is currently low.

Among typable strains, *Haemophilus influenzae* serotype b (Hib) was a common cause of meningitis and epiglottitis among children prior to the widespread use of the conjugate vaccine against *H. influenzae* type b. The incidence of meningitis due to *H. influenzae* has declined more than 90% since the introduction of vaccination. Isolation of this microorganism in older children and adults suggests certain underlying conditions, such as sinusitis, otitis media, epiglottitis, pneumonia, structural lung disease, diabetes mellitus, alcoholism, splenectomy or asplenic states, head trauma with CSF leak, immune deficiency, hematopoietic stem cell transplantation, and chemotherapy or radiation therapy. In the post-Hib vaccination era, nontypable *H. influenzae* has emerged as a cause of invasive infections, including meningitis, particularly among the elderly and young children.

Meningitis caused by *Listeria monocytogenes* is most common in neonates, adults older than 50 years, alcoholics, immunosuppressed adults, pregnancy, conditions associated with iron overload, and in patients with chronic conditions such as diabetes mellitus, collagen vascular

disease, liver disease, and renal disease. Given the likely gastrointestinal portal of entry for this microorganism, outbreaks of *Listeria* infection have been associated with ingestion of contaminated coleslaw, raw vegetables, milk, and cheese. Sporadic cases have been linked to contaminated turkey franks, alfalfa tablets, cantaloupe, diced celery, hog's head cheese, and processed meats. *Listeria* CNS infection has been associated with rhombencephalitis, which refers to inflammation of the hindbrain (brainstem and cerebellum) with concomitant findings on brain imaging and is more commonly seen in immunocompetent persons.

Meningitis caused by aerobic gram-negative pathogens (e.g., *Klebsiella* sp, *Escherichia coli*, *Serratia marcescens*, *Pseudomonas aeruginosa*, *Acinetobacter* sp) are becoming more important as etiologies, particularly in patients with a history of head trauma or neurosurgical procedures. At-risk individuals include neonates, older adults, immunosuppressed patients, those with gram-negative sepsis, and rarely in disseminated strongyloidiasis associated with the hyperinfection syndrome.

Staphylococcus aureus meningitis is usually found in the early period after neurosurgery or recent head trauma, in those with CSF shunts, or in patients with underlying conditions such as diabetes mellitus, alcoholism, chronic kidney disease requiring hemodialysis, injection-drug use, and malignancies. *S. aureus*, particularly methicillin-resistant strains, is most commonly seen in health care-associated ventriculitis and meningitis. Community-acquired *S. aureus* meningitis is found in patients with sinusitis, osteomyelitis, and pneumonia.

Viral Meningitis

Viral meningitis is the most common type of meningitis. The CSF profile of viral meningitis usually includes pleocytosis with elevated WBCs in the tens to hundreds range, lymphocytic predominance, normal glucose, and elevated protein. Overall, meningitis due to a viral etiology is often less severe than bacterial meningitis, and symptoms usually self-resolve. Risk factors for severe infection include young age (less than 5 years) and immunosuppression.

Enteroviruses are the leading identifiable cause of the aseptic meningitis syndrome, a term used to define any meningitis (particularly with lymphocytic pleocytosis) for which a cause is not apparent after initial evaluation, routine CSF stains, and cultures. The CDC estimate that 10 to 15 million symptomatic enteroviral infections occur annually in the United States; of these, 30,000 to 75,000 are meningitis cases, although this is likely an underestimation.

Many other viruses can cause the aseptic meningitis syndrome, including mumps virus (in unimmunized populations), human immunodeficiency virus (HIV), several arboviruses (e.g., St. Louis encephalitis virus, the California encephalitis group of viruses, Colorado tick fever virus, West Nile virus), and herpesviruses (including Epstein-Barr virus, the herpes simplex viruses, and varicella-zoster virus). The

syndrome of herpes simplex virus (HSV) meningitis is most commonly associated with primary genital infection. The DNA of HSV has been detected in the CSF of patients with the syndrome of recurrent benign lymphocytic meningitis (previously known as Mollaret meningitis), with almost all cases caused by herpes simplex virus type 2 (HSV-2).

Spirochetal Meningitis

The most common spirochetes associated with meningitis are *Treponema pallidum* (the etiologic agent of syphilis) and *Borrelia burgdorferi* (the etiologic agent of Lyme disease). The incidence of syphilitic meningitis is greatest in the first 2 years after initial infection, occurring in 0.3% to 2.4% of untreated cases. The overall incidence of neurosyphilis has increased, with the majority of cases reported in patients with HIV infection. Based on the CDC surveillance data from 2008 to 2015, approximately 12.5% of cases of Lyme disease had neurologic manifestations, including facial palsy (8.4%), radiculoneuropathy (3.8%), lymphocytic meningitis (1.3%), and encephalitis (<1%).

Tuberculous Meningitis

Mycobacterium tuberculosis can lead to pulmonary and extrapulmonary disease, including involvement of the CNS. Tuberculous meningitis accounts for approximately 15% of cases of extrapulmonary tuberculosis in the United States. CNS disease is much more common in less developed areas of the world. Factors associated with reactivation of latent foci and progression to the syndrome of late generalized tuberculosis include advanced age, immunosuppressive drug therapy, HIV/AIDS, transplantation, malignancy, gastrectomy, pregnancy, chronic medical conditions, and close contacts to individuals with active infection. The epidemiology of tuberculosis has been influenced by the advent of HIV infection, in which extrapulmonary disease (including CNS infection) occurs in more than 70% of cases with co-infection.

Fungal Meningitis

The incidence of fungal meningitis has risen dramatically in recent years due to the increasing numbers of immunosuppressed patients and broad usage of immunosuppressive drugs. *Cryptococcus neoformans* is the most common etiologic agent of clinically recognized fungal meningitis, most commonly diagnosed in persons who are immunosuppressed or have chronic medical conditions; HIV-infected patients are in the highest-risk group. Cases have also been documented in immunocompetent healthy individuals.

Coccidioides immitis is a thermal dimorphic fungus that is endemic in the semiarid regions of the Americas and desert areas of the southwestern United States (e.g., California, Arizona, New Mexico, Texas), where about one third of the population is infected. Less than 1% of patients develop disseminated infection, and one third to one half of those with disease have meningeal involvement.

Other fungi less commonly cause CNS infection. *Histoplasma capsulatum* is endemic to fertile river valleys, principally the Mississippi and Ohio River basins. *Blastomyces dermatitidis* is also distributed in the Mississippi and Ohio River basins, as well as regions around the Great Lakes and along the Saint Lawrence River. *Candida* meningitis is uncommon and occurs as a manifestation of disseminated candidiasis, usually in premature neonates, individuals with ventricular drainage devices, and as isolated chronic meningitis.

Clinical Presentation

Acute Meningitis

Adult patients with acute meningitis typically seek medical attention within hours to days of illness. Patients with acute bacterial meningitis classically exhibit fever, headache, meningismus, and signs of cerebral dysfunction (i.e., confusion, delirium, or a declining level of consciousness

ranging from lethargy to coma). The presentation may vary based on age, underlying disease status, and specific pathogen involved. The etiology can be very challenging to distinguish early in the onset of illness. In bacterial meningitis, the meningismus may be subtle, marked, or accompanied by Kernig sign or Brudzinski sign, although the sensitivity of these signs is only 5% in adults. Cranial nerve palsies (especially involving cranial nerves III, IV, VI, and VII) and focal cerebral signs are seen in 10% to 20% of cases. Seizures occur in about 30% of patients. Older adult patients with bacterial meningitis, especially those with underlying conditions (e.g., diabetes mellitus, cardiopulmonary disease), may have disease that manifests insidiously with lethargy or obtundation, no fever, and various signs of meningeal inflammation. Older adult patients may have an antecedent or concurrent bronchitis, pneumonia, or paranasal sinusitis.

Viral meningitis is typically a self-limited illness, but symptoms can be difficult to distinguish from bacterial meningitis, particularly early in the disease course. The clinical manifestations of enteroviral meningitis, the most common etiology of viral meningitis, depend on host age and immune status. In adolescents and adults, more than one half of the patients have nuchal rigidity. Adults usually present with headache, which is often severe and frontal. Photophobia is also common in older patients. Nonspecific symptoms and signs include vomiting, anorexia, rash, diarrhea, cough, upper respiratory findings (especially pharyngitis), and myalgias. Other clues to the diagnosis of enteroviral disease are the time of year (more prevalent in summer and autumn months) and known epidemic disease in the community. The duration of illness of enteroviral meningitis is usually less than 1 week, and many patients report improvement after lumbar puncture, presumably from the reduction in intracranial pressure.

Meningitis associated with HSV-2 infections is usually characterized by stiff neck, headache, and fever. Patients with recurrent benign lymphocytic meningitis characteristically develop a few to 10 episodes of meningitis lasting 2 to 5 days, followed by spontaneous recovery. These patients have acute onset of headache, fever, photophobia, and meningism; about 50% of patients have transient neurologic manifestations, including seizures, hallucinations, diplopia, cranial nerve palsies, or altered consciousness. Unlike HSV encephalitis, HSV meningitis is usually benign and resolves without treatment. The second most common herpesvirus causing aseptic meningitis is varicella-zoster virus (VZV) and can occur in the absence of the typical vesicular rash. Epstein-Barr virus (EBV) meningitis can be seen in the presence of concomitant mononucleosis-like picture with rash, pharyngitis, lymphadenopathy, and splenomegaly.

West Nile virus (WNV) causes neuroinvasive disease in approximately 1% of patients with WNV infections, which is most often seen during summer months in the United States. WNV meningitis symptoms typically include fever, headache, nausea, vomiting, stiff neck, photophobia, and occasionally a maculopapular rash. Patients may experience persistent symptoms and exhibit abnormal neurologic findings for years following the acute infection.

In patients infected with mumps virus, CNS infection causes fever, vomiting, and headache. Fevers are usually high and last for 72 to 96 hours. These symptoms usually occur about 5 days after the onset of parotitis, which can be present in about 50% of cases. In uncomplicated cases, defervescence typically leads to clinical recovery; the total duration of illness is usually 7 to 10 days.

Subacute or Chronic Meningitis

Meningitis caused by spirochetes, mycobacteria, or fungi in the adult patient can linger for weeks to years after clinical presentation. The patient may initially have no overt symptoms, suffer from low-grade headaches and fever, or experience gradual mental status and other neurologic changes.

Syphilitic meningitis (neurosyphilis) caused by *Treponema pallidum* usually manifests in a manner similar to that of other forms of aseptic

meningitis. Patients complain of headache, nausea, and vomiting. Other findings include stiff neck, fever, seizures, cranial nerve palsies, and less commonly, other focal neurologic abnormalities (e.g., hemiplegia, aphasia, and mental status changes). Meningovascular syphilis occurs as a result of focal syphilitic arteritis. Most patients experience symptoms including headache, vertigo, personality changes, behavioral changes, insomnia, seizures, or focal neurologic deficits that can last for weeks to months. In rare cases, if untreated, the focal deficits can progress to stroke with irreversible neurologic deficits.

Meningitis is the most important neurologic abnormality of acute disseminated Lyme disease and usually occurs 2 to 10 weeks following erythema migrans. Headache is the most common symptom of Lyme meningitis. Other symptoms include photophobia, nausea, vomiting, and stiff neck. About 50% of patients with Lyme meningitis have mild cerebral symptoms consisting most commonly of somnolence, emotional lability, depression, impaired memory and concentration, and behavioral symptoms. Approximately 50% of patients may exhibit cranial neuropathies, with facial nerve palsy occurring in 80% to 90% of cases.

Patients with tuberculous meningitis experience an insidious prodrome characterized by malaise, lassitude, low-grade fever, intermittent headache, and personality changes. Within 2 to 3 weeks, the meningitic phase manifests as protracted headache, photophobia, stiff neck, vomiting, and confusion. In some adults, the initial prodromal stage may take the form of a slowly progressive dementia, whereas others may have a rapidly progressive meningitis syndrome indistinguishable from pyogenic bacterial meningitis. Fever is an inconstant finding on physical examination (50% to 98% of cases). Meningismus and signs of meningeal irritation are not uniform findings and can be absent in 25% to 80% of patients. Focal neurologic signs frequently consist of unilateral or, less commonly, bilateral cranial nerve palsies; cranial nerve VI is most commonly affected.

The time course of fungal meningitis depends on the clinical setting. Cases may manifest acutely, subacutely, or chronically; some of the fungal meningitides may cause symptoms that persist for years in the absence of antifungal treatment. In contrast, the same organisms can produce severe symptoms and signs within a few days and without clinical signs of meningeal irritation, particularly in the immunocompromised patient. In patients without acquired immunodeficiency syndrome (AIDS), cryptococcal meningitis typically manifests as a subacute process after days to weeks of symptoms. Headache is the most frequent complaint. Fever, stiff neck, photophobia, and personality changes may also occur; confusion, irritability, and other personality changes reflecting meningoencephalitis occur in about 50% of patients. Ocular abnormalities occur in about 40% of patients and include papilledema and cranial nerve palsies.

In AIDS patients, manifestation of cryptococcal meningitis can be subtle, with minimal or no symptoms. AIDS patients may report only headache and lethargy. Although fever is common, meningeal signs occur in a minority of these patients.

Patients with meningeal coccidioidomycosis usually complain of headache, low-grade fever, weight loss, and mental status changes. About one half of patients develop disorientation, lethargy, confusion, or memory loss. Meningeal signs are uncommon. The presenting symptoms of *Histoplasma* meningitis are nonspecific. Symptoms usually include headache and fever. Only about one half of patients have focal neurologic mental status symptoms. Candidal meningitis also manifests with nonspecific findings and is seen as an extension of disseminated disease in at-risk individuals.

Diagnosis

Clinically suspected meningitis is diagnosed by analysis of CSF obtained by lumbar puncture (Table 92.2). Table 92.3 illustrates general CSF

TABLE 92.2 Cerebrospinal Fluid Tests for Patients With Suspected Central Nervous System Infection

Routine Tests

WBC count with differential

CSF, Cerebrospinal fluid; IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction; RBCs, red blood cells; WBCs, white blood cells.

^aCheck in the first and last tubes; in patients with a traumatic tap, there should be a decrease in the number of RBCs with continued flow of CSF. The following formula can be used for determining whether the numbers of CSF red blood cells and white blood cells are consistent with a traumatic tap (all units are number of cells/cubic mm):

$$\begin{aligned} \text{Adjusted WBCs in CSF} \\ = \text{Actual WBCs in CSF} - \frac{\text{WBCs in blood} \times \text{RBCs in CSF}}{\text{RBCs in blood}} \end{aligned}$$

^bCompare with serum glucose concentration measured just before lumbar puncture.

^cYield of viral culture may be low.

^eMay be useful for specific causes of meningitis and encephalitis.

^fMost useful for specific viral causes of encephalitis and causes of chronic meningitis.

^gIn patients with suspected malignancy.

findings for patients with meningitis based on cause, and the following sections detail specific methods for establishing an etiologic diagnosis.

Bacterial Meningitis

Gram stain examination of CSF permits rapid, accurate identification of the causative microorganism in 60% to 90% of patients with bacterial meningitis, and it has a specificity of nearly 100%. CSF culture is the gold standard in diagnosis and is positive in 80% to 90% of patients with community-acquired bacterial meningitis if CSF is obtained before the start of antimicrobial therapy. The probability of identifying the organism decreases for patients who received prior antimicrobial therapy. CSF sterilization may occur more rapidly after initiation of parenteral antimicrobial therapy than previously suggested, with complete sterilization of CSF containing meningococcus within 2 hours and the beginning of sterilization of pneumococcus by 4 hours following initiation of antimicrobial therapy.

TABLE 92.3 Cerebrospinal Fluid Findings for Patients With Infectious Causes of Meningitis

Cause of Meningitis	White Blood Cell Count (cells/mm ³)	Primary Cell Type	Glucose (mg/dL)	Protein (mg/dL)
Viral	50–1000	Mononuclear ^a	>45	<200
Bacterial	1000–5000 ^b	Neutrophilic ^c	<40 ^d	100–500
Tuberculous	50–300	Mononuclear ^e	<45	50–300
Cryptococcal	20–500 ^f	Mononuclear	<40	>45

From Hasbun R, Tunkel AR: Approach to the patient with central nervous system infection. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 9, Philadelphia, 2020, Saunders.

^aMay be neutrophilic early in presentation.

^bMay range from <100 to >10,000 neutrophils/mm³.

^cAbout 10% of patients have a cerebrospinal fluid (CSF) lymphocyte predominance.

^dShould always be compared with a simultaneous serum glucose level; ratio of CSF to serum glucose is ≤ 0.4 in most cases.

^eA therapeutic paradox may exist in which a mononuclear predominance becomes neutrophilic during antituberculosis therapy.

^fMore than 75% of patients with acquired immunodeficiency syndrome have <20 cells/mm³.

Several rapid diagnostic tests have been developed to aid in the etiologic diagnosis of bacterial meningitis. Latex agglutination techniques detect the antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, *E. coli* K1, and the group B streptococci. However, because bacterial antigen testing does not appear to modify the decision to administer antimicrobial therapy and false-positive results have been reported, routine use of this modality for rapid determination of the bacterial cause of meningitis is not recommended. It can, however, be considered for patients who have been pretreated with antimicrobial therapy and when CSF Gram stain and culture results are negative.

Nucleic acid amplification tests, such as polymerase chain reaction (PCR), have been used to amplify DNA from patients with meningitis caused by up to 14 meningeal pathogens including bacterial, viral, and fungal agents in one test known as the Meningitis/Encephalitis Panel or BioFire, which has very high sensitivity and specificity. Despite the more comprehensive and rapid identification potential, use of this testing should be reserved for patients with high likelihood of meningitis or encephalitis without an identified pathogen on initial testing. Prior to considering this test, patients should still have CSF sent for routine Gram stain, culture, and testing for other common pathogens (i.e., PCR for herpes simplex viruses and enteroviruses) based on epidemiology, patient risk factors, and season. Therefore, this comprehensive test is commonly reserved for patients with negative initial tests despite clinical correlation or due to prior antimicrobial therapy.

Differentiation of Bacterial From Viral Meningitis

In patients without a positive CSF Gram stain or culture, the diagnosis of acute bacterial meningitis is often difficult to establish or reject. A combination of clinical features, with or without test results, has been assessed to develop models in an attempt to accurately predict the likelihood of bacterial meningitis compared with other potential causes (most often viruses). In a published meta-analysis of bacterial meningitis score validation studies in which 5312 patients were identified from eight studies, 4896 (92%) had sufficient clinical data to calculate the bacterial meningitis score, which identified children with CSF pleocytosis who were at very low risk for bacterial meningitis. Low-risk features were a negative CSF Gram stain, a CSF absolute neutrophil count less than 1000 cells/mm³, a CSF protein level less than 80 mg/dL, and a peripheral absolute neutrophil count less than 10,000 cells/mm³. Despite the potential utility of this meta-analysis and other similar studies, decisions related to empiric therapy should be based on clinical judgment.

Several proteins have been examined for their usefulness in the diagnosis of acute bacterial meningitis. C-reactive protein (CRP) detected in serum or CSF and serum procalcitonin concentrations have been elevated in patients with acute bacterial meningitis and may be useful in

discriminating between bacterial and viral meningitis. In patients with meningitis in whom the CSF Gram stain result is negative and analysis of other parameters is inconclusive, serum concentrations of CRP or procalcitonin that are normal or below the limit of detection have a high negative predictive value in the diagnosis of bacterial meningitis.

PCR is the most promising alternative to viral culture for the diagnosis of enteroviral meningitis. Enteroviral reverse transcription PCR (RT-PCR) has been tested in clinical settings and found to be more sensitive than culture for the detection of enterovirus; the sensitivity has ranged from 86% to 100% and specificity from 92% to 100% for the diagnosis of enteroviral meningitis. For patients with HSV-2 meningitis, PCR is the recommended test for diagnosis. In patients with recurrent benign lymphocytic meningitis, detection of HSV-2 has been strongly associated with typical cases in patients without symptoms or signs of genital infection.

Spirochetal Meningitis

For the diagnosis of neurosyphilis, no single routine laboratory test is definitive. The specificity of the CSF Venereal Disease Research Laboratory (VDRL) test for the diagnosis of neurosyphilis is high, but the sensitivity is low (30% to 70%). A reactive CSF VDRL test result in the absence of blood contamination is sufficient to diagnose neurosyphilis; a nonreactive result does not exclude the diagnosis. The diagnosis of neurosyphilis is based on elevated CSF concentrations of white blood cells or protein, or both, in the appropriate clinical and serologic setting.

The best currently available laboratory test for the diagnosis of Lyme disease is demonstration of specific serum antibody to *B. burgdorferi*, and this positive test result for a patient with a compatible neurologic abnormality is strong evidence for the diagnosis. However, these tests are not standardized, and marked variations are seen between laboratories.

Tuberculous Meningitis

The identification of tuberculous organisms in CSF by specific stains is difficult due to the small population of organisms. In many series, less than 25% of specimens were smear positive and less than 50% were culture positive. The technique of PCR for detecting fragments of mycobacterial DNA in CSF specimens appears to be a promising tool. The Gen-Probe technique is based on amplification of ribosomal RNA derived from *Mycobacterium tuberculosis* using a labeled DNA probe. A 5-year retrospective study of the performance of this test found a sensitivity and specificity of 94% and 99%, respectively, for patients with positive CSF cultures.

Fungal Meningitis

Conclusive proof of a fungal etiology for meningitis requires identification of the fungus in CSF, although CSF cultures are not always

positive in cases of fungal meningitis. The yield of CSF culture in cryptococcal meningitis is excellent for non-AIDS and AIDS patients. CSF India ink examination remains a rapid, effective test that is positive in 50% to 75% of cases; the yield increases up to 88% among patients with AIDS. In contrast, only 25% to 50% of patients with other causes of fungal meningitis have positive CSF cultures.

Because cultures may be negative or require long periods before yielding positive results for patients with fungal meningitis, adjunctive studies (particularly serologic tests) may be helpful for the diagnosis. The latex agglutination test for cryptococcal polysaccharide antigen is sensitive and specific for the diagnosis of cryptococcal meningitis. Cryptococcal polysaccharide antigen also can be found in the serum and CSF, usually in severely immunosuppressed patients such as those with AIDS. Serologic antibody tests (i.e., coccidioidal and histoplasmal antigens) and antigen urine tests (i.e., histoplasmal antigen) may be useful in other cases of fungal meningitis. Because fungal meningitis is often an indication of disseminated disease, other serologic assays that help in identification of fungal infection, such as galactomannan (component of the cell wall of the mold *Aspergillus* that is released during growth) and 1,3- β -D-glucan (cell wall component of various medically important fungi), may also aid in diagnosis.

Treatment

Initial Treatment of the Patient With Acute Meningitis

Acute bacterial meningitis is a life-threatening illness, and early detection, work-up, and antimicrobial therapy are imperative to reduce morbidity and mortality. The initial management of a patient with presumed bacterial meningitis includes performance of a lumbar puncture to determine whether CSF findings are consistent with the diagnosis (Fig. 92.1). If meningitis is suspected, institution of antimicrobial therapy should be based on the results of Gram staining that suggest an etiologic pathogen (Table 92.4). However, if no etiologic agent can be identified by this means or performance of the lumbar puncture is delayed, institution of empirical antimicrobial therapy after obtaining blood cultures should be based on the patient's age and underlying disease status (Table 92.5).

It is reasonable to proceed with the lumbar puncture without computed tomography (CT) of the head if the patient does not meet any of the following criteria: new-onset seizures, an immunocompromised state, signs that are suspicious for space-occupying lesions (i.e., papilledema or focal neurologic signs, not including cranial nerve palsy), or moderate to severe impairment of consciousness. Patients at risk should undergo CT of the head before lumbar puncture to evaluate for increased intracranial pressure (i.e., result of an intracranial mass lesion or generalized brain edema) due to the potential risk of herniation if a lumbar puncture is performed. In this setting, emergent empirical antimicrobial therapy and adjunctive dexamethasone therapy (if indicated), after obtaining blood cultures, should be initiated before obtaining neuroimaging.

Specific Antimicrobial Therapy for Meningitis

After the infecting meningeal pathogen is isolated and susceptibility testing results are known, antimicrobial therapy can be modified for optimal treatment of patients with bacterial meningitis (Table 92.6). Recommended dosages of antimicrobial agents for adults with infections of the CNS are shown in Table 92.7.

One pathogen requires special discussion. Specific therapy for pneumococcal meningitis depends on the *in vitro* susceptibility of the organism to penicillin and the third-generation cephalosporins. Based on the reduced susceptibility of meningitis strains of pneumococcus to penicillin (approximately one third of isolates in the United States), penicillin is not recommended as empirical therapy in patients with

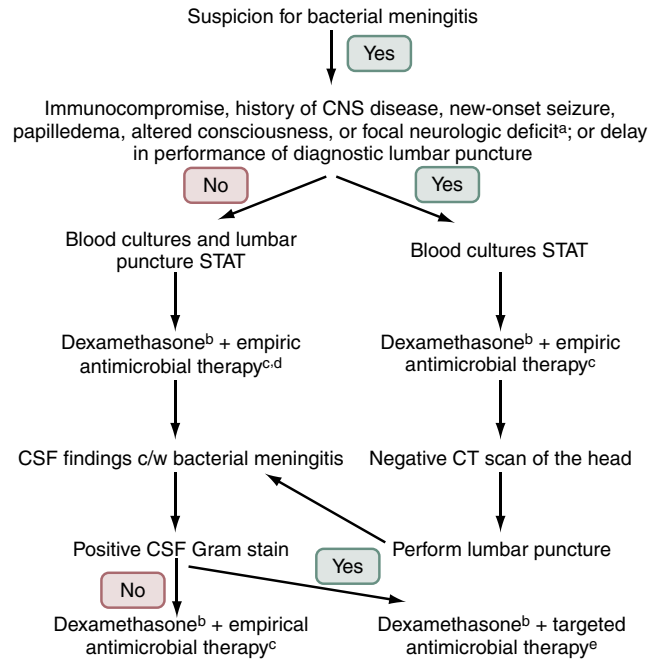

Fig. 92.1 Management algorithm for adults with suspected bacterial meningitis. ^aPalsy of cranial nerve VI or VII is not an indication to delay lumbar puncture. ^bSee text for recommendations for use of adjunctive dexamethasone in patients with bacterial meningitis. ^cSee Table 92.5. ^dDexamethasone and antimicrobial therapy should be administered immediately after CSF is obtained. ^eSee Table 92.4. CNS, Central nervous system; CT, computed tomography; c/w, consistent with; STAT, intervention should be done emergently. (From Tunkel AR, Hartman BJ, Kaplan, SL, et al: Practice guidelines for the management of bacterial meningitis, Clin Infect Dis 39:1267-1284, 2004.)

suspected pneumococcal meningitis. The combination of vancomycin plus a third-generation cephalosporin (i.e., cefotaxime or ceftriaxone) is recommended as an empirical regimen. After susceptibility studies of the isolated pneumococcus are performed, antimicrobial therapy can be modified for optimal treatment (see Table 92.7).

Viral meningitis is usually a benign self-limited illness. Recovery of patients with HSV-2 meningitis is usually complete without neurologic sequelae, and it is not clear whether antiviral treatment alters the course of mild meningitis.

The preferred antimicrobial regimen for the treatment of CNS syphilis is intravenous aqueous crystalline penicillin G at a dosage of 18 to 24 million units daily in divided doses every 4 hours or by continuous infusion for 10 to 14 days. Alternatively, procaine penicillin (2.4 million units intramuscularly daily) plus probenecid (500 mg orally four times daily), both for 10 to 14 days, can be used.

Parenteral antimicrobial therapy is usually needed to treat the neurologic manifestations of Lyme disease, including meningitis. The current recommendation is to treat most patients with Lyme meningitis with intravenous ceftriaxone at a dosage of 2 g daily for 14 days (range, 10 to 28 days); no evidence supports treatment durations longer than 4 weeks.

In patients with tuberculous meningitis, the most important principle of therapy is early initiation on the basis of strong clinical suspicion; it should not be delayed until proof of infection has been obtained. Identification can take weeks due to indolent culture growth. The American Thoracic Society, in conjunction with the CDC and the Infectious Diseases Society of America, recommend 2 months of isoniazid, rifampin, ethambutol, and pyrazinamide, followed by 7 to 10 months of isoniazid and rifampin for patients with drug-sensitive

^aCefotaxime or ceftriaxone.

^bSome experts add rifampin if dexamethasone is also given.

^cAdd ampicillin if meningitis caused by *Listeria monocytogenes* is suspected.

tuberculous meningitis. Therapy for tuberculous meningitis may need to be individualized, with longer durations of therapy used for patients with more severe illness or HIV.

Therapy for cryptococcal meningitis in patients with AIDS is usually an amphotericin B preparation (i.e., amphotericin B deoxycholate, liposomal amphotericin B, or amphotericin B lipid complex) plus flucytosine for 2 weeks, followed by consolidation therapy with fluconazole for 8 weeks. For non-AIDS patients with cryptococcal meningitis, the optimal use of fluconazole is less clear.

In a retrospective review of HIV-negative patients with CNS cryptococcosis, the patients were more likely to receive an induction regimen containing amphotericin B and subsequent therapy with fluconazole. Most experts recommend high-dose fluconazole (800 to 1200 mg daily) as first-line therapy for coccidioidal meningitis.

The current recommended treatment for *Histoplasma* meningitis is liposomal amphotericin B for 4 to 6 weeks, followed by itraconazole for at least 1 year. Amphotericin B, alone or in combination with flucytosine, also is the treatment of choice for *Candida* meningitis.

Adjunctive Therapy

For adult patients with bacterial meningitis, adjunctive dexamethasone should be administered to those with suspected or proven pneumococcal meningitis. This recommendation is based on a prospective, randomized, double-blind trial enrolling 301 adults with bacterial meningitis. Adjunctive dexamethasone was associated with a reduction in the proportion of patients who had unfavorable outcomes (15% vs. 25%, $P = .03$) and in the proportion of patients who died (7% vs. 15%, $P = .04$). The benefits were most striking for the subgroup of patients with pneumococcal meningitis and those with moderate to severe disease as assessed by the admission Glasgow Coma Scale.

Dexamethasone is administered at a dosage of 10 mg intravenously every 6 hours for 4 days in adults. The first dose should be given concomitantly with or just before the first dose of an antimicrobial agent for maximal attenuation of the subarachnoid space inflammatory response. Adjunctive dexamethasone should not be used in patients who have already received antimicrobial therapy or the meningitis is found not to be caused by *S. pneumoniae*. Despite the positive benefits of adjunctive dexamethasone for adults with bacterial meningitis described previously, the routine use of adjunctive dexamethasone for patients with bacterial meningitis in the developing world has been controversial.

Tuberculous meningitis is associated with significant morbidity and mortality despite the availability of effective antituberculous chemotherapy. Use of adjunctive corticosteroids has abrogated the signs and symptoms of disease, and early treatment with adjunctive dexamethasone should be used in all patients with tuberculous meningitis.

Patients with cryptococcal meningitis may have increased intracranial pressure or hydrocephalus, or both. For patients with neurologic deficits and evidence of increased intracranial pressure (usually an opening pressure >25 cm H₂O), daily lumbar puncture is recommended. Rarely, in cases of persistent opening pressure despite frequent lumbar punctures with removal of CSF, surgical CSF shunting may be required.

ENCEPHALITIS

Definition

Encephalitis is inflammation of the brain parenchyma that is associated with neurologic dysfunction. In the absence of pathologic evidence of brain inflammation, an inflammatory response in the CSF

TABLE 92.6 Antimicrobial Therapy for Patients With Meningitis

Microorganism	Therapy of Choice
Bacteria

<i>Candida</i> species	Amphotericin B preparation ^d ± flucytosine

MIC, Minimum inhibitory concentration.

^aAddition of rifampin may be considered; see text for indications.

^bThe choice of a specific antimicrobial agent must be guided by in vitro susceptibility testing.

^cAddition of an aminoglycoside should be considered.

^dAmphotericin B deoxycholate, liposomal amphotericin B, or amphotericin B lipid complex.

or parenchymal abnormalities on neuroimaging are often used as surrogate markers of brain inflammation; however, encephalitis can occur without significant CSF pleocytosis or demonstrable neuroimaging abnormalities. Encephalitis and meningitis share many features. Both syndromes can manifest with fever, headache, and altered mental status, although the encephalitis patient may suffer from more severe alterations in mental status.

There is also clinical overlap between encephalitis and encephalopathy. Patients with encephalopathy, however, exhibit confusion early in the course of their illness that can quickly progress to obtundation. Causes of encephalopathy include metabolic disturbances, hypoxia, ischemia, intoxications, organ dysfunction, paraneoplastic syndromes, and systemic infections.

Epidemiology and Etiology

Encephalitis is characterized by inflammation of the brain in conjunction with symptoms and signs of neurologic dysfunction. Encephalitis results in substantial morbidity and mortality, and it confers considerable

burden on the health care system. The hospital admission rate in one study was 7.3 per 100,000 people. The case-fatality rate among patients with encephalitis varies from 3.8% to 7.4% and is significantly higher among patients also infected with HIV. There is high morbidity among survivors of encephalitis, with resultant loss of productivity, function, and the need for prolonged rehabilitation or skilled nursing care.

Infectious causes of encephalitis are diverse and include viruses (most common), bacteria, fungi, and parasites. Clues in the patient's history that aid identification include seasonal variation, geographic location, prevalence of disease in the local community, travel history, recreational activities, occupational exposures, insect contact, animal contact, vaccination history, and immune status of the patient.

The most commonly identified viral causes of encephalitis in the United States are herpes simplex virus type 1 (HSV-1), West Nile virus, and the enteroviruses, followed by other herpesviruses (e.g., varicella-zoster virus). Other agents may be highly endemic regionally (e.g., La Crosse virus in the Midwest) or internationally (e.g., rabies virus, Japanese encephalitis virus). Bacterial agents, including *Ehrlichia*

TABLE 92.7 Recommended Dosages of Antimicrobial Agents for Meningitis in Adults With Normal Renal and Hepatic Function

Antimicrobial Agent	Total Daily Dose ^a	Dosing Interval (hr)
Amikacin ^b	15 mg/kg	8
Amphotericin B deoxycholate	0.6–1.0 mg/kg	24
Amphotericin B lipid complex	5 mg/kg	24
Ampicillin	12 g	4
Cefepime	6 g	8
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Ethambutol ^d	15 mg/kg	24
Fluconazole	400–800 mg ^c	24
Flucytosine ^{d,e}	100 mg/kg	6
Gentamicin ^b	5 mg/kg	8
Isoniazid ^{d,f}	300 mg	24
Liposomal amphotericin B	5–7.5 mg/kg	24
Meropenem	6 g	8
Nafcillin	12 g	4
Oxacillin	12 g	4
Penicillin G	24 million units	4
Pyrazinamide ^d	15–30 mg/kg	24
Rifampin ^d	600 mg	24
Tobramycin ^b	5 mg/kg	8
Sulfamethoxazole-trimethoprim	10–20 mg/kg ^g	6–12
Vancomycin ^h	30–45 mg/kg	8–12
Voriconazole ⁱ	8 mg/kg	12

^aUnless indicated, therapy is administered intravenously.

^bNeed to monitor peak and trough serum concentrations.

^cDose of 800–1200 mg is recommended for patients with coccidioidal meningitis.

^dOral administration.

^eMaintain serum concentrations of 50–100 µg/mL.

^fInitiate therapy at a dose of 10 mg/kg.

^gDosage based on trimethoprim component; many experts would use a dose of 5 mg/kg every 8 hours.

^hMaintain serum trough concentrations of 15–20 µg/mL.

ⁱIV loading dose of 6 mg/kg every 12 hours for two doses; maintain serum trough concentrations of 2–5 µg/mL.

species and *Rickettsia rickettsii*, are potentially treatable causes of encephalitis, and prompt administration of appropriate antimicrobial therapy may be life-saving.

Perhaps the most challenging aspect of encephalitis is that no pathogen is identified in 50% to 70% of cases. Another difficulty is the relevance of an identification of an infectious agent outside of the CNS in a patient with encephalitis; these agents may cause a systemic illness that also involves neurologic symptoms but does not necessarily invade the CNS directly. Additionally, it may be challenging to distinguish infectious encephalitis from postinfectious or postimmunization encephalitis or encephalomyelitis; the latter process is usually mediated by an immunologic response to a preceding infection or immunization. Up to 10% of patients have a noninfectious cause; examples include paraneoplastic syndromes, vasculitis, or collagen vascular disorders.

Antibody-mediated encephalitis refers to a group of inflammatory brain diseases associated with antibodies against neuronal cell-surface proteins, ion channels, or receptors resulting in neuropsychiatric symptoms. This group of diseases is distinct from traditional autoimmune disorders such as systemic lupus erythematosus. Autoimmune encephalitis may be the third most common cause of encephalitis, and the most common form of autoimmune encephalitis is the type with antibodies against the N-methyl-D-aspartate receptor (NMDAR). In contrast to paraneoplastic syndromes, which are associated with antibodies against intracellular neural antigens, the antibodies bind

to extracellular epitopes of cell-surface proteins in autoimmune encephalitis. Common receptors include NMDAR, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA), γ -aminobutyric acid (GABA) receptor, and glioma-inactivated 1 (LG1) receptor. Two potential triggers of autoimmune encephalitis are tumors and viral encephalitis. However, most cases occur with no apparent immunologic triggers, which may suggest a genetic predisposition to these disorders.

Clinical Presentation

Because encephalitis is infrequently confirmed by pathologic means, the signs and symptoms of neurologic dysfunction are used as surrogate markers, and they are often nonspecific. The clinical signs and symptoms of encephalitis are determined by the specific area of the brain involved and by the severity of the infection. Some organisms show neurotropism for particular anatomic sites. HSV-1 infection almost universally involves the temporal lobe, and the clinical presentation typically includes temporal lobe seizures. Associated signs include personality changes, decreasing consciousness, focal neurologic findings (including dysphagia), paresthesias and weakness, and focal seizures. Sudden onset of fever and headache can also accompany these mental status changes.

Diffuse brain involvement is frequently seen with arboviral infections, and it is associated with global impairment in neurologic

function and coma. Fever and headache frequently precede the onset of altered mental status, which can range from mild confusion to obtundation. Other neurologic manifestations may include behavioral changes (e.g., psychosis), focal paresis or paralysis, cranial nerve palsies, and movement disorders (e.g., chorea). About 80% of patients infected with West Nile virus are asymptomatic, and about 20% have only fever. Symptomatic patients may have fever, headache, myalgia, and flaccid paralysis. A maculopapular rash is seen in 50% of patients.

VZV is an important cause of acute encephalitis in adults, often associated with viral reactivation and leading to a CNS vasculopathy. Importantly, CNS reactivation may occur in the absence of skin lesions. Children, on the contrary, exhibit CNS symptoms concurrently with varicella or in a postinfectious form.

Evidence of inflammation or infection at sites distant from the CNS may be useful in making a microbiologic diagnosis for patients with encephalitis. For instance, rickettsial diseases, varicella-zoster virus, and West Nile virus often have associated skin manifestations. Stomatitis and ulcerative lesions in the mouth or an exanthem in a peripheral distribution can suggest enterovirus infection. Patients with tuberculous and fungal meningoencephalitis may have suggestive pulmonary findings.

A syndrome frequently misclassified as encephalomyelitis, based on the similar clinical presentation, is post-inflammatory encephalomyelitis. The most widely cited example is acute disseminated encephalomyelitis (ADEM), which is seen primarily in children and adolescents. ADEM is characterized by poorly defined white matter lesions on magnetic resonance imaging (MRI) that enhance after gadolinium administration. Post-inflammatory encephalomyelitis is likely mediated by an immunologic response to an antecedent antigenic stimulus such as infection or immunization. Viral infections associated with ADEM include measles, mumps, rubella, varicella-zoster, Epstein-Barr, cytomegalovirus, herpes simplex, hepatitis A, and coxsackieviruses. Immunizations temporally associated with ADEM include vaccines for Japanese encephalitis, yellow fever, measles, influenza, smallpox, anthrax, and rabies, but a direct causal association with these vaccines is difficult to establish. ADEM usually begins between 2 days and 4 weeks after the antigenic stimulus, and patients develop rapid onset of encephalopathy, with or without meningeal signs. The neurologic features depend on the location of the lesions.

In patients with anti-NMDAR encephalitis, prodromal symptoms, including low-grade fever, headache, and malaise, may occur in approximately 60% of patients. Common clinical features include behavioral changes, psychosis, seizures, memory and cognitive deficits, dysautonomia, abnormal movements, and altered consciousness. Females diagnosed with anti-NMDAR encephalitis will have an ovarian teratoma 50% of the time. Symptoms are more often neurologic in children and psychiatric in adults, but in most cases, symptoms progress to a similar syndrome. In contrast, patients with limbic encephalitis are generally older than 45 years and have symptoms including confusion, seizures, behavioral changes, and distinct memory deficits in which they have trouble forming new memories but old ones are preserved.

Diagnosis

The initial laboratory testing of an individual should include a complete blood count, tests of renal and hepatic function, coagulation studies, and serum and urine toxicology studies. A low white blood cell count, low platelet count, and elevated liver transaminase levels may suggest *Ehrlichia* or *Anaplasma* infection. A baseline chest radiograph should be obtained because a focal infiltrate can suggest particular pathogens (e.g., fungal or mycobacterial infections).

Neuroimaging studies are important to perform for all patients with encephalitis; MRI is more sensitive at detecting abnormalities than CT, and it is the preferred study. Diffusion-weighted MRI is superior to conventional MRI for the detection of early signal abnormalities in viral encephalitis caused by HSV, enterovirus 71, and West Nile virus. In patients with HSV encephalitis, there may be significant edema and hemorrhage in the temporal lobes. Patients with flavivirus (e.g., West Nile virus, Japanese encephalitis virus) encephalitis may display characteristic patterns of mixed-intensity or hypodense lesions on T1-weighted images of the thalamus, basal ganglia, and midbrain. MRI findings with linear T2-weighted regions of high signal involving the internal and external capsules (also termed the “parentheses” sign) has been associated with Eastern equine encephalitis (an arbovirus infection) compared to other viral encephalitides, although the frequency of this finding is unclear given the rarity of this infection. In patients with ADEM, MRI usually reveals multiple focal or confluent areas of signal abnormality in the subcortical white matter and, sometimes, in subcortical gray matter on T2-weighted and fluid attenuation inversion recovery (FLAIR) sequences; the lesions are usually enhancing and display similar stages of evolution. MRI of the head is abnormal in 30% of patients with antibody-mediated encephalitis. Positive findings include increased FLAIR signal involving the cortical, subcortical, or cerebellar regions.

Electroencephalography is rarely specific for a given pathogen in patients with encephalitis, but results can be helpful in identifying the degree of cerebral dysfunction by detecting subclinical seizure activity, and it may provide information about the specific area of the brain involved. In more than 80% of patients with HSV encephalitis, there is a temporal lobe focus with periodic lateralizing epileptiform discharges (PLEDs).

Lumbar puncture with CSF analysis (i.e., cell count and differential, glucose and protein levels) and a measurement of the opening pressure should be performed in all patients with encephalitis unless there is a specific contraindication. Most patients with viral encephalitis have a mononuclear cell pleocytosis with cell counts ranging from 10 to 1000/mm³. Early in the disease process, CSF pleocytosis may be absent, or there may be an elevation in neutrophils. While lymphocytic predominance is seen with progression of the viral infection, persistent neutrophilic pleocytosis has been observed in patients with West Nile virus encephalitis. The CSF protein concentration is typically elevated, but usually less than 100 to 200 mg/dL, whereas the CSF glucose concentration is typically normal. Patients may have high RBCs in the CSF due to hemorrhagic encephalitis. CSF viral cultures are usually not recommended. Up to 10% of patients with viral encephalitis will have completely normal CSF findings. The presence of eosinophils in the CSF may suggest certain etiologies, specifically encephalitis caused by helminths. A decreased CSF glucose concentration is indicative of bacterial, fungi, or protozoal etiology. CSF profiles of patients with ADEM are similar to patients with viral encephalitis with lymphocytic pleocytosis (though less marked compared to infectious encephalitis), high protein concentration, and normal glucose concentration. Additionally, oligoclonal bands and elevated IgG index and synthesis may be present.

Brain biopsy has largely been replaced by CSF molecular tests. For certain types of infections, however, brain biopsy may be diagnostic. In rabies infections, for example, Negri bodies are a distinctive histopathologic feature. Intranuclear eosinophilic amorphous bodies surrounded by a halo may be seen in diseases such as HSV encephalitis. Biopsy of skin lesions should be performed in encephalitis patients with concomitant rash including maculopapular or petechial lesions, which can be high yield in identifying the responsible agent (e.g., *R. rickettsii*).

Testing for specific agents includes laboratory methods such as antigen detection, culture, serology, and molecular diagnostics. HSV encephalitis is a treatable and relatively common cause of encephalitis, and an HSV PCR should be performed on the CSF of all patients with a clinical diagnosis of encephalitis. False-negative PCR test results can occur within the first 72 hours after onset, and if HSV encephalitis is strongly suspected (e.g., in a patient with temporal lobe involvement), a repeat HSV PCR on a second sample of CSF within 3 to 7 days is recommended. For enterovirus and varicella encephalitis, CSF PCR testing is recommended; however, detection of antibodies to varicella-zoster virus in the CSF appears to have greater sensitivity than detection of viral DNA. Concomitant serum viral studies are sometimes helpful in diagnosing viral encephalitis. In one report of an enterovirus 71 outbreak, only 31% of cases had a positive CSF result with higher yields from throat and stool PCR specimens; viral shedding from the gastrointestinal tract may occur for weeks following infection. Similarly, for Epstein-Barr virus encephalitis, serum serology including antiviral capsid antigens (VCA), immunoglobulin M/immunoglobulin G (IgM/IgG), and anti-Epstein-Barr nuclear antigen (EBNA) are recommended in addition to CSF PCR due to false positive and false negative results associated with the PCR test.

Testing for other agents should be individualized with consideration of the patient's exposures, travel, season of the year, and clinical and laboratory characteristics. Many infections require acute and convalescent (i.e., paired) serum samples to determine a diagnosis. A serum specimen collected during the acute phase of the illness should be stored and tested in parallel when the convalescent serum sample is drawn. Immunoglobulin M (IgM) and immunoglobulin G (IgG) capture enzyme-linked immunosorbent assays (ELISAs) have become useful and widely available for the diagnosis of arboviral encephalitis. Detection of intrathecal IgM antibody is a specific and sensitive method for the diagnosis of West Nile virus infection. There is substantial cross-reactivity among the flaviviruses (e.g., West Nile virus, St. Louis encephalitis virus, Japanese encephalitis virus); plaque-reduction neutralization assays may be helpful in distinguishing which flavivirus is involved in the event of elevated titers.

Serologic testing for *Rickettsia*, *Ehrlichia*, and *Anaplasma* species should be performed for all encephalitis patients during the appropriate season and with travel to or residence in endemic areas, especially because these are treatable causes. In addition to serologies, concurrent serum PCR testing for *Anaplasma* is recommended, because a positive result may be more indicative of an acute infection. Empiric therapy should not be withheld from patients with a compatible clinical presentation because antibodies are not always detectable early in the course of illness.

Identification of NMDAR antibodies confirms the diagnosis of anti-NMDAR encephalitis. Obtaining both serum and CSF antibodies is also recommended. Diagnosis should lead to the search for a tumor in female patients; the tumor is almost always an ovarian teratoma.

Treatment

One of the most important first steps in managing encephalitis is to consider treatable causes. Specific antiviral therapy is usually limited to infections caused by herpesviruses (especially HSV-1 and varicella-zoster virus) and HIV. Therefore, acyclovir (10 mg/kg intravenously every 8 hours in adults with normal renal function) should be administered to patients with encephalitis. Empirical therapy for acute bacterial meningitis should be initiated when clinical and laboratory testing is compatible with bacterial infection. If rickettsial or ehrlichial infections are suspected, empirical doxycycline should be administered. The management of West Nile virus infection is supportive care.

In patients with suspected postinfectious encephalomyelitis (i.e., ADEM), high-dose intravenous corticosteroids (1 g of methylprednisolone intravenously daily for at least 3 to 5 days) are usually recommended, followed by an oral taper for 3 to 6 weeks. In patients with autoimmune encephalitis, the current approach includes immunotherapy and removal of the immunologic trigger. Most patients are treated with glucocorticoids, intravenous immune globulin, or plasma exchange. If there is no clinical response to these treatments, then rituximab or cyclophosphamide may be used. Rituximab may be helpful in reducing the risk of clinical relapse. Additionally, early identification and removal of this trigger is important for achieving a good outcome (i.e., removal of an ovarian teratoma in patients with anti-NMDAR encephalitis). Time to recovery, degree of residual deficit, and risk of relapse vary depending on the type of autoimmune encephalitis. Spontaneous clinical improvement is rare. Prompt institution of immunotherapy is associated with favorable outcomes.

BRAIN ABSCESS

Definition

A *brain abscess* is a focal intracerebral infection that begins as a localized area of cerebritis followed by the formation of a pus collection.

Pathology and Pathophysiology

Brain abscesses produce symptoms and findings similar to those of other space-occupying lesions (e.g., brain tumors), but they often progress more rapidly and affect meningeal structures more frequently than tumors. Brain abscesses may arise from several mechanisms, the most common of which is spread from a contiguous focus of infection; examples include infections of the middle ear, mastoid cells, paranasal sinuses, as well as dental infections. A second mechanism is hematogenous dissemination from a distant focus of infection. Brain abscesses resulting from hematogenous spread are usually multiple and multiloculated, and they are associated with higher mortality. Original foci of infection include chronic pyogenic lung disease (e.g., lung abscesses, bronchiectasis, empyema, and cystic fibrosis), skin and soft tissue infections, osteomyelitis, intraabdominal infections, infectious endocarditis, cyanotic heart disease, and pulmonary arteriovenous malformations often linked with hereditary hemorrhagic telangiectasia. Traumas, particularly those involving dural breach, and invasive neurosurgical procedures, are also a pathogenic mechanism of brain abscess development. In 10% to 35% of patients, brain abscess is cryptogenic.

The infection is often polymicrobial, and the pathogen(s) involved depend on the mechanism of spread as well as the host characteristics. Commonly isolated pathogens are aerobic and microaerobic streptococci and gram-negative anaerobes such as *Bacteroides* and *Prevotella*. Less common are gram-negative aerobes and *Staphylococcus*. *Actinomyces*, *Nocardia*, and *Candida* are even less prevalent. In immunosuppressed individuals, *Aspergillus* and *Toxoplasma* are important causes of abscesses. Surgical specimens are culture positive in 70% of antibiotic-treated patients and 95% of patients undergoing surgery before antibiotic administration.

Clinical Presentation

The clinical course of brain abscess ranges from indolent to fulminant. The classic clinical picture is composed of signs of systemic infection (e.g., fever), those related to focal brain involvement, and those due to an increased intracranial pressure and mass effect. Elements of one or two categories are often absent in a given case, particularly early in the disease course. For example, almost one half of patients may not have a fever or leukocytosis. The classic triad of fever, headache, and focal neurologic deficit is found only in about 20% of patients on admission. Recent

TABLE 92.8 Location and Clinical Presentation of Brain Abscesses

Location	Clinical Presentation
Frontal lobe	Headache, drowsiness, inattention, deterioration of mental status, hemiparesis with unilateral motor signs, and motor speech disorder
Temporal lobe	Ipsilateral headache and aphasia (dominant side); visual defect
Cerebellum	Ataxia, nystagmus, vomiting, and dysmetria
Brainstem	Fever, headache, facial weakness, hemiparesis, dysphagia, and vomiting

Fig. 92.2 Magnetic resonance imaging features of a brain abscess. (A) Contrast-enhanced scan shows a ring-enhancing lesion in the left frontal lobe. (B) The diffusion-weighted image shows restricted diffusion in the cavity due to viscous pus and cellular material. (C) Corresponding apparent diffusion coefficient map shows dark, viscous material in the cavity and surrounding edema.

onset of a headache is the most common symptom, which may increase in severity associated with focal signs related to the location of the abscess (e.g., hemiparesis, aphasia), followed by obtundation and coma. However, headache may be moderate to severe and hemicranial or generalized but often lacks distinguishing features. Seizures precede the diagnosis in 30% of cases. *Toxoplasma* abscesses are often associated with movement disorders due to their propensity for the basal ganglia. The period of evolution may be as brief as hours or as long as days to weeks with more indolent organisms. The location of the brain abscess can correlate with clinical presentation (Table 92.8). A worrisome complication of brain abscess is rupture. Sudden worsening of a headache with new onset of meningismus may signify rupture of the abscess into the ventricular space. This is associated with a high mortality, up to 85% in some series.

Diagnosis

CSF examination should be avoided; it is seldom diagnostic, and results can be normal. Lumbar puncture in the setting of a mass lesion carries the risk of transtentorial herniation. Because the brain abscess is seeded from a peripheral site of infection, a search for other sites of infection can help to identify the causative organisms and determine appropriate treatment.

MRI with intravenous gadolinium provides better soft tissue visualization than CT and is the imaging of choice in diagnosing brain abscesses. MRI is particularly useful for detecting multiple abscesses and posterior fossa abscesses. It can demonstrate cerebritis, the extent of a mass effect,

and associated venous thrombosis. Repeat or serial imaging can be used to determine response to therapy. In the early cerebritis stage, CT results may be normal, but the MRI FLAIR sequence is very sensitive for visualization of brain edema. On T1-weighted images, the area of cerebritis is seen initially as a low-signal-intensity, ill-defined area. T1-weighted images in the later stages of infection may show the formation of a rim of slightly higher signal intensity and central necrosis. Contrast administration typically shows ring enhancement with central necrosis. This area of central necrosis appears bright on diffusion-weighted images and dark on apparent diffusion coefficient (ADC) images (Fig. 92.2). MRI of tumors shows the opposite features. Differentiating a brain abscess from tumor is important for the stereotactic approach to ring-enhancing lesions before biopsy or surgical excision. An abscess should be drained centrally, whereas a tumor should be biopsied along its rim.

Patient risk factors, location of the brain abscess, and characteristic findings on CT or MRI imaging can help implicate the responsible pathogen. *Nocardia* brain abscesses are often multilobulated. *Listeria* brain abscesses are often located in the brain stem. Findings of cerebral infarcts that develop into single or multiple brain abscesses usually in the frontal or temporal lobes in a patient with risk factors for invasive aspergillosis should suggest that diagnosis. CT or MRI findings of sinus opacification, erosion of bone, and obliteration of deep fascial planes may indicate rhinocerebral mucormycosis. Rounded isodense or hypodense lesions with ring enhancement seen on contrast imaging are consistent with CNS toxoplasmosis in the appropriate patient.

TABLE 92.9 Predisposing Conditions, Microbiology, and Empiric Treatment^a of Brain Abscesses

Predisposing Condition	Usual Organism	Antimicrobial Regimen
Otitis media or mastoiditis	Streptococci (anaerobic and aerobic), <i>Bacteroides</i> and <i>Prevotella</i> sp, Enterobacteriaceae	Metronidazole + a third-generation cephalosporin ^b
Sinusitis	Streptococci, <i>Bacteroides</i> sp, Enterobacteriaceae, <i>Staphylococcus aureus</i> , <i>Haemophilus</i> sp	Vancomycin + a third-generation cephalosporin ^b + metronidazole
Dental infection	Mixed <i>Fusobacterium</i> , <i>Prevotella</i> , <i>Actinomyces</i> , and <i>Bacteroides</i> sp, streptococci	Metronidazole + a third-generation cephalosporin ^b
Lung abscess, empyema, bronchiectasis	<i>Fusobacterium</i> , <i>Actinomyces</i> , <i>Bacteroides</i> , and <i>Prevotella</i> sp, streptococci, <i>Nocardia</i> sp	Third-generation cephalosporin ^b + metronidazole + trimethoprim-sulfamethoxazole
Bacterial endocarditis	<i>S. aureus</i> , streptococci	Vancomycin ^c
Congenital heart disease	Streptococci, <i>Haemophilus</i> sp	Third-generation cephalosporin ^b
Penetrating trauma or invasive neurosurgical procedure	<i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Clostridioides</i> sp	Vancomycin + a third- or fourth-generation cephalosporin
Neutropenia	Aerobic gram-negative bacilli, <i>Aspergillus</i> sp, Mucorales, <i>Candida</i> sp, <i>Scedosporium</i> sp	Vancomycin + ceftipime; consider antifungals
HIV infection	<i>Toxoplasma gondii</i> , <i>Nocardia</i> sp, <i>Mycobacterium</i> sp, <i>Listeria monocytogenes</i> , <i>Cryptococcus neoformans</i>	Add pyrimethamine + sulfadiazine; consider isoniazid, rifampin, pyrazinamide, and ethambutol for possible tuberculosis
Transplantation	<i>Aspergillus</i> sp, <i>Candida</i> sp, Mucorales, <i>Scedosporium</i> sp, Enterobacteriaceae, <i>Listeria monocytogenes</i> , <i>Nocardia</i> sp, <i>Toxoplasma gondii</i> , <i>Mycobacterium tuberculosis</i>	Add voriconazole + trimethoprim-sulfamethoxazole

^aTreatment, namely use of targeted antimicrobials, may be modified based on isolation of specific microbes, sensitivities, and patient characteristics (i.e., allergies, risk factors).

^bCefotaxime or ceftriaxone.

^cAdditional agents should be added based on other likely microbiologic etiology.

Treatment

A suspected brain abscess requires urgent intervention. MRI or contrast CT should be performed to verify the presence of a brain abscess. Unless the surgical procedure poses a substantial risk, aspiration of the lesion is needed for microbial diagnosis. Corticosteroids should be administered to patients with significant edema, with mass effect causing increased intracranial pressure, or with a predisposition to transtentorial herniation. High-dose intravenous dexamethasone (16 to 24 mg/day in four divided doses) may be used for short periods until surgical intervention is possible. Corticosteroids may retard formation of a capsule around the brain abscess in its early stages and the immune response to infection. Seizures should be controlled because the tonic phase of a generalized seizure may increase intracranial pressure. In a patient with a large abscess, seizures may trigger a brain herniation. Seizure prophylaxis should be initiated in all patients with cortical or temporal lobe abscesses. Anticonvulsants that can be administered intravenously are preferred.

Successful treatment of brain abscesses relies on rapid verification of the abscess, identification of the responsible pathogen, timely surgical intervention, and appropriate antimicrobial therapy. Antibiotic management of brain abscess is based on knowledge of proven or suspected pathogens and antibiotic properties, such as CNS drug penetration capabilities and the spectrum of activity. Empirical antibiotic therapy without surgical intervention may be used if the primary source of infection outside of the CNS is identified, in patients with cerebritis without capsule formation, or in those with multiple, small abscesses or abscesses in basal ganglia or brain stem. If the organism is unknown, empirical therapy may include vancomycin, metronidazole, and a third- or fourth-generation cephalosporin. In brain stem abscesses, the possibility of *Listeria* infection should be considered, and treatment should include intravenous ampicillin. In HIV-infected patients with multiple ring-enhancing lesions, empirical therapy for toxoplasmosis should be initiated even if the patient is seronegative for *Toxoplasma*.

Voriconazole is the recommended antifungal therapy for patients with risk factors and imaging findings concerning for invasive aspergillosis. Recommendations for other causes of fungal brain abscess are shown in Table 92.6. Table 92.9 summarizes the predisposing conditions, microbiology, and recommended empiric treatment of brain abscesses.

Patients undergoing empirical therapy should be followed with repeat CT or MRI. Those who fail to respond should undergo surgical intervention. An important aspect of the management strategy is eradication of the predisposing condition or cause of the brain abscess, such as an oral, ear, cardiac, or pulmonary infection.

PARAMENINGEAL INFECTIONS

Parameningeal infections include infections that produce suppuration in potential spaces covering the brain and spinal cord (i.e., epidural abscess and subdural empyema) and those that produce occlusion of the contiguous venous sinuses and cerebral veins (i.e., cerebral venous sinus thrombosis).

Subdural Empyema

Definition

Subdural empyema refers to infection in the space separating the dura and arachnoid.

Pathology and Pathophysiology

Cranial subdural empyemas account for 15% to 20% of all localized intracranial infections. Two thirds of subdural empyemas result from frontal or ethmoid sinus infections, 20% from inner ear infections, and the remainder from trauma or neurosurgical procedures. The empyema is caused by direct or indirect extension from infected paranasal sinuses through a retrograde thrombophlebitis. Unilateral empyema is most common because the falx prevents passage across the midline,

but bilateral or multiple empyemas can occur. Cortical venous thrombosis or brain abscess develops in about 25% of patients. The infection is metastatic in about 5% of patients, primarily from a pulmonary source. In some patients, the subdural empyema may be associated with an epidural abscess or meningitis. These associations occur more often in children than in adults.

Clinical Presentation

The clinical presentation of cranial subdural empyema can be rapidly progressive with signs and symptoms resulting from increased intracranial pressure, meningeal irritation, or focal cortical inflammation. These include fever, intractable headache, vomiting, nuchal rigidity, focal neurologic deficits (e.g., hemiparesis, ocular palsies, dysphasia, dilated pupils, cerebellar signs, or seizures), and varying levels of altered consciousness. If untreated, mental status may decline to obtundation, and the septic mass and swollen underlying brain can lead to venous thrombosis or death from herniation. The clinical presentation of spinal subdural empyema may consist of radicular pain and symptoms of spinal cord compression including saddle anesthesia, lower extremity weakness, and bowel or bladder incontinence. The infection may occur at multiple levels. The presentation can be difficult to differentiate from spinal epidural abscess.

The major differential diagnosis is meningitis. Nuchal rigidity and obtundation occur in meningitis and cranial subdural empyema, but papilledema and lateralizing deficits are more common in cranial subdural empyema.

Diagnosis

Lumbar puncture should be avoided in patients with cranial subdural empyema to prevent cerebral herniation. Contrast-enhanced CT or MRI can be diagnostic of empyema, showing an extra-axial, crescent-shaped mass with an enhancing rim lying just below the inner table of the skull over the cerebral convexities or in the interhemispheric fissures. On MRI, subdural empyema has decreased signal intensity on T1-weighted imaging and increased signal intensity on T2-weighted scans. Similar to brain abscess, subdural empyema has high signal intensity on diffusion-weighted images and low signal intensity on ADC maps.

Treatment

Treatment requires prompt surgical drainage of the empyema cavity and prompt administration of intravenous antibiotics directed at organisms found at the time of craniotomy. Concomitant use of corticosteroids to reduce edema and increased intracranial pressure, as well as anticonvulsants to control seizures, are also important to reduce morbidity and mortality.

SPINAL EPIDURAL ABSCESS

Definition and Epidemiology

A *spinal epidural abscess* is an infection in the epidural space between the dura and the bones of the spine around the spinal cord. It can cause paralysis and death. The incidence is 0.5 to 1.0 cases per 10,000 hospital admissions in the United States, and the frequency is increased among injection drug users.

Pathology and Pathophysiology

Infections of the spinal epidural space originate from contiguous spread or through hematogenous routes from a distant source. Cutaneous infection, particularly in the back, is the most common remote source, especially among injection drug users. Abdominal, respiratory tract,

and urinary sources are also common. As the use of epidural catheters has increased for pain management, epidural abscess and hematoma have been increasingly reported.

The anatomy of the epidural space dictates the location of the abscess. Because the size of the intravertebral canal remains relatively constant but the circumference of the spinal cord changes, abscess formation is maximal in the thoracic and lumbar regions and minimal at the cervical spine. Due to the loose connections between the dura and the bones of the spine, the abscess can extend to multiple levels, causing severe and extensive neurologic manifestations.

Causative organisms can be identified by culture or Gram stain from pus obtained at exploration (90% of patients), blood cultures (60% to 90%), or CSF (20%). *S. aureus* is the most common pathogen, followed by streptococci and gram-negative organisms. Tuberculous abscesses may occur in as many as 25% of patients in high-risk populations. In a previous epidemic, iatrogenic infection occurred with rare fungi after epidural injections of corticosteroids that were contaminated with a plant pathogen, *Exserohilum rostratum*, which rarely infects humans.

Clinical Presentation

The classic triad of fever, back pain, and neurologic deficits may not be identified in all patients, leading to a delay in diagnosis. Patients are usually febrile and have acute or subacute neck or back pain. An important physical finding is focal tenderness over the affected spinous processes. Stiff neck and headache are common. The pain can be mistaken for sciatica, a visceral abdominal process, chest wall pain, or cervical disk disease. If it goes unrecognized at this stage, the symptoms can evolve over a few hours to a few days to weakness, loss of lower extremity reflexes, and paralysis distal to the spinal level of the infection. In this clinical setting, urgent neuroradiologic imaging should be pursued followed by empiric antibiotics with concurrent corticosteroids, and surgical evaluation.

Diagnosis

The diagnosis is made by CT or MRI (Fig. 92.3). The differential diagnosis includes transverse myelitis, intervertebral disk herniation, epidural hemorrhage, and metastatic tumor. These conditions can usually be differentiated by MRI. Epidural abscess is often accompanied by diskitis or osteomyelitis of the vertebral bodies.

Treatment

Unless culture and sensitivities dictate otherwise, a penicillinase-resistant penicillin should be started empirically as antistaphylococcal treatment for presumed bacterial infection. If methicillin resistance is suspected, vancomycin should be used. Considering the severity of the disease, additional gram-negative coverage with a third- or fourth-generation cephalosporin or a fluoroquinolone may be needed. Other empiric agents, including antifungals, can be considered based on clinical suspicion and patient risk factors.

Surgical decompression was previously considered mandatory, but early diagnosis by MRI may allow for effective medical therapy if started before the occurrence of neurologic complications. These patients should be monitored closely, and if signs of neurologic deterioration emerge, surgical intervention may be necessary.

SINUS THROMBOSIS

Septic Cavernous Sinus Thrombosis

Septic cavernous sinus thrombosis usually results from spread of infection from paranasal sinusitis (especially of the sphenoid or ethmoid sinuses) or less commonly from spread of infection from the face and mouth. Symptoms include headache or lateralized facial pain, followed

Fig. 92.3 Magnetic resonance imaging shows an epidural abscess due to *Staphylococcus* in the cervical spine of a patient with human immunodeficiency virus infection. (A) Noncontrast T1-weighted image shows an extensive lesion in the epidural space that extends from C2 to C7. Notice straightening of the cervical spine. (B) After a laminectomy from C2 to T1 and fusion, the short tau inversion recovery (STIR) image shows fluid collection in the epidural space as a high-signal-intensity lesion. Normal curvature of the spine is seen.

in a few days to weeks by fever and involvement of the orbit (i.e., proptosis and chemosis due to obstruction of the ophthalmic vein). Paralysis of oculomotor nerves follows rapidly. In some instances, sensory dysfunction occurs in the first and second divisions of the trigeminal nerve along with a decrease in the corneal reflex. Further involvement of the contiguous orbital contents follows, with mild papilledema and decreased visual acuity that sometimes progresses to blindness.

Extension to the opposite cavernous sinus or to other intracranial sinuses with cerebral infarction or increased intracranial pressure due to impaired venous drainage can result in stupor, coma, and death. The CSF is abnormal if there is accompanying meningitis or parameningeal infection. The most common causative organism is *S. aureus*, followed by streptococci and pneumococci; anaerobes and gram-negative bacilli may also be etiologic agents.

Diagnosis of cavernous sinus thrombosis is usually made by MRI with MR venogram. Radiologic evaluation includes imaging of the sphenoidal and ethmoidal sinuses, which may require drainage if infected. Empirical antimicrobial therapy should include an antistaphylococcal agent. An empirical combination therapy with parenteral metronidazole, vancomycin, and a third- or fourth-generation cephalosporin can achieve reasonable CSF and brain penetration and is likely to be active against *S. aureus* and the usual sinus pathogens.

Lateral Sinus Thrombosis

Septic thrombosis of the lateral sinus results from acute or chronic infections of the middle ear, including otitis media and mastoiditis. The infection spreads through emissary veins that connect the mastoid with the lateral venous sinus. It may spread to involve the sigmoid sinus. The symptoms include ear pain followed over several weeks by fever, headache, nausea, vomiting, and vertigo. Mastoid swelling may be seen. Sixth cranial nerve palsies and papilledema can occur, but other focal neurologic signs are rare.

The diagnosis can be established by MRI. Common pathogens of lateral sinus thrombosis include *S. aureus*, streptococci, and *E. coli*; rarely, *Fusobacterium necrophorum* and *Bacteriodes fragilis* have also been reported. Treatment includes an empirical regimen of broad-spectrum intravenous antibiotics to cover staphylococci, gram-negative bacilli, and anaerobes (i.e., vancomycin with metronidazole and a third- or fourth generation cephalosporin). Surgical drainage (i.e., mastoidectomy) may be required.

Septic Sagittal Sinus Thrombosis

Septic sagittal sinus thrombosis is uncommon and occurs as a consequence of purulent meningitis, infections of the ethmoidal or maxillary sinuses spreading through venous channels, face, scalp, subdural space, compound skull fractures, or neurosurgical wound infections (rare). Symptoms include manifestations of elevated intracranial pressure (e.g., headache, nausea, and vomiting) that evolve rapidly to stupor and coma. Motor deficits, nuchal rigidity, and papilledema may be seen. Seizures occur in more than half of these patients. Similar to other sinus thromboses, the likely microorganisms depend on the associated primary condition. Diagnosis and treatment are similar to the lateral venous sinus thrombosis described earlier.

NEUROLOGIC COMPLICATIONS OF INFECTIVE ENDOCARDITIS

Epidemiology

Neurologic complications are among the most common extra-cardiac complications of infective endocarditis and occur in one third of patients with bacterial endocarditis. They are associated with significant morbidity and triple the mortality rate of the disease. Cerebral (but not systemic) emboli from mitral valve endocarditis are increasingly common. Most emboli, regardless of the bacterial cause of the infection, occur before or early in the course of treatment. By 2 weeks

of therapy, the risk of embolization decreases dramatically. Mycotic aneurysms in the brain complicate endocarditis in 2% to 10% of patients and are more common in acute than subacute disease.

Pathophysiology

The risk of developing neurologic complications from infective endocarditis depends on a number of characteristics, principally the size and location of the vegetation as well as the duration of antibiotic treatment. Larger, left-sided vegetations involving the mitral valve are more likely to embolize.

Cerebral emboli are distributed in the brain in proportion to cerebral blood flow. Most emboli lodge in the branches of the middle cerebral artery peripherally. Multiple microabscesses can result and cause diffuse encephalopathy. Mycotic aneurysms occur most commonly in the middle cerebral artery, with the aneurysms located distally in the vessel. This differentiates them from congenital berry aneurysms.

Clinical Manifestations

Neurologic complications may be the presenting symptoms of infective endocarditis. Patients may present with severe headache, focal neurologic deficits, altered consciousness, mononeuropathy, or seizures. Embolic stroke is the most common complication. Other complications include ischemic or hemorrhagic stroke, meningitis, brain abscess, spinal epidural abscess, and infected intracranial aneurysm.

Diagnosis

The diagnosis of neurologic involvement from endocarditis is best made with CT or MRI. MRI findings in endocarditis include ischemic lesions, hemorrhagic lesions, subarachnoid hemorrhage, brain abscess, mycotic aneurysm, and cerebral microbleeds. The CSF is abnormal in 70% of patients and simulates purulent meningitis (i.e., polymorphonuclear predominance, elevated protein level, and low glucose level) or a parameningeal infection (i.e., lymphocytic predominance, modest protein elevation, and normal glucose level). If concomitant bacteremia is present, positive blood cultures help identify the causative pathogen.

Multidetector CT angiography may be necessary to diagnose aneurysms. Small brain abscesses may complicate the course of endocarditis, but macroscopic abscesses are rare, with most occurring in the setting of acute rather than subacute endocarditis. Multiple microabscesses may escape detection on CT and are not amenable to surgical drainage.

Treatment

Antibiotic treatment of the primary disease is indicated. Stroke is usually treated conservatively. There are no controlled trials for the management of unruptured mycotic aneurysms, although they may be managed with antibiotics alone. Ruptured aneurysms should be managed with a combination of antibiotics with surgery or endovascular therapy because treatment-related mortality is higher in patients with ruptured aneurysms than unruptured aneurysms. Patients with infective endocarditis who do not respond to conservative medical therapy can have prompt valve replacement despite intracerebral hemorrhage. The balance of risks and benefits should be tailored to each individual patient when considering surgical intervention in the setting of neurologic complications, which can significantly increase the risk of surgical complications. In general, anticoagulation use is not recommended due to the potential risk for hemorrhagic complications and because it does not appear to reduce the risk of embolism in patients with infective endocarditis.

PRION DISEASES

Etiology

Several human diseases have been attributed to a unique infectious protein, the prion. The infectious form of the prion protein is rich in β -sheets, detergent insoluble, multimeric, and resistant to proteinase K treatment.

Prion illnesses (i.e., transmissible spongiform encephalopathies) can be classified as sporadic, hereditary, or acquired. The most common form is sporadic Creutzfeldt-Jakob disease (sCJD). Familial forms include Gerstmann-Sträussler-Scheinker syndrome and familial fatal insomnia.

Acquired forms are caused by the transmission of an abnormal prion protein (PrP) from human to human or from cattle to humans. Accidental transmission of CJD between humans appears to have occurred with cadaveric dura mater grafting, corneal transplantation, receipt of human growth hormone or pituitary gonadotropin, contaminated electroencephalogram electrodes, and contaminated surgical instruments. This form of CJD has been called iatrogenic CJD (iCJD).

The appearance of variant CJD (vCJD) in Great Britain, which was associated with the outbreak of bovine spongiform encephalopathy and the contamination of beef, greatly increased interest in this group of illnesses. Kuru is another transmissible spongiform encephalopathy that was spread in New Guinea by cannibalism, a practice that ceased in the 1950s. The disease is now almost extinct.

Sporadic Creutzfeldt-Jakob Disease

Epidemiology

Illness from sCJD is seen worldwide, with an incidence of 0.5 to 1.0 cases per 1 million people in the general population per year.

Pathology

The pathologic hallmarks of CJD are spongiform or vacuolar changes in the brain without cellular inflammatory infiltrates. The pathogenic isoform of the prion protein can be demonstrated in brain tissue by immunocytochemical staining and by Western blot analysis. The fundamental process involved in human prion propagation is intercellular induction of protein misfolding and seeded aggregation of misfolded prion protein.

Clinical Manifestations

CJD is frequently diagnosed incorrectly initially. Prodromal symptoms include altered sleep patterns and appetite, weight loss, changes in sexual drive, and impaired memory and concentration. Disorientation, hallucinations, depression, and emotional lability are early signs, followed by a rapidly progressive dementia associated with myoclonus (about 90% of patients). Myoclonus is usually provoked by tactile, auditory, or visual startle stimuli. CJD has an abrupt onset in 10% to 15% of patients.

Other distinctive features include seizures, autonomic dysfunction, and lower motor neuron disease, suggesting amyotrophic lateral sclerosis-like characteristics. Cerebellar ataxia occurs in one third of patients.

Diagnosis

The clinical tetrad supporting the diagnosis of CJD consists of a subacute progressive dementia, myoclonus, typical periodic sharp waves on electroencephalography, and normal CSF. FLAIR MRI sequences show extensive curvilinear hyperintensity along the neocortex, called *cortical ribboning*, which affects frontal, parietal, and temporal lobes (in decreasing order of frequency). Routine CSF study is usually normal. A CSF test for the protein 14-3-3, which is released into spinal

fluid when brain cells die, in the appropriate clinical context, is supportive for CJD.

Treatment

No effective therapy exists. The disease is inexorably progressive. The median time to death from onset is 5 months, and 90% of patients with sporadic CJD die within 1 year.

Although the illness is not communicable in the conventional sense, a risk exists in handling material contaminated with the prion protein. Gloves should be worn when handling blood, CSF, and other body fluids. Instruments must be disinfected and sterilized appropriately.

Infections of the Head and Neck

David Kim, Roberto Cortez, Tareq Kheirbek

COMMON COLD

Definition and Epidemiology

The common cold is an acute viral syndrome involving the upper respiratory tract with symptoms of sore throat, rhinorrhea, and nasal congestion. It has a considerable economic burden, accounting for over 100 million physician visits annually with approximately 20 million lost workdays and costing \$7 billion per year in sick days and lost productivity. The incidence of the common cold decreases with age with children having six to eight colds on average annually, whereas adults have two to three colds per year.

Pathogenesis and Microbiology

Rhinoviruses are the most common pathogen implicated in the common cold and are associated with more than 50% of all colds. However, the syndrome may be caused by over 200 viruses including influenza virus, coronavirus, adenovirus, respiratory syncytial virus, parainfluenza virus, metapneumovirus, and enterovirus. These viruses are transmitted either by direct contact or by aerosols through which they infect the nasal epithelium, thereby stimulating a nonspecific inflammatory response accounting for the associated symptoms.

Clinical Presentation

Onset of symptoms occurs 1 to 3 days following viral infection. The common cold typically manifests with an initial sore throat followed by rhinorrhea, nasal congestion, and sneezing by the third day. Patients may develop a cough later lasting for several days. Symptoms peak between day 3 and 6 and persist for approximately 7 to 10 days. Clinical findings are limited to the upper respiratory tract with increased nasal secretions. Additionally, patients may demonstrate mild oropharyngeal erythema, injected conjunctiva, edematous nasal mucosa, and anterior cervical lymphadenopathy.

Treatment

Treatment is largely symptomatic with rest, oral hydration, and over-the-counter medications including nasal decongestants, non-steroidal anti-inflammatory drugs, lozenges, and cough suppressants. Antibiotics are not indicated.

ACUTE BACTERIAL RHINOSINUSITIS

Definition and Epidemiology

Acute rhinosinusitis is a common illness with one out of eight adults reporting receiving a diagnosis each year, resulting in more than 30 million patient visits annually. Acute bacterial rhinosinusitis is inflammation secondary to bacterial infection of the nasal cavity and paranasal sinuses lasting less than 4 weeks. Approximately 0.5% to 2% of acute viral rhinosinusitis cases are complicated by bacterial rhinosinusitis.

Pathogenesis and Microbiology

Following an upper respiratory infection, viral inoculation of the nasal cavity and the paranasal sinuses produces an acute viral rhinosinusitis leading to mucosal thickening, edema, and inflammation. Contaminated nasal secretions then enter the typically sterile paranasal sinuses that are normally cleared. However, mucosal inflammation and edema can obstruct sinus drainage and impair mucociliary clearance of bacteria, perpetuating bacterial infection. The most common bacteria associated with acute bacterial rhinosinusitis are *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Clinical Presentation

Symptoms of acute rhinosinusitis may include purulent anterior or posterior nasal discharge, nasal congestion or obstruction, facial congestion or fullness, facial pain or pressure, hyposmia or anosmia, and fever. Patients may complain of headache, ear pain, maxillary tooth pain, cough, and fatigue. Clinical findings may include erythema and swelling of the nasal mucosa, purulent nasal discharge, and sinus tenderness. Clinical history, patterns, and duration of symptoms are helpful in the diagnosis of acute bacterial rhinosinusitis. These include symptoms of nasal congestion, rhinorrhea, and cough persisting greater than 10 days; severe symptoms including fever with purulent nasal discharge for greater than 3 days; or recurrence and worsening of common cold symptoms following a period of initial improvement or “double-sickening.” Imaging is not routinely recommended in patients with uncomplicated acute rhinosinusitis.

Treatment

Acute bacterial rhinosinusitis typically resolves with symptomatic management within 2 weeks. Intranasal sterile saline irrigation has been shown to provide symptomatic relief. If symptoms persist in an otherwise immunocompetent patient or if reliable follow-up is unavailable, antibiotics are indicated and should be initiated for a duration of 5 to 7 days. First-line antibiotics are amoxicillin or amoxicillin-clavulanate. Azithromycin and trimethoprim-sulfamethoxazole are not recommended due to high prevalence of antibiotic resistance. Patients should respond to antibiotic therapy within 72 hours with improvement of symptoms. Failure to respond to initial therapy may require high-dose amoxicillin-clavulanate for a duration of 7 to 10 days.

Complications

Patients with acute bacterial rhinosinusitis who fail to respond to high-dose antibiotics warrant a referral to an otolaryngologist for further evaluation. Intracranial and orbital complications may arise from progressing infection (Fig. 93.1). Orbital complications include peri-orbital cellulitis, orbital cellulitis, and abscess, secondary to acute bacterial ethmoiditis. Intracranial complications include epidural abscess,

Fig. 93.1 (A) A child has an orbital abscess as a complication of ethmoid sinusitis. Note the marked edema and proptosis. (B) Computed tomography scan of the orbit demonstrates a subperiosteal abscess (arrow). (A, Courtesy Gary Williams, MD; B, From DeMuri GP, Wald ER: Sinusitis. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Saunders.)

meningitis, cavernous sinus thrombosis, subdural empyema, and brain abscess. In cases of complicated acute rhinosinusitis, evaluation should include computed tomography (CT) or magnetic resonance imaging with appropriate consultations with otolaryngology and/or ophthalmology. Oftentimes, management involves initiating broad-spectrum intravenous antibiotics and urgent surgical intervention in the setting of abscesses.

PHARYNGITIS AND TONSILLITIS

Definition and Epidemiology

Pharyngitis or sore throat is characterized by inflammation of the pharynx from environmental and chemical exposures or from infectious disease. In the United States, more than 10 million patients are diagnosed annually with acute pharyngitis, with incidence peaking in children and in the winter.

Tonsillitis is an inflammatory condition affecting the palatine tonsils, which, in addition to the pharyngeal, tubal, and lingual tonsils, comprise the Waldeyer ring. Tonsillitis refers to infections primarily involving the palatine tonsils, while pharyngitis affects the oropharynx, although they are frequently used interchangeably. Tonsillitis accounts for 1.3% of all outpatient primary care clinic visits with patients aged 5 to 15 years affected most commonly. Early spring and winter months demonstrate a notable up-tick in reported cases. Those afflicted can range from asymptomatic streptococcal carriers to a quinsy or peritonsillar abscess requiring emergent drainage.

Using a combination of history, clinical presentation, and several immediately available laboratory tests, the health care provider may

readily distinguish patients with self-limited, viral illnesses from those requiring antibiotic treatment or procedural interventions.

Pathogenesis and Microbiology

Viral causes of pharyngitis account for greater than 70% of cases with common pathogens being rhinovirus, adenovirus, Epstein-Barr virus (EBV), and influenza viruses. The most commonly encountered bacterial pathogen is Group A Streptococcus (GAS), accounting for up to 30% of pharyngitis cases in children and 10% in adults.

The palatine tonsils are pharyngeal lymphoid organs surrounded by overlying respiratory epithelium that invaginate into crypts. These crypts may harbor bacteria and lead to acute or recurrent infections. Most cases of acute tonsillitis represent benign, self-limited episodes of viral origin. Pathogens responsible for the common cold frequently result in self-limited, benign cases of tonsillitis and include rhinovirus, coronavirus, respiratory syncytial virus, and adenovirus. More severe viral cases are less frequent but should raise suspicion for EBV, cytomegalovirus, rubella, and human immunodeficiency virus (HIV).

Difficulty in distinguishing viral from bacterial etiologies frequently results in unnecessary antibiotic therapy. While GAS infections are by far the most common bacterial source requiring antimicrobial therapy, infections yielding *S. aureus*, *S. pneumoniae*, and *H. influenzae* are also possible. Unvaccinated individuals may harbor infections with diphtheria-causing *Corynebacterium species*. A social and sexual history may yield prior or active infections with chlamydia, gonorrhea, HIV, and syphilis, which can also be observed in cases of acute or recurrent episodes of tonsillitis. Tuberculosis should be considered in patients

residing in common living quarters, incarcerated facilities, and homeless shelters.

Clinical Presentation

Common presentations include malaise, fever, sore throat, and tender anterior cervical lymphadenopathy. Odynophagia and/or dysphagia warrant further investigation for significant tonsillar swelling and the potential for airway compromise. A thorough history and physical should include onset of symptoms, sick contacts, medical comorbidities, living conditions, prior episodes of tonsillitis, as well as sexual and vaccination history. One must consider the spectrum of illness when navigating diagnostic and management strategies, as this differs greatly when handling benign, minimally symptomatic patients from those demonstrating a toxic appearance with difficulty handling secretions.

The provider should assess the patient's vital signs, paying attention to the presence of a fever, tachycardia, tachypnea, and marginal oxygen saturation levels. Next, a thorough head and neck examination may reveal tonsillar enlargement and exudates, tender cervical lymphadenopathy, and uvular deviation. Both the Infectious Diseases Society of America and the American Society of Internal Medicine recommend the use of scoring systems (i.e., Centor Score), which considers presence of fever, tonsillar exudates and/or enlargement, absence of cough, and tender cervical lymphadenopathy, each of which warrants one point. It has since been modified for age, where patients within age 3 to 15 are given an additional point, and patients 45 years or older have one point subtracted from the overall score. With scores of 0 or 1, no further testing is necessary. With 2 to 3 points, a rapid strep test and throat culture are feasible options. In patients scoring 4 or more points, clinicians should consider testing and beginning empiric antibiotics.

Treatment

Treatment of viral pharyngitis is encouraging symptom control with non-steroidal anti-inflammatory drugs (NSAIDs) and hydration. First-line treatment of GAS pharyngitis is amoxicillin and penicillin V. For penicillin-allergic patients, first-generation cephalosporins, clindamycin or macrolides are reasonable alternatives. Of note, GAS antibiotic resistance to azithromycin and clindamycin are increasingly common. The recommended duration of treatment using β -lactam antibiotics is 10 days.

Complications include peritonsillar abscess, in which patients may appear ill with muffled speech, foul-smelling breath, uvula displacement, and drooling. Less common complications include contiguous neck space infections or rarely rheumatic fever.

DEEP NECK SPACE INFECTIONS

Definition and Epidemiology

Deep neck space infections most commonly arise from oral cavity or odontogenic origin, and knowledge of cervical anatomy (Fig. 93.2) and the fascial planes is paramount in understanding the infectious etiology and their potential for spread. In addition, the deep cervical fascia creates clinically relevant fascial spaces into which infections can spread rapidly with devastating consequences. Risk factors for developing deep neck space infections include uncontrolled or untreated dental infection, spread of infection from other local structures such as the tonsils, intravenous drug use, diabetes, HIV infection, and local trauma.

Submandibular Space Infection

The submandibular space is defined by the mandible anteriorly and laterally; the hyoid bone posteriorly; the mucosa of the floor of the mouth superiorly; and the superficial layer of the deep cervical fascia inferiorly. Ludwig angina is a severe infection of the submandibular

space, typically caused by an infected lower molar tooth. Patients will oftentimes present acutely ill with mouth pain, a swollen, elevated tongue, dysphagia, drooling, stiff neck, and febrile (Fig. 93.3). If left untreated, the infection may spread to the lateral pharyngeal space, resulting in trismus. On exam, the submandibular tissues will appear swollen with woody induration and are generally not fluctuant. Once the disease has been identified, immediate medical and surgical treatment is necessary, which involves initiating broad-spectrum antibiotic therapy as well as surgical decompression through a neck incision and extraction of the infected tooth. Complications of Ludwig angina include death from airway obstruction, aspiration pneumonia, carotid artery erosion, and tongue necrosis.

Retropharyngeal Infection

Defined by the alar fascia anteriorly and the buccopharyngeal layer of the middle layer of cervical fascia covering the pharynx and esophagus posteriorly, the retropharyngeal space extends from the base of the skull to level of T2 approximately, where the two fascial layers fuse. Additionally, there is a distinct prevertebral space that is in between the prevertebral fascia and the vertebral column.

Of note, there is a "danger space" that lies in between the prevertebral space posteriorly and the retropharyngeal space anteriorly, extending from the base of the skull to the diaphragm. This area is of clinical importance because it is continuous with the mediastinum, allowing for infection to spread directly into the thorax and causing mediastinitis.

Many infections can spread into the retropharyngeal space and may develop into abscesses without appropriate treatment. For example, infections in the Waldeyer ring can spread to the retropharyngeal lymph nodes and into this space. Additionally, odontogenic infections that spread to the lateral pharyngeal space can also travel into the retropharyngeal space. Patients will present acutely ill with fever, sore throat, dysphagia, neck stiffness, and dyspnea. Airway obstruction can occur from bulging of the posterior pharyngeal wall anteriorly with supraglottic compression. Definitive treatment requires administration of broad-spectrum antibiotics and oftentimes, surgical drainage of abscess.

Lateral Pharyngeal Space Infection

The lateral pharyngeal space or the parapharyngeal space is located on the lateral aspect of the pharynx, continuous with the retropharyngeal space posteriorly and the submandibular space anteriorly. This space communicates with the submandibular, retropharyngeal, and peritonsillar spaces and is therefore susceptible to both oral cavity and odontogenic infections. Interestingly, *Fusobacterium necrophorum* can cause a rare syndrome called postangina septicemia or Lemierre syndrome, which manifests with severe sore throat and fever. In this syndrome, the lateral pharyngeal space becomes infected with resulting septic thrombophlebitis of the internal jugular vein. The mortality rate can be as high as 50%. Treatment requires prompt initiation of intravenous penicillin and emergent drainage of any abscess.

Bacterial Epiglottitis

Definition and Epidemiology

Epiglottitis is an inflammatory affliction of the epiglottis and nearby structures, which include the arytenoids, aryepiglottic folds, and vallecula. Widespread usage of the *H. influenzae* type b vaccine in children has worked to decrease the incidence of pediatric bacterial epiglottitis by nearly 99%. Prior to widespread vaccination, *H. influenzae* was the leading cause of bacterial meningitis in children and a frequent cause of pneumonia, epiglottitis, and septic arthritis. Health care providers should counsel parents regarding the dangers of *H. influenzae* and

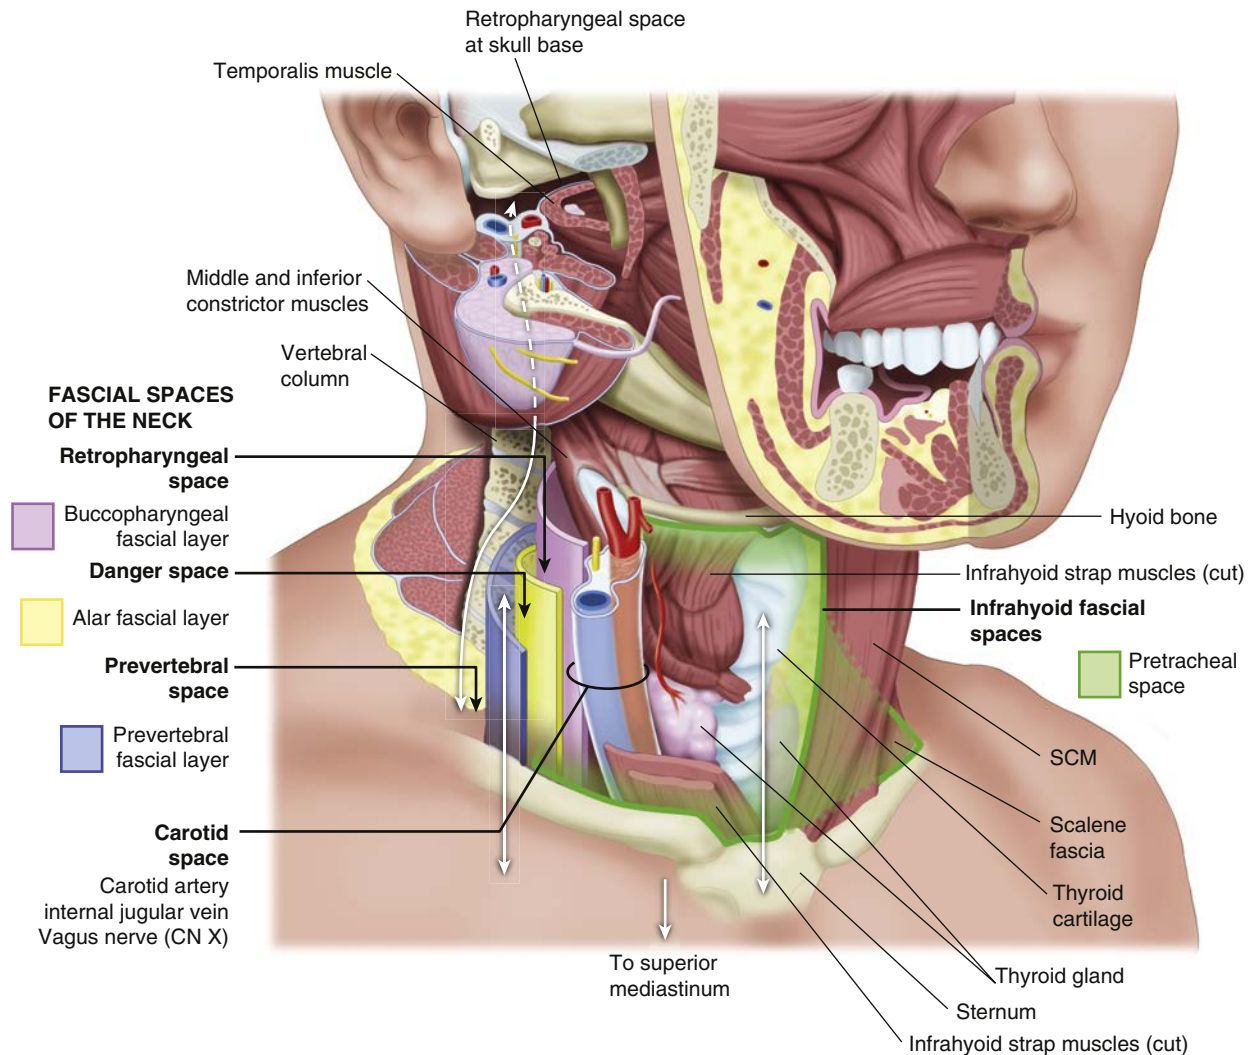

Fig. 93.2 Fascial spaces of the neck. (From Cillo JE: Atlas of oral and maxillofacial surgery, St. Louis, 2016, Elsevier Saunders, Fig. 8-1.)

recommend vaccination starting at 2 months of age. The incidence in adults has remained stable.

Pathogenesis and Microbiology

When compared to adults, the pediatric epiglottis demonstrates a more superoanterior position, more oblique angle, and less rigid structure, which account for increased risk of airway compromise in children compared to adults. Despite vaccination, *H. influenzae* remains the most common infectious cause of pediatric epiglottitis. *S. pyogenes*, *S. pneumoniae*, and *S. aureus* have also been implicated.

Clinical Presentation

Patients may present with fever, toxic appearance, drooling, dysphagia, tripod positioning, and neck hyperextension. Of importance is the sudden onset of symptoms, typically within the preceding 24 hours along with a frequently toxic, alarming appearance. The three D's refer classically to observable drooling, dysphagia, and distress. Inspiratory stridor due to turbulent flow through swollen upper airways represents severe upper airway obstruction and impending respiratory collapse, which should prompt immediate intervention.

Treatment

Airway management is paramount and frequently requires intubation by experienced providers. Edema may present significant challenges with a low threshold to utilize fiberoptic or camera-assisted intubation techniques. After securing the airway, the patient should be admitted to the intensive care unit. Broad-spectrum, empiric antibiotics are initiated and should be narrowed following culture sensitivity and susceptibility results. Although corticosteroids may shorten ICU length of stay, evidence supporting their widespread use is lacking.

Acute Bacterial Otitis Externa

Acute localized otitis externa is usually related to *S. aureus* and represents a localized, superficial infection of the outer ear canal. Oral agents against *Staphylococcus species* are adequate. Acute diffuse otitis externa, also known as swimmer's ear, is typically due to *Pseudomonas aeruginosa*. The infection is brought on by residual water left in the ear canal, which creates a moist environment that promotes bacterial growth. These patients may progress from seemingly benign itching to an erythematous and swollen outer ear canal with pain upon manipulation of the pinna or tragus. Treatment consists of topical antibiotics such as ciprofloxacin or neomycin plus polymyxin. Patients should be

Fig. 93.3 Early appearance of a patient with Ludwig angina, who has a brawny, boardlike swelling in the submandibular spaces. (From Megran DW, Scephifele DW, Chow AW: *Odontogenic Infections, Pediatric Infectious Diseases* 3:262, 1984.)

counseled to keep ears dry after swimming or bathing and to consider preventative strategies such as acetic acid/isopropyl alcohol mixtures to assist in drying the canal.

Malignant otitis externa is a rare infection more commonly found in elderly diabetic patients. It tends to progress over weeks to months and is characterized by fever, deep ear pain, hearing loss, otorrhea, and granulation tissue on the posterior aspect of the external canal. Inciting agents are typical for the populations involved, which include the elderly, advanced diabetics, chemotherapy patients, and immunosuppressed or immunocompromised individuals. CT scan is the initial imaging modality of choice. The infection can progress to skull-based osteomyelitis and meningitis and has a significant mortality. Treatment consists of prompt surgical débridement and antipseudomonal systemic therapy.

Acute Bacterial Otitis Media

Definition and Epidemiology

Acute otitis media is a bacterial infection of the middle ear that commonly afflicts children with nearly all having at least one episode in the first 10 years of life. In fact, it is the most common pediatric bacterial infection, accounting for one fourth of all office visits, and is the second most common reason for surgery in children, only following circumcision.

Pathogenesis and Microbiology

Compared to adults, young children are more susceptible to otitis media because their eustachian tubes are shorter, wider, and more

horizontal. This disease typically progresses from eustachian tube obstruction during or following a viral respiratory tract infection, causing middle ear effusion. Bacteria then colonize the middle ear and cannot be eliminated. The most common bacterial pathogens are *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*.

Clinical Presentation

Acute bacterial otitis media presents with otalgia in the majority of patients as well as otorrhea and fever. The diagnosis can be difficult in young children because the history may be absent or inaccurate. Physical exam may reveal a middle ear effusion with a bulging tympanic membrane. Additionally, mobility of the tympanic membrane is imperceptible or absent by insufflation. Over time, perforation, drainage, fever, and decreased hearing may develop. Patients may also experience vertigo, tinnitus, and nystagmus. The course of otitis media is usually self-limited with most cases resolving within 1 week.

Treatment

Treatment has been controversial because for most patients otitis media is self-limiting. Inappropriate antibiotic use has resulted in the development of resistant organisms in the United States. Although antibiotics may shorten the course of the disease and may prevent complications such as mastoiditis, facial palsy, abscess, or meningitis, convincing data are lacking because the incidence of these complications is low.

Guidelines recommend the use of antibiotics in otitis media for high-risk patients such as those who are immunocompromised and for patients in whom there is complicated disease. If symptoms persist or worsen over 48 to 72 hours, then antibiotics should be initiated.

Despite higher rates of resistance to penicillin in recent years, amoxicillin or amoxicillin-clavulanate remains first-line therapy. Alternative choices include cephalosporins or macrolide antibiotics. There is no role of prophylactic antibiotics in reducing the frequency of recurrent acute otitis media.

Infections of the Lower Respiratory Tract

John R. Lonks, Edward J. Wing

DEFINITION AND EPIDEMIOLOGY

Pneumonia, inflammation of the lung parenchyma, is usually caused by an acute infection. When the disease onset occurs outside of the hospital, it is referred to as community-acquired pneumonia (CAP). CAP ranges in severity from a mild self-limited disease to one that is fatal. CAP is common. Most patients with pneumonia are treated in the outpatient setting. Additionally, pneumonia is one of the most common reasons for hospitalization among all age groups and accounts for approximately 1 million hospitalizations per year. Each year approximately 50,000 people in the United States die from lower respiratory tract infections. Influenza and pneumonia are the leading cause of death due to infection and the eighth most common cause of death overall.

Numerous microorganisms cause pneumonia including bacteria, viruses, mycobacterium, and fungi. These infecting agents range from microorganisms that are part of the normal flora to exogenous microorganisms that are inhaled. Additionally, there are noninfectious diseases that can mimic pneumonia. The incidence of pneumonia is lowest during early adulthood and increases with each decade of life (Fig. 94.1).

PATHOLOGY

Bacterial pneumonia usually causes lobar pneumonia, consolidation of an entire lobe or a large portion of a lobe, or bronchopneumonia, patchy consolidation of the lung. Pneumococcal lobar pneumonia has 4 stages of the inflammatory response: consolidation, red hepatization, gray hepatization and resolution. The initial congestion is characterized by fluid, with some neutrophils and bacteria, filling the alveoli. Red hepatization is characterized by red blood cells along with numerous neutrophils and fibrin filling the alveoli. With gray hepatization there is breakdown of red blood cells and persistence of fibrin and neutrophils. Then the consolidated exudate within the alveolar spaces undergoes resolution.

Pathophysiology

The lower respiratory tract is virtually sterile. Normal host defenses that protect against pneumonia include mucous production and cilia; in combination these form the mucociliary escalator, which removes microorganisms from the lungs. Impairment of host defenses predisposes to the development of pneumonia. Loss or suppression of the cough reflex due to stroke and other neurologic diseases, drugs and alcohol, aging and associated medical illnesses, and environmental factors such as smoking and respiratory irritants impairs ciliary function and increases the likelihood of developing pneumonia. Mechanical obstruction of an airway such as by a tumor or foreign body leads to decreased clearance of microorganisms and may produce

a postobstructive pneumonia. Those infected with HIV virus are at increased risk of developing pneumococcal pneumonia.

The two main mechanisms of entry of microorganisms into the lung are microaspiration of organisms that colonize the upper respiratory tract and inhalation of airborne particles that contain a pathogenic microorganism. When a sufficient inoculum enters the lung and normal host defenses are not able to clear the inoculum, subsequent bacterial replication leads to a lower respiratory tract infection.

Transmission of Respiratory Pathogens

Some pathogens are transmitted from person to person via droplet transmission. Droplets are created when a person coughs, sneezes or talks. Additionally, transmission can occur during medical procedures such as suctioning, endotracheal intubation, cardiopulmonary resuscitation or cough-producing procedures. The greatest distance of transmission is unresolved. Historically, a distance of less than or equal to 3 feet was used for person-to-person droplet transmission. Some data suggest that transmission may occur from as far as 6 feet. Respiratory droplets have also been defined by their size, usually greater than 5 μm in diameter. Pathogens that are transmitted via the droplet route include *S. pneumoniae*, *M. pneumoniae*, and influenza virus. Crowding such as occurs in prisons, barracks, and shelters is associated with increased spread. Infectious agents such as *Mycobacterium tuberculosis*, fungi, and anthrax spores are transmitted via airborne transmission. Microorganisms transmitted in this fashion can be spread over long distances (>6 feet) by air currents and normal airflow. The size of the droplet nucleoli particles that are transmitted via the airborne route are generally less than or equal to 5 μm in diameter.

Specific Etiologic Agents

Many bacteria and viruses cause pneumonia. *Streptococcus pneumoniae* (pneumococcus) is the most common cause of bacterial pneumonia. The classical description of pneumonia is based upon disease caused by *S. pneumoniae*. Hence, *S. pneumoniae* causes “classical” or “typical” pneumonia. Most cases of pneumococcal pneumonia occur between December and April. Pneumococci transiently colonize the upper respiratory tract. Microaspiration leads to entry into the lower respiratory tract. If aspirated in sufficient quantity so that normal host defenses do not clear the bacteria, the patient then develops pneumonia. Pneumococci have a polysaccharide capsule that prevents phagocytosis. Antibodies, acquired from prior exposure or vaccination, against the polysaccharide capsule opsonize pneumococci thus allowing phagocytosis. Other bacteria that can colonize the oropharynx and cause pneumonia when aspirated include *Haemophilus influenzae*, less commonly *Staphylococcus aureus*, and rarely *Streptococcus pyogenes* (group A streptococcus). Similarly, *Moraxella catarrhalis* in patients with chronic obstructive

Fig. 94.1 Rate of hospitalization for pneumonia by age group. PCV7, Pneumococcus conjugate vaccine. (Data from New England Journal of Medicine 369: 155-63, 2013.)

pulmonary disease (COPD) and the elderly and *Klebsiella pneumoniae* in alcoholics colonize the oropharynx and can cause pneumonia. Most cases of community-acquired pneumonia are monomicrobial.

Patients with pneumococcal pneumonia can develop infections at other sites including empyema, pericarditis, meningitis, endocarditis, and septic arthritis. Approximately one out of five patients with pneumococcal pneumonia have bacteremia.

Mycoplasma pneumoniae usually causes milder disease. Its peak incidence is during the first two decades of life. Patients usually do not require hospitalization; however, some patients can develop severe disease.

Chlamydia pneumoniae is a common cause of community-acquired pneumonia. It usually causes a milder disease and hence is seen more commonly among patients treated in the outpatient setting.

Legionella, an environmental organism, can cause pneumonia. *Legionella pneumophila* is the most common species to cause pneumonia. Other *Legionella* species such as *L. micdadei*, *L. bozemanii*, and others can also cause pneumonia. Most cases are sporadic. Outbreaks have occurred from contaminated point sources such as cooling towers and air conditioning units. Transmission is usually due to inhalation of aerosol particles; microaspiration of water containing *Legionella* has also occurred.

Staphylococcus aureus infrequently causes bacterial pneumonia, sometimes as a complication of influenza infection. More recently, community acquired methicillin-resistant strains (MRSA) have caused secondary bacterial pneumonias.

The etiology of CAP requiring hospitalization in adults is changing. More recently, the most commonly identified organisms, in order of decreasing frequency, are human rhinovirus followed by influenza, *Streptococcus pneumoniae*, human metapneumovirus, and respiratory syncytial virus. This change may be due in part to decreased invasive pneumococcal disease after the introduction of the conjugate vaccine, changes in the age distribution of patients and underlying illnesses of the adult population, as well as the ability to detect viral pathogens.

Rapid molecular techniques are now available for the detection of respiratory viral pathogens. The rapid identification of a virus can avoid the unnecessary use of antibiotics. A small subset (approximately 10%) of hospitalized patients with viral pneumonia are coinfecting with a bacterium. This may occur because of damage to the respiratory epithelium caused by viral infection. Additionally, dysfunctional innate immune responses caused by a viral infection have been implicated to enhance susceptibility to secondary bacterial infection.

Fungi that cause pneumonia are not part of the normal flora. Certain dimorphic fungi (*Histoplasma capsulatum*, *Coccidioides immitis*, and

Blastomyces dermatitidis) that reside in the soil cause pneumonia when inhaled. Dimorphic fungi form hyphae at ambient temperatures and yeasts at body temperature. The hyphal form and not the yeast form is the transmissible form of the fungus. The yeast form is not transmissible person to person. These fungi are limited to certain geographic areas: *Histoplasma capsulatum* in the Mississippi, Missouri, and Ohio river valleys; *Coccidioides immitis* in the southwestern United States; and *Blastomyces dermatitidis* in parts of the midwestern, south-central and southeastern regions of the United States. *H. capsulatum*, *C. immitis*, and *Blastomyces dermatitidis* cause disease in the normal host. *Aspergillus*, a mold ubiquitous in the environment, rarely if ever causes disease in the immunocompetent host. Patients that are immunocompromised or have abnormal airways are at risk of infection with *Aspergillus* and rarely other molds such as Zygomycetes (*Mucorales*). *Pneumocystis jirovecii*, an opportunistic fungus, causes pneumonia in immunocompromised patients such as those with lymphoma or HIV (see Chapter 103 for additional information).

Mycobacterium tuberculosis is not part of the normal flora. It is transmitted via small aerosol particles (<5 μm) that are inhaled directly into the alveolus. *M. tuberculosis* is a slow growing organism and usually causes chronic symptoms; however, it rarely can present acutely.

The normal flora of an acutely ill hospitalized patient is different from a healthy outpatient. Hospitalized patients are more frequently colonized with *S. aureus*, including methicillin-resistant strains, and gram-negative bacilli, including *Pseudomonas aeruginosa*. Hence, when a hospitalized patient aspirates their own oropharyngeal flora leading to hospital-acquired pneumonia (HaP) it may contain one of these organisms.

Some microorganisms almost never cause pneumonia; these include *Candida* species and enterococci.

CLINICAL PRESENTATION

Patients usually present with the acute onset of fever, chills, cough, sputum production, dyspnea, and sometimes pleuritic chest pain. Classically, patients may produce blood-tinged sputum that appears rust-colored specifically when infected with *S. pneumoniae*. Extrapulmonary signs and symptoms may include nausea, vomiting, diarrhea, abdominal pain, headache, confusion, arthralgia, myalgias, and change in mental status. Signs and symptoms can be blunted or absent in the elderly. Rales or rhonchi may be present on auscultation of the chest. Patients usually have a leukocytosis with left shift. Pulmonary signs and symptoms in combination with a new infiltrate on chest radiograph are used to diagnose pneumonia.

DIAGNOSIS

When pneumonia is suspected, the next step is to determine the etiologic diagnosis. Unfortunately, there is no single diagnostic test with a high sensitivity and high specificity. The sputum gram stain provides useful diagnostic information. Although epithelial cells from the upper respiratory tract and oropharyngeal flora may “contaminate” an expectorated sputum sample, careful examination of the sputum gram stain can reveal an area of the specimen that originated from the lower respiratory tract and examination for bacteria in that area can be helpful. Unfortunately, some patients do not produce sputum. Additionally, prior antibiotics can alter sputum results.

S. pneumoniae is a gram-positive coccus that forms pairs and chains; the cocci are sometimes pointed at one end (“lancet-shaped”). *H. influenzae* is a pleomorphic gram-negative rod. *S. aureus* is a gram-positive coccus that forms clusters. *M. catarrhalis* is a gram-negative diplococci. These distinct morphologic features allow for a presumptive diagnosis of a specific etiologic agent when seen on a gram stain of sputum (Fig. 94.2).

Mycoplasma, *Legionella*, *Mycobacterium*, and *Chlamydia* are not seen on sputum gram stain. *Mycobacteria* are seen with special staining (acid fast).

Fig. 94.2 Sputum Gram stain. (A) *Streptococcus pneumoniae*. (B) *Haemophilus influenzae*. (C) *Moraxella catarrhalis*. (D) *Staphylococcus aureus*.

Culture of sputum can reveal the etiologic diagnosis and should be correlated with findings on the sputum gram stain. However, pneumococci are fastidious. A study of patients with bacteremic pneumococcal pneumonia found that only 55% grew pneumococci from their sputum culture. *Mycoplasma*, *Legionella*, *Mycobacterium*, and *Chlamydia* do not grow on routine agar. Special culture media are required for certain bacteria, such as Lowenstein-Jensen for *Mycobacteria* and buffered charcoal yeast extract (BCYE) for *Legionella*.

Blood cultures can be helpful. However, the ratio of bacteremic to nonbacteremic pneumococcal pneumonia is approximately 1:4. A positive blood culture is very helpful because the etiologic agent is definitely identified and susceptibility data are available to determine appropriate therapy.

Other diagnostic studies used to identify the causative organism include *Legionella* urinary antigen, histoplasmosis urinary antigen, and polymerase chain reaction (PCR) for respiratory viruses, *Mycoplasma*, and *Chlamydia*.

Chest radiography of patients with pneumococcal pneumonia can show a consolidative lobar infiltrate, a bronchopneumonic (patchy) pattern or, less commonly, an interstitial pattern. A definitive etiologic diagnosis cannot be made based on chest radiograph appearance.

DIFFERENTIAL DIAGNOSIS

Not all patients with fever and a new pulmonary infiltrate have pneumonia. Noninfectious causes of pulmonary infiltrates and fever include pulmonary infarction, vasculitis (granulomatosis with polyangiitis), drug reaction, tumor, congestive heart failure, cryptogenic organizing pneumonia (COP), hypersensitivity pneumonitis, collagen vascular disease, aspiration (macroaspiration) of oropharyngeal or upper gastrointestinal contents, and acute respiratory distress syndrome (ARDS).

TREATMENT

The definitive treatment for pneumonia is to eradicate the infecting microorganism. Antibiotics are used to kill bacteria and hence decrease or stop the spread of infection in the lungs. Normal host responses are needed to repair the inflammatory process in the lungs. Penicillin therapy reduced the mortality rate of bacteremic pneumococcal pneumonia from 84% to 17%. However, antibiotics have little to no effect on mortality during the first 5 days of illness; those destined to die during the first 5 days of illness die whether or not they receive antibiotics.

When an etiologic agent is identified, then the appropriate antibiotic can be given (Table 94.1). When a specific etiologic diagnosis is not made, then empiric treatment with one of many different antimicrobial agents has been recommended. Guidelines are available (IDSA available at <https://www.atsjournals.org/doi/full/10.1164/rccm.201908-1581ST>).

The decision to admit a patient with pneumonia is based upon clinical prediction rules. These rules use mortality and sometimes other factors to stratify patients. The pneumonia severity index (PSI) stratifies patients into one of five risk groups. Those in a low risk group are treated as outpatients while those in a higher risk group are admitted to the hospital for treatment (see *The New England Journal of Medicine* 336: 243-250, 1997). The CURB-65 score (see *Thorax* 58: 377-382, 2003) is easier to calculate but has not been as rigorously validated as the PSI. Furthermore, psychosocial and other factors that impact the decision to admit a patient are not included by PSI or CURB-65.

Duration of therapy ranges from 3 to 28 days depending on the microorganism and clinical response. The shortest duration (3 days) has been given to patients with pneumococcal pneumonia while 28

TABLE 94.1 Treatment of Pneumonia by Specific Etiologic Agent

Etiologic Agent	Preferred Antimicrobial	Alternative Antimicrobial
<i>Streptococcus pneumoniae</i>	Penicillin	Cephalosporin, moxifloxacin, levofloxacin
<i>Haemophilus influenzae</i>	Cefuroxime, ceftriaxone	
<i>Mycoplasma pneumoniae</i>	Macrolide	Moxifloxacin, levofloxacin
<i>Legionella</i>	Macrolide or quinolone	
<i>Staphylococcus aureus</i>

TMP/SMX, Trimethoprim/sulfamethoxazole

days of therapy has been given to patients with *Staphylococcus aureus*. Recent ATS/IDSA guidelines (<https://www.atsjournals.org/doi/full/10.1164/rccm.201908-1581ST>) recommend no less than 5 days of treatment.

PROGNOSIS

Patients with bacteremic pneumococcal pneumonia have a higher mortality rate (21%) compared to those with nonbacteremic pneumococcal pneumonia (13%). Among patients with bacteremic pneumococcal pneumonia, increased mortality is associated with increasing age (Fig. 94.3), number of lobes involved (one lobe 12% mortality, two lobes 24% and three lobes 63%), leukopenia (mortality 35%), normal peripheral white blood cell count (24%) as compared to patients with leukocytosis (14%). Additionally, mortality rates differ for each capsular type of pneumococcus. For example, the mortality rate among patients infected with type I capsular type is 3% compared to patients infected with capsular type III 22%. Patients who survive usually recover without sequelae.

PREVENTION

Influenza vaccine not only protects against influenza but also bacterial pneumonia since patients who do not have influenza are not at risk of developing secondary bacterial pneumonia. The 23-valent pneumococcal polysaccharide vaccine is recommended for adults 65 years and older (see *Morbidity and Mortality Weekly Report Supplement*/Vol. 62, pages 9-18, February 1, 2013 and *Morbidity and Mortality Weekly Report* Vol. 68, No. 46, pages 1069-1075, 2019). The conjugate pneumococcal vaccine has reduced invasive pneumococcal disease in both the recipients (children) as well as adults (Fig. 94.4). By decreasing carriage in children, there is a reduction in transmission to adults and subsequent adult disease. The pediatric conjugate vaccine has reduced the number of adult admissions for pneumonia (see Fig. 94.1). Additionally, the conjugate vaccine has decreased antibiotic resistance since the capsular types of pneumococci that are more likely to be antibiotic resistant are included in the vaccine.

TUBERCULOSIS

Definition

Tuberculosis (TB) is caused primarily by *Mycobacterium tuberculosis* (MTB), an acid-fast rod that has a slow generation time. Related species include *Mycobacterium bovis* that causes disease in cattle but can infect humans and *Mycobacterium africanum* that causes up to 50% of cases of tuberculosis in Africa. TB primarily causes pulmonary disease but can cause infection in almost any part of the body including

Fig. 94.3 Mortality from bacteremic pneumococcal pneumonia by age group. (Data from *Annals of Internal Medicine* 60: 760-776, 1964.)

Fig. 94.4 Incidence of penicillin-resistant pneumococci by year for different age groups. (Data from *New England Journal of Medicine* 354: 1455-63, 2006.)

bone, the central nervous system, the gastrointestinal system, and the cardiovascular system. TB is characterized by asymptomatic, lifetime latency for up to 90% of infected individuals. Primary progressive infection typically occurs in 4% to 5% of patients up to 2 years after infection whereas reactivation disease occurs often decades after infection.

Epidemiology

MTB has caused infection in humans throughout history but became widespread during urbanization and industrialization in Europe in the 18th century, causing up to one quarter of all deaths. Rates of

tuberculosis began falling in the late 19th and early 20th century and the fall was accelerated by the discovery of effective antibiotics, first streptomycin in 1946, and then isoniazid in 1952. Rates in the United States fell until the 1980s when they increased due to HIV and increased intravenous substance use. With effective antiretroviral therapy, the downward trend returned. For example, the incidence in the United States fell from 25,000 cases in 1993 to 9025 cases in 2018. Seventy percent of cases occurred in non-US-born people and approximately half were diagnosed 10 or more years after arriving in the United States, consistent with reactivation of previously acquired tuberculosis. There is a preponderance of cases in ethnic and racial minorities including Hispanic, American Indian/Alaska native, Asian, and Black individuals. Risk factors include diabetes mellitus, alcohol and substance abuse, HIV, homelessness, and incarceration.

Infection occurs when MTB is aerosolized by coughing, sneezing, shouting or singing from a patient with pulmonary disease and inhaled by a susceptible individual. Small infectious particles 1 to 5 μm in size can persist in the air, particularly in enclosed spaces, and very few infectious particles are required for infection. Household contacts are particularly at risk, with up to 50% becoming infected. Group home settings such as homeless shelters and prisons have been the sites of outbreaks.

Worldwide, TB is among the top ten causes of death and the number one cause of death due to an infection. In 2018, 10 million people contracted tuberculosis and 1.5 million died, including 251 thousand with HIV. Encouragingly, the TB mortality rate fell by 42% from 2000 to 2018. Four hundred eighty four thousand fell ill with drug-resistant tuberculosis (multidrug resistant or MDR defined as resistant to the two most effective drugs, INH and rifampin), and 6.2% of those had XDR-TB (defined as resistant to INH, rifampin, a fluoroquinolone, and second-line injectable drugs). Sixty-six percent of new cases occurred in India, China, Indonesia, the Philippines, Pakistan, Nigeria, Bangladesh, and South Africa. Rapid diagnostic tests (e.g., Xpert MTB/RIF) assays are in widespread use, and the global treatment success in 2017 of newly diagnosed cases was 85%. Newer drugs such as bedaquiline are coming into use for resistant TB. Furthermore, there are currently 14 vaccines in clinical trial.

Microbiology

MTB is an aerobic, nonmotile mycobacteria in the family Mycobacteriaceae with a cell wall content high in high-molecular-weight lipids. It has a slow multiplication time, between 15 to 20 hours, compared to most bacteria, which multiply in less than 1 hour. Humans are the only host. The organism can be identified in sputum by acid-fast staining (Ziehl-Neelsen or Kinyoun) or nucleic acid amplification, which is more common. Xpert MTB/RIF is an automated test that identifies MTB and whether the organism is resistant to rifampin, one of the most commonly used and effective anti-TB drugs. Growth on solid media occurs in 3 to 8 weeks whereas growth in liquid media takes up to 20 days. Culture of the organism is necessary to identify the full susceptibility of an isolate.

Pathobiology

Infection occurs when infectious particles reach the alveoli and are ingested by macrophages. MTB can resist destruction by macrophages and neutrophils and persist within phagosomes and multiply intracellularly, in part due to protective mechanisms such as the production of superoxide dismutase, which can neutralize the production of the bactericidal molecule superoxide anion. In addition, the mycobacteria appear to delay antigen presentation and the onset of immune cell responses mediated by CD4⁺ T lymphocytes for 4 to 8 weeks. Infected macrophages produce cytokines that attract monocytes, other alveolar

macrophages, and neutrophils. Eventually, delayed hypersensitivity as a measure of specific T cell immunity can be detected. Macrophages activated by T cell-produced cytokines such as gamma interferon result in a tuberculous granuloma containing Langhans giant cells—fused macrophages forming around tuberculous antigen. A form of incomplete necrosis can occur termed “caseous necrosis.” If the bacterial replication is not controlled initially at the site of infection, the bacilli enter local draining lymph nodes. This leads to lymphadenopathy, a characteristic manifestation of primary TB. The lesion produced at the initial site of lung infection and lymph node involvement is called the Ghon complex (Fig. 94.5). Further dissemination may occur through the bloodstream.

In 90% of individuals the infection will be contained for their lifetime, although viable organisms persist, and the infection will be labelled latent TB or LTBI (Fig. 94.6). In 4% to 5% of individuals, mycobacteria will continue to multiply and spread within the lung and through the bloodstream to other sites, resulting in symptomatic infection usually within 1 year of infection. This is termed primary infection. In another 5% of people who have LTBI, reactivation will occur years later, sometimes triggered by the development of an immunocompromised state such as HIV or older age. A typical site is the posterior apical region of the lungs. Patients with LTBI have a very low number of organisms and do not transmit to other people.

Diagnosis

The diagnosis of LTBI depends on a positive QuantiFERON-TB Gold test (IGRA), which is an in vitro ELISA interferon release assay to MTB antigens, or a positive tuberculin skin test. The Mantoux skin test is an intradermal injection of 0.1 mL of purified protein derivative (PPD) tuberculin into the forearm. The diameter of induration at the injection site is measured 48 to 72 hours later. Both tests have a high sensitivity to previous infection (approximately 90%), but both may be negative in active disease. The IGRA test has the advantages of not requiring a second visit, not being reactive in individuals who had previously received bacillus Calmette-Guérin (BCG) vaccine, and not being dependent on the subjectivity of measurement.

The diagnosis of active TB depends on the identification of the organism in sputum, other body fluids such as cerebrospinal fluid (CSF) or urine, or in tissue as well as growth of MTB in culture. The mycobacteria can be identified as small, beaded rods that are acid fast by Ziehl-Neelsen or Kinyoun stain. Nucleic acid amplification testing (NAAT) is superseding older staining techniques because of its ease of testing and accuracy. One example is Xpert MTB/Rif testing, which can also give information on resistance. Other helpful clinical information for making the diagnosis includes history (e.g., chronic cough, fever and night sweats, weight loss), potential exposures (e.g., household contact or country of origin), imaging (e.g., chest radiograph showing posterior upper lobe infiltrates with or without cavitation), and laboratory data (e.g., anemia of chronic disease).

Neither tuberculin skin testing nor IGRA distinguish between active disease and latent infection. Additionally, patients with primary infection or reactivation may be anergic and have a negative test. Patients who are latently infected have a positive test but do not have active disease (no signs or symptoms).

Clinical Manifestations

Primary Infection

Primary infection with MTB is usually asymptomatic, although mild symptoms with fever, cough, and mid-lung field infiltrates may occur. With the onset of specific immunity as indicated by conversion of TB skin test or IGRA test, symptoms resolve and the patient may be left with a small parenchymal scar.

Fig. 94.5 (A) Ghon complex. (B) Moderately advanced pulmonary tuberculosis (TB). (C) Far advanced pulmonary TB. (D) Pulmonary (*left*) and extrapulmonary (*right*) TB.

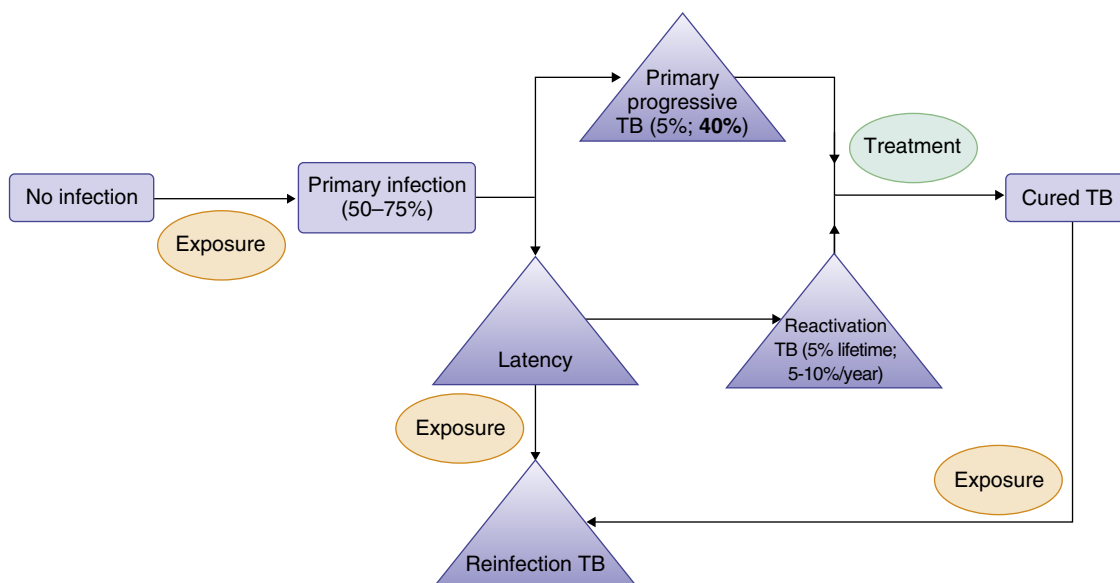

Fig. 94.6 Natural history of TB. The proportion of individuals affected is shown in parentheses. Bolded figures are for HIV infection with severe immunosuppression. A number of medical risk factors besides HIV promote progression from *Mycobacterium tuberculosis* infection to disease.

In approximately 4% to 5% of cases, the infection progresses within 1 to 2 years, manifesting as pulmonary infection either at the original site of infection or in the upper lobe as infiltrates with eventual cavitation. It is termed progressive primary tuberculosis. In high-incidence countries, most cases of pulmonary TB stem from progressive primary infection. In children particularly, hilar or mediastinal lymphadenopathy may be prominent and disseminated disease may occur manifesting as miliary TB or tuberculous meningitis. Young children, the elderly, and those who are immunocompromised (e.g., HIV) are most at risk for progressive primary disease.

Reactivation Infection

After 2 years, but often after decades, despite specific immunity, reactivation of previously latent foci of infection may occur, usually occurring as pulmonary disease. Patients may be asymptomatic with only radiograph findings of upper lobe infiltrates with or without cavitation (see Fig. 94.5). Patients give a history of chronic symptoms, usually greater than 3 weeks, of cough, fever, fatigue, night sweats, and weight loss. Hemoptysis and pleuritic chest pain occur in more advanced disease. Physical examination is often unrevealing. Fine, post-tussive rales may be heard at the apices. Chest radiograph findings are often more extensive than indicated by physical examination. Normocytic, normochromic anemia and hypoalbuminemia are typical for chronic disease. Classically, infiltrates and cavitation are seen in the posterior segment of an upper lobe or the apex of a lower lobe. Initially, cavities are thin walled without fluid but progress to thick-walled cavities. Patients who are immunocompromised, such as those with HIV, may have atypical findings with prominent lymphadenopathy or pulmonary infiltrates throughout the lungs. Patients with TB and cavities are highly infectious and should be placed in isolation immediately.

Extrapulmonary TB

Extrapulmonary TB usually results from a focus of organisms that have spread to extrapulmonary sites by either the bloodstream or lymphatics during initial phases of infection.

Pleural TB usually occurs 3 to 6 months after primary infection when a pleural-based nodule ruptures into the pleural space, producing pleuritic chest pain and a pleural effusion. There are few organisms in the pleural fluid. Pleural TB usually resolves spontaneously within months but is associated with a higher rate of subsequent active TB.

Miliary TB occurs when MTB disseminates widely in the bloodstream, often with nonspecific symptoms of fever, malaise, weight loss, and night sweats without localizing signs. Chest radiograph or CT scan, which has greater sensitivity, may show many small opacities up to 1 mm in size, resembling millet seeds—hence the name miliary—throughout all lung fields. Risk for dissemination is greatest in the very young, very old, and those who are immunocompromised. Physical examination may reveal lymphadenopathy and hepatosplenomegaly. Laboratory abnormalities may include anemia, a leukemoid reaction, and abnormal liver function tests. Mortality is high if the diagnosis and treatment are delayed.

Tuberculous meningitis typically presents over the space of several weeks with fever, stiff neck and headache. Cranial nerve abnormalities such as a VI nerve palsy may be seen. The CSF is characterized by a lymphocytic cell response, low sugar, and high albumin. Mortality is high, particularly if patients present with a prolonged course and have altered consciousness and neurologic findings.

Vertebral TB (also known as Pott disease) involves two adjacent vertebrae with destruction of the intervening disc in the lower thoracic or lumbar spine (see Fig. 94.5). Paraspinal abscess develops frequently. The differential diagnosis includes staphylococcal vertebral osteomyelitis. Bone biopsy may be necessary to establish the diagnosis.

Tuberculous peritonitis is characterized by fever, weight loss, and abdominal pain, either chronic or acute. Peritoneal fluid is exudative but there are few organisms. Mesenteric lymphadenopathy may be prominent. Diagnosis may be made by PCR or biopsy of the peritoneum.

Renal TB is frequently asymptomatic, the only clue being persistent sterile pyuria or hematuria. CT imaging shows cortical scarring and ureteral strictures. Cultures of the urine are positive.

Patients with untreated HIV and low CD4 T cell counts, particularly in endemic regions of the world, are at high risk for acquiring HIV and having disseminated, rapidly advancing TB with high mortality. Clinicians should have a high degree of suspicion for TB and other mycobacterial disease in AIDS patients.

Treatment and Prevention

TB requires prolonged therapy because of the slow multiplication rate of the mycobacteria. Also, multiple drugs are used to treat active TB because of the high rate of resistance each MTB population has to any one drug and because of the increasing rate of resistance of MTB worldwide. Since adherence is critical to successful therapy and prevention of resistance, direct observed therapy (DOT) is recommended for most patients.

Guidelines for treatment can be found at the American Thoracic Society/Centers for Disease Control and Prevention and the Infectious Diseases Society of America: Treatment of Drug-Susceptible Tuberculosis (2016). Initial treatment for most forms of TB in the United States includes isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months and then isoniazid and rifampin for 4 to 6 months longer.

Regimens need to be adjusted for resistance and if there is resistance, it is important to never add one drug to a failing regimen. Treatment of MDR TB is much more difficult and usually includes five drugs to which the isolate is susceptible. This usually includes first-line drugs to which the organism is susceptible, a fluoroquinolone, an injectable such as amikacin, and second-line drugs such as ethionamide or PAS. Newer drugs such as bedaquiline, an ATP inhibitor, have been approved for treatment of MDR-TB. Guidelines for treatment of drug-resistant tuberculosis were published in 2019. Treatment of extensively drug resistant TB (XDR-TB) is based on resistant-based testing and often uses drugs such as linezolid and clofazimine.

Treatment of LTBI requires exclusion of active disease. Prevention is targeted towards those who have recent MTB infection and those with a significant risk factor or comorbidities such as HIV or diabetes. LTBI is treated with a single drug because there are so few organisms within the body that it is unlikely that there is a preexisting spontaneous drug-resistant mutant. Standard regimens include isoniazid alone for 6 or 9 months or rifampin alone for 4 months.

Prognosis

The prognosis for early primary and reactive pulmonary TB with appropriate treatment is excellent. Advanced disease, central nervous system and miliary disease, disease in immunocompromised patients, and disease in those with MDR and XDR-TB have a more guarded prognosis.

Infections of the Heart and Blood Vessels

Raul Macias Gil, Cheston B. Cunha

INFECTIVE ENDOCARDITIS

Definition

Infective endocarditis (IE) is an infection of the endocardium involving one or more cardiac valves or, less commonly, the mural endocardium. The pathologic lesion of IE is the vegetation (infected platelet and fibrin thrombus). The pathologic findings of IE were first described in 1646 by Lazare Rivière, a French physician at the University of Montpellier. At autopsy, Rivière described “small round outgrowths resembling the lungs in texture, the largest of which was about the size of a hazelnut, which blocked the aortic valve.” The term *endocarditis* was first used in 1835 by the French physician Jean-Baptiste Bouillaud, but it was not until the 1880s that Sir William Osler was able to synthesize many of the prior clinical, pathologic, and microbiologic findings into a unified description of the disease.

Over the past 6 decades, the epidemiology, risk factors, and treatment of endocarditis have changed significantly. In the pre-antibiotic era, IE was uniformly fatal. Since the advent of antibiotics and valve replacement surgery, IE can be effectively treated and mortality can be significantly reduced, provided the diagnosis is made early. Despite progress, new challenges continue to arise in diagnosis and treatment. As more patients undergo intravascular manipulation, have intracardiac or intravascular devices placed, and harbor more resistant organisms, effective therapy for IE remains a challenge.

Traditionally, IE has been classified, based on the acuteness of onset, as subacute bacterial endocarditis (SBE) or acute bacterial endocarditis (ABE). This classification reflects the virulence of the causative agent: *Staphylococcus aureus* is a common cause of ABE, whereas low-virulence organisms such as viridans streptococci are more likely to be the cause of SBE. IE may also be subdivided according to the nature of the involved valve, as native valve endocarditis (NVE) or prosthetic valve endocarditis (PVE), or by the number of valves involved (multivalvular IE). IE from invasive procedures is classified as health care–associated IE or nosocomial IE. Endocarditis may be further divided according to the causative organism. These categories are often combined (e.g., *S. aureus* tricuspid valve nosocomial ABE).

Epidemiology

SBE is most common in older adults, and over the last 50 years, the average age of patients diagnosed with IE has gradually increased. More than one half of all cases of IE occur in patients older than 50 years of age. Rheumatic heart disease has decreased in the modern era and is now a less common predisposing factor.

While the incidence of IE can have geographic variations in the United States, the overall annual incidence is approximately 12.7 cases per 100,000 persons. A significant increase from prior years has been

seen in the elderly, but also in younger patients. Multiple studies have shown that this increase in the incidence of IE could be explained by the alarming numbers of intravenous drug users from the current opioid epidemic in the United States. The age-adjusted hospital admission rate has increased by 2.4% annually, mirroring this increase in incidence. SBE usually involves the mitral valve or, less commonly, the aortic valve. IE of the pulmonic valve is relatively rare, and right-sided ABE occurs primarily in intravenous drug abusers. Individuals with congenital heart disease may be predisposed to IE, depending on the lesion.

Pathogenesis

Normal cardiac endothelium is relatively resistant to bacterial invasion. If the cardiac endothelium is damaged, an uninfected platelet and fibrin thrombus may form. This nonbacterial thrombotic endocarditis may become infected due to bacteremia, forming a vegetation. Endothelial damage may result from degenerative valvular disease, rheumatic heart disease, congenital heart disease, or intracardiac instrumentation or devices.

Predisposing Cardiac Factors

Approximately 15% of patients diagnosed with NVE have underlying congenital heart disease. Of these diseases, tetralogy of Fallot has the highest IE potential. Other lesions that predispose to IE include ventricular septal defect, bicuspid valves, and coarctation of the aorta. Significant mitral valve regurgitation is the most important predisposing factor for IE, with mitral valve prolapse accounting for 20% of NVE cases. Degenerative valvular disease predisposes to SBE in the elderly, and the mitral valve is most frequently involved. Aortic valve IE is rare in hypertrophic cardiomyopathy or asymmetric septal hypertrophy.

Noncardiac Predisposing Factors

Some hosts, particularly intravenous drug abusers, are predisposed to IE. Illicit intravenous drug use can lead to valvular or endothelial damage. Bacteremia with skin, oral flora, or with other organisms contaminating the substance(s) to be injected can develop from the act of injecting the drug(s). Central venous catheters and intracardiac devices can cause endocardial injury, predisposing to IE. The most frequent nosocomial IE pathogens are *S. aureus*, coagulase-negative staphylococci, group D enterococci, and aerobic gram-negative bacilli. Infections with these organisms usually occur less than 1 month after the procedure. Nosocomial IE may affect normal or abnormal valves. Because ABE pathogens are more virulent, nosocomial IE is associated with a high mortality rate.

Low-virulence and noninvasive organisms (e.g., viridans streptococci) are the most common SBE pathogens. The SBE potential of

viridans streptococci is directly related to the thickness of the capsule, which permits adherence to damaged cardiac valves. Viridans streptococci are normal inhabitants of the mouth and gastrointestinal tract. Invasive dental procedures frequently cause transient bacteremias that may result in SBE on damaged but not normal cardiac valves. Transient bacteremias of viridans streptococci may form a vegetation in the sterile platelet and fibrin thrombus covering an area of damaged endothelium or intracardiac devices. The gastrointestinal or genitourinary tract is the usual source of bacteremia in cases of native valve SBE due to group D enterococci.

Diagnosis

The clinical diagnosis of IE relies on a combination of clinical, laboratory, and echocardiographic findings. Epidemiologic clues to the potential IE pathogens are outlined in [Table 95.1](#). The most important finding in IE is the demonstration of continuous bacteremia, usually by multiple positive blood cultures. [Table 95.2](#) contains the modified Duke criteria that are frequently used to predict the likelihood that a patient has IE.

Clinical Features

The cardinal clinical features of IE are fever (90% of cases) and heart murmur (85%). In the antibiotic era, fever may not be present if the patient has been taking antibiotics for another reason. Acute versus subacute presentation is determined by the virulence of the IE pathogen. SBE often manifests with sweats, malaise, and anorexia. The course of SBE tends to be more indolent and may be accompanied by back pain, joint pains (>50% of patients), or embolic stroke. As SBE progresses, circulating immune complexes may deposit in the kidney, causing interstitial nephritis, glomerulonephritis, and even renal failure. Osler nodes (painful, subcutaneous nodules on the distal pads of the fingers or toes), Janeway lesions (hemorrhagic, nonpainful macules on the palms and soles), and Roth spots (retinal hemorrhages with small central clearing) are classic findings related to microemboli and SBE immune-mediated vasculitis.

Patients with ABE tend to have a more fulminant course because of the greater virulence of the pathogen. The fever of ABE is usually high (>102° F) and is often accompanied by rigors. If there is mechanical dysfunction of the valve, symptoms of congestive heart failure will predominate. Often, a presenting feature of right-sided ABE is septic pulmonary emboli with pleuritic chest pain. The clinical findings of SBE and ABE are presented in [Table 95.3](#).

Clinically, PVE may be considered as early (<2 months) or late (>2 months) following implantation of the prosthetic valve. Early PVE is caused by virulent pathogens (e.g., *S. aureus*) that infect the prosthetic valve before endothelialization is complete. Endothelialization of a mechanical valve is partially protective against transient bacteremias in late PVE. Over time, bioprosthetic valves have the same IE potential as mechanical ones.

Early PVE pathogens such as *S. aureus* and *Pseudomonas aeruginosa* are typically highly virulent and invasive. Late PVE more closely resembles SBE, is caused by less virulent pathogens, and has a more indolent course. The most common etiologic agents are coagulase-negative staphylococci, but viridans streptococci also cause late PVE.

Nosocomial IE results from invasive intravascular or intracardiac procedures that damage the endothelium or the valves; it can also be caused by direct extension of infection, such as from ABE associated with a pacemaker wire. The organisms causing nosocomial IE originate from the skin (e.g., *S. aureus*, coagulase-negative staphylococci), from gastrointestinal or genitourinary procedures (e.g., group D enterococci), or from central venous catheters, ports, or hemodialysis catheters (e.g., *Candida* spp, aerobic gram-negative bacilli). IE related

to total parenteral nutrition (TPN) is most often caused by *Candida* spp; other TPN-associated fungemias cause IE less frequently. In intravenous drug abusers, tricuspid valve ABE is usually caused by *S. aureus* or *P. aeruginosa* (depending on the geography and drug-related materials).

An otherwise unexplained high-grade or continuous bacteremia and murmur should suggest IE. If blood cultures are negative but a murmur, vegetation, and peripheral manifestations of IE are present, a diagnosis of infectious culture-negative endocarditis (CNE) should be considered. Infectious CNE is caused by organisms that are difficult to culture, such as *Legionella* spp, *Brucella* spp, *Tropheryma whippelii*, and *Coxiella burnetii* (which produces Q fever). Legionnaires disease may cause NVE or PVE. CNE due to *Brucella* spp can be a difficult diagnosis, but an antecedent history of contact with livestock or consumption of unpasteurized dairy products should suggest the diagnosis, and echocardiography often reveals large vegetations. A difficult infectious CNE diagnosis is Q fever. Q fever SBE may be suggested by a history of animal contact. Clinical findings of Q fever are often present, but the diagnosis can be missed because Q fever vegetations are not easily visualized.

Laboratory Findings

The isolation of a microorganism(s) in blood cultures is crucial for the diagnosis and management of IE. At least two sets of blood cultures from two different peripheral veins should be obtained in patients with high suspicion for IE, especially those at high risk (e.g., PVE, intracardiac devices, prior history of IE, etc.). The likelihood of isolating a causative pathogen is higher in patients who are not actively taking or have not received antibiotics 2 weeks prior to collection of blood cultures. Most bacterial and even some fungal organisms can be isolated in standard blood cultures, except for pathogens known to cause CNE.

Diagnosis of *Legionella*-related IE is based on an antecedent pneumonia and elevated titers of urinary antigen. *Brucella*-related IE is confirmed by titers or by polymerase chain reaction or both. A clue to Q fever CNE is enhanced valve uptake on positron-emission tomography (PET) or computed tomography (CT), and such a result should prompt testing for Q fever.

With the advent of sophisticated microbiologic testing, HACEK organisms (*Haemophilus* spp, *Aggregatibacter actinomycetemcomitans* [formerly called *Actinobacillus actinomycetemcomitans*], *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) grow relatively rapidly and no longer manifest as CNE. Newer molecular-based tests using microbial cell-free DNA sequencing may allow improved diagnosis, and implementation of prompt targeted therapy.

With IE, many nonspecific laboratory abnormalities may occur ([Table 95.4](#)); when placed in the appropriate context, these can be a significant aid to diagnosis.

Imaging Studies

Echocardiography is an important element in diagnosis and management; it should be performed for all patients with suspected IE. In those with a low likelihood of having IE or small body habitus, a transthoracic echocardiogram (TTE) may be sufficient. Although TTE is often sufficient to screen for NVE, the “gold standard” remains transesophageal echocardiogram (TEE), which is more sensitive at detecting smaller vegetations, paravalvular abscess, and PVE. If the TTE or TEE demonstrates a vegetation but blood cultures remain negative, the diagnosis of infectious CNE should be considered. A tiered diagnostic approach to such cases is presented in [Table 95.5](#).

Radiologic testing in IE is primarily focused on identifying complications of IE. Although echocardiography is still the preferred method for detecting vegetations, improvements in multislice CT scans have

^bWith alcoholic cirrhosis.

allowed chest CT to detect vegetations and valvular abnormalities in addition to the septic emboli seen in right-sided IE. Magnetic resonance imaging (MRI) of the spine is useful in patients with IE who report back pain; it is the preferred method to detect the presence of vertebral osteomyelitis caused by IE. Mental status changes or new focal neurologic signs should prompt CT or MRI imaging of the head to assess for septic emboli to the brain. Although it is less invasive than TEE, cardiac MRI often lacks the special resolution to detect smaller vegetations; however, it may be helpful in identifying aortic root pseudoaneurysms, sinus of Valsalva aneurysms, and embolic vascular lesions.

Differential Diagnosis and Mimics

The diagnosis of SBE is based on otherwise unexplained high-grade or continuous bacteremia caused by a known endocarditis pathogen plus a cardiac vegetation. Depending on the duration before presentation (usually 1 to 3 months), IE may be accompanied by peripheral manifestations such as Osler nodes, Janeway lesions, splinter hemorrhages, or conjunctival hemorrhages. Splenomegaly or embolic phenomena

may also accompany SBE. However, peripheral manifestations that are seen in SBE may also be present in other disorders. Before ascribing peripheral manifestations to SBE, physicians need to rule out other systemic disorders and confirm the diagnosis of SBE.

Clinically, the disorders most likely to mimic SBE are Libman-Sacks endocarditis (associated with systemic lupus erythematosus [SLE]), marantic endocarditis (caused by a malignancy, usually lymphoma, lung cancer, or pancreatic cancer), and atrial myxoma. Myocarditis of any etiology may mimic SBE with fever, murmur, and peripheral embolic phenomena. Cardiomegaly, which is usually present with myocarditis, is typically absent with SBE. Leukopenia and thrombocytopenia may be clues to viral myocarditis, and either finding argues against a diagnosis of SBE. Cardiac echocardiography shows myocarditis but no vegetations, and bacteremia is not present.

SLE, particularly between flares, may mimic SBE with low-grade fevers, murmur, peripheral manifestations, and splenomegaly. Laboratory findings in SLE include the anemia of chronic disease and a mildly to moderately elevated erythrocyte sedimentation rate (ESR). Even if Libman-Sacks vegetations are present, SBE is rare in

TABLE 95.2 Modified Duke Criteria for Diagnosis of Infective Endocarditis**Diagnostic Criteria**

Definite IE (any of the following):

- Positive findings for IE in the pathology or microbiology of the vegetation
- Two major criteria
- One major and three minor criteria
- Five minor criteria

Possible IE (any of the following):

- One major and one minor criteria
- Three minor criteria

Not IE (any of the following):

- Definite alternative diagnosis or resolution with <4 days of antibiotic therapy
- Does not meet the criteria of possible IE

Major Criteria

Positive blood cultures for IE (any of the following):

Typical microorganism for IE from two separate blood cultures:

- Viridans streptococci, *Streptococcus gallolyticus* (formerly *Streptococcus bovis* biotype I), or the nutritional variant strains (*Granulicatella* spp and *Abiotrophia defectiva*)
- HACEK group: *Haemophilus* spp, *Aggregatibacter actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*
- *Staphylococcus aureus*

Community-acquired enterococci, in the absence of a primary focus

Persistently positive blood culture, defined as recovery of a microorganism consistent with IE from any of the following:

- Blood cultures drawn more than 12 hr apart
- All three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hr apart

^aSingle positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer >1:800

Evidence of endocardial involvement

Positive echocardiogram for IE:

^aTEE is recommended in patients with prosthetic valves rated at least "possible IE" by clinical criteria, or with complicated IE (paravalvular abscess); TTE as first test in other patients

Definition of positive echocardiogram (any of the following):

- Oscillating intracardiac mass, on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation
- Abscess
- New partial dehiscence of prosthetic valve

New valvular regurgitation (increase in or change in preexisting murmur is not sufficient)

Minor Criteria ^aEchocardiographic minor criteria have been eliminated)

Predisposition: predisposing heart condition or intravenous drug use
Fever: 38.0° C (100.4° F)

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

Microbiologic evidence: positive blood culture but not meeting major criterion (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

SLE. A lupus flare may resemble ABE with high fevers (>102° F), tender fingertips (mimicking Osler nodes), and funduscopic findings of cotton-wool spots or Roth spots. Conjunctival and splinter hemorrhages are rare in SLE but common in SBE. Microscopic hematuria is the usual renal manifestation of SBE (i.e., focal glomerulonephritis), but full-blown nephritis with proteinuria and hematuria are typical of SLE renal involvement. Although clinical findings of SLE and SBE may overlap, SBE is ruled out by the absence of high-grade or continuous bacteremia.

Atrial myxomas may mimic SBE with fever, murmurs, and embolic phenomena (e.g., splinter hemorrhages). Highly elevated ESR levels are common with atrial myxomas, but biologically false-positive results on Venereal Disease Research Laboratory (VDRL) testing, elevated rheumatoid factors, and renal involvement are not seen. On TTE or TEE, atrial myxomas appear as masses or vegetations on the atrial surface rather than on a valve as in IE. SBE is ruled out by the absence of bacteremia.

Besides clinical mimics of SBE, there are also echocardiographic mimics, including papillary fibromas, thrombi, calcified valves, myxomatous degeneration, and marantic endocarditis. These disorders are usually unaccompanied by fever or bacteremia. The term *marantic endocarditis* refers to uninfected vegetations with a murmur and negative blood cultures that occur secondary to malignancy. Patients with marantic endocarditis are afebrile unless fever is caused by the underlying malignancy (e.g., lymphoma). The patient with marantic endocarditis due to lymphoma may have fever, splenomegaly, and other manifestations of SBE. Negative blood cultures effectively rule out IE. Infectious CNE (e.g., Q fever) may show little or no visible vegetations. Infectious CNE should be considered if fever, murmur, and vegetation are present along with peripheral manifestations of IE.

Treatment

Effective treatment of IE depends on the antibiotic susceptibility of the pathogen, the penetration of the antibiotic into the vegetation, and the appropriate duration of antibiotic therapy. Antibiotics selected for IE preferably should be bactericidal. In IE, the organisms are deeply embedded in the vegetation, and prolonged therapy is necessary for penetration and sterilization of the vegetation. Early in IE therapy, blood cultures rapidly become negative, but treatment is continued because infection in the vegetation has not been eradicated. Multiplication of bacteria, which is required for bactericidal activity of antibiotics, is reduced within vegetations and is one reason for the requirement for prolonged antibiotics. It is important to note that in cases of *Staphylococcus aureus* endocarditis, blood cultures may not clear rapidly and may remain positive for days despite appropriate antibiotic therapy. Penetration into the vegetation is critical; for example, viridans streptococci are highly susceptible to β -lactam antibiotics but require a prolonged course of antimicrobial therapy to eradicate the pathogens in the vegetation.

Whereas some cases of uncomplicated IE may be treated with 2 weeks of antimicrobial therapy, the usual duration of monotherapy or combination therapy is 4 to 6 weeks, depending on the pathogen.

Current guidelines for the treatment for IE recommend intravenous (IV) antibiotics. However, the POET trial has confirmed what prior evidence had shown, that transition from IV to oral antibiotics showed no inferiority compared to IV antibiotics alone in patients with left-sided IE in patients with *Streptococcus* spp, *Enterococcus faecalis*, *Staphylococcus aureus*, and coagulase-negative *Staphylococcus*. This adds to the significant studies already available, demonstrating the effectiveness of PO therapy for serious systemic infections. As safety and efficacy of oral antibiotic therapy for the treatment of IE is

continued to be proven in future trials, not only would this reduce the morbidity associated with long-term IV catheters, but it would also be ideal for patients who are otherwise not eligible for long-term IV antibiotics. Long-acting lipoglycopeptides (dalbavancin, oritavancin) have been used in a very small number of retrospective studies showing potential promises for treating IE. However, we should be cautious as

TABLE 95.5 Diagnostic Approach to Culture-Negative Endocarditis**Valvular Biopsy Unavailable**

1. Q fever and *Bartonella* serology: If negative, then use lysis-centrifugation system for blood cultures and inform microbiology laboratory of concern for fastidious organisms to allow use of special media and culture techniques: thioglycolate-, pyridoxal hydrochloride-, or L-cystine-enriched media for *Abiotrophia*; buffered charcoal yeast extract (BCYE) agar for *Legionella*; prolonged incubation for HACEK organisms^a
2. Rheumatoid factor (RF), antinuclear antibodies (ANA)
3. PCR for *Bartonella* spp and *Tropheryma whipplei*
4. Nested PCR for fungi, tissue for *Cryptococcus neoformans* capsular antigen, and urine for *Histoplasma capsulatum* antigen: If negative, then obtain serum serology studies for *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Brucella melitensis*, and *Bartonella* spp by Western blot

Valvular Biopsy Available

1. Broad-range PCR for bacteria (16S rRNA) and fungi (18S rRNA)
2. Histologic examination with direct staining for *Chlamydia* spp, *Coxiella burnetii*, *Legionella* spp, fungi, and *T. whipplei*
3. Primer extension enrichment reaction (PEER) or autoimmunohistochemistry (AIHC)

Modified from Fournier PE, Thuny F, Richet H, et al: Comprehensive diagnostic strategy for blood culture-negative endocarditis: a prospective study of 819 new cases, *Clin Infect Dis* 51:131-140, 2010; and Mylonakis E, Calderwood SB: Infective endocarditis in adults, *N Engl J Med* 345:1320, 2001.

failures have been documented, and potential for increasing resistance to standard therapy remains.

Effective antimicrobial therapy does not eliminate suppurative or embolic complications of endocarditis. Therapeutic failure is usually related to valvular destruction, a complication that may require valve replacement. Suppurative intracardiac or extracardiac complications usually require drainage for cure of IE. The overarching principles of IE therapy are presented in [Table 95.6](#), and [Table 95.7](#) provides an outline of specific antibiotic regimens that may be used to treat IE.

Complications of endocarditis may be intracardiac or extracardiac, and they may also be classified by damage mechanism (i.e., immunologic vs. infectious). The infectious intracardiac complications of IE include purulent pericarditis and paravalvular abscess; they manifest clinically with persistent fever or persistent bacteremia despite appropriate antibiotic therapy. Complications may be septic or immunologic; for example, splenic involvement may be immunologic (splenic infarct) or septic (splenic abscess). Embolic events are related to vegetation size. Bland central nervous system emboli (e.g., aseptic meningitis) may complicate SBE, whereas septic emboli (e.g., acute bacterial meningitis) may complicate ABE. Particularly with ABE, there may be valvular perforation or destruction resulting in acute congestive heart failure. It is often these complications that dictate whether and when surgery will occur. The indications for surgical intervention are shown in [Table 95.8](#). As a general principle, paravalvular abscess or intractable congestive heart failure requires urgent surgical intervention. Persistent vegetations or embolic disease that occurs after 1 week of appropriate antibiotic therapy should also prompt surgical consideration.

Prognosis

The prognosis of all forms of IE depends directly on any complications related to the infection. Consequently, early diagnosis and initiation of appropriate antibiotic therapy is the key to limiting mortality. Recent studies have supported the role of early surgical intervention, when appropriate, as a significant aid to decreasing morbidity and mortality, specifically in relation to having fewer embolic events. If treated in a timely fashion and with appropriate antibiotics, the cure rate for viridans streptococci and *S. bovis* is estimated to be 98% in NVE and up to 88% in PVE. Right-sided endocarditis in intravenous drug abusers is usually caused by *S. aureus* and typically has a cure rate of 90% in NVE and 75% to 80% in PVE. However, among non-intravenous drug abusers, cure rates in IE involving *S. aureus* are far lower: 60% to 70% in NVE and 50% in PVE. When gram-negative bacilli or fungal organisms are the causative agent, cure rates are significantly lower (40% to 60%). Increased age, diabetes, aortic valve involvement, and developing complications of IE including congestive heart failure and emboli to the central nervous system are all highly predictive of increased mortality and morbidity.

Infective Endocarditis Prophylaxis

The most recent American Heart Association guidelines state that not all patients require antibiotic prophylaxis and that prophylaxis should be considered only for a specific subset of patients. Antibiotic prophylaxis is indicated for patients with prosthetic heart valves, cardiac transplant recipients with valvular disease, patients with a history of IE, and patients with certain forms of congenital heart disease. Among patients with congenital heart disease, only those with unrepaired or partially repaired lesions and those with prosthetic material should receive prophylactic antibiotics (grade IIa recommendation).

Typically, antibiotic regimens used for prophylaxis against IE prior to invasive procedures above the waist are directed against viridans streptococci. For invasive dental procedures, the recommended prophylactic agent is amoxicillin, 2 g PO as a single dose 30 to 60 minutes before the procedure. In patients with penicillin allergy, clindamycin or a macrolide may be substituted.

ENDARTERITIS AND SUPPURATIVE PHLEBITIS

The term *infectious endarteritis* refers to an intravascular infection of the arteries that affects coarctation of the aorta, aortic valve shunts, or a patent ductus arteriosus, analogous to IE at other sites. As with IE, continuous or high-grade bacteremia in the absence of an intracardiac vegetation should suggest the diagnosis. Imaging studies (e.g., PET scans) delineate the extent of arterial involvement. Treatment is the same as for IE.

The term *suppurative thrombophlebitis* refers to an intravenous infection that is characterized by an intravenous abscess; it is a complication of the use of central venous catheters. Patients have phlebitis with high fevers (>102° F, compared with <102° F in uncomplicated phlebitis with fevers), bacteremia due to a skin organism (e.g., *S. aureus*) and often expressible pus from the catheter site. Treatment consists of a combination of antibiotic therapy and resection of the involved venous segment.

CENTRAL VENOUS CATHETER-RELATED BLOODSTREAM INFECTIONS

Central venous catheter-related bloodstream infections are relatively common, with an annual incidence of approximately

TABLE 95.6 Principles of Therapy for Infective Endocarditis

1. Antibiotic selection initially is made empirically on the basis of physical examination and clinical history.
2. Bactericidal antibiotics are prescribed.
3. The MIC and MBC are measured to ensure adequate dosing of the agent.
4. Intermittent dosing provides superior penetration into the thrombus compared with continuous infusion; penetration is directly related to peak serum level.
5. The patient should be treated in a health care facility for the first 1–2 wk.
6. The usual duration of therapy is 4–6 wk.
7. A 4-wk course is appropriate for an uncomplicated case of NVE (a shorter course of 2 wk may be appropriate in some cases); a 6-wk course is required for the treatment of PVE and those infections with large vegetations (i.e., infection by HACEK organisms^a).

Modified from Bruschi JL: Diagnosis of infective endocarditis. In Bruschi JL, editor: *Infective endocarditis*, New York, 2007, Informa Healthcare, pp 241-254.

MBC, Minimal bactericidal concentration; MIC, minimal inhibitory concentration.

^aHACEK organisms: *Haemophilus* spp, *Aggregatibacter actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

200,000 in the United States. Central venous catheter infection should be suspected if the patient develops fevers, chills, or hypotension without another obvious source of infection. The likelihood of infection increases with the length of time the catheter is in place. In addition to the clinical signs, blood cultures, drawn from the periphery as well as the line, should demonstrate growth of the causative organism. If the culture drawn from the catheter shows growth of bacteria at least 2 hours earlier than the peripheral blood cultures do, infection associated with the central line, rather than bacteremia in the setting of a catheter, should be strongly suspected.

Treatment of catheter-related infections varies depending on what action will be taken with the catheter (i.e., removal, exchange, or salvage). In any case, empirical antibiotic therapy should be initiated against the most likely pathogens. Empirical therapy should cover *S. aureus* and nosocomial gram-negative bacilli. Therapy may then be modified based on the results of blood cultures or catheter tip culture. If a catheter-related bloodstream infection is suspected, immediate removal of the catheter should occur if the infection has led to septic shock or IE. The line also should be removed if blood cultures remain positive for the causative organism for 72 hours longer or if evidence of septic thrombophlebitis develops.

Salvage therapy may be considered in hemodynamically stable patients except when the infection is caused by *S. aureus*, *P. aeruginosa*, *Bacillus* spp, *Micrococcus* spp, *Propionibacterium acnes* or other propionibacteria, fungi, or mycobacteria. Salvage therapy relies on concurrent use of systemic antimicrobial agents and antibiotic or ethanol locks.

Guidewire exchange should be reserved for cases in which there is a high risk for complications if the original catheter were to be removed. Guidewire exchange has a lower chance of eliminating the infection than does removal of the catheter.

For a deeper discussion of these topics, please see Chapter 67, “Infective Endocarditis,” in *Goldman-Cecil Medicine*, 26th Edition. ♦

TABLE 95.7 Antimicrobial Treatment of Infective Endocarditis

Causative Organism	NATIVE VALVE		PROSTHETIC VALVE	
	Antibiotic Therapy	Comments	Antibiotic Therapy	Comments
Penicillin-susceptible viridans streptococci, <i>Streptococcus bovis</i> , and other streptococci with MIC of penicillin ≤ 0.1 $\mu\text{g}/\text{mL}$	Penicillin G or ceftriaxone for 4 wk ^a	A 2-wk regimen of penicillin G or ceftriaxone combined with gentamicin may be considered in patients with right-sided NVE without evidence of embolic disease (excluding pulmonary emboli) or other complications.	Penicillin G for 6 wk and gentamicin for 2 wk ^a	Shorter duration of treatment with an aminoglycoside (2 wk) is usually appropriate for PVE due to penicillin-susceptible viridans streptococci, <i>S. bovis</i> , or other streptococci with MIC of penicillin ≤ 0.1 $\mu\text{g}/\text{mL}$.
Relatively penicillin-resistant streptococci (MIC of penicillin >0.1 to 0.5 $\mu\text{g}/\text{mL}$)	Penicillin G for 4 wk and gentamicin for 2 wk ^a		Penicillin G for 6 wk and gentamicin for 4 wk ^a	
<i>Streptococcus</i> species with MIC of penicillin >0.5 $\mu\text{g}/\text{mL}$, <i>Enterococcus</i> species, or <i>Abiotrophia</i> species	Penicillin G or ampicillin and gentamicin for 4–6 wk ^a	6 wk of therapy is recommended for patients with symptoms lasting >3 mo, myocardial abscess, or selected other complications.	Penicillin G or ampicillin and gentamicin for 6 wk ^a	A study by Fernando-Hidalgo et al. showed that the combination of ampicillin and ceftriaxone is as effective as the combination of ampicillin and gentamicin for treating <i>Enterococcus faecalis</i> IE.
Methicillin-susceptible staphylococci	Nafcillin or oxacillin for 4–6 wk, with or without addition of gentamicin for the first 3–5 days of therapy ^b	In the few patients infected with a penicillin-susceptible staphylococcus, penicillin G may be substituted for nafcillin or oxacillin.	Nafcillin or oxacillin with rifampin for 6 wk and gentamicin for 2 wk ^b	It may be prudent to delay initiation of rifampin for 1 or 2 days, until therapy with two other effective antistaphylococcal drugs has been initiated.
Methicillin-resistant staphylococci	Vancomycin, with or without addition of gentamicin, for the first 3–5 days of therapy		Vancomycin with rifampin for 6 wk and gentamicin for 2 wk	If the staphylococcus is resistant to gentamicin, an alternative third agent should be chosen on the basis of in vitro susceptibility testing.
Right-sided staphylococcal NVE in selected patients	Nafcillin or oxacillin with gentamicin for 2 wk	This 2-wk regimen has been studied for infections caused by an oxacillin- and aminoglycoside-susceptible isolate. Exclusions to short-course therapy include any cardiac or extracardiac complications associated with IE, persistence of fever for ≥ 7 days, and infection with HIV. Patients with vegetations >1 – 2 cm should probably be excluded from short-course therapy.		
HACEK organisms ^c	Ceftriaxone for 4 wk	Ampicillin and gentamicin for 4 wk is an alternative regimen, but some isolates may produce β -lactamase, thereby reducing the efficacy of this regimen.	Ceftriaxone for 6 wk	Ampicillin and gentamicin for 6 wk is an alternative regimen, but some isolates may produce β -lactamase, thereby reducing the efficacy of this regimen.

Modified from Mylonakis E, Calderwood SB: Infective endocarditis in adults, *N Engl J Med* 345:1318-1330, 2001.

HIV, Human immunodeficiency virus; IE, infective endocarditis; NVE, native valve endocarditis; PVE, prosthetic valve endocarditis.

^aVancomycin therapy is indicated for patients with confirmed immediate hypersensitivity reactions to β -lactam antibiotics.

^bFor patients who have IE due to methicillin-susceptible staphylococci and are allergic to penicillin, a first-generation cephalosporin or vancomycin may be substituted for nafcillin or oxacillin. Cephalosporins should be avoided in patients with confirmed immediate-type hypersensitivity reactions to β -lactam antibiotics.

^cHACEK organisms: *Haemophilus* spp, *Aggregatibacter actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

Acute Bacterial Skin and Skin Structure Infections

Sajeev Handa

DEFINITION

Acute bacterial skin and skin structure infections (ABSSSIs) comprise infections of the skin, subcutaneous tissue, fascia, and muscle by a multitude of organisms. The focus of this chapter is on bacterial causes; however, references will be made to select viruses and fungi.

EPIDEMIOLOGY

ABSSSIs are among the most common infections found in all age groups. Although the exact incidence is unknown, several factors predispose to development of ABSSSIs:

- Epidermal breaks caused by trauma, surgical wounds, human or animal bites, or dry and irritated skin with concomitant tinea infection
- Immunosuppressed states caused by malnutrition, diabetes mellitus, or acquired immunodeficiency syndrome (AIDS)
- Chronic venous or lymphatic insufficiency

PATHOLOGY

Infectious Mechanisms

Microbes penetrate the integument after entering through a cut, bite, or hair follicle. Components of the host's defense system, including oxygen radicals, complement, immunoglobulins, macrophages, lymphocytes, and granulocytes, are recruited to the site of invasion through a vast plexus of dermal capillaries.

Bacteria contain proteins whose *N*-terminal amino acid sequence begins with an *N*-formyl-methionine group that is chemoattractive to phagocytes, including macrophages and granulocytes. Other microbial cell wall components, such as the zymosan of yeast, endotoxins of gram-negative bacteria, and the peptidoglycans of gram-positive bacteria, activate the alternative complement pathways, producing serum-derived chemotactic factors. Efflux of phagocytes occurs from the capillary through endothelial cell interstices and follows the gradient of chemotactic factors derived from bacteria and serum to the site of active infection.

Activated endothelial cells also produce chemotactic cytokines such as interleukin-8 (IL-8). Activated granulocytes synthesize leukotriene B₄ from arachidonic acid, a potent chemoattractant for leukocytes. Production of proinflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor augments immune function, inducing fever, priming neutrophils, and increasing antibody production and synthesis of acute phase reactants such as C-reactive protein.

Cytokine-driven stimulation of endothelial cells generates nitric oxide and prostaglandins, both of which cause vasodilatation. The net physiologic effect is greater blood flow to the tissue, causing acute inflammation. As described by Celsus (30 BC to 38 AD), acute

inflammation is characterized by rubor (i.e., redness), calor (i.e., increased heat), tumor (i.e., swelling), dolor (i.e., pain), and, as added by Virchow in the 19th century, function laesa (i.e., loss of function). Chapter 88 discusses host defenses against infection in more depth.

Pathologic Manifestations

Impetigo is characterized by thick, crusted lesions with rounded or irregular margins that typically occur on the face. Most cases are caused by *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), or by group A streptococci (e.g., *Streptococcus pyogenes*). Certain strains of streptococci causing impetigo have been implicated in the development of poststreptococcal glomerulonephritis.

Folliculitis is a superficial bacterial infection of the hair follicles. Purulent material is found in the epidermis. It manifests as clusters of multiple, small, raised, pruritic, erythematous lesions that are typically less than 5 mm in diameter.

Furuncles (i.e., boils) are infections of the hair follicle. Purulent material extends through the dermis into the subcutaneous tissue, where small abscesses may form. A carbuncle is coalescence of several inflamed follicles into a single inflammatory mass. Purulent drainage exudes from multiple follicles.

Cellulitis is superficial inflammation of the skin and underlying tissues. It is characterized by erythema, warmth, and tenderness of the involved area (Fig. 96.1). Erysipelas ("red skin") is a variant of cellulitis that is predominantly caused by toxin-producing *S. pyogenes*. It manifests as a superficial, spreading, warm, erythematous (fiery red) lesion distinguished by its indurated and elevated margin. Lymphatic involvement and vesicle formation are common. Groups B, C, and D streptococci may also be implicated (Fig. 96.2).

Necrotizing fasciitis is a progressive and rapidly spreading inflammatory reaction deep in the fascia associated with secondary necrosis of the subcutaneous tissues. Thrombosis of the dermal vessels is responsible for tissue necrosis. Necrotizing fasciitis may be polymicrobial (type I), involving aerobic microbes (e.g., streptococci, staphylococci, gram-negative bacilli) and anaerobes (e.g., *Peptostreptococcus*, *Bacteroides*, *Clostridioides* spp), or it may be monomicrobial (type II) and caused by *S. pyogenes* (Fig. 96.3). When involving the scrotum and perineal area, it is known as *Fournier gangrene*.

Pyomyositis is a less serious infection involving the musculature that results from direct inoculation of bacteria. For example, infection can result from injection drug use or from secondary seeding by *S. aureus* or group A β -hemolytic streptococci from an incidental bacteremia or a hematoma caused by non-penetrating trauma.

Ecthyma is an ulcerative pyoderma of the skin that extends into the dermis (unlike impetigo). It is caused by group A streptococci and *Pseudomonas* species.

Fig. 96.1 Ill-defined erythema and edema with bullae formation is characteristic of lower extremity cellulitis. (From Pride HB: Cellulitis and erysipelas. In Zaoutis LB, Chiang VW, editors: Comprehensive pediatric hospital medicine, Philadelphia, 2007, Mosby, Fig. 156-1.)

Fig. 96.2 Sharply defined erythema and edema is characteristic of erysipelas. (From Pride HB: Cellulitis and erysipelas. In Zaoutis LB, Chiang VW, editors: Comprehensive pediatric hospital medicine, Philadelphia, 2007, Mosby, Fig. 156-2.)

Fig. 96.3 Spontaneous necrotizing fasciitis due to *Clostridioides septicum*. The patient developed sudden onset of severe pain in the forearm. Swelling rapidly ensued, and he sought medical treatment. Crepitus was found on physical examination, and gas in the soft tissue was verified with routine radiographs. Immediate surgical débridement revealed necrotizing fasciitis but sparing of the muscle. Notice the purple-violaceous appearance of the skin. (From Stevens DL, Aldape MJ, Bryant AE. Necrotizing fasciitis, gas gangrene, myositis and myonecrosis. In Cohen J, Powderly WG, Opal SM, editors: Infectious diseases, ed 3, London, 2010, Mosby, Fig. 10-11.)

ETIOLOGY AND CLINICAL PRESENTATION

Causative Organisms

A multitude of organisms can cause ABSSSIs. However, three are most common: *S. pyogenes*, *S. aureus*, and *Streptococcus agalactiae*.

S. pyogenes (i.e., group A β -hemolytic streptococci) is a gram-positive coccus that may cause erysipelas, streptococcal cellulitis, necrotizing fasciitis, myositis, myonecrosis, and streptococcal toxic shock syndrome. Streptococcal cellulitis arises from infection of wounds, burns, or surgical incisions and may progress to involve large areas. Injection drug users and individuals with impaired lymphatic drainage are at high risk. Systemic manifestations include fever, chills, malaise with or without associated lymphangitis, and bacteremia. In contrast to erysipelas, the affected area is not raised, and the demarcation between involved skin and uninvolved skin is indistinct. The lesions tend to be more pink than fiery red.

Streptococcal toxic shock syndrome manifests with hypotension and is associated with acute kidney injury, elevated aminotransferases, rash or soft tissue necrosis, and coagulopathy. It may be complicated by the acute respiratory distress syndrome. Isolation of the organism from a sterile site provides a definite diagnosis.

S. aureus is a gram-positive coccus that is found in the anterior nares of up to 30% of healthy people. It is responsible for a variety of invasive and suppurative infections. Localized ABSSSIs include furuncles, carbuncles, bullous and nonbullous impetigo, mastitis, ecthyma, cellulitis, and wound and foreign body infections. Bacteremia may be complicated by septicemia, endocarditis, pericarditis, pneumonia, empyema, osteomyelitis, and abscesses of the soft tissue, muscle, and viscera.

Staphylococcal toxic shock syndrome is typically associated with tampon use but may occur after childbirth or surgery and can be associated with cutaneous lesions. It manifests with the acute onset of fever, erythroderma, hypotension, and multisystem involvement (e.g., acute kidney injury, elevated levels of aminotransferases, coagulopathy, nausea, vomiting, diarrhea).

Community-associated MRSA is the most common identifiable cause of ABSSSIs in the emergency department. Isolates contain genes encoding for multiple toxins, including cytotoxins that result in leukocyte destruction and tissue necrosis.

S. agalactiae (a group B streptococcus) is a gram-positive diplococcus. It may account for up to one third of ABSSSIs among adults. Cellulitis, foot ulcers, and infection of decubitus ulcers are common manifestations. Cellulitis has been associated with foreign bodies such as breast or penile implants. Less commonly, polymyositis, blistering dactylitis, and necrotizing fasciitis may occur.

Other Organisms

Aeromonas hydrophila, *Aeromonas veronii*, and *Aeromonas schubertii* are gram-negative rods found in salt and fresh water. They may cause mild to severe wound infections after injury, producing cellulitis, myonecrosis, and rhabdomyolysis. Necrotizing fasciitis has been reported with *A. veronii* and *A. schubertii* infections. *Aeromonas* wound infections have also been reported as a result of the medicinal use of leeches.

Arcanobacterium haemolyticum is a gram-positive, weakly acid-fast bacillus. It has been isolated from soft tissue infections, including chronic ulcers, cellulitis, and paronychia.

Bacillus anthracis is a gram-positive bacillus that forms spores. Transdermal inoculation of the spores from even incidental trauma can result in cutaneous anthrax. It manifests initially as a small, pruritic papule that becomes surrounded by painless, nonpurulent vesicles that easily rupture, leaving a black eschar at the base of the ulceration.

Fig. 96.4 Cutaneous anthrax lesion on the skin of the forearm caused by the bacterium *Bacillus anthracis*. (From Centers for Disease Control and Prevention: Public health image library. Available at <http://phil.cdc.gov/Phil/home.asp>. Accessed October 31, 2014.)

Fig. 96.5 Tularemic ulcer with eschar formation after percutaneous inoculation of *Francisella tularensis*. (From Beard CB, Dennis DT: Tularemia. In Cohen J, Powderly WG, Opal SM, editors: Infectious diseases, ed 3, London, 2010, Mosby.)

Uncomplicated disease heals without scar formation in 1 to 3 weeks. Serious cutaneous disease is marked by extensive edema, worsening inflammation, and toxemia (Fig. 96.4).

Bartonella henselae is a gram-negative bacillus that causes cat-scratch disease. Between 3 and 10 days after a bite or scratch from a cat or other vector, a tender, erythematous papule appears. Lymphadenopathy ipsilateral to the site of inoculation occurs 1 to 3 weeks later, and the patient typically experiences constitutional symptoms. The lymphadenopathy may take months to resolve.

Capnocytophaga canimorsus is a thin, gram-negative bacillus with tapered ends. It is strongly associated with dog (primarily) and cat bites and scratches. Asplenic patients are at particular risk for sepsis due to this organism.

Clostridioides perfringens is an anaerobic, large, gram-positive rod. It can cause cellulitis or life-threatening necrotizing infections of skin, muscle, and other soft tissues. The latter is characterized by rapidly progressive tissue destruction, gas in tissues, shock, and death. Conditions such as trauma or illicit drug injection produce anaerobic tissue conditions that favor the organism. The condition can also develop in patients with bowel carcinoma or neutropenia. Gram stain of tissue or exudate reveals large, gram-positive rods and no inflammatory cells.

Edwardsiella tarda is a gram-negative rod found in fresh water environments. It is associated with wound infections, abscesses, and bacteremia. The mortality rate is high among patients with liver disease and iron overload.

Eikenella corrodens is a gram-negative bacillus that is part of the normal human oral flora. It is an important pathogen in human bite wounds, closed-fist injuries, and infections seen in chronic finger or nail biters. Severe soft tissue infection may occur, leading to septic arthritis and osteomyelitis.

Erysipelothrix rhusiopathiae is a gram-positive rod, but it may appear as gram-negative because of rapid decolorization. Its major reservoir is in domestic swine, and infection occurs by direct cutaneous contact through a cut or abrasion. Disease is characterized as erysipeloid (i.e., subacute cellulitis with vesiculation), as a diffuse cutaneous eruption with systemic symptoms, or as bacteremia that is often associated with endocarditis.

Francisella tularensis is a gram-negative coccobacillus found in rabbits, hares, hamsters, and rodents. Ulceroglandular tularemia occurs 3 to 5 days after humans are inoculated cutaneously during contact with any of these species. A papule is formed initially, followed by ulceration

with enlargement of the regional lymph nodes. Vesicles may be seen. If left untreated, the ulcer remains for weeks before healing, leaving a residual scar. Suppuration of the affected lymph nodes is the most common complication, occurring despite appropriate treatment (Fig. 96.5). *B. anthracis* and *F. tularensis* have been used as agents in bioterrorism.

Mycobacterium marinum is an atypical, acid-fast bacillus; it is the most common atypical mycobacterium that causes infection in humans. After inoculation of a skin abrasion or puncture wound in salt or fresh water (nonchlorinated), lesions appear as papules on an extremity. Lesions progress to shallow ulcers and form scars. Typically, lesions are solitary, but they may take on the appearance of ascending, sporotrichoid-like, nodular lymphangitis that may involve the local joint or tendons.

Mycobacterium leprae is a slow-growing, acid-fast bacillus that cannot be grown in vitro. It is the cause of leprosy (Hansen disease). It is primarily transmitted by the airborne route and causes chronic disfiguring skin lesions and nerve damage.

For a deeper discussion of this topic, please see Chapter 310, “Leprosy (Hansen Disease)” in *Goldman-Cecil Medicine*, 26th Edition. ❖

Pasteurella multocida is a gram-negative coccobacillus that may occur at the site of a scratch or bite from a dog or cat. Cellulitis results within 24 hours of the injury, producing swelling, erythema, tenderness, serous or purulent discharge with or without regional lymphadenopathy, chills, and fever.

Pseudomonas aeruginosa is a gram-negative rod and primarily a nosocomial pathogen. In the community, serogroup 0:11 may cause folliculitis related to the use of hot tubs, whirlpools, and swimming pools. Typically, the eruption occurs 48 hours after exposure and consists of tender, pruritic papules, papulopustules, or nodules. It is an important pathogen in burn wound infections, which may progress to sepsis.

Vibrio vulnificus is a gram-negative bacillus that is spread by contamination of a superficial wound with warm seawater. It can cause rapidly developing and intense cellulitis, necrotizing fasciitis, and ulcer formation. Aggressive soft tissue infection may occur with necrosis, fever, sepsis, and bullae formation. Ingestion of raw oysters, particularly by immunocompromised patients (e.g., liver cirrhosis, iron overload) may be followed 1 to 3 days later by septicemia associated with necrotizing cutaneous lesions.

Select Fungi and Viruses

Cryptococcus neoformans, *Candida albicans*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, and

opportunistic fungi can have skin manifestations. Opportunistic fungi, including *Aspergillus* species, fungi in the order Mucorales, and *Fusarium* species, can infect the skin of immunocompromised patients. Skin manifestations of fungal infections include papules, nodules, circumscribed erythematous lesions, ulcers, verrucous lesions, and eschars.

Sporothrix schenckii is a dimorphic fungus ubiquitous primarily in the tropical parts of North and South America. Cutaneous inoculation from thorny plants (e.g., rose bushes) is followed by development of a painless papule that enlarges slowly to become a nodular lesion with a violaceous hue or ulceration. Secondary lesions may form along the lymphatic drainage distribution. Exposure to herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) at abraded skin sites allows entry into the epidermis and dermis. Infection typically occurs from sexual contact, but it occasionally occurs at extraoral or extragenital sites, such as the hands of health care workers, producing a painful erythema primarily at the junction of the nail bed and skin (i.e., whitlow). This progresses to a vesicopustular lesion that can mimic a bacterial infection (i.e., paronychia). Sexually transmitted diseases are discussed in Chapter 100.

Primary varicella-zoster virus (VZV) infection occurs by the respiratory route but may occur through contact with infected lesions. Viremia results in crops of papules that primarily occur on the trunk and progress to vesicles and then to pustules, followed by crusting. Zoster or shingles represents reactivation of the latent virus in the sensory neurons of the dorsal root ganglion, resulting in pain that proceeds to a rash in the distribution of the affected dermatome in a few days. The appearance of papules and vesicles in a unilateral dermatomal distribution confirms the diagnosis. Ramsay Hunt syndrome occurs when the VZV infection involves the geniculate ganglia and causes a painful eruption in the ear canal and tympanic membrane that is associated with ipsilateral seventh cranial nerve palsy. Vesicles that appear on the tip of the nose (i.e., Hutchinson sign) may be preceded by development of ophthalmic zoster and involvement of the cornea. Immunosuppressed individuals are at higher risk for disseminated disease.

Table 96.1 provides a classification of the spectrum of skin involvement by bacteria and fungi.

TABLE 96.1 Classification of Bacterial and Mycotic Infections of the Skin

Disease or Disorder	Microorganisms
Primary Pyodermas	
Impetigo	<i>Staphylococcus aureus</i> , group A streptococci
Folliculitis	<i>S. aureus</i> , <i>Candida</i> spp, <i>Pseudomonas aeruginosa</i> (diffuse folliculitis), <i>Malassezia furfur</i> , <i>Pityrosporum ovale</i>
Furuncles and carbuncles	<i>S. aureus</i>
Paronychia	<i>S. aureus</i> , group A streptococci, <i>Candida</i> , <i>P. aeruginosa</i>
Ecthyma	Group A streptococci, <i>Pseudomonas</i> spp
Erysipelas	Group A streptococci
Chancriform lesions	<i>Treponema pallidum</i> , <i>Haemophilus ducreyi</i> , <i>Sporothrix</i> , <i>Bacillus anthracis</i> , <i>Francisella tularensis</i> , <i>Mycobacterium ulcerans</i> , <i>Mycobacterium marinum</i>
Membranous ulcers	<i>Corynebacterium diphtheriae</i>
Cellulitis	Group A or other streptococci, <i>S. aureus</i> ; rarely, various other organisms
Infectious Gangrene and Gangrenous Cellulitis	
Streptococcal gangrene and necrotizing fasciitis	Group A streptococci, mixed infections with Enterobacteriaceae and anaerobes
Progressive bacterial synergistic gangrene	Anaerobic streptococci plus a second organism (<i>S. aureus</i> , <i>Proteus</i> spp)
Gangrenous balanitis and perineal phlegmon	Group A streptococci, mixed infections with enteric bacteria (<i>Escherichia coli</i> , <i>Klebsiella</i> spp), anaerobes
Gas gangrene, crepitant cellulitis	<i>Clostridioides perfringens</i> and other clostridial species; <i>Bacteroides</i> spp, peptostreptococci, <i>Klebsiella</i> spp, <i>E. coli</i>
Gangrenous cellulitis in immunosuppressed patients	<i>Pseudomonas</i> , <i>Aspergillus</i> spp, agents of mucormycosis
Preexisting Skin Lesions With Secondary Bacterial Infections	
Burns	<i>P. aeruginosa</i> , <i>Enterobacter</i> spp, various other gram-negative bacilli, various streptococci, <i>S. aureus</i> , <i>Candida</i> spp, <i>Aspergillus</i> spp
Eczematous dermatitis and exfoliative erythrodermas	<i>S. aureus</i> , group A streptococci
Chronic ulcers (varicose, decubitus)	<i>S. aureus</i> , streptococci, coliform bacteria, <i>P. aeruginosa</i> , peptostreptococci, enterococci, <i>Bacteroides</i> spp., <i>C. perfringens</i>
Dermatophytosis	<i>S. aureus</i> , group A streptococci
Traumatic lesions (abrasions, animal bites, insect bites)	<i>Pasteurella multocida</i> , <i>C. diphtheriae</i> , <i>S. aureus</i> , group A streptococci
Vesicular or bullous eruptions (varicella, pemphigus)	<i>S. aureus</i> , group A streptococci
Acne conglobata	<i>Cutibacterium</i> (formerly <i>Propionibacterium</i>) <i>acnes</i>
Hidradenitis suppurativa	<i>S. aureus</i> , <i>Proteus</i> spp. and other coliforms, streptococci, peptostreptococci, <i>P. aeruginosa</i> , <i>Bacteroides</i> spp.
Intertrigo	<i>S. aureus</i> , coliforms, <i>Candida</i> spp
Pilonidal and sebaceous cysts	Peptostreptococci, <i>Bacteroides</i> sp, coliforms, <i>S. aureus</i>
Pyoderma gangrenosa	<i>S. aureus</i> , peptostreptococci, <i>Proteus</i> spp and other coliforms, <i>P. aeruginosa</i>

TABLE 96.1 Classification of Bacterial and Mycotic Infections of the Skin—cont'd

Disease or Disorder	Microorganisms
Cutaneous Involvement in Systemic Infections	
Bacteremias	<i>S. aureus</i> , group A streptococci (and other groups such as D), <i>Neisseria meningitidis</i> , <i>Neisseria gonorrhoeae</i> , <i>P. aeruginosa</i> , <i>Salmonella typhi</i> , <i>Haemophilus influenzae</i>
Infective endocarditis	Viridans streptococci, <i>S. aureus</i> , group D streptococci, and others
Fungemias	<i>Candida</i> spp., <i>Cryptococcus</i> spp., <i>Blastomyces dermatitidis</i> , <i>Fusarium</i>
Listeriosis	<i>Listeria monocytogenes</i>
Leptospirosis (Weil disease and pretibial fever)	<i>Leptospira interrogans</i> serotypes
Rat-bite fever	<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>
Melioidosis	<i>Burkholderia pseudomallei</i>
Glanders	<i>Burkholderia mallei</i>
Carrión's disease (verruca peruana)	<i>Bartonella bacilliformis</i>
Scarlet Fever Syndromes	
Scarlet fever	Group A streptococci, rarely <i>S. aureus</i>
Scalded skin syndrome	<i>S. aureus</i> (phage group II)
Toxic shock syndrome	Group A streptococci, <i>S. aureus</i> (pyrogenic toxin-producing strains)
Parainfectious and Postinfectious Nonsuppurative Complications	
Purpura fulminans (manifestation of disseminated intravascular coagulation)	Group A streptococci, <i>N. meningitidis</i> , <i>S. aureus</i> , pneumococcus
Erythema nodosum	Group A streptococci, <i>Mycobacterium tuberculosis</i> , <i>Mycobacterium leprae</i> , <i>Coccidioides immitis</i> , <i>Leptospira autumnalis</i> , <i>Yersinia enterocolitica</i> , <i>Legionella pneumophila</i>
Erythema multiforme-like lesions (rarely), guttate psoriasis	Group A streptococci
Other Lesions	
Erythrasma	<i>Corynebacterium minutissimum</i>
Nodular lesions	<i>Candida</i> , <i>Sporothrix</i> , <i>S. aureus</i> (botryomycosis), <i>M. marinum</i> , <i>Leishmania brasiliensis</i> ; leprosy due to <i>M. leprae</i> can cause papular lesions, nodular, and ulcerative lesions
Hyperplastic (pseudoeplitheliomatous) and proliferative lesions (e.g., mycetomas)	<i>Nocardia</i> spp., <i>Scedosporium apiospermum</i> (formerly <i>Pseudallescheria boydii</i>), <i>Blastomyces dermatitidis</i> , <i>Paracoccidioides brasiliensis</i> , <i>Phialophora</i> , <i>Cladosporium</i>
Vascular papules/nodules (bacillary angiomatosis, epithelioid angiomatosis)	<i>Bartonella henselae</i> , <i>Bartonella quintana</i>
Annular erythema (erythema chronicum migrans)	<i>Borrelia burgdorferi</i>

Modified from Mandell GL, Bennett JE, Dolin R, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 9, Philadelphia, 2020, Elsevier.

DIAGNOSIS

A thorough medical history is critical; it should assess the specific risk factors, such as travel history, animal contacts, marine exposures, occupational and avocational hazards (e.g., farming, gardening), and immune status. If an animal bite has occurred, the timing of the bite, circumstances of injury, and health status of the animal should be determined. Human bites are classified as self-inflicted, occlusal (i.e., intentional), or closed-fist injuries.

In addition to wound assessment, evaluation for other transmissible pathogens, including human immunodeficiency virus (HIV), HSV, *Treponema pallidum* (the etiologic agent of syphilis), and hepatitis B and C viruses, should be pursued. A thorough clinical examination should follow. Initial antimicrobial management, if indicated, is directed by the history and physical examination findings.

Evaluation of hospitalized patients should include a complete blood count and a basic metabolic panel. The C-reactive protein level may be useful as a marker for inflammation and guidance

for treatment. The creatine phosphokinase concentration may be helpful, but it is not specific for cases of compartment syndrome and necrotizing fasciitis involving the musculature. Cultures are not indicated for uncomplicated common forms of ABSSSIs managed in the outpatient setting. The benefit of blood cultures for cellulitis in hospitalized patients is uncertain because the yield is low. Cultures are indicated for patients who require incision and drainage because of the risk of deep structure and underlying tissue involvement.

The most sensitive and specific test for the diagnosis of HSV and VZV cutaneous lesions is nucleic acid amplification. A sample is scraped from the base of an active dermal lesion with a swab. Direct fluorescent antibody testing is less sensitive. Incision and drainage of these lesions is contraindicated.

Special Diagnostic Considerations

Animal Bites

Blood cultures, tissue biopsy, and aspirates for culture of aerobic or anaerobic organisms are preferred methods in cases of animal bites.

Fig. 96.6 Radiograph of patient with clostridial myonecrosis shows gas in the tissues. (Courtesy J.W. Tomford, MD.)

Human Bites

Wounds swabs may produce misleading information in cases of human bites. A Gram stain should be performed to assess organisms, neutrophils (i.e., inflammation), and squamous epithelial cells (i.e., superficial contamination). If feasible, tissue biopsy or aspiration of the infected site can provide specimens for aerobic and anaerobic culture.

Traumatic Wounds

The optimal time to acquire specimens for cultures is immediately after débridement of the wound site and not within the first 48 hours post-trauma. Analysis of initial cultures should focus on common pathogens, and additional testing should be reserved for uncommon or rare infections associated with unusual circumstances, such as *Vibrio* species after salt water exposure. Tissue biopsy and special stains may be required in certain situations, such as suspected infection with *M. marinum*.

Burn Wounds

Before sampling, the burn area must be clean and devoid of topical antimicrobial agents. Sampling of the burn wound by either surface swab or tissue biopsy for culture is recommended for monitoring the presence and extent of infection. Quantitative evaluation of swab or culture specimens is recommended twice weekly to monitor colonization. Evidence of systemic infection related to the wound should prompt blood cultures.

Diabetic Foot Infections

Superficial swab cultures of ulcerations can be misleading and should be avoided. If surgical débridement is performed, deep tissue specimens should be sent to the microbiology laboratory for evaluation.

Radiographs should be obtained if bone involvement is suspected, and they may also be useful in demonstrating soft tissue gas before crepitus is detected (Fig. 96.6). Magnetic resonance imaging is the most sensitive modality. Chapter 89 discusses the laboratory diagnosis of infectious diseases in more detail.

Differential Diagnosis

Many noninfectious conditions can mimic SSTIs:

- Brown recluse spider bite
- Contact dermatitis
- Gout
- Psoriatic arthritis with distal dactylitis
- Reactive arthritis
- Relapsing polycondritis

- Ruptured Baker cyst
- Mixed cryoglobulinemia due to immune complex disease from chronic hepatitis C or B infection (may have an erythematous rash)
- Pyoderma gangrenosum
- Sweet syndrome (acute febrile neutrophilic dermatosis)
- Venous stasis

TREATMENT

Pharmacologic and Supportive Care

Mild cases of cellulitis may be managed on an outpatient basis with penicillin VK, amoxicillin, or if the patient has a history of a penicillin skin rash and nothing to suggest an IgE-mediated reaction, cephalexin. If clinically unclear whether the infection is due to *S. pyogenes* or *S. aureus*, get cultures and start empiric therapy with amoxicillin or penicillin VK or cephalexin and trimethoprim-sulfamethoxazole (TMP-SMX).

Azithromycin, linezolid, tedizolid or delafloxacin may be used in patients with a past history of IgE-mediated allergic reaction to β -lactam antibiotics. Severe cellulitis should be managed with parenteral penicillin, cefazolin or ceftriaxone. Vancomycin may be used in patients with allergies to penicillin.

Concomitant tinea infection should be treated with a topical antifungal agent such as clotrimazole or terbinafine.

For suspected methicillin-susceptible *S. aureus* (MSSA) (fluctuance or positive Gram stain) dicloxacillin may be used as an outpatient, nafcillin or oxacillin as an inpatient. For MRSA, doxycycline or TMP-SMX may be used as an outpatient, vancomycin as an inpatient. Other inpatient options include daptomycin, telavancin, ceftaroline, clindamycin (watch for inducible resistance), or linezolid. Dalbavancin and oritavancin may be used as alternatives in ABSSSIs for those who are moderately ill and who refuse hospitalization.

Note that neither doxycycline nor TMP-SMX provides adequate streptococcal coverage. A β -lactam antibiotic may be considered for hospitalized patients with nonpurulent cellulitis, with modification to MRSA-active treatment if there is no clinical response. Cellulitis associated with an abscess requires surgical drainage.

In addition to supportive care, urgent surgical consultation should be obtained in the event that crepitus, bullae, rapidly evolving cellulitis, or pain disproportional to physical examination findings suggests necrotizing fasciitis. Initial parenteral therapy with vancomycin, daptomycin, or linezolid combined with piperacillin-tazobactam or a carbapenem (either meropenem or ertapenem) is appropriate. Type II necrotizing fasciitis due to *S. pyogenes* or clostridial myonecrosis should prompt combined therapy with parenteral penicillin and clindamycin. Clindamycin by virtue of its mechanism of action suppresses streptococcal toxin and cytokine production. The use of intravenous immune globulin in cases of necrotizing fasciitis remains controversial.

Compartment syndrome requires emergent surgical decompression to prevent muscle necrosis and irreversible neuronal damage.

Special Treatment Considerations

Animal Bites

Mild cases of animal bites (dog or cat) may be treated with amoxicillin-clavulanate. Inpatient parenteral agents including ampicillin-sulbactam or piperacillin-tazobactam may be used for those who require hospitalization.

For patients with a penicillin allergy, a fluoroquinolone plus clindamycin may be used in dog bites, doxycycline in cat bites. As with all animal bites, rabies postexposure prophylaxis and vaccination should be considered.

Human Bites

Patients who have human bite wounds without evidence of infection should receive prophylactic treatment with amoxicillin-clavulanate for 3 to 5 days. Closed-fist injuries require radiographic evaluation and consultation with a hand surgeon for possible wound exploration. Parenteral treatment with ampicillin-sulbactam or moxifloxacin is recommended.

Burn Wounds

Systemic therapy with antibiotics and antifungals is reserved for burn patients demonstrating signs of sepsis or septic shock. Infection due to mucormycoses requires liposomal amphotericin B.

Diabetic Foot Infections

Simple infections such as cellulitis are most often caused by group A streptococci or *S. aureus* and should be managed accordingly. If ulcers do not have purulence or inflammation, antimicrobials are not indicated. Severe limb-threatening infections require surgical evaluation and broad-spectrum antibiotic coverage because infection tends to include aerobic and anaerobic organisms. Empirical therapy directed at *P. aeruginosa* is not usually necessary unless the patient has other risk factors. MRSA-active treatment is recommended for patients with a history of MRSA, when the local prevalence of MRSA is high in the community, or if the infection is severe. All wounds require adequate wound irrigation and débridement.

Marine Lacerations and Punctures

The treatment regimen for marine lacerations and punctures should include doxycycline and ceftazidime or a fluoroquinolone to provide adequate coverage for *V. vulnificus*. Treatment of fresh water injuries should also include a third- or fourth-generation cephalosporin (i.e., ceftazidime or cefepime) or a fluoroquinolone. If *M. marinum* is suspected, treatment with clarithromycin, minocycline, doxycycline, sulfamethoxazole-trimethoprim, or rifampin plus ethambutol is appropriate. Aeromonas wound infections may be treated with either ciprofloxacin or levofloxacin.

Others

Cellulitis or wound infections attributed to *A. hemolyticum* may be treated with clindamycin, erythromycin, vancomycin, or tetracycline.

Animal handlers with cutaneous anthrax infection (naturally acquired) require treatment with amoxicillin or penicillin. Cases of suspected bioterrorism, however, must be treated with ciprofloxacin or levofloxacin and must be reported immediately.

Tularemia is treated with streptomycin or gentamicin/tobramycin. Mild cases may be treated with ciprofloxacin or doxycycline. Azithromycin is the drug of choice for cat-scratch disease. For individuals at risk for *E. rhusiopathiae* infection, the treatment of choice is penicillin or amoxicillin for localized skin infection and parenteral penicillin or ceftriaxone for widespread skin infection.

Lymphocutaneous/cutaneous sporotrichosis (*S. schenckii*) may be treated with itraconazole.

HSV and VZV infections are susceptible to acyclovir, famciclovir, or valacyclovir if treatment is indicated.

PROGNOSIS

Full recovery is expected for patients with simple ABSSSIs provided they receive appropriate treatment. For those who develop complications such as necrotizing fasciitis, the estimated mortality rate is between 30% and 70%. The prognosis is guarded for patients with multiple comorbidities and those who are immunosuppressed.

Intraabdominal Infections

Eric Benoit

INTRODUCTION

Intraabdominal infections are common in hospitalized patients, both as a primary indication for admission and as a complication. Although antibiotics play a central role in treatment, many of these patients require source control and warrant surgical consultation to manage complications such as perforation and peritonitis. Intraabdominal infections are usually polymicrobial and are caused by components of bowel flora most commonly including aerobic *Escherichia coli* and other Enterobacteriaceae and anaerobic *Bacteroides fragilis* and streptococci.

SOURCE CONTROL AND TIMING OF ANTIBIOTICS

Early administration of broad-spectrum antibiotics has become standard of care in patients with suspected infection. Mortality increases with every hour delay to antibiotic therapy in septic patients. However, antibiotics alone are not sufficient for most intraabdominal infections, which require an intervention to control the source of infection. Purulence must be drained. This may be surgical removal of the infected tissue as in appendectomy, percutaneous drainage of an abscess by interventional radiology, or endoscopic retrograde cholangiopancreatography (ERCP) to remove obstructing stones in cases of cholangitis. Appropriate source control has been shown to be as important to outcomes as early antibiotics.

The Study to Optimize Peritoneal Infection Therapy (STOP-IT) trial demonstrated that most intraabdominal infections may be treated for 4 days after achieving source control, and this is true even for complicated intraabdominal infections. Furthermore, prolonged antibiotic administration in the setting of intraabdominal infection has been shown to increase the risk of further infections including bacteremia and *Clostridioides difficile* infections as well as increase the rate of in-hospital mortality. Source control and limited duration of antibiotic therapy, therefore, are critical considerations in management of intraabdominal infections.

PERITONITIS

Peritonitis is a disseminated infection of the peritoneal cavity and typically presents with diffuse, rather than localized, tenderness. Primary peritonitis is most often seen in patients with ascites from cirrhosis. It may be managed with antibiotics alone and after therapy may require suppressive antibiotics. Diagnosis is made by sampling peritoneal fluid; the diagnosis is likely if the number of neutrophils is greater than 250/microliter. Cultures may be negative.

Secondary peritonitis is due to an inciting event, such as hollow viscus perforation, ischemia, or a localized abscess that has spread, and is more common than primary peritonitis. Any intraabdominal infection

may progress from localized to diffuse peritonitis. Patients with peritonitis are tachycardic, tachypneic, and acutely uncomfortable. They avoid movement, and merely jostling the bed exacerbates the pain. The patient's abdomen may be rigid due to involuntary tightening of the muscles of the abdominal wall (guarding). The onset of peritonitis is ominous as it may herald the progression to sepsis and septic shock. These cases mandate emergent surgical consultation prior to imaging and almost always require operative exploration. Elderly patients or those with diabetes or on steroids may have a blunted response to peritonitis, and they should therefore be approached with a high degree of suspicion regarding complications of intraabdominal infections.

APPENDICITIS

When the lumen of the appendix is occluded either by a lymphatic tissue or a fecalith, mucosal fluid secretion and bacterial overgrowth cause an increase in pressure within the appendix. This eventually leads to venous outflow obstruction and further increases in pressure until arterial inflow is compromised, and the resulting ischemia leads to perforation. The classic presentation is periumbilical pain that migrates to the right lower quadrant, frequently associated with anorexia and nausea. Patients in whom the appendix has perforated often describe a sudden relief of localized pain followed several hours later by the onset of diffuse peritonitis. Leukocytosis, if present, is often not severe.

CT scan of the abdomen has become the diagnostic tool of choice with both sensitivity and specificity over 90% for detection of acute appendicitis. Findings of dilated appendix, fecalith, and stranding of the fat around the appendix are suggestive of acute appendicitis. CT scan may also detect a phlegmon (inflamed infected tissue) or abscess associated with perforated appendicitis (Fig. 97.1). Ultrasound may be useful in children, and MRI is an alternative imaging modality in pregnant women. Clinical diagnosis of appendicitis can be challenging, but the prevalence of CT scanning has markedly decreased the negative appendectomy rate.

Management of appendicitis is appendectomy, most often performed laparoscopically. Although there is active research into antibiotic therapy alone for appendicitis, this is not standard of care. Those patients who do not undergo appendectomy at initial presentation are often brought back for an interval appendectomy 6 to 8 weeks later. More advanced appendicitis may present with a phlegmon. These patients may be treated with antibiotics until an abscess develops, at which time drainage by interventional radiology is appropriate. Patients who develop signs of physiologic compromise (tachycardia, tachypnea, peritonitis) should instead proceed urgently to the operating room. Patients with perforated appendicitis may require more extensive surgery (e.g., ileo-cecectomy) and have a higher risk of intraabdominal abscess. Appendicitis is a polymicrobial infection with colonic bacteria *E. coli* and *Bacteroides* species being common. Antibiotics should be

Fig. 97.1 CT scan may detect (A) a phlegmon (inflamed infected tissue) or (B) an abscess associated with perforated appendicitis.

administered until time of operation and may be stopped thereafter in uncomplicated cases. Perforated appendicitis should be treated with antibiotics for 4 days after surgery. Uncomplicated appendicitis has a mortality rate less than 1%, but perforation, particularly in pediatric or elderly patients, increases the risk significantly. Other complications after appendicitis include intraabdominal abscess and wound infection.

DIVERTICULITIS

Diverticula are herniations of the colonic mucosa through naturally occurring openings in the taenia coli through which vessels run (Fig. 97.2). They are most commonly found in the sigmoid colon but may also be present in the right colon. The presence of diverticula (diverticulosis) increases with age, and diet influences their development. Low dietary fiber present in the Western diet contributes to rates of diverticulosis as high as 50% in Americans over the age of 80. Dietary fiber is thought to protect against the development of diverticulosis as demonstrated by lower rates of disease in countries in Asia and Africa. While right-sided diverticular disease is prone to bleeding, sigmoid diverticulosis risks development of diverticulitis, the infection of diverticula. Approximately 10% to 25% of patients with diverticula will develop diverticulosis in their lifetime. The pathophysiology of diverticulitis is similar to appendicitis: occlusion of a diverticulum results in bacterial overgrowth, vascular compromise, ischemia, and perforation.

Diverticulitis can present with varying degrees of severity that are enumerated by the Hinchey classification (Table 97.1). Local infection and inflammation may be self-limited or managed by outpatient antibiotics. More severe cases result in microperforation of diverticula with contained air or abscess within the bowel wall. Complicated diverticulitis results in a distant abscess in the abdomen, pelvis, or retroperitoneum. The most severe cases present with free intraabdominal air and purulent or feculent peritonitis.

Patients with diverticulitis most often present with left lower quadrant pain and tenderness. More severe cases may develop fever and leukocytosis whereas the most critical cases have frank peritonitis and physiologic compromise such as acidosis, acute kidney injury, and hypotension.

Imaging with IV contrast CT scan is standard of care, both to diagnose the presence and severity of diverticulitis and to identify complications such as abscess. However, patients with peritonitis due to suspected diverticulitis should not undergo CT imaging but instead belong in the operating room. An upright chest radiograph may demonstrate free air under the diaphragm in cases of perforation.

Simple diverticulitis may be managed with outpatient antibiotics. More severe cases require admission for intravenous antibiotics, bowel rest, and IV hydration. As the pain and tenderness resolve, the diet may be advanced. Complicated diverticulitis with uncontained abscess requires source control, and these patients should be evaluated for drainage by interventional radiology or laparoscopic drainage by surgery. Patients with free perforation require urgent surgery for control of contamination and resection of perforated bowel. The most common procedure is sigmoid resection with colostomy, although there is increasing evidence to support primary anastomosis with or without a diverting loop ileostomy.

Delayed complications of diverticulitis include abscess, colonic stricture, and fistulae (colovesical, colovaginal or coloenteric). Patients should undergo colonoscopy 6 to 8 weeks after diverticulitis to assess for colorectal cancer. Diverticulitis may recur in up to 20% of patients over 10 years. Although recurrence does make patients more prone to future episodes, the risk of complications such as free perforation does not increase with recurrence. Recurrent diverticulitis does not mandate surgery, but for those patients who wish to avoid future episodes elective sigmoid resection removes the burden of left-sided diverticulosis, effectively eliminating the source of disease. Regardless of treatment plan, patients should be encouraged to pursue a high-fiber diet. Former teaching suggested eliminating such foods as seeds and nuts, but this has not been shown to influence the recurrence of diverticulitis.

Like appendicitis, diverticulitis is a polymicrobial infection with colonic flora such as *E. coli* and bacteroides predominating. Accordingly, broad-spectrum antibiotics such as piperacillin/tazobactam are appropriate, and the duration of therapy is 7 to 10 days. Patients who have resolution of pain while on IV antibiotics may be transitioned to oral agents (such as amoxicillin/clavunate) and complete their course as outpatients.

INFECTIOUS BOWEL DISEASE

Infectious Colitis

Infectious colitis is an infection of the bowel that may be caused by bacteria (*E. coli*, *Campylobacter*, *Shigella*), viruses (*norovirus*, *rotavirus*, *cytomegalovirus*) or parasites (*Entamoeba histolytica*) (see Chapter 98). These patients present with abdominal pain that is frequently crampy in nature and diarrhea. In older patients particularly, infectious colitis may be difficult to distinguish from ischemic colitis. CT scan with IV contrast demonstrates inflammation of the bowel wall, in contrast to the lack of enhancement seen in ischemic disease. The presence of free fluid is ominous. For many patients with infectious colitis either symptomatic relief or a course of antibiotics directed at potential bacterial

Fig. 97.2 Diverticulosis. (From the Netter Collection of Medical Illustrations. Available at www.netterimages.com. Accessed October 31, 2014.)

pathogens may be sufficient. Stool samples may aid in diagnosis and treatment of different pathogens. Regardless of etiology these patients require frequent abdominal exams, and in rare cases, should they progress to worsening pain, fever, tachycardia, hypotension or peritonitis, they belong in the operating room for colectomy.

Cytomegalovirus Colitis

Cytomegalovirus is a common, self-limited viral infection, but it may cause colitis in immunocompromised patients, such as transplant patients, those who undergo frequent steroid therapy for ulcerative

colitis or as a complication of acquired immunodeficiency syndrome (AIDS). Diagnosis of CMV colitis requires a high degree of suspicion in the correct clinical context. Colonoscopy may demonstrate ulcerated lesions and CMV immunohistochemistry on biopsy specimens. Antimicrobial therapy is with an antiretroviral agent such as ganciclovir. Surgery is reserved for complications such as perforation.

Clostridioides difficile Colitis

Clostridioides difficile colitis is most often a complication of antibiotic therapy. It occurs when healthy intraluminal bacteria are depleted,

TABLE 97.1 Hinchey Classification of Diverticulitis

Class	Description	Treatment
0	Mild clinical diverticulitis	Oral antibiotics
Ia	Contained pericolic inflammation or phlegmon	IV antibiotics, bowel rest
Ib	Contained pericolic abscess	IV antibiotics, bowel rest
II	Pelvic, distant intraabdominal or retroperitoneal abscess	Percutaneous drainage, IV antibiotics
III	Purulent peritonitis	Operative drainage/resection
IV	Feculent peritonitis	Operative drainage/resection

allowing pathogenic species to predominate. Agents such as cephalosporins, fluoroquinolones, and clindamycin are commonly implicated, but any antibiotic in the preceding several months—even a single dose—increases the risk of *C. difficile* colitis. Hospitalized patients are at greater risk due to exposure, although community strains of *C. difficile* have been identified. Patients most often present with frequent diarrhea as well as abdominal pain. The disease is associated with leukocytosis sometimes as high as 30,000 to 40,000. Diagnosis is ideally sought in those with greater than or equal to three unformed stools in 24 hours. The diagnosis is confirmed by stool studies with PCR for toxin.

Infectious Disease Society Guidelines recommend oral vancomycin or fidaxomicin for 10 days for an initial episode of *C. difficile* colitis. Metronidazole is an alternative if vancomycin or fidaxomicin are not available. Fulminant cases may be treated with oral vancomycin and, if ileus is present, vancomycin enema. Intravenous metronidazole should also be given. First recurrent infection should be treated with oral vancomycin as a tapered and pulsed regimen or a course of fidaxomicin. Fecal microbiota transplant, which aims to repopulate the gut with healthy bacteria, should be considered investigational; while studies have demonstrated utility in patients with recurrent or refractory disease, it carries the risk of disease transmission.

Patients with *C. difficile* colitis remain at high risk of bowel perforation as well as progression to toxic megacolon. Those patients with signs of unremitting inflammation, such as fevers, tachycardia, and tenderness despite antibiotic therapy should be considered for surgery. Patients who progress to perforation often present in shock with hypotension and altered mental state. These patients have a high mortality, and surgery mandates subtotal colectomy, often with vancomycin enemas to the rectal stump.

BILIARY INFECTIONS

Cholecystitis

The gallbladder, like the appendix, is an anatomic cul-de-sac, and the narrow neck of the cystic duct is prone to occlusion by gallstones or edema, preventing drainage of bile and leading to bacterial overgrowth. The undrained, infected fluid present in cholecystitis leads to an increase in pressure that may progress to ischemia of the gallbladder wall, gangrene, and perforation.

Cholecystitis may be distinguished from biliary colic by its duration; biliary colic typically resolves spontaneously and patients are able to eat. Cholecystitis, on the other hand, is marked by prolonged pain and tenderness and is frequently associated with leukocytosis. Patients report right-sided or epigastric pain, often associated with a recent meal. On examination, tenderness is usually localized to the right upper quadrant. However, in cases of gallbladder perforation, infected

bile may flow down the right paracolic gutter, leading to right-sided abdominal or even pelvic tenderness. The classic finding of Murphy's sign is the abrupt cessation of inspiration when palpating the right upper quadrant; the excursion of the diaphragm during inspiration displaces the gallbladder inferiorly to the examiner's hand, resulting in sudden, exquisite pain that interrupts the patient's breathing.

Right upper quadrant ultrasound is the imaging modality of choice in which gallbladder wall thickening, a distended, fluid-filled gallbladder, and pericholecystic fluid are findings consistent with acute cholecystitis. Occasionally the ultrasound will demonstrate air within the gallbladder wall; emphysematous cholecystitis carries a high mortality and these patients warrant urgent surgery. Although CT scan is sensitive and specific for diagnosis of cholecystitis, it exposes patients to radiation and may miss non-cholesterol stones. Laboratory values include leukocytosis and elevated total bilirubin from the blockage of bile drainage.

Treatment of acute cholecystitis is cholecystectomy, most often performed laparoscopically. In patients who are too sick to tolerate operation, percutaneous drainage with a cholecystostomy tube is appropriate to decompress the infected gallbladder. Some of these patients will recover sufficiently to undergo surgery 6 weeks later. Other patients, particularly those who are elderly and frail, may require prolonged cholecystostomy tube drainage.

Acalculous Cholecystitis

Acalculous cholecystitis occurs in critically ill patients, particularly those who have not been receiving enteral nutrition. Diagnosis requires a high index of suspicion, especially in intubated patients. Patients with unexplained fever or leukocytosis without an obvious source should undergo a right upper quadrant ultrasound, which demonstrates a distended gallbladder with a thickened wall. These patients are frequently too sick to tolerate surgical cholecystectomy and instead are referred to interventional radiology for a cholecystostomy tube to decompress the infected bile. Tube drainage is often continued until the patient recovers sufficiently to tolerate cholecystectomy, although for some chronically debilitated patients tube drainage may suffice.

Cholangitis

Cholangitis is an infection due to the blockage of the bile ducts, most commonly from gallstones. These patients present with right upper quadrant or epigastric pain. The classic findings are right upper quadrant pain, fever and jaundice (Charcot's triad) that may progress to include altered mental status and shock (Reynold pentad). These patients have infected bile or pus within the biliary tree, and this is best drained by ERCP with sphincterotomy and stenting. Ascending cholangitis can be an aggressive infection, with patients rapidly progressing to septic shock. Antibiotics alone are not sufficient and source control is mandated. Suspicion of cholangitis should prompt urgent consultation with a gastroenterologist and a surgeon, and these patients often require fluid resuscitation and admission to a critical care unit.

Right upper quadrant ultrasound in cases of cholangitis may demonstrate cholelithiasis without findings of cholecystitis, but a dilated common bile duct as evidence of a stone that has passed out of the gallbladder. Important laboratory values include hyperbilirubinemia, leukocytosis, and an elevated alkaline phosphatase as evidence of bile duct irritation. Patients who undergo ERCP with sphincterotomy may have pneumobilia on subsequent imaging; this is due to retrograde passage of air from the duodenum into the biliary tree and may not indicate infection.

Bacteria associated with biliary infections include *E. coli*, *Klebsiella*, and *Pseudomonas* but may also include *Enterobacter* and *Bacteroides*. Biliary cultures are rarely used to guide therapy and therefore

antimicrobial therapy uses broad-spectrum agents such as piperacillin/tazobactam. For patients with uncomplicated acute cholecystitis, antibiotics may be stopped after surgery. For those too sick to undergo surgery, antibiotics are continued for 7 to 10 days, depending on clinical improvement. Patients with cholangitis require broad-spectrum antibiotics and source control in addition to fluid resuscitation.

PANCREATITIS AND PANCREATIC INFECTION

Pancreatitis is usually a self-limited inflammation of the pancreas. A small percentage progress to pancreatic necrosis, which is a risk factor for infected pancreatitis. Percutaneous aspiration of pancreatic fluid collections is not advised due to the risk of seeding sterile collections. The question of prophylactic antibiotics in cases of pancreatic necrosis has been actively debated for decades. In the interest of limiting antibiotic exposure and selecting resistant organisms, we defer antibiotics until there is evidence of infected pancreatic necrosis such as air within the fluid collections. Antibiotic therapy consists of a carbapenem and the duration is dictated by clinical improvement. Patients with infected pancreatic necrosis may undergo percutaneous drainage, but the infected material is often too thick to allow drainage. However, drain placement may be preliminary to creating a tract for videoassisted retroperitoneal dissection (VARDS) of the necrotic pancreas. Patients with unremitting signs of infection and inflammation may require surgery for drain placement and lavage.

INTRAABDOMINAL ABSCESS

Solid Organ Abscesses

Solid organ abscesses may form in the liver, spleen, and less commonly, the kidneys. The most common causes of hepatic abscess in the United States are biliary tract infection and portal vein bacteremia from diverticulitis, appendicitis or inflammatory bowel disease. Colonic bacteria predominate, including *Klebsiella pneumoniae* as well as anaerobes such as *Bacteroides* spp, *Fusobacterium*, and streptococcal species. Hepatic abscesses present with fevers as well as right upper quadrant pain. Laboratory data may show leukocytosis and an elevated alkaline phosphatase. CT scan is the imaging modality of choice for solid organ abscesses. Hepatic abscesses may be multifocal. Multiple, small abscesses are best treated with antibiotics whereas large, persistent abscesses may require percutaneous drainage. An important but less common cause of liver abscess is due to *Entamoeba histolytica* found frequently in patients from developing countries (see [Chapter 105](#)).

Splenic abscesses are seen in patients with infected endocarditis resulting from septic emboli or those who have undergone splenic artery embolization. The resulting ischemia and necrosis of splenic parenchyma serves as a nidus of infection. The presence of a splenic abscess should prompt a search for the source, including an echocardiogram. Patients may be treated with antibiotics and percutaneous drainage. Splenic abscesses may prove difficult to eradicate, in which case splenectomy is an option.

Renal abscesses may occur with recurrent pyelonephritis, particularly in the setting of urinary tract obstruction such as staghorn renal calculi. Source control may require percutaneous nephrostomy tubes to drain infected urine that cannot drain distally, and nephrectomy is indicated in cases of recurrent, fistulizing disease.

Intraabdominal and Intrapelvic

Intraabdominal and intrapelvic abscesses may form as a result of other infections, such as perforated appendicitis or diverticulitis, or after surgery for perforation of the alimentary tract. The omentum may

form adhesions around the site of infection, walling it off from the remainder of the peritoneal cavity and allowing an abscess to form. This appears as a rim-enhancing fluid collection on CT scan (with IV contrast). Small abscesses (≈ 2 cm) in an otherwise healthy patient with a functional immune system may be treated with antibiotics alone. Larger abscesses, however, may require drainage because antibiotics may not penetrate the infected area. Source control may be accomplished with percutaneous drainage, although this warrants a conversation with the interventional radiologist as the location may preclude safe drainage due to surrounding structures. Operative source control may be accomplished by laparoscopic washout and drain placement, although this carries the risk of bowel injury due to the friable nature of the inflamed bowel. Small bowel often forms the wall of deep abscesses and surgical source control often requires bowel resection in these cases.

CONCLUSIONS

Although early administration of broad-spectrum antibiotics remains a mainstay of treatment of intraabdominal infections, source control and early identification of complications such as peritonitis from free perforation or disseminated infection are critical concepts for the clinician to understand. CT scan with intravenous contrast is the imaging modality of choice for most intraabdominal infections. Elderly patients, those with diabetes, those taking steroids, or immunocompromised patients may not mount the same exuberant response of peritonitis, and therefore they must be approached with a high degree of suspicion regarding complications.

Infectious Diarrhea

Awewura Kwara

DEFINITION AND EPIDEMIOLOGY

Diarrhea is defined as the passage of three or more unformed stools or more than 250 g of unformed stools per day. Based on duration, diarrhea can be classified as *acute* (less than 14 days), *persistent* (14 to 29 days), or *chronic* (30 or more days). *Infectious diarrhea* is diarrhea that has an infectious etiology and is often associated with symptoms and signs of enteric involvement, such as nausea, vomiting, abdominal cramps, passage of bloody stool (dysentery), or systemic symptoms. Organisms responsible for infectious diarrhea include bacteria, viruses, and parasites.

In the United States (US), acute diarrhea is common, with an estimated annual burden of 179 million outpatient visits, nearly 500,000 hospitalizations, and more than 5000 deaths. The Foodborne Diseases Active Surveillance Network (FoodNet) maintained by the Centers for Disease Control and Prevention (CDC) provides data on pathogen-specific burden of diarrheal diseases in the United States by monitoring cases of laboratory-diagnosed infections caused by eight enteric pathogens transmitted through food in 10 US sites. During 2018, FoodNet identified 25,606 infections, 5893 hospitalizations, and 120 deaths. *Campylobacter*, *Salmonella*, and Shiga toxin-producing *Escherichia coli* (STEC) were the most common identified infections.

PATHOLOGY

Diarrhea is an alteration of movement of ions and water that leads to an increase in water content, volume, or frequency of stools. Under normal conditions, up to 9 L of fluid is passed through the adult gastrointestinal tract daily. Almost 98% of this fluid is absorbed, and only 100 to 200 mL is excreted in stools. Enteric pathogens or microbial toxins that are ingested can overcome host defenses and alter this balance toward a net secretion, leading to diarrhea. A large number of microorganisms are normally ingested with every meal. Host defense mechanisms against enteric pathogens include low gastric pH, rapid transit of bacteria through the proximal small intestine, cellular immune responses, and antibody production. In addition, large numbers of normal bacterial flora inhabit the intestines and prevent colonization by enteric pathogens.

Alteration of the normal defense mechanisms can put individuals at risk for infectious diarrhea. Individuals with gastric resection or achlorhydric states have increased frequency of infection due to *Salmonella*, *Giardia lamblia*, and helminths, whereas some organisms, such as *Shigella* or rotavirus, survive the extreme acidity of the gastric environment. Some viral, bacterial, and parasitic infections are more common in patients with impaired cellular or humoral immunity. More than 99% of the normal colonic flora is made up of anaerobic bacteria; they produce fatty acids and cause acidic pH,

which is important for resistance to colonization. Alteration of the bacterial flora due to broad-spectrum antibiotic therapy predisposes some individuals to the development of *Clostridioides difficile* infection (CDI).

The virulence factors employed by enteric pathogens include inoculum size, adherence factors, toxin production, and invasion. Organisms such as *Shigella*, enterohemorrhagic *Escherichia coli* (EHEC), *G. lamblia*, and *Entamoeba histolytica* need as few as 10 to 100 organisms to produce infection, whereas *Vibrio cholerae* needs 10^5 to 10^8 organisms to cause disease. Infectious diarrhea can be classified as noninflammatory or inflammatory based on pathogenesis. Noninflammatory diarrhea is caused by pathogens that adhere to the mucosa of small intestine, disrupting the absorptive and/or secretory processes without causing inflammation or destruction. Pathogens that cause noninflammatory diarrhea include viruses, enterotoxin-producing organisms, *G. lamblia*, and *Cryptosporidium parvum*. Inflammatory diarrhea is caused by pathogens that target the distal ileum or the colon and cause acute inflammatory reaction by secreting cytotoxins or invading the intestinal epithelium. Cytotoxin-producing bacteria include enteroaggregative *E. coli* (EAEC), EHEC, and *C. difficile* and invasive organisms include *Salmonella*, *Shigella*, and *Campylobacter*.

Enterotoxin-Induced Secretory Diarrhea

Ingested enterotoxin-producing bacteria colonize the small bowel, and then produce enterotoxin, which binds to the mucosa and causes watery diarrhea through hypersecretion of isotonic fluid that overwhelms the absorptive capacity of the colon. *V. cholerae* produces the cholera toxin, a heterodimeric protein composed of a single toxic active A subunit (CTA) and a B subunit pentamer (CTB), which is responsible for binding of the toxin to the intestinal mucosa. The bound toxin through a series of processes activates adenylate cyclase to produce cyclic adenosine monophosphate (cAMP), which causes increased chloride secretion and decreased sodium absorption, leading to hypersecretion of fluid. Enterotoxigenic *E. coli* (ETEC) produces both a heat-labile enterotoxin that acts by the same mechanism as the cholera toxin and a heat-stable enterotoxin that causes secretory diarrhea through activation of guanylate cyclase to produce cyclic guanosine monophosphate (cGMP).

Cytotoxin-Induced Diarrhea

In contrast to enterotoxins, cytotoxins elaborated by enteric pathogens destroy mucosal epithelial cells, causing acute inflammatory reaction and bloody diarrhea (dysentery). *Shigella dysenteriae* produces the Shiga toxin, which causes dysenteric diarrhea in patients with shigellosis. Other toxin-producing bacteria include *Vibrio parahaemolyticus*, *C. difficile*, and STEC.

TABLE 98.1 Epidemiologic and Clinical Characteristics of Common Enteric Pathogens

Organism	Epidemiologic Features	Common Clinical Features
<i>Campylobacter jejuni</i>	Consumption of undercooked poultry, travel to tropical and semitropical regions	Acute watery diarrhea, fever, abdominal pain, fecal evidence of inflammation (positive fecal leukocytes or lactoferrin)
<i>Vibrio cholerae</i>	Inadequately cooked seafood, travel to endemic regions	Acute dehydrating watery diarrhea; fever is usually absent
<i>Clostridioides difficile</i>	Antibiotic use, recent hospitalization, elderly patients with coexisting conditions	Diarrhea with fever, fecal evidence of inflammation, marked leukocytosis
Enterotoxigenic <i>Escherichia coli</i>	Travel to tropical and semitropical regions	Watery diarrhea, abdominal cramps, nausea and vomiting; leukocytes absent in stools
Nontyphoidal <i>Salmonella</i>	Food-borne outbreaks, exposure to animals	Acute watery diarrhea, fever, abdominal pain, evidence of inflammation
<i>Shigella</i>	Person-to-person transmission, daycare center contact	Severe diarrhea with fever, abdominal pain, bloody diarrhea, fecal evidence of inflammation
Shiga toxin–producing <i>E. coli</i>	Food-borne outbreaks, undercooked hamburgers, raw seed sprouts, water and wading pool exposure	Abdominal pain, bloody stools, absence of fever, fecal evidence of inflammation
Noncholeraic <i>Vibrio</i>	Ingestion of shellfish and undercooked seafood	Watery diarrhea, abdominal cramps, nausea; fever and vomiting are less frequent
<i>Yersinia enterocolitica</i>	Contaminated food or water, inadequately cooked meats, unpasteurized milk	Acute watery diarrhea, fever, abdominal pain, bloody diarrhea
Norovirus	Winter outbreaks in congregate settings, outbreaks on cruise ships	Watery diarrhea, nausea, vomiting, abdominal pain
<i>Cyclospora</i>	Food-borne outbreaks, travel to tropical and subtropical regions (especially Nepal)	Persistent noninflammatory diarrhea
<i>Cryptosporidium</i>	Waterborne outbreaks, travel to tropical and subtropical regions	Persistent noninflammatory diarrhea
<i>Entamoeba histolytica</i>	Travel to tropical regions, recent immigration from endemic regions	Bloody diarrhea, extraintestinal involvement (liver abscess)
<i>Giardia lamblia</i>	Waterborne outbreaks, travel to mountainous areas of North America, Russia	Abdominal pain, persistent watery diarrhea, flatulence, steatorrhea, nausea and vomiting

Invasive Diarrhea

Some bacteria cause dysentery through direct invasion and destruction of intestinal mucosa. *Shigella* and enteroinvasive *E. coli* (EIEC) invade and multiply in epithelial cells and spread to adjacent cells. Diarrhea is often accompanied by fever, abdominal cramps, and small amounts of bloody mucoid stools. Other bacteria, such as *Salmonella typhi* and *Yersinia enterocolitica*, penetrate the mucosa before disseminating into the bloodstream to cause a systemic illness.

Bacterial Food Poisoning

Bacterial food poisoning is caused by ingestion of preformed toxins in food that results in a toxic illness. The toxins may include cytotoxins, enterotoxins, and neurotoxins. Pathogens that cause bacterial food poisoning include *Staphylococcus aureus*, *Clostridioides perfringens*, and *Bacillus cereus*. These organisms grow in food and produce toxins that are ingested directly in the food. Symptoms occur soon after food ingestion, with incubation periods of 1 to 16 hours. The illness is rarely associated with fever, and symptoms usually resolve within 12 to 24 hours after onset.

The staphylococcal and *B. cereus* toxins act on the nervous system to cause vomiting. *S. aureus* causes vomiting and diarrhea within 2 to 7 hours after ingestion of improperly cooked or stored food containing its heat-stable enterotoxin. *C. perfringens* produces secretory and cytotoxin-induced watery diarrhea within 8 to 14 hours after ingestion of contaminated vegetables, meat, or poultry. *B. cereus* often contaminates fried rice, vegetables, or sprouts; it produces one of two toxins that cause disease resembling that of *S. aureus* or *C. perfringens* infection within 1 to 6 hours after ingestion.

SPECIFIC PATHOGENS

The epidemiologic and clinical features of common enteric pathogens and the recommended methods for diagnosis and treatment are summarized in Tables 98.1 and 98.2.

Shigella

Diarrhea due to *Shigella* spp (shigellosis) occurs after ingestion of fecally contaminated food or water. The main strains include *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*. Ingestion of as few as 10 to 100 microorganisms can lead to infection because the bacteria are relatively resistant to gastric acid. Person-to-person transmission is common, and the attack rate is highest among infants and young children in child-care centers. The incubation period is 6 to 72 hours. Illness may initially manifest as noninflammatory watery diarrhea caused by enterotoxin production or multiplication of bacteria in the small intestines. Invasion of the colonic epithelium and mucosa often manifests as dysentery. Complications of *S. dysenteriae* type 1 shigellosis include hemolytic-uremic syndrome (HUS). Reactive arthritis is associated with *S. flexneri* infection.

Salmonella

Salmonella enterica serovars typhi and paratyphi cause enteric fever whereas nontyphoidal *Salmonella* spp cause diarrhea. Nontyphoidal salmonellosis results from ingestion of contaminated meat, dairy, or poultry products or from direct contact with animals such as birds, pet turtles, snakes, and other reptiles. An oral inoculum of 10^5 to 10^8 organisms is needed but smaller inocula can cause disease in patients

TABLE 98.2 Diagnosis and Recommended Antimicrobial Treatment for Diarrhea With Specific Pathogens in Adults

Organism	Diagnosis	Recommendations
<i>Campylobacter jejuni</i>	Routine stool culture	Azithromycin 500 mg PO daily for 3 days. Alternative ciprofloxacin 500 mg PO bid for 3 days
<i>Vibrio cholerae</i> O1	Stool culture in special salt-containing media (TCBS), test isolate for O1 serotype	Doxycycline 300 mg or azithromycin 1000 mg PO single dose, or tetracycline 500 mg PO qid or TMP-SMZ 160/800 mg PO bid or ceftriaxone 1–2 g IV/IM q24h for 3 days
<i>Clostridioides difficile</i>	Stool test for <i>C. difficile</i> toxin A or B by EIA, or PCR for the B toxin gene	Stop implicated antibiotic. Vancomycin 125 mg PO qid or fidaxomicin 200 mg PO bid for 10 days. For fulminant CDI, vancomycin 500 mg four times daily orally or by NGT is recommended.
Enterotoxigenic <i>Escherichia coli</i>	Stool culture for <i>E. coli</i> , with assay for enterotoxin	Azithromycin 1000 mg PO single dose or 500 mg PO daily for 3 days or ciprofloxacin 500 mg PO bid for 3 days
Nontyphoidal <i>Salmonella</i>	Routine stool culture	Antimicrobials not recommended except for groups at risk of invasive disease. Ciprofloxacin 500 mg bid for 5 to 7 days or ceftriaxone 100 mg/kg/day in one or two divided doses for 5 to 7 days, or longer if endovascular infection or relapsing
<i>Shigella</i>	Routine stool culture	Ciprofloxacin 500 mg bid for 3 days or ceftriaxone 1–2 g IV/IM for 3 days or azithromycin 500 mg PO daily for 3 days
Shiga toxin–producing <i>E. coli</i>	Stool culture with sorbitol–MacConkey agar, followed by serotyping for O157, then H7, with EIA for Shiga toxins	Antibiotics and antimotility drugs should be avoided
Noncholeraic <i>Vibrio</i>	Stool culture in special salt-containing media (TCBS)	Ceftriaxone 1–2 g IV/IM q24h plus doxycycline 100 mg PO bid for 3 days
<i>Yersinia enterocolitica</i>	Stool culture on MacConkey media incubated at 25° to 28° C	Antibiotics usually not required. For severe infection or bacteremia, treat with TMP-SMZ or fluoroquinolone or doxycycline plus aminoglycoside
<i>Cyclospora</i>	Stool trichrome or acid-fast stain for parasites	TMP-SMZ 160/800 mg bid for 7–10 days
<i>Cryptosporidium</i>	Stool trichrome or acid-fast stain for parasites, EIA for <i>Cryptosporidium</i> species	Self-limited in immunocompetent persons. If severe or if patient is immunocompromised, nitazoxanide 500 mg PO bid for 3 to 14 days
<i>Isospora</i>	Stool trichrome or acid-fast stain for parasites	TMP-SMZ 160/800 mg PO bid for 7–10 days
<i>Entamoeba histolytica</i>	Stool examination for ova and parasites, EIA for <i>E. histolytica</i>	Metronidazole 750 mg tid for 5–10 days, plus iodoquinol 650 mg tid for 20 days or paromomycin 500 mg tid for 7 days
<i>Giardia</i>	Stool examination for ova and parasites, EIA for <i>Giardia</i> species	Single dose tinidazole 2 g or nitazoxanide 500 mg bid for 3 days. Metronidazole 250 to 750 mg tid for 5 to 10 days

EIA, Enzyme immunoassay; PCR, polymerase chain reaction; PO, per oral; bid, twice a day; qid, four times a day; TCBS, thiosulfate-citrate-bile salts-sucrose agar; tid, three times a day; TMP-SMZ, trimethoprim-sulfamethoxazole.

with impaired gastric acidity or compromised immunity. The organisms invade the distal ileum and cause diarrhea with fever, nausea, or vomiting. Diarrhea usually resolves in 2 to 3 days. Complications include bacteremia and metastatic seeding of atherosclerotic plaques and prostheses. Antibiotic treatment does not shorten the duration of diarrhea and may prolong intestinal carriage in stools. Antibiotics are indicated only for cases of severe disease or extraintestinal involvement.

Campylobacter

Disease caused by *Campylobacter jejuni* usually results from ingestion of undercooked poultry or direct contact with animals. The infective dose is 10^4 to 10^6 organisms, with an incubation period of 1 to 5 days. Acute watery, noninflammatory diarrhea is the most common presentation. Less frequently, acute inflammatory enterocolitis with systemic symptoms may occur. Prodromal symptoms such as fever, myalgia, headache, and malaise may precede diarrhea. Complications include postinfectious irritable bowel syndrome, reactive arthritis, especially associated with the human leukocyte antigen B27 (HLA-B27), and Guillain-Barré syndrome, which can occur 2 to 3 weeks after diarrhea has resolved. Antibiotic therapy shortens the carriage state.

Vibrio

V. cholerae can be divided by the O-antigen of lipopolysaccharide into more than 150 strains. The toxigenic strains *V. cholerae* O1 and O139 produce cholera toxin and are associated with clinical illness. The infectious oral inoculum is about 10^5 to 10^8 organisms, with an incubation period of 6 hours to 5 days. Classic cholera starts with vomiting, abdominal pain, and diarrhea. Diarrhea progresses to voluminous watery stools that have been described as “rice water” because they are clear with flecks of mucus. Massive diarrhea can lead to dehydration and shock within a few hours. The illness may be fulminant, with death occurring 3 to 4 hours after onset. Fever and bacteremia are rare. In endemic areas, the diagnosis is usually made on clinical grounds. Toxigenic *V. cholerae* non-O1, non-O139 produces cholera toxin and has caused sporadic cases of diarrhea or small outbreaks in some parts of the United States through consumption of contaminated seafood or water. *V. parahaemolyticus* has also been reported to cause acute gastroenteritis from consumption of contaminated seafood. The characteristics of noncholeraic *Vibrio* species are covered in [Tables 98.1](#) and [98.2](#).

Listeria

Listeria monocytogenes is an uncommon cause of diarrhea in the United States. The two major clinical syndromes of *Listeria* infection are

gastroenteritis and listeriosis. Outbreaks may be due to ingestion of contaminated ready-to-eat foods such as unpasteurized milk, cheeses, meats, vegetables, and unwashed raw produce. Gastroenteritis is usually mild, non-invasive, and generally self-limiting. Symptoms including diarrhea, fever, chills, headache, joint pains, and myalgia that may occur 9 to 32 (median, 20) hours after ingestion of contaminated food. The diagnosis of gastroenteritis is often missed, as stool is not routinely cultured. In febrile gastroenteritis where traditional pathogens are not isolated using standard media, culture of stools with selective media for *L. monocytogenes* may demonstrate the organism. If diagnosed in a susceptible host, *Listeria* gastroenteritis may be treated with amoxicillin 500 mg orally three times a day or TMP/SMX 160/800 mg for 7 days.

Listeriosis is a more severe invasive illness, which may manifest as bacteremia, central nervous system disease, or sepsis in pregnant women with fetal loss. Risk factors for listeriosis include extremes of age, pregnancy, and immunocompromised state. In 2019, the FoodNet reported 134 laboratory-diagnosed cases of listeriosis in the United States, of which 131 (98%) were hospitalized and 21 (16%) died. The overall incidence was 0.3 per 100,000 population.

Diarrhea-Causing *Escherichia coli*

There are several types of diarrheagenic *E. coli*, each with a different pathogenesis leading to diarrhea. These include ETEC, STEC, enteropathogenic (EPEC), EIEC, EAEC, and diffusely adherent *E. coli*. ETEC is the most common cause of traveler's diarrhea. EPEC has been associated with epidemic diarrhea in neonates.

EHEC is acquired by eating contaminated food or water. The oral inoculum is 10 to 100 organisms, with an incubation period of 3 to 4 days. Most disease in the United States is caused by *E. coli* O157:H7. Infection with EHEC, including *E. coli* O157:H7 and other STEC serotypes can cause hemorrhagic colitis. It is classically associated with bloody diarrhea, abdominal pain, and fecal leukocytes. Systemic complications include HUS in children and thrombotic thrombocytopenia purpura in adults. Antibiotic therapy may increase the risk of HUS.

Clostridioides difficile

C. difficile infection is the main cause of nosocomial diarrhea among adults in the United States. The main risk factor for CDI is antibiotic use. Advanced age and severe underlying disease contribute to susceptibility. Virtually all antibiotics have been implicated in the development of CDI, but the most common agents are clindamycin, cephalosporins, fluoroquinolones, ampicillin, and amoxicillin. Infection is transmitted by spores, which occur in the environment and are resistant to alcohol-based handwashing solutions. The spores of toxigenic *C. difficile* are ingested, survive gastric acidity, germinate, and colonize the lower intestinal tract, where they elaborate two exotoxins, toxin A (an enterotoxin) and toxin B (a cytotoxin). The toxins disrupt cell and tight junctions, leading to fluid leakage. The cellular toxicity results in neutrophilic colitis and formation of a pseudomembrane in some cases.

The hypervirulent strain referred to as the North American pulsed-field gel electrophoresis type 1 (NAP1/027) strain is associated with a severe course, higher mortality, and increased risk of relapse. Bacterial factors implicated in outbreaks of CDI caused by the NAP1/027 strain include increased production of toxins A and B, fluoroquinolone resistance, and production of a binary toxin. Patients often have abdominal pain and watery diarrhea but may also have bloody stools. Markers of severe or fulminant CDI include pseudomembranous colitis, acute renal failure, marked leukocytosis, hypotension, and toxic megacolon. The indigenous intestinal microbiota is important for colonization resistance and for recovery from antibiotic-associated CDI.

Yersinia enterocolitica

Y. enterocolitica is a zoonosis caused by ingestion of contaminated food or water or undercooked meats. Oral inoculation requires 10^9 organisms for infection, with an incubation period of 3 to 7 days. The illness may mimic acute appendicitis and may be complicated by ileal perforation, mesenteric adenitis, or terminal ileitis. Postinfectious reactive arthritis may occur.

Viral Causes of Diarrhea

Viruses cause diarrhea by adhering to the intestinal mucosa and disrupting the absorptive and secretory processes without causing inflammation. They may invade intestinal villous epithelial cells and cause sloughing of villi. Rotavirus is a common cause of severe diarrhea in children younger than 5 years of age. The incidence of rotavirus disease has fallen in many countries following the introduction of the rotavirus vaccine. Rotavirus still results in greater than 200,000 deaths annually, mostly in low-income countries. Norovirus is highly contagious and is a very common cause of food-borne gastroenteritis in adults and children in the United States. It has been the cause of epidemic diarrhea on cruise ships. Other viruses that cause diarrhea are adenoviruses, sapoviruses, and astroviruses. The incubation period is usually longer than 14 hours, and vomiting may be a prominent feature of diarrheal disease caused by viral agents.

Protozoan Causes of Diarrhea

Important parasitic causes of diarrhea include *G. lamblia*, *C. parvum*, and *E. histolytica*. Contaminated water sources tend to be the cause of outbreaks. *G. lamblia* trophozoites adhere to the epithelium of the upper small intestine and damage the mucosal brush border without invasion. Ingestion of a few organisms can lead to disease. *C. parvum*, *Isospora belli*, and *Cyclospora cayetanensis* occasionally cause self-limited diarrhea in immunocompetent individuals but may cause severe disease in patients with advanced acquired immunodeficiency syndrome (AIDS). *E. histolytica* causes a syndrome ranging from mild diarrhea to fulminant amebic colitis and extraintestinal amebic abscesses.

Traveler's Diarrhea

Traveler's diarrhea affects 10% to 40% of travelers from industrialized countries who visit tropical and semitropical developing countries. The causative agent is identified in about 85% of cases, and 90% of those identified are bacterial pathogens, most often ETEC or EAEC. Less common bacterial causes include EIEC, diffusely adherent *E. coli*, *Shigella* spp, *Salmonella* spp, *Campylobacter* spp, *Aeromonas*, *V. cholerae*, noncholeraic *Vibrio*, and *Plesiomonas*. The viral etiologies include rotavirus and norovirus. Protozoal causes are rare. Travelers to high-risk areas should be counseled to wash hands, avoid uncooked food, and drink bottled water. Patients with traveler's diarrhea should be treated empirically with antibiotics without stool examination.

CLINICAL PRESENTATION

The epidemiologic and clinical characteristics are important to identify the potential etiologic agent and to guide management (see Table 98.1). The initial evaluation should consider the severity of illness, signs of dehydration, and intestinal inflammation indicated by the fever, abdominal pain, blood in stools (dysentery), or tenesmus. Important epidemiologic clues in the history include age, travel history, ingestion of undercooked or raw food and meat, antibiotic use, sexual activity, daycare attendance, and outbreaks involving others with similar exposure (see Table 98.1). Fever (temperature 38.5° C or 101.3° F or higher) is associated with invasive pathogens that cause

intestinal inflammation. The examination should determine the severity of dehydration and need for rehydration as well as the likely cause. Signs of dehydration or hypovolemia include lax skin turgor and tenting, dry mucus membranes, decreased urination, tachycardia, and hypotension.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

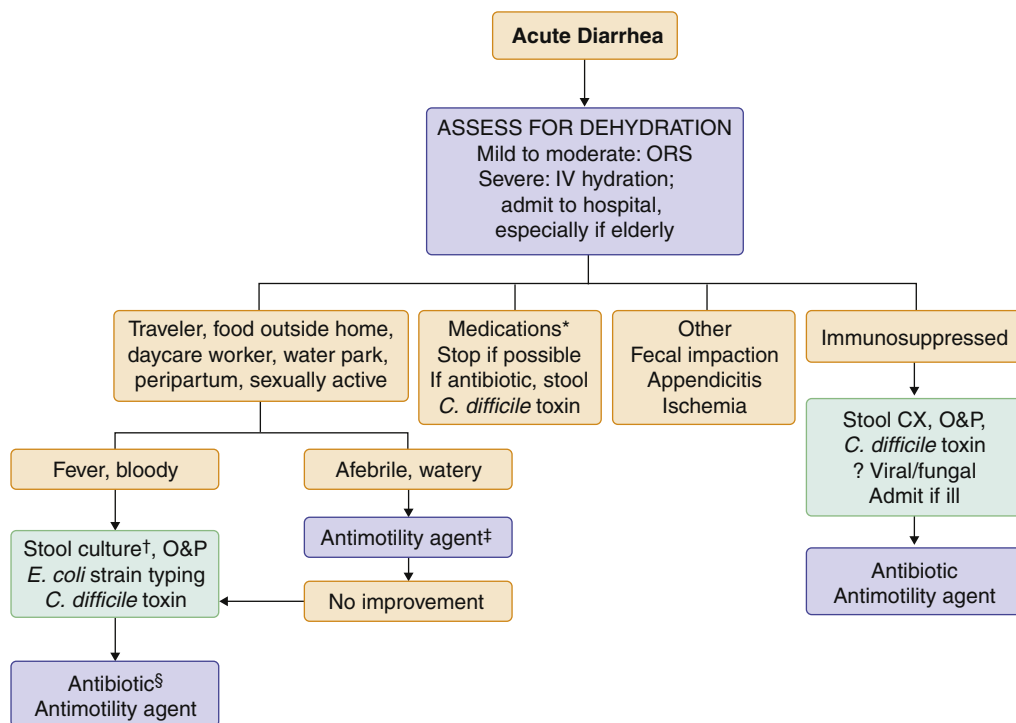

The approach to diagnosis and management of infectious diarrhea is shown in Fig. 98.1. Most cases of diarrheal illnesses are self-limiting with almost half resolving within 1 day. Therefore, microbiologic investigation is usually not necessary for patients who are seen within 24 hours of the onset of illness unless certain conditions are present.

The indications for stool culture include severe diarrhea (six or more stools per day), diarrhea lasting longer than 1 week, fever, dysentery, hospitalization, inflammatory diarrhea, and multiple cases in a suspected outbreak. Routine stool culture will identify *Shigella*, *Salmonella*, *Campylobacter*, and *Aeromonas*. Polymerase chain reaction (PCR)-based diagnostic tests are now available and include a multiplex approach that allows several bacterial, viral, and parasitic enteropathogens to be detected in a single test simultaneously. The Luminex xTAG Gastrointestinal Pathogens Panel tests for 14 viruses, bacteria, and parasites and the FilmArray Gastrointestinal

panel (Biofire Diagnostics) tests for 22 viruses, bacteria, and parasites. These methods are faster and have higher sensitivity than culture-based methods but they do not distinguish pathogenic and nonpathogenic organisms. If the patient has bloody diarrhea or HUS, stool culture for *E. coli* O157:H7 and tests for Shiga-like toxin (or the genes that encode them) should be performed. If there is a history of recent antibiotic use, hospitalization, or age greater than 65 years with coexisting conditions, immunosuppression, or neutropenia, stool samples should be tested for *C. difficile* toxin. Available tests for *C. difficile* toxin include enzyme immunoassay (EIA), nucleic acid amplification test (NAAT) and glutamate dehydrogenase (GDH plus toxin) test. No single test is suitable as a stand-alone test and often a multistep algorithm testing is used. Consider protozoa, and check stools for ova and parasites (e.g., trophozoites) and/or for *Giardia* antigen test if diarrhea duration is greater than 7 days. If a patient has AIDS, stools should be checked for *Cryptosporidium*, *Microsporidium*, and *Mycobacterium avium* complex.

TREATMENT

Initial therapy should include fluid and electrolyte repletion with or without antimicrobial therapy. Oral rehydration is often adequate unless the patient is comatose or severely dehydrated. Nutritional support with continued feeding improves outcomes in children.

Report to Public Health and save blood/stool.

Fig. 98.1 Approach to the diagnosis and management of acute infectious diarrhea. *More than 700 medications cause diarrhea, including furosemide, caffeine, protease inhibitors, thyroid preparations, metformin, mycophenolate mofetil, sirolimus, cholinergic drugs, colchicine, theophylline, selective serotonin reuptake inhibitors, proton pump inhibitors, histamine-2 blockers, 5-ASA derivatives, angiotensin-converting enzyme inhibitors, bisacodyl, senna, aloe, anthraquinones, and magnesium- or phosphorus-containing medications. †Specifically request culture for *Yersinia*, *Plesiomonas*, enterohemorrhagic *Escherichia coli* serotype O157:H7, and *Aeromonas* if suspected. ‡If high suspicion for *Clostridioides difficile* or invasive bacterial infection, wait for stool culture and toxin studies before starting. Racecadotril has antisecretory effects without paralyzing intestinal motility and can be used if available. §Not recommended for patients with bloody diarrhea due to *E. coli* O157:H7. CX, Culture; IV therapy, intravenous rehydration; O&P, ova and parasites; ORS, oral rehydration solution. (From Goldman L, Schafer AI: *Goldman-Cecil Medicine*, 25th ed. Philadelphia, Elsevier, 2016, Fig. 140-1.)

Oral Fluid Therapy

In most patients with diarrhea, fluid repletion can be achieved with oral rehydration therapy using isotonic fluids containing glucose and electrolytes. An effective solution can be prepared by the addition of 2 tablespoons of sugar, one fourth of a teaspoon of salt (NaCl), and one-fourth of a teaspoon of baking soda (NaHCO₃) to 1 L of boiled drinking water. In the United States, fluids such as Pedialyte or Rehydrolite solutions are recommended. Fluid should be administered in large quantities until there is clinical evidence that fluid balance is restored and then as maintenance therapy. Oral rehydration therapy can be life-saving for patients in developing countries with severe diarrhea.

Intravenous Fluid Therapy

Massive fluid loss due to diarrhea should be rapidly replaced by the administration of intravenous fluids. Lactated Ringer's solution is the fluid of choice because the composition is similar to electrolyte loss during diarrhea. The rate of fluid administration and maintenance should be guided by clinical signs including vital signs, appearance of the mucosa, neck veins, and skin turgor.

Antimicrobial Therapy

Most cases of infectious diarrhea do not require antimicrobial therapy. However, antibiotics may decrease the volume of diarrhea (e.g., in cholera) or the duration and severity of the illness. Antibiotics are effective in the treatment of shigellosis, traveler's diarrhea, and *Campylobacter* infection. In uncomplicated salmonellosis, antibiotics may prolong the shedding of *Salmonella*. The choice and dose of antimicrobials for specific pathogens are described in [Table 98.2](#). For traveler's diarrhea in adults, empiric therapy with azithromycin 500 mg daily, or ciprofloxacin 500 mg twice a day, or trimethoprim-sulfamethoxazole (TMP-SMZ) 160/800 mg twice a day, for 3 days is adequate. For antibiotic-associated *C. difficile* colitis, broad-spectrum antibiotics should be discontinued, if possible. Preferred therapy for an initial episode of CDI is oral vancomycin 125 mg four times a day or fidaxomicin 200 mg twice daily for 10 days. If those antibiotics are not available, metronidazole 500 mg three times daily for 10 days is an alternative therapy. Fecal microbiota transplantation may be indicated for patients with multiple recurrences of CDI who have failed appropriate antibiotic

treatments. Antibiotics must be avoided in patients with STEC O157 or other STEC that produce Shiga toxin.

Symptomatic Therapy

Antidiarrheal agents such as loperamide and bismuth subsalicylate can be used in some instances for symptomatic relief. Loperamide inhibits intestinal peristalsis and has some antisecretory properties. When used with or without antibiotics in cases of traveler's diarrhea, it may reduce the duration of diarrhea by about 1 day. Antimotility agents should be avoided in patients with bloody or suspected inflammatory diarrhea. The use of these agents has been implicated in prolonging the duration of fever in shigellosis, development of toxic megacolon in CDI, and development of HUS in children with STEC infection.

PROGNOSIS

The prognosis is generally good but is variable depending on the etiology and the severity of illness. Most patients recover completely within 3 to 5 days. However, serious complications, including death, can be seen in individuals who become severely dehydrated, infants, elderly patients, and those with underlying medical conditions or immunosuppression. Untreated severe dehydration may lead to shock, renal failure, and death. Postinfectious reactive polyarthritides can complicate cases due to *Yersinia*, *Campylobacter*, and *Shigella*, and Guillain-Barré syndrome may occur after diarrhea caused by *Campylobacter*.

Infections Involving Bone and Joints

Jerome Larkin

DEFINITION

Osteomyelitis refers to infection of any component of the bony skeleton, whereas *septic arthritis* refers to that of native or prosthetic joints. Tendons, ligaments, and bursae can also become infected, especially if they involve prosthetic or bio-grafted material. Osteomyelitis and septic arthritis can occur by seeding during bacteremia, due to extension from a contiguous focus of infection in an adjacent tissue or structure, as a consequence of vascular insufficiency or as a complication of trauma. In the case of hematogenous infection, the bacteremia itself may be relatively transient and of little clinical consequence. Hematogenous osteomyelitis is common in children but accounts for only 20% of osteomyelitis in adults. The vertebrae and pelvis are the most commonly involved sites of hematogenous osteomyelitis in adults. Peripheral vascular disease leading to tissue hypoxia and related to diabetes, hypertension, hyperlipidemia, and smoking is the biggest risk factor for the development of osteomyelitis in adults older than 50. There is often preceding soft tissue infection or destruction as a result of vascular insufficiency and neuropathy. It is most common in the lower extremities, particularly in the feet, and often occurs in diabetics. Trauma, especially when it involves open fracture with its attendant disruption of the bony architecture and vascular supply, is a second major risk factor for the development of osteomyelitis and septic arthritis. This is particularly true when an open fracture, as may be experienced in a fall or motor vehicle accident, is heavily contaminated with soil or other environmental materials. Such fractures often require internal fixation (i.e., the placement of rods, screws, and other metal devices to stabilize the bone). The presence of such internal fixation provides a nidus for bacteria and other microorganisms including fungi to elude the immune system and incubate. Chronic osteomyelitis is a possible complication of such injuries and is often a result of multiple or unusual organisms. It may occur despite aggressive débridement and prophylactic antibiotic treatment at the time of injury and can arise months or even years afterwards. Individuals who experience prolonged periods of immobility such as those suffering from paraplegia are also at risk for osteomyelitis. Infection typically involves the pelvis, sacrum, and lower spine corresponding to areas of unrelieved pressure as a result of the immobility.

Osteomyelitis may be conceptualized as acute or chronic. The former is typically hematogenous, associated with signs of inflammation in the overlying soft tissue and with an onset over the course of days to a week. Radiographs are usually normal at presentation. Chronic osteomyelitis is more indolent with onset over the course of months, is more likely to exhibit bony destruction on plain radiograph at the time of presentation, and is often associated with a draining sinus tract. Sequestra (areas of dead bone) and involucra (new bone formed around sequestra) may also be seen. Whereas acute osteomyelitis may require a 6-week course of antibiotics alone to effect cure, chronic

osteomyelitis more typically requires surgical intervention and a prolonged (3 or more months) course of antibiotic therapy.

PATHOPHYSIOLOGY

Aspects of the vascular supply of the bone as well as properties of the most common pathogen, *Staphylococcus aureus*, may combine to lead to infection. Although bone is generally resistant to infection, the vasculature of the metaphysis contains capillary loops composed of a single layer of discontinuous endothelial cells, which may allow bacteria to enter the extracellular matrix. These capillary beds lack functionally active phagocytes. *S. aureus* can elaborate proteins expressed on its surface that promote adherence to tissues of the extracellular matrix. When engulfed by osteoblasts, *S. aureus* can survive for prolonged periods of time in an almost spore-like state leading to potential recurrences of infection. Finally, many bacteria can elaborate biofilms that allow them to elude clearance by the immune system. Prosthetic material such as in joint replacements and other grafts can serve as a platform for the formation of such biofilms.

In the case of septic arthritis there is usually some underlying abnormality in the joint, but this abnormality may be as mundane as osteoarthritis. It is hypothesized that relatively trivial injury, which may in fact go unnoticed or unremembered by the patient, leads to minor bleeding into the joint, which in turn provides a hospitable environment for bacteria to incubate.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with osteomyelitis will often present with pain at the site of infection. The overlying soft tissue may have signs of inflammation or tissue destruction, the latter often seen in diabetics with soft tissue ulceration. Historically, the diagnosis of osteomyelitis relied on the presence of lucency on plain radiograph of the affected area. Diagnosis could be confirmed histologically by bone biopsy with culture to identify the pathogenic organism. Currently, diagnosis is typically made by MRI with gadolinium, which demonstrates marrow edema with or without bony destruction. Alternatively, diagnosis may be made by three-phase bone scan or CT. These may be especially helpful in patients with renal insufficiency who cannot undergo gadolinium-enhanced studies due to the risk of nephrogenic systemic fibrosis. An elevated C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR) supports the diagnosis. Microbiologic diagnosis is made either by positive blood cultures or bone biopsy and culture. Culture of cutaneous ulcers is typically not helpful because results of such studies usually demonstrate multiple colonizing organisms and do not correlate with organisms isolated on bone culture. An exception is the isolation of *S. aureus* or *Salmonella* from a draining fistula or on occasion *Pseudomonas* from an ulcer. In the former case, the bacterium can then

be presumed to be the pathogen; in the latter, a decision would then need to be made to include coverage for this organism in an empiric antibiotic regimen. If cultures of bone obtained by noninvasive techniques under radiographic guidance are negative, either the procedure should be repeated or an open biopsy with culture performed.

Septic arthritis of native joints typically will present with the cardinal features of inflammation (i.e., erythema, swelling, warmth, and pain) when involving joints of the extremities. Fever may often be present and septic arthritis is more likely to present with an associated bacteremia. Septic arthritis of the spine, pelvis, and hip may require imaging, usually MRI, because these may be difficult to assess by examination alone. Persistent back, pelvic or hip pain that is otherwise unexplained should prompt radiographic evaluation even in the absence of fever. Diagnosis ultimately relies on joint aspiration with débridement. Such procedures should occur prior to the administration of antibiotics. Fluid should be sent for cell count with differential, crystal analysis, Gram stain, anaerobic culture, and fungal and acid-fast stains and cultures. Positive stains and/or cultures are taken as evidence of infection in most cases in which an appropriate clinical syndrome is also present. White blood cell (WBC) counts higher than 50,000 cells/mL are suggestive of infection. In cases that are difficult to diagnose or instances where antibiotics have been given prior to aspiration, it may be appropriate to have cultures held for up to 14 days. Specialized culture techniques for fastidious organisms such as anaerobes and nutritionally deficient streptococci may be required. Ultimately, tagged WBC scans may help to clarify the presence or absence of septic arthritis in difficult cases. Evolving molecular technologies such as PCR, especially microarray assays that detect multiple pathogens, and 16-S ribosomal sequencing may offer alternative and more rapid and precise diagnosis in the future.

Prosthetic joint infections (PJI) are defined by their timing following implantation: acute (less than 3 months), delayed (3 to 12 months) or late (12 months). Early PJI presents similarly to native joint infections. Delayed and late infections are more indolent, presenting with pain, decreased function, and evidence of loosening of the prosthesis on plain films. More overt signs of inflammation or systemic infection may be subtle or absent altogether. Diagnosis relies on the presence of either a draining sinus tract that communicates with the prosthesis or two or more periprosthetic cultures harboring the same organism. Minor criteria have been proposed with three or more of the following used to diagnose PJI: elevated CRP or ESR, synovial fluid WBC greater than 3000, elevated synovial polymorphonuclear cells (PMNs), a single positive culture or greater than five PMNs per high-power field on examination of periprosthetic tissue. A point scoring system as advanced by Parvizi and colleagues may increase the sensitivity of the use of minor criteria or be used as a tool in more diagnostically obscure cases.

Most cases of osteomyelitis and septic arthritis are due to *Staphylococcus*, *Streptococcus*, and aerobic gram-negative bacilli, although virtually any pathogenic microorganism can cause such infections in the appropriate circumstance. Infecting staphylococci include both *S. aureus* and coagulase-negative staphylococci. Coagulase-negative staphylococci are often implicated in prosthetic joint infections or infections associated with orthopedic hardware. *Streptococcus* spp causing bone and joint infections include groups A, B, C, G and F as well as *Abiotrophia* and *Gemella* (formerly termed nutritionally deficient streptococci). Gram-negative organisms account for as much as 30% of hematogenous infections. Gram-negative infections are seen more commonly in the elderly as a result of urinary tract infections with associated bacteremia. Isolated species include *Escherichia coli*, *Haemophilus influenzae*, and *H. parainfluenzae*. Infections with *Serratia marcescens* and *Pseudomonas* are associated with exposure to water and are usually nosocomial or related to intravenous drug use. Fungi such

as *Candida*, *Aspergillus*, and *Zygomycetes* may cause bone and joint infections, particularly in immune-compromised patients, diabetics or those who have suffered trauma. *Nocardia* and other acid-fast organisms may be seen following trauma or in association with prosthetic joints and may require several attempts at débridement before being isolated. *Cutibacterium acnes* is often isolated from shoulder infections, especially those involving prosthetic joints. The variety of potential pathogens underscores the need to obtain appropriate specimens for culture prior to the administration of antibiotics.

Infection with *Borrelia burgdorferi*, the causative agent of Lyme disease, can lead to a multifocal or monoarticular septic arthritis. Fluid analysis is consistent with bacterial septic arthritis but is negative for typical organisms on culture. Associated findings of erythema migrans, diffuse myalgias and arthralgias, cranial nerve palsies, fever, and aseptic meningitis may also be present. Polymerase chain reaction of joint fluid has a reported sensitivity of between 30% and 75%. Diagnosis relies on serology and associated findings in patients who reside in endemic areas. Later-stage disease may present with a less inflammatory-appearing effusion, often without any other symptoms. Treatment is with either doxycycline or ceftriaxone depending on the stage of disease.

Neisseria gonorrhoea may cause a solitary or multifocal septic arthritis. It is usually seen in sexually active younger adults. Culture of the joint fluid may be negative but testing of specimens from the pharynx, urethra or rectum are usually positive by nucleic acid amplification. The treatment of choice is ceftriaxone.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of both osteomyelitis and septic arthritis includes other noninfectious inflammatory disorders such as gout, pseudogout, rheumatoid arthritis, inflammatory bowel disease, and other inflammatory and autoimmune disorders. Occasionally, neoplasms such as sarcomas or metastatic lesions may present similarly to osteomyelitis. Several viruses such as rubella, parvovirus B19, Chikungunya and hepatitis B can cause arthritis. Chronic recurrent multifocal osteomyelitis is a noninfectious inflammatory lesion of bone thought to be autoimmune in nature and characterized by findings on MRI similar to osteomyelitis. It is culture-negative and unresponsive to antibiotics. It is a diagnosis of exclusion often made only after several attempts at diagnosing and treating presumed bacterial osteomyelitis. Although typically seen in children, with peak incidence between 7 and 12 years of age, it can also occur in adults.

TREATMENT

Treatment of osteomyelitis involves débridement of appropriate infected and/or necrotic tissue as well as the administration of antibiotics. It is critically important to remove all necrotic or devitalized tissue, which may serve as a nidus of chronic or recurrent infection if not removed. In this regard, it is often necessary to remove any fixating hardware, plastic devices, bone grafts or other donor tissue if infection has been present for greater than one month or is recurrent. Cadaveric donor tissue infections often are caused by atypical organisms such as *Clostridioides* spp. Historically, sequestra developed in the site of chronically infected bone. These are produced by the action of the immune system and histologically are characterized by granulomatous tissue that serves to isolate the infection. While effective in containing infection, they also represented a risk for recurrence as well as an area of bone weakening. When present, they should be surgically excised. Infection that occurs in the immediate postoperative period (i.e., within 1 month after placement of hardware and grafts)

and that appears to only involve the soft tissue may be treated with débridement and antibiotics alone with a reasonable chance of success. Occasionally, infected hardware must be left in place in order to stabilize the bone while a fracture is healing. In this instance, it may be necessary to continue antibiotic treatment until hardware removal can be accomplished. Infected spine hardware that must remain in place may require prolonged antibiotic treatment, at times indefinitely. The addition of rifampin for staphylococcal infections with retained hardware to which the infecting organism is susceptible improves overall cure rates.

Septic arthritis requires serial débridement of the joint until active purulence has resolved. This is indicated by decreasing cell count and sterilization of joint fluid cultures. Prosthetic joint infection typically requires removal of the infected prosthesis with placement of an antibiotic spacer for 4 to 6 weeks while antibiotics are administered. This is followed by placement of a new prosthesis once all signs and symptoms of infection have resolved. Selected infections with coagulase-negative staphylococci and *Streptococcus* infections may be treated with débridement, joint retention, and a 6-week or longer course of antibiotics. Consideration should then be given to chronic suppressive antibiotic therapy, assuming an appropriate agent is available.

Antibiotic treatment should be with agents active against the infecting organism if culture and susceptibility data are available. β -Lactams are the preferred agent in most cases. Therapy with quinolones for Enterobacteriaceae and in combination with rifampin for staphylococci may be considered. These drugs have the advantage of high oral bioavailability that approaches or equals tissue levels when given intravenously. Care should be taken regarding drug interactions with rifampin and the risk of *Clostridioides difficile* colitis and Achilles tendon rupture with quinolones. Recent literature also indicates a small increased risk of aortic aneurysm or dissection with this class of antibiotics. In the face of negative cultures, empiric therapy with an agent active against typical pathogens, including methicillin-resistant *S. aureus*, is reasonable. Vancomycin remains the standard agent for empiric therapy. Prior administration of antibiotics may lead to negative cultures even in cases of unequivocal infection. In this situation, empiric therapy should be based on the activity of the agents previously administered, as well as on potential pathogens based on exposure history. In all cases, the clinical response to infection should be monitored and should inform subsequent decision making regarding the need for additional débridement or changes in antibiotic therapy. Monitoring inflammatory markers such as CRP or ESR is helpful in determining the adequacy of response to treatment. If elevated at the start of treatment they should fall to normal or near normal by the time treatment is finished. Signs and symptoms of inflammation at the site of infection should have also resolved at the cessation of treatment.

There are few randomized, controlled trials comparing different durations of antimicrobial therapy. Acute osteomyelitis should be treated for 4 to 6 weeks. Continuing treatment in a patient who is improved but who has failed to resolve elevated inflammatory markers or local signs of inflammation is reasonable. Such patients should be closely monitored and evaluated for the need for additional débridement or other measures aimed at diagnosis and source control. Chronic osteomyelitis may require 12 or more weeks of therapy, and treatment is usually individualized based on the clinical situation. Patients on therapy should also be monitored weekly for toxicity to antibiotics. Assessment of renal and hepatic function, complete blood count, and drug levels are typically followed depending on the specific agent used. In the case of aminoglycosides, renal function and peak and trough levels should be followed twice weekly. Long-acting glycopeptides such as dalbavancin and oritavancin are promising alternatives to daily antibiotic dosing.

A recent open-label study of the treatment of osteomyelitis that included over 1000 randomized patients demonstrated a lack of inferiority of oral therapy when compared with intravenous therapy. Costs were reduced and patient satisfaction was higher in the orally treated group. The incidence of serious side effects and adverse reactions was similar between the two groups. Oral therapy was largely with quinolones. The study encompassed a heterogeneous population so, although promising, application of the findings to particular patients should be done thoughtfully. Adjunctive therapies such as bone grafting, revascularization procedures, and the placement of muscle flaps to cover and protect exposed bone may be utilized in the appropriate clinical situation.

Native joint septic arthritis may be treated with a 4-week course of antibiotics; prosthetic joint infections are typically treated for 6 or more weeks. Monitoring for toxicity and response to treatment is similar to that for osteomyelitis.

PROGNOSIS

The prognosis for osteomyelitis and septic arthritis is excellent, assuming adequate diagnosis, débridement, and antimicrobial therapy. The most common complication is residual pain and/or decreased function of the affected bone or joint. These are relatively rare and relatively minor. An exception involves prosthetic joint infections, in which 25% to 50% of patients experience some loss of function as a result of the infection. Recurrence rates for chronic osteomyelitis, especially in diabetics, may be as high as 30%. In more complex cases such as open contaminated fractures or infected hardware that requires retention, complications include nonunion, prosthesis failure, and chronic osteomyelitis. Infections that cannot be controlled may lead to the need for amputation and its attendant loss of function and mobility. Occasionally, bone or joint infections can lead to dissemination to other joints or the bloodstream. Such cases usually involve infection with *S. aureus* and fortunately remain the exception.

Urinary Tract Infections

Abdullah Chahin, Steven M. Opal

DEFINITION AND DIAGNOSIS

The term *urinary tract infection* (UTI) refers to significant bacteriuria in a patient with symptoms or signs attributable to the urinary tract and no alternative diagnosis. UTI includes asymptomatic bacteriuria, urethritis, cystitis, pyelonephritis, catheter-associated UTI, prostatitis, and urosepsis. This chapter focuses primarily on the two major forms of UTI, cystitis and pyelonephritis.

A practical classification divides these infections into uncomplicated and complicated UTI. Uncomplicated UTIs are episodes of cystitis and mild pyelonephritis occurring in healthy, premenopausal, sexually active, nonpregnant women with no history suggestive of abnormalities in the urinary tract. All other episodes of UTI are deemed to be potentially complicated and deserving of further evaluation.

The term *asymptomatic bacteriuria* refers to isolation of bacteria in an appropriately collected urine specimen from an individual who describes no symptoms for urinary tract infection. In women, asymptomatic bacteriuria is defined as two consecutive voided midstream urine specimens with isolation of the same bacterial strain at levels of at least 10^5 colony-forming units (CFU) per milliliter from patients without genitourinary symptoms. In men, a single clean-catch, midstream voided urine specimen with one bacterial species at a concentration greater than 10^5 CFU/mL defines asymptomatic bacteriuria. The diagnosis of asymptomatic bacteriuria is also established in both women and men from a single catheterized urine specimen (not an indwelling catheter) with one bacterial species isolated at concentrations greater than 10^2 CFU/mL. Although infants and toddlers infrequently have asymptomatic bacteriuria, the incidence increases with age, owing to the incomplete bladder emptying from various obstructive urologic conditions that develop with advanced age, reaching up to 15% or greater in women and men age 65 to 80 years and as high as 50% after age 80. Asymptomatic bacteriuria is therefore commonly encountered in clinical practice, and it frequently poses a challenge in determining the exact source of infection in elderly patients presenting with sepsis. Asymptomatic bacteriuria is a common cause for unnecessary use of antibiotics and the array of complications that can result from antibiotic misuse, ranging from mild adverse reactions to devastating complications such as antibiotic-associated *Clostridioides difficile* infections.

The presence of asymptomatic bacteriuria therefore should not be considered as equivalent to UTI except in neutropenic patients and individuals with anatomic or functional defects in the urinary tract. Asymptomatic bacteriuria in pregnancy has been an indication for treatment. However, the most recent Systematic Review for the US Preventive Services Task Force in September of 2019 showed that screening and treatment for asymptomatic bacteriuria during pregnancy was associated with reduced rates of pyelonephritis and low birth weights, but the available evidence was not current, with only one study conducted in the past 30 years. It is difficult to define

asymptomatic bacteriuria in the patient who has undergone renal transplantation, and bacteriuria in such patients often indicates the need to treat for UTI.

To increase the sensitivity of urinalysis and culture, *significant bacteriuria* is defined as greater than 10^2 CFU/mL of urine in a woman with symptoms of uncomplicated cystitis and pyuria (≥ 5 white blood cells per milliliter of urine per high-power field). Among women with symptoms of uncomplicated pyelonephritis and men with UTI, significant bacteriuria is defined as greater than 10^4 CFU/mL plus pyuria. In patients with complicated UTI, a concentration of 10^5 CFU/mL or higher is required for the definition of significant bacteriuria independently of pyuria.

In order for these definitions to be valid, the urine must remain in the bladder for at least 2 hours, and after urine collection the sample should be incubated immediately. If urine is not incubated immediately, it can be refrigerated for up to 8 hours before proper incubation.

Although the presence of bacteriuria is vital for the establishment of the diagnosis of UTI, clinical symptomatology is the hallmark of UTI. The presence of dysuria, increased frequency of urination, suprapubic tenderness, and hematuria associated with bacteriuria or pyuria on urinalysis is unequivocally consistent with the diagnosis of cystitis. Back or flank pain, nausea, vomiting, and the presence of fever or rigors suggest infection of the upper urinary tract, although it is not easy to distinguish cystitis from pyelonephritis on clinical grounds alone. The diagnosis of UTI gets more difficult when patients cannot ascribe symptoms to the urinary tract (e.g., patients with paraplegia or neurogenic bladder, confused elderly or sedated patients) or when they have atypical symptoms, such as changes in mental status, agitation, or hypotension. Sometimes patients have urinary symptoms without bacteriuria (the pyuria-dysuria or “urethral syndrome” commonly caused by *Chlamydia trachomatis* or other difficult-to-culture genitourinary pathogens).

With the widespread utilization of indwelling catheters, *catheter-associated urinary tract infection* (CAUTI) remains a challenge in health care and one of the most common nosocomial infections. Essentially, CAUTI has similar symptoms to a typical UTI but requires the presence of an indwelling urinary catheter for the term to apply. The standard Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) CAUTI definition is complex and subjective. Moreover, it can be difficult to diagnose in patients who are already hospitalized due to the resemblance of the potential signs and symptoms of CAUTI with many other acute disorders that were part of the original reason for hospitalization.

LABORATORY FINDINGS

Young, sexually active women with typical symptoms of UTI have a high pretest probability for UTI. Therefore, no laboratory test is indicated. In this population, pretreatment urine analysis and culture are

indicated only if the diagnosis is not straightforward or if an antibiotic-resistant organism is suspected. Urinalysis and culture are indicated in all cases of suspected complicated UTI. The presence of white blood cell casts in urinalysis indicates pyelonephritis, and this finding suggests a complicated UTI with possible obstructive lesions within the kidney or collecting system (e.g., papillary necrosis). Blood cultures are mandatory for patients with suspected pyelonephritis. *Staphylococcus aureus* bacteriuria should prompt work-up for *S. aureus* bacteremia and for renal abscesses in non-catheter-related UTIs, particularly in those who are hospitalized and have laboratory evidence of infection. *S. aureus* UTI may also occur without hematogenous seeding in cases of indwelling catheters, with frequent instrumentation, or in the presence of hardware in the genitourinary tract. *Candida* is a commonly isolated organism on urine cultures (candiduria). Yeasts can be detected in contaminated samples during collection, in patients who have bladder or indwelling catheter colonization, and rarely in patients who have upper urinary tract infection that developed either from retrograde spread from the bladder or hematogenous spread from a distant source. The presence of pyuria and quantitative cultures of urine in cases of candiduria have proved to be of little use in separating infection from colonization. Therefore, clinical symptoms are of great importance, because diagnosing UTI with *Candida* might necessitate an extensive work-up to assess for invasive fungal infections (Candidemia or perinephric abscesses). Imaging studies are indicated if kidney stones, malignancy, obstructive uropathy, and urologic malformations are suspected.

EPIDEMIOLOGY

At the extremes of age, men are more prone to UTI than women. In young boys, urethral malformation is commonly the cause, and in older men, UTI is usually caused by bladder neck obstruction secondary to prostatic hypertrophy. Homosexual men are at increased risk for acquiring UTIs. Teenage girls and sexually active women have more UTIs than their male counterparts. A higher than expected incidence of UTI among young girls might suggest sexual abuse. Sexually active women have the highest rate of UTI. Postmenopausal women have increased prevalence of UTI due to estrogen deficiency and age-related pelvic relaxation with poor bladder emptying.

The most common etiologic agent in patients with uncomplicated UTI is *Escherichia coli* (90% of cases), followed by *Staphylococcus saprophyticus*. Other agents include *Klebsiella* spp, *Enterococcus faecalis*, *Enterococcus faecium*, *Proteus* spp, *Providencia stuartii*, and *Morganella morganii*. In patients with complicated UTI, *E. coli* is still the most frequent uropathogen, but at a lower rate than in uncomplicated UTI. Other causative organisms are *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Enterobacter* spp, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Enterococcus* spp, and *Candida* spp.

Anaerobic agents are infrequent causes of UTI; when present, they represent fistulae between the digestive tract and the urinary tract. *Staphylococcus aureus* UTI most often represents bacteremia with bacteriuria resulting from clearance of bloodstream bacteria by the kidney. Whereas 1% of individuals with a UTI get pyelonephritis, 20% to 40% of pregnant women with a UTI develop pyelonephritis, and 30% of patients with pyelonephritis have bacteremia. In diabetic and transplanted patients with UTI, the incidence of bacteremia is higher.

PATHOGENESIS

There are at least three routes by which bacteria can enter the bladder or kidney: ascending, hematogenous, and lymphatic. Lymphatic spread is the least common route. The hematogenous route is important for gram-positive organisms such as *S. aureus* or *Candida* spp but unimportant for gram-negative bacilli. The ascending route is the most

important for enteric bacteria, and this mechanism is supported by higher frequency of UTI in women, given the shorter length of the female urethra, and in individuals with an indwelling Foley catheter.

Before reaching the urinary bladder or kidney, the microorganism must colonize the external part of the urinary tract. Probably the most important aspect in the establishment of UTI is the interaction between host factors (e.g., secretor phenotype, P1 blood group, uroplakin I and II) and bacterial virulence factors (the adhesins, P fimbriae, and type I fimbriae [pili]). The urinary bladder is normally covered by a glycosaminoglycan surface that prevents binding of bacteria that transiently enter the bladder. P-fimbriated uropathogenic *E. coli* bind to alpha 1-4 linked, galactose-galactose disaccharide moieties found on uroepithelial cells, and these gal-gal glycolipids are also expressed on the P1 blood group. People with P1 blood group are overrepresented among individuals with either recurrent UTI or pyelonephritis. Also, people who lack P1 blood group are less prone to complicated UTI.

Studies have shown that P-fimbriated *E. coli* is present in 60% to 100% of isolates from patients with UTI. Ascending UTI infection can be inhibited experimentally by epithelial cell surface receptor analogues. Type I fimbriae bind to glycoprotein uroplakin I and II. *E. coli* expressing type I fimbriae are responsible for most cases of cystitis.

Once *E. coli* is attached to uroepithelial cells, both mechanical and biochemical factors facilitate the development of full-blown UTI. The local trauma and mechanical massage of the urethra during sexual intercourse help deliver bacteria into the bladder and, if vesicoureteral reflux or another ureteral anatomic defect is present, into the kidney. Urinary catheter placement also helps to propel bacteria into the bladder, and all patients with a long-term indwelling catheter in place will eventually develop asymptomatic UTI. All uropathogenic organisms have the ability to multiply in the urine.

From the standpoint of the host, other factors associated with the development of UTI are a new sex partner (within 1 year), use of diaphragms and spermicides, family history of UTI in a first-degree relative, and lower expression of CXCR1, an interleukin 8 receptor. Pathogenic factors associated with the development of UTI are flagellae, diverse adhesins, siderophores, toxins, polysaccharide coating, and the ability to cause a deleterious inflammatory response.

Patient behaviors that are not associated with UTI include precoital or postcoital voiding patterns, daily beverage consumption, frequency of urination, delayed voiding habits, wiping patterns, tampon use, douching, use of hot tubs, and type of underwear.

TREATMENT

The goal of treatment in uncomplicated UTI is to decrease symptoms and prevent complications. Treatment should be guided by two important principles: the prevalence of resistant genitourinary pathogens in the community and collateral damage to ecologic microbiota (i.e., the risk of propagation of resistant organisms). First-line agents for uncomplicated UTI are nitrofurantoin, trimethoprim-sulfamethoxazole (TMP-SMX), and fosfomycin trometamol; alternative agents are the fluoroquinolones (except moxifloxacin) and the β -lactams (Table 100.1).

Treatment of complicated UTI should be based on culture results and the other comorbidities that are present. Recurrent UTI in sexually active women can be prevented with postcoital TMP-SMX 40/200 mg single dose (if the patient has more than two UTIs per year related to coitus) or with daily, every other day, or weekly antibiotic. If the patient has a UTI unrelated to coitus or there are fewer than two UTIs per year related to coitus, the prevention of the UTI recurrence can be achieved with patient-initiated therapy. Daily topical application of intravaginal estriol can be helpful in postmenopausal women. After completion of the treatment, urine culture is indicated for pregnant women and on an individualized basis for other patients with complicated UTI.

❖ For a deeper discussion on this topic, please see Chapter 268, “Approach to the Patient with Urinary Tract Infection,” in *Goldman-Cecil Medicine*, 26th Edition.

COMPLICATIONS

Unrecognized and untreated UTIs can quickly develop grave complications. Recurrent infections, structural damage of the urinary tract and scar tissue formation, loss of renal function, increased risk of delivering low-birthweight or premature infants in pregnant women, and septic shock could all develop

in untreated UTI cases. Serious complications include renal abscesses which usually present with fever, back and abdominal pain and may include urinary tract symptoms. Abscesses are usually due to ascending urinary tract infection often with an obstructive process. *E. coli* or other enteric aerobic rods are typical organisms. Renal abscess can also be due to hematogenous spread of *S. aureus*. Prolonged antibiotic therapy directed at the offending organism is usually curative. Perinephric abscess results from rupture of an intrarenal abscess into the perinephric space between the renal capsule and Gerota’s fascia. Treatment is drainage and antibiotics. Some other serious complications of urinary tract infections are listed in Table 100.2.

TABLE 100.1 Therapy for Uncomplicated Urinary Tract Infections

Antimicrobial Agent	CYSTITIS			PYELONEPHRITIS		
	Useful Therapeutically	Dose and Duration	Comments	Useful Therapeutically	Dose and Duration	Comments
Nitrofurantoin monohydrate macrocrystals	^a Yes, first line	100 mg bid for 5 days	Cheap, well tolerated SE: N, H Low impact on microbiome	No	NA	Reduced renal tissue penetration
Trimethoprim-sulfamethoxazole	^a Yes, first line	160/800 mg bid for 3 days	If resistance is known to be <20% SE: rash, urticaria, N, V	Yes	160/800 mg bid for 14 days	^a If organism susceptibility is known ^c If not, give an initial LA IV agent
Fosfomycin trometamol	^a Yes, first line	3 g single-dose sachet	May be less efficient SE: N, D, H	No	NA	Active against MRSA ESBL, VRE
Fluoroquinolones (ciprofloxacin, levofloxacin)	^b Yes, second line	3-day regimen 250 mg bid 250 mg qd	High collateral damage SE: N, V, D, H, tendinitis	^a Yes, first line	Dose varies; 7–14 days	If resistance is known to be <10%
β-Lactams	^c Yes, second line	Dose varies by agent; 5–7 days	Less effective, increased side effects SE: N, V, D, rash, urticaria	^c Yes Use cautiously Less efficient	Dose varies; 10–14 day regimen	^c Give an initial LA IV agent

Data from Gupta K, Hooton TM, Naber KG, et al: International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases—executive summary, *Clin Infect Dis* 52:561-564, 2011.

D, Diarrhea; ESBL, extended-spectrum β-lactamase; H, headache; IV, intravenous; LA, long acting; MSRA, methicillin-resistant *Staphylococcus aureus*; N, nausea; NA, not applicable; SE, side effects; V, vomiting; VRE, vancomycin-resistant enterococci.

^aAI level of evidence from current guidelines.

^bAIII level of evidence from current guidelines.

^cBI level of evidence from current guidelines.

TABLE 100.2 Complications of Urinary Tract Infections

Complications	Pathophysiology	Diagnostic Methods/Likely Pathogens	Treatment
Cortico-medullary abscess	Focal abscesses can occur with ascending, generalized pyelonephritis, often occur with anatomic abnormalities of the GU tract	CT scanning is the study of choice. Ultrasound findings are less specific. Likely pathogens are gram-negative bacilli.	Antibiotics alone for lesions <3 cm. Drainage and antibiotics for larger lesions.
Cortical abscess (Renal carbuncle)	Focal abscess within the kidney parenchyma from hematogenous blood stream infection	Ultrasound or CT scanning. <i>Staphylococcus aureus</i> , enteric gram-negative bacteria.	Treat source of bacteremia, large lesions need drainage
Septic shock	Urinary tract infections are a common source of gram-negative bacteremia sepsis and septic shock	Blood cultures, imaging studies for possible urinary obstruction/enteric gram-negative bacteria	Urgent antibiotic therapy, urinary drainage if needed, IV fluids and vasopressors
Perinephric abscess	Insidious purulent collection between the kidney capsule and Gerota fascia; secondary to urinary tract obstruction and/or hematogenous spread	CT scan or renal ultrasonography. Fifty percent have accompanying pleural effusion or lung pathology. Gram-negative bacterial pathogens.	Percutaneous drainage and antibiotics. Septation of the perinephric space makes drainage more difficult.

Continued

TABLE 100.2 Complications of Urinary Tract Infections—cont'd

Complications	Pathophysiology	Diagnostic Methods/Likely Pathogens	Treatment
Emphysematous pyelonephritis	Rapid onset, severe infection of the kidney with accumulation of gas in the tissues. Seen in uncontrolled diabetes and impaired host immunity.	Detection of air surrounding the kidney by chest radiography or CT scan. <i>E. coli</i> accounts for most cases.	Intravenous antibiotics and drainage; urgent nephrectomy often needed
Papillary necrosis	Necrosis of the renal medullary pyramids and papillae secondary to vascular impairment. Can occur with infectious and noninfectious processes.	CT scanning or intravenous urography (IVU). Associated with a variety of enteric gram-negative and gram-positive bacteria.	Treat the underlying cause and ameliorate the ischemia with hydration and alkalization
Xanthogranulomatis pyelonephritis	Chronic, insidious, and destructive disease of the kidney marked by a granulomatous inflammatory response with lipid-laden macrophages	Rare chronic, infectious, inflammatory disease of the kidney seen in diabetes, lipid storage diseases, obstructive uropathy. <i>Proteus</i> sp is the most common bacterial pathogen.	Treat underlying cause, mass effects from kidney can form fistula tracts and be confused for neoplastic disease

Health Care–Associated Infections

Paul G. Jacob, Thomas R. Talbot

INTRODUCTION

A health care–associated infection (HAI) is an infection that did not exist or was not incubating at the time of admission to the health care facility. These infections can occur in all types of health care settings, including acute care units, long-term care facilities, rehabilitation facilities, outpatient dialysis clinics, and outpatient surgical centers. Surgical site infections (SSI), central line–associated bloodstream infections (CLABSI), and catheter-associated urinary tract infections (CAUTI) are common examples.

HAIs cause a substantial degree of morbidity and mortality. A 2018 study of 199 hospitals found a prevalence rate of 3.2% among a population of 12,299 patients in 2015. Extrapolating from this data, researchers concluded there were approximately 687,200 HAIs in US acute care hospitals in 2015. The Centers for Disease Control and Prevention (CDC) estimates that on any given day, approximately 1 in 31 hospitalized patients has an HAI. Beyond the extensive morbidity and mortality they cause, HAIs are costly, with costs ranging from \$896 per catheter-associated urinary tract infection to \$45,814 per central line–associated bloodstream infection. These costs are likely to be underestimated because of incomplete estimation of the outpatient costs of parenteral antibiotics, skilled nursing care, physical rehabilitation, and lost work days.

As of January 2011, the Centers for Medicare and Medicaid Services (CMS) required public reporting of certain facility-specific HAI outcomes as part of value-based purchasing. As of August 2019, the following acute care–related HAIs are required for reporting by CDC’s National Healthcare Safety Network (NHSN): catheter-associated urinary tract infections and central line–associated bloodstream infections in all adult, pediatric, and neonatal intensive care units (ICU) and from all patient care locations meeting the NHSN definition for adult and pediatric medical, surgical or combined medical/surgical wards, colon and abdominal hysterectomy SSIs, hospital-onset *Clostridioides difficile* infections (CDIs), and hospital-onset methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremias. The importance of preventing HAIs has never been more apparent.

The major types of HAIs include the infections reported to CMS, hospital-acquired pneumonia (HAP) or ventilator-associated pneumonia (VAP), health care–associated respiratory viral infections (e.g., influenza and respiratory syncytial virus acquired within a health care facility) and other multidrug-resistant organisms (MDROs). MDROs are pathogens with resistance to various important antibiotics (e.g., MRSA, vancomycin-resistant *Enterococcus* (VRE), antibiotic-resistant gram-negative bacilli). This chapter reviews the major classes of HAIs, with a focus on prevention, diagnosis, and treatment.

HEALTH CARE EPIDEMIOLOGY AND INFECTION PREVENTION

In the age of increasing MDROs, shortage of new antibiotics, and public reporting of HAIs, the importance of efforts to prevent HAIs

is growing. The fields of health care epidemiology and infection prevention focus on the practices of tracking HAIs in a systematic fashion (i.e., surveillance) to implement evidence-based HAI prevention practices.

Although HAIs were once thought to be the cost of being critically ill and receiving care in a hospital, several key events have occurred during the past 20 years that have shifted that perception. In 2006, Pronovost and colleagues implemented a “simple and inexpensive intervention” in 103 ICUs in the state of Michigan while participating in the Michigan Health and Hospital Association Keystone ICU project. This landmark study showed a reduction in the median rate of CLABSIs from 2.7 per 1000 catheter days to zero. These results shifted the discussion from merely controlling HAIs to preventing them. Other major events have included the recognition and effectiveness of using bundles of evidence-based practices to reduce HAIs; the recognition of the HAI burden in nonacute, non-ICU settings (including ambulatory clinics, long-term care facilities, and other venues where healthcare is delivered); and the importance of quality improvement science in reducing HAIs.

The prevention of HAIs has become increasingly possible, and various types of prevention interventions can reduce the HAI burden dramatically. In 2010, Wenzel and Edmund described these interventions as horizontal and vertical strategies (Table 101.1). Horizontal infection prevention strategies are broad practices (e.g., hand hygiene, isolation precautions) aimed at preventing many or all types of HAIs, regardless of the specific pathogen, procedure, or device. Vertical HAI prevention strategies are directed at specific types of HAIs or target a specific organism. Vertical strategies include using procedural checklists or standardized bundles and MRSA decolonization.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

CAUTIs were the third most common device-related infection according to a survey performed in 2018. In comparison to data in 2011, the percentage of patients with an HAI due to CAUTI in 2015 declined from 23.6% to 18.7%. The additional cost of a CAUTI, according to a 2013 meta-analysis, has been estimated at approximately \$896 (range: \$603 to \$1189) per episode.

CAUTI complications include cystitis, pyelonephritis, and in up to 4%, bacteremia. Although urinary catheter–associated bacteremias are rare, they are an underappreciated cause of health care–associated bacteremias and have been estimated to cost an additional \$3744 per episode. Though surveillance of CAUTI has long been emphasized in the ICU, efforts have increasingly focused on understanding its impact in non-ICU settings. A 2013 study of 506 CAUTIs among 15 hospitals revealed 72% occurred in non-ICU settings.

Most health care–associated urinary tract infections are catheter associated. A catheterized patient’s daily risk of developing bacteriuria

is about 3% to 10%. Indwelling urinary catheters disrupt several mechanisms of the natural defense against infection, including urine flow, length of the urethra, and micturition to prevent attachment of potential pathogens to the uroepithelium. Tamm-Horsfall proteins, the most abundant soluble proteins in the urine, play a significant role by binding uropathogenic bacteria, facilitating wash out, and lowering the threshold for activating local innate immunity. These soluble proteins are prevented from entering the lower urinary tract by the catheters.

An indwelling catheter allows colonization, attachment, and biofilm formation by certain microorganisms. Most of the organisms causing CAUTIs arrive by ascending the urethra from the meatus and perineum. The most common uropathogens identified in CAUTIs are *Escherichia coli*, *Candida* spp, *Klebsiella* spp, *Pseudomonas aeruginosa*, and *Enterococcus* spp (Fig. 101.1).

Common symptoms of a urinary tract infection (e.g., dysuria, urinary frequency) may not be useful in diagnosing a patient with an indwelling catheter. However, the most common clinical manifestations of a CAUTI are fever ($\geq 38^\circ\text{C}$) and bacteriuria. Other signs and symptoms of a CAUTI can include rigors, altered mental status, pelvic or suprapubic pain, costovertebral angle tenderness, and acute onset of hematuria without another underlying cause. One of these signs or symptoms plus a positive urine culture with a known uropathogen ($>10^5$ colony-forming units) strongly suggests a CAUTI. Pyuria (>5 leukocytes/mL of urine) is not always a reliable indicator for infection in patients with indwelling catheters; pyuria and asymptomatic bacteriuria are not necessarily indications for treatment. Risk factors for CAUTI acquisition include duration of catheterization, underlying fatal illness, age older than 50 years, having a nonsurgical underlying illness, and nonadherence to proper catheter care (E-Table 101.1).

The most effective method of preventing CAUTIs is to avoid placing urinary catheters unless absolutely necessary and to restrict catheter use to institutionally accepted indications. Proper insertion and care of urinary catheters are paramount (see Table 101.1). Maintenance of unobstructed flow with the collection bag below the bladder, use of a closed catheter system (even when sampling urine), and discontinuation of the catheter as soon as appropriate are key elements for preventing a CAUTI. Nurse-directed discontinuation protocols in which frontline personnel have defined parameters for removing catheters without requiring a provider's order are increasingly used to eliminate unnecessary catheters. The routine use of antimicrobial-coated catheters is not recommended except when infection rates remain elevated despite proper adherence to all other prevention strategies.

Treatment of asymptomatic bacteriuria usually is not recommended, with exception of pregnant women and patients who will undergo urologic procedures. Treatment of CAUTI is based on current Infectious Disease Society of America (IDSA) guidelines, and the choice of antimicrobial regimen should be based on the local antibiogram and identified syndrome (e.g., pyelonephritis). Before treatment, urine culture and sensitivity results are used to evaluate a resistant organism and tailor an empirical antimicrobial regimen. To ensure accurate diagnosis of urinary tract infections, many hospitals have adopted algorithms that will only allow for cultures if there is pyuria demonstrated on urinalysis (also known as reflexive culture).

Most clinicians prefer to replace or discontinue the catheter after a urinary tract infection is diagnosed. Guidelines recommend replacement if it has been in place for more than 2 weeks. There is good evidence based on review by expert committees that duration of treatment can be 7 days if symptoms quickly resolve or 10 to 14 days if resolution is delayed. In nonpregnant women younger than 65 years of age, a 3-day course of antibiotic therapy can be considered after the urinary catheter has been removed.

HOSPITAL-ACQUIRED AND VENTILATOR-ASSOCIATED PNEUMONIA

Pneumonia remains one of the most common HAIs, following *C. difficile* infection. Both HAP and VAP are included in the surveillance of HAIs. As of the most recent American Thoracic Society and IDSA guidelines in 2016, the term "health care-associated pneumonia (HCAP)" has been retired due to overlap with HAP and VAP. Other definitions are given in Table 101.2.

The incidence of HAP or VAP is difficult to determine due to the various definitions that have been used for surveillance and the subjective nature of these diagnoses. Some studies have estimated that the incidence of VAP ranges from 2 to 16 cases per 1000 ventilator days. VAP is associated with an increased length of hospital stay (10 days in one study), costs (approximately \$40,000), and mortality (attributable mortality rate of 13%, highest among surgical patients).

Risk factors for VAP include conditions that lead to increased aspiration or impairment of host defenses and bacterial colonization of the respiratory and upper gastrointestinal tracts (see E-Table 101.1). In a ventilated patient, the body's natural mechanical defense mechanisms (e.g., ciliated epithelium, mucus, cough) are interrupted, leading to colonization of the lower airways by potentially pathogenic organisms. The most significant source of these organisms tends to be the patient's own oropharynx and upper gastric contents.

The most commonly implicated respiratory pathogens are *S. aureus* and *P. aeruginosa*, followed by several Enterobacteriaceae species and *Acinetobacter baumannii* (see Fig. 101.1). Colonization with MDROs correlates with an increasing duration of hospitalization. Guidelines argue that late (>4 days after admission) compared with early HAP may be the most useful factor when determining empirical antimicrobial therapy. Although bacteria play the largest role in HAP, fungi and viruses also must be considered in immunosuppressed patients.

One definition of HAP or VAP includes clinical, radiographic, and microbiologic criteria. Signs and symptoms indicating an infection include fever ($\geq 38^\circ\text{C}$), peripheral leukocytosis, purulent sputum, and worsening respiratory status. A tracheal aspirate for Gram stain and culture provides the last piece of diagnostic information. When several of these signs and symptoms exist in the absence of a pulmonary infiltrate, alternative diagnoses should be considered, including ventilator-associated tracheobronchitis.

The greatest risk factor for the prediction of MDRO-related pneumonia is prior intravenous antibiotic therapy, whether for HAP or VAP (see Table 101.2). Longer duration of hospitalization increases the risk for acquisition of multidrug resistant pathogens, though the concept of early- and late-onset pneumonia has been challenged by more recent studies. Prior intravenous antibiotic therapy within the last 90 days is an independent risk factor for both MRSA and MDR *Pseudomonas aeruginosa*. Additional risk factors in VAP include septic shock, acute respiratory distress syndrome (ARDS), 5 or more days prior to occurrence, and prior receipt of acute renal replacement therapy.

INFECTIONS ASSOCIATED WITH VASCULAR CATHETERS

The NHSN collects data on CLABSIs, and public reporting is required for CLABSIs in ICUs and certain non-ICU inpatient units. In 2011, the incidence of CLABSIs ranged from 0 to 3.7 cases per 1000 catheter days. In 2015, CLABSIs made up a smaller percentage of HAIs (16.9%) than in 2011 (18.8%). Although CLABSIs have the lowest prevalence

E-TABLE 101.1 Risk Factors for Developing a Health Care–Acquired Infection**Catheter-Associated Urinary Tract Infection**

Duration
Female gender
Age >50 years
Not maintaining an unobstructed, closed drainage system

Ventilator-Associated Pneumonia

Endotracheal tube
Underlying chronic lung disease
Age >70 years
Depressed levels of consciousness
Gastric alkalization
Nasogastric or enteral feeding tube
Previous antibiotic exposure

Central Line–Associated Bloodstream Infection

Prolonged hospitalization before insertion
Duration of catheterization
Site of catheterization (femoral > subclavian)
Heavy colonization at the site of insertion and on the hub
Neutropenia
Total parenteral nutrition
Substandard maintenance of the catheter

Surgical Site Infection

Increased age
Perioperative hyperglycemia
Obesity
Smoking
Immunosuppressive medications
Infections present at time of surgery
Malnutrition
Operative characteristics: inadequate surgical scrub and skin preparation have been implicated, along with poor timing and dosing of antimicrobial prophylaxis, lower-skilled surgeon, longer operative time, inappropriate tissue oxygenation, and not maintaining normothermia

***Clostridioides difficile* Infection**

Age >65 years
Antimicrobial exposure
Health care exposure
Gastric acid suppression (controversial whether this is an independent risk factor)

TABLE 101.1 Strategies for Preventing Health Care–Associated Infections

Horizontal Strategies (to Prevent All or Many Types of HAIs)

- Standard precautions
 - Hand hygiene
 - Use of appropriate PPE
 - Respiratory hygiene and cough etiquette
 - Appropriate environmental cleaning and waste disposal
- Chlorhexidine bathing in all ICU patients and in non-ICU acute inpatients with central lines^a
- Isolation precautions appropriate for pathogen
- Steps to prevent needlestick injuries
- Education of health care workers on IC/IP protocols

Vertical Strategies (Specific to HAI Type)**CAUTI**

Urinary catheter placed only for appropriate indications:

- Urinary retention or obstruction
- Need for accurate UOP measurement in critical illness
- Incontinence and perineal or sacral wounds
- Comfort care use for terminal illness

Consider alternatives:

- Condom catheters
- Intermittent catheterization

Proper insertion and maintenance:

- Maintain aseptic technique
- Properly secure catheter to patient
- Maintain closed drainage system
- Maintain unobstructed flow

Urinary catheter premeditated stop order or RN-initiated discontinuation policy

Anti-infective catheters if infection rates remain high

Reflexive culture testing algorithms to reduce false diagnosis of urinary tract infection

VAP

Use noninvasive ventilation when able

On intubation:

- Semirecumbent position (30–45 degrees) unless contraindicated
- Hypopharyngeal suctioning
- Avoid gastric overdistention
- Use cuffed ET tube
- Oral care, tooth brushing
- Keep ventilatory circuit closed unless changing for soiling or malfunctioning
- Daily targeted sedation management
- Spontaneous breathing trial if screening finds applicable

Use weaning protocols to minimize duration of ventilation

CLABSI

Use checklist for device insertion:

- Bundle supplies
- All present use at least face mask, then proceduralist uses sterile gown and gloves, mask, and head cap
- Avoid femoral line placement if possible
- Skin antisepsis with alcohol and >0.5% chlorhexidine
- Use of chlorhexidine-impregnated dressing or sponge at insertion site
- Empower personnel to stop nonemergent insertion if improper technique is followed

Maintenance:

- Access as infrequently as feasible
- Scrub the access hub or port with antiseptic
- Daily bathing with chlorhexidine and intranasal antiseptic with mupirocin or povidone-iodine

Daily audits for assessment of device need and potential discontinuation

Interventions to reduce blood culture contamination that may be falsely assessed as true bacteremia

SSI

Preoperative strategies:

- Nonirritative hair removal with clippers on the day of surgery (not razors)
- Eradicate remote infection
- Decolonization of *Staphylococcus aureus*
- CHG bathing
- Smoking cessation
- Glucose control, hemoglobin A_{1c} <7% if possible
- Avoid immunosuppressive medication in perioperative period
- Identify and address malnutrition

Intraoperative strategies:

- In OR: proper ventilation, minimize traffic, proper attire, and surgical scrub
- Proper skin preparation (chlorhexidine plus alcohol or povidone plus alcohol) and draping
- Antimicrobial prophylaxis; proper timing, dosing, and intraoperative redosing
- Maintain normothermia
- Glucose control
- Tissue oxygenation, preoperative and postoperative supplementation

CDI

Prevention of acquisition:

- Antimicrobial stewardship

Prevention of transmission:

- Contact precautions (e.g., empiric placement for those suspected of CDI before confirmation of diagnosis)
- Hand hygiene with soap and water before leaving the patient's room
- Continue contact precautions
- Appropriate environmental cleaning with bleach-containing agents

CAUTI, Catheter-associated urinary tract infection; CDI, *Clostridioides difficile* infection; CHG, chlorhexidine gluconate; CLABSI, central line–associated bloodstream infection; ET, endotracheal; HAI, health care–associated infection; IC/IP, infection control or prevention; ICU, intensive care unit; MDRO, multidrug-resistant organism; OR, operating room; PPE, personal protective equipment; RN, registered nurse; SSI, surgical site infection; UOP, urine output; VAP, ventilator-associated pneumonia.

^aCurrent data are not strong for prevention of CAUTI, VAP, and CDI by this method.

Fig. 101.1 Causative pathogens by specific type of health care-associated infection as reported to the Centers for Disease Control and Prevention National Healthcare Safety Network. CAUTI, Catheter-associated urinary tract infections; CLABSI, central line-associated bloodstream infections; SSI, surgical site infections; VAP, ventilator-associated pneumonia. (Modified from Sievert DM, Ricks P, Edwards JR, et al: Antimicrobial-resistant pathogens associated with healthcare-associated infection: summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2009-2010, *Infect Control Hosp Epidemiol* 34:1-14, 2013.)

among HAIs, the cost per episode and morbidity rate remain high. The estimated additional cost of an infection related to an intravenous catheter has been estimated at \$45,814 (95% confidence interval [CI]: \$30,919 to \$65,245) per episode. The attributable increase in length of stay has been between 6.5 and 22 days, and the attributable mortality rate is about 10% among hospitalized patients.

The most common pathogens that cause primary CLABSIs are flora arising at the percutaneous insertion site or from contamination of the catheter hub. Hematogenous seeding from a gastrointestinal or other endovascular source occurs but is less likely. The most common pathogens that cause CLABSIs are coagulase-negative staphylococci, *Candida* species, *S. aureus*, and *Enterococcus* spp (see Fig. 101.1). The risk factors for CLABSI are provided in E-Table 101.1. The rising proportion of infections caused by *Enterococcus* and *Candida* spp since the 2006 to 2007 period suggests that skin colonization is being adequately addressed by the adoption of evidence-based prevention strategies and that an increasing fraction of CLABSIs are caused by secondary hematogenous seeding. Patients who are more severely ill, are neutropenic, have burns, or are on total parenteral nutrition are also at increased risk for candidemia. Other types of catheter-related infections include phlebitis, exit site infection, and pocket infection, tunnel infection, and septic thrombophlebitis.

Many CLABSIs are preventable through the use of evidence-based prevention practices for line insertion and maintenance. Strategies include appropriate decolonization of the skin before insertion with chlorhexidine plus alcohol, use of maximal sterile barriers (i.e., proceduralist wears sterile gloves and gown, cap, and mask, and a large barrier drape is placed over the patient), hand hygiene, and sterile technique (see Table 101.1). Appropriate maintenance of the central line mandates scrubbing the hub with an antiseptic and discontinuing the catheter as soon as it is not needed. Additional strategies with evidence for prevention of CLABSIs in the ICU include daily chlorhexidine bathing and nasal decolonization with mupirocin or povidone-iodine.

For a patient with a fever or systemic symptoms who has a central venous catheter, a bloodstream infection should be suspected. The diagnostic evaluation should begin with paired peripheral and catheter blood samples for culture before initiation of antimicrobial therapy. In a suspected case of bloodstream infection, the exudate at the exit site should be cultured.

TABLE 101.2 Definitions of Types of Health Care–Associated Pneumonia

Pneumonia Type	Definition
Hospital-acquired pneumonia (HAP)	Pneumonia that occurs at least 48 hours after admission and that was not incubating at the time of admission
Ventilator-associated pneumonia (VAP)	Pneumonia that arises 48–72 hours after endotracheal intubation

Data from American Thoracic Society, Infectious Diseases Society of America: Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia, *Am J Respir Crit Care Med* 171:388-416, 2005. IV, Intravenous; LTCF, long-term care facility; NH, nursing home.

The type of device (e.g., peripheral vs. central, short term vs. long term), associated infectious complications, and the implicated organism all play a role in treatment. For CLABSIs associated with short-term, nontunneled catheters and no complicating factors (e.g., suppurative thrombophlebitis, endocarditis, intravascular hardware), it may be appropriate to treat for 7 to 14 days after removal of the catheter. However, for long-term catheters, salvage may be attempted with systemic plus antibiotic lock therapy (as indicated by only a moderate amount of evidence from well-designed clinical trials or cohort or case series). Salvage of catheters associated with *S. aureus* bacteremia and fungemia have largely been unsuccessful, and it is not recommended. In the setting of an endovascular complication, removal of the catheter is strongly recommended, and systemic antibiotic therapy should be prolonged (i.e., 4 to 6 weeks). In many cases, septic thrombophlebitis may require surgical attention. Tunnel and pocket infections may also require débridement, but after the catheter is removed, 7 to 14 days of antimicrobial therapy should be sufficient.

SURGICAL SITE INFECTIONS

Standard definitions of SSIs classify them as superficial incisional, deep incisional (involving fascia or muscle), and organ space depending on the depth of tissue involvement. Most SSIs occur within 30 days of the operation, but some may develop later, especially in the setting of implanted foreign bodies (e.g., arthroplasty). The 2015 HAI Prevalence study from the CDC estimated an annual national burden of over 110,800 SSIs among hospitalized adult patients, a figure that does not include those patients with an SSI that did not require hospitalization. A patient who develops an SSI while hospitalized has a greater than 60% risk of being admitted to the intensive care unit, is 15 times more likely to be readmitted to the hospital within 30 days after discharge, and incurs an attributable extra hospital course of 6.5 days, leading to a direct cost of an additional \$3000 per infection.

Endogenous seeding from the patient's skin flora is the most common avenue of infection. *S. aureus* and coagulase-negative *Staphylococcus* cause more than 40% of SSIs. In clean-contaminated operations, including open abdominal surgeries, gram-negative bacilli are predominant. An SSI should be suspected when postoperative patients have wound-associated purulent drainage, pain, tenderness, swelling, or redness. Positive culture growth from an aseptically obtained specimen is most convincing.

Many practices are used to prevent SSIs (see Table 101.1). One of the earliest and most effective strategies has been active surveillance and subsequent reporting of infection rates to the surgeons and staff. Much of the reduction in rates was attributed to the Hawthorne effect (i.e., active monitoring changes the behaviors of those being monitored). Other important interventions designed to reduce SSIs include

TABLE 101.3 Pathogenic Isolates Resistant to Selected Antimicrobial Agents According to the NHSN, 2014

Organism	Antimicrobial	CLABSI	CAUTI	VAP ^a	SSI
<i>Staphylococcus aureus</i>	Oxacillin, methicillin, ceftaxitin	50.7%	52.0%	42.4%	42.6%
<i>Enterococcus faecium</i>	Vancomycin	82.2%	85.1%	n/a	58.4%
<i>Klebsiella pneumoniae</i>	Ceftriaxone, ceftazidime, cefotaxime, or cefepime	24.1%	22.5%	21.0%	11.3%
	Carbapenems	10.9%	9.5%	10.1%	3.3%
<i>Escherichia coli</i>	Ceftriaxone, ceftazidime, cefotaxime, or cefepime	22.2%	16.1%	16.7%	15.3%
	Fluoroquinolones	49.3%	34.8%	30.8%	30.9%
<i>Enterobacter</i> spp	Ceftriaxone, ceftazidime, cefotaxime, or cefepime	36.1%	40.5%	26.9%	27.5%
	Carbapenems	6.6%	6.5%	3.2%	3.4%
<i>Pseudomonas aeruginosa</i>	Fluoroquinolones	30.2%	32.6%	31.9%	11.5%
	Piperacillin-tazobactam	18.4%	15.5%	19.4%	7.4%
	Cefepime, or ceftazidime	24.2%	22.5%	25.7%	9.9%
	Carbapenems	25.8%	23.9%	28.4%	7.7%
<i>Acinetobacter baumannii</i>	Carbapenems	46.6%	64.0%	55.5%	33.3%

Modified from Weiner LM, Webb AK, Limbago B, et al. Antimicrobial-resistant pathogens associated with healthcare-associated infections: summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2011-2014. *Infect Control Hosp Epidemiol.* 2016;37(11):1288-1301.

^a2012.

antimicrobial prophylaxis (i.e., the right drug at the right dose and right time), appropriate skin antiseptics, and maintenance of glucose control (see [Table 101.1](#)).

Management of SSIs often involves opening of the incision, evacuation of infected tissue, and allowing the wound to heal by second intention. The decision for initiating antibiotics is made on an individual basis and depends on the appearance of the wound, systemic signs of infection, depth of the infection, host's immune system, and type of surgery. Culture and Gram stain results help to dictate antibiotic coverage. For SSIs from a clean operation, empirical therapy covering *S. aureus* and *Streptococcus* species is recommended. For procedures involving the perineum, intestinal tract, or urogenital tract, broader coverage is needed to address gram-negative and anaerobic pathogens. When the SSI occurs within 48 hours of the index operation, *Streptococcus pyogenes* and *Clostridioides* spp are often implicated.

CLOSTRIDIODES DIFFICILE INFECTION

CDI is defined as diarrhea or toxic megacolon with detection of the *C. difficile* organism or toxin A or B, or both, in the stool or evidence of pseudomembranous colitis detected endoscopically, surgically, or histopathologically. This colonic infection is often accompanied by fever and leukocytosis.

C. difficile is the most common pathogen responsible for HAIs, approximating 12.1% of all HAIs. The incidence and severity of CDIs had been steadily increasing until more recently. Most reports have implicated the emerging BI/NAP1/027 strain, antibiotic overuse, and the aging population of hospitalized patients, who are disproportionately affected by CDI. Virtually every antibiotic has been associated with increasing the risk of CDI. Intensive efforts to combat CDI have also focused on several avenues: accurate diagnosis, reducing vectors for transmission, and judicious use of antimicrobials. Diagnosis of CDI must correctly identify infection versus colonization. The strategy of diagnostic stewardship aims to employ proper testing algorithms to ensure only patients exhibiting clear signs and symptoms receive diagnostic evaluation. Transmission prevention has focused on efforts to reduce the environmental burden of pathogens through

environmental cleaning and hand hygiene as well as through the use of transmission-based precautions (e.g., contact precautions).

The continued rise of CDI, increasing resistance to antimicrobials by many different pathogens, and lack of antimicrobials with novel mechanisms of action underscore the importance of antimicrobial stewardship. Antimicrobial stewardship is a strategy that emphasizes optimal selection, dose, and duration of antimicrobial therapy, producing the best clinical outcome while decreasing the risk of subsequent complications.

The consequences of poor stewardship include the emergence of resistance, CDI, and excessive drug expenditures. Antimicrobials have different probabilities of invoking resistance or CDI. Strategies implemented by antimicrobial stewardship programs include provider education and guidelines, de-escalation or tailoring of empirical therapy when possible, use of more appropriate empirical treatments, and front-end restriction of certain antibiotics.

For a deeper discussion of these topics, please see Chapter 267, "Approach to the Patient with Suspected Enteric Infection," and Chapter 280, "Clostridial Infections," in *Goldman-Cecil Medicine*, 26th Edition.

MULTIDRUG-RESISTANT PATHOGENS

MDROs are organisms that are resistant to more than one class of antimicrobial agents, although the names of some (e.g., MRSA, VRE) imply resistance to only one drug. According to NHSN data reported from the 2011 to 2014 period, high rates of resistance persist for a multitude of common bacterial pathogens ([Table 101.3](#)).

Infections caused by MDROs lead to increased length of hospitalization, health care costs, and mortality rates for patients compared with those who are infected by antimicrobial-susceptible organisms. Kollef and colleagues found that patients who received inadequate antimicrobial therapy for their HAIs had an infection-related mortality rate 2.37 times that of those in the ICU who received adequate coverage. The principal reason for inadequate coverage was multidrug resistance.

The predominant gram-positive MDRO pathogens are MRSA and VRE. Methicillin resistance in *S. aureus* is caused by the production of an alternative penicillin-binding protein (PBP2A) that has a low affinity

for β -lactam antibiotics and forms stable peptidoglycan products in the presence of adequate levels of the β -lactam. MRSA infections tend to have worse outcomes compared with methicillin-susceptible *S. aureus* (MSSA), but the typical health care–acquired strains are not necessarily more virulent. However, community-acquired MRSA, the most prevalent of which is the USA-300 strain, tends to be more virulent, and many of these isolates produce the Panton-Valentine leukocidin toxin, which is associated with greater leucocyte destruction and tissue necrosis. The largest reservoirs of MRSA are patients with the greatest contact with the health care system, and most carriers are asymptomatic.

Vancomycin resistance in *S. aureus* is another concern. Vancomycin intermediate-resistant strains, vancomycin heteroresistant strains, and vancomycin-resistant strains have been detected. The intermediate resistance or decreased susceptibility to vancomycin is thought to result from cell wall and biomatrix thickening, making the drug target more difficult to reach. Complete vancomycin resistance occurs by acquisition of the *vanA* gene from VRE. VRE, unlike many MRSA strains, is almost entirely a health care–associated phenomenon. Clusters of *vanA* or *vanB* genes are carried on mobile genetic elements that are readily transmitted between strains. These genes encode peptidoglycan precursors that have a low affinity for vancomycin.

Gram-negative MDROs have a greater tendency to form resistance to multiple antimicrobials, and new antimicrobials to target these pathogens are not available. The Enterobacteriaceae are gram-negative bacteria that usually reside in the gastrointestinal tract, are glucose fermenters, and account for about 29% of HAIs. These organisms tend to be the most common pathogens in SSIs associated with abdominal operations. The non-glucose fermenting organisms, including *P. aeruginosa*, *Acinetobacter baumannii*, and *Stenotrophomonas maltophilia*, account for about 9% of HAIs.

Multidrug-resistant gram-negative bacteria are making their way into the limelight largely due to the emergence of isolates that are resistant to most or all available antimicrobials (e.g., MDROs that exhibit β -lactamases, extended-spectrum β -lactamases (ESBL), carbapenem and fluoroquinolone resistance). The emergence of carbapenem-resistant Enterobacteriaceae (CRE) has become particularly concerning. The predominant carbapenem-resistance mechanisms are the loss of OprD, an outer membrane protein, *Klebsiella pneumoniae* carbapenemases (KPCs), and the metallo- β -lactamases (MBLs), which hydrolyze carbapenems. The New Delhi metallo- β -lactamase 1 (NDM1) is one of the first MBLs to cause outbreaks in the United States. The carbapenemases and MBLs are easily transmissible and tend to be associated with other genes encoding mechanisms of resistance to other antimicrobial classes. Fluoroquinolone resistance can occur by efflux pumps or mutations in genes encoding the drug targets DNA gyrase and

topoisomerase IV. Emerging resistance among fungi (e.g., *Candida* spp) is an additional concern. In particular, *Candida auris* has led to outbreaks in ICUs and often harbors high rates of resistance to first- and second-line antifungal agents as well as some routine disinfectants.

Limiting the spread of MDROs in the health care setting should be a comprehensive and system-wide program at any institution. Infection prevention programs should include optimized surveillance practices to identify emerging MDROs and appropriate intervention strategies. The mainstay of these programs includes use of evidence-based prevention practices and antimicrobial stewardship programs. Prevention also necessitates increased communication between hospitals and public health institutions to limit the spread of MDROs, conduct proper surveillance, and implement infection control actions.

Sexually Transmitted Infections

Philip A. Chan, Susan Cu-Uvin

INTRODUCTION

Sexually transmitted infections (STIs) encompass a wide variety of organisms that have been causing human disease for thousands of years. Recognition of STIs can be challenging due to the heterogeneous nature and multiple symptoms of a single disease. Diagnosis and management of STIs is further complicated by underlying social bias and hesitancy by medical providers and patients to discuss issues related to sexuality and disease transmission.

The diagnosis of STIs should be based on a detailed history with special attention to sexual orientation and behaviors, a physical examination, and laboratory confirmation when appropriate. Professional and respectful attitudes by medical providers are essential to obtaining an accurate clinical history pertinent to STIs. Patients often deny risky behavior because of embarrassment or social stigma. Patients may also underestimate risky behaviors, and the diagnosis of STIs should therefore be based on a combination of history, epidemiology, clinical examination, and diagnostic testing.

A detailed sexual history should be obtained from all individuals with a suspected STI. They should be informed that the information is necessary to appropriately diagnose and manage STIs. The history should include sexual preferences for male or female partners; gender identity; the number of main, casual, and one-time partners; the use of condoms, drugs, and alcohol; and use of preexposure prophylaxis (PrEP) for human immunodeficiency virus (HIV) prevention as well as last HIV/STI testing. The history of partners should be elicited, including current symptoms and diagnosed STIs. If possible, counseling and education should be incorporated during the encounter. Prevention topics include abstinence, routine testing, disclosure of STIs to partners, behavior modification (i.e., avoiding risky sexual activities), condom use, prophylactic treatment for STI exposures, and PrEP.

Because of the diverse nature of STIs, it is useful to categorize the infections into a few major groups. There is overlap between different categories, and clinical judgment must be used to accurately diagnose STIs. For example, STIs that typically manifest with an ulcer may occasionally manifest with urethritis. Importantly, many STIs are asymptomatic or have symptoms that go unnoticed. When an individual has one STI, other STIs should be considered. The main categories of STIs are urethritis and cervicitis, genital ulcer disease, and genital warts. Symptomatic individuals with an STI usually fit into one of these categories.

URETHRITIS AND CERVICITIS

Urethritis and cervicitis are characterized by dysuria, burning, and urethral discharge. The discharge may range from barely noticeable to watery or frank pus. Urethritis has been categorized as gonococcal (i.e., caused by *Neisseria gonorrhoeae* and visible on Gram stain)

or nongonococcal (i.e., commonly caused by *Chlamydia trachomatis*). Nongonococcal urethritis can be caused by other organisms, many of which are rarely tested for. Urethritis has historically been classified as gonococcal or nongonococcal because *N. gonorrhoeae* can easily be visualized on Gram stain. Most patients with symptomatic urethritis should be treated empirically with antibiotics directed against gonorrheal and chlamydial organisms without waiting for test results.

Chlamydia

Definition and Epidemiology

Chlamydia is the most prevalent bacterial STI in the United States and the world. The infection is caused by the bacterium *C. trachomatis*, which causes 30% to 40% of nongonococcal urethritis and cervicitis cases. In the United States, approximately 1.8 million cases were reported to the Centers for Disease Control and Prevention (CDC) in 2018, with an estimated number of infections that is more than twice the number of reported cases.

Age is a factor. Chlamydia has a 5% to 10% prevalence among adolescents and young adults. Other risk factors include having multiple sex partners, having condomless sex, or living in a lower socioeconomic area. In men, chlamydia is uncommonly associated with complications. In women, untreated chlamydia is associated with potentially severe complications, including pelvic inflammatory disease (PID), ectopic pregnancy, and infertility.

The CDC and USPTF recommends all sexually active women age 24 years or younger and other at-risk women be screened for chlamydia. Screening should also be considered for individuals who have a history of chlamydia or other STIs, have new or multiple sex partners, or exchange sex for drugs or money. All pregnant women should be screened. Men who have sex with men (MSM) should be screened at least annually and more frequently if there are ongoing risk factors such as multiple partners. The rationale for screening men is to prevent symptomatic epididymitis, proctitis, and urethritis. Importantly, MSM should also be screened at sites of exposure, which may include oropharyngeal and rectal screening for men that perform oral sex or have receptive anal sex, respectively. Screening MSM only for urogenital infection will miss up to 80% of chlamydia and gonorrhea infections. The presence of a rectal STI is a notable risk factor for HIV infection.

Pathology

C. trachomatis is an obligate intracellular, gram-negative bacterium that is evolutionary distinct from other bacteria. Several serovars of *C. trachomatis* are associated with human disease. They include serovars A-C (i.e., trachoma or ocular disease), D-K (i.e., anogenital disease), and L1-L3 (i.e., lymphogranuloma venereum [LGV]). *C. trachomatis* exists as an extracellular elementary body before attachment to susceptible epithelial cells and subsequent endocytosis. On entering the cell, the elementary form of *C. trachomatis* reorganizes into a reticulate

body within vacuoles that is functionally active, leading to growth and replication of the organism.

Clinical Presentation

Chlamydia may manifest with signs and symptoms ranging from none (most common) to life-threatening PID in women. When individuals have symptoms, the most common is urethritis in men and cervicitis in women. The incubation period varies but is usually 7 to 14 days after exposure.

Among men, 40% to more than 90% of chlamydia cases may be asymptomatic. Urethritis usually manifests as dysuria or discharge. *C. trachomatis* and *N. gonorrhoeae* infections are common causes of epididymitis in younger men. The infection typically manifests with unilateral testicular pain, swelling, and tenderness. *C. trachomatis* infection may also cause prostatitis and proctitis; the latter is typically found in MSM. The symptoms of proctitis in MSM should raise the possibility of LGV. The rates of transmission from infected men to women are as high as 65%.

In women and men, more than 85% of infections are asymptomatic. When symptomatic, *C. trachomatis* infection in women can be difficult to diagnose due to the nonspecific nature of symptoms. The classic manifestation is cervicitis, which can cause discharge, bleeding, pelvic pain, cervical friability, and ulcers. Complications of chlamydia include chronic pelvic pain, infertility, ectopic pregnancy, and PID. The lifetime prevalence of PID due to *C. trachomatis* infection depends on the population studied but is approximately 4%. PID usually manifests as abdominal or pelvic pain, cervical motion tenderness, and uterine or adnexal tenderness. Infection may also cause perihepatitis (i.e., Fitz-Hugh–Curtis syndrome), which is inflammation of the liver capsule. It occurs in 5% to 15% of PID cases. Chlamydia is the leading cause of preventable infertility worldwide.

Chlamydia may cause conjunctivitis and ocular trachomatis, the most common cause of preventable blindness worldwide. The disease also may manifest with pharyngitis and LGV. Classically a disease endemic in Africa, Southeast Asia, and the Caribbean, LGV has been identified in the United States and Europe, particularly among MSM with symptoms of proctitis. Typically, LGV manifests with genital ulceration and inguinal lymphadenopathy. Recognition of LGV is important given the longer duration of treatment.

Diagnosis and Differential Diagnosis

C. trachomatis cannot be routinely cultured on growth media, which has made diagnosis difficult. The introduction of nucleic acid amplification testing (NAAT) was a major advance and is now the standard diagnostic test. NAAT encompasses several laboratory methods including polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification. The reported sensitivity of NAAT is 80% to 90%, with a specificity of 99%. The test may be performed on urine and vaginal or urethral (men) endocervical swab specimens. NAAT may also be performed on rectal and pharyngeal swab specimens.

Individuals who test positive and are treated for chlamydia should not be retested for at least 3 weeks after treatment. NAAT may remain positive during this time due to remnant material that does not signify persistent infection. Repeat testing to demonstrate cure should be performed for pregnant women or those with a concern about persistent infection. Individuals are usually retested at 3 months and then periodically depending on risk behaviors. Having had an STI places individuals at risk for becoming infected again. For individuals with multiple partners, including MSM, general STI testing that includes chlamydia is recommended every 3 to 6 months.

Treatment

Standard treatment regimens for urethritis or cervicitis due to chlamydia are azithromycin (1 g taken once orally) or doxycycline (100 mg twice daily for 7 days). These two medications are effective and cure more than 95% of infections. Azithromycin should be used in situations where adherence is a concern given the simplicity of dosing, which facilitates adherence. However, doxycycline may be more effective in achieving cure. Azithromycin can also be used in pregnancy. Other drugs that are effective in treating chlamydia include quinolones and penicillin. Sulfonamides (e.g., Bactrim) and cephalosporins should not be used. Doxycycline, ofloxacin, and levofloxacin are contraindicated in pregnant women.

Epididymitis due to chlamydia should be treated with doxycycline (100 mg taken orally twice per day for 10 days). Treatment for LGV proctitis depends on the severity of symptoms and should include doxycycline (100 mg orally twice each day for up to 3 weeks). In women, PID should be treated with ceftriaxone (250 mg given once intramuscularly) to cover gonorrhea and doxycycline (100 mg taken orally twice each day for 14 days) for chlamydia. Women who have concerning symptoms should be hospitalized and started on intravenous antibiotics, including cefoxitin (2 g given intravenously every 6 hours) or cefotetan (2 g given intravenously every 12 hours) and doxycycline (100 mg taken orally every 12 hours) (if not pregnant). Alternative treatment regimens include clindamycin (900 mg given intravenously every 8 hours) and gentamicin (2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours). The duration depends on clinical improvement but is usually 2 weeks.

Prognosis

The natural history of untreated *C. trachomatis* infection varies. Individuals may remain asymptomatic for long periods, and the infection may resolve spontaneously or progress to symptoms and complications. Approximately 20% of individuals diagnosed with chlamydia but without symptoms may clear the infection before returning for treatment. Infection does not translate to protective immunity, and reinfection is common (10% to 20%). Therefore treatment of sex partners is important. In many areas, expedited partner therapy is allowed, and medical providers may prescribe treatment for sex partners without seeing them.

Gonorrhea

Definition and Epidemiology

Gonorrhea is caused by the bacterium *N. gonorrhoeae* and is the second most common reportable STI in the United States behind chlamydia. Similar to chlamydia, gonorrhea is a significant cause of urethritis in men and cervicitis in women and has the same complications. In the United States, the rate of gonorrhea declined in 2009 to a nadir of 98.1 cases per 100,000 people. Much of this was attributed to screening and treatment programs. Since 2009, however, cases of gonorrhea have increased each year to 104.2 cases per 100,000, with almost 600,000 cases reported in 2018.

Most individuals diagnosed with gonorrhea are adolescents or young adults. Cases among males are now more common than among females. MSM have also emerged as an important at-risk group. Risk factors for infection include younger age, multiple sexual partners, race or ethnicity, low socioeconomic status, and previous STIs. African Americans and Hispanic/Latinos have significantly higher rates of gonorrhea than white individuals in the United States.

Pathology

N. gonorrhoeae is a gram-negative bacterium with an outer membrane, peptidoglycan cell wall, and cytoplasmic membrane. Several

components contribute to the virulence of the organism. Attachment to columnar epithelial cells is facilitated by pili, which extend from the cell surface and allow entry into the host cell by endocytosis. Organisms without pili are thought to be noninfectious. Gonococci are able to replicate within host epithelial cells and phagocytes. After mucosal infection, immune activation of neutrophils produces significant inflammation and exudate as pus.

Clinical Presentation

Gonorrhea is transmitted during sex with an infected partner. The risk of infection ranges from 20% to 50% per single act of sexual intercourse and increases with multiple acts. The incubation period is 2 to 7 days. When symptomatic, individuals with gonorrhea tend to have more purulent discharge than individuals with nongonococcal urethritis. In men, urethritis is the most common symptom at clinical presentation. Ten percent of men may be asymptomatic. Other manifestations of gonorrhea include epididymitis, proctitis, and pharyngitis. Rare but severe complications include abscesses and urethral strictures.

Between 50% and 80% of women with gonorrhea are asymptomatic. Typical symptoms include those of cervicitis, such as pelvic or adnexal pain, discharge, dysuria, and abnormal bleeding. As in men, gonorrhea can cause proctitis and pharyngitis in women. Most of these infections are asymptomatic. The most common complication of gonorrhea is PID. It may result in severe infection, chronic pelvic pain, and infertility. Infection during pregnancy may lead to complications such as premature labor, rupture of membranes, and spontaneous abortions.

Gonorrhea infection may also be associated with perihepatitis (Fitz-Hugh–Curtis syndrome). In less than 3% of individuals, disseminated gonococcal infection can lead to a classic triad of tenosynovitis (i.e., affecting multiple tendons), dermatitis (i.e., painless, few transient pustular lesions), and polyarthralgias (i.e., nonpurulent forms). Alternatively, individuals with disseminated infection may have purulent arthritis alone. Clinical presentation usually includes fever and other nonspecific systemic symptoms.

Diagnosis and Differential Diagnosis

N. gonorrhoeae is a gram-negative diplococcus that can be visualized easily on Gram stain of purulent material. However, the most common method of diagnosis is NAAT, which has more than 98% sensitivity. NAAT testing can be performed on urethral, cervical, oropharyngeal, and rectal specimens. The major disadvantage of NAAT is the inability to evaluate antibiotic susceptibilities. *N. gonorrhoeae* can also be cultured from swab specimens from the rectum, urethra, pharynx, or cervix. Samples often contain many different microorganisms. Selective media such as modified Thayer–Martin media (with vancomycin, colistin, nystatin, and trimethoprim) is used to inhibit growth of indigenous flora. The sensitivity of cultures varies from 65% to 95%. When drug resistance is a concern, cultures should be sent for sensitivity testing.

Treatment

Antibiotic resistance of *N. gonorrhoeae* continues to be a worldwide problem. In the last decade, treatment of gonorrhea has been complicated by an increase in higher minimum inhibitory concentrations (MICs) for commonly used antibiotics, including first-line cephalosporins. The resistance patterns of gonorrhea vary by region.

To address the concern of antibiotic resistance, uncomplicated urogenital gonorrhea should be treated with dual therapy; one agent should be ceftriaxone (250 mg given once intramuscularly)

and the other azithromycin (1 g taken once orally). This regimen is 99% effective in curing gonorrhea. Azithromycin can also treat concurrent chlamydia. Alternatively, doxycycline (100 mg taken orally twice each day for 7 days) may be given instead of azithromycin. High resistance rates (10% to 20%) limit the use of tetracyclines. Cefixime (400 mg taken once orally) should be reserved only if ceftriaxone is unavailable and given with azithromycin (1 g taken once orally). Cefixime may be less effective in the treatment of pharyngeal gonorrhea. In patients allergic to ceftriaxone, dual treatment with single doses of gentamicin (240 mg intramuscular once) and azithromycin (2 g taken orally once) may be used cautiously. Gastrointestinal side effects are common with the higher dose of azithromycin.

Other antibiotics with activity against gonorrhea include spectinomycin. Antibiotics that should not be used to treat gonorrhea due to resistance include penicillins and fluoroquinolones. Disseminated or complicated gonococcal infections should be treated with intravenous ceftriaxone and doxycycline or azithromycin. The duration of these regimens depends on the clinical course and response to therapy.

Prognosis

Gonorrhea is curable with proper antibiotic therapy. Untreated disease often resolves over several weeks, but prompt treatment halts transmission and prevents complications.

Vaginitis

Definition and Epidemiology

The term *vaginitis* refers to disorders of the vagina characterized by inflammation or irritation of the vulva and an abnormal vaginal discharge. Although a separate entity from urethritis, there is significant overlap of symptoms and the organisms that cause vaginitis and urethritis. The three main types of infectious vaginitis are *Candida* vulvovaginitis, bacterial vaginosis, and trichomoniasis. The latter two are strongly associated with sexual transmission.

Trichomoniasis is the most common nonviral STI worldwide. In the United States, 3.1% of women between the ages of 14 and 49 years are infected with *Trichomonas vaginalis*. Screening is recommended for trichomoniasis in women who are at high risk for other STIs as determined by commonly accepted measures (i.e., having new or multiple partners). Screening for bacterial vaginosis in pregnant women is a controversial topic.

Pathology

Candida albicans and *Candida glabrata* are the most common organisms responsible for *Candida* vulvovaginitis. These species may colonize asymptomatic women but their presence does not necessarily mean infection. Symptomatic cases are caused by an overgrowth of the species and penetration of the superficial vaginal epithelial cells. Overgrowth can result from increased estrogen levels or suppression of other vaginal flora by antibiotics.

Trichomoniasis is caused by the protozoan *T. vaginalis*, which infects the squamous epithelium in the urogenital tract. *T. vaginalis* is not normally present in the vagina and has an incubation period of a few days.

Bacterial vaginosis is caused by a variety of organisms flourishing in the vaginal ecosystem in conjunction with a reduction of normally occurring lactobacilli. The bacterium *Gardnerella vaginalis* is especially prominent in cases of bacterial vaginosis and is thought to infect the vaginal epithelium, creating a biofilm to which other bacteria may adhere. *G. vaginalis* is also the organism thought to play the most likely role in sexual transmission of bacterial vaginosis.

Clinical Presentation

Symptoms of vaginitis may include pruritus (i.e., primary feature of *Candida* vulvovaginitis); a change in the volume, color, or odor of discharge; burning; irritation; erythema; dyspareunia; spotting; and dysuria. In the case of trichomoniasis and bacterial vaginosis, infection is often asymptomatic but can be associated with sex. Symptomatic trichomoniasis in women most commonly includes a purulent vaginal discharge, erythema, and irritation of the vulva. An abnormal odor is also often associated with infection.

Bacterial vaginosis manifests with milder symptoms of irritation and erythema and is rarely associated with dysuria or dyspareunia. Patients with bacterial vaginosis most commonly have a notably fishy odor in the vaginal discharge, which may also be abnormally colored or textured.

Diagnosis and Differential Diagnosis

Laboratory testing and microscopy are needed for a diagnosis of vaginitis. Examination of vaginal pH can be a helpful differentiating tool. *Candida* vulvovaginitis typically does not cause a change in vaginal pH, whereas bacterial vaginosis and trichomoniasis do increase the pH up to 6. The identification of *Candida* organisms on a wet mount or culture of discharge from women with characteristic clinical symptoms indicates *Candida* vulvovaginitis.

The diagnosis of trichomoniasis may be based on laboratory testing (NAAT), motile trichomonads on a wet mount, or positive culture results. NAAT testing for vaginitis is also available that evaluates for *Candida*, trichomoniasis, and bacterial vaginosis. Amsel criteria or Nugent criteria may be used to diagnose bacterial vaginosis when Gram stain or microscopy is not available.

Treatment

Vaginitis is curable with proper antibiotic therapy. Trichomoniasis is treated with metronidazole (500 mg orally twice each day for 7 days or 2 g taken orally once) or tinidazole. Pregnant women can be treated with 2 g of metronidazole in a single dose at any stage of pregnancy. The safety of tinidazole has not been fully established.

Treatment of all recent sexual partners is recommended because trichomoniasis is almost exclusively transmitted by sexual contact. The same twice-daily regimen of 500 mg of oral metronidazole is the primary treatment for bacterial vaginosis; however, the single 2-g oral dose is *not* recommended for treatment of bacterial vaginosis. Treatment of *Candida* vulvovaginitis with a single 150-mg dose of fluconazole is highly effective. Use of a topical agent depends on whether the case is considered complicated or uncomplicated. Only topical azole therapies, applied for 7 days, are recommended for use by pregnant women.

Prognosis

Bacterial vaginosis is treatable with various antibiotics, but the primary concern is failure of normal *Lactobacillus* flora to reestablish colonization in the vagina. This leads to repeated infections and necessitates prolonged treatment. Oral and vaginal administration of *Lactobacillus* bacteria is sometimes recommended. Bacterial vaginosis increases risk of infection with HIV, herpes simplex virus type 2 (HSV-2), and *N. gonorrhoeae*, making treatment critical for the management of other STIs.

Other Causes of Nongonococcal Urethritis

There are several other known causes of urethritis and cervicitis and likely more that are unknown. Significant causes may include *Mycoplasma genitalium*, HSV-1/2, *Treponema pallidum*, adenovirus, and *Ureaplasma urealyticum*. *U. urealyticum* can be part of the normal flora, and its role in urethritis has not been validated.

The most common of these organisms is *M. genitalium*. It is a bacterium that lacks a cell wall, cannot be Gram stained, and is very difficult to grow in culture. The organism accounts for 15% to 25% of men with nongonococcal urethritis in the United States and is thought to be a cause of cervicitis and PID in women. NAAT testing of urine, urethral, vaginal, and cervical specimens for *M. genitalium* is available and is the recommended diagnostic test. Testing for *M. genitalium* should be considered for individuals with persistent urethritis or cervicitis. Treatment of *M. genitalium* is complicated by concerns of emerging resistance across the world. Empirical treatment of symptomatic individuals includes azithromycin (1 g taken orally once or a 500-mg dose followed by 250 mg daily for 4 days; a longer duration of azithromycin may be more effective). Moxifloxacin (400 mg daily for 7 to 14 days) is also effective and should be used if individuals have persistent symptoms.

GENITAL ULCER DISEASE

Genital ulcers are a major manifestation of several STIs. Genital ulcers are best classified as painful (e.g., HSV, chancroid) or nonpainful (e.g., syphilis). LGV due to *Chlamydia* also manifests with ulcerations. Ulcers may be classified as single (e.g., syphilis, chancroid) or multiple or grouped (e.g., HSV-1/2). All of these STIs manifest with diverse signs and symptoms, and clinical examination alone may be inadequate for accurate diagnosis (Table 102.1).

Syphilis

Definition and Epidemiology

Syphilis is caused by the spirochete *T. pallidum*, which can result in a wide spectrum of clinical disease. At the beginning of the 20th century, it was thought that an astounding 10% of the general population in the United States had syphilis. The CDC began reporting rates of syphilis in 1941. The rates peaked in the early 1940s at almost 600,000 cases and subsequently reached a nadir in 2000 with a rate of 2.1 cases per 100,000 people in the general population. However, since that time, the number of reported syphilis cases has been increasing. The major at-risk group is MSM, but the disease is observed in people across all ages, genders, sexual orientations, socioeconomic status, and racial and ethnic classes.

The resurgence of a generalized syphilis epidemic among MSM with HIV infection has had important consequences. Clinicians at STI clinics and those treating individuals with HIV need to be aware of guidelines for the diagnosis and treatment of syphilis in this population. Furthermore, clinicians need to be aware of less common presentations of syphilis and have a high degree of suspicion. Given the increasing number of MSM living with HIV, it is not uncommon to see coinfection in this population. All MSM, regardless of HIV status, should be considered for syphilis screening on an annual basis and more frequently if they have other risk factors.

Pathology

T. pallidum organisms are thinly coiled bacteria that move in a corkscrew motion. *T. pallidum* cannot be easily cultured, hindering diagnosis and study of the organism. *T. pallidum* infects and penetrates mucosal membranes, resulting in the classic chancre lesion. The organism then infects local lymph nodes and disseminates systemically. The median incubation period is approximately 3 weeks. In more than 60% of infected individuals, syphilis does not progress to tertiary stages. Immune host factors are thought to contribute to the development of tertiary syphilis.

Clinical Presentation

Primary syphilis classically involves the genitals, although lesions may also be observed in the rectum or oropharynx. The estimated risk of

TABLE 102.1 Differential Diagnosis of Genital Ulcer Disease

Disease	Primary Lesion	Adenopathy	Systemic Features	Diagnosis and Treatment
Genital herpes (HSV-1/2)				
Primary	Incubation 2-7 days; multiple, painful vesicles on erythematous base; lasts 7-14 days	Tender, soft, and usually bilateral	Fever, malaise	Viral cultures, DFA, antibody testing, Tzanck smear Tx: acyclovir, famciclovir, or valacyclovir for 7-10 days (shorter for recurrent cases)
Recurrent	Grouped, painful vesicles on erythematous base; lasts 3-10 days	None	None	
Primary syphilis (<i>Treponema pallidum</i>)	Incubation 10-90 days (average, 21) Chancere: painless papule that ulcerates with firm, raised border and smooth base; usually single; may be genital or almost anywhere; heals in 3-6 weeks without treatment	1 week after chancre appears; bilateral or unilateral; firm, discrete, no overlying skin changes, painless, nonsuppurative	During later stages	Nontreponemal tests (RPR, VDRL), treponemal tests (FTA-ABS), darkfield microscopy; cannot be cultured Tx: see Table 102.3
Chancroid (<i>Haemophilus ducreyi</i>)	Incubation 3-5 days; vesicle or papule to pustule to ulcer; soft, not indurated; very painful	1 week after primary in 50%; painful, unilateral in two thirds; suppurative	None	Gram stain and culture. Tx: azithromycin, ceftriaxone, ciprofloxacin
Lymphogranuloma venereum (<i>Chlamydia trachomatis</i> serovars L1, L2, L3)	Incubation 5-21 days; self-limited, painless papule, vesicle, or ulcer; lasts 2-3 days; found in only 10-40%	5-21 days after primary; one third bilateral, tender, matted iliac or femoral groove sign; multiple abscesses; coalescent, caseating, suppurative; thick yellow pus; sinus tracts; fistulas; strictures; genital ulcerations	Fever, arthritis, pericarditis, proctitis, meningoencephalitis, keratoconjunctivitis, preauricular adenopathy, erythema nodosum	NAAT for <i>Chlamydia</i> . Samples can be sent to the CDC to evaluate for LGV specific serotypes. Tx: incision and drainage, doxycycline
Granuloma inguinale (donovanosis)	Incubation 9-50 days; at least one painless papule that gradually ulcerates; ulcers are large (1-4 cm), irregular, nontender, with thickened, rolled margins and beefy red tissue at base; older portions of ulcer show depigmented scarring, white areas; advancing edge contains new papules	No true adenopathy; in one fifth of patients, subcutaneous spread through lymphatics leads to indurated swelling or abscesses of groin (pseudobuboes)	Metastatic infection of bones, joints, liver	Wright or Giemsa staining with short, plump, bipolar staining pattern, Donovan bodies in macrophage vacuoles Tx: doxycycline
Condyloma acuminatum (genital warts)	Characteristic large, soft, fleshy, cauliflower-like excrescences around vulva, glans, urethral orifice, anus, perineum	None	None	Clinical diagnosis, biopsy if necessary Tx: topical podophyllin, surgery, others

DFA, Direct fluorescent antibody test; FTA-ABS, fluorescent treponemal antibody absorption test; HSV, herpes simplex virus; NAAT, nucleic acid amplification test; RPR, rapid plasma reagin; Tx, treatment; VDRL, venereal disease research laboratory.

transmission from an individual with primary syphilis to an uninfected individual is 30% per sexual act. Syphilis may also be transmitted to others sites (i.e., rectum, oropharynx) through exposure with any contact of a primary lesion. Inoculation of the organism by surgeons through needlesticks has been well documented and typically does not result in a chancre at the site of infection (i.e., syphilis d'emblee).

The four classic stages of syphilis are primary, secondary, latent, and tertiary. Staging is best thought of as a continuum rather than discrete stages of infection. The states can manifest individually, but individuals often have symptoms consistent with primary and secondary symptoms. The primary and secondary stages of syphilis are extremely

infectious, and cases of transmission during the tertiary stage have been reported.

It can be very difficult to diagnose primary syphilis based solely on the physical examination. The primary chancre is generally described as a painless, clean-based, indurated ulcer. The borders are firm and raised. However, the presentation of a primary chancre may vary and any dermatologic manifestation in the right clinical setting (i.e., sexually active MSM) should be tested for syphilis. The chancre is teeming with spirochetes and should be considered extremely infectious. It is rare for a primary chancre to be absent, but it may go unnoticed. The chancre spontaneously heals without treatment over several weeks.

Secondary syphilis usually manifests as a diffuse, maculopapular rash that classically involves the palms and soles. However, a wide range of early skin manifestations exists, including macular, papular, pustular, vesicular, or any combination of these. Vesicular lesions may easily be confused with other STIs, including HSV-1/2. Syphilis may also have late skin manifestations, including nodular, squamous, or gummosis appearances.

The rash typically develops a few weeks after the chancre and results from dissemination of the organism. Up to 80% of patients have some cutaneous manifestations of disease. The rash is usually symmetrical and pink, with no pain or burning, and it usually spares the face. It resolves on its own over weeks to months and may be confused with pityriasis rosea, erythema multiforme, drug rashes, tinea, measles, and seborrheic dermatitis. The maculopapular rash of secondary syphilis is considered noninfectious, although lesions in axillary or inguinal folds or other regions exposed to chaffing may erode and become infectious.

Syphilis then enters a latent stage, during which an infected individual has no symptoms but does have positive serologic test results (Table 102.2). Tertiary syphilis may then develop at any point from years to decades after the initial infection.

Approximately 30% to 40% of individuals with untreated syphilis infection develop tertiary disease, which can include neurosyphilis, cardiovascular syphilis, and gummatous disease. Neurosyphilis has classically been thought of as a complication of tertiary syphilis. However, *T. pallidum* may invade and cause symptoms of the central nervous system at the time of initial infection. Early neurosyphilis may be characterized by signs and symptoms of meningitis and milder symptoms, including headache. Other manifestations of neurosyphilis include otosyphilis (i.e., hearing loss) and ocular syphilis, which is classically characterized as posterior uveitis. Late neurosyphilis may manifest with general paresis (i.e., progressive dementia, forgetfulness, psychiatric disease, and personality change), Argyll-Robertson pupils (i.e., no response to light but normal accommodation), and tabes dorsalis (i.e., ataxia and lancinating pains). The most common finding in late neurosyphilis is irregular pupils.

Gummas, a result of immune system activation, may develop in any tissue or organ in the body. Classic cardiovascular symptoms of syphilis include aortitis, which often affects the ascending thoracic aorta causing a tree-bark appearance with dilation and aortic valve regurgitation.

Diagnosis and Differential Diagnosis

The diagnosis of syphilis is limited by the inability of *T. pallidum* to grow on standard laboratory media. Diagnostic testing for syphilis

relies on the direct and indirect measurement of antibodies against treponema. Nontreponemal tests such as the rapid plasma reagin (RPR) and venereal disease research laboratory (VDRL) test rely on anticardiolipin antibodies, which usually resemble antibodies against treponema. These tests are usually sensitive but nonspecific, and false-positive results are relatively common, especially in individuals with other autoimmune diseases or who are pregnant. Nontreponemal tests report antibodies in terms of dilutions; a titer of 1:2 is extremely low compared with a titer of 1:1024. This measurement can be used as a general representation of spirochete load in the patient. With treatment, nontreponemal test results may revert to nonreactive. However, some individuals may not have a serologic response (12%) or may have persistent nontreponemal titers (“serofast”; 35% to 44%) despite appropriate treatment.

Treponemal tests such as the fluorescent treponemal antibody absorption (FTA-ABS) test rely on antibodies that directly target the organism and are therefore more specific. Test results may be positive or negative, and a positive result usually remains so for life. The normal testing algorithm employs the sensitive, nontreponemal tests, followed by a more specific treponemal test to confirm the diagnosis. However, the “reverse” algorithm, which employs a treponemal test first followed by a nontreponemal test, is also commonly used. In the case of a discordant result (i.e., a positive treponemal test and a negative nontreponemal test), a third different treponemal test is used (*Treponema pallidum* particle agglutination assay, TP-PA). The inherent limitation of antibody testing results in many cases of unclear diagnoses.

Several mistakes may be made by clinicians in the diagnosis of syphilis. In primary syphilis, the initial nontreponemal test result may be negative up to 30% of the time. A patient with a lesion suspicious for syphilis should undergo repeat testing or empirical treatment regardless of the serologic results. In the event of a recent exposure, a patient should be counseled that a syphilis and HIV antibody test may be negative. A patient who is treated early in the course of disease may never develop an antibody response and may therefore never have a positive test result.

After successful treatment, patients with an initial episode of syphilis should see a 4-fold decrease in nontreponemal titers at approximately 6 to 12 months. Titers may never return to normal and should be followed periodically. For MSM, CDC guidelines suggest yearly STI testing and more frequent testing (3 to 6 months) for patients with multiple partners, anonymous partners, or other risk factors for infection.

TABLE 102.2 Serologic Testing for Syphilis

Features	Nontreponemal	Treponemal
Technique	Antibody to cardiolipin-lecithin (RPR, VDRL)	Antibody to <i>Treponema pallidum</i> (FTA-ABS, EIA)
Indications	Screening and assessing response to therapy; should be quantified by diluting serum and reporting in titers	Confirmatory test; usually remains positive for life; may be used as a screening test
Positive for syphilis		
Primary	77%	86%
Secondary	98%	100%
Early latent	95%	99%
Late latent	73%	96%
False positives	1-2% of the population may have a false-positive RPR/VDRL; common in pregnancy, recent immunization, autoimmune diseases, acute infectious illness, HIV, chronic liver disease, prozone reaction (negative result due to high antibody titers)	Borderline positive is common in pregnancy, and test should be repeated

EIA, Enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption test; HIV, human immunodeficiency virus infection; RPR, rapid plasma reagin; VDRL, venereal disease research laboratory test.

Treatment

Despite the classic staging of syphilis as primary, secondary, latent, or tertiary, the disease is best thought of in terms of early infection (<1 year) or late infection (≥ 1 year) when considering treatment. Early infection consists of primary, secondary, and early latent stages. Late infection consists of late latent and tertiary disease. *T. pallidum* remains sensitive to penicillin. Individuals with early syphilis can be treated with a single intramuscular injection of benzathine penicillin G (Bicillin), which achieves high and prolonged serum concentrations. Individuals with late syphilis or disease of unknown duration should be treated with three weekly injections of intramuscular benzathine penicillin G (Table 102.3). This cures most patients. Importantly, other formulations of penicillin are less effective and should not be used.

Although penicillin remains the drug of choice, doxycycline may also be used in individuals who have severe allergies to penicillin. However, every effort should be made to use penicillin because of the sensitivity of the organism. For pregnant women who are allergic to penicillin, penicillin desensitization should occur in collaboration with a pharmacist and an allergist specialist. As a result of treatment, individuals may experience a febrile reaction (i.e., Jarisch-Herxheimer reaction). Symptoms are caused by killing of the spirochetes and should not be confused with an allergic reaction.

The co-epidemic of syphilis and HIV has led to an increase in individuals with manifestations of neurosyphilis. In cases of syphilis with neurologic symptoms, a lumbar puncture and CSF examination is warranted to rule out neurologic involvement. Any pleocytosis or increase in protein concentration warrants treatment for neurosyphilis. A cerebrospinal fluid (CSF) sample should be sent for VDRL testing, but the test lacks sensitivity (50%), and a negative test result does not rule out neurosyphilis. Usually, HIV-negative individuals with syphilis without neurologic symptoms should not undergo a lumbar puncture. Many HIV-infected individuals with syphilis, however, have asymptomatic neurosyphilis. The clinical implications of this are unclear, but these individuals may fail intramuscular therapy at a high rate. Some experts recommend CSF examination in all HIV-infected individuals with a CD4⁺ count lower than 350 cells/ μ L or a nontreponemal titer greater than 1:32. These criteria capture almost everyone with asymptomatic neurosyphilis.

Individuals with neurosyphilis should be treated with intravenous penicillin G for 10 to 14 days. In tertiary disease with manifestations of neurologic disease, treatment with intravenous penicillin halts disease progression but does not reverse existing structural damage. Ocular disease or other similar neurologic manifestations should be treated as neurosyphilis. Nontreponemal titers should be followed to ensure an appropriate response. Repeat treatment may be necessary in a small number of cases.

Prognosis

Although penicillin is the treatment of choice for syphilis, it has not been validated in clinical trials but is based on a long history of clinical use. However, a significant number of individuals with syphilis do not respond with the recommended decline in nontreponemal titer. Individuals who do not respond should be retreated.

For a deeper discussion of these topics, please see Chapter 303, “Syphilis,” in *Goldman-Cecil Medicine*, 26th Edition.

Herpes Simplex Virus

Definition and Epidemiology

HSV-1/2 cause a wide variety of clinical disease. HSV-1 is historically the cause of herpes labialis (i.e., cold sores), and HSV-2 is the cause of genital herpes, although there is overlap. After infection occurs, HSV-1/2 enters a latent state and may later reactivate to cause disease in a subset of individuals.

The overall prevalence of HSV-1 and HSV-2 in the population is approximately 60% and 20%, respectively. However, the incidence of HSV-1 infection approaches 90% to 100% among middle-aged adults. Seroprevalence of HSV-2 is associated with a patient’s sexual activity, including number of partners and history of other STIs, and with age, gender (women are at higher risk than men), and race or ethnicity. More than 50 million people in the United States are infected with genital HSV-1/2, and most are asymptomatic. CDC guidelines do not recommend routine screening for HSV-1/2 in people without symptoms. There is no evidence that screening for HSV-1/2 reduces its spread or has an impact on the disease. HSV-1/2 is not a reportable disease in the United States.

Pathology

HSV-1 and HSV-2 are two of eight double-stranded DNA human herpesviruses. Others include varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesviruses 6, 7, and 8. Infection with one type of HSV does not prevent or increase the chances of infection with other types. After initial infection, HSV-1/2 enters a latent state within neuronal cells of sensory or autonomic peripheral ganglia. Reactivation can occur at any time and is mediated in part by immune factors. HSV-1 most commonly infects the trigeminal ganglia and HSV-2 the sacral nerve root ganglia (S2-S5).

Clinical Presentation

Transmission of HSV-1/2 is through skin-to-skin contact, including sexual contact at mucosal surfaces such as the oropharynx, vagina, rectum, cervix, and conjunctivae. Importantly, transmission may occur in the absence of symptoms.

TABLE 102.3 Syphilis Treatment

Clinical Category	Regimen of Choice	Alternative ^a
Early syphilis (<1 year)	Benzathine penicillin, 2.4 million units IM, given once	Penicillin desensitization Doxycycline, 100 mg PO bid for 14 days Tetracycline, 500 mg PO qid for 14 days Azithromycin 2 g PO qd
Late syphilis (≥ 1 year) or unknown duration	Benzathine penicillin, 2.4 million units IM, given once each week for 3 wk	Penicillin desensitization Doxycycline, 100 mg PO bid for 28 days Tetracycline, 500 mg PO qid for 28 days
Neurosyphilis	Penicillin G, 4 million units IV q4h or 24 million units by continuous infusion qd for 10-14 days	Penicillin desensitization Ceftriaxone 2 g qd IM or IV for 10-14 days

^aIf patient has a penicillin allergy.

The stages of HSV-1/2 infection include primary, latent, and recurrent. Primary infection of genital HSV-1/2 may include fever, headache, other systemic symptoms, and the classic local symptoms of painful genital vesicles or ulcers (multiple) and lymphadenopathy. Oral infections of HSV-1 may include gingivostomatitis and pharyngitis. Symptoms may vary from none to serious and require hospitalization. HSV-1/2 then enters a latent state. Reactivation occurs in a subset of individuals with symptoms less severe than those of primary infection. Some individuals have no reactivation, and others have multiple reactivations per year.

Complications of HSV-1/2 infection include meningitis and proctitis. Recurrent episodes of meningitis (i.e., Mollaret meningitis) may be caused by HSV-1/2. Other manifestations of HSV-1/2 include herpetic whitlow (e.g., infection of a finger of a health care worker), herpes gladiatorum (e.g., HSV-1/2 skin infections in athletes such as wrestlers), and ocular disease (e.g., keratitis, acute retinal necrosis). HSV-1/2 infection may rarely be associated with erythema multiforme, hepatitis, and encephalitis.

Diagnosis and Differential Diagnosis

The diagnosis of HSV-1/2 is typically made clinically. If possible, lesions should be tested for HSV-1/2 using viral culture (50% sensitivity), PCR, or direct fluorescent antibody (DFA) testing. Alternatively, serology testing for immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies is available. This test should be reserved for individuals with suspected primary infection or to document chronic infection, and it should usually not be used for screening purposes.

Treatment

Recommended regimens for primary HSV-1/2 infection include acyclovir (400 mg orally three times per day for 7 to 10 days or 200 mg orally five times per day for 7 to 10 days), famciclovir (250 mg orally three times each day for 7 to 10 days), or valacyclovir (1 g orally twice each day for 7 to 10 days). Treatment can also be used for reactivation disease: acyclovir (400 mg orally three times each day for 5 days, 800 mg orally twice each day for 5 days, or 800 mg orally three times each day for 2 days), famciclovir (125 mg orally twice each day for 5 days or 1000 mg orally twice each day for 1 day or 500 mg once followed by 250 mg twice each day for 2 days), or valacyclovir (500 mg twice each day for 3 days or 1 g orally once each day for 5 days).

Individuals with frequent recurrences may be candidates for suppressive therapy. Severe disease should be treated with intravenous acyclovir (5 to 10 mg/kg intravenously every 8 hours). Duration and transition to oral medication should be based on clinical improvement. Total treatment duration is usually at least 10 days. The safety of systemic acyclovir, valacyclovir, and famciclovir therapy in pregnant women is not established.

Prognosis

Although HSV-1/2 infection cannot be cured, most people are asymptomatic, and suppressive therapy is available. Individuals with HSV-1/2 infection should be educated regarding the disease, including transmission and available treatments. They should be encouraged to discuss their status with sexual partners, including the possibility that transmission may occur in the absence of symptoms. Individuals should abstain from sex during an outbreak.

Chancroid

Chancroid is a rare cause of genital ulceration in the United States. The infection is caused by the gram-negative rod *Haemophilus ducreyi* and is endemic in parts of Africa and the Caribbean. Classic symptoms include a single or multiple painful, nonindurated genital ulcers and inguinal lymphadenopathy. Growth of the organism in cultures

requires hemin-containing media, and it may appear as a school of fish on Gram stain. PCR may be available in certain areas.

Testing for HSV-1/2 and syphilis should always be performed. Recommended treatment regimens include azithromycin (1 g orally once), ceftriaxone (250 mg intramuscularly once), or ciprofloxacin (500 mg orally twice each day for 3 days). Ciprofloxacin is contraindicated in pregnant and lactating women.

Granuloma Inguinale

Granuloma inguinale is also known as donovanosis. It is caused by the gram-negative bacterium *Klebsiella granulomatis*. The disease is rare in the United States but endemic in regions of Africa, India, Oceania, and the Caribbean. Clinical manifestations include painless, ulcerative genital lesions with erythema. Classic Donovan bodies may be observed on histopathology.

The recommended treatment regimen is doxycycline (100 mg orally twice each day for at least 3 weeks). Alternative regimens include azithromycin, ciprofloxacin, and sulfamethoxazole-trimethoprim. Azithromycin may be useful for treating granuloma inguinale during pregnancy. Doxycycline and ciprofloxacin are contraindicated in pregnant women.

Other Causes of Genital Ulcers

Other causes of genital ulcers should be considered when the results of routine testing are negative. Noninfectious causes include trauma, Behçet's disease, malignancy, and drug-mediated disease.

OTHER SEXUALLY TRANSMITTED INFECTIONS

Genital Warts

Human papillomavirus (HPV) is responsible for a spectrum of cutaneous and mucosal disease, ranging from genital warts to invasive cancer. HPV has been linked to cervical, anal, and oropharyngeal cancer. There are more than 100 types of HPV. Sexually transmitted HPV infection is responsible for genital warts and anogenital carcinoma. More than 80% of sexually active adults acquire HPV infection in their lifetime. Genital warts tend to be benign and asymptomatic, and 90% are caused by HPV types 6 and 11. The HPV types most often linked to anogenital carcinoma are 16 and 18; HPV-16 is the most common.

Warts are usually described as flat and papular in the genital regions. Diagnosis of genital warts is usually made by clinical examination. If unclear, a biopsy may be performed. Treatment of genital warts may include podofilox (0.5% solution or gel), imiquimod (5% cream), sinecatechins (15% ointment), cryotherapy, podophyllin resin (10% to 25% concentration), trichloroacetic acid (TCA), and surgical excision.

HPV vaccination is available with Gardasil (quadrivalent vaccine) and Cervarix (bivalent vaccine). The main objective of vaccination is to prevent cervical and other cancers. The vaccines are also effective in preventing genital warts. The vaccines are most effective before sexual debut. Guidelines suggest vaccination of males and females between the ages of 11 to 26 years. Vaccines may be administered to individuals as young as 9 years old. HPV vaccination is approved for men and women up to 45 years of age. In several countries including the United States, there has been a decline in anogenital warts in adolescents, young women, older women, heterosexual men, as well as men who have sex with men.

Pubic Lice

Pubic lice (i.e., *Pediculosis pubis*) may spread from the genitalia to other areas of the body. The most common symptom is pruritus. Small macules and localized lymphadenopathy may occur. Diagnosis of this STI is made by light microscopy of the organism.

Treatment includes permethrin (1% cream applied to affected areas, rinsed off in 10 minutes) or pyrethrins (similar application). Alternative medications include malathion (0.5% lotion) or ivermectin. Clothing, bed sheets, and other linens should be thoroughly washed.

Scabies

Scabies is caused by the skin mite *Sarcoptes scabiei*. Transmission occurs by skin contact, and among adults, it is usually sexual. Clinical presentation usually includes pruritus and small erythematous papules that are classically present on the wrists, forearms, fingers, and genital areas.

Diagnosis is usually based on clinical presentation and examination of skin scrapings. Recommended treatment regimens include permethrin (5% cream applied from the neck down and washed off after 8 to 14 hours) or ivermectin.

Human Immunodeficiency Virus Infection

Joseph Metmowlee Garland, Timothy Flanigan, Edward J. Wing

HISTORY

Human immunodeficiency virus (HIV) infection was first diagnosed in 1981 in the United States, when it was recognized as an immunodeficiency syndrome in young gay men and people who inject drugs. Soon after, the disease was recognized in patients with hemophilia, others who had received blood transfusions, previously healthy women, and rarely, health care workers. Patients with the syndrome were susceptible to unusual opportunistic infections such as *Pneumocystis jirovecii* pneumonia and unusual tumors such as Kaposi's sarcoma. Tragically, once patients had clinically identified disease, mortality over several years was very high. Patients developed recurrent infections, progressive tumors such as Kaposi's sarcoma and B cell lymphoma, wasting, and progressive neurologic syndromes including dementia. The immunodeficiency was characterized by weakened cell-mediated immunity marked by low CD4 T cells in the peripheral blood. Subsequently this disease was labeled the acquired immunodeficiency syndrome, or AIDS. In 1983, the causative agent, the human immunodeficiency virus, was identified by Luc Montagnier in France (winner of the Nobel Prize in Medicine) and Robert Gallo in the United States. By 1985, there was a serum test to identify the virus. Transmission in the United States was primarily through sex, particularly anal sex in men who had sex with men (MSM), through sharing needles during injection drug use, and through infusion of blood products.

The effect on a generation of young people was devastating. Initially, the cause was unknown, the modes of transmission uncertain, and the infectivity unclear. There was no treatment available, other than specific therapy for the opportunistic infections and tumors. All classes, races, and ethnic groups were affected. The incidence of the disease rose to greater than 50,000/year, and the number infected in the United States increased to over 1 million. Discrimination against people living with HIV (PLWH) was widespread. The government's response was slow. The early epidemic is poignantly described in Randy Shilts' book *And The Band Played On*. In 1987 the first drug, zidovudine or AZT, was approved for use against HIV and heralded a new era of virus-directed treatment. Unfortunately because of the virus' ability to mutate, resistance developed in most patients after several months of use. Other drugs with other mechanisms were developed over the next decade so that by 1995, with the discovery and approval of protease inhibitors, widespread use of effective combinations of antiretroviral therapy (ART) became available (initially called highly active antiretroviral therapy [HAART] or combination ART [cART]). This transformed HIV from a progressive disease to a manageable chronic condition in those diagnosed and engaged in treatment. Even patients

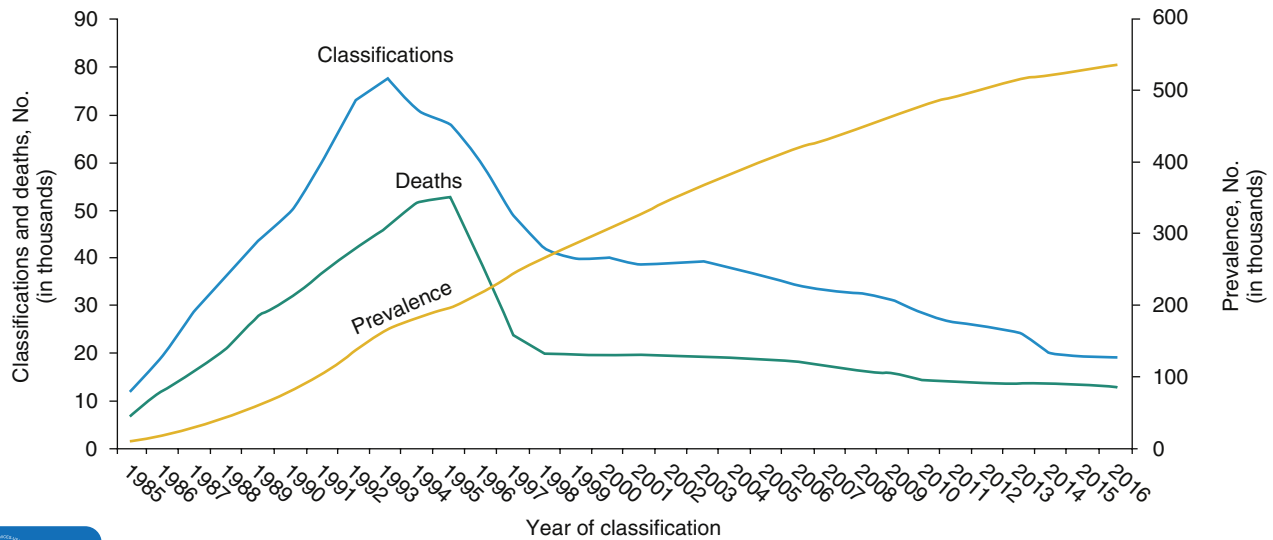

with severe end-stage AIDS could resolve their opportunistic infections and recover CD4 T cell counts.

Once the virus was identified, there was a vigorous search for the geographic and animal origins of the virus. By the late 1980s, AIDS was recognized as a worldwide pandemic. Because early cases had been identified in Africa, particularly West Africa, and because HIV was closely related to endemic simian viruses, early samples from West Africa were sought and tested. The earliest human case was identified retrospectively from serum taken from a sailor in 1959 in Kinshasa, now in the Democratic Republic of Congo. Because the virus mutates at a very fast rate, a retrospective "molecular clock" technique with mathematical modeling was used to project that the origin of HIV occurred in the early 20th century during several cross-species transmission events from chimpanzees, which harbor simian immunodeficiency virus (SIV), to humans, likely in southeast Cameroon. Such transmission occurred presumably in hunters during the killing and butchering of primates for food. Sexual transmission between humans followed, and the disease progressed along rivers and highways in West Africa during a time of social change and development in the early 20th century. Spread throughout the world eventually occurred due to increased international travel and interaction.

Subsequent virologic studies of HIV have demonstrated that HIV-1 can be divided into four groups that include group M (90% to 95% of all infections) and groups N, O, and P that account for much smaller numbers. Group M is further divided into subgroups or clades labeled A through D, F through N, and J and K. Clade B is the most frequent in the United States and Europe, whereas C and A are found in Africa, where they account for 50% and 12% of all HIV cases, respectively. A separate distinct retrovirus, HIV-2, was identified in 1986. Confined primarily to West Africa, it causes a less severe form of AIDS.

EPIDEMIOLOGY

The course of the HIV epidemic in the United States is shown in [Fig. 103.1](#). Stage 3 (AIDS) classification refers to those with CD4 count less than 200 or with specific opportunistic infections/tumors. As can be seen, the incidence of HIV/AIDS rose until 1993, and the death rate until 1995. Subsequently, both fell dramatically with the widespread use of multidrug effective ART. From 1998 onward, there was a leveling off, with little change in the death rate but a slow decline in number of AIDS diagnoses. Overall there has been a linear increase in the prevalence, that is, in PLWH.

Note. Deaths of persons with HIV infection, stage 3 (AIDS) may be due to any cause.

Fig. 103.1 Stage 3 (AIDS) classifications, deaths, and persons living with diagnosed HIV infection ever classified as stage 3 (AIDS) 1985–2016: United States and six dependent areas. (From the Centers for Disease Control and Prevention; National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention Division of HIV/AIDS Prevention. *Trends in HIV Infection Stage 3 [AIDS]*. <https://npin.cdc.gov/publication/trends-hiv-infection-stage-3-aids>. Accessed January 23, 2019.)

In 2017, there were 38,739 new cases of HIV infection in the United States, a rate that has been unchanged since 2012. In 2017 it was estimated that 1.2 million people were living with HIV in the United States and 86% had been diagnosed. Sixty-three percent of those who had been diagnosed had a suppressed viral load. Geographically, the rates of new HIV diagnoses are highest in the South followed by the Northeast, the West, and finally the Midwest. Those at greatest risk remain MSM, accounting for 66% of all HIV diagnoses in 2017. The risk of acquiring HIV is 22 times higher than in the general population in men who have sex with men. Women are at risk primarily through heterosexual contact (17% of new diagnoses), with African American women being at greatest risk. Minority populations, particularly African American and Hispanic individuals are at greater risk for HIV compared to other races/ethnicities. In 2017 African Americans accounted for 43% of new HIV diagnoses, though they accounted for only 13% of the entire population. Hispanic individuals accounted for 26% of new diagnoses but were only approximately 17% of the total population.

Though still considered a traditional risk factor, injection drug use has fallen markedly as a cause of HIV transmission, largely through the use of syringe exchange programs and other harm reduction practices among people who inject drugs. In 2017, injection drug use accounted for only 9% of new HIV diagnoses in the United States. The risk of acquiring HIV is 22 times higher in those who inject drugs and 21 times higher in sex workers. Unfortunately, in 2018, only 18% of persons at high risk with indications had been prescribed medications for preexposure prophylaxis (PrEP, see later section) for prophylaxis.

Since the 1980s, HIV infection has become a worldwide pandemic and HIV continues to spread throughout all continents. Since the late 1990s, rapid transmission has occurred throughout Africa, India, Southeast Asia, the former Soviet Union, and some parts of Eastern Europe. Today, approximately 70% of PLWH live

in Africa; the Americas and South-East Asia account for slightly more than 9% each, and Europe accounts for 6%. Because of latency between HIV infection and the development of AIDS-associated illnesses, the clinically recognized epidemic of AIDS has lagged 6 to 8 years behind the spread of the virus into new populations.

Since the start of the epidemic, according to UNAIDS, 74.9 million people have become infected with HIV and 32 million people have died from HIV. In 2018 it was estimated that 37.9 million people globally were living with HIV and of those, 1.7 million people were younger than 15 years of age. In that year 1.7 million people were newly infected and 770,000 people died from HIV. In 2018, 23.3 million people living with HIV were taking ART. As a result of increasing availability of ART, the number of new infections has been reduced by 40% since 1997 and AIDS-related deaths have been reduced by more than 56% since 2004. With more access to ART worldwide and increasing efforts at availability and adherence, incidence and mortality rates should continue to fall. Tuberculosis remains the leading cause of death among PLWH, accounting for approximately one in three deaths due to HIV. It is estimated that almost half of people infected with HIV and TB are unaware of their coinfection and therefore are not receiving appropriate care.

VIROLOGY

HIV contains two single-stranded copies of the viral RNA genome, together with the virus-encoded enzymes reverse transcriptase, protease, and integrase (Fig. 103.2). Surrounding the structural (p24 and p18) proteins is a lipid bilayer derived from the host cell, through which protrude the transmembrane (gp41) and surface (gp120) envelope glycoproteins. The HIV envelope glycoproteins have a high affinity for the

Fig. 103.2 HIV viral replication. Key steps in the pathway targeted by antiretroviral therapy include membrane binding and fusion, reverse transcription, integration of proviral DNA, and protein synthesis. *LTR*, Long terminal repeat; *mRNA*, messenger RNA. (Modified from Furtado MR, Callaway DS, Phair JP, et al: Persistence of HIV-1 transcription in patients receiving potent antiretroviral therapy, *N Engl J Med* 340:1614–1622, 1999.)

CD4 molecule on the surface of T-helper lymphocytes and other cells of monocyte-macrophage lineage. After HIV binds to the CD4 molecule, the envelope undergoes a conformational change that facilitates binding to another cellular coreceptor; the most important of these are the chemokine receptors CCR5 and CXCR4. This second binding event promotes a major conformational change that causes approximation of the viral and cellular membranes; fusion of these membranes is mediated by insertion of the newly exposed fusion domain of the envelope gp41 into the host cell membrane.

As a result of these processes, the HIV nucleoprotein complex enters the cytoplasm, where the RNA viral genome undergoes reverse transcription by the virally encoded reverse transcriptase. The resulting double-stranded

viral DNA enters the nucleus, where proper localization of the viral preintegration complex is mediated by host proteins, and integration of the DNA provirus into the host chromosome is catalyzed by the retroviral integrase. Latently infected resting memory CD4 lymphocytes serve as reservoirs of persistent infection for the life of the patient even with effective ART (see later discussion). However, the bulk of viral replication takes place in activated T cells, which are both more susceptible to HIV infection and more capable of supporting productive HIV replication.

When a CD4⁺ lymphocyte is activated, expression of HIV messenger RNA (mRNA) is enhanced. Core proteins, viral enzymes, and envelope proteins are encoded by the *gag*, *pol*, and *env* genes of HIV, respectively. More than 100 host proteins, in addition to the viral proteins,

Fig. 103.3 The natural progression of HIV disease. (From Bennett JE, Dolin R, Blaser MJ. Mandell Douglas and Bennett's Principles and Practice of Infectious Diseases, 9th ed. Figure 122.1, page 1659.)

may be important for viral replication. Viral particles are assembled at the cell membrane, each containing two copies of unspliced mRNA within the core as the viral genome, and virions are released from the cell by budding. Productive viral replication is lytic to infected lymphocytes. A number of other host cells, including macrophages and certain dendritic cells, are also infected by HIV, but viral replication does not appear to be lytic to these cells.

Following acute infection, high-level viral multiplication occurs in mucosal lymphoid tissues of the gut and in other lymphatic sites. Plasma HIV RNA levels (i.e., the plasma viral load [PVL]) often exceed 1 million copies per milliliter during the second to fourth weeks after infection. Almost all instances of acute HIV infection are caused by R5 tropic viruses, viruses that use the chemokine receptor CCR5 for cellular entry. During subsequent weeks, the PVL decreases, often rapidly. This decrease in viremia results largely from a partially effective immune response. After 6 to 12 months, the PVL typically stabilizes at a level denoted the viral *set point*, and it may remain at approximately that level for several years, entering a period of clinical latency (Fig. 103.3). The set point, assessed as the PVL at 6 to 12 months after infection, is a significant predictor of the subsequent rate of progression of HIV disease but accounts for only half of the population variability in disease progression rates.

After recovery from the acute retroviral syndrome, the patient may feel entirely well for several years, but even in the asymptomatic individual, more than 100 billion new virions may be produced daily. Rapid production and turnover of circulating CD4⁺ cells also occurs throughout the course of HIV infection, and a progressive decline in circulating CD4⁺ cells occurs in most individuals. Cell lysis associated with HIV replication accounts only partially for this progressive loss of CD4 cells. During the years of clinical latency, virions are present in large numbers in the follicular dendritic processes of the germinal centers of the lymph nodes, which undergo both hyperplasia and progressive fibrosis. As HIV disease progresses over several years, the lymphatic tissue atrophies and plasma viremia intensifies. In later-stage HIV disease, a more dramatic CD4 cell decline is observed, following a sharp rise in the PVL (see Fig. 103.3).

The decline in the number of CD4 cells is accompanied by profound functional impairment of the remaining lymphocyte populations. Anergy may develop early in HIV infection and eventually occurs in almost all persons with AIDS. T-helper lymphocyte proliferation in

response to antigenic stimuli is dramatically impaired, T cell cytotoxic responses are diminished, and natural killer cell activity against virus-infected cells is greatly impaired. Decrease in function as well as number of CD4 cells is central to the immune dysfunction, and this impairment partly underlies the failure of B-lymphocyte function, as measured by impaired capacity to synthesize antibody in response to new antigens.

IMMUNOLOGY AND INFLAMMATION

Acute HIV infection results in massive destruction of T cells in lymphoid tissue throughout the body, particularly in the intestinal wall, and the decrease can be easily quantified in the peripheral blood. Partial recovery of T cell numbers and partial control of HIV viral load occurs due to the initial immune response in which both CD4 and CD8 cell clones react to HIV antigens (see Fig. 103.3). Robust inflammatory responses to initial infection occur. Within weeks to months, this response decreases but persists above baseline compared to the inflammation in the age-matched general population. One of the hallmarks of HIV infection is the continuous slow destruction of the CD4 T cell population with eventual loss of antigenic reactivity. Continuous stimulation of the CD8 cell population results in a reversal of the usual CD4:CD8 ratio. Eventually there is an increase in the CD8 phenotype termed (CD28⁻, CD57⁺) that is reactive towards viruses, particularly cytomegalovirus. This phenotype is termed senescent and secretes proinflammatory cytokines. In late stages, destruction of lymph tissue architecture inhibits normal immune cell interaction, furthering immunodeficiency. In addition, there is hemopoietic progenitor cell loss and thymic dysfunction, both reducing T lymphocyte homeostasis.

Cells of the monocyte/macrophage and dendritic lineage are also infected by HIV but are not destroyed. This includes macrophages in tissues such as adipose tissue and brain microglia. Because of gut immunodeficiency and microbial translocation, as well as stimulation by HIV and other viruses, chronic activation of macrophages occurs, as indicated by elevated levels of soluble CD14 and soluble CD163 in serum, with resultant secretion of proinflammatory cytokines. HIV itself can stimulate immune responses through stimulation of toll-like receptors 7, 8, and 9 on antigen presenting cells with subsequent production of interferons. As a result, cytokine levels, particularly IL-6 and type I interferons among others have been shown to be elevated in PLWH.

ART markedly decreases HIV viral replication (and hence serum viral load) and allows recovery and stabilization of CD4 T cell numbers. However, even with effective ART, decreased immune reactivity and low-level chronic inflammation persist in PLWH. This decreased reactivity depends roughly on the level of CD4 T cells on stable ART. For example, decreased immunity to *Streptococcus pneumoniae* persists in PLWH on ART even in those with recovered CD4 T cell numbers and suppressed viral loads.

Persistent chronic inflammation in people living with HIV, even in those on effective ART, is presumed to be multifactorial in etiology including: (1) low levels of HIV replication; (2) gut immunodeficiency allowing continuous exposure to microbial antigens resulting in macrophage activation; (3) reactivation of herpes viruses, particularly CMV and EBV; and (4) cytokine production by cells including macrophages and senescent CD8 T cells. This low-level inflammation is linked in part to increased risk for chronic diseases including cardiovascular, bone, kidney, and other morbidities associated with aging.

CLINICAL DIAGNOSIS OF HIV

Since 2013, the US Preventive Services Task Force has recommended routine HIV testing in all persons ages 15 to 65, to be offered in primary care settings. Despite this recommendation, almost a quarter of new

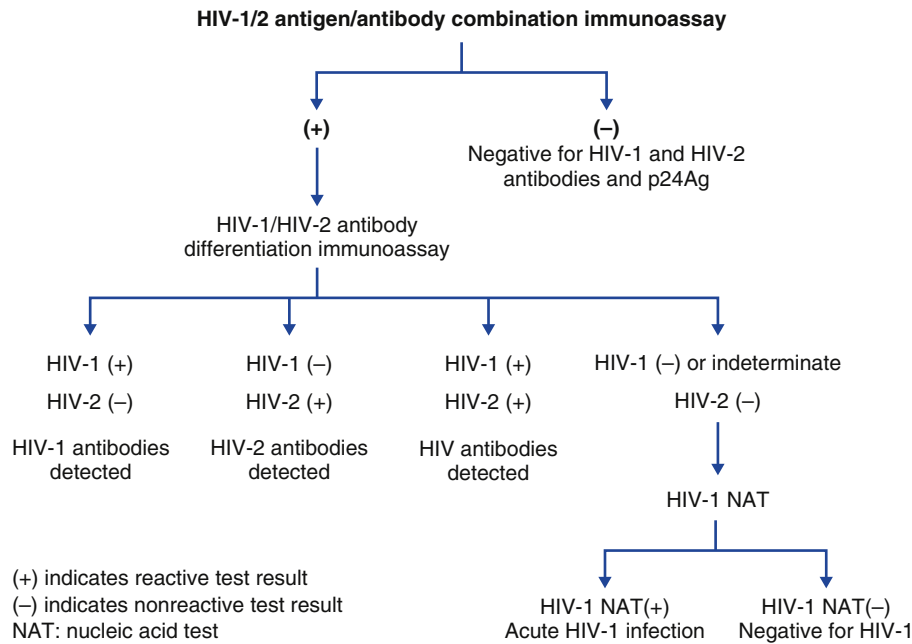

Fig. 103.4 Recommended HIV testing algorithm (CLSI).

HIV diagnoses are made when the patient already has an AIDS diagnosis (CD4 count <200 or AIDS-defining condition), indicating late diagnosis and missed opportunities for earlier testing remain an issue. All pregnant women should be offered HIV testing as well. Standard testing for HIV in the United States is through use of a fourth-generation immunoassay for HIV-1 and HIV-2 antibodies and an HIV early antigen (p24). Confirmation is by an HIV-1 and HIV-2 antibody differentiation immunoassay and nucleic acid testing if these are both negative or indeterminate (Fig. 103.4). The “window period” from disease acquisition to test positivity has greatly reduced as compared with earlier generations of the test; fourth-generation testing is usually positive within 18 to 45 days. Rapid point-of-care testing methods also exist and may play an important role in HIV testing in many clinical and community settings. These rapid tests are lateral-flow (immunochromatographic) or vertical-flow (immunofiltration) assays that detect the presence of HIV-1/2 antibodies and/or HIV p24 antigen and can be performed on oral fluid or a drop of serum (“finger stick”) to provide results within 30 minutes. They do not require confirmation by serum antibody-based tests. If HIV is diagnosed, it is important to pursue further testing to characterize the stage of disease, including a CD4 count and PVL.

Identification of persons with HIV and linkage to effective care are critical public health priorities. Early identification of infection affects prognosis; patients who have AIDS at diagnosis have a lower predicted life expectancy than those with higher CD4 counts. Further, studies have demonstrated that patients who are diagnosed and treated with effective ART do not transmit virus to others once their serum viral load is undetectable, therefore HIV treatment is also a cornerstone of HIV prevention efforts.

Any discussion of HIV diagnosis raises the important question of disclosure. Respect for patients’ right to confidentiality is important to remember at all points of contact with the health care system, particularly given the often-stigmatized nature of HIV infection in society. Communication of a new diagnosis, and any subsequent discussion of treatment, prognosis, transmission, or other aspects of care, must be performed in a confidential setting. Whether and how to disclose to partners or family members is a patient decision, and disclosure should be done by the patient or by the patient with the provider’s assistance. State-by-state laws differ on the legality of disclosing patients’ HIV

status without their consent, but best practices generally discourage this practice because it will damage the patient-provider relationship and increases the risk of losing the patient to care entirely. After establishing a relationship with a patient, providers should also discuss designating a health care proxy (HCP) and gain an understanding of what the HCP knows about the patient’s health, so that the patient’s wishes around confidentiality can be respected even in the setting of incapacitation.

THE NATURAL PROGRESSION OF HIV DISEASE

Acute Retroviral Syndrome

Up to 50% of PLWH report a mononucleosis-like syndrome (acute retroviral syndrome) occurring 2 to 6 weeks after initial infection. The symptoms may include fever, sore throat, gastrointestinal symptoms, diffuse lymph node enlargement, rash, arthralgias, and headache that usually persist for several days to 3 weeks (Table 103.1). The rash is typically maculopapular and short-lived and usually affects the trunk or face. Ten percent of infected individuals experience an acute, self-limited, aseptic meningitis, which on lumbar puncture can be characterized by cerebrospinal fluid (CSF) pleocytosis with detectable HIV in the CSF; however, this syndrome is often not recognized. Rarely, patients may present with opportunistic infections during this period, most commonly thrush (*Candida* pharyngitis). The acute retroviral syndrome is often sufficiently severe that the patient seeks medical attention, though it is uncommon to require hospitalization. During acute infection, the plasma viral load can be extremely high, often greater than 1 million copies per mL, and the CD4 count will dip lower than where it will eventually settle (see Fig. 103.3). It is critical to maintain a high index of suspicion for acute HIV retroviral syndrome because the very high plasma HIV RNA level during this period confers a high likelihood of HIV transmission to sexual or needle-sharing partners, or from mother to infant (e.g., during breast-feeding).

Natural Clinical Progression of Untreated Disease

Untreated HIV infection usually results in a slow, nonlinear progression to severe immunodeficiency over the course of years. However, the progression of disease varies greatly among individuals. Within

TABLE 103.1 Symptoms and Signs of Acute Retroviral Syndrome in 209 Patients

Symptom or Sign	No. With Finding	Frequency (%)
Fever	200	96
Adenopathy	154	74

Encephalopathy	12	6

Modified from Niu MT, Stein DS, Schnittman SM. Primary human immunodeficiency virus type 1 infection: review of pathogenesis and early treatment intervention in human and animal retrovirus infections. *J Infect Dis* 1993;168:1490-1501.

10 years after infection, approximately 50% of untreated individuals will develop AIDS, 30% will have milder symptoms, and fewer than 20% will be entirely asymptomatic (see Fig. 103.3). Children and adolescents progress to AIDS at a slower rate than older persons. The rate of progression of immunodeficiency is not influenced by the route of HIV transmission and appears mostly to be inherent to characteristics of the individual rather than the transmitted virus. In the long term, disease does not appear to differ by gender, although typically women with HIV infection tend to experience more rapid disease progression with lower levels of HIV in plasma.

Clinically recognized lymph node enlargement occurs in 35% to 40% of asymptomatic HIV-infected persons but is not significantly associated with either rate of progression of immunodeficiency or with subsequent development of lymphoma. During early HIV infection, thrombocytopenia, probably caused by autoimmune platelet destruction, is common. Most PLWH remain asymptomatic until their CD4 count falls to less than 200 cells/mm³, a fact that contributes to the late diagnosis of disease.

Patients with moderate immunodeficiency (CD4 counts between 200 and 500 cells/mm³) exhibit diminished antibody response to protein and polysaccharide antigens, as well as decreased cell-mediated immune function. These functional impairments are manifested clinically by a 3-fold to 4-fold increase in the incidence of bacterial pneumonias caused by common pulmonary pathogens (especially *Streptococcus pneumoniae* and *Haemophilus influenzae*) and by a marked increase in incidence of active pulmonary tuberculosis in endemic areas (Table 103.2). Mucocutaneous lesions may be the first manifestations of immune dysfunction; these include reactivation of varicella zoster (shingles), recurrent genital herpes simplex virus (HSV) infections, oral or vaginal candidiasis, and oral hairy leukoplakia (see later discussion). Women living with HIV show an increased prevalence of high-grade squamous intraepithelial lesions on Papanicolaou (Pap) smear. Both men and women may show similarly increased rates of dysplasia or neoplasia on anal Pap smear.

With advanced immunodeficiency, indicated by CD4 counts lower than 200 cells/mm³, patients are at high risk for development of opportunistic diseases, including infections and malignancies (see Table

TABLE 103.2 Progressive Complications of HIV Infection by CD4 Count

CD4 Count (cells/mm ³)	Opportunistic Infection or Neoplasm
>500	Herpes zoster Tuberculosis
200-500	Oral hairy leukoplakia <i>Candida</i> pharyngitis (thrush) Kaposi's sarcoma, mucocutaneous Bacterial pneumonia, recurrent Cervical or anal neoplasia
100-200	<i>Pneumocystis jirovecii</i> pneumonia <i>Histoplasma capsulatum</i> infection, disseminated Kaposi's sarcoma, visceral Progressive multifocal leukoencephalopathy
<100	Lymphoma, non-Hodgkin's <i>Candida</i> esophagitis Cytomegalovirus retinitis <i>Mycobacterium avium-intercellulare</i> <i>Toxoplasma gondii</i> encephalitis <i>Cryptosporidium parvum</i> enteritis <i>Cryptococcus neoformans</i> meningitis Herpes simplex virus, chronic, ulcerative Cytomegalovirus esophagitis or colitis Primary central nervous system lymphoma

103.2). Prior to the advent of antiretroviral therapy, time from diagnosis of AIDS to death was on average 1.3 years; death was generally due to opportunistic disease, including *Pneumocystis jirovecii* pneumonia and *Toxoplasma* meningitis, among many others. CD4 counts lower than 50 cells/mm³ indicate profound immunosuppression and, in the absence of effective ART, are associated with a high mortality rate within the subsequent 12 to 24 months. Cytomegalovirus (CMV) retinitis, which can lead rapidly to blindness, and disseminated *Mycobacterium avium* complex (MAC) infection occur frequently in the absence of therapy at these low CD4 counts. They respond adequately to specific therapy only if it is accompanied by effective control of viral replication.

Opportunistic Infections

Candida Infections

Perhaps one of the earliest indications of HIV disease in many patients is the development of *Candida* disease. Both oropharyngeal and esophageal candidiasis are common in PLWH. Angular cheilosis may also be a manifestation of *Candida* infection. Typically, but not exclusively, caused by *Candida albicans*, oropharyngeal candidiasis may manifest as painless, creamy white, plaque-like lesions on the buccal surface, classically on an erythematous base. Esophageal disease is often symptomatic, usually presenting with odynophagia and/or retrosternal burning pain. In women living with HIV, *Candida* vulvovaginitis usually presents with white adherent vaginal discharge and a burning or itching sensation. *Candida*-associated disease may occur at any CD4 count, but esophageal disease is generally associated with lower CD4 counts. Treatment with oral fluconazole is as effective as or superior to localized topical therapy and is generally better tolerated and therefore preferred. Primary and secondary prophylaxis against *Candida* infection is generally not recommended unless patients have severe or frequent recurrences because therapy for acute disease is rapidly effective, mortality is extremely low, therapy is costly, and potential for development of resistance is of concern.

TABLE 103.3 Primary Antimicrobial Prophylaxis for Adults Living With HIV and a Low CD4 Count

Opportunistic Infection	Treatment	When to Start	When to Stop
<i>Pneumocystis jirovecii</i>	TMP/SMX 1 DS or SS daily A/t: TMP/SMX 1 DS TIW A/t: Dapsone 100 mg daily or 50 mg BID A/t: Nebulized pentamidine 300 mg monthly A/t: Atovaquone 1500 mg daily	CD4 <200 or CD4% <14%	CD4 >200 for >3 mo (AI) or CD4 between 100-200 if HIV VL is undetectable >3 mo (BII)
<i>Toxoplasma gondii</i>	TMP/SMX 1 DS daily A/t: TMP/SMX 1 DS TIW A/t: TMP/SMX 1 DS daily A/t: Dapsone-pyrimethamine + leucovorin A/t: Atovaquone 1500 mg daily	CD4 <100	CD4 >200 for >3 mo (AI) or CD4 between 100-200 if HIV VL is undetectable >3 mo (BII)
<i>Mycobacterium avium</i> complex	Azithromycin 1200 mg weekly Clarithromycin 500 mg BID A/t: Rifabutin	Not recommended if effective ART initiated immediately. Recommended for those who are not on fully suppressive ART, after ruling out active disseminated MAC disease	CD4 >100 for >3 mo
<i>Mycobacterium tuberculosis</i>	Isoniazid (INH) 300 mg daily × 9 months A/t: Rifapentine + INH 900 mg once weekly for 12 weeks A/t: Rifampin 10 mg/kg/day (600 mg max) × 4 months	Positive screening test for LTBI with no evidence of active TB, and no prior treatment for active TB or LTBI	Stop after completion of recommended LTBI treatment duration
Histoplasmosis	Itraconazole 200 mg daily	CD4 <150 if high-risk environmental or occupational exposure exists	CD4 >150 for >6 mo
Cryptococcosis	Fluconazole	Not recommended in United States	

Pneumocystis Pneumonia

Pneumocystis jirovecii is a ubiquitous yeast in the environment. It is not associated with disease except in the setting of immunocompromise. Before the widespread use of ART and prophylactic medications, *Pneumocystis jirovecii* pneumonia (PJP or PCP; both abbreviations are still used) occurred in 70% of patients with AIDS, and the course of treated PCP was still associated with 20% to 40% mortality. The typical presentation is subacute, with progressive fever, shortness of breath, and weight loss over weeks. Profound desaturation with exertion is a common clinical sign, as is a substernal catch on inspiration. Hypoxemia is the most common laboratory abnormality. A serum LDH greater than 500 is common, and a serum 1,3- β -D-glucan is commonly elevated as well. Both of these can be helpful diagnostically. Definitive diagnosis can be made on sputum sample; induced sputum may be positive, though often bronchoscopic sampling for DFA and/or PCR testing is needed. Radiographic findings are classically described as diffuse, bilateral, symmetrical “ground-glass” interstitial infiltrates emanating from the hila in a “butterfly” pattern. However, it is important to remember that 10% of patients will have a normal radiograph, and 30% will have nonspecific findings. Atypical findings such as nodules, blebs, or cysts, can occur, as can spontaneous pneumothorax. Early initiation of treatment is crucial, and treatment should not be delayed while waiting for diagnostic results in patients with a high index of suspicion. First-line therapy is trimethoprim-sulfamethoxazole 15 to 20 mg/kg/day in divided doses over a 21-day course. Steroids should be added in patients with moderate or severe disease, generally defined as a PO₂ of less than 70 or an Aa gradient of 35 mm Hg or greater. Alternative treatments for mild-to-moderate disease include primaquine with clindamycin, dapsone with trimethoprim, or atovaquone. Alternative treatments for moderate-to-severe disease include primaquine with clindamycin or intravenous pentamidine. Due to the high prevalence of *Pneumocystis*, prophylaxis with trimethoprim-sulfamethoxazole is recommended for all patients with a CD4 count less than 200. Alternatives include dapsone, atovaquone, or

inhaled pentamidine. In patients with a CD4 count between 100 and 200, prophylaxis can be discontinued once the serum HIV viral load is undetectable for 3 to 6 months. See [Table 103.3](#) for prophylaxis guidelines.

Cryptococcal Disease

Cryptococcus neoformans is a yeast that generally affects immunocompromised individuals. It enters the body through the lungs, though pulmonary disease is often asymptomatic. Meningitis is the most common clinical presentation of cryptococcal disease, but cutaneous manifestations, classically presenting as umbilicated papules, may be present in 10% of patients. Cryptococcal meningitis occurs in about 1 million cases per year worldwide, with an estimated 600,000 deaths annually. Classic meningeal symptoms occur in only 25% of patients; more commonly, patients present with progressive headache, lethargy progressive to encephalopathy, personality changes, memory loss, coma, and death. A serum cryptococcal antigen test is generally positive, but a lumbar puncture must be performed both for diagnosis and for therapeutic purposes to evaluate CSF pressure (and relieve it, if elevated). CSF studies will generally show an elevated total protein and low glucose, and CSF cryptococcal antigen testing will be positive. India ink staining of the CSF, though uncommon now in the United States, will show encapsulated yeast forms. CSF lymphocyte counts may be elevated or may be normal. A minimal inflammatory response is common; in fact, 55% of patients with AIDS-related cryptococcal meningitis have a CSF lymphocyte count of less than 10 cells/mL. This lack of immunologic response is associated with a poorer prognosis. Treatment is focused on (1) management of CSF pressures through serial lumbar puncture with removal of CSF until pressures return to normal range and (2) antifungal therapy. Therapy is generally divided into three phases: induction, consolidation, and maintenance. Induction therapy is with amphotericin B and flucytosine. Once CSF cultures have cleared and patients have completed at least 2 weeks of therapy, consolidation with high-dose oral fluconazole is continued

for 8 additional weeks. Maintenance therapy is with oral fluconazole 200 mg daily for a minimum of 1 year.

Toxoplasma Encephalitis

Toxoplasma gondii is an obligate intracellular protozoan that most commonly causes encephalitis in patients with AIDS, though it may also present with retinitis or in skeletal muscle or myocardium. Primary infection occurs from eating undercooked meat containing tissue cysts or ingesting oocysts that have been shed in cat feces and sporulated into the environment. Clinical disease in PLWH is usually due to reactivation. Patients present with a focal encephalitis with headache, confusion, motor weakness, and fever. In the absence of treatment, disease will progress to seizures, stupor, coma, and death. Imaging is usually the means of diagnosis, with contrast-enhanced MRI showing multiple contrast-enhancing lesions in the gray matter of the cortex or basal ganglia, often associated with edema. Because disease is usually due to reactivation of latent disease, patients may have a positive serum anti-toxoplasma IgG. CSF testing for toxoplasma PCR may be positive as well. Treatment is initiated based on high clinical suspicion rather than definitive diagnosis. If repeat imaging in 1 to 3 weeks does not show response to treatment in all visualized lesions, brain biopsy may be necessary. In this scenario, biopsy is important to rule out alternative diagnoses such as CNS lymphoma, progressive multifocal leukoencephalopathy (PML), or tuberculosis, among others. Treatment consists of pyrimethamine and sulfadiazine with leucovorin to reduce hematologic toxicity. Treatment is for a minimum of 6 weeks; then patients should be put on chronic maintenance therapy until the CD4 has been greater than 200 for over 6 months. Primary prophylaxis for *Toxoplasma* with trimethoprim-sulfamethoxazole should be initiated in any patient with a CD4 count less than 100, with atovaquone as an alternative. See [Table 103.3](#) for prophylaxis guidelines.

Mycobacterium Tuberculosis

Tuberculosis is the most common opportunistic infection seen worldwide in people living with HIV disease and in fact is the leading cause of death due to infectious disease worldwide. PLWH may either acquire acute disease through inhaling droplet nuclei or suffer reactivation disease due to impaired cellular immunity. The annual risk of reactivation tuberculosis disease in people living with HIV is estimated to be 3% to 16% per year. Reactivation can occur at any CD4 count but is higher risk the more significant the immunodeficiency. The greatest risk in people living in the United States is birth or residence outside the United States because global rates of tuberculosis are much higher than in the United States itself. Clinical presentations of people living with HIV are generally not different than in people who do not have HIV, but presentations of severe systemic disease and disseminated disease are more common. Clinical manifestations can be protean, but classic symptoms of fever, cachexia, and night sweats remain common. Pulmonary disease is still the most common presentation. Chest radiographs in patients may show features of primary tuberculosis, including hilar adenopathy, lower or middle lobe infiltrates, miliary pattern, or pleural effusions, as well as classic patterns of reactivation with upper lobe disease. Less common presentations include pericarditis, pericardial effusions, meningitis, CNS lesions, and bony disease. Diagnosis is determined in the same manner as in HIV-negative patients, and treatment does not differ, though careful review of medications is important to avoid significant drug/drug interactions that can occur between antiretrovirals and anti-tuberculous medications. See [Chapter 94](#) for more details.

Nontuberculous Mycobacterial Disease

A number of different nontuberculous mycobacteria are associated with advanced HIV disease, though far and away the most common is *Mycobacterium avium* complex (MAC). The incidence of MAC in

patients with severe AIDS-associated immunosuppression is 20% to 40% in the absence of effective ART or chemoprophylaxis. Disease tends to occur with a CD4 count less than 50 and a high HIV viral load (usually greater than 100,000). MAC often presents as a disseminated disease with fever, night sweats, weight loss, diarrhea, and abdominal pain. On physical examination, hepatosplenomegaly and lymphadenopathy are common. Laboratory testing is often initially nonspecific, though anemia and an increased alkaline phosphatase are common. Diagnosis is usually made on a compatible clinical syndrome and isolation of MAC on culture or AFB stain on tissue with confirmation on culture. Cultures can be sent from blood, lymph node biopsy, bone marrow, or other tissues or fluids felt to be infected. Treatment is with two or more drugs, usually clarithromycin or azithromycin with ethambutol. Rifabutin may be added as a third agent in some cases. Treatment is for a minimum of 12 months and may then be discontinued when patients are asymptomatic and have a CD4 count greater than 100 for over 6 months. Prophylaxis against MAC is no longer recommended routinely for those who are immediately initiating ART, based on literature demonstrating no added benefit when ART is initiated promptly. Prophylaxis is therefore only recommended in those with a CD4 count less than 50 who are not receiving ART or who are not on fully suppressive ART, and only once active MAC disease has been ruled out based on clinical assessment, including a baseline AFB blood culture. Prophylaxis is generally with azithromycin 1200 mg once weekly.

Progressive Multifocal Leukoencephalopathy

PML is an opportunistic infection of the CNS caused by JC virus, a polyoma virus that causes focal demyelination. JC virus is common throughout the world and demonstrates a seroprevalence of 39% in healthy adults. PML is a disease that occurs with profound immunosuppression in people with HIV (CD4 <50) or in people receiving certain immunomodulatory humanized antibodies (e.g., natalizumab, rituximab). Prior to the advent of ART, PML developed in 3% to 7% of patients with advanced AIDS. PML manifests with focal neurologic deficits, usually of slow and insidious onset, that become progressive. Seizures occur in 20% of patients. Patients do not have headache or fever. Diagnosis is suspected based on MRI findings of distinct non-enhancing white matter lesions in areas of the brain corresponding to clinical deficits. Confirmation of diagnosis is usually through testing of the CSF for JC virus DNA by PCR, which is positive in 70% to 90% of patients. In some patients, however, brain biopsy is required to establish the diagnosis. There are no specific therapies for treating JC virus or PML. Initiation of antiretroviral therapy is the cornerstone of treatment; over 50% of patients will experience remission, though some neurologic deficits often persist.

Cytomegalovirus Disease

Cytomegalovirus (CMV) is a ubiquitous DNA virus. In patients with advanced AIDS and a CD4 count less than 50, it may present with end-organ disease. Before the advent of ART, 30% of patients with advanced AIDS developed CMV retinitis. Retinitis often begins unilaterally but then progresses to bilateral disease. This may be asymptomatic or present with floaters, scotomata, or visual field deficits. Ophthalmologic exam is generally diagnostic, with fluffy, yellow-white retinal lesions with or without intraretinal hemorrhage, and absent or minimal vitreous inflammation. Other manifestations of CMV can occur, including colitis, esophagitis, and CNS disease. CMV pneumonitis is extremely uncommon in patients with HIV. For these other manifestations, diagnosis based on biopsy is still necessary. An elevated CMV viral load in serum may be present but does not confirm disease. Treatment is oral valganciclovir or intravenous ganciclovir.

Varicella-Zoster Disease

Varicella-zoster is a ubiquitous virus known to have infected over 95% of adults in the United States. Reactivation varicella (termed herpes zoster, or “shingles”) occurred at a 15-fold higher rate in PLWH prior to the advent of ART, and rates remain elevated in PLWH. Varicella reactivation can occur at any CD4 count, but reactivation is strongly associated with CD4 counts less than 200 and with active HIV viremia. Herpes zoster, or reactivation varicella virus, manifests as a painful vesicular eruption on the skin in a dermatomal distribution; 50% are in thoracic dermatomes, but cranial nerves and cervical nerves are also common, and any nerve distribution can be involved. The probability of a recurrence within 1 year is 10% in PLWH. If the eye is involved, acute retinal necrosis (ARN) or progressive outer retinal necrosis (PORN) can occur; both are associated with high rates of vision loss. In patients with CD4 counts less than 200, disseminated herpes zoster can also occur, including with CNS involvement that may manifest with CNS vasculitis, multifocal leukoencephalitis, ventriculitis, myelitis, optic neuritis, cranial nerve palsies, focal brainstem lesions, or aseptic meningitis. Diagnosis of varicella reactivation can be made based on clinical exam demonstrating classic dermatologic manifestations; VZV PCR of an unroofed vesicle can assist with diagnosis of unclear cases. PCR can also be performed on CSF or vitreous humor to help diagnose disease in those locations. Treatment of uncomplicated herpes zoster is similar to HIV-negative patients with use of oral valacyclovir, famciclovir, or acyclovir for 7 to 10 days. Intravenous acyclovir is recommended for treatment of severe or complicated varicella disease. Ophthalmologic disease should be managed by an experienced ophthalmologist. Current recommendations regarding primary vaccination (in patients with no reported history of childhood illness or vaccination) and to prevent reactivation disease are addressed in [Table 103.6](#).

Other Opportunistic Infections

A number of other infections are considered opportunistic in patients living with HIV disease. These infections include bacterial and parasitic intestinal infections (including *Cryptosporidium*, *Cystoisospora*, and *Microsporidia* spp). Other bacterial infections, such as *Bartonella* spp, syphilis, and bacterial pneumonias, also occur at increased rates in patients living with HIV. Systemic fungal infections, including endemic fungi such as *Coccidioides*, *Histoplasma*, and *Talaromyces* infections, occur regionally. Viral diseases, including hepatitis B, hepatitis C, HSV, and HPV, are associated with worsened disease in PLWH, as is reactivation of varicella virus (herpes zoster).

HIV and Malignancy

Early in the HIV epidemic, rates of certain cancers were noted to be high in PLWH. Kaposi's sarcoma (KS) and non-Hodgkin's B-cell lymphoma were recognized as markers of the disease. Other AIDS-defining tumors, including invasive cervical cancer and primary central nervous system lymphoma, were also detected early. These AIDS-defining tumors were associated with viral coinfections, and the interplay of the immune dysregulation of advanced HIV disease and other viruses with potential for oncogenesis raise the risk of an opportunistic malignancy.

Kaposi's Sarcoma

In the early days of the HIV epidemic, rates of KS, a rare angiogenic cutaneous tumor found previously in elderly men, were present at rates 1000 times that of the general population. In the United States, KS occurred predominantly in young MSM infected with HIV and human herpes virus 8 (HHV-8). In Africa, rates of KS were particularly high in people living with HIV, accounting in some series for as much as 40% of all cancers in men. Ninety-five percent of patients with KS will have

skin lesions characterized as violaceous, red macules or nodules with a wide distribution. Thirty percent will also have oral lesions and 40% will have gastrointestinal disease. Pulmonary disease and rarely visceral disease can also occur. Rates of KS have fallen dramatically with the widespread use of ART, although they remain significantly higher than in the non-HIV population. The mainstay of treatment is initiation of ART. Of note, paradoxical worsening of disease after initiation of ART is well described (see section on Immune Reconstitution Inflammatory Syndrome). Radiotherapy and intralesional chemotherapy may be used for skin disease, and chemotherapy, usually with liposomal doxorubicin, is used for widespread disease.

Non-Hodgkin's Lymphoma

The incidence of non-Hodgkin's B-cell lymphoma (NHL) early in the epidemic was 100 times the incidence seen in the general population. This has fallen significantly with the use of ART. Similar to other AIDS-defining malignancies, lymphoma in PLWH is usually associated with a viral coinfection, in this instance, Epstein-Barr virus (EBV). The most common types of lymphoma in patients living with HIV in decreasing order of prevalence include diffuse large B-cell lymphoma, Burkitt's lymphoma, and primary CNS lymphoma. Primary CNS lymphoma complicates advanced HIV infection in 3% to 6% of cases and is almost invariably associated with detectable EBV DNA in the CSF. Lesions may be single or multiple and are often weakly ring enhancing. Irradiation often provides remission, which may be sustained as immune function is restored by effective ART. Treatment for other types of lymphoma in HIV is with standard chemotherapy and radiation regimens.

HPV-Associated Cancers

Cervical and anal cancers appear at increased rates in people living with HIV. This is related to both HPV persistence and the degree of immunodeficiency. It appears that ART decreases the persistence of cervical HPV and the rate of invasive cervical cancer. Screening for cervical cancer with Pap smear and/or high-risk HPV according to guidelines for cervical cancer remains very important for HIV-positive women throughout their lives (see recommendations later). Anal cancer is also increased in both men and women with HIV. At this time, no national recommendations exist for screening for anal cancer, though the Infectious Disease Society of America (IDSA) HIV Primary Care Guidelines do recommend anal Pap smear testing. Treatment for both cervical and anal cancer, if found, is per guidelines, and treatment is not different for people living with HIV disease. Rates for oropharyngeal cancer, related to both smoking and HPV, are also increased in PLWH.

Non-AIDS-Defining Cancers

Non-AIDS-defining cancers (NADC) in PLWH include lung, liver, renal, colorectal, and oropharyngeal cancer, as well as Hodgkin's disease. The incidence of many of these malignancies has historically been increased for PLWH and although they have fallen recently with the use of ART, many persist with higher incidence than in the general population.

- *Lung cancer* is increased 2 to 3 times in PLWH compared with the general population, primarily because of high rates of smoking (42% to 59% of PLWH smoke), though the risk for lung cancer in PLWH is increased even when smoking is controlled for. Non-small cell carcinoma is the most common form of lung cancer in PLWH, as with the general population. Treatment follows guidelines for the general population, but it should be noted that protocols for lung cancer therapy have historically excluded PLWH, and thus data do not exist specifically for this population. The effect of ART on lung cancer risk or prognosis is not clear. Unfortunately,

survival for PLWH and lung cancer is poorer than the general population.

- *Colorectal cancer* is the third leading cause of cancer death in the United States in the general population. HIV has historically not been associated with increased rates of colorectal cancer, but of concern, the rates of colorectal cancer in PLWH appear to be increasing and occurring at a younger age. Both screening rates for colorectal cancer, and as a result survival rates, are lower for PLWH. Future efforts will need to focus on appropriate screening and treatment for this increasingly common and lethal malignancy, particularly as the population ages.
- Rates of *liver cancer*, particularly hepatocellular carcinoma, are increased in PLWH in part due to the increased rates of hepatitis B and C virus coinfection and increased alcohol use leading to cirrhosis. In addition, with increasing rates of obesity in people living with HIV, the risk for cirrhosis due to nonalcoholic steatohepatitis (NASH) and subsequent malignancy will rise as well. Treatments for viral hepatitis are now available and treatment is recommended for all PLWH. Similarly, identifying and then treating NASH remains a priority.
- Rates of *skin cancer*, including squamous cell carcinoma and malignant melanoma, are increased in PLWH and skin screening is an important part of primary care.
- Rates of *prostate and breast cancer* are not increased in PLWH. Screening recommendations and treatment guidelines do not differ for this population.

As the population of PLWH ages, rates of all malignancies will increase. Unfortunately, cancer-related mortality is predicted to increase along with increased rates. Screening and appropriate treatment for both AIDS-defining malignancies and NADC are essential in this at-risk population.

Immune Reconstitution Inflammatory Syndrome

The immune reconstitution inflammatory syndrome (IRIS) is a syndrome strongly associated with HIV, though the phenomenon is not specific to HIV and has been seen in association with other conditions, most notably tuberculosis. HIV-associated IRIS occurs after initiation of ART, usually in patients with low CD4 counts, and manifests as either a paradoxical worsening of treated opportunistic infections, called paradoxical IRIS, or an unmasking of a previously subclinical (untreated) infections, called unmasking IRIS. In both of these syndromes, patients are initiated on ART but subsequently develop a clinical decline, generally 2 weeks to several months later. Fever is extremely common with IRIS. Paradoxical IRIS will often present with fever and a clinical worsening of a known OI that is being treated. Unmasking IRIS usually presents as new-onset fevers and tachycardia, sometimes with localizing symptoms suggestive of a previously undiagnosed OI (e.g., headache and obtundation in the setting of cryptococcal disease, or abdominal pain in the setting of MAC). The frequency of IRIS in patients with HIV disease demonstrates a broad range; a meta-analysis found a rate in the published literature of around 13%, with differences by disease process: highest with CMV retinitis, cryptococcal meningitis, PML, and tuberculosis. IRIS is a clinical diagnosis, and there is no specific diagnostic test. Clinicians should have a suspicion for IRIS in the setting of recent ART initiation, particularly in patients with baseline low CD4 counts in which either a known OI appears to worsen, or a patient appears to worsen clinically despite evidence of immune reconstitution. There is significant morbidity to IRIS; up to 50% of IRIS cases require hospitalization, and patients often require extensive testing and both diagnostic and therapeutic procedures. Diagnostic work-up is driven by clinical presentation but generally would involve blood cultures, mycobacterial isolators on serum, sputum for bacterial and AFB

staining and culture if respiratory symptoms or radiographic findings are suggestive, imaging such as CT abdomen and pelvis or brain imaging if symptoms are suggestive, a retinal exam if any eye symptoms are present, a lymph node biopsy if any lymphadenopathy is notable, and further additional work-up as dictated by symptoms. Management of IRIS focuses on management of the identified opportunistic infection and use of corticosteroids and/or NSAIDs to calm the immunologic response. In all but life-threatening cases, ART should be continued. Steroid treatment is often prolonged, generally for 4 weeks or more, with gradual tapering as symptom management tolerates.

CO-OCCURRING DISEASE AND MULTIMORBIDITY WITH HIV

Neurologic Disease in HIV

Nervous system complications ultimately occur in most persons with untreated HIV infection. They range from mild cognitive disturbances or peripheral neuropathy to severe dementia and life-threatening central nervous system (CNS) infections. As with other lentiviruses, HIV enters microglial cells of the CNS early in the course of infection. Both direct neuronal destruction and effects of viral proteins on neuronal cell function may contribute to nervous system disease in AIDS. Infection in the CNS can be documented by CSF viral load and elevated immune markers. ART generally suppresses viral load in the CNS as well as the peripheral blood, although rarely elevated viral loads can occur in the CSF while the PVL remains suppressed; this is termed “CSF viral escape.” CNS penetration by ART is variable depending on the drug, and treatment of CNS HIV infection is an area of active research.

Before effective ART therapy, a variety of severe neurologic complications were noted in patients with AIDS, including progressive dementia (termed the AIDS dementia complex), focal CNS disease, and peripheral neuropathy. ART has dramatically decreased the incidence of neurocognitive complications of HIV but has led to recognition of more subtle neurologic manifestations on the spectrum of what is now described as HIV-associated neurocognitive disorder (HAND), which includes asymptomatic neurologic impairment (ANI), mild cognitive dysfunction (MCD), and HIV-associated dementia (HAD). Approximately 40% of people living with HIV will have some abnormalities based on careful neuropsychological testing. Most of these patients will be asymptomatic (ANI), but 12% will have minor manifestations (MCD), and 2% severe disorders (HAD). Patients may have memory deficits, decreased executive function, and flattened affect, all of which may markedly affect quality of life. Screening tools such as the Montreal Cognitive Assessment (MoCA) test and the Frontal Assessment Battery test can be used to diagnose HAND. MRI findings may show diffuse cerebral atrophy, which correlates with symptoms. Risk factors for developing HAND include age at seroconversion, low CD4 count, comorbidities such as hepatitis C virus, other CNS infections, and trauma. Neurologic manifestations in PLWH on ART generally seem to be nonprogressive or very slowly progressive, and thus adherence to ART is critical. Interestingly, therapy early after initial infection may lower the CNS reservoir for the virus and result in less immune activation compared to those initiated on treatment later in chronic infection.

Focal Lesions of the Central Nervous System

A large variety of neurologic problems can occur in patients with low CD4 T-cell counts. A neuroanatomic classification of these manifestations is presented in [Table 103.4](#). Some of the more frequent or treatable problems are discussed here and in the next section.

Several opportunistic complications of HIV infection produce focal CNS lesions, as mentioned previously. Patients with focal neurologic signs, seizures of new onset, or recent onset of rapidly progressive cognitive impairment should undergo magnetic resonance imaging (MRI) or CT of the brain. Toxoplasmosis, CNS lymphoma, and PML are the most common causes of CNS focal lesions in this setting (Table 103.5). A more detailed review of these opportunistic diseases was discussed previously.

Central Nervous System Diseases Without Prominent Focal Signs

Evaluation of PLWH with fever and headache is difficult because of the often subtle manifestations of serious CNS lesions in immunocompromised patients. Bacterial meningitis management is the same as for non-immunocompromised patients. Meningeal diseases in PLWH fall into the broad categories of aseptic meningitis, chronic meningitis, and meningoencephalitis.

A brief review of these conditions is as follows:

- **Aseptic Meningitis:** Patients with aseptic meningitis, which can be a manifestation of the acute retroviral syndrome, complain most

often of headache. Their sensorium is generally intact, and findings on neurologic examination are normal. In the individual with established HIV infection, aseptic meningitis may result from several potentially treatable causes.

- **Chronic Meningitis:** As discussed previously, *Cryptococcus* followed by tuberculosis are the most common causes of chronic meningitis in PLWH. Patients with an AIDS diagnosis with chronic meningitis characteristically have headache, fever, difficulty in concentrating, or changes in sensorium. Neurosyphilis in PLWH is more common than in uninfected patients and may manifest earlier after infection.
- **Meningoencephalitis:** Patients with meningoencephalitis manifest alterations in sensorium varying from mild lethargy to coma. Patients may be febrile, and neurologic examination often shows evidence of diffuse CNS involvement. MRI may show only nonspecific abnormalities, whereas electroencephalography often is consistent with diffuse disease of the brain. CMV, HSV, and HIV itself are possible causes.

Distal symmetrical peripheral neuropathy (PN) is a common neurological complication of HIV. In addition to the direct effect of the virus itself, older ART drugs, particularly stavudine and didanosine, were associated with PN. Distressing pain, hyperesthesia, or hypesthesia, occurring most commonly in the lower extremities and worse at night, were previously common and were difficult to treat. With newer drugs and earlier treatment of all patients with HIV, new diagnoses of PN are becoming less common. Treatment consists of removing potentially neurotoxic drugs and, depending on symptoms, typically initiating gabapentin therapy.

TABLE 103.4 Neuroanatomic Classification of Neurologic Complications of HIV Infection

Category	Condition
Meningitis and headache	Aseptic meningitis Cryptococcal meningitis Tuberculous meningitis Neurosyphilis
Diffuse brain diseases	
With preservation of consciousness	AIDS dementia complex Neurosyphilis
With decreased arousal	<i>Toxoplasma</i> encephalitis Cytomegalovirus encephalitis
Focal brain diseases	Tuberculous brain abscess Primary central nervous system lymphoma Progressive multifocal leukoencephalopathy Cerebral toxoplasmosis Neurosyphilis
Myelopathies	Subacute or chronic progressive vacuolar myelopathy Cytomegalovirus myelopathy
Peripheral neuropathies	Predominantly sensory polyneuropathy Toxic neuropathies Autonomic neuropathy Cytomegalovirus polyradiculopathy
Myopathies	Noninflammatory myopathy Zidovudine myopathy

Gastrointestinal Diseases

Patients with advanced HIV disease have a variety of potential gastrointestinal complications, whereas those with elevated CD4 counts and suppressed viral loads on ART have far less risk. Thus, in the pre-ART era, gastrointestinal complications ranging from severe oral stomatitis and esophagitis caused by *Candida* infections, to acalculous cholecystitis, severe chronic hepatitis, and chronic diarrhea caused by protozoal parasites, were common. In the ART era, these complications in diagnosed and treated patients are far rarer.

Mouth and Esophagus

Thrush, or *Candida* pharyngitis, and *Candida* esophagitis have been some of the historic markers of HIV, although many other causes of immunodeficiency can also put people at risk for these infections (see prior section on *Candida* disease). Other causes of ulcerations in the mouth and esophagus include aphthous ulcers and herpes virus reactivation, including HSV-1 and CMV. In patients with AIDS, KS frequently occurs in the mouth and may also occur in the stomach and liver.

Large and Small Intestines

The lower GI tract was previously the site of chronic infection due to a variety of microorganisms, including *Cryptosporidium*, *Cystoisospora*

TABLE 103.5 Neurologic Complications of HIV Infection

Condition	CLINICAL ONSET			NEURORADIOLOGIC FEATURES		
	Time	Alertness	Fever	Number of Lesions	Characteristics of Lesions	Location of Lesions
Cerebral toxoplasmosis	Days	Reduced	Common	Usually multiple	Spherical, ring enhancing	Basal ganglia, cortex
Primary CNS lymphoma	Days to weeks	Variable	Absent	One or few	Irregular, weakly ring enhancing	Periventricular
PML	Weeks to months	Variable	Absent	Often multiple	Multiple lesions visible on MRI	White matter

MRI, Magnetic resonance imaging; PML, progressive multifocal lymphoma.

belli, *Microsporidia* spp, CMV, and mycobacteria. These infections caused chronic diarrhea leading to inanition and wasting. In the era of ART, these infections are much less common and have been superseded in frequency by *Clostridioides difficile* infection due to frequent antibiotic exposure in PLWH. Additionally, increased risk of anal cancer has been recognized in PLWH. With the aging population of PLWH, colon cancer risk is also on the rise (see prior section on HIV and malignancy).

Hepatobiliary Disease

Abnormalities on liver function testing are common in HIV disease and often are nonspecific. Elevations of serum alanine aminotransferase and aspartate aminotransferase may represent chronic active viral hepatitis B or C but may also reflect hepatic inflammation caused by alcohol or medications, including trimethoprim-sulfamethoxazole or antiretroviral agents. Alcohol use is highly prevalent among PLWH and may contribute, as can use of other drugs such as MDMA (“ecstasy”). Marked elevations in serum alkaline phosphatase levels may reflect infiltrative disease of the liver (e.g., MAC, CMV, tuberculosis, tumor) but also may occur in patients with acalculous cholecystitis, cryptosporidiosis, AIDS-associated sclerosing cholangitis, or syphilitic hepatitis.

Viral hepatitis, particularly hepatitis C, are an important cause of morbidity and mortality among PLWH. More than 80% of persons with HIV who have a history of injection drug use are coinfecting with hepatitis C, and the risk of progression to end-stage liver disease is greater for those with HIV and hepatitis C coinfection. Recently, therapy of hepatitis C has been revolutionized by combination directly acting agents (DAAs), which achieve hepatitis C cure rates of over 95%. Response rates among PLWH appear to be similar to those among HIV-negative persons. In contrast, treatment of hepatitis B is rarely curative; however, very effective suppression can be achieved utilizing combination therapy. Common agents used for HIV ART, such as tenofovir, emtricitabine, and lamivudine, have potent hepatitis B antiviral activity, and an ART regimen that treats both HIV and hepatitis B coinfection is easily possible. Occult hepatitis infections (antibody negative but with detectable virus on RNA/DNA testing) have been described for both hepatitis C and hepatitis B, particularly in the context of advanced immunodeficiency. Hepatocellular carcinoma is a complication of both hepatitis B and C infection. Regular screening with liver imaging is indicated for all patients with hepatitis C and known cirrhosis, all patients with hepatitis B who are at increased risk, namely those with active hepatitis (elevated serum ALT) and/or high viral load (>20,000 IU/mL), those with a family history of hepatocellular carcinoma, Asian males over 40, Asian females over 50, and all Africans and African Americans.

Cardiovascular Disease

Before ART, patients with HIV with low CD4 counts were at risk for myocarditis, pericardial effusion, and dilated cardiomyopathy, but at present these conditions are markedly less common. What has become apparent, however, is an increased risk for cardiovascular disease, including both myocardial infarction and stroke. In a landmark study from the US Veteran Affairs system in 2013, PLWH were found to have a 50% increase in acute myocardial infarction compared to HIV-uninfected patients, even after controlling for traditional risk factors such as smoking and diabetes. In a more recent review in 2018, a relative risk of 2.16 for cardiovascular (CV) disease in PLWH was noted. Unlike HIV-negative patients, there is an increased rate (up to 50%) of type II myocardial infarction (vasospasm, endothelial dysfunction) compared to type I (thromboembolic) infarction, suggesting different etiologic processes. Longitudinal studies have shown that the risk for stroke and, more recently, congestive heart failure are similarly elevated.

Several additional features of CV disease are worth noting. Long-term studies from the Kaiser Permanente system in California and from Europe initially demonstrated increased rates of CV disease in PLWH but found that more recent data in selected populations saw a convergence of rates with HIV-negative patients, perhaps due to improvements in CV prevention, such as the widespread use of HMG co-A reductase inhibitors (“statins”). It is also worth noting that PLWH do have a higher prevalence of some risk factors for CV disease, particularly smoking, diabetes mellitus, renal disease, metabolic syndrome, and hypertension. The risk conveyed by these factors in total is of a much larger magnitude than that contributed by HIV itself. Thus, addressing these risk factors is particularly important in this population that has a baseline elevated CV risk due to HIV. Proven interventions include smoking cessation and the use of antihypertensives and statins, which should be prescribed following American College of Cardiology/American Heart Association guidelines. Improving diet and exercise also are important, especially for patients as they age.

The effect of certain antiretrovirals on CV risk remains an area of controversy. Protease inhibitors (PIs) are known to have an adverse effect on the metabolic profile, including inducing hyperlipidemia, when compared to newer classes of ART drugs such as integrase inhibitors. Risk is not necessarily uniform across the class; a recent cohort analysis specifically identified darunavir to be associated with increased risk when compared to atazanavir. In addition, several studies have shown that abacavir increases CV risk, but these findings have not been confirmed in others. Integrase inhibitors and newer reverse transcriptase inhibitors have a lesser effect on patients’ lipid profiles, although integrase inhibitors have been associated with more weight gain than other classes, which itself may raise the risk of other diseases that raise CV risk (e.g., diabetes, hypertension).

Renal Disease

In the early years of the HIV epidemic, a new form of progressive renal disease was identified, termed HIV-associated nephropathy (HIVAN). It was characterized by rapidly progressive renal failure and nephrotic-range proteinuria. This disease was found to be more common in African Americans. The incidence of HIVAN rose until the mid-1990s and then fell with the advent of effective ART. Although HIVAN has become uncommon, the incidence of chronic renal disease in PWHV remains significantly higher than in the general population. The prevalence of stage III chronic kidney disease (glomerular filtration rate of 30 to 59 mL/min) has ranged from 3.5% to 9.7%. PLWH are more than 16 times more likely to need renal replacement therapy.

The etiology of renal disease in PLWH is multifactorial; risk factors include low CD4 counts, high viral loads, hypertension, diabetes mellitus, cardiovascular disease, African American race, hepatitis C coinfection, and prior exposure to certain ART drugs such as tenofovir. Patients are also at risk of acute kidney injury, particularly in the setting of dehydration, infection, and polypharmacy. In addition, patients may develop immune complex kidney disease and thrombotic microangiopathy. Most important in prevention and treatment of renal disease is the use of effective ART and consistent monitoring of renal function. Controlling both hypertension and diabetes are also essential in preventing the progression of renal disease.

Osteoporosis and Bone Disease

PLWH have increased rates of osteopenia and osteoporosis and consequently longitudinal controlled studies have shown an almost 3-fold rate of fractures compared to that of the general population. Risk factors for decreased bone density are usually multiple and include effects of ART, particularly protease inhibitor- and tenofovir disoproxil fumarate-containing regimens; low body weight; vitamin D deficiency;

alcohol use; hypogonadism; opiate exposure; smoking; and effects of HIV itself. Patients should be assessed for vitamin D deficiency and other risk factors and treated and counseled appropriately. Bone density assessment by dual-energy x-ray absorptiometry (DXA) is recommended for all men with HIV who are over 50, all postmenopausal women, those with a history of fragility fractures, patients on chronic corticosteroids, and patients at high risk for fall. Risk of fragility fracture should be assessed primarily using the Fracture Risk Assessment Tool (FRAX). ART regimens should be reviewed for osteopenia and osteoporosis risk. Patients diagnosed with osteopenia or osteoporosis should be treated following established guidelines.

Endocrine Disorders

Metabolic Syndrome

PLWH are at increased risk for metabolic syndrome, which includes central obesity, insulin resistance, hypertension, and hypertriglyceridemia. Some classes of ART such as protease inhibitors seem to increase the risk for metabolic syndrome, and this risk translates into increased risk for CV disease. Treatment with weight loss and exercise, anti-hypertensives, and diabetic medications if diabetes is diagnosed, are recommended.

Diabetes Mellitus

The risk for diabetes mellitus (DM) in PLWH patients was not initially appreciated but has become apparent in more recent years. One estimate is that the relative risk for DM in PLWH is 2.4 when compared to the general population. This risk is compounded by the rates of metabolic syndrome, obesity, and adverse lifestyle (such as poor diet and low rates of exercise). In addition, a diagnosis of DM markedly increases the risk for CV disease, including stroke and peripheral vascular disease, as well as renal disease. Screening PLWH with a hemoglobin A_{1c} or fasting blood sugar on an annual basis is important, particularly as the population ages. Treatment for patients at risk for DM and those with DM should follow established guidelines for management of diabetes.

Other Endocrine Disorders

Other endocrine disorders that disproportionately affect PLWH, particularly those with low CD4 counts, include adrenal insufficiency (AI), hypogonadism, and male gynecomastia. In the pre-ART era, adrenal gland pathology caused by CMV and mycobacteria was frequent, but clinical AI characterized by malaise, orthostatic hypotension, weight loss, hyponatremia, and hypoglycemia, was uncommon. Clinical AI remains rare. Hypogonadism is common in men with HIV and may manifest as erectile dysfunction and loss of libido but may also occur more subtly with low energy, depression, or inability to gain muscle mass. Screening with serum testosterone may indicate hypogonadism that can be treated with androgen replacement therapy. Gynecomastia in men with HIV may also occur and be due to hypoandrogenism, liver disease, medication side effects, or as a part of normal aging.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NFLD) ranges from simple hepatic steatosis (or fatty liver) to NASH and hepatic fibrosis that can lead to cirrhosis. The rates of steatosis and NASH in PLWH are increasing and appear to be greater than in the general population, perhaps because of the increased rates of obesity, metabolic syndrome, and diabetes mellitus. NASH and subsequent cirrhosis pose a significant risk for PLWH and emphasize the importance of preventative measures including weight control.

Obesity

In the early years of the HIV epidemic, advanced AIDS was associated with low weight, and in fact one of the characteristics of the disease

was wasting and inanition. Effective ART prevented and even reversed this manifestation of infection, even in end-stage AIDS. Now with PLWH on ART, a new problem has arisen—obesity. In countries like the United States, the rates of obesity in PLWH (20% to 31%) match the rates in the general population. Rates of complications related to obesity in PLWH, such as diabetes mellitus and cardiovascular disease, are nearly twice the rates in uninfected patients. Rates of obesity in PLWH may be related to a combination of factors including poor diet quality, greater food insecurity, lack of exercise, and genetics. Perhaps most important, however, has been the lack of awareness of the consequences of obesity and also the best approaches to losing weight. Although there has been a dearth of research in the treatment of obesity in PLWH, behavioral weight loss programs focusing on behavior change, diet, and exercise have been shown to be effective for this population. In addition, bariatric surgery for morbidly obese patients has been an effective strategy in individual cases.

Aging and HIV

The average age of the first 1000 cases of HIV reported in 1983 was 34 years. With the advent of effective ART, the age of PLWH has steadily increased so that by the year 2015, it was estimated that 50% of PLWH were over the age of 50, and by the year 2030 it is estimated that 70% will be over the age of 50. Similar trends, although delayed, are being observed worldwide in low- to medium-income countries. Despite this increase in the age of PLWH, mortality remains elevated compared to the general population, although there is great heterogeneity. Individuals with risk factors such as low CD4 count, elevated viral loads, drug use, hepatitis coinfections, and other comorbidities have increased mortality rates, whereas subgroup analysis of population studies have shown that individuals with CD4 counts greater than 350 cells/microliter at diagnosis, consistent viral suppression, and an absence of other risk factors have a life expectancy similar to uninfected individuals. Nonetheless, most population studies comparing PLWH to the general population, controlling for risk factors, have shown a decrease in life expectancy of anywhere from 2 to 13 years depending on the subpopulation.

Whether HIV infection accelerates the aging process has been a controversial subject and continues to be investigated. It is known, however, that HIV is associated with chronic inflammation at levels that are similar to older individuals. Inflammation is presumed to be driven by ongoing low-level viral replication, even in virally suppressed individuals, and by the effect of the initial damage to the immune system during acute HIV infection (e.g., injury to gut immune tissue). Elevated markers of inflammation include elevated levels of IL-6, elevated markers of microbial translocation, and elevated levels of macrophage activation. In addition, immune dysregulation and immune senescence as evidenced by decreased pools of CD4 T cells, increased senescent CD8 T cells that secrete cytokines, and an inability to respond robustly to new antigens, all occur in PLWH as well as elderly noninfected people. Increased inflammation and immune dysregulation are part of the normal aging process but appear to occur earlier in PLWH. In addition, as discussed previously, PLWH are at increased risk for a variety of comorbidities, some of which are associated with increased inflammation, such as cardiovascular disease.

Compared to age-matched controls, PLWH have higher rates of geriatric syndromes including falls, urinary incontinence, difficulty with activities of daily living, slow gait, decreased vision and hearing, and frailty. As a result, they are at increased risk for associated morbidity. In addition, PLWH are more likely to develop frailty early. Frailty is defined several ways, but Fried's criteria are commonly used and include decreased strength, endurance, activity, and walking speed, as well as weight loss. Patients with frailty are at significant risk for poor outcomes including hospitalization and death. Risks for frailty

in PLWH include low current and nadir CD4 counts as well as other comorbidities and geriatric syndromes. As the population of PLWH ages, recognizing and addressing both geriatric syndromes and frailty will be increasingly important in their care.

Finally, aging patients in general face a number of challenges to their health and well-being including comorbidities, increasing physical impairments, loss of partners, and family and social isolation. PLWH are particularly at risk for some of these challenges and in addition many face challenges such as poverty, housing and/or food insecurity, and concern for safety. The loss of friends and community is particularly stressful and has been described by one aging PLWH as “a shrinking kind of life.” It is important for physicians caring for PLWH to be aware of these issues.

Mental Health

As HIV has changed to a chronic and manageable illness, the emphasis of mental health treatment has shifted from managing acute syndromes to helping patients live well. Depression and anxiety, as well as other mental illnesses, are very common among PLWH. Often patients will not feel comfortable acknowledging the need for mental health care. For many PLWH, their HIV physician may be their only health care provider, and therefore it is crucial for providers to offer routine screenings for mental health concerns such as depression and anxiety. Screenings will also offer opportunities for physicians to facilitate referrals for additional mental health evaluation and appropriate behavioral and psychiatric care. Trauma is not uncommon and treatment of PTSD can be very helpful.

Substance Use Disorder

Substance/alcohol use and substance/alcohol use disorders are common among PLWH. Alcohol use (e.g., problematic and binge drinking) may also co-occur with the use of substances (e.g., cocaine, methamphetamine). Both alcohol use and substance use have been associated with higher rates of risk-taking behaviors (e.g., condomless sex with multiple partners) and have also been associated with decreased adherence to ART. It is also important to note that many individuals who use substances maintain high levels of adherence to ART; thus, the existence of substance or alcohol use should not prevent physicians from prescribing ART. There are many factors that contribute to or exacerbate substance and alcohol use. For instance, among methamphetamine users, there exists a high correlation between methamphetamine use and chemsex behaviors. Other common factors that may perpetuate continued use include co-occurring mental health diagnoses (e.g., PTSD, anxiety, ADHD), minority stress, and environmental instability. Many studies have shown that treatment of opiate use disorders with medication assisted therapy, such as buprenorphine, can be done in conjunction with HIV treatment. Likewise, treatment of alcohol use disorders can be done in conjunction with HIV treatment. Whereas pharmacotherapy for stimulant use disorders is lacking, the patient-physician relationship can still play an important role in facilitating referral for evidence-based behavioral care for stimulant use. Importantly, patient-centered HIV care cannot focus solely on HIV viral suppression but must proactively address mental health and substance use concerns to promote the goal of patients living meaningful lives with the chronic disease of HIV. Routine screening for substance abuse treatment (i.e., at regular follow-up visits) is recommended. Co-locating substance abuse treatment with HIV care (i.e., one stop shopping) is preferred.

Sexually Transmitted Infections

Rates of sexually transmitted infections (STIs) continue to rise in the United States, reaching an all-time high in 2018 (the last available reported data at the time of this publishing), with no sign of leveling

off in the coming years. The presence of STIs increases the risk of HIV transmission from partner to partner, particularly syphilis and herpes simplex disease. In people living with HIV, rates of STIs have also increased. As “undetectable = untransmittable” becomes a more commonly understood concept among patients, education about protecting themselves from acquiring STIs is important as patients make informed decisions about condom use. Annual STI screening, or more frequent depending on risk behavior, is important in sexually active patients. Treatment of these STIs is the same in HIV-negative as in HIV-positive persons and the response to treatment is good.

HIV MANAGEMENT AND TREATMENT

Initial Counseling and Ambulatory Evaluation

Once HIV is diagnosed, the health care provider should talk to the patient about the clinical course and treatment of HIV infection and the use of immunologic and virologic studies (e.g., CD4 counts, PVL assays) to guide therapy. Stigma related to HIV remains an important concern and a key barrier to engagement in care. Addressing this as part of post-test counseling and intake to care is key to retention in care for persons newly diagnosed. The patient should be educated about modes of HIV transmission through unprotected sex or sharing of needles. The benefit of “U=U” (undetectable = untransmittable) should be discussed with patients so they understand that initiating treatment and achieving an undetectable viral load is both important for their own health as well as their partners.

The initial evaluation should include both an HIV-oriented review of systems and a complete physical examination. In particular, the skin must be examined for HIV-associated rashes and Kaposi’s sarcoma. Examination of the oral cavity may reveal thrush, gingivitis, hairy leukoplakia, superficial ulcers caused by HSV, aphthous ulcers, or lesions characteristic of Kaposi’s sarcoma. In persons with very advanced disease, the optic fundi may have hemorrhagic lesions characteristic of CMV retinitis. Lymph node enlargement, hepatomegaly, splenomegaly, and any genital lesions should be carefully noted. Neurologic examination for both peripheral neuropathy and decreased global cognition deserves close attention.

Laboratory Monitoring

The CD4 count and the PVL should be measured at the first visit, and the patient should be shown the results. Graphic illustrations of the interaction between PVL and CD4 can be useful to increase patient understanding. HIV genotyping to assess for drug resistance should also be performed. The PVL is a key measure of treatment adherence and is repeated at regular intervals, generally 2 to 8 weeks after initiation of therapy and every 3 to 6 months once patients are stably on treatment. Once a patient is stable on treatment with suppressed virus (<200 copies) and CD4 counts higher than 200 cells/mL, the value of CD4 monitoring is less clear, and guidelines allow for extending the monitoring interval to yearly. If a patient’s count is greater than 500 for greater than 1 year, CD4 monitoring becomes optional, as long as the PVL remains undetectable.

An initial assessment of basic chemistries (including a creatinine), hepatic function testing, a complete blood count with differential, a random or fasting glucose, and a urinalysis should be performed to establish a baseline. Women should have a pregnancy test. Once patients are initiated on ART, they should have a basic chemistry panel and hepatic function testing (along with a PVL as noted previously) repeated between 2 to 8 weeks after starting therapy. Patients stably on ART should have these same labs repeated every 6 months, to monitor for toxicity and changes that might affect dosing. A yearly complete

TABLE 103.6 Recommended Vaccinations in Adults With HIV

Vaccine	Recommendation
Influenza vaccination (inactivated or recombinant)	Recommended annually
Influenza vaccination (live attenuated)	Not recommended
Tdap (tetanus, diphtheria, pertussis) or Td	Recommended primary series then every 10 years
MMR (measles, mumps, rubella)	Not recommended if CD4 <200; recommended if nonimmune and CD4 >200
Varicella primary vaccination (Varivax)	Not recommended if CD4 <200; recommended if nonimmune and CD4 >200
Recombinant zoster vaccination (RZV; Shingrix)	No recommendation at this time ^a
Live attenuated varicella vaccination (ZVL; Zostavax)	Not recommended if CD4 <200; no recommendation at this time ^a if CD4 >200
Human papillomavirus (HPV) vaccination	Three-dose series recommended through age 26
PCV-13 (pneumococcal conjugate)	One lifetime dose recommended, at least 8 weeks prior to, or 1 year following PPS-23
PPS-23 (pneumococcal polysaccharide)	Recommended once, with a repeat dose at least 5 years later, and 1 dose after age 65
Hepatitis A	Recommended two-dose series, or three-dose HAV/HBV combined vaccine for all patients
Hepatitis B	Recommended two- or three-dose series for all patients
Meningitis ACYW135	Recommended two-dose series at least 8 weeks apart; repeat every 5 years
Meningitis B	Recommended only if additional risk factors exist (e.g., asplenia, complement deficiency)
Hib	Recommended only if additional risk factors exist (e.g., asplenia, hematopoietic stem cell transplant)

^aCurrent ACIP guidelines do not recommend for or against RZV due to limited data. DHHS guidelines state that “given that risk of herpes zoster is high among persons with HIV, and the vaccine appears safe, experts recommend administration of RZV to persons with HIV aged ≥50 years following the FDA-approved schedule for persons without HIV (IM dose at 0 and 2 months).”

blood count is recommended in all patients. A urinalysis every 6 months is also recommended in patients on tenofovir-based regimens.

Screening for Associated Infections

Tuberculosis

Tuberculin skin test (TST) or blood interferon- γ release assays (IGRA) testing should be performed early in the course of HIV management. Induration of 5 mm or more on the TST should be considered positive. IGRA testing will provide an interpretation based on patient results. Any patient with a positive tuberculous test result should be evaluated for the presence of active tuberculosis with a thorough physical exam, chest radiograph, and symptom screen. If no active disease is present, the patient should receive 9 months of prophylaxis with isoniazid or combination drug therapy for a shorter period (see [Chapter 94](#)). If active tuberculosis is identified, multidrug therapy should be initiated after careful consideration of possible interactions with ART. It is important to remember that false-negative TB testing, both TSTs and IGRAs, can occur in patients with HIV, especially those with CD4 count less than 200.

STIs

Serologic testing for syphilis should be followed by prompt treatment if the patient is confirmed to be positive. Syphilis infections are common within many populations highly impacted by HIV, and coinfection with syphilis increases the risk of transmission of HIV to others. Gonorrhea and chlamydia testing of any potentially exposed orifice is recommended, and “triple-point testing” (oral, rectal, and urine PCR testing) should be offered whenever appropriate. All women should be tested for vaginal trichomonas as well. Following initial screening, annual STI screening is recommended. (See [Chapter 102](#).)

Viral Hepatitis

Liver disease is an important cause of morbidity and mortality for PLWH. Screening for hepatitis B and C at baseline is recommended and vaccination offered if appropriate. Hepatitis C is highly prevalent among persons who acquired HIV from injection drug use, and MSM populations are also at higher risk due to sexual transmission. Given the lack of an effective vaccine for hepatitis C, regular screening is recommended for persons with ongoing risk of exposure.

Other Infections

Screening for antibodies to *Toxoplasma gondii* should be considered for persons with low CD4 counts who are potentially in need of prophylaxis. Persons from endemic areas may be screened for histoplasmosis and coccidiomycosis and considered for prophylaxis if positive.

Immunization

Antibody responses to polysaccharides are better among patients with higher CD4 counts, though the optimal timing of immunization is uncertain. For persons with low CD4 counts, many physicians provide initial immunization and reimmunization for certain vaccines after immune reconstitution occurs. Live vaccines should be avoided in persons with CD4 counts lower than 200 cells/mm³. The US Centers for Disease Control and Prevention (CDC) recommends ensuring routine childhood vaccination (e.g., tetanus series, measles, mumps, rubella, varicella vaccination or reported history of disease). The following vaccines are additionally recommended in PLWH ([Table 103.6](#)).

Streptococcus pneumoniae Vaccination

All persons with HIV should receive a single lifetime dose of PCV13 (Prevnar13), followed by a dose of PPV23 (Pneumovax) at least 8 weeks later. If previously vaccinated with PPV23, the patients should receive PCV13 at least 1 year after PPV23. Patients should have a CD4 cell count greater than or equal to 200/microliter. A second PPV23 dose is recommended 5 years after the first PPV23, and again after the age of 65.

Influenza Virus Vaccination

PLWH have excess morbidity and mortality associated with influenza and its complications. They should receive seasonal influenza vaccination yearly.

Human Papillomavirus Vaccination

The CDC recommends use of the human papillomavirus (HPV) vaccine in boys or girls at age 11 or 12 regardless of HIV status, in MSM, and in persons with immune compromise, including those with HIV, up to the age of 26 if not previously vaccinated. Vaccination is now FDA-approved through age 45.

Hepatitis A and B Viruses Vaccination

PLWH should be assessed by serology for prior exposure to hepatitis B. All PLWH who are not immune to hepatitis B should receive immunization. All PLWH should receive immunization against hepatitis A. Antibody testing prior to vaccination is reasonable in patients likely to have had childhood exposure (e.g., immigrants from endemic countries).

Neisseria meningitidis Vaccination

Due to a higher incidence of meningococcal meningitis in PLWH, the CDC recommends all PLWH receive the quadrivalent conjugate meningitis A, C, Y, W-135 vaccine (MCV4). This vaccine can be administered as two doses spaced 8 weeks apart, with boosters given every 5 years.

Other Health Screening

Cervical Cancer

Women living with HIV should be screened for cervical cancer with a Pap smear. Due to the increased risk for cervical cancer in PLWH, screening guidelines are more aggressive for women living with HIV. Women with normal cytology with no high-risk HPV on Pap smear are recommended to have repeat screening in 3 years (whereas HIV-negative women undergo repeat screening at 5 years).

Anal Cancer

As discussed previously, HPV is associated with an increased risk of anal cancer in both men and women living with HIV. At this time, no national recommendations exist for routine screening for anal cancer, though the IDSA HIV Primary Care Guidelines do recommend anal Pap smear testing in MSM, women with a history of receptive anal intercourse or abnormal cervical Pap smears, and all patients with genital warts. The quality of supporting evidence is low and no specific timing interval for repeat testing is suggested. Despite clear national guidelines, anal Pap smear testing is commonly performed in clinical practice due to an acknowledgement of the increased risk of anal cancer in PLWH.

ANTIRETROVIRAL TREATMENT

The goal of ART is to ensure that all PLWH can lead symptom-free, productive lives. Currently available therapy makes achieving this goal possible in almost all individuals. Treatment guidelines in the United States and worldwide recommend that all patients be offered ART regardless of CD4 count, as early treatment has been demonstrated to have significant health benefit to the individual regardless of CD4 count; further, treatment is prevention because patients who are undetectable are do not transmit to others (“U=U”). This confers a significant public health benefit in addition to the benefit to the health of the individual.

Current Antiretrovirals

Currently available antiretrovirals fall into five classes:

- 1. The nucleotide/nucleoside reverse transcriptase inhibitors (NRTIs):** These are nucleotide or nucleoside analogs that lack a 3'-hydroxyl group on the deoxyribose moiety, causing chain termination of viral DNA and inhibition of viral reverse transcriptase. Examples include tenofovir alafenamide, tenofovir disoproxil fumarate, lamivudine, emtricitabine, abacavir, and zidovudine.
- 2. Non-nucleotide reverse transcription inhibitors (NNRTIs):** NNRTIs are also inhibitors of the reverse transcriptase enzyme, but they are not nucleotide analogs and do not bind at the nucleotide binding site of the enzyme. These agents have “-vir-” in their

names. Agents available in this class include efavirenz, nevirapine, etravirine, rilpivirine, and doravirine.

- 3. PIs:** PIs are inhibitors of the virally encoded protease, an enzyme necessary for proteolytic cleavage of protein precursors necessary for the production of an infectious viral particle. These agents end with the suffix “-navir.” Examples include darunavir, atazanavir, and lopinavir.
- 4. Entry Inhibitors:** “Entry inhibitors” is an “umbrella” grouping of agents that block viral entry into CD4⁺ cells through a variety of mechanisms. This grouping includes attachment inhibitors (fos-temsavir), fusion inhibitors (enfuvirtide), entry inhibitors (ibalizumab, a monoclonal antibody that binds to CD4), and CCR5 antagonists (maraviroc); none of these agents is first-line, and all are only used in salvage regimens.
- 5. Integrase Inhibitors or Integrase Strand Transfer Inhibitors (INSTIs):** InSTIs are drugs that inhibit the viral integrase, which is responsible for integrating reverse-transcribed viral DNA into the host genome of infected cells. These agents end with the suffix “-tegravir.” Agents in this class are raltegravir, elvitegravir, dolutegravir, and bictegravir.

Some agents, including all protease inhibitors and the integrase inhibitor elvitegravir, are paired with “boosters,” agents that serve as cytochrome P450 3A4 enzymatic inhibitors. This inhibition slows the metabolism of the antiviral drug to decrease the needed dose and lower toxicity and slow metabolism to allow once-daily dosing. The two boosters utilized today are ritonavir and cobicistat. Both can be given independently or co-formulated into combination tablets. Boosting agents must be used with caution as they also affect the metabolism of a number of other drugs as well.

Treatment Guidelines

Since 1996, treatment of HIV has utilized the concept of “combination antiretroviral therapy,” which involves treating patients with multiple agents targeting multiple steps in the viral replication cycle. This multitargeted approach overcomes the virus’ ability to mutate and evolve resistance to single agents. A complete regimen is generally composed of three active agents (three drugs to which the virus is not believed to harbor resistance), though there are clinical situations in which fewer (two) or more agents are used. Co-formulations are common, as they are simpler for patients and improve adherence. The US Department of Health and Human Services (DHHS) and the International AIDS Society-USA (IAS-USA) both issue HIV treatment guidelines that are considered standard-of-care for HIV providers in the United States. They are available online at <https://aidsinfo.nih.gov/guidelines> and <https://www.iasusa.org/resources/guidelines/>, respectively. Both are updated frequently. The World Health Organization (WHO) also publishes treatment recommendations for resource-limited settings, which delineate first- and second-line regimen recommendations. The last decade has seen a major shift in recommended treatment guidelines such that a combination of NRTIs plus an InSTI are now recommended as the components of all first-line therapies for patients initiating HIV treatment.

Tables 103.7A and 103.7B review the current first-line recommended regimens of the DHHS and IAS-USA. Decisions on which regimen to recommend to patients should be made in cooperation with the patient and should take into consideration any known resistance, drug/drug interactions, coexisting conditions (e.g., hepatitis B, cardiovascular disease, renal disease), patient preference about time of day and taking the medication with or without food, and insurance coverage.

Resistance Testing

Approximately 16% of treatment-naïve patients have detectable baseline mutations that confer resistance in the genome of their HIV.

TABLE 103.7A Recommended Initial Regimens for Most People With HIV (DHHS)

Drug Combination	Restrictions	Strength
Bictegravir/tenofovir alafenamide/emtricitabine (Biktarvy)		AI
Dolutegravir/abacavir/lamivudine (Triumeq)	Only for patients who are HLA-B*5701 negative and without chronic hepatitis B coinfection	AI
Dolutegravir (Tivicay) <i>plus</i> emtricitabine <i>or</i> lamivudine <i>plus</i> tenofovir alafenamide <i>or</i> tenofovir disoproxil fumarate		AI
Dolutegravir/lamivudine (Dovato)	Except for individuals with HIV RNA >500,000 copies/mL, HBV coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available	AI
Raltegravir (Isentress) <i>plus</i> emtricitabine <i>or</i> lamivudine <i>plus</i> tenofovir alafenamide <i>or</i> tenofovir disoproxil fumarate		BI for TDF BII for TAF

TABLE 103.7B Generally Recommended Initial Regimens (IAS-USA)

Drug Combination	Details	Strength
Bictegravir/tenofovir alafenamide/emtricitabine (Biktarvy)		Ala
Dolutegravir/abacavir/lamivudine (Triumeq)	Testing for HLA-B*5701 allele should be performed before abacavir use (evidence rating Ala); patients who test positive should not be given abacavir (evidence rating Ala). Because it typically takes several days or longer to obtain results for HLA-B*5701 testing, tenofovir-containing regimens should be used when starting ART on the same day as HIV diagnosis or until HLA-B*5701 testing results are available. In patients with or at high risk for cardiovascular disease, a tenofovir-containing regimen, rather than an abacavir-containing regimen, should be used if possible.	Ala
Dolutegravir (Tivicay) <i>plus</i> emtricitabine/tenofovir alafenamide (Descovy)	In settings in which TAF/emtricitabine is not available or if there is a substantial cost difference, TDF (with emtricitabine or lamivudine) is effective and generally well tolerated, particularly if the patient does not have, or is not at high risk for, kidney or bone disease	Ala

Because of this, baseline resistance testing is recommended prior to initiation of ART. Treatment does not necessarily need to be delayed until results are available, as resistance testing can take several weeks to result. If treatment is initiated empirically, adjustments should be made promptly if resistance is discovered. Repeat resistance testing should be considered in the setting of treatment failure to help determine whether the patient's virus has developed resistance to the current regimen, or whether medication adherence, drug/drug interactions, absorption, or another issue is the reason for virologic failure.

Resistance testing can be performed in three major ways. The most common method is HIV-1 RNA genotyping. This involves direct sequencing of viral genes that encode the drug target proteins (i.e., reverse transcriptase, protease, and integrase). Genes are sequenced and compared to the wild-type genotype and previously determined resistance mutations. A second method for identifying resistance is by performing HIV-1 phenotype testing. This involves replication of the virus in culture when exposed to various antivirals. This provides a direct measure of viral resistance *in vitro*; growth would be expected to occur in the presence of a drug if the virus harbors resistance mutations to that agent. Finally, cellular-associated DNA genotyping allows for resistance testing even in the setting of patients with undetectable PVLs. This testing involves sequencing of archived HIV-1 proviral DNA that has been integrated into infected host cells during virus replication. The choice of a resistance test depends on the patient's viral load and the desired information.

In patients determined to have resistance, several resources are available to help choose a new regimen. The IAS-USA has developed a useful catalog of resistance mutations that is available online at [https://](https://www.iasusa.org/resources/hiv-drug-resistance-mutations/)

www.iasusa.org/resources/hiv-drug-resistance-mutations/. Stanford University also maintains an interactive web-based database of known HIV resistance mutations, which is also freely available online at <https://hivdb.stanford.edu>. Its interactive format allows the user to input specific mutations and it will generate a predicted susceptibility profile of all available drugs. Use of these resources and expert consultation with an HIV specialist experienced in treatment of resistant virus is recommended.

Future Directions of Antiretroviral Treatment

Current antiretroviral therapy has made leaps and bounds from the early regimens, which involved multiple drugs with high toxicity given multiple times per day. Today, most patients can be treated with a small number of pills—usually one—dosed once or twice a day. Still, treatment is advancing. Several new regimens are challenging the “triple-therapy” paradigm, including two-drug combinations that demonstrate noninferiority when compared to traditional three-drug first-line regimens. More are sure to come. A few other treatment options that are likely close on the horizon include the following:

1. **Injectable regimens:** Clinical trials of injectable therapy have been completed, showing high efficacy and patient acceptance of once-monthly injectable treatments. Some issues of concern with these regimens include the need for more frequent appointments, how to provide oral “bridge” therapy to patients missing an appointment, how to deal with adverse reactions of medications with long half-lives, and concern over the subtherapeutic tail that follows discontinuation of an injectable depot-type regimen. Even so, these regimens present an exciting new direction for therapy.

2. **Implantable slow-release medications:** Similar to implantable contraceptive devices, implantable antiretroviral-delivery devices offer an attractive approach to infrequent (once-monthly or even longer) dosing. The minor surgery needed for placement of the device is a concern, as is any complication of removal.
3. **Oral agents with longer half-lives:** Several oral agents are in development that might be able to be dosed once weekly or longer. As with injectable regimens, concerns remain about how to deal with adverse reactions of medications with long half-lives and the subtherapeutic tail that follows discontinuation.
4. **New drug classes:** Several new drug classes with novel mechanisms of action are in development and provide hope for patients with complex resistance patterns, patients who struggle with side effects of current regimens, and those seeking new delivery methods or dosing intervals. Classes currently in development include attachment inhibitors, nucleoside reverse transcriptase translocation inhibitors (NRTTIs), maturation inhibitors, monoclonal antibodies to CCR5, capsid inhibitors, and broadly neutralizing antibodies.

HIV CURE RESEARCH

Thus far, there have only been two documented cases of HIV cure. The first case, described as the “Berlin patient,” was reported in 2009. He was a man with refractory AML who had HIV infection with a CCR5-tropic virus. He received two hematopoietic stem cell transplants, the second from a CCR5-negative donor. He also received total body irradiation and anti-thymocyte globulin. The second case, the “London patient,” was reported in 2019. This patient had refractory Hodgkin’s lymphoma and HIV with CCR5-tropic virus and received a stem cell transplant from a CCR5-negative donor. The patient did not receive irradiation, and T-cell depletion was achieved with an anti-CD52 agent. Both patients had mild graft-versus-host disease (GVHD). Both patients have had no recurrence of HIV viremia and no isolation of active virus from any tissue samples despite remaining off of antiretroviral therapy. These cases both illustrate extreme examples of potential routes to a cure—stem cell transplants carry a very high mortality, and GVHD is a lifelong disease that can have significant morbidity. However, the cases do demonstrate that the possibility of a cure is more than just theoretical, and ongoing studies for a cure to HIV is an area of intense research.

As a retrovirus, HIV integrates into the host genome, and latently infected cells are the primary reason that ART is not curative. All current ART targets viral proteins involved in viral replication; therefore, they are ineffective at removing the viral reservoir of latent disease, as the target viral proteins are not active in latently infected cells. Stopping ART always results in a recurrence of viremia over time in PLWH, as latent cells awaken and replication resumes. Thus the problem of finding a cure for HIV is largely a problem of determining how to cure latently infected cells. Further, currently ART is highly effective and very well tolerated, resulting in an essentially normal life expectancy. Ethically, the “cure” cannot be worse than treatment; this poses a high bar for researchers. A safe, effective, scalable, well-tolerated, and cost-effective intervention that is fully curative, or that allows for long-term viral control without the use of ART, is still many years away, but the groundwork has now been laid.

HIV PREVENTION, PEP AND PREP

Three broad approaches have had a major impact on reducing HIV transmission: harm reduction and behavioral modification, ART for “treatment as prevention,” and the use of medications for pre- and

postexposure prophylaxis. All of these activities are supported by expanded testing and improved linkage to care.

Harm reduction and behavior modification are broad categories of public health interventions to prevent HIV transmission. An example is the adoption of safer sexual practices, especially the use of condoms during sexual activity to prevent HIV transmission. Other interventions, such as those targeted toward people who inject drugs, including syringe exchange programs, safe injection facilities, and community methadone and buprenorphine programs, have also had a marked effect on reducing risk of HIV transmission. Many other approaches in the appropriate clinical and societal context can also have significant impact, such as male circumcision in highly impacted communities.

Treatment as prevention is the cornerstone of efforts to control the worldwide HIV epidemic, and widespread access to ART is a key goal of HIV prevention efforts today. Antiretroviral treatment of HIV-infected pregnant women and their infants in the peripartum period has decreased maternal-child transmission from 25% to less than 5% in North America. If a pregnant woman maintains viral suppression during pregnancy and during breast-feeding, the risk of transmission to her infant is less than 1%. Among sexually active individuals, a number of studies across thousands of individuals have demonstrated that patients who are on treatment and undetectable cannot transmit HIV to their sexual partners, regardless of condom use. The strength of these data are robust and results are consistent across multiple large studies in different populations across multiple countries, including in both heterosexual and MSM populations. In fact, none of the studies demonstrated a single case of transmission from an undetectable patient to their partner. The power of treatment as prevention has led to the popular educational campaign of “U=U” or “undetectable = untransmittable.”

The use of ART has also been shown to be an effective tool for HIV prevention as postexposure prophylaxis after both occupational exposures to HIV (termed “PEP”) and after unprotected sexual exposures (termed “nPEP”). Guidelines for PEP and nPEP recommend treatment as early as possible, within 72 hours at the most after an exposure. The treatment regimen should be based on the source patient’s resistance pattern, if known, or if unknown, is generally with two NRTIs (tenofovir disoproxil fumarate and emtricitabine) and an integrase inhibitor (either raltegravir or dolutegravir) for 28 days. Occupational PEP is highly effective, and post exposure seroconversion of health care workers is virtually nonexistent since implementation of PEP. Guidelines for both PEP and nPEP are available through the CDC at: <https://www.cdc.gov/hiv/risk/pep/index.html>.

The use of ART for PrEP in HIV-negative individuals at high risk for HIV exposure has demonstrated excellent efficacy across multiple studies and populations. In individuals at high risk for sexual exposure, including MSM, individuals in serodiscordant relationships, sex workers, and individuals with multiple sexual partners, the daily use of either tenofovir disoproxil fumarate with emtricitabine (the combination tablet Truvada) or tenofovir alafenamide with emtricitabine (Descovy) has been shown to reduce risk of HIV transmission by 99% if taken with consistent adherence. PrEP has also been shown to be effective in people who inject drugs, with a 74% reduction with consistent daily use. Studies have been performed and others are ongoing to evaluate more risk-based, intermittent dosing. Additionally, studies are underway to look at other potential medications and delivery methods (e.g., injectable drugs, implantable devices).

Universal linkage, retention, and access to high-quality, culturally appropriate, and affordable HIV treatment should be the central goals of both HIV treatment and prevention, because effective treatment is effective prevention. Individuals should also be supported to protect themselves, and harm reduction techniques and behavior modification

interventions play an ongoing important role in HIV prevention for at-risk populations, with both PEP and PrEP offering additional pharmacologic aids to the universal goal of bringing an end to new HIV infections.

Infections in the Immunocompromised Host

Dimitrios Farmakiotis, Ralph Rogers

INTRODUCTION

Individuals with an impaired immune system are at risk for infections due to typical pathogens and less virulent organisms that usually do not cause illness. Diagnosis can be challenging due to atypical disease manifestations. The pace and severity of illness in tenuous patients demands that complicated treatment decisions are made early, despite lack of diagnostic certainty. This chapter aims to provide a clinically oriented framework for diagnosis and management of infections in immunocompromised hosts, excluding patients with HIV/AIDS (Figs. 104.1 and 104.2).

EPIDEMIOLOGY

The population of immunocompromised individuals is rapidly growing and becoming more diverse, including patients with primary (congenital) immunodeficiencies, some of which are newly recognized; individuals with hematologic malignancies (HM), who are now surviving longer; solid organ (SOT) and hematopoietic cell transplant (HCT) recipients; and finally, patients being treated with newly developed immunomodulatory medications (TNF- α inhibitors, monoclonal antibodies, ibrutinib) that expose more and more individuals to potential infectious complications.

PATHOGENESIS

Not all immunocompromised individuals are at equal risk for every possible infection. Instead, “immunocompromised hosts” are a heterogeneous group, in which specific immune deficits come with distinct risks (see Fig. 104.1 and Tables 104.1 and 104.2).

Neutropenia

Neutrophils are the primary defense against bacterial and fungal infections. Neutropenia associated with increased risk for infection is defined as absolute neutrophil count less than 500/ μ L. Primary immunodeficiency syndromes such as congenital neutropenia (inadequate production), chronic granulomatous disease (ineffective microbial killing), and leukocyte adhesion deficiency (ineffective recruitment to sites of infection) are associated with increased number and severity of infections, usually caused by typical bacterial (e.g., *Staphylococcus*, *Streptococcus*, Enterobacteriaceae) and fungal (e.g., *Candida*) colonizers of skin, gastrointestinal, genitourinary, and respiratory tracts.

Neutropenia is common with HM, due to decreased neutrophil production from both bone marrow infiltration and cytotoxic chemotherapy. Cytotoxic chemotherapy acts primarily on rapidly dividing

cells, thus in addition to its desired effect it also has negative impact on the rapidly dividing cells of the gastrointestinal tract lining (mucositis). This decrease in an anatomic barrier in combination with decreased neutrophil defense can lead to rapidly progressive infections from microbial translocation. Therefore, “neutropenic fever” is a medical emergency, and such patients need prompt and broad antimicrobial therapy against typical enteric pathogens and *Pseudomonas* (which is associated with high mortality).

Cell-Mediated and Humoral Immune Deficits

The adaptive immune response provided by the cell-mediated and humoral components of the immune system allows for effective intracellular and extracellular microbial killing and is critical against viral infections, while also contributing to antibacterial and antifungal defenses. Many primary immunodeficiency syndromes affect cellular and humoral immunity, each causing increased susceptibility to various bacterial, fungal, and viral infections. Severe combined immunodeficiency (underdevelopment of both T cells and B cells) predisposes infants to serious infections from common viruses (e.g., Herpesviridae), bacteria, and fungi (e.g., *Pneumocystis*). DiGeorge syndrome (thymic hypoplasia leading to underdevelopment of T cells) and hyperimmunoglobulin-E syndrome (impaired T cell differentiation and function) predispose individuals to recurrent bacterial skin or sinopulmonary infections. X-linked agammaglobulinemia (underdevelopment of B cells) predisposes patients to bacterial infections with encapsulated organisms (pneumococcus, *Haemophilus influenzae*, *Neisseria meningitidis*) and common viral pathogens (e.g., Enteroviridae). Secondary causes of hypogammaglobulinemia (e.g., chronic lymphocytic leukemia [CLL], protein-losing enteropathy, nephrotic syndrome) may also lead to increased risk for viral and bacterial infections.

Asplenia and Complement Deficits

Functional or anatomic asplenia leads to increased risk for severe infections due to encapsulated bacteria and blood-borne parasites (e.g., *Plasmodium*, *Babesia*) since the spleen is the primary site that filters out parasitized red blood cells. The complement system acts by opsonization of pathogens allowing for subsequent phagocytosis and can also act on its own to eliminate pathogens via the membrane attack complex. Complement deficiencies lead to an increased risk for infections due to encapsulated bacteria, especially *N. meningitidis*. They can be congenital or from eculizumab, a monoclonal antibody that is effective treatment for atypical hemolytic uremic syndrome by inhibiting terminal complement.

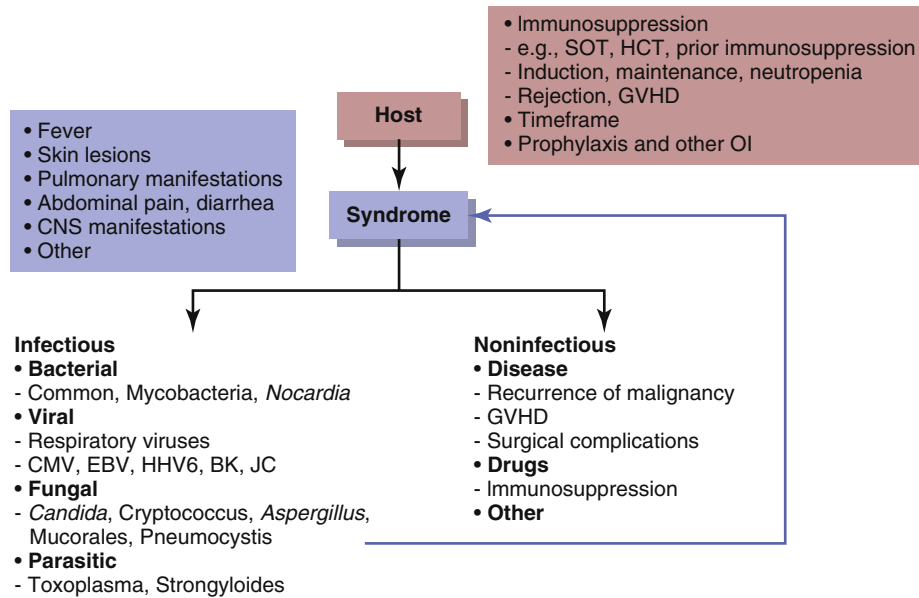

Fig. 104.1 Algorithmic approach to the diagnosis of syndromes suspicious for infection in the immunocompromised host. Continuous reassessment is paramount. For a discussion of abbreviations and specific pathogens see “Specific Pathogens” section below.

Fig. 104.2 Management decisions should be based on the balance between the likelihood of a diagnosis and the clinical consequences of not treating immediately, given the toxicities and drug-drug interactions of antimicrobials.

Hematologic Malignancies

Neutropenia is the main risk factor for infection in patients with acute leukemia. At the time of diagnosis, an individual may have already been neutropenic for an extended time and thus at risk for infection by environmental molds, such as *Aspergillus* or the Mucorales. After induction chemotherapy, patients stay profoundly neutropenic for several weeks, leading to increased risk for infection as outlined previously. Lymphoma patients usually do not experience extended periods of neutropenia from chemotherapy, which is, nonetheless, profoundly lymphocyte-depleting. Risk for infection sometimes depends on dosing (e.g., there is increased risk for *Pneumocystis* with R-CHOP-14, i.e., bi-weekly, due to more frequent administration of steroids). CLL is a chronic leukemia that is often monitored but not treated given its indolent course. However, these patients frequently have hypogammaglobulinemia and may be at increased risk for bacterial or viral sinopulmonary infections.

TABLE 104.1 Primary Immunodeficiency Syndromes

Syndrome	Description
Defects in Phagocytes	
Congenital neutropenia	Inadequate neutrophil production
Chronic granulomatous disease	Ineffective microbial killing by phagocytes due to decreased NADPH oxidase activity
Leukocyte adhesion deficiency	Ineffective recruitment of phagocytes to sites of infection
Defects in Cellular and Humoral Immunity	
Severe combined immunodeficiency	T- and/or B-cell deficiency or absence
ZAP-70 deficiency	Defects in T-cell proliferation and activation
DiGeorge syndrome	Thymic hypoplasia leading to defects in T-cell maturation
Idiopathic CD4 lymphopenia	Inadequate CD4 ⁺ T-cell production
Hyper-IgE syndrome	Defect in JAK/STAT signaling pathway leading to multiple immune deficits
Hyper-IgM syndrome	Defect in class-switch recombination leading to inadequate IgG/IgA/IgE production
X-linked agammaglobulinemia	Defect in B-cell maturation leading to decreased or absent immunoglobulin production
Common variable immunodeficiency	Defective immunoglobulin production
Defects in Innate Immunity	
NK cell deficiency	Absent or defective NK cells
Complement deficiencies	Absent or defective complement components

Solid Organ Transplantation

SOT is a life-saving procedure, but unless the transplanted organ (allograft) is coming from the recipient’s identical twin, the transplant recipient must take immunosuppressive medications in order to prevent their immune system from rejecting the allograft as “nonself.”

TABLE 104.2 Immunosuppressive Medications

Class	Examples	
Cytotoxic agents	Bleomycin	
	Cisplatin	
	Cyclophosphamide	
	Cytarabine	
	Doxorubicin	
	Etoposide	
	Fluorouracil	
	Methotrexate	
	Paclitaxel	
	Vincristine	
	Lymphocyte depleting agents	Alemtuzumab
		Anti-thymocyte globulin
		Basiliximab
Belatacept		
TNF- α inhibitors	Rituximab	
	Adalimumab	
	Etanercept	
Corticosteroids	Infliximab	
	Prednisone	
Common antirejection medications	Azathioprine	
	Cyclosporine	
	Mycophenolate	
	Sirolimus	
	Tacrolimus	
	Other monoclonal antibodies and signal transduction inhibitors associated with increased risk for infection	Eculizumab
		Ibrutinib
Idelalisib		
Natalizumab		
Ruxolitinib		
Tocilizumab		

SOT recipients are given potent immunosuppressive medications to prevent acute rejection at the time of their transplant (induction) and thereafter stay on two to three immunosuppressants (maintenance). The risks for specific types of infection differ, depending on the time since transplantation (Table 104.3). Infections early on are related to the transplant surgery itself (anastomotic leak, surgical site infection) or are hospital acquired (catheter infection, *C. difficile colitis*); early infections can also be donor derived (i.e., present in the donor at the time of transplant, then transferred to the recipient with the allograft). Infections in the “middle period” are often due to reactivation of pre-existing latent infections (CMV, hepatitis B or C, *Toxoplasma*) or to opportunistic pathogens (*Pneumocystis*, *Aspergillus*). Late infections are usually community acquired (e.g., pneumonia) and organ specific (recurrent urinary tract infections in kidney transplant recipients, cholangitis in liver transplant recipients, late aspergillosis in lung transplant recipients). Augmented immunosuppression for rejection increases the risk for infection. So does “immunosenescence,” and elderly SOT recipients sometimes present with opportunistic infections many years after transplantation.

Hematopoietic Cell Transplantation

Hematopoietic (stem) cell transplantation (HCT) involves replacing the bone marrow and immune system with a new, healthier one. This life-saving procedure is associated with many infectious and noninfectious post-transplantation complications. HCT recipients

TABLE 104.3 Infections After Solid Organ Transplantation

Risk Category	Examples
Early Infections	
Anatomic disruption	Anastomotic leak Surgical site infection
Donor derived	Bacterial: <i>Mycobacterium tuberculosis</i> Fungal: <i>Aspergillus</i> Viral: CMV, EBV, HBV, HCV, HIV, HSV, LCMV, VZV Parasite: <i>Toxoplasma</i>
Hospital acquired	Catheter-related infection <i>Clostridioides difficile</i> colitis Ventilator-associated pneumonia
Middle Infections	
Reactivation of latent pathogens	Bacterial: <i>M. tuberculosis</i> Fungal: <i>Candida</i> Viral: BKPv, CMV, HBV, HCV, HSV, VZV Parasite: <i>Strongyloides</i> , <i>Toxoplasma</i>
Opportunistic infections	Bacterial: <i>Nocardia</i> Fungal: <i>Aspergillus</i> , <i>Pneumocystis</i> Parasite: <i>Microsporidia</i>
Late Infections	
Community acquired	Pneumonia Urinary tract infection
Post-prophylaxis reactivation	CMV HSV VZV

are given high doses of cytotoxic medications and/or radiation therapy to destroy their old immune system (conditioning) and thus are at risk for many infections while waiting for their new hematopoietic cells to populate the bone marrow and begin functioning (engraftment). A common complication after HCT is graft-versus-host disease (GVHD), where the donor immune system recognizes recipient organs (mostly the skin and gastrointestinal tract) as “nonself” and mounts a potentially devastating immune response. Additional immunosuppressive medications are given to prevent or treat GVHD, adding to the risk for infection. Further, GVHD is itself an immunosuppressive condition given that it acts to slow immune expansion after HCT.

As in individuals receiving SOT, risks for specific types of infection differ depending on the time since transplantation and presence of GVHD (Table 104.4). Early on, infections are related to profound neutropenia and mucositis from the conditioning regimen. Functional neutrophils are newly present after engraftment, but other arms of adaptive and innate immunity are slowly reconstituted thereafter, first NK-cells, then CD8⁺ T cells, and finally B cells and CD4⁺ T cells, sometimes years later. This process can be delayed by both GVHD and immunosuppressive medications for it (see Table 104.4).

Novel Immunomodulatory Medications

The number and variety of immunomodulatory medications has dramatically increased in recent years, leading to newly recognized syndromes. Examples are invasive fungal infections with ibrutinib (a tyrosine kinase inhibitor used to treat lymphoid malignancies),

TABLE 104.4 Infections After Hematopoietic Cell Transplant

Risk Category	Examples
Pre-engraftment	
Neutropenia	Bacterial: skin/GI/GU flora
Mucositis	Fungal: <i>Candida</i> , <i>Aspergillus</i> Viral: HSV, VZV
Hospital acquired	Catheter-related infection <i>Clostridioides difficile</i> colitis Ventilator-associated pneumonia
Early Post-engraftment	
Reactivation of latent pathogens	Bacterial: <i>Mycobacterium tuberculosis</i> Fungal: <i>Candida</i> Viral: adenovirus, BKPvV, CMV, HBV, HCV, HHV-6, HHV-8, HSV, JCPvV, VZV Parasite: <i>Strongyloides</i> , <i>Toxoplasma</i>
Opportunistic infections	Bacterial: <i>Nocardia</i> Fungal: <i>Aspergillus</i> , <i>Mucorales</i> , <i>Pneumocystis</i> Parasite: <i>Microsporidia</i>
Late Post-engraftment	
Community acquired	Pneumonia Sinusitis Urinary tract infection
Post-prophylaxis reactivation	CMV HSV VZV

progressive multifocal encephalopathy (PML) with natalizumab (selective adhesion molecule inhibitor used to treat multiple sclerosis), hepatitis B reactivation or rituximab (anti-CD20⁺ monoclonal antibody used for treatment of B-cell lymphomas), and mycobacterial infections and histoplasmosis with TNF- α inhibitors (see Table 104.2).

CLINICAL PRESENTATION

Central Nervous System Infection

Headache, neck stiffness, photophobia, encephalopathy, or new focal neurologic deficits, with or without fever, may be indicative of central nervous system (CNS) infection. Clinical symptoms of meningitis and cerebrospinal fluid (CSF) pleocytosis may be dampened in the setting of immunosuppression. In addition to typical pathogens (pneumococcus, enterovirus, herpes simplex virus [HSV]), one should consider other bacterial (*Listeria*, *Nocardia*), viral (e.g., arbovirus, astrovirus, CMV, Epstein-Barr virus [EBV], lymphocytic choriomeningitis [LCMV], varicella zoster virus [VZV]), fungal (e.g., *Cryptococcus*), and parasitic (*Toxoplasma*) etiologies. CNS infection can be part of a systemic syndrome, and dysfunction of other organs may give a clue to the etiology (e.g., severe pneumonia with adenovirus meningitis, *Nocardia* lung nodules). CNS imaging is paramount and can aid in diagnosis (e.g., multiple ring-enhancing lesions with *Toxoplasma* encephalitis, multifocal white matter changes with PML [Fig. 104.3]).

Pneumonia

Although fever and productive cough are the hallmark sign and symptom of pneumonia, both may be muted in immunocompromised hosts. Alternatively, pneumonia may be rapidly progressive and fulminant.

Beyond typical bacterial and viral etiologies, pneumonia in immunocompromised patients can be caused by atypical bacterial (*Legionella*, *Nocardia*, *Mycobacterium tuberculosis* or nontuberculous mycobacteria), viral (adenovirus, CMV, HSV, VZV), fungal (*Aspergillus*, *Cryptococcus*, dimorphic fungi, non-*Aspergillus* molds, *Pneumocystis*), and parasitic (*Toxoplasma*, *Strongyloides* hyperinfection) etiologies. Associated nonpulmonary manifestations (e.g., cryptococcal meningitis) can help make the diagnosis. Computed tomography (CT) and bronchoscopy are often necessary to better define the infectious process.

Diarrhea

Clinicians should consider bacterial (*Clostridioides difficile*, *Salmonella*), viral (adenovirus, CMV, enterovirus, norovirus), and parasitic (*Cryptosporidium*, *Giardia*) etiologies. Stool PCR panels can be useful but sometimes cannot differentiate between colonization and infection for some organisms, such as enteropathogenic *E. coli*. A careful exposure history can help narrow the possible diagnoses, especially for infections with regional endemicity. Colonoscopy with tissue biopsy may be necessary to make a definite diagnosis. At our institution, multiplex PCR, *C. difficile* toxin in the stool, and CMV viral load in the blood are standard protocol for SOT recipients with diarrhea. Leading noninfectious causes are medications, especially mycophenolate (an antimetabolite used for maintenance immunosuppression), and GVHD.

Skin Manifestations

Skin lesions in the immunocompromised patient can be a sign of localized (“outside-in”) or disseminated (“inside-out”) infection. Necrotic lesions raise concern for angioinvasive mold, although they can also be seen with severe bacterial infections and neutropenia, due to toxin effect with minimal inflammation. The most classic lesion is ecthyma gangrenosum, a painful eschar in neutropenic sepsis caused by *Pseudomonas*, but also other gram-negative or gram-positive (*S. aureus*) bacteria. Disseminated candidiasis can present with diffuse maculopapular rash and *Fusarium* sepsis with painful nodules. Vesicular lesions always raise concern for herpetic infection, although HSV (especially resistant or HSV2) can also cause large ulcerated lesions. “Sporotrichoid lesions” (cordlike clusters of inflammatory nodules) can be due to *Sporothrix*, *S. aureus*, *Nocardia* or atypical mycobacteria. Noninfectious causes are very common, such as drug rash, primary skin cancer (the most common malignancy after SOT), skin metastases and leukemia cutis, GVHD, neutrophilic eccrine hidradenitis, and Sweet syndrome (febrile neutrophilic dermatosis, an inflammatory reaction to tumors and chemotherapy that is best treated with corticosteroids). For accurate diagnosis, a skin biopsy with cultures is often necessary.

Fever of Unknown Origin

Persistent fever in an immunocompromised host without a clear etiology or any focal signs or symptoms is a relatively common clinical scenario. History and physical examination will often reveal subtle signs or symptoms integral to steering further diagnostic efforts. Careful attention to the mouth (Fig. 104.4), skin, and perineal area is imperative, because each may provide easily overlooked clues. Perineal infection can manifest with rectal pain alone. Beyond typical screening studies such as blood and urine cultures and a chest radiograph, an algorithmic approach to further investigation may involve stepwise additional testing including fungal markers, PCR-based testing for viruses (CMV, EBV, HHV-6), and cross-sectional imaging of the chest, abdomen, and pelvis. Advanced laboratory tests (e.g., cell-free DNA sequencing, an emerging technology that detects and identifies nonhuman DNA fragments in a clinical sample) and

Fig. 104.3 Progressive multifocal encephalopathy (PML) in an immunocompromised patient with severe combined immunodeficiency (SCID) and autoimmune hemolytic anemia requiring many cycles of rituximab and high-dose corticosteroids. MRI shows significant progression of white matter abnormalities after 3 months.

Fig. 104.4 Oral lesions in an HCT recipient with GVHD on high-dose steroids who developed disseminated HSV1 infection with fulminant hepatitis.

imaging studies (positron emission tomography-PET) may be useful adjuncts depending on the clinical scenario.

DIAGNOSIS

The pace and breadth of diagnostic testing is best driven by the pace and severity of a patient's underlying illness. Although there is a vast number of potential pathogens that may be the cause of an individual's presenting illness, the history the patient gives along with their physical examination is usually enough to dramatically narrow the differential diagnosis. Although most patients present with a single unifying diagnosis, it is not uncommon for immunocompromised patients to present with multiple ongoing processes. Therefore, we favor a structured approach, frequently revisiting the initial or new clinical manifestations (see Fig. 104.1).

Host Considerations

First, one should understand the host, mainly the immune deficits specific to the individual patient: How long has the patient been

neutropenic and what potential pathogens has the patient been exposed to while neutropenic? How long has it been since SOT and what is the immunosuppression? For HCT recipients, are they pre- or post-engraftment, do they have GVHD, and what immunosuppressive medications are they on? What prophylactic antimicrobials are they taking, and for how long? What previous chemotherapy have they received? Previous and concomitant opportunistic infections often speak for the host.

Syndrome Considerations

Next, one identifies the syndrome using presenting complaints. Often there is a single clinical syndrome such as pneumonia or diarrhea. At other times, the signs and symptoms are less focal, and instead the presenting syndrome may simply be fever and fatigue; more than one clinical syndrome can be present. One structured way to construct a broad differential diagnosis for the host and the syndrome is to first consider infectious versus noninfectious causes and then build a differential diagnosis by pathogen kingdom (bacterial, fungal, viral, parasitic) and noninfectious causes (underlying disease, GVHD, medication toxicities, unusual causes) (see Fig. 104.1).

Laboratory Testing

In immunocompromised hosts, direct tests for pathogens (antigen or PCR-based testing) are much more useful than antibody assays, which mainly indicate past exposure, and because the measured immune response may be absent. Fungal markers are components of the fungal cell wall that can be detected in blood or other body fluids and help make the diagnosis of fungal infections. The most commonly used are serum and CSF cryptococcal antigen, serum, bronchoalveolar lavage (BAL) or CSF *Aspergillus* galactomannan, and serum or CSF 1,3- β -D-glucan, which is a broad fungal marker that can aid in the diagnosis of invasive aspergillosis, candidiasis, and pneumocystis pneumonia. However, fungal markers can be falsely elevated (e.g., false-positive 1,3- β -D-glucan in patients receiving hemodialysis or intravenous immunoglobulin [IVIG]) and should be interpreted in context. Peripheral blood cultures (including standard bacterial cultures and those facilitating growth of acid-fast bacilli and fungi) and cultures from more invasive procedures (BAL) may provide a diagnosis and also give a measure of antimicrobial susceptibility. Invasive tissue biopsy may at times be necessary for a definitive diagnosis and to help differentiate between colonization and infection.

Diagnostic Imaging

Imaging studies are also important in the diagnostic process. As with laboratory testing, the lack of inflammation can lead to misleading imaging findings (e.g., relatively normal abdominal imaging despite ongoing acalculous cholecystitis). Some findings can be suggestive of specific diagnoses when interpreted in the context of a specific syndrome in an at-risk immunocompromised host (e.g., the halo sign [ground-glass opacities surrounding a pulmonary nodule] suggestive of invasive pulmonary aspergillosis [Fig. 104.5] versus the reversed halo sign [ground-glass opacity surrounded by a ring of consolidation] suggestive of mucormycosis).

TREATMENT

General Principles

Choosing an appropriate empiric treatment regimen for an immunocompromised patient can be challenging. Waiting for test results may not be wise given the potentially rapid progression of infection in this population. Medication toxicities and drug-drug interactions

Fig. 104.5 Invasive aspergillosis in a patient receiving high-dose corticosteroids. Chest CT shows dense consolidation and surrounding “halo sign” (i.e., hazy, ground-glass-like opacities surrounding a nodule or mass), which represents hemorrhage and is typically seen in invasive aspergillosis. Blood and BAL cultures grew *A. fumigatus*; the value of *Aspergillus* antigen (galactomannan) in the blood was great than the assay cut off.

(DDI) are often a determining factor in the clinical outcome. Early and aggressive treatment is often necessary, though given the breadth of potential infectious etiologies, treating every possible pathogen is not feasible. Instead, when considering empiric treatment, the unlikelihood of a specific diagnosis should be balanced against the potential consequences of not treating. As a rule, broad coverage is in order while the patient’s clinical presentation is unfolding, with de-escalation of therapy to prevent toxicities after further diagnoses are ruled out and as the patient improves (see Fig. 104.2).

Source Control

Control of the source of infection is imperative. In immunosuppressed patients, antimicrobials alone are often insufficient to combat infection. Given the diminished clinical reserve and lack of expected immune response, an undrained abscess or an infection due to a bio-film-forming agent on a blood stream or unremoved intravascular catheter or urinary catheter can be devastating.

Adjusting Immunosuppression

Reducing immunosuppression can be life-saving. With neutropenia in particular, granulocyte colony-stimulating factor (G-CSF) administration can help early ANC recovery. In SOT, acute rejection can develop after reducing immunosuppression, but it is very unusual to have simultaneous acute rejection and overwhelming infection given the polarization of an already impaired immune system towards fighting infection. There is also the possibility of developing immune reconstitution inflammatory syndrome (IRIS) (i.e., increased inflammation from reduction of immunosuppression), which often needs to be treated with corticosteroids. Further, some immunosuppressive medications have desirable adjuvant properties (e.g., antifungal effect of calcineurin inhibitors [CNI]). Specifically, in cryptococcal infections, CNI discontinuation leads to increased risk for IRIS and unfavorable outcomes. Immunosuppression adjustments are thus individualized. Reinstitution of immunosuppressive therapy may be indicated as infection resolves.

Drug-Drug Interactions

It is imperative to check for DDI with immunosuppressive or other medications every time any antimicrobial is started and stopped (see Fig. 104.2). For instance, triazole antifungal medications predictably increase the serum concentration of CNI (via triazole-mediated inhibition of their metabolism by cytochrome P-450), and thus empiric dose adjustments of CNI are usually indicated when stopping or starting a triazole.

PREVENTION

Lifestyle Precautions

While in the hospital, neutropenic patients often have specific measures in place to reduce the risk of acquisition of new infections by ingestion (bottled water, avoidance of foods with potential for bacterial or fungal colonization), inhalation (air filtration and positive pressure ventilation, no flowers or plants, avoidance of nearby heavy construction or remodeling activities), or mucosal translocation (avoidance of hard food that can cause oral trauma). Many of these commonsense precautions can also be implemented at home. For immunocompromised patients, close contact with other individuals with viral infection should be avoided, and thorough evaluations before travel are advised.

Immunizations

The best time to give immunizations is prior to the onset of immunosuppression, which allows for the most robust immune response. Otherwise, most vaccines are administered 1 year post-transplant. Live vaccines are generally contraindicated in immunocompromised individuals, out of concern for clinical illness caused by the vaccine strain. Immunization of household contacts and health care workers is mandated.

Antimicrobial Prophylaxis

At many centers, individuals with acute leukemia undergoing induction chemotherapy and patients receiving HCT are given a fluoroquinolone (levofloxacin) and a yeast-only (fluconazole) or mold-active (voriconazole, posaconazole) triazole. Antiviral prophylaxis with acyclovir protects against reactivation of latent herpesviruses (e.g., HSV, VZV).

Fluconazole is used sometimes in liver transplant recipients and anti-*Aspergillus* prophylaxis in lung transplant recipients. Antiviral prophylaxis active against CMV ([val]ganciclovir) is given to many SOT patients. Given the potential myelotoxicity of (val)ganciclovir, alternative strategies are used to prevent CMV infection in HCT (close monitoring of viral load or alternative antivirals such as letermovir). Prophylaxis against *Pneumocystis* is indicated in SOT and HCT recipients for 6 to 12 months after transplant and in patients receiving prolonged high-dose corticosteroids. Some HCT recipients with severe GVHD receive antibacterial prophylaxis active against encapsulated bacteria and antifungal prophylaxis.

SPECIFIC PATHOGENS

HSV and VZV

HSV1/2 cause mainly mucocutaneous disease (oral or genital lesions), but in immunocompromised patients they can more frequently disseminate, cause CNS infection, multiorgan failure, predominantly fulminant hepatitis, and protean manifestations (e.g., pneumonia) (see Fig. 104.4). VZV can also cause disseminated disease and various CNS syndromes, including vasculitis. The treatment of choice for severe infections is intravenous acyclovir. (Val)acyclovir and (val)ganciclovir are effective prophylaxis; (val)acyclovir administration in very immunosuppressed patients can lead to resistance, mostly in HSV1. Resistant herpetic infections are treated with foscarnet.

CMV

Similar to other herpesviruses, CMV remains dormant after primary infection and can reactivate, causing disease. The highest-risk patients are SOT recipients who are not immune to CMV and receive it from the donor (D+/R-), as well as lymphocyte-depleted and D-/R+ HCT recipients (because they adopt the immune system of their donor). CMV causes fever and infectious mononucleosis-like symptoms and signs, gastrointestinal disease (esophagitis, gastritis, colitis) and pneumonia (mostly in lung and HC transplant recipients). Retinitis is rare in HIV-negative patients. Treatment of choice is (val)ganciclovir and foscarnet for resistant CMV. Multidrug-resistant CMV is rare but an emerging threat. Prophylaxis with (val)ganciclovir is used in most SOT recipients for the first few months after transplant. The main toxicity of (val)ganciclovir is bone marrow suppression, whereas foscarnet can cause nephrotoxicity and electrolyte abnormalities.

Other Herpesviruses

EBV can manifest as lytic infection (directly caused by proliferating virus, such as infectious mononucleosis or CNS infection). However, it is mainly associated with post-transplant lymphoproliferative disorder (PTLD) (progressive transformation of EBV-infected B-lymphocytes to lymphoma). Treatment is reduction of immunosuppression to allow for cytotoxic T-cell surveillance of the abnormal EBV-infected B cells. For the same reason, rituximab is often used early on, even preemptively with rising EBV viremia in HCT recipients.

Other pathogenic human herpesviruses include HHV-6, which typically causes CNS infection in HCT recipients (PALE: Post-transplant acute limbic encephalopathy) treated with ganciclovir or foscarnet, and HHV-8, which causes Kaposi's sarcoma.

Polyomaviruses

In addition to patients with AIDS, JC virus causes PML in a variety of hosts (SOT, HCT recipients, and patients with HM) (see Fig. 104.3). PML manifests with progressive cognitive decline, focal neurologic deficits, and characteristic MRI findings; it overall has poor prognosis. BK virus causes renal allograft dysfunction in kidney transplant recipients, hemorrhagic cystitis in HCT or (less commonly) other severely T-cell depleted individuals; BK can rarely cause PML and disseminated infection. The cornerstone of management for polyomavirus infections is decrease in immunosuppression. A promising recent approach to the management of PML and other refractory viral infections is infusion of virus-specific active T cells (adoptive immunity).

As a rule, laboratory diagnosis of viral infections in immunocompromised patients is based on detection of the virus by quantitative PCR and, sometimes, histopathology.

Candida

Candida albicans is the most common fungal pathogen in the Western world and an important commensal of the normal skin, oral, gastrointestinal, and vaginal flora. Non-albicans *Candida* species can be resistant to antifungal drugs, therefore an important threat with rising frequency in patients receiving antifungal prophylaxis. *Candida auris* has recently emerged as the first virulent fungus that exhibits multi-drug resistance and the potential for nosocomial transmission, which is considered a public health emergency.

Candida species cause mucocutaneous (dermatitis, thrush, esophagitis or vaginitis) and invasive candidiasis. Neutropenia, corticosteroids, and abdominal pathology are the main risk factors. Indwelling catheters are an important source of candidemia, given the strong propensity of this organism to form biofilms (Fig. 104.6). Therefore, central line removal is strongly advised for the successful management of candidemia. Echinocandins (caspo/mica/anidulafungin) are the

treatment of choice for severe invasive candidiasis, except for urinary, eye or CNS infections given their poor penetration in these compartments. Amphotericin-B and azoles have activity against most *Candida* species; the latter can be used for mild infections and as step-down oral therapy.

Cryptococcus

Cryptococcus can cause meningitis, encephalitis, pneumonia, sepsis-like syndrome, and atypical infections (such as cellulitis) in patients with significant T-cell immunosuppression (SOT or HCT recipients, lymphoma patients). Diagnosis is made by culture, detection of cryptococcal antigen in blood or CSF, and histopathology. Severe infections, including meningitis, are treated with amphotericin-B and flucytosine, followed by many months of fluconazole. Decrease in immunosuppression without discontinuation of CNI should be individualized. Fluconazole and other azoles, often used as antifungal prophylaxis in immunosuppressed patients, decrease the risk for cryptococcosis.

Aspergillus

Unlike *Candida*, molds such as *Aspergillus* and the Mucorales are not part of normal flora but inhaled from the environment. In the setting of impaired immune (especially neutrophil) defenses, they grow and invade tissues, causing invasive sinopulmonary or even disseminated mold infections. Individuals with prolonged neutropenia, those receiving high-dose corticosteroids, and lung

transplant recipients are the highest risk groups, especially with exposure to high inocula (e.g., construction). *Aspergillus* can often be a colonizer (saprophytic aspergillosis), without causing invasive disease, such as in the absence of radiographic abnormalities, or as an isolated aspergilloma (Fig. 104.7). Fungal markers (*Aspergillus* galactomannan, 1,3- β -D-glucan), with careful review of imaging findings (see Fig. 104.5), host factors, and clinical presentation, can help differentiate between colonization and infection.

An interesting entity at the intersection of saprophytic and invasive disease is chronic necrotizing (also known as cavitary or semi-invasive) aspergillosis. It affects “immunomodulated” patients, such as elderly patients with chronic obstructive pulmonary disease (COPD), often with negative fungal markers but positive anti-*Aspergillus* antibodies, and warrants antifungal treatment (Fig. 104.8).

The treatment for the majority of aspergilloses is voriconazole, with close follow-up of drug levels and dose adjustments of other medications that have significant DDI. Alternative agents include isavuconazole, amphotericin, or the echinocandins; the latter are static and not preferred as monotherapy.

Fig. 104.6 Spectrum of invasive candidiasis.

Fig. 104.8 Chronic cavitary aspergillosis of the left lung in a patient with severe COPD. *A. fumigatus* antibodies were positive, galactomannan negative, BAL cultures grew *A. fumigatus*. The lesions on CT progressed over months.

Fig. 104.7 Aspergilloma (saprophytic aspergillosis) in a patient with emphysema. Chest CT shows a mobile mass (Left: supine, right: prone) within a small cavity.

Mucorales and Other Fungi

Clinical syndromes caused by molds of the order Mucorales (e.g., *Rhizopus*, *Mucor*, *Rhizomucor*, *Cunninghamella*, *Lichtheimia*, and *Apophysomyces* spp) are rare, aggressive infections with the potential for rapid progression and high mortality. The most common manifestations are sinus and pulmonary infections in neutropenic patients, those receiving high-dose corticosteroids, diabetics, and even immunocompetent individuals when there is high inoculum exposure (e.g., in natural disasters and trauma with significant soil inhalation or contamination of deep wounds). These organisms are highly angioinvasive, and necrotic tissue is an important clue on physical exam. The “reversed halo” sign on CT is considered suggestive of pulmonary mucormycosis. The Mucorales do not have significant amounts of 1,3- β -D-glucan or galactomannan, therefore fungal markers will typically be negative. In vitro culture can be challenging. Therefore, the diagnosis of mucormycoses is elusive and often made by tissue histopathology with visualization of aseptate, broad-angled hyphae. In contrast, *Aspergillus* hyphae are narrow branching at 45° angles and septate (Fig. 104.9). Surgical débridement, when possible, and timely initiation of appropriate treatment with amphotericin-B are paramount. Posaconazole and isavuconazole have activity against the Mucorales, but voriconazole and the echinocandins do not.

Immunocompromised patients are at risk for endemic infections from dimorphic fungi (histoplasmosis, blastomycosis, and coccidiomycosis); preemptive testing and/or prophylaxis might be indicated in certain geographic areas. Histoplasmosis in particular has been associated with TNF- α inhibition.

Pneumocystis infection can manifest as typical interstitial or focal (“granulomatous”) pneumonia, almost exclusively in patients not receiving prophylaxis. Treatment is similar to patients with AIDS (first line: trimethoprim/sulfamethoxazole [TMP/SMX]).

Microsporidia, now classified as fungi, can cause diarrhea, CNS, and multiorgan infections (including donor-derived outbreaks), for which albendazole is the treatment of choice.

Nocardia

Nocardia species are abundant in soil and cause subacute pulmonary, CNS or skin infections in patients with impaired cellular immunity, mainly SOT/HCT recipients and those on high-dose corticosteroids. Most species are sensitive to TMP/SMX. Initial combination of at least two antibiotics (TMP/SMX with a carbapenem, linezolid or minocycline)

is usually indicated given distinct susceptibilities of different *Nocardia* species. Targeted treatment should be continued for many months.

Mycobacteria

Individuals with latent tuberculosis (LTB) are at high risk for reactivation after TNF- α inhibition or T-cell immunosuppression, such as SOT/HCT. In immunosuppressed patients, active TB is often disseminated and its treatment challenging due to medication toxicities and DDI. Therefore, candidates for SOT, HCT, or TNF- α inhibitors are tested for LTB by protocol and if positive treated with isoniazid or an alternative regimen, prior to or shortly after onset of immunosuppression.

Atypical (nontuberculous) mycobacteria (NTM) cause diverse clinical syndromes, mainly pulmonary, skin, and catheter-related infections. The immune deficits predisposing to such infections are similar to TB. NTM are frequent colonizers of the respiratory tract. Treatment regimens are often complicated, with multiple toxicities and DDI; therefore, it is important to differentiate infection from colonization and treat, when indicated, in a timely manner, especially lung transplant candidates and recipients.

Parasites

Immunocompromised patients (especially heart transplant recipients) are at risk for donor-derived or reactivation of toxoplasmosis. TMP/SMX is effective prophylaxis. Toxoplasmosis can manifest as CNS lesions, pneumonia, or fever of unknown origin (FUO) and severe sepsis, the latter mainly in HCT recipients who are not on prophylaxis prior to engraftment, given concern for bone marrow suppression from TMP/SMX. Sulfamethoxazole with pyrimethamine or high-dose TMP/SMX are effective treatments.

Strongyloides hyperinfection is rare but devastating and can be recipient- or donor-derived. It develops usually weeks after onset of T-cell immunosuppression (e.g., transplant, high-dose steroids) with diarrhea, and, as the larvae translocate from the bowel and disseminate to different organs, ileus, pulmonary infiltrates, skin lesions, and gram-negative sepsis from intestinal bacterial co-translocation. Diagnosis is made by visualization of *Strongyloides* larvae in the stool, BAL or tissue. The treatment for hyperinfection is oral or parenteral veterinary ivermectin for days. Mortality is very high. Transplant candidates and donors from endemic areas are typically screened by serology (antibody) and, if positive, receive 1 to 2 days of ivermectin.

Fig. 104.9 *Aspergillus* (left: narrow-angled, septate) and *Lichtheimia* (right: wide-angled, aseptate) hyphae on Gomori-methenamine silver (GMS) stains of lung and heart tissue, respectively, from the autopsy of a patient with CLL on high-dose steroids. In immunocompromised patients, Ockham’s razor doesn’t always apply and multiple infections can coexist. (Tsikala-Vafea M, Weibiao C, Olszewski AJ, et al. Fatal mucormycosis and aspergillosis in an atypical host: What do we know about mixed invasive mold infections? Case Rep Infect Dis 2020;8812528, 2020.)

Intestinal parasites (*Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium parvum*) can cause acute or chronic diarrhea in immunocompromised patients. *Giardia* in particular affects patients with IgA deficiency. Free-living amoebas can cause severe meningoencephalitis with almost 100% mortality.

Infectious Diseases of Travelers: Protozoal and Helminthic Infections

Jessica E. Johnson, Rebecca Reece

INTRODUCTION

Medical advice for overseas travelers, recommended protective measures, and the diagnosis and treatment of common parasitic diseases endemic in the United States and abroad are reviewed in this chapter.

PREPARATION OF TRAVELERS

Americans made more than 70 million international trips in 2015, and this number continues to increase every year. If we look at a breakdown of where these travels occur, 75% were to a malaria-endemic country. Increases in international travel are associated with exposures to infectious diseases worldwide and bring the issues of prevention and management of health problems in travelers into the office of every physician. The risk of becoming ill while traveling internationally depends on the destination and duration of the trip, the underlying health and age of the traveler, and activities/exposures that occur while abroad. Major issues to be addressed before traveling include required and recommended immunizations, malaria prophylaxis, and traveler's diarrhea, as well as measures to prevent tick and mosquito bites. Information about health risks in specific geographic areas, updated weekly, can be obtained from the US Centers for Disease Control and Prevention (CDC) through its publications or website (www.cdc.gov/travel/destinations/list).

Immunizations

All international travelers should ensure they are up-to-date on routine vaccinations. Only yellow fever vaccination may be required by law for international travel, but other immunizations are often strongly recommended, depending on the destination, type, and duration of travel. Before immunization, a thorough history should be obtained to determine the safety of immunizations and any allergies to eggs or chick embryo cells. Pregnant women and individuals who are immunocompromised by human immunodeficiency virus (HIV), malignancy, or chemotherapy pose specific and important concerns requiring review before receiving vaccinations.

Hepatitis A

In the United States, one of the most frequently identified risks for hepatitis A infection is travel. The risk varies with living conditions, length of stay, and incidence of hepatitis A in the area visited. In some areas, the disease affects an estimated 1 of every 500 to 1000 travelers on a 2- to 3-week trip. Therefore, hepatitis A vaccination is recommended for all susceptible persons traveling to or working in countries with intermediate or high endemicity of infection. Hepatitis A vaccine should be given at least 2 weeks before departure but remains effective if given up until the time of travel. A single dose provides protection

for 1 to 2 years; a booster 6 to 18 months later is required for long-lasting immunity (at least 20 years and possibly lifelong).

Influenza

Although influenza is not necessarily considered a travel-related illness, it is the most common vaccine-preventable disease in travelers. The influenza vaccine should be considered in the panel of vaccines offered to the traveler. Influenza seasons can occur at different times of the year in different parts of the world. If a patient cannot be immunized, a course of the antiviral medication oseltamivir can be provided to take at the first sign of a flu-like illness.

Japanese Encephalitis

Japanese encephalitis (JE) virus is closely related to the West Nile and Saint Louis encephalitis viruses and is transmitted to humans through the bite of an infected mosquito. JE virus is the most common vaccine-preventable cause of encephalitis in Asia. It occurs throughout most of Asia and parts of the western Pacific. The overall incidence of JE among people from non-endemic countries traveling to Asia is estimated to be less than 1 case per 1 million travelers. However, expatriates and travelers who stay for prolonged periods in rural areas with active JE virus transmission are likely to be at similar risk as the susceptible resident population (i.e., 5 to 50 cases per 100,000 children per year). Even during brief trips, travelers might be at increased risk if they have extensive outdoor or nighttime exposure in rural areas during periods of active transmission. Short-term (<1 month) travelers whose visits are restricted to major urban areas are at minimal risk for JE. The inactivated JE vaccine, a two-dose series given 28 days apart, is approved for individuals 2 months old and up.

Measles

In the United States, most measles cases result from international travel, and measles remains a common disease in many parts of the world. A large outbreak in 2015 originating from Disney parks in California demonstrated how imported diseases can spread widely to unvaccinated individuals. Currently, measles vaccination is recommended at 15 months of age, with a second vaccination after age 5. Individuals born after 1956 who have no physician-documented record of immunization or who have not received a booster after early childhood should have a one-time booster before travel.

Meningococcal Meningitis

Vaccination for meningococcal disease is recommended to persons who travel to or reside in countries in which the bacterium *Neisseria meningitidis* is hyper-endemic or epidemic, particularly if they will be in close contact with the local population. Vaccination is recommended

for travelers to Saudi Arabia during the Hajj, along the “meningitis belt” of sub-Saharan Africa, and in other locations for which travel advisories have been issued (information available on the CDC website). The meningococcal conjugate vaccine (MCV4) is preferred for people age 9 months through 55 years, and the meningococcal polysaccharide vaccine (MPSV4) is the recommended vaccine for persons older than 55. Serogroup B vaccine was approved in the United States in 2015; however, there are no specific recommendations for travelers because serogroup B is rare internationally. It should be considered in the setting of a reported outbreak or in those with certain risk factors.

Polio

Polio remains endemic in only three countries since 2016: Nigeria, Pakistan, and Afghanistan. Before traveling to areas where poliomyelitis cases are still occurring, travelers should ensure that they have completed the recommended age-appropriate polio vaccine series and have received a booster dose with the inactivated polio vaccine as an adult.

Typhoid

International travelers are at greatest risk for contracting typhoid in the Indian subcontinent, Central America, western South America, and sub-Saharan Africa. Vaccination is recommended for travel to endemic areas where exposure to contaminated food and water is likely. Both a live oral vaccine (four enteric-coated capsules given over 7 days) and an injectable vaccine (single-dose) are available; they are essentially equivalent in effectiveness, which ranges from 50% to 70%.

Yellow Fever

The yellow fever vaccine is a live, attenuated virus vaccine that is recommended for persons traveling to areas in South America and Africa where yellow fever is endemic. Proof of vaccination is required for entry into several countries in these regions unless the traveler meets medically exempt criteria. Since 2016, the World Health Organization (WHO) has lifted the recommendation of a booster every 10 years, stating that a single vaccination is protective for life except in three situations: pregnancy, bone marrow transplant, and HIV infection. Severe adverse events are rare and include yellow fever vaccine-associated viscerotropic and neurologic disease, both of which are more common in elderly persons and in those with thymus disease. Because the adverse events occur more commonly in people older than 60 years of age, a careful assessment of risks and benefits for these travelers should be made before vaccination.

Other Vaccines

Some individuals live for prolonged periods in developing countries or are at special risk for contracting certain highly contagious diseases. Consideration should be given to immunization against hepatitis B, cholera, plague (not commercially available in United States), and rabies. Tetanus vaccinations should be up to date: for travel, a tetanus booster within the previous 5 years is recommended. The cholera vaccine became approved in the United States as of 2016 as a single-dose oral vaccine. Immunity is not long-lasting, with protection less than 80% at 3 months. Given this and limited travel to areas of active cholera transmission, it is not routinely recommended for travelers in the United States, but standard cholera prevention and control measures are emphasized.

Malaria Prophylaxis

Malaria infection is associated with significant morbidity and mortality, particularly if the causative agent is *Plasmodium falciparum*. Worldwide, over 200 million cases occur per year, with increasing numbers of cases among travelers. The need for, as well as the type

of, malaria prophylaxis depends on known resistance patterns and the exact itinerary within a given country because the risk of transmission is regional. In general, travelers to areas where chloroquine-sensitive *P. falciparum* strains are exclusively found (i.e., parts of Central America, the Caribbean, and some countries in the Middle East) should take chloroquine phosphate (300 mg base or 500 mg salt) weekly, starting 1 week before travel to malarious areas and continuing during the trip and for 4 weeks after leaving the area.

Travelers to Southeast Asia, sub-Saharan Africa, South America, and South Asia, where chloroquine-resistant *P. falciparum* is common, may take mefloquine (Lariam), atovaquone-proguanil (Malarone), or doxycycline. Mefloquine may be associated with neurologic side effects (dizziness, tinnitus, and vivid dreams) and, rarely, with significant neuropsychiatric side effects. A US Food and Drug Administration (FDA) black box warning issued in 2013 indicated that the neurologic side effects can occur at any time and persist indefinitely; this has lent some caution to the prescription of mefloquine. Mefloquine is also not completely effective in Myanmar, rural Thailand, or some parts of East Africa, where resistance is a growing problem. Mefloquine is taken once weekly for prophylaxis, so is an attractive option for long-term travelers, but must be taken for 4 additional weeks on return. Atovaquone-proguanil and doxycycline are effective in Southeast Asia and may be used in other areas of chloroquine resistance. Atovaquone-proguanil is well tolerated but must be taken every day and extended for 1 week on return. Daily doxycycline can be associated with photosensitivity, esophagitis, and, occasionally, vaginal candidiasis. Doxycycline must also be taken for 4 additional weeks on return from travel.

Where it is approved, primaquine can be used for primary prophylaxis in areas with higher rates of *Plasmodium vivax* or *Plasmodium ovale* infection. It has the advantage of both preventing acute infection from all malaria parasites and preventing the later recurrent infections of *P. vivax* and *P. ovale*. This is taken as a daily dose and continued for 4 weeks on return. It cannot be used in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Tafenoquine is a newer agent that also prevents acute infection and the later recurrent disease of *P. vivax* and *P. ovale*, as in primaquine, but must be avoided in those with G6PD deficiency. Emphasis must also be given to the use of mosquito bite prevention measures, including netting, screens, permethrin for clothing, and insect repellents, because this can help prevent malaria as well as other vector-borne diseases.

Traveler's Diarrhea

Each year between 30% and 75% of international travelers develop diarrhea. Bacterial infections such as enterotoxigenic *Escherichia coli* are most common, causing more than 80% of traveler's diarrhea; other causes include parasites (i.e., *Giardia*) and viruses (i.e., Norovirus). The average duration of an episode of traveler's diarrhea is 3 to 6 days, but about 10% of episodes last longer than 1 week. The diarrhea may be accompanied by abdominal cramping, nausea, headache, low-grade fever, vomiting, or bloating. Travelers with fever greater than 101° F (38° C), bloody stools, or both should see a physician at once (see Chapter 98).

Diarrheal illness can be avoided by taking precautions with regard to food and beverages. All water and ice should be presumed to be unsafe. Salads are often contaminated by protozoal cysts; along with street vendor foods, they are the most dangerous foods encountered by most travelers. Food should be well cooked, and unpasteurized dairy products should be avoided.

Prophylactic antibiotics are not generally recommended. Diphenoxylate (Lomotil) and loperamide (Imodium) may provide symptomatic relief of mild diarrhea. Oral rehydration is recommended in all cases regardless of severity and serves as an adjunct to antibiotics

in moderate and severe disease. First-line treatment includes fluoroquinolones, although increasing resistance is being seen in South and Southeast Asia, as well as other destinations. Alternative to quinolones is azithromycin. Updated guidelines by the International Society of Travel Medicine recommends a single-dose antibiotic regimen (of either choice above) as treatment for traveler's diarrhea.

Special Problems

Pregnant Women

Although travel is rarely contraindicated during a normal pregnancy, complicated pregnancies require special consideration and may warrant a recommendation that travel be delayed. The risk of obstetric complications is highest during the first and third trimesters.

Most live-virus vaccines are contraindicated during pregnancy. Yellow fever vaccine, for which pregnancy is considered a precaution by the Advisory Committee on Immunization Practices (ACIP), should be avoided if possible. If travel is unavoidable and the risks for yellow fever virus exposure are believed to outweigh the risks of vaccination, a pregnant woman should be vaccinated. Pregnant women should avoid or delay travel to malaria-endemic areas because no prophylactic measures provide complete protection. If travel is unavoidable, pregnant women should take utmost precautions to avoid mosquito bites; for chemoprophylaxis, chloroquine and mefloquine are the drugs of choice for destinations with chloroquine-sensitive and chloroquine-resistant malaria, respectively.

Zika virus has been shown to cause congenital brain abnormalities including microcephaly as seen in the 2015-2016 outbreak throughout the Americas and Pacific Islands. Though WHO declared an end of the epidemic in November 2016, pregnant women should be counseled to avoid travel to areas with active local transmission. If travel is unavoidable, pregnant women should be counseled on mosquito prevention methods to reduce their risk. Zika virus can also be sexually transmitted, and barrier precaution with condoms, or abstinence, should be advised throughout pregnancy.

Acquired Immunodeficiency Syndrome

Several countries continue to have policies that bar entry to persons with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS). Several countries require serologic testing for HIV from all travelers applying for visas lasting longer than 3 months; official documentation is required well in advance of travel. Patients with HIV infection need special preparation before travel to developing countries because of their increased susceptibility to certain illnesses (e.g., pneumococcal infection, tuberculosis). Risk of HIV infection and other sexually transmitted diseases should be discussed, especially with young, sexually active adults.

The Returning Traveler

The most common medical problems encountered by travelers after their return home are diarrhea, fever, respiratory illnesses, and skin lesions. A detailed history should focus on the traveler's exact itinerary, including dates of travel, exposure history (e.g., food indiscretions, drinking-water sources, freshwater contact, sexual activity, animal contact, insect bites), style of travel (urban vs. rural), immunization history, and use of antimalarial chemoprophylaxis.

Diarrhea

Traveler's diarrhea is an acute condition that usually resolves within 2 weeks. If the traveler's diarrhea is not responsive to empiric antibiotic treatment, a work-up should be performed to evaluate for *Giardia lamblia* (see later discussion). Three stool specimens for ova and parasites and a stool culture are indicated (E-Fig. 105.1). If *Giardia* tests are

negative, an empirical trial of metronidazole for treatment of a possible infection with *Giardia* or other protozoan (e.g., amebiasis) should be considered. Noninfectious causes such as temporary lactose intolerance, irritable bowel syndrome, and, less commonly, inflammatory bowel disease should also be in the differential diagnosis.

Fever

Malaria should be the first diagnosis considered in a febrile traveler who has returned from a malarious area. *P. falciparum* malaria can be fatal if it is not diagnosed and treated promptly. Detection of the *Plasmodium* species on Giemsa-stained blood smears by light microscopy is the standard tool for diagnosis of malaria. Rapid diagnostic tests for detection of malaria parasite antigens are becoming increasingly important tools in resource-limited endemic settings because of their accuracy and ease of use.

Travelers with chloroquine-sensitive *P. falciparum* malaria should be treated with chloroquine. Reasonable agents for uncomplicated malaria caused by chloroquine-resistant *P. falciparum* include atovaquone-proguanil, artemisinin derivative combinations (if available) and mefloquine- or quinine-based regimens. Quinine- and mefloquine-based regimens are more frequently associated with adverse effects, and mefloquine should not be used to treat *P. falciparum* malaria acquired in the Thai-Myanmar-Cambodia area because of high resistance rates.

Severe malaria is defined as acute malaria with major signs of organ dysfunction or a high level of parasitemia (>5%) or both. It should be treated with intravenous quinidine for 7 days with close monitoring of the QTc interval. In many parts of the world, intravenous artesunate is used, but it may be associated with high rates of relapse.

Other important causes of fever after travel include viral hepatitis (hepatitis A and E), typhoid fever, bacterial enteritis, arboviral infections (e.g., dengue, chikungunya, Zika), rickettsial infections, and, in rare instances, leptospirosis, acute HIV infection, and amebic liver abscess (see also Chapter 90).

Skin Diseases

Sunburn, insect bites, skin ulcers, and cutaneous larva migrans are the most common skin conditions affecting travelers after their return home. Persistent skin ulcers should prompt a work-up for cutaneous leishmaniasis, mycobacterial infection, or fungal infection. Careful, complete inspection of the skin is important in detecting the rickettsial eschar in a febrile patient or the central breathing hole in a "boil" caused by myiasis.

PROTOZOAL INFECTIONS

Protozoal infections, though endemic to certain regions, can be encountered all around the world, partly because of the increase in travel and migration (Table 105.1). They cause a tremendous burden of disease in the tropics and subtropics as well as more temperate climates. Immunosuppression associated with various conditions, particularly HIV infection, leads to more severe manifestations. Of all protozoal diseases, malaria causes the most deaths globally, approximately 1 million people each year.

Protozoal Infections in the United States

Giardiasis

Giardiasis is a common cause of nonbloody diarrhea in returning travelers. *G. lamblia* and *G. intestinalis* are found worldwide, including in the United States. However, giardiasis is most commonly diagnosed in travelers returning from Latin America, Southeast Asia, or the Middle East. Transmission is by the fecal-oral route in the setting of contaminated

Three stool specimens for ova and parasites and a stool culture are indicated (E-Fig. 105.1). If *Giardia* tests are

E-Fig. 105.1 *Giardia* wet preparation.

TABLE 105.1 Protozoal Infections

Protozoan	Setting	Vectors	Diagnosis	Special Considerations	Treatment
Endemic in the United States					
<i>Babesia microti</i>	New England	Ixodid ticks, transfusions	Thick or thin blood smear	Severe disease in asplenic persons	Quinine and clindamycin
<i>Giardia lamblia</i>	Mountain states	Humans, small mammals	Microscopic examination of stool or duodenal fluid	Common in homosexual men, travelers, children in daycare centers	Quinacrine, nitazoxanide, or metronidazole
<i>Toxoplasma gondii</i>	Ubiquitous	Domestic cats, raw meat	Clinical; serologic confirmation	Pregnant women, immunosuppressed host (AIDS)	Pyrimethamine and sulfadiazine
<i>Entamoeba histolytica</i>	Southeast	Human	Microscopic examination of stool or touch preparation from ulcer	Common in homosexual men, travelers, institutionalized persons	Metronidazole
<i>Cryptosporidium</i> species	Ubiquitous	Human	Acid-fast stain of stool	Severe in immunosuppressed hosts (AIDS)	Nitazoxanide
<i>Trichomonas vaginalis</i>	Ubiquitous	Human	Wet preparation of genital secretions	Common cause of vaginitis	Metronidazole
Primarily Seen in Travelers and Immigrants					
<i>Plasmodium</i> species	Africa, Asia, South America	<i>Anopheles</i> mosquito	Thick and thin blood smears	Consider in returning travelers with fever	Dependent on regional resistance pattern (see text)
<i>Leishmania donovani</i>	Middle East	Sandfly	Tissue biopsy	Consider in immigrants with fever and splenomegaly	Sodium stibogluconate
<i>Trypanosoma</i> species	Africa, South America	Reduviid bugs, transfusion	Direct examination of blood or CSF	Very rare in travelers, transfusion associated	Dependent on species and stage of disease

AIDS, Acquired immunodeficiency syndrome; CSF, cerebrospinal fluid.

food or water or public swimming areas, or by person-to-person contact in certain risk populations such as men who have sex with men. It is usually a self-limited diarrheal illness that lasts 2 to 4 weeks but may persist longer. Rarely, individuals have associated fevers, nausea, or vomiting. The diagnosis is made by microscopic examination of stool for cysts or trophozoites or by an antigen detection test. Treatment options include metronidazole, tinidazole, or nitazoxanide.

Amebiasis

Amebiasis is another diarrheal illness that occurs in travelers. Like *Giardia*, *Entamoeba histolytica* is found worldwide, and transmission is by the fecal-oral route. However, most infected individuals (80%) are asymptomatic. The presentation in those acutely infected includes bloody or watery diarrhea with abdominal cramping lasting up to 4 weeks. In immunocompromised individuals, a severe invasive infection can occur with risk of necrotizing colitis or bowel perforation. Extraintestinal amebiasis can occur as well, particularly liver abscesses. The diagnosis can be made by microscopic examination of stool for ova and parasites or by antigen detection tests of stool or serum. Treatment is with metronidazole or tinidazole in symptomatic individuals, followed by paromomycin or iodoquinol. Asymptomatic patients should also be treated with iodoquinol or paromomycin to prevent spread or later disease development.

Protozoal Infections Common in Travelers and Immigrants

Leishmaniasis

Leishmaniasis is transmitted by the sandfly and can manifest with cutaneous, mucocutaneous, or visceral involvement. The skin finding is a persistent ulcer with raised edges in a traveler returning from the Middle East (Old World: *Leishmania major*, *Leishmania tropica*) or Latin America (New World: *Leishmania braziliensis*, *Leishmania*

peruviana, others). Diagnosis is by tissue biopsy. Visceral leishmaniasis can have hepatic, splenic, or bone marrow involvement and is more commonly identified in immigrants from Asia (*Leishmania donovani*) or South America (*Leishmania chagasi*). Diagnosis is by tissue biopsy or culture of the involved organ.

Treatment varies based on severity of presentation and resistance characteristics. Most cutaneous lesions are self-limited, but treatment options include sodium stibogluconate (Pentostam) or paromomycin. For visceral involvement, treatment includes sodium stibogluconate, amphotericin B, or a combination of these two agents.

African Trypanosomiasis

African trypanosomiasis, or African sleeping sickness, is a protozoal infection caused by *Trypanosoma rhodesiense* (East Africa) or *Trypanosoma gambiense* (Central and West Africa), which is transmitted by the tsetse fly. Presenting symptoms include fever, headache, and central nervous system involvement. The disease is rarely reported in travelers returning from sub-Saharan Africa but should be considered in immigrants from these areas. Frequently, the patient remembers a chancre at the site of the insect bite (E-Fig. 105.2). The diagnosis is made by microscopic examination of blood, lymph, or cerebrospinal fluid for the parasite (E-Figs. 105.3 and 105.4). Treatment varies by species and is highly toxic. Consultation with an expert in infectious disease or tropical medicine is recommended.

American Trypanosomiasis

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi* and is endemic in Central and South America. Transmitted by contact with feces of reduviid bugs (kissing bugs) (E-Fig. 105.5), it can also be acquired through blood transfusion or organ transplantation from an infected individual. The risk to travelers is extremely low but increases with prolonged stays in poor-quality

E-Fig. 105.2 African trypanosomiasis chancre.

E-Fig. 105.3 African trypanosomiasis blood smear.

E-Fig. 105.5 Reduviid bug ("kissing bug") on the skin.

housing. The presentation has an acute phase of 3 months followed by a chronic infection for life. The classic acute presentation involves swelling and erythema of the eyelid and ocular tissue at the entry site of infection, known as the Romaña sign. However, most individuals are asymptomatic throughout the infection and are identified only at the time of blood donation. Between 20% and 30% of individuals develop manifestations of chronic infection decades later that can include cardiomegaly and heart failure, megaesophagus, or megacolon.

Diagnosis in the acute phase is by microscopic examination of peripheral blood (E-Fig. 105.6). In the chronic phase, various serologic analyses are available to aid in diagnosis. Treatment is recommended early because it may prevent chronic manifestations. In the United States, antitrypanosomal drugs are available through the CDC in consultation with an expert in the field. For most chronic manifestations, however, treatment is supportive.

HELMINTHIC INFECTIONS

Infestation by nematodes, or roundworms, is the most common parasitic infection in the world. The intestinal nematodes *Ascaris* and *Trichuris* are the two most prevalent types. Other important helminths include *Strongyloides*, *Enterobius*, schistosomes, and tapeworms (see later discussion). Although most helminths are found worldwide, they disproportionately affect the developing world and pose potential risk to travelers to those areas (Table 105.2).

Helminthic Infections Common in the United States

Pinworm

Enterobiasis is common in the United States and worldwide. Children are predominantly infected, and transmission is by the fecal-oral route. The clinical presentation is perianal pruritus. Diagnosis is made by the tape test, in which transparent tape is applied to the perianal skin overnight and then examined microscopically for ova on the tape. Treatment is with mebendazole or albendazole.

Roundworm

Ascaris lumbricoides is found worldwide, including in the United States, but mostly affects people in the developing world. Although affected individuals are usually asymptomatic, some develop pulmonary infiltrates during the migration phase of the worm or obstruction of the biliary, pancreatic, or intestinal tract. These manifestations usually occur in the setting of high worm burden. Diagnosis is by stool examination for ova and parasites (E-Fig. 105.7). Treatment is with mebendazole or albendazole.

Whipworm

Trichuris trichiura are called whipworms because of their characteristic shape in the adult form. Like *Ascaris*, this is an intestinal nematode that infects mostly children. It is usually asymptomatic except in the setting of heavy worm burden, which can lead to rectal prolapse and bloody diarrhea among children in the developing world. Diagnosis is made by stool examination for ova and parasites or by endoscopy revealing colitis and the presence of adult worms. The treatment of choice is mebendazole or albendazole.

Hookworm

Ancylostoma duodenale and *Necator americanus* (hookworms) are similar to roundworms in their worldwide distribution and are common among immigrants from Asia and sub-Saharan Africa. Infection occurs through direct penetration of the skin by the larvae, which travel through the lymphatics and the bloodstream to the lungs and are then swallowed. Infected individuals may be asymptomatic, or they

may develop pruritic dermatitis at the site of entry. As with the roundworm, pulmonary infiltrates can occur during the migration phase; this is known as Löfller syndrome. Chronic iron deficiency anemia associated with heavy hookworm infection can be severe and debilitating. Eosinophilia is common. The diagnosis is made by stool examination for ova and parasites (E-Fig. 105.8). The treatment is mebendazole or albendazole.

Helminth Infections Common in Travelers and Immigrants

Strongyloidosis

Strongyloides stercoralis is a helminthic parasite that is found worldwide, although more commonly in the tropics. Infection occurs from contact with contaminated soil; the larva penetrates the skin, migrates to the lungs, and is then swallowed by the individual. The infection is usually asymptomatic, but infection can persist into the chronic phase decades later. Those with symptoms usually have gastrointestinal complaints of bloating, diarrhea, and abdominal pain. Eosinophilia is a common finding in these individuals. In immunocompromised individuals, a hyperinfection syndrome with dissemination of the organism can occur. Hyperinfection syndrome has a higher mortality rate and occurs usually in immigrants who become immunosuppressed as a result of chemotherapy, use of steroids, or illness. Diagnosis is made by stool examination (approximately 30% to 50% sensitivity) (E-Fig. 105.9) or by serology but this does not distinguish between chronic and acute disease. Treatment is with ivermectin for 2 days; in the setting of hyperinfection, a longer course is required.

Schistosomiasis

Schistosomiasis is found throughout the tropics and the developing world. Also known as blood flukes, schistosomes use freshwater mollusks as their intermediate host and penetrate the skin of individuals, leading to infection. The three major species are: *Schistosoma mansoni* (Africa, Middle East, South America), *Schistosoma haematobium* (Africa, Middle East), and *Schistosoma japonicum* (China, Philippines, and Southeast Asia). Acute infection can manifest with dermatitis, although most cases are asymptomatic. Chronic infection develops from the immune response to egg deposition. *S. haematobium* can lead to urinary obstruction or hematuria and is associated with an increased risk of bladder cancer. *S. mansoni* and *S. japonicum* can lead to hepatosplenomegaly, hepatic fibrosis, obstruction of portal blood flow, and varices. *S. japonicum* can infect the central nervous system causing ring enhancing lesions and seizures. Diagnosis is by examination of stool or urine for schistosome eggs in individuals from endemic areas, who have a high egg burden; among travelers, in whom the egg burden is usually low, serology is used for diagnosis. The treatment of choice is praziquantel.

Lymphatic Filariasis (Elephantiasis)

Wuchereria bancrofti and *Brugia malayi* are found throughout the tropics; they are lymph-dwelling filariae that cause elephantiasis. The presentation can vary from acute lymphadenitis, to asymptomatic microfilaremia, filarial fevers, or tropical pulmonary eosinophilia. Lymphadenitis can involve both upper and lower extremities with both of these filarial species, but scrotal involvement only occurs with *W. bancrofti*. The diagnosis is made by examination of a peripheral blood smear for microfilariae obtained between 10 PM and 4 AM because these organisms are nocturnally periodic.

Diethylcarbamazine is used for lymphatic filariasis to eradicate the microfilariae and the adult worms. However, the management of chronic lymphatic obstruction remains a challenge because it is not fully reversible and requires supportive therapy.

E-Fig. 105.6 Chagas' disease blood smear.

TABLE 105.2 Helminthic Infections

Helminth	Setting	Vectors	Diagnosis	Treatment
Endemic in the United States				
Pinworm (enterobiasis)	Ubiquitous	Human	Direct examination for ova	Mebendazole, albendazole
<i>Ascaris lumbricoides</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
<i>Trichuris trichiura</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
Hookworm	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
Common in Travelers and Immigrants				
<i>Strongyloides stercoralis</i>	Developing world	Human	Stool examination for larvae	Thiabendazole, ivermectin
<i>Schistosoma</i> species	Developing world	Snails	Stool or urine examination for ova	Praziquantel
<i>Wuchereria</i> and <i>Brugia</i> species	Asia, some parts of Africa	Mosquitoes	Nocturnal blood examination	Ivermectin
<i>Onchocerca volvulus</i>	Africa, South and Central America	Black flies	Biopsy	Ivermectin
<i>Loa loa</i>	Africa	Tabanid flies	Blood examination, clinical setting	Diethylcarbamazine or ivermectin
<i>Clonorchis sinensis</i>	Asia	Undercooked fish and snails	Stool examination for ova, radiology	Praziquantel
<i>Echinococcus</i> species	Worldwide	Canines and livestock	Radiology, serology, biopsy	Surgery, supportive therapy
<i>Taenia solium</i> (cysticercosis)	Developing world	Humans, pigs	Radiology, serology	Surgery, albendazole
<i>T. solium</i> , <i>Taenia saginata</i> , <i>Diphyllobothrium latum</i> (tapeworms)	Worldwide	Pigs, bovine, fish	Stool examination for ova or proglottids	Praziquantel

Loa loa (Eyeworm)

Loiasis is caused by the eyeworm (*Loa loa*) and is found in West and Central Africa. Presentation can vary and may include pruritus, subcutaneous swellings, joint manifestations, or neurologic symptoms. In the rarest presentation, the adult worm can be seen in the anterior chamber of the individual's eye. Diagnosis is confirmed by the presence of microfilariae in blood samples or isolation of the adult worm. Treatment is as for lymphatic filariasis, with diethylcarbamazine.

River Blindness

Onchocerca volvulus infection mostly occurs in regions of West and Central Africa but also in South and Central America. Pruritic dermatitis is the most common presentation; but involvement of the eye is the most serious presentation. Ocular involvement occurs in endemic areas in individuals with heavy worm burden. The complications can begin with conjunctivitis and photophobia. Corneal involvement with the microfilariae causes an inflammatory reaction leading to sclerosing keratitis and blindness. River blindness is the most common cause of blindness in Africa. The diagnosis is made by examination of skin snips for microfilariae. Ivermectin is the drug of choice; an initial single dose is followed by a repeat dose at 3 or 6 months to suppress any further microfilariae because this does not eliminate the adult worm.

Clonorchiasis

Clonorchis sinensis is the Chinese liver fluke. This is an important infection to consider in Asian immigrants who have symptoms consistent with biliary tract disease, including right upper quadrant pain, anorexia, and weight loss. Though the disease is uncommon, untreated infections can lead to cholangiocarcinoma. Treatment is curative with praziquantel in 85% of cases.

Cysticercosis

Cysticercosis is caused by the pork tapeworm, *Taenia solium*. Individuals report new-onset seizures or headaches. Head computed

tomographic (CT) scans show ring enhancing lesions. The diagnosis is usually based on the history and imaging findings, and confirmation can be made by immunoblot assay. Treatment depends on the site of infection and symptoms. It may include antiparasitic treatment, anti-seizure medications, and surgical removal. The antiparasitic drug of choice is praziquantel or albendazole. Expert consultation before treatment is recommended because of the risk of increasing focal cerebral edema and seizure activity.

Intestinal Tapeworms

Tapeworms that commonly infect humans include *Taenia solium* (from raw pork), *Taenia saginata* (raw beef), and *Diphyllobothrium latum* (raw fish). Most infections are asymptomatic except in the case of invasive disease with *T. solium*, as discussed earlier (see Cysticercosis). Praziquantel is the treatment of choice for all three tapeworms.

Echinococcus

The tapeworm *Echinococcus granulosus* causes hydatid disease with production of a cystic liver mass. This occurs in immigrants from sheep-raising parts of the world such as South America, Central Asia, and the Middle East. The characteristic appearance of the cyst includes a calcified wall with a dependent hydatid on CT scans. This appearance and the supporting history help to make the diagnosis; the serologic testing available can be falsely negative. Treatment often includes percutaneous drainage or surgical removal. Care must be taken to avoid rupture or spillage of the contents, which can result in life threatening anaphylaxis. Albendazole is usually given before surgical removal.

Less common is *Echinococcus multilocularis*, which causes alveolar cyst disease. This more aggressive infection leads to liver lesions as well as brain and lung involvement. Treatment includes resection of liver lesions in combination with antiparasitic therapy with mebendazole or albendazole. However, these agents are not parasiticidal, so the mortality rate remains high. Other potential therapies, such as amphotericin B and nitazoxanide, are being explored.

FUTURE DIRECTIONS

The field of travel medicine is constantly changing as infectious diseases do not always follow a historical pattern. With the increasing globalization of travel, we can see outbreaks and epidemics develop in new areas such as the West Africa Ebola outbreak in 2014–2015, the Zika epidemic 2015–2016, and the ongoing MERS-CoV outbreak in the Middle East that alter our guidance to patients and our management of returning travelers from these areas. As a physician caring for travelers, we must stay informed of the changing landscape of infectious diseases across the world.

Neurologic Evaluation of the Patient

Frederick J. Marshall

INTRODUCTION

To arrive at an accurate neurologic diagnosis, the clinician generates and tests hypotheses about the location and the mechanism of injury to the nervous system. Hypotheses are refined as the clinician progresses from the interview to the physical examination to the laboratory assessment of the patient. The focus is first placed on entities that are common, serious, and treatable. Common presentations of common diseases account for roughly 80% of cases, rare presentations of common diseases account for roughly 15%, typical presentations of rare diseases roughly 5%, and rare presentations of rare diseases less than 1% of cases. Focus your energy on common diseases but learn the rare disorders too.

TAKING A NEUROLOGIC HISTORY

The clinician should strive to determine the location, quality, and timing of symptoms. Encourage the patient to report the progression of symptoms rather than a list of diagnostic procedures and specialty evaluations. Establish when the patient last felt normal, whether the progression has been relentless or remitting, and whether it has been chronic, subacute or acute. This information substantially constrains the differential diagnosis. Ambiguous descriptors such as *dizzy* should be rejected in favor of evocative descriptors such as *light-headed* (which may implicate cardiovascular insufficiency) or *off balance* (which may implicate cerebellar or posterior column dysfunction).

Family members and other witnesses should corroborate historical information when appropriate. Historical information should include the medical and surgical histories; current medications; prior responses to efforts at treatment; allergies; family history; review of systems; and social history, including the patient's level of education, work history, possible toxin exposures, substance use, sexual history, current life circumstance, and overall function.

Clues to localization are sought during the interview. For example, pain is usually caused by a lesion of the peripheral nervous system, whereas aphasia (i.e., disordered language processing) indicates an abnormality of the central nervous system. Because sensory and motor functions are anatomically relatively distant in the cerebral cortex but progressively closer together as fibers converge in the brain stem, spinal cord, roots, and peripheral nerves, the coexistence of sensory loss and motor dysfunction in a limb implies a large lesion at the level of the cortex or a smaller lesion lower down in the neuraxis. Small lesions in areas of high traffic such as the spinal cord or brain stem can result in widespread neurologic dysfunction, whereas small lesions elsewhere may be asymptomatic.

Table 106.1 lists the potential localizing values of common neurologic symptoms to help address the issue of lesion localization. Tables 106.2 and 106.3 list symptoms that are commonly associated

with lesions at specific locations in the nervous system. Some symptoms can result from a lesion at any of several levels of the nervous system. For example, double vision can result from a focal lesion in the brain stem, peripheral nerves (cranial nerve III, IV, or VI), neuromuscular junction, or extraocular muscles; or it can be nonfocal and result from an increase in intracranial pressure. Associated symptoms (or their lack) may lead the interviewer to reject certain hypotheses that at first seemed most likely. Table 106.4 lists the most important types of neuropathologic conditions and provides examples of diseases in each category.

Some neuroanatomic locations point to a specific diagnosis or a limited number of diagnoses. For example, disease of the neuromuscular junction is usually caused by an autoimmune process such as myasthenia gravis (common) or Eaton-Lambert myasthenic syndrome (uncommon). The exceptions—botulism and congenital myasthenic disorders—are rare. Alternatively, some areas of the nervous system (e.g., the cerebral hemispheres) are vulnerable to practically any of the categories of disease outlined in Table 106.4.

The pace and temporal order of symptoms are important. Degenerative diseases usually progress gradually, whereas vascular diseases (e.g., stroke, aneurysmal subarachnoid hemorrhage) progress rapidly. Certain symptoms such as double vision almost invariably develop abruptly, even if the underlying disorder has been developing gradually over days to weeks.

NEUROLOGIC EXAMINATION

Performance of the main elements of a general screening neurologic examination is imperative (Table 106.5), but the examination should be tailored to confirm or disprove the clinical hypotheses generated from the patient's history. Unexpected signs must be explained, often with a return to the history for further clarification. The goal of the exam is to determine whether the cause is diffuse, focal or multifocal.

The examination is approached as if only one of two possible injuries has occurred—the final common pathway to a structure is disrupted, or the input to that pathway is disrupted (Fig. 106.1). In the case of the motor system, the *final common pathway* is the motor unit and includes the anterior horn cells giving rise to axons in a nerve, the nerve itself, the neuromuscular junction, and the muscle. Injury to any of these structures results in dysfunction of the muscle. Conversely, if these structures are intact, observing the muscle function may be possible under the right circumstances. If all modes of engaging the final common pathway fail to elicit a response, the clinician can conclude that the lesion is located somewhere within the final common pathway.

For example, a man with paralysis of facial movement on one side that is caused by a lesion of cranial nerve VII cannot smile voluntarily, close his eye, or wrinkle his forehead on the affected side. Spontaneous laughter or smiling as an automatic response to a joke also fails to

move the paretic side. If the problem is central, however, facial movement with involuntary (spontaneous) smiling may be preserved or increased. This observation is common in patients with facial weakness caused by a stroke.

Central input to a final common pathway in the nervous system is usually tonically inhibitory. Damage to this input typically results in overactivity of the involved muscle group. Signs of damage to central inhibitory systems include spasticity and hyperreflexia (i.e., motor cortex, subcortical white matter, or corticospinal pathways in the brain stem and spinal cord); dystonia, rigidity, tremor, and tic (i.e., basal ganglia or extrapyramidal systems); and ataxia and dysmetria (i.e., cerebellum). An exception is hypotonia, which may be seen in cerebellar disease.

TECHNOLOGIC ASSESSMENT

Laboratory investigations and special testing should be used to confirm a clinical suggestion and to finalize the diagnosis. Testing should be selectively performed because of expense, risk, and discomfort to the patient. Frequently helpful tests are discussed in subsequent sections. Diagnostic tests should never be ordered without a specific differential diagnosis firmly in mind. Many neurodiagnostic tests disclose incidental abnormalities unrelated to a patient's symptomatic disease process.

Lumbar Puncture

Investigation of the cerebrospinal fluid (CSF) is indicated in a small number of specific circumstances, usually infections, malignancy, or inflammatory/immune mediated conditions (Table 106.6). When taken, a CSF specimen should be routinely sent for laboratory testing to determine cell and differential counts, protein and glucose levels, and bacterial cultures. The CSF should also be examined for its color and clarity. Cloudy or discolored CSF should be centrifuged and examined for xanthochromia in comparison with water. Additional, special studies may be obtained as appropriate, including Gram stain; fungal, viral, and tuberculous cultures; cryptococcal and other antigens; tests for syphilis; Lyme titers; malignant cytologic patterns; paraneoplastic and other specific protein antibodies; and oligoclonal bands. Polymerase chain reaction for specific viruses may also be appropriate. Assessment of specific CSF proteins such as tau, phosphorylated tau, and amyloid- β in selected patients at risk for dementia may be considered. The 14-3-3 protein, found in Creutzfeldt-Jakob disease, may be found in patients with rapid-onset dementia.

TABLE 106.1 Potential Localizing Value of Common Neurologic Symptoms

Potential Localizing Value	Sign or Symptom
High	Focal weakness, sensory loss, or pain
	Focal visual loss
	Language disturbance
	Neglect or anosognosia
Medium	Vertigo
	Dysarthria
	Clumsiness
Low	Fatigue
	Headache
	Insomnia
	Dizziness
	Anxiety, confusion, or psychosis

Recording the opening and closing pressures is important. Tissue infection in the region of the puncture site is an absolute contraindication to lumbar puncture. Relative contraindications include known or probable intracranial or spinal mass lesion, increased intracranial pressure as a result of mass lesions, coagulopathy caused by thrombocytopenia (usually correctable), anticoagulant therapy, and bleeding disorders.

Rare but severe complications of lumbar puncture include transtentorial or foramen magnum herniation, spinal epidural hematoma, spinal abscess, herniated or infected disk, meningitis, and adverse reaction to a local anesthetic agent. More common and relatively benign complications include headache and backache.

Tissue Biopsies

In selected specialty centers, a diagnostic biopsy is performed on various tissues, including brain, peripheral nerve (see Chapter 123),

TABLE 106.2 Symptom Localization in the Central Nervous System

Sign or Symptom	Location
Cerebral Hemispheres	
Unilateral weakness or sensory complaints	Contralateral cerebral hemisphere
Language dysfunction	Left hemisphere (frontal and temporal)
Spatial disorientation	Right hemisphere (parietal and occipital)
Anosognosia (lack of insight into deficit)	Right hemisphere (parietal)
Hemivisual loss	Contralateral hemisphere (occipital, temporal, and parietal)
Flattening of affect or social disinhibition	Bihemispheric (frontal and limbic)
Alteration of consciousness	Bihemispheric (diffuse)
Alteration of memory	Bihemispheric (hippocampus, fornix, amygdala, and mammillary bodies)
Cerebellum	
Limb clumsiness	Ipsilateral cerebellar hemisphere
Unsteadiness of gait or posture	Midline cerebellar structures
Basal Ganglia	
Slowness of voluntary movement	Substantia nigra and striatum
Involuntary movement	Striatum, thalamus, and subthalamus
Brain Stem	
Contralateral weakness or sensory complaints in the body with ipsilateral weakness or sensory complaints in the face	Midbrain, pons, and medulla
Double vision	Midbrain and pons
Vertigo	Pons and medulla
Alteration of consciousness	Midbrain, pons, medulla (reticular formation)
Spinal Cord	
Weakness and spasticity (ipsilateral) and anesthesia (contralateral) below a specified level	Corticospinal and spinothalamic tracts
Unsteadiness of gait	Posterior columns
Bilateral (can be asymmetrical) weakness and sensory complaints in multiple contiguous radicular distributions	Central cord

TABLE 106.3 Symptom Localization in the Motor Unit^a

Sign or Symptom	Location
Anterior Horn Cell	
Weakness and wasting with muscle twitching (fasciculation) but no sensory complaints	Anterior horn of spinal cord (diffuse or segmental)
Spinal Root	
Weakness and sensory loss confined to a known radicular distribution (pain, a common feature, may spread)	Cervical, thoracic, lumbar, and sacral
Plexus	
Pain, weakness, and sensory loss in a limb; not limited to a single radicular or peripheral nerve distribution	Brachial and lumbosacral (may also be caused by polyradiculopathy)
Nerve	
Pain, distal weakness, and/or sensory changes confined to a single peripheral nerve distribution	Peripheral nerves (mononeuropathy)
Pain, distal weakness, and/or sensory changes affecting both sides symmetrically (usually starting in feet)	Peripheral nerves (polyneuropathy)
Pain, distal weakness, and/or sensory changes affecting scattered single peripheral nerve distributions	Peripheral nerves (mononeuropathy multiplex)
Unilateral special sensory loss	Cranial nerves I, II, V, VII, VIII, and IX
Unilateral facial weakness involving entire one half of face	Cranial nerve VII (ipsilateral)
Neuromuscular Junction	
Progressive weakness with repeated use of a muscle; no sensory complaints	Ocular, pharyngeal, and skeletal
Muscle	
Proximal weakness; no sensory complaints	Diffuse and various patterns

^aAnterior horn cell and the peripheral nervous system.

muscle (see [Chapter 124](#)), and skin. Occasionally, biopsy provides the only means of arriving at a definitive diagnosis.

Electrophysiologic Studies

Electrophysiologic studies include electroencephalography, electromyography, nerve conduction studies, and evoked potentials. These studies are helpful in situations in which the patient cannot be examined or interviewed adequately.

Electroencephalography is most often used to investigate seizures (see [Chapter 120](#)). It can document encephalopathy, in which case the background electrical activity of the brain is slowed, and it is also used in the evaluation of brain death.

Electromyography is useful in the differential diagnosis of muscle disease, neuromuscular junction disease, peripheral nerve disease, and anterior horn cell disease. Nerve conduction studies (see [Chapters 123 and 124](#)) may show decreased amplitude (characteristic of axonal neuropathy) or decreased velocity (characteristic of demyelinating neuropathy).

Visual-evoked potential studies are commonly used in the evaluation of possible multiple sclerosis (see [Chapter 122](#)). Asymmetrical

TABLE 106.4 Categories of Neurologic Disease

Disease Category	Example
Genetic	
Autosomal dominant	Huntington's disease
Autosomal recessive	Friedreich's ataxia
X-linked recessive	Duchenne muscular dystrophy
Mitochondrial	Progressive external ophthalmoplegia
Sporadic	Down syndrome
Neoplastic	
Intrinsic	Glioblastoma
Extrinsic	Metastatic melanoma
Paraneoplastic	Cerebellar degeneration
Vascular	
Stroke	Thrombotic, embolic, lacunar, hemorrhagic
Structural	Arteriovenous malformation
Inflammatory	Cranial arteritis
Infectious	
Bacterial	Meningococcal meningitis
Viral	Herpes encephalitis
Protozoal	Toxoplasmosis
Fungal	Cryptococcal meningitis
Helminthic	Cysticercosis
Prion	Creutzfeldt-Jakob disease
Degenerative	
Central	Parkinson's disease
Central and peripheral	Amyotrophic lateral sclerosis
Autoimmune	
Central demyelinating	Multiple sclerosis
Peripheral demyelinating	Guillain-Barré syndrome
Neuromuscular junction	Myasthenia gravis
Toxic and Metabolic	
Endogenous	Uremic encephalopathy
Exogenous	Alcoholic neuropathy
Other Structural	
Trauma	Spinal cord injury
Hydrodynamic	Normal pressure hydrocephalus
Psychogenic	Hysterical paraparesis

slowing of the cortical response to visual pattern stimulation suggests demyelination in the optic nerve or central optic pathways. Brain stem auditory-evoked potential studies are useful in the diagnosis of diseases affecting cranial nerve VIII or its central projections. Lesions at the cerebellopontine angle and the brain stem cause abnormal delay in conduction. Brain stem auditory-evoked potentials are helpful in the diagnosis of deafness in infants. Somatosensory-evoked potentials are used to identify a slowing of central sensory conduction that results from demyelinating disease, compression, or metabolic derangements. They are also used to evaluate spinal cord–mediated sensory abnormalities.

Imaging Studies

Magnetic resonance imaging (MRI) and computed tomography (CT) are high-resolution imaging techniques that provide extraordinary

TABLE 106.5 Elements of a General Screening Neurologic Examination

Systemic Physical Examination

Head (trauma, dysmorphism, and bruits)
 Neck (tone, bruits, and thyromegaly)
 Cardiovascular (heart rate, rhythm, and murmurs; peripheral pulses and jugular venous distention)
 Pulmonary (breathing pattern, cough and cyanosis)
 Abdomen (hepatosplenomegaly)
 Back and extremities (skeletal abnormalities, peripheral edema, and straight-leg raising)
 Skin (neurocutaneous stigmata and hepatic stigmata)

Mental Status

Level of consciousness (awake, drowsy, and comatose)
 Attention (coherent stream of thought, serial 7s)
 Orientation (temporal and spatial)
 Memory (short and long term)
 Language (naming, repetition, comprehension, fluency, reading, and writing)
 Visuospatial skills (clock drawing and figure copying)
 Judgment, insight, thought content (psychotic)
 Mood (depressed, manic, and anxious)

Cranial Nerves

Olfactory (smell in each nostril)
 Optic (afferent pupillary function, fundoscopic examination, visual acuity, visual fields, and structural eye findings)
 Oculomotor, trochlear, and abducens (smooth pursuit and saccadic eye movements, nystagmus, efferent pupillary function, and eyelid opening)
 Trigeminal (jaw jerk, facial sensation, afferent corneal reflex, and muscles of mastication)
 Facial (efferent corneal reflex, facial expression, eyelid closure, nasolabial folds, and power and bulk)
 Vestibulocochlear (nystagmus, speech discrimination, Weber test, and Rinne test)
 Glossopharyngeal and vagus (afferent and efferent gag reflex and uvula position)
 Spinal accessory (power and bulk of sternocleidomastoid and trapezii muscles)
 Hypoglossal (position, bulk, and fasciculations of tongue)

Motor Examination

Pronator drift (subtle corticospinal lesion)
 Tone and bulk of muscles (basal ganglia lesion yields rigidity, cerebellar lesion yields hypotonia, corticospinal lesion yields spasticity, nonspecific bihemispheric disease yields paratonia [inability to relax muscles], hypertrophy indicates dystonia, pseudohypertrophy indicates muscle disease, and atrophy indicates lower motor neuron disease)
 Adventitious movements (tremor, tic, dystonia, and chorea indicate disease of the basal ganglia; asterixis and myoclonus may indicate toxic metabolic process)
 Power of major muscle groups (scale 0-5)
 Upper extremities: deltoids, biceps, triceps, wrist extension and flexion, finger extension and flexion, and interossei
 Lower extremities: hip flexion, extension, abduction, and adduction; knee extension and flexion; ankle dorsiflexion, plantar flexion, inversion, and eversion; toe extension and flexion

Sensory Examination

Light touch (posterior columns)
 Pinprick (spinothalamic tract)
 Temperature (spinothalamic tract)
 Joint position sense (posterior columns)
 Vibration (posterior columns)
 Graphesthesia (cortical sensory)
 Double simultaneous stimulation (cortical sensory)
 Two-point discrimination (posterior columns and cortical sensory)

Reflex Examination

Standard reflexes (grades 0-4)
 Biceps
 Triceps
 Brachioradialis
 Knee jerk
 Ankle jerk
 Pathologic reflexes
 Babinski sign (if present)
 Myerson sign (glabellar sign) (if present)
 Snout (if present)
 Jaw jerk (if brisk)
 Palmomenta (twitch of chin muscles when palm is stroked) (if present)
 Hoffmann sign (thumb or index finger flexion when nail of middle finger is flicked) (if brisk)

Coordination and Gait

Finger-nose-finger (action tremor suggesting cerebellar disease)
 Rapid alternating movements (dysdiadochokinesia suggesting cerebellar disease)
 Fine motor movements (slowness and small amplitude suggesting basal ganglia or corticospinal tract abnormalities)
 Heel-to-shin (ataxia suggesting cerebellar disease)
 Arising from chair with arms folded across chest (inability in advanced basal ganglia, cerebellar, corticospinal, or muscle disease)
 Walking naturally (look for decreased arm swing, spasticity, broad base, festination (quickenening and shortening of normal gait), waddle, footdrop, start hesitation, and dystonia)
 Tandem gait (look for ataxia)
 Walking with feet everted or inverted (look for latent dystonia)
 Hopping on each foot separately (look for latent dystonia)
 Stand with feet together and eyes open, eyes closed (sensory ataxia and cerebellar disease)
 Response to retropulsive stress (loss of postural righting mechanisms)

diagnostic precision for central nervous system lesions. Most neurologic diseases, however, can have normal CT and MRI findings. Moreover, many abnormal findings on CT and MRI bear no relation to the diagnosis responsible for the patient's symptoms.

Table 106.7 compares CT with MRI. MRI is used for most purposes, although CT has the advantage of wider accessibility, greater speed of acquisition, and better tolerability by the patient. CT detects acute hemorrhage and is preferred for emergencies. MRI provides more detail and simultaneously obtains images in the horizontal,

vertical, and coronal planes. Contrast media for CT or MRI are useful in the diagnosis of tumors, abscesses, and other processes that derange the blood-brain barrier. MRI can be used for functional imaging and spectroscopy; both techniques have great promise for the evaluation of cognitive and metabolic disorders, epilepsy, multiple sclerosis, and many other conditions.

MR- and CT-angiography allow noninvasive visualization of the major vessels of the head and neck. Conventional angiography with an intra-arterial injection of contrast agent is used for evaluation of

Fig. 106.1 The nervous system can be conceptually reduced to a series of higher-order inputs that converge on final common pathways. For example, upper motor neurons converge on lower motor neurons, whose axons form the final common pathway to an effector muscle.

TABLE 106.6 Indications for Lumbar Puncture

Urgent (Do Not Wait for Brain Imaging)

Acute central nervous system infection in the absence of focal neurologic signs

Less Urgent (Wait for Brain Imaging)

Vasculitis, subarachnoid hemorrhage, or cryptic process
Increased intracranial pressure in the absence of mass lesion on magnetic resonance imaging or computed tomography
Intrathecal therapy for fungal or carcinomatous meningitis
Symptomatic treatment for headache from idiopathic intracranial hypertension or subarachnoid hemorrhage

TABLE 106.7 Magnetic Resonance Imaging Versus Computed Tomography

Magnetic Resonance Imaging (MRI)

Resolution 1-2 mm (higher with newer 3-Tesla magnets)
Gadolinium contrast relatively safe, except in severe renal insufficiency
Unaffected by bone; multiple planes of imaging available; functional (physiologic) imaging capacity

Computed Tomography

Resolution >5 mm
Iodine contrast associated with anaphylaxis and rash
Faster acquisition than MRI
Metallic objects such as pacemaker or aneurysm clip preclude MRI
Acute hemorrhage well visualized
Better tolerated by patients who are severely ill or claustrophobic

many intracranial vascular abnormalities, including small aneurysms and arteriovenous malformations, and inflammation of small blood vessels.

Noninvasive ultrasonography of the carotid and vertebral arteries can define stenotic vessels. It has been supplemented by transcranial Doppler technology, which allows characterization of blood flow in intracranial arteries.

TABLE 106.8 Some Neurologic Conditions for Which Genetic Tests Are Commercially Available

- Neuromuscular diseases: nerve (Charcot-Marie-Tooth disease); muscle (myotonic dystrophy, Duchenne-Becker muscular dystrophy); spinal muscular atrophy, familial amyotrophic lateral sclerosis
- Movement disorders: ataxia (spinal cerebellar ataxias, Friedreich ataxia); dystonia, parkinsonism, chorea
- Dementias: Alzheimer's disease, frontotemporal dementia, hereditary prion disease
- Mental retardation (fragile X syndrome)
- Mitochondrial diseases: *mitochondrial encephalomyelopathy*, *lactic acidosis*, and *stroke-like symptoms* (MELAS syndrome); *myoclonus epilepsy with ragged red fibers* (MERRF syndrome)

Single-photon emission CT (SPECT) is useful for the evaluation of intracranial blood flow. The development of iodine-123 ioflupane injection (DaTscan) makes it possible to visualize the dopamine transporter to follow cell loss in patients with Parkinson's disease.

Positron-emission tomography (PET) is a functional imaging technology that can demonstrate specific metabolic derangements. It is useful for evaluating local abnormalities of glucose and oxygen metabolism. PET is of particular value in defining the site of origin of focal seizures. Customized ligands can be used to identify specific pathologic processes. Examples include three FDA-approved agents for estimating β -amyloid neuritic plaque density in Alzheimer's disease and fluorodopa F18 in Parkinson's disease.

Genetic and Molecular Testing

There are more neurologic diseases than diseases of all other systems combined. Discoveries have revolutionized the diagnostic approach to many of these diseases, and new genetic tests are discovered every year. Table 106.8 outlines the tests that are commercially available.

Genetic testing for a disorder requires the clinician to perform a thoughtful and caring evaluation of the patient, usually with input from and evaluation of the patient's family. Important ethical issues surround the use of genetic tests, including the ability to ensure privacy, to ensure adequate psychological and social support for patients who may be given devastating news, and to address adequately the appropriateness of prenatal screening or presymptomatic testing when no treatment is available.

PROSPECTS FOR THE FUTURE

Novel imaging techniques and molecular diagnostic studies are beginning to shed light on the pathogenesis of neurologic conditions that have been identifiable only by clinical phenomenology. Studies of previously untreatable neurodegenerative disorders are now targeting presymptomatic individuals in the hope that earlier intervention can modify disease outcomes. Despite these and foreseeable future advances, the clinical aspects of neurologic disease remain fundamentally important in understanding the impact of disease on patients and their families.

Disorders of Consciousness

Leah Dickstein, Paul M. Vespa

INTRODUCTION

Coma is a state in which the patient is unresponsive and the eyes remain closed even with vigorous stimulation. A poorly responsive state in which the eyes are spontaneously open, or an agitated and confused state, or delirium is not coma but may represent early stages of the same disease processes and should be investigated in the same manner.

Consciousness requires that the brain stem reticular activating system and its cortical projections be intact and functioning. The reticular formation begins in the mid pons and ascends through the dorsal midbrain to synapse in the thalamus; it then innervates higher centers through thalamocortical connections. Knowledge of this anatomic substrate provides the short list of regions to be investigated in the search for a structural cause of coma: Brain stem or bihemispheric dysfunction, be it medication or lesion-related, is typically needed to impede consciousness, whereas structural lesions elsewhere are not the cause of the patient's unconsciousness. In addition to structural lesions, meningeal inflammation, metabolic encephalopathy, sedation, and seizures diffusely affect the brain and complete the differential diagnosis for the patient in coma.

PATHOPHYSIOLOGIC FACTORS

Meningeal irritation caused by infection or blood in the subarachnoid space is an essential early consideration in coma evaluation because its cause requires immediate attention (especially with purulent meningitis) and may not be diagnosed by computed tomography (CT).

Hemispheric mass lesions result in coma either by expanding across the midline laterally to compromise both cerebral hemispheres or by impinging on the brain stem to compress the rostral reticular formation. These processes—*lateral herniation* (lateral movement of the brain) and *transtentorial herniation* (vertical movement of the brain)—most commonly occur together. At the bedside, clinical signs of an expanding hemispheric mass evolve in a level-by-level, rostral-caudal manner (Fig. 107.1). Hemispheric lesions of adequate size to produce coma are readily seen on CT.

Brain stem mass lesions produce coma by directly affecting the reticular formation. Because the pathways for lateral eye movements—the pontine gaze center, medial longitudinal fasciculus, and oculomotor (third nerve) nucleus—traverse the reticular activating system, impairment of reflex eye movements is often the critical element of diagnosis of a brain stem lesion. A comatose patient without impaired reflex lateral eye movements does not have a mass lesion compromising brain stem structures in the posterior fossa. CT is not able to show some lesions in this region. Posterior fossa lesions may block the flow of cerebrospinal fluid from the lateral ventricles, resulting in the dangerous situation of *noncommunicating hydrocephalus*.

Metabolic abnormalities are caused by deficiency states (e.g., thiamine, glucose), by derangements of metabolism (e.g., hyponatremia), or by the presence of *exogenous toxins* (e.g., drugs) or *endogenous toxins* (e.g., organ system failure). Metabolic abnormalities result in diffuse dysfunction of the nervous system; therefore, with rare exceptions, they produce no localized signs such as hemiparesis or unilateral papillary dilation. The diagnosis of *metabolic encephalopathy* means that the examiner has found no focal anatomic features on examination or neuroimaging studies to explain coma but that a specific metabolic cause has not been established. Drugs have a predilection for affecting the reticular formation in the brain stem and for producing paralysis of reflex eye movement on examination. *Multifocal structural disorders* may simulate metabolic coma (Table 107.1).

In the late stages of status epilepticus, motor movements may be subtle even though *seizure activity* is continuing throughout the brain (nonconvulsive status epilepticus). Once seizures stop, the so-called *postictal state* can also cause unexplained coma.

DIAGNOSTIC APPROACH

The history and examination are essential in the diagnosis and are not replaced by brain imaging (Table 107.2). A history of a premonitory headache supports a diagnosis of meningitis, encephalitis, or intracerebral or subarachnoid hemorrhage. A preceding period of intoxication, confusion, or delirium points to a diffuse process such as meningitis or endogenous or exogenous toxins. The sudden apoplectic onset of coma is particularly suggestive of ischemic or hemorrhagic stroke affecting the brain stem or of subarachnoid hemorrhage or intracerebral hemorrhage with intraventricular rupture. Lateralized symptoms of hemiparesis or aphasia before coma occur in patients with hemispheric masses or infarctions.

The physical examination is critical, quickly accomplished, and diagnostic. The issues are three: (1) Does the patient have meningitis? (2) Are signs of a mass lesion present? and (3) Is this condition a diffuse syndrome of exogenous or endogenous metabolic etiology? Emergency management should then be instituted accordingly (Table 107.3).

Identification of Meningitis

Signs of meningeal irritation are not invariably present and have differing sensitivities depending on the cause: They are extremely common with acute pyogenic meningitis and subarachnoid hemorrhage and less common with indolent, fungal meningitis. Nevertheless, the presence of these signs on examination is the central clue to the diagnosis. Missing these signs results in time-consuming additional tests such as brain imaging and the potential loss of a narrow window of opportunity for directed therapy.

Fig. 107.1 The evolution of neurologic signs in coma from a hemispheric mass lesion as the brain becomes functionally impaired in a rostral-caudal manner. The terms *early diencephalic* and *late diencephalic* refer to levels of dysfunction just above and just below the thalamus, respectively. (From Aminoff MJ, Greenberg DA, Simon RP: Clinical neurology, Stamford, Conn., 1996, Appleton and Lange.)

TABLE 107.1 Multifocal Disorders Indicating Metabolic Coma

Disseminated intravascular coagulopathy
Sepsis
Pancreatitis
Vasculitis
Thrombotic thrombocytopenic purpura
Fat emboli
Hypertensive encephalopathy
Diffuse micrometastases

Passive neck flexion should be tested (Fig. 107.2) in all comatose patients unless a history of head trauma exists. When the neck is passively flexed by attempting to bring the chin within a few fingerbreadths of the chest, patients with irritated meninges reflexively flex one or both knees. This sign, called the *Brudzinski reflex*, is usually asymmetrical and not dramatic, but any evidence of knee flexion during passive neck flexion mandates that the cerebrospinal fluid be examined.

Is CT required before lumbar puncture in this setting? In the absence of lateralized signs (e.g., hemiparesis) supporting a superimposed mass lesion, a spinal puncture should be performed immediately. Although rare cases of herniation after lumbar puncture have been reported in children with bacterial meningitis, the urgency of diagnosis and treatment at the point of coma is paramount. The time required for CT may result in a fatal therapeutic delay. An alternative approach involves obtaining blood cultures and immediately initiating antibiotic therapy with subsequent lumbar puncture. With this approach, the cerebrospinal fluid cell count, glucose determination, and protein content are unchanged, and Gram stain and culture often remain positive despite a short period of antibiotic treatment. Bacterial antigens in the cerebrospinal fluid or blood can also be detected.

Separation of Structural From Metabolic Causes of Coma

The goal of this differential diagnosis is achieved by neurologic examination. Because the evaluation and potential treatments for structural and metabolic coma are widely divergent and the disease processes in both categories are often rapidly progressive, initiating prompt medical and surgical evaluation may be life-saving. Identification of a structural versus a metabolic cause is accomplished by focusing on three features of the neurologic examination: the *motor response* to a painful stimulus, *pupillary function*, and *reflex eye movements*.

Motor Response

Asymmetrical or reflex function of the motor system provides the clearest indication of a mass lesion. Elicitation of a *motor response* requires that a painful stimulus be applied, to which the patient will react. The patient's arms should be placed in a semiflexed posture, and a painful stimulus should be applied to the head or trunk. Strong pressure on the supraorbital ridge or pinching of the skin on the anterior chest or inner arm is the most useful method; finger nail bed pressure is also used, but it makes the interpretation of upper limb movement difficult.

The neurologic examination of a patient with an expanding hemispheric mass lesion is shown in Fig. 107.1. Hemispheric masses in their *early diencephalic* stage (i.e., compromising the brain above the thalamus) produce appropriate movement of one upper extremity—that is, movement toward the painful stimulus. The attenuated contralateral arm movement reflects a hemiparesis. This lateralized motor response in a comatose patient establishes the working diagnosis of a hemispheric mass. As the mass expands to involve the thalamus (*late diencephalic* stage), the response to pain becomes reflex arm flexion associated with extension and internal rotation of the legs (*decorticate posturing*); asymmetry of the response in the upper extremities is seen. With further brain compromise at the midbrain level, the reflex posturing in the arms changes such that both arms and legs respond by extension (*decerebrate posturing*); at that level, the asymmetry tends to

Conversion or malingering

^aGeneral anesthetic, similar to γ -aminobutyric acid; used as a recreational drug and body building aid. It has a rapid onset and rapid recovery, often with myoclonic jerking and confusion. It causes deep coma lasting 2 to 3 hours (Glasgow Coma Scale score = 3) with maintenance of vital signs.

^bComa associated with cholinergic signs: lacrimation, salivation, bronchorrhea, and hyperthermia.

^cComa after seizures or status epilepticus (i.e., a prolonged postictal state).

^dAn antihypertensive agent that is active through the opiate receptor system; overdose is frequent when used to treat narcotic withdrawal.

be lost. At this point, the pupils become mid-position in size, and the light reflex is lost, first unilaterally and then bilaterally. With further progression to the level of the pons, the most frequent finding is no response to painful stimulation, although spinal-mediated movements of leg flexion may occur.

TABLE 107.3 Emergency Management

1. Ensure airway adequacy.
2. Support ventilation and circulation.
3. Obtain blood for glucose, electrolytes, hepatic and renal function, prothrombin and partial thromboplastin times, complete blood count, and drug screen.
4. Administer 100 mg of thiamine intravenously (IV).
5. Administer 25 g of dextrose IV (typically 50 mL of 50% dextrose) to treat possible hypoglycemic coma.^a
6. Treat opiate overdose with naloxone (0.4-2 mg IV repeated every 2-3 minutes as needed).
7. The specific benzodiazepine antagonist flumazenil (0.2 mg IV every 1 min, \times 1-5 doses; max is 1 mg) should be given for reversal of benzodiazepine-induced coma or conscious sedation.^b

^aThe glucose level is poorly correlated with the level of consciousness in hypoglycemia; stupor, coma, and confusion are reported with blood glucose concentrations ranging from 2 to 60 mg/dL.

^bNot recommended in coma of unknown origin because seizures may be precipitated in patients with polydrug overdoses that include benzodiazepines with tricyclic antidepressants or cocaine.

Fig. 107.2 Elicitation of Brudzinksi sign of meningeal irritation, as seen in infectious meningitis or subarachnoid hemorrhage. (From Aminoff MJ, Greenberg DA, Simon RP: Clinical neurology, Stamford, Conn., 1996, Appleton and Lange.)

The classic postures illustrated in Fig. 107.1, and particularly their asymmetry, strongly support the presence of a mass lesion. However, these motor movements, especially early in coma, are most frequently seen as fragments of the fully developed, asymmetrical flexion or extension of the arms (illustrated as decorticate and decerebrate postures in Fig. 107.1). A small amount of asymmetrical flexion or extension of the arms in response to a painful stimulus carries the same implications as the full-blown postures of decortication or decerebration.

Metabolic lesions do not compromise the brain in a progressive, level-by-level manner as do hemispheric masses, and they rarely produce the asymmetrical motor signs typical of masses. Reflex posturing may be seen, but it lacks the asymmetry of decortication seen with a hemispheric mass, and it is not associated with the loss of pupillary reactivity at the stage of decerebration.

Pupillary Reactivity

In metabolic coma, one feature is central to the examination: Pupillary reactivity is present. This reactivity is seen both early in metabolic coma, when an appropriate motor response to pain may be retained, and late in coma, when no motor responses can be elicited. The pupillary reaction in metabolic coma is lost only when coma is so deep that the patient requires ventilatory and blood pressure support.

Reflex Eye Movements

The presence of inducible lateral eye movements reflects the integrity of the pons and midbrain. These reflex eye movements (see Fig. 107.1) are brought about with the use of passive head rotation to stimulate the semicircular canal input to the vestibular system (so-called *doll's eyes maneuver*) or by inhibiting the function of one semicircular canal by infusing ice water against the tympanic membrane (caloric testing).

In metabolic coma, reflex eye movements may be lost or retained. Lack of inducible eye movements with the doll's eyes maneuver, in the setting of preserved pupillary reactivity, is virtually diagnostic of drug toxicity. With metabolic coma of non-drug-induced origin, such as organ system failure, electrolyte disorders, or osmolar disorders, reflex eye movements are preserved.

Brain stem mass lesions are most commonly caused by hemorrhage or infarction. Reflex lateral eye movements, the pathways for which traverse the pons and midbrain, are particularly affected, and the reflex postures of decortication and decerebration typical of brain stem injury are common. Lesions restricted to the midbrain (e.g., embolization from the heart to the top of the basilar artery) cause sluggish pupillary reflexes or their absence, with or without impaired medial eye movements; both are controlled by the third cranial nerve. With lesions restricted to the pons (e.g., intrapontine hypertensive hemorrhage), pupils are reactive but very small (pinpoint or pontine pupils), reflecting focal impairment of sympathetic innervations; pinpoint pupils are rare. Ocular bobbing (spontaneous symmetrical or asymmetrical rhythmic vertical ocular oscillations) is most often a manifestation of a pontine lesion.

Seizures occurring in a patient with acute brain injury (such as that resulting from encephalitis, hypertensive encephalopathy, hyponatremia, hypernatremia, hypoglycemia, or hyperglycemia) or chronic brain injury (such as dementia or mental retardation) often result in prolonged postictal coma. The examination shows reactive pupils and inducible eye movements (in the absence of overtreatment with anticonvulsants), and often up-going toes or focal signs are observed (Todd paresis).

Nonconvulsive status epilepticus should be considered as a diagnosis even if there are no obvious seizure movements. Nonconvulsive seizures can cause coma and also can complicate other etiologies of coma, including infectious and metabolic disorders. Nonconvulsive seizures should be suspected in patients with (1) a seemingly prolonged "postictal state" after generalized convulsive seizures or prolonged alteration of alertness after an operative procedure or neurologic insult; (2) acute onset of impaired consciousness or fluctuating mentation interspersed with episodes of normal awareness; (3) altered mental status or consciousness associated with facial myoclonus or nystagmoid eye movements; or (4) episodic blank staring, aphasia, automatisms (e.g., lip-smacking, fumbling with fingers), or acute-onset aphasia without an acute structural lesion. The diagnosis is made by electroencephalography (EEG) (see Chapter 120). EEG provides information about brain electrical activity even when brain function is depressed and cannot be evaluated otherwise, as in comatose patients. EEG is essential to detect electrical seizures and document their duration as well as the response to therapy and to improve coma prognostication.

Current evidence suggests that the presence of nonconvulsive seizures or periodic discharges, delay to diagnosis, and duration of nonconvulsive status in patients with or without acute brain injury are independent predictors of worse outcome.

PROGNOSIS IN COMA AFTER CARDIAC ARREST

Historically, prognostication after cardiac arrest was solely based on neurologic examination. Pupillary, corneal, and motor responses are

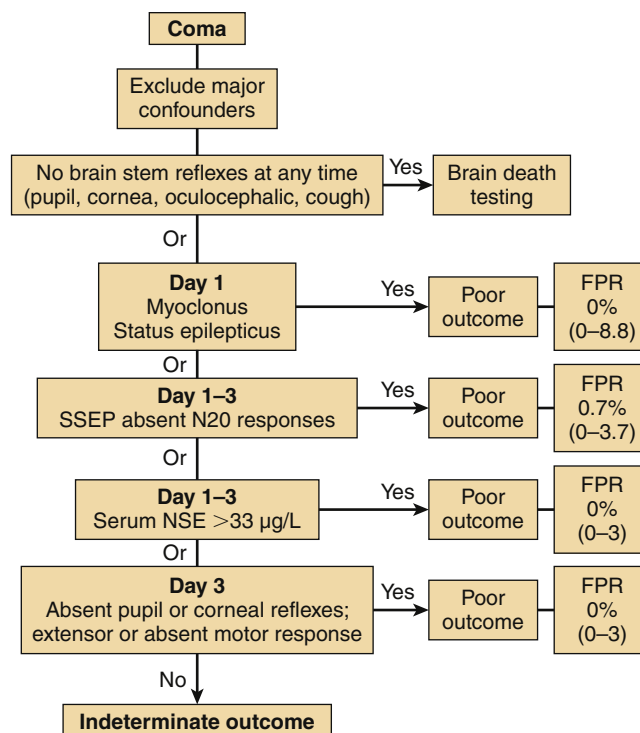

Fig. 107.3 Decision algorithm for use in prognostication of comatose survivors after cardiopulmonary resuscitation (CPR). The numbers in parentheses show the exact 95% confidence intervals. *FPR*, False-positive rate; *N20*, a negative peak at 20 ms on SSEP; *NSE*, neuron-specific enolase; *SSEP*, somatosensory evoked potential. (Data from Wijidicks EFM, Hijdra A, Young GB, et al: Practice parameter: prediction of outcome in comatose survivors after CPR [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology, *Neurology* 67:203-210, 2006.)

the best clinical indicators of prognosis that can be assessed at bedside. Such responses reflect the functionality of the brain stem, which is the most resilient portion of central nervous system (Fig. 107.3).

Although the neurologic exam is still the cornerstone of prognostication, there has been extensive work using other modalities to better predict prognosis. Current guidelines endorse using EEG to guide prognostication in comatose survivors of cardiac arrest. The absence of normal background activity or reactivity predicts a poor prognosis. Conversely, continuous background activity and the presence of reactivity are among the few reliable predictors of good neurologic recovery. Somatosensory evoked potentials (SSEPs), another electrophysiologic marker of cortical responsiveness, are most helpful for predicting which patients will remain in a persistent coma. By 24 hours after cardiac arrest, bilateral absence of the N20 cortical response (a negative peak at 20 ms) to median nerve stimulation predicts a grave outcome. The early onset of generalized myoclonic status is an ominous sign. Neuron-specific enolase (NSE) is the most promising of several serum biomarkers that have been evaluated. NSE level greater than 30 ng/mL predicts persistent coma. Despite tremendous potential, the role of neuroimaging as a prognostic tool after hypoxic-ischemic injury from cardiac arrest has yet to be clearly defined. Severe reductions in the apparent diffusion coefficient (ADC), as well as bilateral hippocampal hyperintensities on magnetic resonance imaging (MRI), suggest severe global damage and extensive ischemic injury and are predictive of poor neurologic recovery.

Therapeutic hypothermia has been demonstrated to improve neurologic outcomes in patients who have return of spontaneous circulation

but remain comatose after cardiac arrest. The use of therapeutic hypothermia quite likely influences the clinical examination and ancillary test findings. There are a scarcity of data about the utility of physical examination, EEG, and evoked potentials in predicting outcomes among cardiac arrest patients with induced hypothermia. It is well accepted that one should consider observation for longer than 72 hours before prognosticating outcome in patients treated with hypothermia.

COMA-LIKE STATES

Patients with *locked-in syndrome* have a lesion (usually a hemorrhage or an infarct) that transects the brain stem at a point below the reticular formation (thereby sparing consciousness) but above the ventilatory nuclei of the medulla (thereby maintaining cardiopulmonary function) (Table 107.4). Such patients are awake, with eye opening and sleep-wake cycles, but the descending pathways through the brain stem that are necessary for volitional vocalization or limb movement have been transected. Voluntary eye movement, especially vertically, is preserved, and patients can open and close their eyes or produce appropriate numbers of blinking movements in answer to questions. The EEG is usually normal, reflecting normal cortical function.

Psychogenic unresponsiveness is a diagnosis of exclusion. The neurologic examination shows reactive pupils and no reflex posturing in response to pain. Eye movements during the doll's eyes maneuver show volitional override rather than the smooth, uninhibited reflex lateral eye movements of coma. Ice water caloric testing either arouses the patient because of the discomfort produced or induces cortically mediated nystagmus rather than the tonic deviation typical of coma. The slow, conjugate roving eye movements of metabolic coma cannot be imitated and therefore rule out psychogenic unresponsiveness. Likewise, the slow, often asymmetrical, and incomplete eye closure seen after passive eye opening in a comatose patient cannot be feigned. In contrast, conscious patients usually exhibit some voluntary muscle tone in the eyelids during passive eye opening. The EEG in psychogenic unresponsiveness is that of normal wakefulness, with reactive posterior rhythms on eye opening and eye closing. In patients with catatonic stupor, lorazepam administration may produce awakening.

Unresponsive wakefulness syndrome, previously called vegetative state (VS), is exhibited by patients with eye opening and sleep-wake cycles. The reticular activating system of the brain stem is intact to

produce wakefulness, but the connections to the cortical mantle are interrupted, precluding awareness.

A VS is termed *persistent* after 3 months if the brain injury was ischemic in nature or after 12 months if the brain injury was traumatic in nature. The determination as to when *persistent* equals *permanent* cannot be stated absolutely. Prediction early in VS of which patients will remain persistently vegetative is particularly difficult in cases of trauma. Lesions of the corpus callosum and dorsolateral brain stem seen on MRI 6 to 8 weeks after trauma correlated with persistence of VS at 1 year. A combined analysis of morphologic MRI studies and post-traumatic brain stem spectroscopy can be a predictor of persistent vegetative states (PVS) and minimally conscious states (MVS). In rare cases, patients show late improvement, but they do not return to normal. Bilateral absence of SSEPs in the first week predicts death or VS.

Patients in a PVS open their eyes diurnally and in response to loud sounds; blinking occurs with bright lights. Pupils react and eye movements occur both spontaneously and with the doll's eyes maneuver. Yawning, chewing, swallowing, and, uncommonly, guttural vocalizations and lacrimation may be preserved. Spontaneous roving eye movements (very slow, with constant velocity) are particularly characteristic and distressing to the patient's visitors because the patient appears to be looking about the room. The brain stem origin of the eye movements is documented by their being readily redirected by the oculocephalic (doll's eyes) reflex. The limbs may move, but motor responses are only primitive; pain usually produces decorticate or decerebrate postures or fragments of these movements.

Minimally conscious state (MCS) is a newly described entity in which patients do not meet criteria for PVS. Both patients in PVS and those in MCS demonstrate severe alteration in consciousness. In contrast to PVS, subjects with MCS exhibit evidence of limited interaction with the environment by visually tracking, following simple commands, answering yes or no (not necessarily reliably), or having intelligible verbalization or restricted purposeful behavior. It is estimated that the rate of misdiagnosis between the VS and MCS is about 40%.

Novel applications of functional neuroimaging in patients with disorders of consciousness may aid in differential diagnosis, prognostic assessment, and identification of pathophysiologic mechanisms. In one study, authors prospectively evaluated cortical activation in response to a familiar voice in seven patients in VS and four subjects in MCS. All four of the MCS patients and only two of the VS patients showed activation that extended beyond the primary auditory cortex to hierarchically higher-order associative temporal areas. Over the course of 3 months, these two VS patients improved clinically to MCS.

Brain death characterizes the *irreversible cessation* of brain function. Therefore, death of the organism can be determined based on death of the brain. Although local laws may dictate some details, the standard definition permits a diagnosis of brain death based on documentation of irreversible cessation of all brain function, including function of the brain stem (Table 107.5). Documentation of *irreversibility* requires that the cause of the coma is known, that the cause is adequate to explain the clinical findings of brain death, and that exclusionary criteria are absent (Table 107.6). Confirmatory tests are sometimes used but are not required for diagnosis (Table 107.7). Brain death results in asystole, usually within days (mean, 4 days), even if ventilatory support is continued. Recovery after appropriate documentation of brain death has never been reported. Removal of the ventilator results in terminal rhythms (most often complete heart block without ventricular response), junctional rhythms, or ventricular tachycardia. Purely spinal motor movements may occur in the moments of terminal apnea (or during apnea testing in the absence of passive administration of oxygen); these may include arching of the back, neck turning, stiffening of the legs, and upper extremity flexion.

TABLE 107.5 Criteria for Cessation of Brain Function^a

Anatomic Region Tested	Confirmatory Sign
Hemispheres	Unresponsive and unreceptive to sensory stimuli including pain ^b
Midbrain	Unreactive pupils ^c
Pons	Absent reflex eye movements ^d
Medulla	Apnea ^e

CO₂, Carbon dioxide; Pco₂, partial pressure of carbon dioxide.

^aSequential testing is necessary for a clinical diagnosis of brain death; it should be done at least every 6 hours in all cases and at least every 24 hours in the setting of anoxic-ischemic brain injury.

^bThe patient does not rouse, groan, grimace, or withdraw limbs. Purely spinal reflexes (deep tendon reflexes, plantar flexion reflex, plantar withdrawal, and tonic neck reflexes) may be maintained.

^cMost easily assessed by the bright light of an ophthalmoscope viewed through its magnifying lens when focused on the iris. Unreactive pupils may be either midposition, as they will be in death, or dilated, as they often are in the setting of a dopamine infusion.

^dNo eye movement toward the side of irrigation of the tympanic membrane with 50 mL of ice water. The oculocephalic response (doll's eyes maneuver) is always absent in the setting of absent oculovestibular testing.

^eNo ventilatory movements in the setting of maximum CO₂ stimulation (≥60 mm Hg); with apnea, Pco₂ passively rises 2 to 3 mm Hg/min). Disconnect the ventilator from the endotracheal tube and insert a cannula with 6 L of oxygen per minute.

TABLE 107.6 Exclusionary Criteria for Brain Death

Seizures
Decorticate or decerebrate posturing
Sedative drugs
Hypothermia (<32.2° C)
Neuromuscular blockade
Shock

TABLE 107.7 Confirmatory Tests for Brain Death

EEG isoelectricity	Deep coma from sedative drugs or hypothermia (temperature <20° C) can produce EEG flattening.
Nuclear medicine	The most common radionuclide modality for brain imaging uses the tracer HMPAO. Absence of isotope uptake ("hollow skull phenomenon") indicates no brain perfusion and supports the diagnosis of brain death.
Transcranial Doppler	Findings of small systolic peaks without diastolic flow or a reverberating flow pattern suggest high vascular resistance and support the diagnosis of brain death. No cerebral blood flow is the most definitive confirmatory test.
CT angiography	Nonopacification of the cortical segments of MCAs and ICVs appears to be highly sensitive for confirming brain death, with a specificity of 100%. Lack of opacification of the ICVs is the most sensitive sign.

CT, Computed tomographic; EEG, electroencephalogram; HMPAO, ^{99m}Tc-labeled hexamethylpropyleneamine oxime; ICV, internal cerebral vein; MCA, middle cerebral artery.

Disorders of Sleep

Sagarika Nallu, Selim R. Benbadis

INTRODUCTION

The *International Classification of Sleep Disorders (ICSD-3)* groups disorders with sleep into six major categories: insomnia, sleep-related breathing disorders, central disorders of hypersomnolence, circadian rhythm sleep-wake disorders, parasomnias, and sleep-related movement disorders. From a practical point of view, sleep disorders are better classified by their clinical presentation, which is the approach taken here. This chapter focuses on primary sleep disorders rather than sleep disturbances that result from self-evident medical or psychiatric diseases.

DISORDERS OF EXCESSIVE DAYTIME SLEEPINESS

History and Examination

Evaluating patients with sleep disorders should include a thorough sleep history and physical examination that includes the respiratory, cardiovascular, and neurologic symptoms. The majority of the patients with sleep disorders present with excessive daytime somnolence (EDS) as their chief symptom. A careful history is the starting point and often uncovers the likely causes (e.g., insufficient sleep time with sleep deprivation, lifestyles, circadian rhythm disorders, medications, systemic illnesses). Most of these causes do not require any diagnostic interventions. To subjectively quantify EDS, various scales have been developed. The most validated and useful in the clinical practice is the Epworth Sleepiness Scale (ESS). The ESS consists of a brief questionnaire on the likelihood of dozing off in eight situations. This yields a score between 0 and 24 (Table 108.1). Scores of 10 or above warrant investigation.

Sleep Studies

Polysomnography (PSG) is an all-night sleep study that measures multiple parameters such as sleep staging, respiration, leg movements, and electrocardiographic patterns. The limited channel sleep monitoring version is also called portable home sleep testing (HST) and is used in patients with high probability of obstructive sleep apnea (OSA). The multiple sleep latency test (MSLT) and the maintenance of wakefulness test (MWT) are used to measure and quantify EDS. They consist of a series of daytime naps during which sleep latency is measured and sleep stages are determined. MSLT must be performed with a prior night PSG.

SLEEP-DISORDERED BREATHING

Definition and Epidemiology

Sleep-disordered breathing encompasses a spectrum of chronic conditions in which partial or complete cessation of breathing occurs multiple times throughout sleep. This group includes the most common disorders: OSA, central sleep apnea, and sleep-related hypoventilation.

Respiratory events are classified as apneas and hypopneas; apneas are further subdivided into obstructive, central or mixed. Obstructive apneas are episodes of complete upper airway collapse, defined as a greater than 90% drop in the airflow/thermal sensor in the presence of continued respiratory effort lasting at least 10 seconds. Hypopnea is defined as a 30% or more drop in the nasal pressure signal lasting for at least 10 seconds, associated with a 3% or more oxygen desaturation or an arousal. In contrast, central apnea is defined as a greater than 90% drop in the airflow/thermal sensor accompanied by absent respiratory effort that lasts for at least 10 seconds. The severity of sleep apnea is based on the polysomnographic scoring and is defined by the apnea-hypopnea index (AHI), a ratio of the sum of all respiratory events to the total hours of sleep on the PSG or HST.

The estimated prevalence rates of obstructive sleep apnea have increased substantially over the last two decades, most likely due to the obesity epidemic. It is now estimated that 26% of adults between the ages of 30 and 70 years have sleep apnea.

Pathophysiology

The pathophysiology of OSA is recurrent upper airway closure/collapse with resulting oxygen desaturation leading to arousals. The sleep fragmentation caused by arousal is responsible for sleep deprivation and EDS.

Clinical Manifestation

OSA patients typically present with at least one of these symptoms: snoring, waking up with gasping/choking or witnessed apneas in sleep by their bed partners. EDS, nonrestorative sleep, fatigue, and insomnia also have comorbid conditions such as hypertension, coronary artery disease (CAD), mood disorders, cognitive dysfunction or type 2 diabetes. Risk factors for OSA are both modifiable and nonmodifiable. Modifiable risk factors include sedative medication, alcohol, tobacco use, obesity, endocrine disorders (e.g., hypothyroidism, polycystic ovary syndrome, acromegaly) and nasal obstruction/congestion. Nonmodifiable factors include genetic predisposition, craniofacial anomalies and congenital syndromes (e.g., Down, Pierre Robin, and Treacher Collins syndromes).

Treatment and Prognosis

Depending on the severity, treatment modalities of OSA include positive airway pressure therapy (PAP), oral appliance therapy, surgical modifications of upper airway, weight loss, and positional measures to prevent sleeping supine (positional therapy). Initial treatment of OSA requires close monitoring and early identification of difficulties with PAP use (including troubleshooting and monitoring of objective efficacy and usage data to ensure adequate treatment and adherence). Success over the first few days to weeks has been shown to predict long-term adherence.

TABLE 108.1 Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations in contrast to just feeling tired? The situations refer to your usual way of life. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze

1 = slight chance of dozing

2 = moderate chance of dozing

3 = high chance of dozing

What is your chance of dozing in the following situations?

Sitting and reading _____

Watching TV _____

Sitting and inactive in a public place (theater or meeting) _____

As a passenger in a car for an hour without a break _____

Lying down to rest in the afternoon when possible _____

Sitting and talking to someone _____

Sitting quietly after lunch (without alcohol) _____

In a car while stopped for a few minutes in traffic _____

Total _____

Modified from Johns MW: A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale, *Sleep* 14:540-545, 1991.

Central sleep apnea (CSA) is seen in a variety of settings, including periodic breathing in infancy, healthy adults at altitude, and Cheyne-Stokes respirations in heart failure. In most cases of CSA, the cyclic absence of effort is a paradoxical consequence of hypersensitive ventilatory chemo reflex responses that oppose changes in airflow, producing elevated loop gain and leading to overshoot/undershoot ventilatory oscillations. Therapies for CSA affect loop gain by improving lung volumes (PAP therapy), reducing the alveolar-inspired P_{CO_2} difference (stimulants) and lowering chemosensitivity (supplemental oxygen). CSA is further differentiated by a hypercapnic (e.g., brain stem lesions, opioids, obesity hypoventilation syndrome, congenital central alveolar hypoventilation syndrome, neuromuscular disorders, chest wall deformities) or hypocapnic response (e.g., Cheyne-Stokes respiration).

NARCOLEPSY

Narcolepsy is a complex sleep disorder that can manifest in childhood or adolescence. It is the most common cause of excessive daytime sleepiness and can occur in isolation or in combination with other symptoms such as cataplexy, hypnagogic/hypnopompic hallucinations, disturbed nocturnal sleep, and sleep paralysis. Cataplexy distinguishes type 1 (narcolepsy with cataplexy) from type 2 narcolepsy (narcolepsy without cataplexy). Cataplexy is reported by 60% to 75% of patients with narcolepsy and is defined as a transient, sudden-onset loss of skeletal muscle tone with retained consciousness. It is often seen in response to a strong emotion (e.g., laughter, startle, anger). Hypnagogic or hypnopompic hallucinations are vivid, dreamlike sensations that an individual feels, hears or sees and that occur near the onset of sleep (hypnagogic) or upon waking up from sleep (hypnopompic). Sleep paralysis is defined as temporary inability to move or speak while being conscious and that occurs when a person is falling asleep or waking up from sleep.

Pathophysiology

Genetic and environmental factors reportedly play a role in the etiology of narcolepsy. Evidence suggests that the loss of hypocretin is

TABLE 108.2 Agents Promoting Wakefulness

Drug	Dose Range (mg)
Amphetamine (Dexedrine, Desoxyn, Adderall, Adderall XR)	5-60
Methylphenidate (Ritalin, Metadate, Methylin, Concerta)	10-60
Modafinil (Provigil)	200-400
Armodafinil	150-250

highly associated with its development. Hypocretin, a neuropeptide found in the lateral and posterior hypothalamus, targets monoaminergic and cholinergic areas. The loss of hypocretin neurons results in characteristic symptoms of narcolepsy including the inability to sustain long periods of wakefulness and frequent lapses into sleep. Evidence suggests a link between HLA DQB1*06:02 and narcolepsy, indicating an autoimmune basis for narcolepsy that is mediated by hypocretin neurons.

Diagnosis and Differential Diagnosis

Diagnosis of narcolepsy requires a detailed clinical history and diagnostic studies such as an overnight PSG followed by an MSLT. An MSLT with sleep latency of 8 minutes or less and two or more sleep-onset REM periods and the exclusion of other sleep disorders on PSG provide a definitive diagnosis of narcolepsy. The PSG performed the night prior to MSLT is important for excluding other primary sleep disorders such as sleep apnea and periodic limb movement disorder. Abnormal MSLT findings are not specific for narcolepsy and may be produced by other sleep disorders such as sleep apnea, circadian misalignment, other mental or medical conditions, medications or substance use or sleep deprivation. An alternative criterion for diagnosis is a CSF hypocretin level 110 pg/mL or less.

Treatment

Narcolepsy treatment includes a multimodal approach with both nonpharmacologic and pharmacologic components. Pharmacologic therapy includes stimulant therapy, which aims to improve alertness and functioning (Table 108.2). Wake-promoting medications such as modafinil and armodafinil are considered first-line therapy for excessive daytime sleepiness. Sodium oxybate (Xyrem), a precursor for GABA, is the only treatment for cataplexy that has been approved by the FDA. Tricyclic antidepressants (e.g., clomipramine), selective serotonin reuptake inhibitors (e.g., fluoxetine), and serotonin and norepinephrine reuptake inhibitors (e.g., venlafaxine) have all been used to treat cataplexy. Nonpharmacologic treatments include scheduled brief naps, practicing good sleep hygiene, and regular exercise during the day to improve alertness.

IDIOPATHIC HYPERSOMNIA

Definition and Epidemiology

Idiopathic hypersomnia (IH) is a chronic neurologic disorder that manifests as pathologic daytime sleepiness with or without prolonged sleep durations. Etiology of IH is presently unknown, although a genetic predisposition is suggested by the strong family history of similar symptoms. Patients report unrefreshed (i.e., sleep inertia) nocturnal sleep and long daytime naps, and they can have prolonged states of foggy despite long sleep hours (i.e., sleep drunkenness).

Diagnosis and Differential Diagnosis

Diagnosis of IH involves a careful history, with particular attention to the possibility of other disorders with similar symptomatology, and objective testing with sleep studies. Other causes of EDS must be excluded, and the PSG should be normal with no sleep-disordered breathing. MSLT confirms sleep latency of less than 8 minutes but without sleep-onset REM.

Treatment and Prognosis

There are no FDA-approved treatments for IH symptoms, which are typically treated with off-label use of medications approved for narcolepsy.

KLEINE-LEVIN SYNDROME

Kleine-Levin syndrome is a rare, recurrent or cyclic hypersomnia with a prevalence of 1 case per 1 million people. Its cause is unknown. Its onset is usually in the second decade of life.

These episodes of hypersomnia are also associated with other symptoms including hyperphagia, hypersexuality, confusion and hallucinations. Episodes can last days to weeks and reoccur every few months, and at least once a year. Lithium is the choice of medication along with other stimulants and wake-promoting agents (see Table 108.2).

Other symptomatic causes of EDS must be excluded. With time, episodes tend to become less severe, less prolonged, and less frequent.

RESTLESS LEGS SYNDROME, PERIODIC LIMB MOVEMENTS IN SLEEP, AND PERIODIC LIMB MOVEMENT DISORDER

Restless legs syndrome (RLS), also known as Willis-Ekbom disease, is a common neurologic sensorimotor disorder that manifests as an irresistible urge to move the body to relieve the uncomfortable sensations. These sensations always occur during resting, sitting or sleeping. Symptoms commonly worsen at night, causing difficulties with initiating sleep. It is more prevalent in females, and a family history of RLS was detected in 90.9% of the patients with RLS, indicating high heritability.

Periodic limb movements in sleep (PLMS) are polysomnographic findings and are characterized by stereotypical jerks lasting between 0.5 to 10 seconds and occurring at 15- to 40-second intervals. PLMS are present in approximately 80% of patients with RLS. A periodic limb movement index of 15 or greater, when associated with a sleep complaint not accountable by any other sleep disorder, may suggest a periodic limb movement disorder (PLMD).

Clinical Manifestations

Leg movements may be reported by the bed partner, and the patient may report EDS, insomnia, or symptoms of RLS (i.e., urge to move legs or walk due to unpleasant “creepy-crawly” sensations at rest). Most patients with RLS have PLMD, but the reverse is not true.

Treatment and Prognosis

The management of RLS and PLMD involves both nonpharmacologic and pharmacologic approaches. Secondary causes that can aggravate both RLS and PLMD symptoms should be investigated, which includes polyneuropathy, spinal cord disease, pregnancy, iron and B₁₂ deficiencies, uremia, sleep deprivation, irregular sleep schedules, caffeine, nicotine, alcohol, and certain medications (e.g., antihistamines, serotonergic antidepressants, neuroleptics).

Dopamine agonists and alpha₂delta calcium-channel ligands are considered first-line treatments, but these treatments have very

TABLE 108.3 Treatments for Restless Legs Syndrome

Drug	Dose Range (mg)
Levodopa or carbidopa (Sinemet)	50-200
Ropinirole (Requip)	0.25-4.0
Pramipexole (Mirapex)	0.125-0.5
Rotigotine (Neupro) transdermal patch	1-3

different side effect profiles that should be taken into consideration. Doses of dopamine agonists used for RLS treatment are much lower than typical doses in patients with Parkinson’s disease and are timed to be taken approximately 2 hours before typical symptom onset. The starting dose of ropinirole is 0.25 mg/d, then is titrated as follows: 0.25 mg for 2 days, then 0.5 mg for 5 days, then may increase by 0.5-mg increments every week until an effective or maximum dose is achieved, whichever comes first. Doses above 4 mg/d should be avoided in patients with RLS whenever possible. The pramipexole starting dose is 0.125 mg/d, and it may be increased by 0.125-mg increments every 4 to 7 days until symptom control or maximum dose is reached. The maximum recommended RLS dose of pramipexole is 0.75 mg/d (although this is an expert consensus recommendation that differs from the FDA labeling of 0.5 mg/d). Rotigotine is the only dopamine agonist that is dosed via daily transdermal patch, which is initiated at 1 mg/d, and may be escalated to 2 mg/d or 3 mg/d in increments of 1 mg/d every week (Table 108.3).

For a deeper discussion of these topics, please see Chapter 382, “Other Movement Disorders,” in *Goldman-Cecil Medicine*, 26th Edition.

INSOMNIA

Definition and Epidemiology

Insomnia is the most common sleep complaint in the United States, affecting as many as 30 million people in the general population. A diagnosis of insomnia can be present either with or without a comorbid mental or physical disorder. Insomnia is defined as persistent difficulty with sleep initiation, duration, and consolidation, or sleep quality that occurs despite adequate opportunity and circumstances for sleep, and results in some form of daytime impairment. Individuals who report these sleep-related symptoms in the absence of daytime impairment are not regarded as having insomnia disorder that warrants clinical attention other than education and reassurance. The three diagnostic categories for insomnia include chronic insomnia, short-term insomnia, and other insomnia disorder.

Pathophysiology

Acute or short-term insomnia is caused by identifiable factors and can become a chronic, persistent problem. Chronic insomnia results from predisposing (genetic), precipitating (environmental), and perpetuating (behaviors) factors. With the exception of rare conditions such as the prion disease of fatal familial insomnia, insomnia alone is almost never the symptom of a neurologic disease.

Clinical Manifestations

Insomnia may manifest as the inability to fall asleep (i.e., onset insomnia) or to stay asleep (i.e., maintenance insomnia). In addition to nighttime symptoms, the diagnosis demands daytime symptoms considered to be the consequence of insomnia (e.g., fatigue, EDS, poor concentration, altered mood, headache).

TABLE 108.4 Sleep Hygiene

1. Maintain a regular schedule each day.
2. Wake at the same time each morning.
3. Exposure to natural light entrains the circadian rhythm.
4. Exercise in the morning or early afternoon; avoid vigorous exercise in the evening.
5. Avoid napping during the day, especially after 3 PM.
6. Avoid stimulants such as caffeine and nicotine and avoid alcohol close to bedtime.
7. Avoid large meals close to bedtime.
8. Maintain regular and relaxing routines at bedtime.
9. Maintain a comfortable sleep environment.
10. Reserve the bed for sleep; avoid other activities (e.g., TV, radio, reading).
11. Sleep only when sleepy.
12. Try to resolve worries (or list for future thought) before sleeping.
13. Get out of bed if not sleeping in 20 minutes.

Adjustment insomnia is an acute reaction to some type of stress. When the trigger combines with a propensity for poor or fragile sleep, the condition can become chronic (>1 month) and lead to maladaptive behaviors and a conditioned arousal associated with sleep. This is known as *psychophysiological insomnia*, and it is by far the most common insomnia syndrome. A vicious cycle is created by poor sleep habits that worsen the insomnia. Because of its chronicity, it is typically associated with poor sleep habits, multiple treatment trials, and anxiety about sleep. If there was no trigger at onset, there may be a lifelong history of poor sleep (i.e., idiopathic insomnia) with the same end result of psychophysiological insomnia.

Paradoxical insomnia and *sleep-state misperception* are terms applied to patients who claim to not sleep. However, when studied objectively, they have normal sleep amounts and architecture.

Diagnosis and Differential Diagnosis

The diagnosis is based on the history, which should include a sleep diary. Identifiable medical, psychiatric, or drug-related disease and other sleep disorders (e.g., OSA) require exclusion. Sleep studies (PSG and MSLT) are occasionally helpful.

Treatment and Prognosis

Non-drug treatments include commonsense sleep hygiene recommendations (e.g., avoiding caffeine, exercising late in the day) (Table 108.4) and behavior modifications to avoid the conditioned arousal responses associated with sleep (e.g., using the bedroom only for sleep and sex). Other strategies include cognitive behavior therapy specifically for insomnia (CBT-I), relaxation techniques, biofeedback, and behavioral changes such as sleep restriction therapy and stimulus control therapy.

The principles of the pharmacologic treatment of insomnia include using the lowest effective dose, intermittent (not daily) use, using the appropriate (i.e., short or intermediate half-life) drug based on the type of insomnia (i.e., onset or maintenance), and limiting the duration of treatment. Treatment should be tapered to avoid rebound. Medications should be used only in combination with non-drug (i.e., behavioral) treatments. Behavioral treatment has been effective.

Over-the-counter sleep aids (usually antihistamines) are typically safe, but use is limited by anticholinergic and hangover effects. Melatonin may promote sleep and be used for circadian rhythm disorders, including jet lag. The selective melatonin agonist ramelteon is helpful for sleep-onset insomnia.

Prognosis is usually good with the combination of drug and non-drug treatments. Behavior modification may be limited by the willingness of patients to participate.

PARASOMNIAS

Parasomnias are undesirable phenomena that occur in sleep or during transition to or from sleep. They may occur in REM or NREM sleep. They usually consist of complex and seemingly purposeful behaviors, sometimes dramatic, of which the patient is not aware. They are often classified by the sleep stage in which they arise.

NREM Parasomnias

NREM-related parasomnias include confusional arousals, sleep walking (somnambulism), and sleep terrors (pavor nocturnus), and arise as a result of incomplete arousals from deep sleep. They tend to begin in childhood and a family history of similar symptoms is common. The events usually occur during the first third of sleep when delta sleep predominates. Episodes are often triggered by precipitants such as intercurrent illness, sleep deprivation, alcohol use, and stress. Sleep walking episodes typically begin as confusional arousals. These patients often start with sitting up in bed and looking about in a confused manner. Sleep terrors differ from sleep walking in that episodes are more dramatic, with abrupt arousal, a scream or cry and autonomic hyperactivity (e.g., mydriasis, diaphoresis, flushing, piloerection, tachycardia). The child appears terrified and is inconsolable.

Diagnosis and Differential Diagnosis

The main differential diagnosis is nocturnal seizures, which requires video-monitored electroencephalogram (EEG) for diagnosis. Nocturnal seizures tend to be more stereotyped than parasomnias, and they often include tonic or clonic motor activity. Treatment consists of reassurances and measures to avoid injuries during these episodes. Other sleep disorders such as OSA can precipitate these episodes and should be ruled out as part of the treatment. For severe episodes with injurious behaviors, low-dose benzodiazepines such as clonazepam are often recommended.

Treatment and Prognosis

Reassurance and measures to avoid injuries usually are sufficient. For episodes with injurious behaviors, low-dose benzodiazepines (clonazepam, 0.5 to 1 mg) are often effective. Prognosis is good, and most patients do not require treatment.

Rapid Eye Movement Behavior Disorder

Definition and Epidemiology

REM behavior disorder (RBD) is a disorder of REM sleep regulation in which there is a dissociation of REM features with loss of the muscle atonia, leading to patients acting out their dreams. RBD typically affects patients after the age of 50 (usually older) and the male-to-female ratio is 10:1.

Pathophysiology

REM inhibition is lost due to bilateral degeneration of REM atonic neurons in the pons. RBD occurs with α -synucleinopathies (i.e., Parkinson's disease, multiple system atrophy, and dementia with Lewy bodies), and RBD typically heralds these neurodegenerative diseases, sometimes by 10 to 15 years.

Clinical Manifestations

Typically, the episodes are reported by the bed partner and consist of high-amplitude, flailing, injurious behaviors during sleep. When awakened, the patient typically recalls the dream. As is typical of REM arousals, the patient is alert and coherent immediately (unlike slow-wave sleep arousal). Medications, especially psychotropics, can exacerbate RBD.

Diagnosis and Differential Diagnosis

The diagnosis can usually be made by the history alone, and PSG is not needed. When performed, PSG shows a lack of REM atonia or increased phasic and tonic REM. Like slow-wave parasomnias, the main differential diagnosis is nocturnal seizure, and this occasionally requires epilepsy monitoring. Home video (cell phone) recordings can be useful.

Treatment and Prognosis

Low-dose clonazepam (0.5 to 2 mg) is usually effective. Symptoms initially respond to treatment, but a neurodegenerative disease is likely to become evident.

Cortical Syndromes

Sinéad M. Murphy, Timothy J. Counihan

FUNCTIONAL ANATOMY

The cerebral cortex consists of two hemispheres connected by a large band of white matter fibers, the *corpus callosum*. Each hemisphere consists of four anatomically and functionally distinct regions: the frontal, temporal, parietal, and occipital lobes (Fig. 109.1). It is worth considering in some detail the regional functionality of specific brain regions, as they can provide valuable localizing information in assessing patients with cerebral dysfunction syndromes.

- Frontal Lobe: Motor control of the opposite side of the body, attention, executive function, social cognition, language production
- Temporal Lobe: Memory, emotion, speech comprehension
- Parietal Lobe: Sensation for the opposite side of the body, spatial perception
- Occipital Lobe: Vision

Although the two cerebral hemispheres share a number of behavioral and sensorimotor tasks, certain functions, particularly language, manual dexterity, and visuospatial perception are strongly lateralized to one hemisphere. Language function is lateralized to the left hemisphere in 95% of the population; although 15% of people are left-handed, the right hemisphere is dominant for language in only about 10%. Visuospatial perception is largely a function of the right (nondominant) hemisphere. On either side of the central sulcus lie the pre- and post-central gyri; in these regions, cortical representations of the different parts of the body are arranged as the motor (frontal lobe) and sensory (parietal lobe) homunculi (Fig. 109.2). It is worth noting that the juxtaposition of facial and hand representation in the homunculus accounts for the facio-brachial predominant pattern of weakness in syndromes affecting the cerebral lateral convexity such as is seen in many patients with ischemic stroke. Similarly, motor or sensory signs confined to the lower extremities may suggest a parasagittal lesion.

CLINICAL ASSESSMENT

Although lesions in specific regions of the cerebral cortex can result in well-defined syndromes, it is important to be aware of potential pitfalls in interpreting symptoms and signs of cortical origin.

- Patients with lesions of the nondominant hemisphere are often unaware of the extent of their deficit.
- Symptoms and signs caused by cortical lesions may be less consistent than deficits caused by lesions of the spinal cord or more peripheral nerves.

REGIONAL SYNDROMES

Table 109.1 summarizes some of the more common syndromes associated with damage to individual cerebral lobes.

Aphasia

Aphasia or *dysphasia* refers to a loss or impairment of language function as a result of damage to the specific language centers of the dominant hemisphere. It is distinct from dysarthria, which is a disturbance in the articulation of speech. The principal types of aphasia are summarized in Table 109.2.

Clinical assessment for aphasia requires testing of fluency, comprehension, repetition, naming, reading, calculation, and writing. *Anomia* refers to difficulty in the naming of objects. Patients may

TABLE 109.1 Cortical Syndromes and Their Localization

Function	Location	Clinical Signs
Frontal Lobe		
Executive function	Dorsolateral prefrontal cortex	Motor sequencing
Motor function	Primary motor cortex (prefrontal gyrus)	Contralateral weakness
Language	Broca area (inferior frontal cortex)	Expressive aphasia
Behavior	Cingulate (medial frontal lobe)	Obsessive-compulsive traits
	Orbitofrontal	Disinhibition apathy
Oculomotor (frontal eye fields)	Middle frontal gyrus	Forced contralateral eye deviation
Temporal Lobe		
Hearing	Superior temporal gyrus	Auditory hallucinations
Smell	Uncus of temporal lobe	Olfactory hallucinations
Emotion	Amygdala of temporal lobe	Irrational fear
Memory	Hippocampus (medial temporal lobe)	Amnesia; déjà vu
Language	Posterior superior temporal lobe	Wernicke aphasia
Parietal Lobe		
Sensation	Post-central gyrus	Contralateral sensory loss
Visuo-spatial	Posterior parietal lobe	Constructional apraxia
Language	Inferior parietal lobe	Gerstmann syndrome (acalculia, finger agnosia, agraphia, left-right disorientation)
Occipital Lobe		
Vision	Calcarine cortex of occipital lobe	Cortical blindness; visual hallucinations; contralateral homonymous hemianopia

TABLE 109.2 Principal Types of Aphasia

Type	Lesion Site	Fluency	Comprehension	Repetition	Naming	Other Signs
Broca (expressive)	Inferior frontal lobe	↓	Good	↓	↓	Contralateral weakness
Wernicke (receptive)	Posterior superior temporal lobe	Good	↓	↓	↓	Homonymous hemianopia
Transcortical motor	Inferior frontal gyrus	↓	Good	Good	May be normal	May be contralateral weakness
Transcortical sensory	Middle temporal gyrus, thalamus	Good	↓	Good	Usually normal	May be normal
Conduction	Supramarginal gyrus	Good	Good	↓	↓	None
Global	Frontal lobe (large)	↓	↓	↓	↓	Hemiplegia

↓, Reduced.

have difficulty with the correct identification of common items such as a watch, often using a word that either sounds like the intended word (“a spotch”—a literal paraphasic error) or a word with a broadly similar meaning (“a clock”—a semantic paraphasic error). There are two broad types of aphasia depending on the anatomic site of the lesion: anterior (Broca) aphasia and posterior (Wernicke) aphasia.

Broca aphasia is characterized by a severe disruption in the fluency of speech, with profound impairments of expression in both speech and writing. Comprehension may be mildly affected. The language disturbance is almost invariably accompanied by contralateral face and arm weakness as a result of the proximity of the motor homunculus to the Broca speech area in the inferior frontal lobe.

Wernicke aphasia is characterized by an inability to comprehend spoken or written language. Affected patients speak fluently, but the content is meaningless. The lesion is located in the posterior superior temporal area and may be associated with a homonymous hemianopic visual field deficit.

Conduction aphasia is characterized by normal comprehension and fluent speech but a striking inability to repeat a phrase. The responsible lesion lies in the arcuate fasciculus connecting the Broca and Wernicke areas. *Global aphasia* results from large lesions of the frontal lobe; all aspects of language are affected. Lesions of the language areas of the nondominant hemisphere result in *dysprosody*. For instance, patients with lesions in the inferior frontal lobe of the nondominant hemisphere, analogous to the Broca area, speak with a monotonous voice, losing the ability to add emotional cadence to their speech. Similarly, lesions affecting the nondominant Wernicke area result in patients failing to pick up on the emotional inflexions (such as anger) of what is said to them.

Writing is almost invariably affected in patients with disturbances of language (Fig. 109.3). An exception to this occurs in the syndrome of *alexia without agraphia*, which results from a lesion in the dominant occipital lobe and splenium of the corpus callosum (usually caused by infarction in the territory of the posterior cerebral artery). The patient’s language center is “disconnected” from the contralateral (unaffected) visual cortex. Such patients can write a sentence but are unable to read what they have written.

Agnosia and Apraxia

Agnosia is the inability to recognize a specific sensory stimulus despite preserved sensory function. For instance, visual agnosia is the inability to recognize a visual stimulus despite normal visual acuity. Other agnosia syndromes include the inability to recognize sounds (auditory agnosia), color (color agnosia), or familiar faces (prosopagnosia). Usually, the responsible lesions are located in the occipitotemporal region.

Fig. 109.3 Neologisms written by a patient with aphasia who was attempting to name cell phone, keys, camera, watch, pen, bag, and boots.

Apraxia refers to an inability to perform learned motor tasks despite sufficient sensorimotor function to physically execute the movement; it is a disorder of motor planning (Fig. 109.4). The responsible lesions are usually in the dominant inferior parietal lobe. A simple test of apraxia is to ask the patient to perform a pantomime (e.g., combing the hair, blowing out a candle). Lesions of the nondominant parietal lobe often result in *hemispatial neglect*: the patient does not attend to stimuli in the contralateral (usually the left) visual field or on the contralateral side of the body. In a milder form of neglect, called *extinction*, patients can attend to stimuli contralateral to the side of the brain with the lesion (typically the right hemisphere), but

Copy this cube:

Draw a clock, fill in the numbers and put the time at ten after 2:

Fig. 109.4 Attempts to copy a cube and draw a clock by patients with neurodegenerative disorders demonstrate constructional apraxia and right-sided neglect.

when presented with bilateral stimuli simultaneously, they respond to stimuli only on the right hemibody side. *Anosognosia*, or the lack of awareness of one's deficit, frequently accompanies hemispatial neglect. In severe cases, patients may even deny that the affected limb belongs to them. Patients with anosognosia may present a challenge to rehabilitation therapists.

PROSPECTUS FOR THE FUTURE

Recent advances in neuroimaging technology have added to our understanding not only of the structural and functional anatomy of the brain but also its metabolic activity. Functional magnetic resonance imaging (fMRI) permits mapping of the metabolic anatomy of subcortical gray and white matter structures, such as the basal ganglia, and their roles in conditions such as dystonia. Furthermore, a modality known as diffusion tensor imaging allows for the mapping of white matter tracts (tractography) in great detail.

Several new strategies are emerging in an attempt to reverse the deficit in self-awareness in patients with neglect or anosognosia resulting from degenerative or ischemic lesions of the nondominant hemisphere. The development of virtual reality computer interface programs has opened the possibility to generate a variety of computer-based simulation environments to provide patients with detailed feedback options to improve self-awareness as part of a rehabilitation program.

Dementia and Memory Disturbances

Frederick J. Marshall

MAJOR DEMENTIA SYNDROMES

Dementia places an enormous burden on the patient, family, and society. A third of older adults in the United States die of Alzheimer disease (AD) or other form of dementia, but only one in six older adults receives routine cognitive screening. The annual direct and indirect expenditure for AD and other dementias in the United States was \$290 billion in 2019.

The term *dementia* refers to a syndrome of progressive cognitive decline leading to the loss of fully independent function in daily life. Memory loss is the most common central feature, and specific dementia syndromes characteristically cause particular forms of memory impairment. Different dementias produce specific abnormalities of cognition in language, spatial processing, praxis (the ability to execute learned motor behaviors), and executive function (the ability to plan and sequence thoughts and activities), and many have associated non-cognitive features. *Cortical dementia* and *subcortical dementia*, although older terms, remain helpful for subdividing the dementias (Table 110.1).

Neurodegeneration is the most common underlying cause of dementia. Table 110.2 provides the differential diagnosis of neurodegenerative causes of dementia. Table 110.3 outlines other causes of dementia.

Most causes of dementia are currently untreatable. Potentially correctable causes account for less than 5% of dementia cases. Structural processes or infections must be considered, along with metabolic and nutritional diseases. Every patient with dementia should have tests of serum electrolytes and vitamin B₁₂ and assessments of liver, renal, and thyroid function. Serologic studies for syphilis, human immunodeficiency virus (HIV), and Lyme exposure should be done if risk factors are identified. Chronic infections (see Chapter 92), normal-pressure hydrocephalus (NPH), and autoimmune encephalopathies should be considered. Brain imaging should be performed.

Neuropsychological testing characterizes the pattern of cognitive and memory impairments and is helpful in the differential diagnosis. The Montreal Cognitive Assessment (MoCA) (Table 110.4) is a standard test that can be used as a bedside or office screening tool for identifying patients with dementia. It typically takes about 10 minutes to administer. This examination is superior to the Mini-Mental Status Examination (MMSE) in that it is more sensitive to abnormalities in a wider array of cognitive domains, including visual-spatial or executive function, naming, attention, fluency; abstract reasoning, short-term memory encoding and retrieval, and orientation.

In addition to the MoCA, patients with dementia should have tests of praxis (e.g., show how you would comb your hair; show how you would blow out a match) and neglect (e.g., testing of double-simultaneous extinction to visual, tactile, and auditory stimuli). Depending on

the results of these screening procedures, more detailed neuropsychological studies can be pursued.

Alzheimer Disease

AD accounts for approximately 70% of dementia cases among older adults. There is widespread confusion among the lay population about the relationship between the terms *Alzheimer disease*, *senility*, and *dementia*. Patients and their family members often need clarification. *Alzheimer disease* (a specific diagnosis) is only one possible cause (albeit by far the most common cause) of *dementia* (a syndrome). Nearly six million persons in the United States are affected, and this number is estimated to approach 14 million by 2050 as the population ages. The disease occurs in 32% to 47% of persons older than 80 years of age. Incidence at age 65 is one in 200 people per year. Incidence at age 80 is one case per 10 people per year. More than 50% of caregivers develop depression or a major medical illness. Deaths from heart disease decreased 9% between 2000 and 2017, while deaths from AD increased 145%.

AD has many causes, but none is fully defined. All causes produce similar clinical and pathologic findings. The disease is characterized by the progressive loss of cortical neurons and the formation of amyloid plaques and intraneuronal neurofibrillary tangles. β -Amyloid (A β) is the major component of the plaques, while hyperphosphorylated tau protein is the major constituent of the neurofibrillary tangles. The process starts in the hippocampus and entorhinal cortex and spreads to involve diffuse areas of association cortex in the temporal, parietal, and frontal lobes. The relative deficiency of cortical acetylcholine (resulting from the loss of neurons in the nucleus basalis) provides the rationale for symptomatic treatment of the disease with centrally acting acetylcholinesterase inhibitors.

Pathogenesis

AD is often categorized as a young-onset hereditary or familial form, which is rare (\approx 5% overall) and for which three specific genetic abnormalities have been determined, or as a common (\approx 95% overall), sporadic form that typically occurs in persons older than 65 years of age (Table 110.5).

The autosomal dominant early-onset forms of AD have in common abnormalities of A β production and processing that have provided clues to the molecular pathogenesis of sporadic AD. Abnormal processing of amyloid precursor protein into the amyloidogenic peptide A β (1-42) is thought to be important in the pathogenesis of AD. It is thought to provoke downstream abnormalities of tau protein processing, with hyperphosphorylation of tau yielding intraneuronal tangles.

The apolipoprotein E (Apo E) gene (*APOE*) is a susceptibility locus for sporadic AD in late-onset familial AD pedigrees. The gene is

TABLE 110.1 Distinguishing Characteristics of Cortical and Subcortical Dementias**Cortical Dementia**

Symptoms: major changes in memory, language deficits, perceptual deficits, praxis disturbances

Affected brain regions: temporal cortex (medial), parietal cortex, and frontal lobe cortex

Examples: Alzheimer disease, diffuse Lewy body disease, vascular dementia, frontotemporal dementias

Subcortical Dementia

Symptoms: behavioral changes, impaired affect and mood, motor slowing, executive dysfunction, less severe changes in memory early on in the course

Affected brain regions: thalamus, striatum, midbrain, striatofrontal projections, subcortical white matter

Examples: Parkinson's disease, progressive supranuclear palsy, normal-pressure hydrocephalus, Huntington's disease

TABLE 110.2 Etiologic Diagnosis of Neurodegenerative Dementia in Adults

polymorphic ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$), and first-degree relatives of AD patients who inherit both $\epsilon 4$ alleles have a greater than 60% lifetime risk of developing AD. Apo E- $\epsilon 4$ interacts selectively with A β and with tau protein, but how Apo E- $\epsilon 4$ increases the risk of AD remains unknown.

Clinical Features

AD begins gradually and affects memory, orientation, language, visuospatial processing, praxis, judgment, and insight. Depression is common early in AD, and psychosis with agitation and behavioral disinhibition often occur in advanced stages. Patients become dependent on others for all activities of daily living. The rate of progression of AD varies but usually takes 5 to 15 years to progress from presentation to advanced illness.

Diagnostic criteria are outlined in Table 110.6. Although a definitive diagnosis of AD requires biopsy (rarely done) or autopsy confirmation, these diagnostic criteria establish the diagnosis with more than 85% specificity in moderately demented patients.

There are now three different positron emission tomography (PET) ligands that bind to A β plaques approved by the US Food and Drug Administration (FDA) for use in the clinical diagnosis of AD.

These compounds are costly, however, and not universally approved by insurances, limiting their utility in clinical practice. Cerebral amyloid accumulation is largely completed at a relatively early stage of AD when patients may be asymptomatic or have only isolated impairment of memory but no overt loss of independent function in daily life (a stage known as *mild neurocognitive disorder*). Research efforts are underway to find disease modifying approaches that ameliorate plaque and possibly prolong the time to patients' loss of independence.

Another protein, known as *tau*, plays an important role in the stabilization of microtubules involved in the transport of nutrients and other substances within the neuron. In AD, tau becomes hyperphosphorylated and forms intraneuronal neurofibrillary tangles that cannot be effectively disposed of by the cell. Smaller forms of tau (oligomers) are known to circulate among neurons and interfere with their function and can be found in AD brains more than a decade prior to symptom onset. Because tau continues to accumulate throughout the course of AD, it is a potentially useful marker of disease progression. The FDA has recently approved a PET ligand that binds to tau.

TABLE 110.4 Elements of the Montreal Cognitive Assessment

Cognitive Domain	Items	Score
Visual-spatial or executive	Complete a trail-making task, copy a cube, draw a clock	5
Naming	Name three depicted animals	3
Attention	Recall five digits forward, three digits backward, maintain letter vigilance, subtract 7s serially	6
Language	Repeat two phrases, generate a list of words starting with a specific letter	3
Abstraction	Identify the similarity between nouns (train/bicycle; watch/ruler)	2
Delayed recall	Recall five words rehearsed twice previously (face, velvet, church, daisy, red)	5
Orientation	Identify the date, month, year, day, place, and city	6
Total possible score		30

A score of 26 or greater is considered normal.

From Nasreddine ZS, Phillips NA, Bedirian V, et al: The Montreal Cognitive Assessment, MoCA: a brief screening tool for mild cognitive impairment, *J Am Geriatr Soc* 53:695-699, 2005.

TABLE 110.5 Familial Versus Sporadic Alzheimer Disease

Chromosome and Gene	Age at Onset (Yr)	% of All FAD Cases	% of All SAD Cases
Familial Alzheimer Disease^a			
Chromosome 1, <i>PSEN2</i> (presenilin 2)	40-80	5-10	<0.5
Chromosome 14, <i>PSEN1</i> (presenilin 1)	30-60	70	<1
Chromosome 21, <i>APP</i> (amyloid- β precursor protein)	35-65	5	<0.5
Sporadic Alzheimer Disease^b			
No single determinant gene ^c	Usually >60	—	98

^aFamilial Alzheimer disease (FAD) has early onset and is autosomal dominant.

^bSporadic Alzheimer disease (SAD) has late onset and may be polygenetic and/or environmental.

^cApolipoprotein E- ϵ 4 allele on chromosome 19 increases the risk compared with the ϵ 2 or ϵ 3 allele.

TABLE 110.6 Diagnostic Criteria for Probable Alzheimer Disease

Progressive functional decline and dementia established by clinical examination and mental status testing and confirmed by neuropsychological assessment
Insidious onset
Clear-cut history of worsening cognition by report or observation
Initial and most prominent cognitive deficits evident on history and examination in one of the following categories:
Amnesic presentation (plus at least one other domain)
Nonamnesic presentations (plus deficits in other domains): language, visuospatial, executive dysfunction
No evidence of vascular dementia, dementia with Lewy bodies, frontotemporal dementias, or other concurrent active neurologic or non-neurologic medical comorbidity or use of medication that could have a substantial effect on cognition

Tau has been implicated in several other neurodegenerative diseases, but the abnormal tau in these diseases is not identical. Along with AD, these diseases are sometimes referred to as *tauopathies*. These include: chronic traumatic encephalopathy (CTE), corticobasal-ganglionic degeneration (CBGD), frontotemporal dementia with parkinsonism-17 (FTDP-17), Pick disease, and progressive supranuclear palsy (PSP) (see later for further discussion).

Analysis of cerebrospinal fluid (CSF) for A β , total-tau, and phosphorylated-tau protein levels has been commercialized as an aid to diagnosis. Because amyloid plaques accumulate extraneuronally and sequester soluble A β , the level of A β found in CSF samples from patients with AD is lower than normal. Alternatively, tau is intraneuronal and is released into the CSF when neurons die, thereby increasing the level of tau in CSF from patients with AD and a variety of other diseases that involve neuronal cell death. In AD, the ratio of CSF tau to

CSF A β goes up. Because of the invasive nature of the testing (involving a spinal tap) and the relatively high pretest probability of AD in older individuals with dementia who meet diagnostic criteria, CSF analysis is more commonly performed in young-onset patients.

Treatment

Although their benefits are modest, the cholinesterase-inhibiting drugs donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne) represent important advances. These drugs may be given in once-daily formulations. Rivastigmine is also available as a transdermal patch.

In clinical trials, cholinesterase inhibitors benefited less than 50% of patients. They have not been shown to prevent AD in patients with mild cognitive impairment (MCI), a condition in which the memory or another domain of cognition is impaired in the absence of meaningful

dysfunction in daily life. Approximately 12% of patients with MCI go on to develop AD per year, with roughly two thirds of patients with MCI developing clinical AD within 5 years of symptom onset.

The glutamate antagonist memantine (Namenda) has been shown to prolong daily function in patients with moderate to advanced AD.

Treatment strategies in clinical trials over the past decade have included decreasing A β peptide production by blocking α -secretase or β -secretase or upregulating cleavage of the amyloid precursor protein at the α -secretase site. Studies of active and passive immunization have been designed to lower brain A β levels. However, these approaches have failed to deliver on the promise of disease modification, necessitating a wide-reaching reassessment of current theories of disease pathogenesis.

Nursing services provide oversight of hygiene, nutrition, and medication compliance. Antipsychotics, antidepressants, and anxiolytics are useful for patients with behavioral disturbances, which are the most common cause of nursing home placement. Patients and families can be referred to a local Alzheimer's Association chapter for further information on available community support.

Prevention

There is relatively strong epidemiologic evidence, but no well controlled prospective randomized clinical trial evidence, that the following five things lower the lifetime incidence of dementia in populations: (1) alcohol in moderation (no more than one drink per day), (2) cardiovascular risk-factor mitigation, (3) regular socialization, (4) Mediterranean diet, and (5) regular exercise (three times weekly to the point of sweating). There is some epidemiologic evidence that statin medications and fish oil lower the risk of AD in populations (though there are individuals for whom statins may provoke encephalopathy). There is randomized clinical trial evidence that *gingko biloba* does not have benefit in AD. There is a moderate level of scientific evidence that conjugated equine estrogen with methyl-progesterone increases the risk of AD. There is a low level of scientific evidence that some nonsteroidal anti-inflammatory drugs, depressive disorder, diabetes mellitus, hyperlipidemia in midlife, current tobacco use, traumatic brain injury, pesticide exposure, and relative social isolation increase the risk of AD.

Diffuse Lewy Body Disease

Lewy bodies are pathologic intraneuronal alpha-synuclein inclusions that are the hallmark of Parkinson's disease when they are restricted to the brain stem (see [Chapter 116](#)). Patients with diffuse Lewy body disease have clinical parkinsonism (i.e., slow movement, rigidity, and balance problems) combined with early and prominent dementia. Pathologically, Lewy bodies are found in the brain stem, limbic system, and cortex. Visual hallucinations and cognitive fluctuations are common, and patients are unusually sensitive to the adverse effects of neuroleptic medication.

Diffuse Lewy body disease may represent the second most common cause of dementia after AD. However, the common concurrence of the pathologic features of diffuse Lewy body disease with the classic neuritic plaques and neurofibrillary tangles of AD complicates the identification of the cause of dementia in a given patient.

Vascular Dementia

Approximately 10% to 20% of older patients with dementia have radiographic evidence of focal stroke on magnetic resonance imaging (MRI) or computed tomography (CT), combined with focal signs on the neurologic examination. When the dementia syndrome begins with a stroke and progression of the illness is stepwise (suggesting recurrent vascular events), the diagnosis of vascular dementia is likely.

Patients typically develop early incontinence, gait disturbances, and flattening of affect. A subcortical dementing process attributed to small vessel disease in the periventricular white matter has been referred to as *Binswanger disease*, but it may be a radiographic finding rather than a true disease. Appropriate treatment of risk factors for vascular disease—blood pressure control, smoking cessation, diet modification, and anticoagulation (in select settings such as atrial fibrillation)—is mandatory and may be of benefit.

Frontotemporal Dementias

Patients with the behavioral variant of frontotemporal dementia (FTD) are frequently socially disinhibited, but they may also be lethargic and lack motivation and spontaneity. Patients with the progressive non-fluent aphasia variant of FTD have loss of speech fluency with poor articulation and syntactic errors but relative preservation of comprehension. Those with the semantic dementia variant of FTD remain fluent with normal phonation but have progressive difficulty with naming and word comprehension. Memory and spatial skills and praxis are relatively preserved early on in all of these forms, whereas executive function, emotional regulation, and conduct are relatively impaired.

There are several frontotemporal lobar degenerations (FTLDs), including Pick disease (now referred to as FTLD-tau). In some families, a mutation in the microtubule-associated protein tau gene (*MAPT*) on chromosome 17 causes tau-positive frontotemporal dementia with parkinsonism (FTDP-17). Transactive response DNA-binding protein (TDP-43) pathology accounts for 40% of FTD with or without motor neuron disease. Although mutations in the fused sarcoma gene (*FUS*) had previously been identified as a cause of familial amyotrophic lateral sclerosis (ALS), some also give rise to 5% to 10% of clinically diagnosed FTD (typically the behavioral variant). Hexanucleotide repeat expansions in *C9orf72* cause neurodegeneration in FTD and ALS. RNA processing is abnormal in both conditions.

As in AD, all forms of FTD progress over years. No intervention slows the inevitable decline of these patients. Approximately 50% of patients have a family history of the disease.

Parkinson's Disease

The majority of patients with Parkinson's disease (see [Chapter 116](#)) become demented in the later stages of illness. The dementia of Parkinson's disease affects executive function out of proportion to its impact on language. Thought processes appear to slow down (*bradyphrenia*), analogous to the slowing of movement (*bradykinesia*).

Because dementia occurs relatively late in the progression of Parkinson's disease, most patients are taking drugs to improve their movement disorder by enhancing dopaminergic neurotransmission. These drugs can induce psychosis. Dose reductions should be attempted before the diagnosis of underlying dementia is made for these patients. Acetylcholinesterase inhibition has been helpful for patients with dementia caused by Parkinson's disease, and the FDA has specifically approved rivastigmine for this indication.

Normal-Pressure Hydrocephalus

The triad of dementia (typically subcortical), gait instability, and urinary incontinence suggests the possibility of normal-pressure hydrocephalus. These patients appear to walk with their feet stuck to the floor, without lifting up the knees and with a broad base. Symptoms evolve over the course of weeks to months, and brain imaging reveals ventricular enlargement out of proportion to the degree of cortical atrophy.

Numerous diagnostic tests have been described, including radio-nuclide cisternography and MRI flow studies. The most important test remains the clinical response to removal of large volumes of CSF

through serial lumbar punctures or the temporary placement of a lumbar drain, followed by examination of the patient's gait and cognitive function. Neurosurgical placement of a permanent ventriculoperitoneal shunt may correct the problem. Patients likely to benefit from shunt placement have a clear response to the removal of 30 to 40 mL of spinal fluid, with improved gait and alertness within minutes to hours of the procedure. The cause of normal-pressure hydrocephalus is a derangement of the CSF hydrodynamics. Shunt placement is most likely to be effective if normal-pressure hydrocephalus occurs after severe head trauma or subarachnoid hemorrhage.

Prion Infection, Chronic Meningitis, and Dementia Related to Acquired Immunodeficiency Syndrome

Creutzfeldt-Jakob disease (CJD) is a subacute, dementing, transmissible illness with typical onset between 40 and 75 years of age and an incidence of one case per 1 million people (see [Chapter 92](#)). The disease causes spongiform degeneration and gliosis in widespread areas of the cortex. Clinical variants of the disorder are differentiated by the relative predominance of cerebellar symptoms, extrapyramidal hyperkinesias, or visual agnosia and cortical blindness (*Heidenhain variant*).

Ninety percent of patients with CJD have myoclonus, compared with 10% of patients with AD. Patients with all forms of the disease share a relentlessly progressive dementia and disruption of personality over weeks to months. The electroencephalogram shows characteristic abnormalities, including diffuse slowing and periodic sharp waves or spikes.

The transmissible agent, a prion protein, is invulnerable to routine modes of antiseptics. CSF can be tested for the 14-3-3 protein, although this test is not as sensitive or specific for CJD as once hoped. Real-time quaking-induced conversion (RT-QuIC) assays are currently considered more sensitive and specific but can be adversely affected if the protein, red or white cell count in the CSF sample studied is elevated.

Certain infectious agents can cause the subacute or chronic development of subcortical dementia. These chronic meningitides are discussed in [Chapter 92](#).

Human immunodeficiency virus accesses the central nervous system through monocytes and the microglial system and causes associated neuronal cell loss, vacuolization, and lymphocytic infiltration. The dementia associated with this infection is characterized by bradyphrenia and bradykinesia. Patients have executive dysfunction, impaired memory, poor concentration, and apathy. Treatment of the underlying viral infection with effective antiretroviral therapy may slow the progression of the dementia (see [Chapter 103](#)).

There is increasing recognition of the potential for abnormal production of antibodies misdirected against brain epitopes to cause encephalopathy that can sometimes mimic classical dementia. Waxing and waning mental status rather than insidious progression of cognitive decline should prompt consideration of this category of illness as should cancer comorbidity, a history of autoimmune disease, or seizures in a patient presenting with cognitive changes. CSF should be sent for analysis to centers specializing in this emerging area of neuroimmunology.

OTHER MEMORY DISTURBANCES

Structure of Memory

Memory function is divided into introspective processes (i.e., declarative, explicit, aware memories) and processes that are not accessible to introspection (i.e., nondeclarative, implicit, procedural memories). Short-term memory (e.g., words on a list) is a form of declarative memory. Other forms include the conscious recall of episodes from personal experience (i.e., episodic memory) and factual knowledge

(i.e., semantic memory) that can be consciously recalled and stated (i.e., declared). Declarative memory involves consciously *knowing that...* Patients with amnesia resulting from lesions of the medial temporal lobes or midline diencephalic structures have deficits of declarative memory.

Nondeclarative memory encompasses several distinct and neuroanatomically less clearly localized functions related to the performance of specific learned motor, cognitive, or perceptual tasks. Nondeclarative (procedural) memories involve unconsciously *knowing how...* Deficits in nondeclarative memory may involve various areas of association neocortex, depending on the nature of the task (e.g., parietal-temporal-occipital junction cortex for visual perceptual tasks, frontal association cortex for motor tasks). Patients with amnesia resulting from lesions of the medial temporal lobes tend to perform normally on tests of nondeclarative memory.

Anterograde amnesia is the inability to learn new information. It commonly occurs after brain injury or in association with dementia. The inability to recollect prior information is retrograde amnesia. Both types of amnesia usually occur together in brain injury syndromes, although the extent of one type or the other may vary. The degree of anterograde amnesia after head injury correlates with the severity of the injury.

Isolated Disorders of Memory Function

Memory can be impaired in relative isolation as a consequence of head injury, thiamine deficiency (i.e., Korsakoff syndrome), benign forgetfulness of aging, transient global amnesia, or psychogenic disease.

Head injury typically results in retrograde amnesia in excess of anterograde amnesia, with both forms stretching out over time from the discrete event. As time passes, these disrupted memories gradually return, although rarely to the point at which the events immediately surrounding the trauma are recalled.

Korsakoff syndrome is characterized by the near-total inability to establish new memory. Patients often confabulate responses when they are asked to convey the details of their current circumstance or to relay the content of a recently presented story. Deficiency of thiamine and other nutritional deficiencies in the context of chronic alcoholism are the most common underlying causes. Thiamine is a necessary cofactor in the metabolism of glucose, and thiamine must be replenished at the same time glucose is administered whenever a comatose patient is seen in the emergency department.

Aging is associated with mild loss of memory, exhibited by difficulty in recalling names and by forgetfulness for dates. Population-based assessments of neuropsychological function have demonstrated that poor performance on delayed-recall tasks is the most sensitive indicator of cognitive change with advancing age. Verbal fluency, in contrast, remains intact with advancing age, and vocabulary may increase with time, even into old age.

Transient global amnesia is a dramatic memory disturbance that affects older patients (>50 years). Patients usually have only one episode; occasionally, episodes recur over the course of several years. Patients have complete temporal and spatial disorientation; orientation for person is preserved. Near-total retrograde and anterograde amnesia persists for various periods, typically 6 to 12 hours. Patients are often anxious and may repeat the same question over and over again. Transient global amnesia may be confused with psychogenic amnesia, fugue state, or partial complex status epilepticus. Transient global amnesia is thought to reflect underlying vascular insufficiency to the hippocampus or midline thalamic projections.

Unlike patients with organic memory disturbances, patients with psychogenic amnesia typically have inconsistent loss of recent and remote memory, relatively more loss of emotionally charged memory

(rather than relatively less loss of such memory in organic disease), and an apparent indifference to their own plight; they ask few questions. Most characteristically, patients with psychogenic amnesia tend to express disorientation to person (asking, *Who am I?*), a phenomenon seldom seen in organic memory disturbance.

Patients with severe depression may exhibit pseudodementia. Vegetative signs, including changes in appetite, weight, and sleep pattern, are common, whereas signs of cortical impairment, such as aphasia, agnosia, and apraxia, are rare. Memory and bradyphrenia improve with antidepressant therapy. Depression often coexists with other causes of dementia, such as AD, Parkinson's disease, and vascular dementia.

❖ For a deeper discussion on this topic, please see Chapter 374, "Cognitive Impairment and Dementia," in *Goldman-Cecil Medicine*, 26th Edition.

Major Disorders of Mood, Thoughts, and Behavior

Jeffrey M. Lyness, Jennifer H. Richman

CLASSIFICATION OF MENTAL DISORDERS

Mental (psychiatric) disorders are alterations in thoughts, feelings, or behaviors that produce substantive subjective distress or affect the patient's functional status. Many mental disorders are caused by the direct effects of drugs, systemic disease, or neurologic disease on brain physiology. They may be broadly considered as secondary psychiatric disorders, as opposed to the primary or idiopathic psychiatric disorders. The distinguishing feature of neurocognitive disorders is impairment in intellectual functions such as level of consciousness, orientation, attention, or memory; however, these disorders also often include disruption of mood, thoughts, and behaviors similar to that seen in other psychiatric syndromes. Neurocognitive disorders are the focus of [Chapter 126](#).

The noncognitive secondary syndromes by definition cause psychiatric phenomena similar to their idiopathic counterparts. During the evaluation of any patient with new or worsened psychiatric symptoms, it is essential to conduct a thorough evaluation for other medical causes, including a careful history and physical examination (with a screening neurologic examination) that often are supplemented by laboratory evaluations. [Table 111.1](#) outlines important causes of psychiatric syndromes. Although some conditions are likely to produce certain psychiatric syndromes, many manifest as any of several psychiatric syndromes. Conversely, a psychiatric syndrome may be caused by a wide range of conditions.

Because the cause of primary psychiatric disorders is unknown, approaches to classification depend on reliable empirical observations of phenomena clustered into recognizable syndromes. [Table 111.2](#) shows the most important psychiatric syndromes and the disorders in which they may manifest. [Table 111.3](#) shows the major idiopathic disorders, excluding addictive disorders (see [Chapter 128](#)). Many psychiatric disorders manifest with multiple syndromes. For example, major depression with psychotic features manifests with a depressive syndrome and a psychotic syndrome. In evaluating a patient with new or worsened psychiatric symptoms, the clinician must construct a differential diagnosis based on syndromes alongside the differential diagnosis based on potential secondary causes.

DEPRESSIVE AND BIPOLAR DISORDERS

Depressive and bipolar disorders are characterized by idiopathic episodes of depression alone (i.e., unipolar) or mania and depression (i.e., bipolar). The core symptoms of depressive episodes include emotional symptoms (e.g., dysphoria, irritability, anhedonia, loss of interests), ideational symptoms (e.g., thoughts with hopeless, worthless, guilty, or suicidal themes), and neurovegetative symptoms and signs (e.g., anergia; psychomotor slowing or agitation; decreased concentration; altered sleep, appetite, and weight).

Major depressive disorder is defined by episodes of at least five symptoms, including depressed mood, anhedonia, or loss of interests, that occur almost every day for at least 2 consecutive weeks, sufficient to cause significant distress and affect functional status. Other prominent symptoms may include associated anxiety, somatic worry, or new somatic symptoms, and in the most severe cases, psychotic symptoms, including nihilistic or self-deprecatory (i.e., mood-congruent) delusions.

Major depression is common, with a 12-month prevalence of approximately 7% and a lifetime prevalence of up to 10% among men and 20% to 25% in women. New depressive episodes have an annual incidence of approximately 3%. First onset may occur at any age but is most common in the third through fifth decades of life. Whereas most episodes of major depression fully remit spontaneously or with treatment, the lifetime risk of recurrence is at least 50% to 70%, and up to 20% of patients may experience chronic symptoms over many years. Major depression is a leading correlate of disability worldwide, is an important determinant of death by suicide, and is associated with increased risk of death from comorbid physical illnesses. Major depression also causes significant economic burden, costing approximately 210.5 billion inflation-adjusted dollars in the United States alone in 2010. Persistent depressive disorder (i.e., dysthymia) is a condition defined by chronic depressive symptoms, often of insufficient severity to meet criteria for major depression.

Depressive disorders are heterogeneous, with many potential pathogenic mechanisms. Genetic factors, such as polymorphisms of the serotonin transporter protein, affect vulnerability to depressive episodes in the face of psychosocial stressors. Depression is polygenic and multifactorial, with genetic factors accounting for about 40% of the risk. Alterations in the functioning of brain serotonergic and noradrenergic systems and of the hypothalamic-pituitary-adrenal axis are found in depression. Neuroimaging studies show smaller hippocampal volumes and altered metabolic activity in several regions, including the anterior cingulate cortex. However, the information in these studies is not sufficient for making the clinical diagnosis, which depends on identification of the clinical syndrome. Dysfunctional, negativistic patterns of thinking, impaired social relationships, and stressful life events also contribute to depression.

Mild to moderate forms of major depression respond to focused psychotherapies or antidepressant medications ([Table 111.4](#)). More severe forms of depression do not respond to psychosocial interventions alone. Severe or refractory depression may be treated safely and effectively with electroconvulsive therapy. Other evidence-based somatic therapies include light therapy (for depression with a seasonal component) and vagal nerve stimulation. Data suggest that the dissociative anesthetic ketamine, an *N*-methyl-D-aspartate (NMDA)

receptor antagonist, may rapidly improve patients with treatment-resistant depression, although the general clinical applicability of ketamine remains to be determined.

Bipolar disorder (i.e., bipolar I) is characterized by recurrent episodes of mania, usually with episodes of major depression. Manic episodes include elevated (euphoric) or irritable mood, goal-directed hyperactivity (often for pleasurable activities with poor judgment leading to substantial adverse consequences such as sexual, spending, or gambling sprees), pressured speech, increased energy level with a decreased need for sleep, and distractibility.

Compared with unipolar depression, bipolar disorder has a lower 12-month prevalence (approximately 0.6%) and a younger average age of onset (typically late teens to 20s). Unlike unipolar depression, bipolar disorder is slightly more common among males. Most patients return to baseline functioning between acute mood episodes, but some have a deteriorating course, and others have frequent debilitating episodes (i.e., rapid cycling of four episodes per year).

Genetic factors play a greater role in the pathogenesis of bipolar disorder than in major depressive disorder, accounting for approximately 50% of the risk and representing a greater than 50-fold increase over the population base rate. Bipolar disorder is polygenic and has been linked in individual families to different loci. The pathogenesis is unclear but likely involves dysregulation of frontostriatal systems. Structural neuroimaging studies show increased ventricular-to-brain ratios, suggesting parenchymal atrophy. Psychosocial stressors often play a role in precipitating episodes of mania and depression.

The mainstay of treatment for bipolar disorder is mood stabilizer medications (e.g., lithium, anticonvulsants such as valproic acid and

TABLE 111.2 Important Psychiatric Syndromes

Syndrome	Main Symptoms and Signs	Disorders
Neurocognitive	Impairment in intellectual functions (e.g., level of consciousness, orientation, attention, memory, language, praxis, visuospatial, executive functions)	Neurocognitive disorders Intellectual disability (if onset in childhood)
Mood	Depressive: lowered mood, anhedonia, negativistic thoughts, neurovegetative symptoms Manic: elevated or irritable mood; grandiosity; goal-directed hyperactivity with increased energy; pressured speech; decreased sleep need	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Trauma- and stressor-related disorders Psychotic disorders (schizoaffective disorder)
Anxiety	All include anxious mood and associated physiologic signs and symptoms (e.g., palpitations, tremors, diaphoresis) May include various types of dysfunctional thoughts (e.g., catastrophic fears, obsessions, flashbacks) and behaviors (e.g., compulsions, avoidance behaviors)	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders (primary or secondary) Anxiety disorders (primary or secondary) Obsessive-compulsive and related disorders Trauma- and stressor-related disorders
Psychotic	Impairments in reality testing: hallucinations, thought process derailments	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders
Somatic symptom syndromes	Somatic symptoms with associated distressing thoughts, feelings, or behaviors	Mood disorders (bipolar or depressive) (primary or secondary) Anxiety disorders (primary or secondary) Obsessive-compulsive and related disorders Trauma- and stressor-related disorders Somatic symptom disorders
Personality pathology	Dysfunctional enduring patterns of emotional regulation, thought patterns, interpersonal behaviors, impulse regulation	Neurocognitive disorders Personality change due to another medical condition Personality disorders

Other Conditions With Anxiety as a Prominent Feature

Obsessive-compulsive disorder
Acute stress disorder, post-traumatic stress disorder

Psychotic (Schizophrenia and Related) Disorders

Schizophrenia
Schizophreniform disorder
Brief psychotic disorder
Schizoaffective disorder
Delusional disorder

Somatic Symptom Disorders

Somatic symptom disorder
Illness anxiety disorder
Conversion (functional neurologic symptom) disorder
Psychological factors affecting physical condition
Factitious disorder (i.e., Munchausen syndrome)

Personality Disorders**Cluster A: Odd Eccentric**

Schizoid personality disorder (detachment from social relationships, restricted emotional expression)
Schizotypal personality disorder (social and emotional deficits, cognitive or perceptual distortions, eccentric behavior)
Paranoid personality disorder (pervasive distrust and suspiciousness)

Cluster B: Dramatic or Emotional

Borderline personality disorder (instability of interpersonal relationships, self-image, and affects, and impulsivity)
Narcissistic personality disorder (grandiosity, need for admiration, lack of empathy)
Antisocial personality disorder (disregard for and violation of the rights of others)
Histrionic personality disorder

Cluster C: Anxious or Fearful

Avoidant personality disorder (social inhibition, feelings of inadequacy, hypersensitivity to criticism)
Dependent personality disorder (pervasive and excessive need to be taken care of, leading to submissive and clinging behavior and fears of separation)
Obsessive-compulsive personality disorder (preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency)

carbamazepine) for acute episodes and maintenance therapy. The anti-convulsant lamotrigine may be particularly useful for bipolar depression. Antipsychotic medications are useful for acute manic episodes and may have a role in maintenance therapy. Benzodiazepines may be used to treat acute agitation and aggression while waiting for more definitive antimanic therapies to take effect. Antidepressants have long been used for depressive episodes, although they may precipitate manic episodes.

Electroconvulsive therapy is effective for refractory mania and depression. Psychosocial treatments alone do not effectively treat mania and may be less effective for bipolar depression, but psychoeducation and support to manage psychosocial stressors and encourage medication compliance improve longer-term outcomes.

A spectrum of less severe bipolar disorders includes conditions marked by episodes of hypomania (i.e., low-level manic symptoms without psychosis or significant impairment in functioning). They include bipolar II disorder, characterized by episodes of hypomania and major depression, and cyclothymic disorder, characterized by hypomania and low-level depression not meeting criteria for major depression. Because patients with bipolar II disorder are most likely to seek care during depressive episodes, it is important to inquire about a history of manic symptoms to avoid precipitating mania with the use of antidepressant medications. The pathogenesis of these less severe mood disorders is unclear.

DISORDERS WITH ANXIETY AS A PROMINENT FEATURE

The idiopathic anxiety disorders manifest with troublesome thoughts and somatic symptoms (Table 111.5) along with the emotional sensation of anxiety. A panic attack is a transient episode of crescendo anxiety, catastrophic thoughts (e.g., fears of dying, going insane, losing self-control), and somatic symptoms. If panic attacks or other clinically significant anxiety symptoms occur only in predictable response to environmental stimuli, the anxiety disorder is known as a *phobia*, which may further be classified as agoraphobia (i.e., anxiety about being in places from which escape may be difficult or embarrassing such as being alone, in crowds, in tunnels, or on bridges), social phobia (i.e., anxiety in interpersonal situations), and specific phobia (i.e., anxiety provoked by other situations or objects such as blood, animals, or heights). *Panic disorder* manifests with recurrent panic attacks, some of which are unexpected and unpredictable, along with anticipatory anxiety (i.e., fear of having another attack) and avoidance behaviors (i.e., avoiding situations that may provoke a panic attack or in which having an attack is perceived to be embarrassing or dangerous). Other disorders may not cause discrete panic attacks. Enduring anxiety in various domains that the individual finds difficult to control is classified as *generalized anxiety disorder*. Those with generalized anxiety disorder may also experience physical symptoms such as feeling keyed up, muscle tension or fatigue; however, they are not in discrete episodes.

Obsessive-compulsive disorder is characterized by recurrent obsessions (i.e., thoughts, impulses, or mental images that are anxiety-producing, perceived as intrusive and inappropriate, and resistant to attempts to suppress or neutralize them) and compulsions (i.e., repetitive behaviors or mental acts performed in response to obsessions or other rigid rules). Recognizing its distinct pathogenesis involving striatofrontal function and central serotonergic systems, it has been classified separately from the anxiety disorders.

Individuals exposed to severely stressful events (typically involving the actual or threatened loss of life or limb) may experience any of a wide variety of psychiatric sequelae. If the sequelae include symptoms of intrusion (e.g., intrusive memories, dreams, flashbacks,

Data from American Psychiatric Association: Diagnostic and statistical manual of mental disorders, ed 5, Washington, D.C., 2013, American Psychiatric Association.

TABLE 111.4 Psychotherapies for Depression and Antidepressant Medications

Name	Approach or Mechanism of Action
Psychotherapy	
Cognitive psychotherapy	Identify and correct negativistic patterns of thinking
Interpersonal psychotherapy	Identify and work through role transitions or interpersonal losses, conflicts, or deficits
Problem-solving therapy	Identify and prioritize situational problems; plan and implement strategies to deal with top-priority problems
Commonly Used Antidepressants	
Selective serotonin reuptake inhibitors (SSRIs)	Inhibit presynaptic reuptake of serotonin
Citalopram and escitalopram	
Fluoxetine	
Fluvoxamine	
Paroxetine	
Sertraline	
Serotonin and norepinephrine reuptake inhibitors (SNRIs)	Inhibit presynaptic reuptake of serotonin and norepinephrine
Duloxetine	
Venlafaxine and desvenlafaxine	
Milnacipran and levomilnacipran	
Tricyclic antidepressants (TCAs)	Inhibit presynaptic reuptake of serotonin and norepinephrine (in various proportions depending on the specific TCA)
Amitriptyline	
Desipramine	
Doxepin	
Imipramine	
Nortriptyline	
Monoamine oxidase inhibitors (MAOIs)	Inhibit monoamine oxidase, the enzyme that catalyzes oxidative metabolism of monoamine neurotransmitters
Isocarboxazid	
Phenelzine	
Selegiline	Selective MAO-B inhibitor
Tranylcypromine	
Other drugs	
Bupropion	Unknown, although it is weak inhibitor of presynaptic reuptake of norepinephrine and dopamine
Mirtazapine	Serotonin (5-hydroxytryptamine [5-HT]) antagonist at α_2 and 5-HT ₂ receptors
Trazodone	Inhibits presynaptic reuptake of serotonin; antagonist at 5-HT ₂ and 5-HT ₃ receptors
Vilazodone	Inhibits presynaptic reuptake of serotonin; agonist at 5-HT _{1A} receptors
Vortioxetine	Inhibits the reuptake of serotonin (5-HT); antagonist at 5-HT ₃ , 5-HT _{1D} , and 5-HT ₇ receptors; agonist at 5-HT _{1A} receptors; 5-HT _{1B} receptor partial agonist

intense distressing responses to reminders of the trauma), avoidance of distressing memories or external reminders, negative cognitions and mood (e.g., amnesia for aspects of the event, negativistic thoughts about oneself in general or self-blame for the event, diminished interests or activities, feelings of detachment), and alterations in arousal and reactivity, the disorder is called *acute stress disorder* (duration up to 1 month) or *post-traumatic stress disorder* (duration is more than 1 month). These disorders also have been classified separately, as in addition to anxiety symptoms, they can present with prominent dysphoric symptoms, externalizing aggressive symptoms, or dissociative symptoms.

These disorders are common, with point prevalence of 1% to 2% each for panic disorder and obsessive-compulsive disorder and up to 10% for phobias. Although there are fewer data on long-term outcome than for mood disorders, many of these disorders tend to have a chronic waxing and waning course. Most of these disorders have a first onset in the teens, 20s, and 30s. Although new-onset anxiety is common in later life, the cause is rarely a late-onset primary anxiety disorder (see Table 111.2).

The pathogenesis of most anxiety disorders may be understood as inappropriate activation of the stress response system involving a variety of neuroendocrine and autonomic outputs and coordinated

by the central nucleus of the amygdala and other brain structures. The amygdala receives excitatory glutamatergic inputs from cortical sensory areas and the thalamus and has outputs to the major monoaminergic centers (e.g., noradrenergic neurons of the locus coeruleus, dopaminergic neurons of the ventral tegmental area, and serotonergic neurons of the raphe nuclei), which project to the many brain regions subserving the symptoms of anxiety.

The identification and correction of dysfunctional patterns of thinking (i.e., cognitive therapy) and the extinction of pathologic behaviors and positive reinforcement of more functional behaviors (i.e., behavior therapy) are evidence-based psychotherapies useful in most anxiety disorders. They are the sole therapies for specific phobias and may be the sole or primary therapy for most other anxiety disorders or combined with pharmacotherapy.

Antidepressant, anxiolytic, and other drug therapies are used in treatment. Increasingly, antidepressant medications have replaced anxiolytics as the mainstay of pharmacotherapy for panic disorder, post-traumatic stress disorder, generalized social phobia, and generalized anxiety disorder. For obsessive-compulsive disorder, only antidepressant agents with pronounced activity on the serotonergic system (i.e., clomipramine and selective serotonin reuptake inhibitors [SSRIs]; see Table 111.4) are efficacious.

PSYCHOTIC DISORDERS

Psychosis is a loss of reality testing, manifested as hallucinations (i.e., false sensory perceptions), delusions (i.e., fixed false beliefs), and thought process derailments. Schizophrenia is the prototypic psychotic disorder; it includes acute episodes of psychosis (i.e., positive symptoms) and often declining overall functioning over time related to the negative symptoms such as affective flattening, abulia, apathy, and social withdrawal.

The lifetime prevalence of schizophrenia is slightly less than 1%, and its chronic, debilitating course takes a considerable toll on

patients, families, and society. Peak onset is in late adolescence to young adulthood, with slightly younger ages for males than females. The annual incidence is approximately 15 cases per 100,000 people, but with marked variability across study samples and populations. The condition is slightly more common in males than females.

The pathogenesis of schizophrenia remains unknown, but it is clearly multifactorial. Genetic factors account for up to 50% of the risk, with multiple loci implicated. Studies of postmortem brains indicate a nongliotic neuropathologic process with subtle disruptions of cortical cytoarchitecture. It is likely that psychosocial factors and neurodevelopment interact with a nonlocalizable brain lesion present at birth or acquired early in life. Dopaminergic mesocortical and mesolimbic pathways are important in the production of psychotic symptoms.

Antipsychotic medications, often with adjunctive benzodiazepines, are used to treat acute psychotic episodes (Table 111.6). Although maintenance antipsychotic medications help reduce the severity and frequency of acute psychotic episodes, comprehensive psychosocial rehabilitation programs are required to help patients manage interpersonal and other stressors and to improve overall clinical outcomes. Adjunctive cognitive-behavioral therapy also may improve outcomes for some patients. Second-generation (atypical) antipsychotic medications have replaced first-generation antipsychotics in common US practice because of their lower rates of extrapyramidal side effects, including tardive dyskinesia. However, second-generation drugs contribute to an increase in obesity and metabolic syndrome.

Schizoaffective disorder is a chronic, recurrent disorder with a prevalence slightly lower than that of schizophrenia. It is characterized by episodes of non-mood psychosis and mood episodes (i.e., manic or depressed) with psychotic features. Its diagnosis therefore cannot be based on the patient's clinical findings at any one point in time but requires knowledge of the overall course. The outcomes of schizoaffective disorder are heterogeneous but on average are intermediate between schizophrenia and mood disorders. Treatment is symptomatic, using antipsychotic, mood stabilizing, and antidepressant medications to target specific psychotic and mood symptoms.

Delusional disorder is characterized by delusions in the absence of thought process disorder, prominent hallucinations, or the negative symptoms of schizophrenia. The delusions may be potentially

TABLE 111.5 Common Somatic Symptoms of Anxiety

Cardiorespiratory

Palpitations
Chest pain
Dyspnea or sensation of being smothered

Gastrointestinal

Sensation of choking
Dyspepsia
Nausea
Diarrhea
Abdominal bloating or pain

Urinary frequency or urgency

Neurologic or Autonomic

Diaphoresis
Warm flushes
Dizziness or presyncope
Paresthesia
Tremor
Headache

TABLE 111.6 Commonly Used Antipsychotic Medications

Name	Mechanism of Action/Side Effect Profile
First Generation ("Typical")	Blocks D2 receptors in addition to some level of muscarinic, histaminic and alpha-adrenergic blockade; tend to have higher rates of neurologic side effects
Chlorpromazine	High blockade of histaminic, alpha adrenergic receptors, higher likelihood of sedation and anticholinergic effects, "low potency"
Fluphenazine	
Haloperidol	Higher blockade of D2 receptors with little blockade of others, higher likelihood of extrapyramidal side effects, "high potency"
Perphenazine	
Thioridazine	
Thiothixene	
Trifluorophenazine	
Second Generation ("Atypical")	Blocks D2 receptors and 5HT _{2A} receptors; higher rates of metabolic side effects
Aripiprazole	Partial D2 agonist
Asenapine	
Brexiprazole	
Cariprazine	
Clozapine	
Iloperidone	
Lurasidone	

plausible (i.e., not bizarre). Delusional disorder has a lifetime prevalence of approximately 0.2%. It often is only partially responsive to antipsychotic medications, but patients' functioning may be largely unimpaired if they are able with the aid of antipsychotics and psychotherapy to avoid acting on their delusions. The pathogenesis of the non-schizophrenic primary psychotic disorders remain largely unknown.

SOMATIC SYMPTOM DISORDER AND RELATED DISORDERS

Formerly called *somatoform disorders*, these conditions include somatic symptoms and associated thoughts, feelings, or behaviors that are distressing and disabling. Prominent types include somatic symptom disorder (i.e., excessive thoughts, feelings, or behaviors associated with one or more somatic symptoms), illness anxiety disorder (i.e., illness preoccupation and health-related behaviors disproportionate to somatic symptoms), conversion (i.e., functional neurologic symptom) disorder (i.e., neurologic somatoform symptoms incompatible with recognized neurologic or general medical conditions), and psychological factors affecting physical conditions. Factitious disorder (i.e., Munchausen syndrome) is a mental disorder in which patients consciously produce stigmata of disease (e.g., simulated or artificially induced fever or hypoglycemia) for the unconscious gain of assuming the sick role.

Although identifiable physical disease is insufficient to fully explain the patient's presentation, in all these conditions other than factitious disorder, the patient's distress and dysfunction are *not* consciously produced and are just as distressing to patients as would be similar symptoms produced by other medical conditions. Malingering is the conscious feigning of illness for conscious gain and therefore is not a mental disorder.

PERSONALITY DISORDERS

Personality is defined as the repertoire of enduring patterns of inner mental experience and behavior, including affect and impulse regulation, defense and coping mechanisms, and interpersonal relatedness. Personality traits must be distinguished from time-limited states. For example, a patient who exhibits dependent features solely while acutely depressed does not have a dependent personality.

A personality disorder is diagnosed when personality traits lead to pervasive (if variable) subjective distress or dysfunction in a broad range of situations. The major personality disorders are listed in [Table 111.3](#). Personality and personality disorders are the result of complex interactions among genetic, environmental, and developmental factors. Approaches to patients with personality disorders depend on the specific type, but in most clinical circumstances other than long-term psychotherapy, the realistic goal is not to alter fundamental personality structure but to help the patient maximize use of personality strengths (e.g., optimal defense mechanisms) while minimizing the harmful effects of emotional dysregulation, unhelpful defenses, and destructive behaviors.

Although not the mainstay of most treatments for personality disorders, pharmacotherapy can be useful in selected patients (e.g., antipsychotics to target escalating paranoia in paranoid personality disorder, mood stabilizers or antidepressants to target emotional dysregulation in borderline personality disorder). Patients with personality disorders are also prone to mood, anxiety, eating, addictive, and other treatable psychiatric disorders.

PROSPECTUS FOR THE FUTURE

Advances in neuroscience will lead to not only better pharmacologic and other somatic therapies, but may hold the key to more accurate diagnosis of psychiatric illness. In the future, precision medicine in psychiatry will allow us to use information such as genomics and brain imaging to more accurately define, diagnose, and treat illness. Although not ready to be used clinically, the National Institute of Mental Health (NIMH) has initiated the Research Domains Criteria in order to test a framework of mental illness that goes beyond the traditional syndrome-based diagnosis by aligning more closely with underlying neural systems. The recent approval of two drugs with different mechanisms of action from previous antidepressants, intranasal esketamine and brexanolone, exemplifies the potential to discover new ways to treat mood and other psychiatric disorders. What is particularly exciting regarding these new medications is that they appear to work more quickly than other antidepressants. It remains to be seen how they will be optimally deployed among other therapeutic choices. Prevention remains an important area of growth in psychiatry, albeit an area that historically had lagged behind many other medical specialties. Promising data showing that early intervention teams for patients suffering from first onset psychosis improve long-term outcomes is a step in the right direction. Evidence is also growing that late-life depression can be prevented by cost-effective preventive interventions in at-risk patients in primary care and several specialty settings. Advances in prevention, diagnosis, and treatment will contribute to a new understanding of mental illness and lead to a future in which the global burden of mental illness can be decreased.

Autonomic Nervous System Disorders

William P. Cheshire, Jr.

DEFINITION AND EPIDEMIOLOGY

The autonomic nervous system reaches throughout the body and governs all visceral activity. Its central network and peripheral sympathetic and parasympathetic divisions integrate complex organ functions, maintain internal homeostasis in response to environmental change, modulate the flight-or-fight physiologic response to stress, and enable circulation, digestion, and procreation.

Benign dysautonomias are common. Neurally mediated syncope and situational reflex syncope in response to emotional distress, carotid sinus stimulation, micturition, defecation, coughing, straining, or other factors occur in about 20% of people during a lifetime and account for 1% to 3% of all emergency room visits. Hyperhidrosis of the palms and soles affects about 1% of the population. Anhidrosis can contribute to increased mortality rates during severe heat stress.

One of the most disabling manifestations of autonomic failure is orthostatic hypotension, the prevalence of which increases with age, physical inactivity, and in diseases that impair sympathetic adrenergic nerves. Orthostatic hypotension affects about 5% to 20% of the elderly.

Diabetes mellitus is the most common cause of autonomic neuropathy in industrialized nations. About 30% of diabetics develop autonomic neuropathy, and symptomatic orthostatic hypotension occurs in 5% of patients. Other features of autonomic neuropathy include constipation in 40% to 60% of diabetics, gastroparesis in 20% to 40%, bladder dysfunction in 30% to 80%, and erectile impotence in more than 30% of men.

❖ For a deeper discussion of these topics, please see Chapter 22, “Common Clinical Sequelae of Aging,” and Chapter 216, “Diabetes Mellitus,” in *Goldman-Cecil Medicine*, 26th Edition.

PATHOLOGY

Many brain, spinal cord, peripheral nerve, and systemic disorders that impair autonomic nerves can cause autonomic dysfunction or failure. They include a wide range of degenerative, traumatic, cerebrovascular, autoimmune, genetic, metabolic, toxic, and pharmacologic conditions.

Small-caliber peripheral autonomic nerves are unmyelinated or thinly myelinated, and small-fiber peripheral neuropathies that cause distal sensory loss may also involve sympathetic or parasympathetic nerves. Diabetic autonomic neuropathy results from microvascular damage to autonomic nerves. Several hereditary, infectious, metabolic, toxic, and drug-induced sensory and autonomic neuropathies are recognized causes.

Accumulation of abnormal proteins distinguishes some of the degenerative dysautonomias. Oligodendroglial cytoplasmic inclusions composed of aggregates of misfolded α -synuclein are pathognomonic of multiple system atrophy. Abnormally folded sympathetic neuronal accumulation of α -synuclein occurs in Lewy body disorders such as Parkinson’s disease. Peripheral autonomic nerve deposition of β -pleated sheet amyloid protein causes a severe autonomic

neuropathy, which is frequently seen in primary amyloidosis, immunoglobulin light chain–associated disease, and hereditary amyloidosis, although rarely in reactive amyloidosis.

Other dysautonomias have an autoimmune basis. Autonomic instability has long been recognized in Guillain-Barré syndrome, which is an acute inflammatory, demyelinating polyradiculoneuropathy associated with antiganglioside antibodies (e.g., anti-GM₁, anti-GM₃). The list of autoimmune autonomic neuropathies includes acute autonomic ganglionopathy; patients with acute pandysautonomia have antibodies against the nicotinic acetylcholine receptor in autonomic ganglia, which is sometimes associated with lung cancer or thymoma. Additional paraneoplastic autonomic neuropathies include those associated with antineuronal nuclear antibody type 1 (i.e., ANNA-1 or anti-Hu) and antibodies against collapsing response mediator proteins (i.e., CRMP-5 or anti-CV2). Lambert-Eaton myasthenic syndrome is associated with antibodies to voltage-gated calcium channels. Antibodies to voltage-gated potassium channels cause autoimmune neuromyotonia and dysautonomia with hyperhidrosis and orthostatic intolerance.

Pharmacologic agents frequently alter autonomic function. Diuretics, sympatholytic drugs, α -adrenoreceptor blockers, and vasodilators can cause or contribute to orthostatic hypotension. Anticholinergics and carbonic anhydrase inhibitors decrease sweating, whereas opioids and selective serotonin reuptake inhibitors increase sweating. Opioids slow intestinal transit. Anticholinergics, tricyclic antidepressants, and antihistamines may cause urinary retention.

Functional dysautonomias are medical conditions in which autonomic function is impaired in the absence of a known structural neurologic deficit. Some psychological disorders may manifest with autonomic symptoms because emotional and autonomic centers are closely linked in the limbic system.

❖ For a deeper discussion of these topics, please see Chapter 392, “Peripheral Neuropathies,” Chapter 179, “Amyloidosis,” and Chapter 41, “Mechanisms of Immune-Mediated Tissue Injury,” in *Goldman-Cecil Medicine*, 26th Edition.

CLINICAL PRESENTATION

Clinical manifestations of autonomic disorders vary according to which nerves are involved and how severely. Autonomic signs and symptoms may be benign or serious, paroxysmal or continuous, or localized or generalized, and they may represent hypofunction or hyperfunction.

Afferent autonomic lesions that separate central autonomic nuclei from incoming information needed to gauge an appropriate response may cause excessive or erratic autonomic outflow. An example of afferent dysautonomia is the volatile hypertension in carotid arterial baroreceptor failure after irradiation to treat laryngeal carcinoma. Spinal cord injuries above the level of sympathetic outflow at T5 can cause autonomic dysreflexia, a condition of paroxysmal sympathetic surges

with hypertension, diaphoresis, flushing, and headache. Catastrophic brain disorders such as subarachnoid hemorrhage, trauma, or hydrocephalus may also cause autonomic storms if hypothalamic circuits are released from cortical inhibition.

More common are efferent autonomic lesions, which cause failure of outflow to neuroeffector junctions, resulting in inadequate excitatory or inhibitory autonomic responses. An example of efferent dysautonomias is autonomic peripheral neuropathy, which may accompany distal sensory loss and decreased Achilles tendon jerks.

Cardiovascular adrenergic failure impairs the cardiac and peripheral vascular response needed to maintain blood pressure during orthostatic stress. Patients present with orthostatic hypotension and may report lightheadedness or fatigue on standing that is relieved by sitting.

Vagal failure impairs cardiac parasympathetic tone that may protect against arrhythmogenic sympathetic activity. Patients have a fixed heart rate that does not vary with respiration.

Sudomotor failure (failure to stimulate the sweat glands) with extensive anhidrosis may coexist with tonic pupils (sluggish response to light) and areflexia (i.e., Ross syndrome), and it can increase the risk of heat exhaustion or heat stroke. A dramatic example of regional sudomotor failure is harlequin syndrome, in which hemifacial cutaneous sympathetic denervation divides the pale and dry denervated half of the face from the intact half that flushes red in response to heat stress. Horner syndrome (i.e., unilateral ptosis, miosis, and anhidrosis) may be identified.

The clinical hallmark of generalized autonomic failure is severe orthostatic hypotension without pulse acceleration. In at least one half of patients, it is accompanied by supine and nocturnal hypertension, a reversal of the normal diurnal decrease in blood pressure during sleep. In addition to vagal and sudomotor failure, patients with generalized autonomic failure may have constipation, gastroparesis, bladder dysfunction, male erectile dysfunction, dry mouth, or dry eyes. Some have postprandial hypotension, in which a large meal high in carbohydrate content causes a reduction in blood pressure.

One of the most severe autonomic disorders is multiple system atrophy, which is a sporadic, progressive, ultimately fatal neurodegenerative disorder in which autonomic failure occurs in combination with parkinsonism or cerebellar ataxia. Bladder hypotonia with overflow incontinence and nocturnal respiratory stridor may occur. The parkinsonian phenotype (i.e., Shy-Drager syndrome) tends to respond poorly to levodopa. Orthostatic hypotension is also common in Lewy body disorders such as Parkinson's disease. Pure autonomic failure consists of widespread autonomic failure without other neurologic features.

In contrast to autonomic failure, neurally mediated syncope occurs in patients with a functioning autonomic nervous system in which there is a reversal of normal autonomic outflow. Prodromal features typically include pallor, sweating, nausea, abdominal discomfort, mydriasis, increased respiratory rate, and cognitive slowing, which may progress to transient loss of consciousness if the patient continues in an upright posture. Withdrawal of peripheral sympathetic vasomotor tone (i.e., vasodepressor syncope) or an increase in parasympathetic tone (i.e., vasovagal syncope) causes a fall in blood pressure, heart rate, and cerebral perfusion.

Orthostatic intolerance refers to a heterogeneous group of conditions in which patients have difficulty sustaining the autonomic outflow needed to maintain blood pressure during the gravitational stress of prolonged standing. Some patients experience a gradual decline in blood pressure, but others experience an abnormal increase in heart rate without a drop in blood pressure.

❖ For a deeper discussion of these topics, please see Chapter 56, "Approach to the Patient with Suspected Arrhythmia," Chapter 70, "Arterial Hypertension," Chapter 127, "Disorders of Gastrointestinal Motility," and Chapter 381, "Parkinsonism," in *Goldman-Cecil Medicine*, 26th Edition.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A careful history and discerning physical examination are essential for reaching a diagnosis. The astute clinician inquires about the time course of symptoms and the circumstances that provoke or modify them. How long have they been present? Are they stable, improving, or worsening? Do they occur consistently or episodically? Orthostatic disorders are typically worse in the early morning, in heat, and after physical exercise or a large meal. How well the patient tolerates standing in line or taking a warm shower are helpful clues to identifying orthostatic intolerance.

Physical signs of autonomic dysfunction may include pupillary asymmetry or sluggishness, ptosis, or mucosal dryness. An acutely distended bladder may be suspected by percussion. Asymmetrical sweating may be visible or palpable.

The most important part of the examination, but one that is frequently omitted, is measurement of orthostatic blood pressure (Fig. 112.1). Blood pressure and heart rate should be assessed when the patient is resting supine and again after standing for 1 to 3 minutes. Correlation with symptoms is key. Patients with orthostatic

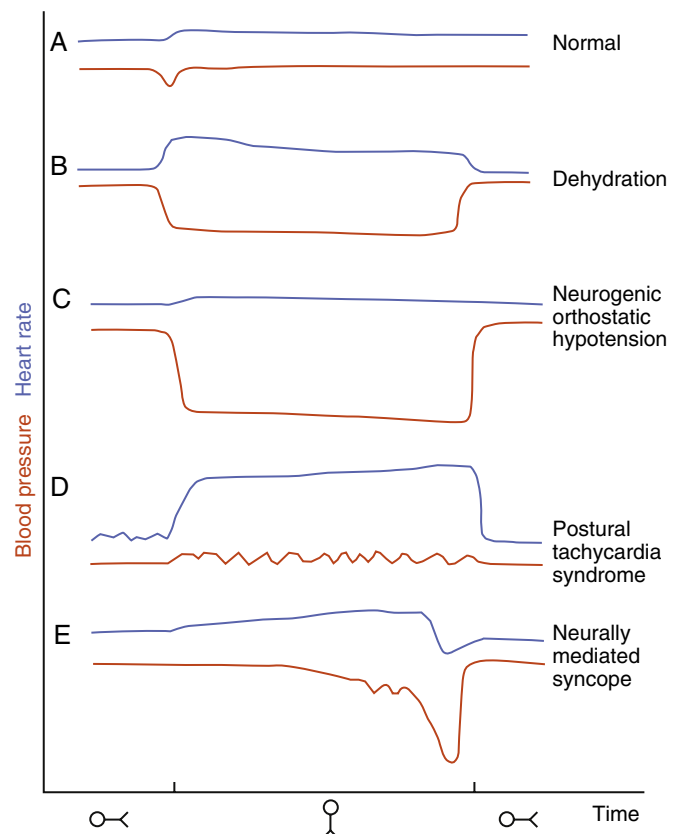

Fig. 112.1 Orthostatic blood pressure profiles. (A) The normal response to standing or head-up tilt is no change or a small decrease in blood pressure that recovers within half a minute and a small increase in heart rate. (B) Dehydration causing intravascular hypovolemia may cause a fall in blood pressure accompanied by reflex tachycardia. (C) Neurogenic orthostatic hypotension may cause a more profound drop in blood pressure. Hypotension occurs immediately and is sustained without recovery during standing and often without adequate compensatory tachycardia. (D) Postural tachycardia syndrome is characterized by an abnormal increase in heart rate without orthostatic hypotension. (E) Neurally mediated syncope develops after standing for some time, may be preceded by oscillations in blood pressure, and may be accompanied by bradycardia with loss of consciousness in about 7 seconds if cerebral perfusion is not restored.

hypotension may appear less alert, or they may shift weight from one leg to the other to improve venous return, lower the head to bring the cerebral circulation closer to the level of the heart, or exhibit lower extremity rubor if cutaneous vasomotor function is impaired.

Orthostatic hypotension is a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg, with or without symptoms, within 1 to 3 minutes of assuming an erect posture. Neurogenic orthostatic hypotension, a cardinal manifestation of sympathetic adrenergic failure, is typically sustained with continued standing and may lack the reflex tachycardia seen when hypotension is caused by blood loss, dehydration, or excessive venous pooling.

Orthostatic intolerance is difficulty tolerating the upright posture because of symptoms that resolve when supine. These patients do not have orthostatic hypotension but may have a sustained increase in postural heart rate (postural tachycardia syndrome) of more than 30 beats per minute in adults (40 in adolescents).

Laboratory testing of autonomic responses under controlled conditions is useful to determine the presence, severity, and distribution of autonomic failure and to distinguish neurogenic from other causes of orthostatic hypotension. Clinical autonomic testing typically evaluates beat-to-beat blood pressure and heart rate responses to the Valsalva maneuver, upright tilt, and periodic deep breathing, along with quantitative assessment of axons that produce sweating responses. Ambulatory blood pressure testing is useful for the assessment of episodic or postprandial hypotension, nocturnal hypertension, and the volatile hypertension of autonomic storms.

TREATMENT

Treatment options for orthostatic hypotension are outlined in [Table 112.1](#). The goal is to enable the patient to stand long enough to engage in daily activities without symptoms. Medication is not always needed and can potentially exacerbate recumbent hypertension. Orthostatic

intolerance was shown in a randomized controlled trial to improve after endurance exercise training.

Generalized hyperhidrosis may be reduced by oral anticholinergic agents such as 1 to 2 mg of glycopyrrolate taken one to three times daily. Topical glycopyrrolate reduces regional gustatory sweating. Subdermal botulinum toxin injections are helpful for some forms of focal hyperhidrosis, and palmar hyperhidrosis may respond to tap water iontophoresis or, in severe cases, to endoscopic thoracic sympathectomy.

For a deeper discussion of these topics, please see Chapter 390, “Autonomic Disorders and Their Management,” in *Goldman-Cecil Medicine*, 26th Edition.

PROGNOSIS

Orthostatic intolerance and neurally mediated syncope are frequently benign, manageable, and improve or recover with time. Autonomic failure, in contrast, can signify a more serious prognosis, depending on the nature and extent of its pathophysiology. Persistent or severe orthostatic hypotension carries a worse prognosis.

Diabetic cardiovascular autonomic neuropathy doubles the risk for silent myocardial ischemia and overall mortality. Amyloid autonomic neuropathy is especially grave, with a median survival of less than 1 year if the patient has orthostatic hypotension. Pure autonomic failure may remain stable for many years, although some patients with this phenotype eventually develop signs of multiple system atrophy, which denotes a life expectancy of 7 to 9 years after diagnosis.

Regular physical exercise can reverse the autonomic deconditioning that comes from inactivity. In the elderly, it may compensate for some age-associated decline in autonomic function.

For a deeper discussion of these topics, please see Chapter 390, “Autonomic Disorders and Their Management,” in *Goldman-Cecil Medicine*, 26th Edition.

TABLE 112.1 Treatment of Orthostatic Hypotension

Intervention	Rationale	Dosage
Avoid prolonged bed rest and increase time spent upright	Reverses physiologic deconditioning	
Liberalize fluid intake	Expands plasma volume	2-2.5 L/day
Increase sodium intake	Expands plasma volume	Salt 10-20 g/day
Compressive leg garments and abdominal binder	Reduces venous pooling	20-40 mm Hg (10 mm Hg for abdominal binder)
Physical counter-maneuvers	Tensing limb muscles augments venous return	Isometric contractions for 30 sec
Water bolus treatment	Sympathetic reflex increases blood pressure for 1-2 hr	16 oz. plain water
Elevate head of bed 4 inches	Decreases nocturnal natriuresis and nocturnal hypertension	
Avoid large meals high in carbohydrate content	If patient is subject to postprandial hypotension	
Discontinue or decrease dose of blood pressure-lowering drugs		
Midodrine	α -Adrenergic agonist, constricts capacitance vessels	5-10 mg tid
Droxidopa	Norepinephrine prodrug, stimulates sympathetic nerves	100-600 mg tid
Fludrocortisone	Retains sodium and sensitizes peripheral vascular α -adrenergic receptors	0.1-0.4 mg/day
Pyridostigmine	Stimulates sympathetic ganglionic transmission	30-60 mg bid or tid

Headache, Neck and Back Pain, and Cranial Neuralgias

Shane Lyons, Timothy J. Counihan

HEADACHE

Definition and Epidemiology

Headache is caused by irritation of pain-sensitive intracranial structures, including the dural sinuses; the intracranial portions of the trigeminal, glossopharyngeal, vagus, and upper cervical nerves; the large arteries; and the venous sinuses. Many structures are insensitive to pain, including the brain parenchyma, the ependymal lining of the ventricles, and the choroid plexuses. The insensitivity of the brain parenchyma to pain accounts for the common clinical observation of patients who, despite having large intracerebral lesions (such as a hematoma or a brain tumor), complain of little or no headache. The term “cervicogenic” headache is sometimes used to indicate that the source of headache (usually occipital in location) arises from an abnormality in the cervical spine.

Classification of Headache

Headache is generally classified into primary, secondary, and cranial neuralgia syndromes (Table 113.1, Table 113.2, Table 113.3). It is essential that the clinician make every effort to make an accurate clinical diagnosis of the presenting headache syndrome; Table 113.4 provides some key questions in the assessment of the patient with headache.

Migraine

Definition. Migraine is a common episodic neurologic disorder characterized by disabling headache and reversible neurologic and systemic symptoms. Migraine may be heralded by a premonitory phase of fatigue and neck stiffness, which precedes attacks by hours or days. One third of patients with migraine experience various combinations of neurologic, gastrointestinal, and autonomic phenomena (termed the “aura”). The diagnosis is based on the headache’s characteristics and associated symptoms. Results of the physical examination as well as the laboratory studies are usually normal.

Every year, up to 18% of women and 6% of men experience a migraine attack. It is estimated that 28 million Americans have disabling migraine headaches. All varieties of migraine may begin at any age from early childhood on, although peak ages at onset are adolescence and early adulthood.

Several subtypes of migraine are described (Table 113.5). The two most common are migraine without aura and migraine with aura; migraine without aura accounts for 70% of patients. Migraine auras are focal neurologic symptoms that precede, accompany, or, rarely, follow an attack. The aura usually develops over 5 to 20 minutes, lasts less than 60 minutes, and can involve visual, sensorimotor, language, or brain stem disturbances. The most common aura is typified by positive visual phenomena (such as scintillating scotomata [zig zag, shimmering or colored lines] or fortification spectra [more complex

images sometimes resembling a fortress]) that often precede the headache. Auras may also occur in the absence of headache (acephalgic migraine), particularly later in life. Migraine auras are stereotyped and a sudden change in a previously predictable aura pattern should prompt evaluation for an aura mimic.

The differential diagnosis of an aura includes a focal epileptic seizure arising from the visual cortex of the occipital lobe, a transient ischemic attack (TIA), or “amyloid spells” occurring in the context of cerebral amyloid angiopathy. In the latter, there is no evolution of symptoms, and the symptoms themselves are typically “negative” (such as a hemianopia) rather than the “positive” visual phenomenon of phosphenes that is characteristic of the migrainous aura. Amyloid spells are associated with evolving and “positive” symptoms and may be difficult to accurately distinguish clinically from migraine aura. The pain of migraine is often pulsating, unilateral, frontotemporal in distribution, exacerbated by movement, and usually accompanied by anorexia, nausea, and, occasionally, vomiting. In characteristic attacks, patients are markedly intolerant of light (photophobia) and seek rest in a dark room. There may also be intolerance to sound (phonophobia) and occasionally to odors (osmophobia). The diagnosis of migraine requires the presence of at least one of these features, particularly in the absence of gastrointestinal symptoms. The presence of these symptoms results in a syndrome that is invariably disabling for the patient, to the extent that for the duration of the attack he or she is unable to function normally. Following resolution of headache, a postdromal phase characterized by asthenia, fatigue, poor concentration, and nausea may persist for hours. In children, migraine is often associated with episodic abdominal pain, motion sickness, vertigo, and sleep disturbances. Onset of typical migraine late in life (older than age 50) is rare, although recurrence of migraine that had been in remission is not uncommon. Recurrent migraine headache associated with transient hemiparesis or hemiplegia occurs rarely as a clearly genetically determined (mendelian) disease, most commonly due to mutations of the *CACNA1A* gene (*familial hemiplegic migraine*).

Migraine with basilar aura is unusual and occurs primarily in childhood. Severe episodic headache is preceded, or accompanied by, signs of bilateral occipital lobe, brain stem, or cerebellar dysfunction (e.g., diplopia, bilateral visual field abnormalities, ataxia, dysarthria, bilateral sensory disturbances, other cranial nerve signs, and occasionally coma). *Vestibular migraine* is characterized by symptoms of vertigo with or without the other typical migraine symptoms. A number of episodic syndromes have been identified that bear similarities to migraine; these include cyclical vomiting, abdominal migraine, benign paroxysmal vertigo, and benign paroxysmal torticollis.

Complications of migraine. *Status migrainosus* refers to a severe migraine lasting greater than 72 hours. *Migrainous infarction* is a rare complication of migraine with aura. The term *migraine epilepsy* has been suggested for patients in whom an aura triggers a seizure.

Central facial pain syndromes (e.g., cold-stimulus headache)

Pathophysiology of migraine. A migraine attack is the end result of the interaction of a number of factors of varying importance in different individuals. These factors include a genetic predisposition, a susceptibility of the central nervous system to certain stimuli, hormonal factors, and a sequence of neurovascular events. A positive

TABLE 113.4 Key Questions in the Assessment of Headache

1. For how long have you been having headaches?
2. What were they like when they first began? Were they intermittent, daily persistent, or progressive from the beginning?
3. What is the length of time from the start of the headache until its peak intensity?
4. Are there any warning symptoms (e.g., aura)?
5. Does the headache interfere significantly with normal activity (e.g., work, school)?
6. What aggravates the headache (e.g., light, noise, odors)?
7. What do you do for relief from the headache (e.g., rest, move around, take medication)?
8. What time of day are the headaches most likely to occur? Do they regularly awaken you from sleep?
9. Are you aware of any specific triggers (e.g., foods, stress, lack of sleep, menstrual cycle)?
10. Does anyone else in the family have headaches?

family history is reported in 65% to 91% of cases. Three distinct ion channel gene mutations have been identified in patients with familial hemiplegic migraine (FHM), including a mutation in the *P/Q* type calcium channel on chromosome 19 (FHM 1) and a gene encoding a Na/K⁺ ion pump on chromosome 1 (FHM 2). These findings lend support to the theory that migraine may be a true channelopathy in which mutations of diverse channels result in a common phenotype. The etiology of migraine in the majority of patients remains unknown.

The migrainous aura is likely caused by a “cortical spreading depression,” corresponding to a wave of neuronal depolarization spreading over the cortex from posterior to anterior. One of the key structures in the mechanism of pain in migraine is the trigeminal vascular system. Stimulation of the trigeminal nucleus caudalis can activate serotonin receptors and nerve endings on small dural arteries and result in a state of neurogenic inflammation. Activation of the trigeminal ganglion nociceptive (pain) neurons results in the release of calcitonin gene-related peptide (CGRP), a vasoactive peptide that is strongly implicated in the generation of migraine. The critical role of CGRP in migraine has been demonstrated through the induction of migraine by infusing CGRP, while treatment with potent CGRP inhibitors can abort an acute migraine attack. It is postulated that these processes, in turn, stimulate perivascular nerve endings, with resultant orthodromic (normal direction) stimulation of trigeminal nerve and pain referred to its territory. Furthermore, positron emission tomographic (PET) studies have demonstrated activation of brain stem neuromodulatory structures, including the periaqueductal gray matter, locus coeruleus, and raphe nuclei during a migraine attack.

Treatment of migraine. The goals of treatment are (1) making an accurate and confident diagnosis of migraine to reassure the patient that there is no more sinister cause for the headache; (2) relieving acute attacks; and (3) preventing pain and associated symptoms

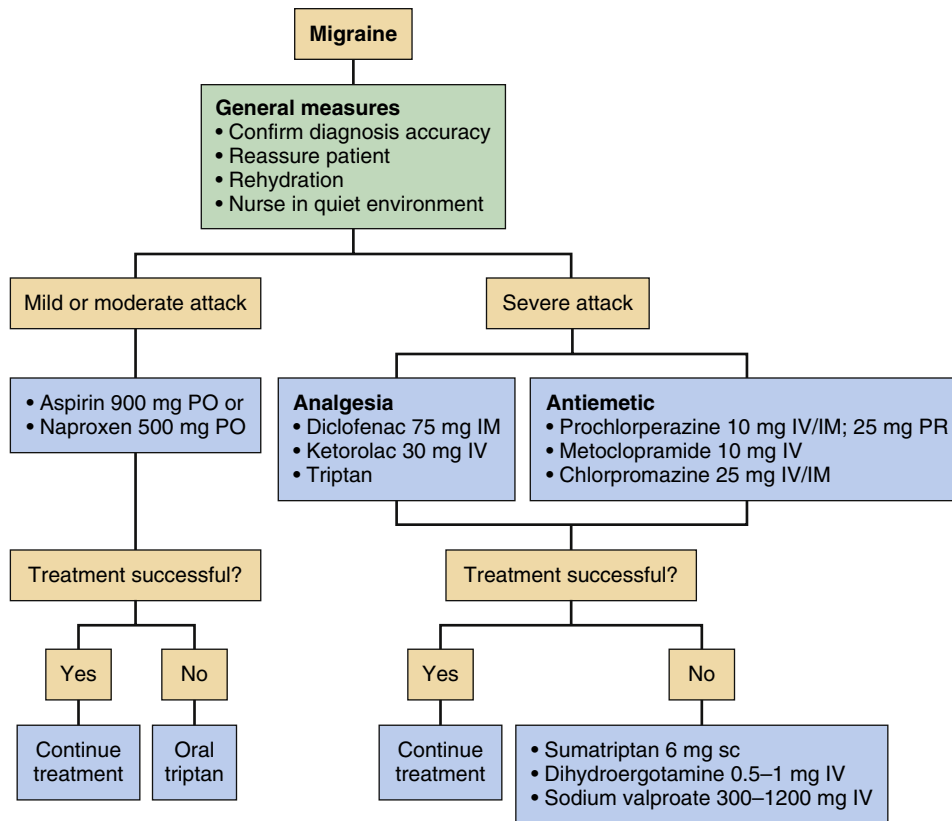

Fig. 113.1 Algorithm for the treatment of migraine. *DHE*, Dihydroergotamine; *IM*, intramuscular; *IV*, intravenous; *NS*, normal saline; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *SC*, subcutaneous.

of recurrent headaches. The first step is to inform the patient that he or she has a migraine. The benign nature of the disorder and the patient's central role in the treatment plan should be emphasized. It is important that the patient keep a headache diary, which serves to help identify covert headache triggers, assists in monitoring headache frequency and response to treatment, and actively involves the patient in the management of the condition. A sustained pain-free therapeutic response should aim to have the patient pain-free at 2 hours with no recurrence and no need for subsequent rescue medication.

Acute migraine attack. Acute attacks are best alleviated using a stratified, rather than stepped care approach, using single agents or varying combinations of drugs as well as with behavioral modification therapy. Many attacks of migraine respond to simple analgesics, such as acetaminophen, aspirin, or nonsteroidal anti-inflammatory agents (NSAIDs). Opioid drugs and butalbital should not be used in the routine management of patients with migraine. Overuse of analgesics is particularly frequent in headache patients; therefore, one of the most important aspects of therapy is the monitoring of amounts of analgesic used to avoid both side effects and the emergence of medication-associated headache. In patients who are nauseated, it is often helpful to prescribe an antiemetic agent early in an attack. Phenothiazine drugs have antiemetic, prokinetic, and sedative properties, but they can produce involuntary movements as an acute adverse effect (acute dystonic reaction) or with prolonged use (tardive dyskinesias).

A number of *migraine-specific* serotonin agonist drugs have become available. These agents, commonly referred to as “triptans,” are useful in the acute treatment of migraine, having a rapid onset of action. The increasing availability of non-oral (parenteral, inhaled, and transdermal) preparations has largely circumvented the problem of emesis and gastroparesis in migraine patients resulting in greater efficacy. For instance, sumatriptan, available as a subcutaneous preparation, results

in a headache response rate of close to 70% (Fig. 113.1). Although triptans are highly effective in alleviating migraine, patients must be carefully instructed in their appropriate use. Moreover, a response to these medications does not confirm a diagnosis of migraine.

Treating acute migraine in the emergency room. Migraine is one of the most common reasons for emergency room visits and presents some treatment challenges; typically migraine is more difficult to treat once it is fully established. It is essential to confirm that the diagnosis is accurate, even in patients with an established history of migraine. Patients will usually be aware that the headache will have started as their typical migraine, although it may be more severe than usual. In patients who state that the new headache is different than their usual headache, consideration should be given to exclude a more sinister cause. Thereafter the core principles of treatment include reassurance that the headache can be treated effectively, hydration, pain control, and relief of accompanying symptoms such as nausea and photophobia. The majority of patients presenting with acute migraine as an emergency will have already tried some form of abortive therapy, and they are likely to be dehydrated. In this setting parenteral therapy with an NSAID, a triptan, and an antiemetic is often effective. 5-HT_{1F} receptor agonists (ditans), such as lamitan, may offer similar benefits to triptans without the vasoconstrictive effect of triptans.

Migraine prevention. Several agents have a strong evidence base for efficacy in the prevention of migraine (Table 113.6). The use of these agents should be restricted to patients who have frequent attacks (usually more than four per month) and who are willing to take daily medication. With any of the medications, an adequate trial period should be given, using adequate doses, before it is declared ineffective. Combination therapy is occasionally required but is not routinely prescribed. For a preventative drug to be considered successful, it should reduce the headache frequency rate by at least

TABLE 113.6 Preventive Therapies for Migraine

Drug Class	Agent	Dose Range	Adverse Effects
β-Adrenoceptor blockers	Propranolol	80-240 mg	Contraindicated in asthma, syncope
	Metoprolol	50-150 mg	
	Timolol	10-20 mg	
Antiepileptic drugs	Divalproex sodium	200-1500 mg	Weight gain, thrombocytopenia, tremor Renal calculi, weight loss, amnesia, glaucoma, dysequilibrium
	Topiramate	25-150 mg	
	Gabapentin	300-1800 mg	
Antidepressants	Amitriptyline	10-150 mg	Somnolence Insomnia, hypertension
	Nortriptyline	25-100 mg	
	Venlafaxine	37.5-150 mg	
Calcium-channel blockers	Verapamil	180-480 mg	Constipation, hypotension, edema Weight gain, depression
	Flunarizine ^a	5-10 mg	
Other	Onabotulinum toxin A	Variable	Discomfort, ecchymosis
CGRP monoclonal antibodies	Erenumab	70-140 mg every 4 week, subcut	Injection site reactions, muscle spasm, hypersensitivity reaction. Hypersensitivity and injection site reactions Injection site reactions, vertigo, pruritus, constipation
	Fremanezumab	225 mg monthly or 675 mg 3-monthly, subcut	
	Galcanezumab	120 mg monthly subcut	

^aNot available in the United States.

50%. Other medications commonly used for migraine prevention include gabapentin, cyproheptadine, methysergide, and clonidine, but these have limited evidence to support their use as first-line therapy. Magnesium supplementation, the plant extract feverfew, butterbur, and high-dose riboflavin (vitamin B₂) have been effective in some patients.

Recent years have seen the emergence of the first medications specifically designed to treat migraine based on pathophysiologic understanding of migraine; monoclonal antibodies directed against CGRP. A number of medications targeting the CGRP cascade in migraine have been developed, including small molecule CGRP antagonists (gepants) and monoclonal antibodies directed against both the CGRP receptor and the CGRP molecule itself. Three CGRP monoclonal antibodies have been approved for the prevention of migraine (erenumab, fremanezumab, and galcanezumab). They are administered by infusion or subcutaneous injection and in trials improved headache by 75% in one third of patients.

A variety of interventional procedures including greater occipital nerve blockade, botulinum toxin injection to the scalp and cervical musculature, and sphenopalatine ganglion (SPG) blockade are deployed in the management of severe and chronic migraine. Neuromodulation, by means of noninvasive vagal nerve stimulation, external trigeminal nerve stimulation, and transcranial magnetic stimulation represents a novel, nonpharmacologic method of migraine management.

Cluster Headache

Clinical features. Cluster headache is the prototypic trigeminal autonomic cephalgia, entirely distinct from migraine, although there may be some clinical overlap. It is uncommon, occurring in less than 10% of all patients with headache. Unlike migraine, it is much more common in men than in women, and the mean age at onset is later in life. Also, unlike migraine, cluster headache rarely begins in childhood, and there is less often a family history. The pain in cluster headache is extremely intense, is strictly unilateral, and is associated with congestion of the nasal mucosa and injection of the conjunctiva on the side of the pain. Increased sweating of the ipsilateral side of the forehead and face may occur. There may be associated ocular signs of

Horner syndrome: miosis, ptosis, and the additional feature of eyelid edema. Attacks often awaken patients, usually 2 to 3 hours after the onset of sleep (“alarm-clock headache”). In contrast to migraineurs, the pain is not relieved by resting in a dark, quiet area; on the contrary, patients sometimes seek activity that can distract them. The duration of headache is usually around 1 hour, although it may recur several times in a day, paroxysmally (in *clusters*) for several weeks.

These periods of frequent headaches are separated by headache-free periods of varying duration, often several months or years. Attacks have a striking tendency to be precipitated by even small amounts of alcohol. There are rare variants of cluster headache: a “chronic variety” in which remissions are brief (less than 14 days); *chronic paroxysmal hemicrania*, in which attacks are shorter and strikingly more prevalent in women; and *hemicrania continua*, in which there is continuous, moderately severe, unilateral headache. The cause of all these syndromes is unknown, although the distribution of the pain suggests dysfunction of the trigeminal nerve.

Treatment. Therapy for cluster headache may be abortive for acute headache or prophylactic to prevent headache. Acute headache may respond to oxygen by mask (7 to 10 L/min for 15 minutes), which is effective within several minutes in 70% of patients. Sumatriptan and dihydroergotamine are also effective. Preventive medications include lithium, divalproex sodium, verapamil, methysergide, melatonin, and corticosteroids. Noninvasive vagal nerve stimulation is now licensed for the acute treatment of episode cluster headache and has evidence to support its use in prevention. Emerging treatments include galcanezumab and SPG stimulation. Paroxysmal hemicrania and related syndromes are often strikingly responsive to indomethacin.

Tension-Type Headache

In contrast to migraine, tension-type headache is featureless. The pain is usually not throbbing, but rather steady and often described as a “pressure feeling” or a “viselike” sensation. It is usually not unilateral and may be frontal, occipital, or generalized. There is frequently pain in the neck area, unlike in migraine. Pain commonly lasts for long periods of time (days) and does not rapidly appear and disappear in attacks. There is no “aura.” Photophobia and phonophobia are not

prominent. Although tension-type headache may be related by the patient to occur or be exacerbated at times of particular emotional stress, the pathophysiology may relate to sustained craniocervical muscle contraction; hence, a more useful term for this syndrome is *muscle-contraction headache*.

A careful evaluation should be made of the patient's psychosocial milieu and the presence of anxiety or depression. The tricyclic antidepressant drugs in low doses have proven the most useful for prevention of tension-type headache. Although the best documented is amitriptyline, newer agents with fewer side effects may be equally effective. Nonpharmacologic therapies such as relaxation therapy, massage, physiotherapy, or acupuncture may be useful in refractory cases. Intramuscular botulinum toxin injections have been used both in migraine and tension-type headache but are of established benefit only in patients with chronic migraine.

Other Defined Primary Headache Syndromes

Other acute short-lasting headache syndromes need to be differentiated from migraine, cluster, or tension headache. These include primary "thunderclap" headache, *primary stabbing headache*, *primary exertional headache*, and coital headache. The latter may be indistinguishable from the headache of intracranial aneurysm rupture and requires computed tomography (CT) and lumbar puncture to exclude subarachnoid hemorrhage (SAH). All of these headache syndromes are more common in migraineurs. Two additional rare, short-lasting headache syndromes deserve mention: short-lasting unilateral neuralgiform headache with conjunctival tearing (SUNCT) and *hypnic headache*. The latter refers to multiple episodes of very brief headache that awaken the patient (typically an older woman) from sleep. The syndrome of SUNCT causes multiple very brief (seconds to minutes) episodes of cluster-like headache and autonomic disturbance.

Chronic daily headache is defined arbitrarily as headache lasting for more than 4 hours on more than 15 days in the month for more than 3 months. In clinical practice this means that the patient has a headache more often than not. In these cases it is important to establish whether the headache syndrome began as an episodic disorder (as in migraine or tension-type headache) or whether it consists of new daily persistent headaches.

New daily persistent headache. New daily persistent headache needs to be distinguished from tension-type or migraine headaches that have transformed into chronic daily headache and necessitates investigation to exclude a secondary cause.

Headache may be a manifestation of underlying structural brain disease (see Table 113.2). Headache can be seen in all forms of cerebrovascular disease, including infarction, intracerebral hemorrhage, and SAH, although headache is rarely prominent in cerebral infarction. In contrast, the headache in SAH is usually extremely severe and often described by the patient as "the worst headache of my life." Nuchal rigidity, third nerve palsy (usually involving the pupil), and retinal, preretinal, or subconjunctival hemorrhages may be found. CT of the head usually shows subarachnoid, intraventricular, or other intracranial blood.

Certain symptoms raise suspicion for a structural brain lesion (Tables 113.7 and 113.8).

The patient with headache and fever presents a common diagnostic problem in the emergency department. Neck stiffness is a common symptom. Meningismus is confirmed by eliciting Brudzinski and Kernig signs. Vomiting occurs in about 50% of patients. Suspicion for meningitis should prompt immediate investigation, including a lumbar puncture. If the patient shows focal signs, papilledema, or profound alteration in level of consciousness, CT of the head before

TABLE 113.7 Differential Diagnosis of Acute Headache: Major Causes

Migraine

Signs
Nuchal rigidity
Fever
Papilledema
Pathologic reflexes or reflex asymmetry
Altered state of consciousness

lumbar puncture is required to rule out focal disease such as an abscess or subdural empyema. These lesions, however, are rare.

Acute sinusitis. Head and face pain is the most prominent feature of sinusitis. Malaise and low-grade fever are usually present. The pain is dull, aching, and nonpulsatile; is exacerbated by movement, coughing, or straining; and is improved with nasal decongestants. The pain is most pronounced on awakening or after any prolonged recumbency and is diminished with maintenance of an upright posture.

The location of the pain depends on the sinus involved. Maxillary sinusitis provokes ipsilateral malar, ear, and dental pain with significant overlying facial tenderness. Frontal sinusitis produces frontal headache that may radiate behind the eyes and to the vertex of the skull. Tenderness to frontal palpation may be present with point tenderness on the undersurface of the medial aspect of the superior orbital rim. In ethmoidal sinusitis, the pain is between or behind the eyes with radiation to the temporal area. The eyes and orbit are often tender to palpation, and, in fact, eye movements themselves may accentuate the pain. Sphenoidal sinusitis causes pain in the orbit and at the vertex of the skull and occasionally in the frontal or occipital regions. Given that the trigeminal nerve mediates pain perception from the sinuses, many patients who complain of "sinus headaches" are probably suffering from the trigeminovascular disturbance of migraine, rather than sinusitis. Chronic sinusitis is seldom a cause of headache.

Brain tumors. Posterior fossa tumors (particularly of the cerebellum) frequently produce headache, especially if hydrocephalus

occurs because cerebrospinal fluid (CSF) flow is partially obstructed. Supratentorial tumors, however, are less likely to cause headache and are more frequently heralded by altered mental status, focal deficits, or seizures. Although increased intracranial pressure is often associated with headache, it is usually not the primary mechanism because uniform pressure elevations do not usually produce distortions of pain-sensitive structures.

Idiopathic intracranial hypertension. Idiopathic intracranial hypertension (IIH), also called *benign intracranial hypertension*, is defined as a syndrome of elevated intracranial pressure without evidence of focal lesions, hydrocephalus, or frank brain edema. It usually occurs between the ages of 15 and 45 years and is more frequent in obese women. The disorder is characterized by headache with features of raised intracranial pressure. The headache is usually insidious in onset, is typically generalized, is relatively mild in severity, and is often worse in the morning or after exertion (e.g., straining or coughing).

At times, patients have visual disturbances, such as restricted peripheral visual fields, enlarged blind spots, visual blurring (*obscuration*), or diplopia secondary to abducens nerve palsies. Funduscopic examination shows papilledema, which is often more impressive than the clinical picture. IIH is usually a benign and self-limited disorder, but it may lead to visual loss, including blindness. IIH often coexists with other disorders, including polycystic ovary syndrome, sleep apnea, anxiety, and cognitive dysfunction.

The condition has been associated with drugs—vitamin A intoxication, nalidixic acid, danazol (Danocrine), and isotretinoin (Accutane)—as well as corticosteroid withdrawal and systemic disorders such as hypoparathyroidism and lupus.

CT scans are usually normal but can show small ventricles and an “empty sella”; in some cases flattening of the posterior aspect of the ocular globe, tortuosity of the optic nerve, and distension of the perioptic subarachnoid space may be seen. CSF opening pressure is elevated, usually in the range of 250 to 450 mm of water, with the pressure fluctuating markedly when monitoring occurs over a prolonged period. Some cases of IIH are caused by cerebral venous sinus occlusion. These cases can occur in hypercoagulable states, including peripartum, in association with the combined oral contraceptive pill, and in association with antiphospholipid antibody syndrome. After secondary causes of IIH have been eliminated, the patient should have dietary counseling for weight loss; up to 15% weight loss is required to put IIH into remission. Carbonic anhydrase inhibitors (acetazolamide) and corticosteroids have proved useful in headache control. As a second-line agent, furosemide also acts to lower CSF production. In cases where the headache has migrainous features (68%), acute and preventative treatments for migraine may be useful. Topiramate can prevent headache and may facilitate weight loss. Serial lumbar punctures are understandably unpopular with patients even though transient headache relief is obtained. CSF shunting procedures (ventriculoperitoneal shunt) are occasionally necessary. For patients with progressive visual loss, optic nerve sheath fenestration preserves or restores vision in 80% to 90% of cases and provides headache relief in a majority. Patients should be followed for visual acuity, pupil examination, formal visual field assessment, dilated fundal examination to grade papilledema, and BMI monitoring.

Idiopathic intracranial hypotension. Also known as *low pressure headache*, idiopathic intracranial hypotension is commonly encountered as a sequela of lumbar puncture, resulting from leakage of CSF through the dural sac. Low pressure headaches may also occur spontaneously as a result of rupture of subarachnoid cysts. The headache is initially characteristically positional, being severe on standing but relieved rapidly on lying down. Occasionally the headache

is associated with focal or “false localizing” signs, especially abducens nerve palsies.

Post-traumatic headache. Headache following trauma has no specific quality and is associated with irritability, concentration impairment, insomnia, memory disturbance, and lightheadedness. Anxiety and depression are present to variable degrees. Multiple treatment options are available, and amitriptyline and nonsteroidal anti-inflammatory agents are useful. Occasionally, muscle relaxants and anxiolytics are beneficial. Training is occasionally associated with the onset of typical migraine.

Medication-associated headache. Medication overuse of “rebound” headache accounts for a significant portion of the headache burden in the population and in headache clinics. The term describes a chronic (≥ 15 days/month) headache that occurs in patients with a preexisting headache syndrome (most commonly migraine or tension-type headache) who use analgesic medication. Opioids, such as codeine, are particularly apt to give rise to this syndrome, but triptans, NSAIDs, and even paracetamol may have the same effect. Treatment involves the reduction or cessation of analgesic medication with a “washout” period of several weeks, during which time the headaches may worsen. Nonpharmacologic methods of pain management play a crucial role in this period. A range of other medications and substances, such as nitrous oxide, carbon monoxide, cocaine, alcohol, and phosphodiesterase inhibitors have also been reported to induce headache.

Giant cell arteritis. Headache occurs in 60% of patients with giant cell arteritis, a granulomatous vasculitis of medium and large arteries. Over 95% of patients are 50 years of age or older. Malaise, fever, weight loss, and jaw claudication occur early, in addition to headache. Polymyalgia rheumatica, a syndrome of painful stiffness of the neck, shoulders, and pelvis, is found in half the patients. Visual impairment secondary to ischemic optic neuritis may occur. The headache is usually described as aching and is exacerbated at night and after exposure to cold. The superficial temporal artery is frequently swollen, tender, and may be pulseless. The erythrocyte sedimentation rate is usually elevated; the mean is 100 mm/hr. Anemia is frequently present. Doppler ultrasound of the temporal arteries demonstrates a hypochoic “halo sign” around the lumen of affected arteries. Temporal artery biopsy usually confirms the diagnosis, but, because the arteritis is segmental, large or multiple sections may be required. Prednisone therapy is often dramatically effective and must be given promptly to preserve vision on the affected side. Tocilizumab, a monoclonal antibody directed against the interleukin-6 receptor, is now available for the treatment of GCA, particularly in refractory or relapsing disease.

Evaluation of the Patient With Acute Headache

It is important to distinguish benign from ominous causes of headache. A detailed history (the quality, location, duration, and time course of the headache) helps in determination of which patients have a symptomatic structural intracranial lesion (see [Table 113.7](#), [Table 113.8](#), [Table 113.4](#)). Pain intensity is not of much diagnostic value, except for the patient who complains of the acute onset of the worst headache of his or her life. The quality of pain (“throbbing,” “pressure,” “jabbing”) and the location may also be helpful, especially if the pain is of extracranial origin, such as temporal in temporal arteritis. Posterior fossa lesions cause occipitocervical pain, occasionally associated with unilateral retro-orbital pain. In general, multifocal pain usually implies a benign cause. It is most important to clarify the acuity of onset of the headache; patients who describe the onset of pain as “like being hit on the head with a bat” should be suspected of having the sentinel headache of subarachnoid headache. Equally important is to establish the time course of the headache. Is this paroxysmal, nonprogressive

headache (typical of migraine or tension-type headache)? Or is the headache daily persistent (such as in temporal arteritis) or progressive (suggesting the presence of a structural brain lesion)? Patients should be asked about any known triggers for the headache, such as menses, particular foods, caffeine, alcohol, or stress. Positional headache (headache that is maximal in the upright position and disappears rapidly on lying down) is characteristic of intracranial hypotension (low pressure headache). Diurnal variation in headache severity may give a clue to cause; morning headache or headache that awakens a patient from sleep may indicate raised intracranial pressure or sleep apnea as a cause. The presence of associated symptoms such as visual disturbances, nausea, or vomiting should be noted. The history should include inquiries about medications, especially use of analgesics and over-the-counter remedies. Information regarding the patient's past medical history as well as family history should also be taken into consideration. In the majority of patients with headache, the physical and neurologic examination findings are normal, although special attention may be directed toward examination of the eyes for papilledema, as well as the temporal arteries for a palpable nonpulsatile artery. Assessment of the patient with acute nontraumatic headache in the emergency room can be challenging; it is essential to establish how the headache evolved. Acute-onset severe headache should prompt investigation to exclude SAH, intracranial hemorrhage, acute obstructive hydrocephalus, and meningitis (see [Table 113.7](#)). Appropriate initial investigations should include brain imaging with CT or magnetic resonance imaging (MRI). Patients with suspected meningitis without focal neurologic signs or impaired consciousness should not have their lumbar puncture delayed unnecessarily before imaging. All patients should have standard blood tests, including blood cultures if bacterial meningitis is suspected.

A wide variety of systemic diseases have headache as a prominent symptom; some of the more prevalent disorders are summarized in [Table 113.2](#).

CRANIAL NEURALGIAS

Neuralgias are differentiated from other head pains by the brevity of the attacks (usually 1 to 2 seconds or less) and by the distribution of the pain (see [Table 113.3](#)).

Trigeminal Neuralgia

In trigeminal neuralgia (tic douloureux), stabbing, spasmodic pain occurs unilaterally in one of the divisions of the trigeminal nerve. It lasts seconds, but it may occur many times a day for weeks at a time. It is characteristically induced by even the lightest touch to particular areas of the face, such as the lips or gums. Trigeminal neuralgia is the most frequent neuralgia of the elderly and is thought to be caused by compression of the trigeminal nerve root in the pons by an aberrant arterial loop. A small minority of cases are caused by multiple sclerosis, cerebellopontine angle tumors, aneurysms, or arteriovenous malformations, although in these cases (unlike "true" trigeminal neuralgia) there are usually objective signs of neurologic deficit, such as areas of diminished sensation. In these cases of "symptomatic" neuralgia, the pain is often atypical. MRI is indicated in patients who have sensory loss, those who are under 40, and those with bilateral or atypical symptoms. Trigeminal neuralgia may be life threatening when it interferes with eating. Neuralgic pain is often responsive to treatment with standard doses of an anticonvulsant such as phenytoin, carbamazepine, gabapentin, pregabalin, and, occasionally, baclofen. Antidepressant drugs such as amitriptyline and, more recently, duloxetine may also be useful in this setting. Combination therapy, including an antidepressant, anticonvulsant, and opiate analgesic, has been shown to have synergistic effects.

If medical treatments are unsuccessful, surgical treatment may be indicated: microvascular decompression or radiofrequency lesioning of the sensory portion of the trigeminal nerve. The latter occasionally gives rise to the complication of *anaesthesia dolorosa*, in which the loss of sensation resulting from the procedure is experienced as being extremely unpleasant.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is less common than trigeminal neuralgia. Brief paroxysms of severe, stabbing, unilateral pain radiate from the throat to the ear or vice versa and are frequently initiated by stimulation of specific "trigger zones" (e.g., tonsillar fossa or pharyngeal wall). Swallowing often provokes an attack; yawning, talking, and coughing are other potential triggers. Microvascular decompression is necessary if medical treatment is ineffective.

Postherpetic Neuralgia

Herpes zoster produces head pain by cranial nerve involvement in one third of cases. In some cases a persistent intense burning pain follows the initial acute illness. The discomfort may subside after several weeks or persist (particularly in the elderly) for months or years. The pain is localized over the distribution of the affected nerve and associated with exquisite tenderness to even the lightest touch. The first division of the trigeminal nerve is the most frequent cranial nerve involved (ophthalmic herpes) and is occasionally associated with keratoconjunctivitis. When the seventh nerve is affected ("geniculate herpes"), the pain involves the external auditory meatus and pinna. Occasionally, concomitant facial paralysis may occur (Ramsay Hunt syndrome).

Occipital Neuralgia

Occipital neuralgia is a syndrome that includes occipital pain starting at the base of the skull and often provoked by neck extension. Physical examination shows tenderness in the region of the occipital nerves and altered sensation in the C2 dermatome. Treatment includes the use of a soft collar, muscle relaxants, physical therapy, and local injections of analgesics and anti-inflammatory agents. The term *cervicogenic headache* is often used to describe headache associated with myofascial trigger points in the neck. Importantly, cervical spondylosis (discussed next) is not usually typically associated with headache.

CERVICAL SPONDYLOSIS

Cervical spondylosis is a degenerative disorder of the cervical intervertebral disks leading to osteophyte formation and hypertrophy of adjacent facet joints and ligaments. In contrast to the lumbar spine, herniation of cervical intervertebral disks (nucleus pulposus) accounts for only 20% to 25% of cervical root irritation. Cervical spondylosis is one of the most common pathologies seen in office practice and is present radiographically in over 90% of the population older than 60 years. For unknown reasons, the degree of anatomic abnormality is not directly correlated with the clinical signs and symptoms. Clinical disease may represent a combination of normal, age-related, degenerative changes in the cervical spine and a congenital or developmental stenosis of the cervical canal; the process may be aggravated by trauma. Cervical spinal myelopathy results from a combination of degenerative disc disease, spondylosis aggravated by biomechanical instability, as well as stiffening and buckling of the ligamentum flavum. It may manifest as a painful stiff neck, with or without symptoms or signs of cervical root irritation or spinal cord compression. Patients with root irritation (cervical radiculopathy) complain of pain and paresthesias radiating down the arm roughly in the dermatomal distribution of the affected nerve root. More typically, the pain radiates in a myotomal

TABLE 113.9 Common Cervical Root Syndromes

Disk Space	Root Affected	Muscles Affected	Distribution of Pain	Distribution of Sensory Symptoms	Reflex Affected
C4-5	C5	Deltoid; biceps	Medial scapula; shoulder	Shoulder	Biceps
C5-6	C6	Wrist extensors	Lateral forearm	Thumb; index finger	Triceps
C6-7	C7	Triceps	Medial scapula	Middle finger	Brachioradialis
C7-T1	C8	Hand intrinsic	Medial forearm	Fourth and fifth fingers	Finger flexion

pattern, whereas numbness and paresthesias follow a dermatomal distribution. Discrete sensory loss is uncommon and less prominent than symptoms (Table 113.9). For relief, patients often adopt a position with the arm elevated and flexed behind the head. Pain is exacerbated by turning the head, ear down, to the side of the pain (Spurling maneuver). Objective neurologic findings may be limited to reflex asymmetry because weakness may be obscured by pain. Patients who have some degree of spinal cord compression demonstrate gait and bladder disturbances and evidence of spasticity on examination of the lower extremities. These patients require investigation with MRI. Plain radiographs of the cervical spine add little information except in patients with rheumatoid arthritis in whom basilar invagination or atlantoaxial subluxation is suspected.

Cervical spondylosis is so common in the general population that it may be present coincidentally in a patient with another disease of the spinal cord. Among other diseases that may mimic cervical spondylosis are multiple sclerosis, amyotrophic lateral sclerosis, and, less commonly, subacute combined system disease (vitamin B₁₂ deficiency). Conservative treatment includes the use of anti-inflammatory medication, cervical immobilization, and physical therapy for isometric strengthening of neck muscles once pain has subsided. Surgery should be considered if there is progression of the neurologic deficit, especially the emergence of signs of cervical cord compression. There is some evidence to suggest that cervical spondylosis is an active degenerative disease rather than simply the process. Furthermore, early studies with the glutamate antagonist riluzole suggest a potential role in reducing disease progression.

ACUTE LOW BACK PAIN

Low back pain without sciatica (radiating radicular pain) is common, with a reported point prevalence of up to 33%. Acute low back pain lasting several weeks is usually self-limiting, with a low risk for serious permanent disability. Risk factors for prolonged disability include psychological distress, compensation conflict over work-related injury, and other coexistent pain syndromes. The evaluation of patients with acute low back pain should focus on distinguishing pain of mechanical origin from neurogenic pain caused by nerve root irritation. The same pathologic changes that affect the cervical spine may also affect the lumbar spine. Because the spinal cord ends at the level of the first lumbar vertebra, lumbar canal stenosis from intervertebral disk disease and degenerative spondylosis will affect the roots of the cauda equina. The most common levels for lumbar degenerative disk disease are at L4 to L5 and L5 to S1, resulting in the common complaint of sciatica caused by irritation of the lower lumbar roots. Pain tends to improve with sitting or lying down, in contrast to the pain from spinal or vertebral tumors, which is aggravated by prolonged recumbency. Examination shows loss of the normal lumbar lordosis, paraspinal muscle spasm, and exacerbation of pain with straight leg rising, owing to stretching of the lower lumbar roots. About 10% of disk herniations occur lateral to the spinal canal, in which case the more rostral root is compressed. Percussion of the spine may elicit focal tenderness of one of the vertebrae, suggesting bony infiltration by infection or tumor.

Spinal stenosis of the lumbar region may manifest as “neurogenic claudication,” which is usually described as unilateral or bilateral buttock pain that is worse on standing or walking and relieved by rest or flexion at the waist. Patients may have pain that is worse when walking downhill, in contrast to patients with vascular claudication, whose pain is maximal when walking up an incline.

MRI in many patients with isolated low back pain shows nonspecific findings; MRI assessment early in the course of an episode of low back pain does not improve clinical outcome. MRI should be limited to patients with back pain who have associated neurologic symptoms or signs, especially new-onset disturbances of bladder or bowel continence or perineal sensory symptoms suggestive of a *cauda equina syndrome*. Patients with risk factors for malignancy, infection, or osteoporosis, as well as those with pain maximal at rest (or nocturnal pain) require imaging. Patients with primary and metastatic tumor can present with acute back pain. Moreover, developmental anomalies are often associated with pain (see Chapter 117).

Treatment strategies for lumbar pain are similar to those for cervical pain, with surgery reserved for patients with neurologic signs and clear pathologic processes seen on imaging studies. Most cases of acute low back pain, even with rupture of an intervertebral disk, can be treated conservatively with a short period of rest, muscle relaxants, and analgesics. Prolonged bed rest is recommended only for patients in severe pain. Patient education regarding proper posture and appropriate back exercises is helpful, as is a formal physical therapy program. Chiropractic manipulation should not be performed for patients who have evidence of neurologic injury or spine instability.

For a deeper discussion on this topic, please see Chapter 370, “Headaches and Other Head Pain,” in *Goldman-Cecil Medicine*, 26th Edition.

Disorders of Vision and Hearing

Eavan Mc Govern, Timothy J. Counihan

DISORDERS OF VISION AND EYE MOVEMENTS

Examination of the Visual System

Visual Acuity

The clinical examination of visual function begins with testing visual acuity.

Examination technique.

- Use a Snellen chart at a distance of 20 feet (Fig. 114.1).
- If applicable, test visual acuity with a patient's corrective lenses.
- Examine each eye separately.
- Record the smallest line the patient can read. This is the visual acuity for the eye tested; for instance, acuity of 20/40 refers to letters that the patient sees maximally at 20 feet, which a normal individual can see at 40 feet.
- If a patient is unable to read the largest letter, visual acuity is recorded using finger counting or light perception.

Clinical clues. When errors of refraction are responsible for decreased visual acuity, vision may be improved by having the patient look through a pinhole. Corrected vision in one eye of less than 20/40 suggests damage to the lens (cataract) or retina or a disorder of the anterior visual (prechiasmatic) pathway. Color vision should be tested using Ishihara color plates to detect an acquired unilateral or bilateral cause of color loss. Patients with optic nerve lesions with normal visual acuity can report that colors appear "washed out" in the affected eye (color desaturation).

Visual Fields

Confrontational examination of visual fields is helpful when localizing lesions interrupting the afferent visual system (Fig. 114.2).

Examination technique.

- The examiner's head should be level with the patient's head.
- Test each eye separately, by initially asking the patient to cover the other eye.
- Visual fields should be tested in all four quadrants using finger counting by comparing the patient's field with that of the examiner.
- Use a white pin to map peripheral visual fields and a red pin to assess for the presence of a central area of visual field loss (referred to as a scotoma).

Examination tips. Finger counting is more sensitive than presenting moving objects in detecting visual field deficits. The field should be tested first unilaterally and then bilaterally. A defect (particularly in the left hemifield) with bilateral testing only (extinction) suggests visual neglect and a lesion in the contralateral parietal lobe.

Clinical clues. The following questions are helpful to help localize the lesion within the visual afferent system.

- Is the defect monocular or binocular? Monocular lesions localize the defect to the retina or to the optic nerve. A binocular lesion localizes posterior to and including the optic chiasm.

- Is the defect central or peripheral? *Scotomas* are areas of partial or complete visual loss and may be central or peripheral. Central scotomas result from damage to the macula. A scotoma affecting one half of a visual field is known as a *hemianopia*. Field defects are said to be *homonymous* if the same part of the visual field is affected in both eyes; a homonymous hemianopia implies a postchiasmatic lesion.
- Is the defect congruous or incongruous? A homonymous defect may be *congruous* (the visual defect is identical in each hemifield) or *incongruous* (the visual defect is not identical in each hemifield). The closer the visual field defect to the occipital lobe the more congruous the defect.
- Does the defect involve the superior, inferior or bitemporal visual fields? *Quadrantanopsias* are smaller defects in the visual field and may be superior (which suggests a temporal lobe lesion) or inferior (which suggests a parietal lobe lesion). Bitemporal hemianopia implies a lesion at the chiasm, such as a pituitary tumor. An altitudinal hemianopia occurs with vascular damage to the retina.
- Is the visual defect associated with positive symptoms? Scintillating scotomas are hallucinations of flashing lights. If they are monocular, they may be caused by retinal detachment; binocular scintillations suggest occipital oligemia (as in migraine) or seizure. Any suspicious findings on bedside confrontation testing warrant formal visual field testing using perimetry (Fig. 114.3).

Pupils

Pupil constriction is mediated by the parasympathetic system of the oculomotor (third cranial) nerve, whereas dilation is mediated by the sympathetic system. If the balance of these systems is disrupted, *anisocoria* (unequal pupil size) results.

Examination technique.

- Observe the pupillary size and shape at rest.
- Examine the pupils in both dim and bright light.
- Note the direct and consensual light responses for each eye. This is best tested using the "swinging light test," in which the light is moved quickly from one eye to the other.
- Test for accommodation by asking the patient to first look at a distant object and then at the examiner's fingers, held 12 inches away.

Clinical clues. If the degree of anisocoria increases going from dim to bright light, this suggests that the larger lesion is failing to constrict due to a lesion of the parasympathetic system. Similarly, if the degree of pupillary asymmetry is maximal in a dimly lit environment, this suggests that the smaller pupil fails to dilate appropriately due to a lesion of the sympathetic nervous system. *Physiologic anisocoria* is characterized by pupillary asymmetry that is unchanged irrespective of the ambient light intensity; this occurs in approximately 20% of the population. When light is shone into one eye, both eyes should

Fig. 114.1 Snellen chart.

constrict simultaneously. When the light source is shone from a normal eye to an affected, relative dilatation of both pupils is observed. This abnormality is referred to as an *afferent pupillary defect* and indicates severe retinal disease or an optic neuropathy. *Argyll-Robertson pupils* are small, irregular pupils that constrict to near vision (accommodation reflex) but not in response to light. They are associated with neurosyphilis, diabetes, and other disorders. This so-called *light-near dissociation* may also occur in rostral dorsal midbrain lesions, in which there may be associated abnormalities of vertical gaze, eyelid retraction, and convergence retraction nystagmus (Parinaud syndrome). This constellation of clinical findings is occasionally found in patients with lesions of the pineal gland.

The presence of drooping of the eyelid (ptosis) should be noted. A large, unreactive pupil with complete ptosis indicates a lesion of the oculomotor nerve (*third cranial nerve palsy*) interrupting the parasympathetic nerve supply to the pupil. The associated paralysis of the medial and inferior rectus and inferior oblique muscles (see later discussion) results in distortion of the eye (inferolaterally, “*down and out*”) and a subjective complaint of diplopia by the patient. Common causes of a third nerve palsy include compression by an aneurysm of the posterior communicating artery, by transtentorial herniation, or from ischemia, usually in the setting of diabetes or vasculitis. A third cranial nerve palsy caused by ischemia often spares the pupil but results in complete paralysis of the oculomotor and eyelid levator muscles. Acute painful third nerve palsy should be treated as an emergency, with the need to investigate for an intracranial aneurysm.

A small, poorly reactive pupil with associated partial ptosis is known as *Horner syndrome* and results from damage to the sympathetic fibers to the pupil, which may occur anywhere along their course from the hypothalamus, brain stem, and ascending sympathetic chain

Fig. 114.2 Visual fields that accompany damage to the visual pathways. 1, Optic nerve: unilateral amaurosis. 2, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopia. 3, Central optic chiasm: bitemporal hemianopia. 4, Optic tract: incongruous, incomplete homonymous hemianopia. 5, Temporal (Meyer) loop of optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. 6, Parietal (superior) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. 7, Complete parieto-occipital interruption of optic radiation: complete congruous homonymous hemianopia with psychophysical shift of foveal point often sparing central vision, giving “*macular sparing*.” 8, Incomplete damage to visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Baloh RW: Neuro-ophthalmology. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 1998, WB Saunders, p 2236.)

Fig. 114.3 Humphrey visual fields demonstrating an incongruent homonymous hemianopia.

from the superior cervical ganglion to the orbit. There may be associated unilateral anhidrosis resulting from damage to sympathetic fibers. Horner syndrome may be the first sign of an apical lung tumor (Pancoast) or may occur in diseases affecting the carotid artery such as dissection.

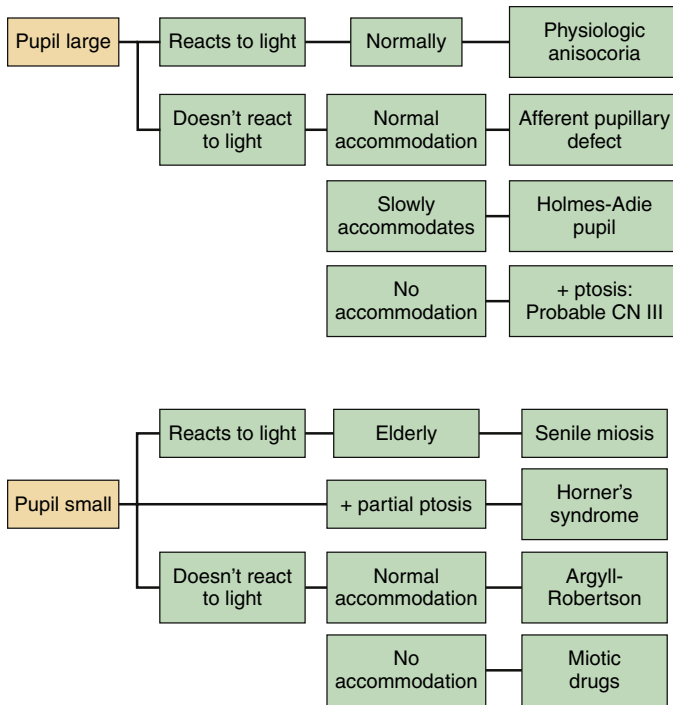

Fig. 114.4 Algorithm for the approach to unequal pupils (anisocoria).

Tonic (Adie) pupils constrict slowly and incompletely in response to light. This is usually an incidental finding on examination but may be associated with areflexia (Holmes-Adie syndrome). Reaction to accommodation is preserved, and it has been suggested that the disorder is a result of parasympathetic denervation. *Hippus* refers to pupillary unrest with synchronous oscillation of the pupil size; it is considered a normal phenomenon. Fig. 114.4 summarizes common pupillary abnormalities and their associated features.

Eye Movements

Abnormalities in ocular motility may arise from lesions of the cerebral hemisphere, brain stem, cranial nerves and ocular muscles. The ability to localize lesions disrupting binocular vision can provide valuable diagnostic information for the clinician.

Examination technique. First note the position of the head and eyes with the eyes in primary gaze. Next, the four components of oculomotor function should be tested:

1. Pursuit eye movements: Smooth pursuit eye movements allow fixation on a moving object. Ask the patient to follow a moving target such as a pin in all directions of gaze.
2. Saccadic eye movements: These movements allow rapid switching of gaze from one target to another. Both horizontal and vertical saccadic movements should be checked.
3. Vestibulo-ocular reflex: This reflex enables fixation on an object even if the head is moving. It is assessed by using the *doll's eye maneuver*.
4. Convergence response: This tests the ability of the eyes to track an object as it is brought close to the limit of accommodation. Ask the patient to look into the distance and then at your finger held close to their eyes.

Both smooth pursuit and (voluntary) saccadic eye movements in horizontal and vertical directions are checked to determine whether the movements are conjugate or dysconjugate.

Clinical clues from history. The following questions from the clinical history can be helpful in evaluating the patient with diplopia.

- Is the diplopia primarily horizontal or vertical, or is it greater looking to the right or to the left?
- Is there diurnal variation? Double vision that varies during the day suggests myasthenia gravis.
- Is the diplopia maximal with near or distant vision? Greater difficulty with near vision suggests impairment of the medial rectus, oculomotor nerve, or convergence system, whereas abducens nerve weakness results in horizontal diplopia when objects are viewed at a distance. Diplopia that worsens on going down stairs may suggest a fourth nerve lesion.
- Is the diplopia monocular or binocular? Monocular diplopia is usually caused by an optical problem (i.e., diseases of the retina or lens). It is corrected by having the patient look through a pinhole, unless the cause is psychogenic. Binocular diplopia suggests ocular misalignment that is a disorder of the brain stem (at the level of the ocular motor nuclei or their connections), the peripheral nerves (cranial nerves III, IV, or VI), the neuromuscular junction (myasthenia gravis or botulism) or individual eye muscles (ocular myopathy). A large deficit in the range of eye movements may provide sufficient diagnostic information. However, in many cases, although the patient complains of diplopia, no clear misalignment is visible on testing eye movements. The corneal reflection test may help identify misalignment in these cases. The patient is instructed to look at a light shining directly at the eyes. If the eyes are normally aligned, the light reflection will be about 1 mm nasal to the center of the cornea. If one eye is deviated medially, the reflection will be displaced outward; the reflection will be displaced inward if the eye is deviated outward.

When assessing eye movements, it is important to know the cranial nerves and muscles involved in eye movement. The abducens (sixth cranial) nerve supplies the lateral rectus muscle. The trochlear (fourth cranial) nerve subserves the superior oblique muscle, which intorts the eye as well as depresses the eye in adduction (such as when a patient tries to look downstairs). All other muscles are supplied by the oculomotor nerve (Fig. 114.5). Abnormalities of the cranial nerves in the brain stem are usually accompanied by other signs, such as weakness, ataxia, or dysarthria. The abducens nerve has a long ascending course through the posterior fossa, where it is prone to compression at multiple sites and as a result of raised intracranial pressure; hence, a sixth nerve palsy may be a false localizing sign. Conjugate eye movement is regulated by supranuclear pathways from the cerebral hemisphere to the medial longitudinal fasciculus in the brain stem. A lesion in the cerebral hemisphere resulting from hemorrhage, infarction, or tumor disrupts conjugate gaze to the contralateral side, so that the eyes “look away” from the hemiplegia. Lesions of the brain stem cause conjugate paralysis to the ipsilateral side (eyes looking toward the side of the hemiplegia). Lesions of the medial longitudinal fasciculus, which connects the nuclei of the oculomotor and abducens nerves, lead to *internuclear ophthalmoplegia*. In this case, horizontal gaze results in failure of adduction in one eye and nystagmus in the abducting eye. The lesion is on the side of failed adduction; bilateral lesions are frequently seen in multiple sclerosis. Table 114.1 lists the major causes of acute ophthalmoplegia.

Funduscopy

The retina should be carefully examined in each patient by direct ophthalmoscopy, which provides a magnified view of the fundus without the necessity for dilation of the pupil (Fig. 114.6).

Examination technique.

- The examiner's head should be level with the patient's head.
- The examiner's right eye should be used to examine the patient's right eye.

Fig. 114.5 Movements of eye muscles and their innervation.

Fig. 114.6 A normal optic disk on funduscopic examination.

TABLE 114.1 Major Causes of Acute Ophthalmoplegia

Condition	Diagnostic Features
Bilateral	
Botulism	Contaminated food; high-altitude cooking; pupils involved
Myasthenia gravis	Fluctuating degree of paralysis; responds to edrophonium chloride (Tensilon) IV
Wernicke encephalopathy	Nutritional deficiency; responds to thiamine IV
Acute cranial polyneuropathy	Antecedent respiratory infection; elevated CSF protein level
Brain stem stroke	Other brain stem signs
Unilateral	
P Comm aneurysm	Third cranial nerve, pupil involved
Diabetic-idiopathic	Third or sixth cranial nerve, pupil spared
Myasthenia gravis	As above
Brain stem stroke	As above

CSF, Cerebrospinal fluid; IV, intravenous; P Comm, posterior communicating artery.

- Locate the red reflex in both eyes. While focusing on one eye, move closer until the retina comes into view.
- While focusing on the retina, follow the vessels toward the patient's nose to locate the optic disc.
- To view the macula, ask the patient to look directly at the light.

Clinical clues from patient history. In eliciting the history the most important thing to establish is whether the visual loss is monocular or binocular.

Monocular Visual Loss

Loss of vision in one eye localizes to the prechiasmatic visual pathway (i.e., the eye itself or the optic nerve). Causes include lesions of the cornea, lens, vitreous, retina, or optic nerve. Loss of the red reflex suggests a lesion of the anterior chamber. Careful funduscopic examination will usually reveal ocular and retinal lesions, but acute lesions of the optic nerve (optic neuritis) may not be associated with abnormalities of the optic nerve head.

Optic neuritis is characterized by inflammation of the optic nerve accompanied by non-homonymous visual defects. Optic neuropathies acutely associated with a normal appearing optic disk on funduscopic examination are posterior or *retrobulbar optic neuritis* (“the doctor sees nothing and the patient sees nothing”). Those with a swollen disk on funduscopic examination are anterior optic neuropathies. In

most cases of optic neuropathy, the optic disc becomes pale after 4 to 6 weeks.

Clinical Clues From Patient Examination

In assessing a patient presenting with an optic neuropathy the following features are important to identify on clinical examination and can be helpful in guiding the differential diagnosis:

- Visual acuity
- Color vision
- Visual field
- The presence or absence of a relative afferent pupillary defect (RAPD)
- Optic nerve head appearance on funduscopic examination

The patient with optic neuritis complains of difficulty with vision in the affected eye. Loss of vision may be insidious and recognized only when the unaffected eye is accidentally occluded. Patients often complain of periorbital pain on eye movement on presentation. The evolution of visual loss is highly variable, progressing over a period ranging from less than a day to several weeks, although most patients will have reached their maximal visual deficit in 3 to 7 days.

At the time the patient is first examined, visual acuity may range from almost 20/20 to the extreme of total blindness. Patients may describe their vision as blurred or dim, and colors may appear less bright than usual or “gray.” Red desaturation may occur with optic neuritis and may be detected using Ishihara color plates. Examination of the visual field shows defects within the central 25 degrees, with central and paracentral scotomas being the most common types. An afferent pupillary defect is frequently present. The funduscopic examination is abnormal in only about one half of the cases. The disc may appear hyperemic with blurred margins, and hemorrhages, when present, are few and found only on the disc or in the area immediately surrounding the disc.

There are many causes of optic neuropathy. Broadly speaking, the causes may be divided into inflammatory, vascular, or compressive/infiltrative. Treatment is directed at the underlying cause. Inflammatory causes usually result in subacute painful loss of central vision. In this instance, high-dose intravenous corticosteroids should be used to shorten time to recovery. The most common cause of inflammatory optic neuritis is multiple sclerosis. Bilateral optic neuritis is much less common and may coincide with longitudinally extensive transverse myelitis, known as *neuromyelitis optica* (NMO) or *Devic disease*. The recent discovery of antibodies directed toward aquaporin 4 (a water channel present on astrocytes and vascular endothelial cells), associated with NMO, has identified this as a separate disease entity, with a different treatment regimen emerging for it. The NMO antibody

is the first sensitive and specific biomarker associated with a central demyelinating disorder.

The optic nerve may be compressed by tumors that originate in the nerve itself or in the region of the optic chiasm. Compressive/infiltrative causes typically cause progressive visual loss, color desaturation, and no pain on eye movement. Headache may result in the presence of raised intracranial pressure. Proptosis and diplopia occurs with orbital lesions. Cranial nerve palsies result with lesions involving the cavernous sinus. Causes may be broadly divided into neoplastic and non-neoplastic causes such as thyroid eye disease.

Ischemic optic neuropathy (ION) is the most common cause of acute optic neuropathy in patients over 50 years. The posterior ciliary artery, a branch of the ophthalmic artery, supplies the optic nerve. Due to its anatomic arrangement, optic nerve ischemia results in superior or inferior segmental optic nerve atrophy and clinically manifests as altitudinal defects. ION occurs in two forms. The *atherosclerotic* variety occurs mostly between the ages of 50 and 70 years, and typically no evidence of systemic disease is present. The *arteritic* form is usually a manifestation of giant cell arteritis. There may be systemic manifestations of the disease, including headache, scalp tenderness, and generalized myalgias. Laboratory evaluation shows anemia and elevated erythrocyte sedimentation rate in almost every case. Patients with arteritis should be treated with high doses of corticosteroids to prevent permanent loss of vision.

Acute transient monocular blindness is usually the result of embolization to the central retinal artery from an atheromatous plaque in the carotid artery (*amaurosis fugax*). Any complaint of transient visual loss constitutes an emergency, and steps must be taken to prevent permanent loss of vision by making a prompt diagnosis and initiating appropriate therapy. Examples of sight-saving procedures include corticosteroid therapy for cranial arteritis, reduction of intraocular pressure for acute glaucoma, and carotid surgery, anticoagulation, or antiplatelet therapy for embolic cerebrovascular disease.

Binocular Visual Loss

Binocular visual loss usually suggests retro-chiasmatic pathology. Gradual bilateral visual loss caused by optic nerve lesions is rare. Causes include Leber hereditary optic neuropathy and a toxic nutritional-deficiency state. Acute transient bilateral visual loss (visual obscuration) may be a symptom of raised intracranial pressure caused by a brain tumor or idiopathic intracranial hypertension (IIH); papilledema is often severe. IIH, formerly known as *pseudotumor cerebri*, requires prompt investigation and treatment to prevent potential bilateral visual failure. It is often associated with a high body mass index (BMI) and is more common in young females. Vitamin A and tetracycline ingestion have been associated with the condition. Unilateral or bilateral lateral rectus palsy may be present. It is one of the few situations in which, after imaging, performance of a lumbar puncture is safe in the setting of marked bilateral papilledema. Cerebral venous sinus thrombosis may mimic IIH and should be screened for with neuroimaging.

Bilateral damage to the optic radiations or visual cortex results in cortical blindness. The pupillary light reflex is normal, as are the fundoscopic examination findings, and the patient may occasionally be unaware that he or she is blind (*Anton syndrome*). Patients are often misdiagnosed as having a conversion reaction. Transient cortical blindness occurs most often in basilar artery insufficiency but is also seen in hypertensive encephalopathy. Positive visual phenomena (e.g., phosphenes, scintillating scotomas) are characteristic of migrainous aura and probably reflect oligemia to the occipital lobes from vasoconstriction. Arteriovenous malformations, tumors, and seizures may produce similar symptoms and should be distinguished from migraine

with aura by a careful history and examination as well as by imaging in appropriate cases.

Visual hallucinations are visual sensations independent of external light stimulation; they may be either simple or complex, may be localized or generalized, and may occur in patients with a clear or clouded sensorium. Visual illusions are alterations of a perceived external stimulus in which some features are distorted. The simplest visual phenomena consist of flashes of light (photopsias), blue lights (phosphenes), or scintillating zigzag lines, which last a fraction of a second and recur frequently or which appear to be in constant motion. These can arise from dysfunction within the optic pathways at any point from the eye to the cortex. Glaucoma, incipient retinal detachment, retinal ischemia, or macular degeneration can cause simple visual hallucinations. Lesions of the occipital lobe are often associated with simple hallucinations; classic migraine is by far the most common condition of this type. Complex visual hallucinations such as seeing objects as people, animals, landscapes, or various indescribable scenes occur most frequently with temporal lobe lesions or parieto-occipital association areas. Visual hallucinations of epileptogenic origin are typically stereotyped.

HEARING AND ITS IMPAIRMENTS

Symptoms of Auditory Dysfunction

The two main symptoms of lesions affecting the auditory system are hearing loss and tinnitus. Hearing loss can be classified as conductive, sensorineural, mixed, or central, based on the anatomic site of pathology (Figs. 114.7 and 114.8). Tinnitus can be either subjective or objective. Conductive hearing loss results when there is difficulty transferring sound waves from the external to the middle ear. Any lesion along this pathway can cause conductive hearing loss. Patients with conductive loss have particular difficulty hearing low-frequency sounds and hear better in noisy backgrounds than in quiet environments. Patients often report frequently ear fullness as if their ear is blocked.

Sensorineural hearing loss usually results from lesions of the cochlea or the auditory division of the vestibulocochlear (eighth cranial) nerve. The cochlea analyzes the frequency of sounds and activates appropriate sensory cells depending on the frequency. Patients with sensorineural hearing loss often have difficulty hearing speech that is mixed with background noise and may be annoyed by loud speech. Low tones are better heard than high-frequency ones. Distortion of sounds is common with sensorineural hearing loss. Central (retrocochlear) hearing disorders are rare and result from bilateral lesions of the central auditory pathways, including the cochlear and dorsal olivary nuclear complexes, inferior colliculi, medial geniculate bodies, and auditory cortex in the temporal lobes. Damage to both auditory cortices may result in pure word deafness, in which patients are selectively unable to discriminate language but may be able to hear nonverbal sounds.

Tinnitus is the perception of a noise or ringing in the ear that is usually audible only to the patient (subjective), although, rarely, an examiner can hear the sound as well. The latter, so-called *objective tinnitus*, can be heard when the examining physician places a stethoscope against the patient's external auditory canal. Tinnitus that is pulsatory and synchronous with the heartbeat suggests a vascular abnormality within the head or neck. Aneurysms, arteriovenous malformations, and vascular tumors can produce this type of tinnitus.

Subjective tinnitus, heard only by the patient, can result from lesions involving the external ear canal, tympanic membrane, ossicles, cochlea, auditory nerve, brain stem, and cortex. The character of the tinnitus does not usually aid in determining the site of the disturbance. For this, one must rely on associated symptoms and signs. When tinnitus results from a lesion of the external or middle ear, it is usually accompanied by a

conductive hearing loss. The patient may complain that his or her voice sounds hollow and that other sounds are muffled. Because the masking effect of ambient noise is lost, the patient may be disturbed by normal muscular sounds such as chewing, tight closure of the eyes, or clenching of the jaws. The characteristic tinnitus associated with Meniere's syndrome is low pitched and continuous, although fluctuating in intensity. Often the tinnitus becomes very loud immediately preceding an acute attack of vertigo and then may disappear after the attack. Tinnitus resulting from lesions within the central nervous system is usually not associated with hearing loss but is nearly always associated with other neurologic symptoms and signs. High-dose salicylates frequently result in tinnitus.

Examination of the Auditory System

Examination Technique

Hearing is first tested in the speech range to observe the response to spoken commands at different intensities (whisper, conversation, and shouting). The examiner must be careful to prevent the patient from reading his or her lip movement. A high-frequency stimulus such as a watch tick should also be used because sensorineural disorders often

involve only the higher frequencies. Tuning fork tests permit a rough assessment of the hearing level for pure tones of known frequency. The Rinne test compares a patient's hearing by air and by bone conduction. A 512-cps tuning fork is first held against the mastoid process until the sound fades. It is then placed 1 inch from the ear. Normal subjects can hear the fork about twice as long by air conduction as compared with bone conduction. If hearing by bone conduction is longer than by air conduction, a conductive hearing loss is suggested. The Weber test compares the patient's hearing by bone conduction in the two ears. The fork is placed at the center of the forehead, and the patient is asked where he or she hears the tone. Normal subjects hear it in the center of the head, patients with unilateral conductive loss hear it on the affected side, and patients with unilateral sensorineural loss hear it on the side opposite the loss. Otoscopic examination may reveal impacted cerumen as a cause of conductive hearing loss.

Causes of Hearing Loss

Presbycusis is bilateral hearing loss associated with advancing age. It is not a distinct disease entity. It represents multiple effects of aging on

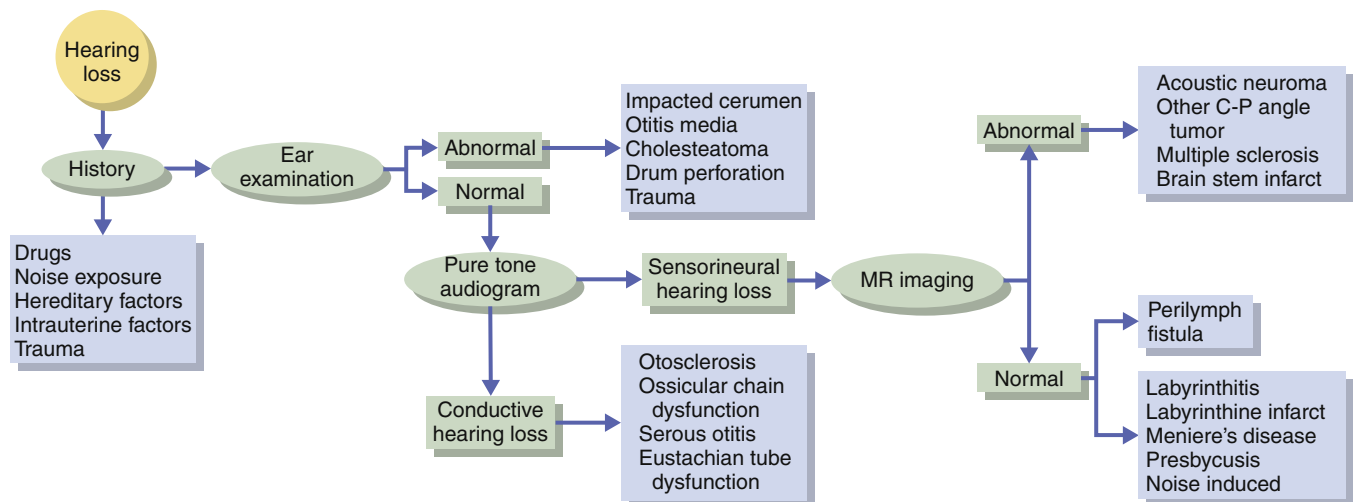

Fig. 114.7 Evaluation of deafness (unilateral and bilateral). *C-P*, Cerebellopontine; *MR*, magnetic resonance. (Modified from Baloh RW: Hearing and equilibrium. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 1998, WB Saunders, p 2250.)

the auditory system. Presbycusis may include conductive and central dysfunction, although the most consistent effect of aging is on the sensory cells and neurons of the cochlea; as a result, higher tones are lost early.

Stroke

Otosclerosis is a disease of the bony labyrinth that usually manifests itself by immobilizing the stapes, thereby producing a conductive hearing loss. Seventy percent of patients with clinical otosclerosis notice hearing loss between the ages of 11 and 30. A family history of otosclerosis is observed in approximately 50% of cases. *Stapedectomy*, a procedure in which the stapes is replaced with a prosthesis, is effective in correcting the conductive component of hearing loss.

A lesion of the cerebellopontine angle, such as a vestibular schwannoma, causes slowly progressive unilateral hearing loss (Table 114.2). Symptoms are caused by compression of the nerve in the narrow confines of the canal (Fig. 114.9). The most common symptoms associated with vestibular schwannomas are slowly progressive hearing loss and tinnitus from compression of the cochlear nerve. Vertigo occurs in fewer than 20% of patients, but approximately 50% complain of imbalance or disequilibrium. Next to the auditory nerve, the cranial nerves most commonly involved by compression are the seventh (facial weakness) and fifth (sensory loss). Loss of the corneal reflex on the affected side is often the first clinical sign. Diagnosis is confirmed with gadolinium-enhanced MRI brain imaging. Treatment in most cases is surgical removal.

Fig. 114.9 Magnetic resonance imaging scan of the brain showing coronal and axial views of a tumor of the left cerebellopontine angle, consistent with a schwannoma.

Meniere's syndrome presents with a clinical triad of fluctuating hearing loss, tinnitus, and episodic vertigo. It is thought to be caused by endolymphatic hydrops in the lymphatic system of the inner ear. Typically the patient develops a sensation of fullness and pressure, along with decreased hearing and tinnitus in one ear. Vertigo rapidly follows, reaching a maximum intensity within minutes and then slowly subsiding over the next several hours. The patient is usually left with a sense of unsteadiness and dizziness for days after the acute vertiginous episode. In the early stages the hearing loss is completely reversible, but in later stages a residual hearing loss remains. Up to 50% of patients with idiopathic Meniere's syndrome have a positive family history, suggesting genetic predisposing factors. The key to the diagnosis of Meniere's syndrome is to document fluctuating hearing levels in a patient with the characteristic clinical history. Medical therapy for endolymphatic hydrops includes dietary sodium restriction and oral diuretics.

Acute unilateral deafness usually results from damage to the cochlea and may be caused by viral or bacterial labyrinthitis or vascular occlusion in the territory of the anterior inferior cerebellar artery. Perilymphatic fistulas may also cause abrupt unilateral deafness, usually in association with tinnitus and vertigo.

Drugs that cause acute irreversible bilateral hearing loss include aminoglycosides, cisplatin, and furosemide. Salicylates may cause reversible hearing loss and tinnitus.

Treatment of Hearing Loss

The best treatment is prevention, particularly by the appropriate use of earplugs for those working in a noisy environment. Hearing

aids help patients with conductive hearing loss, and developments with cochlear implants may help patients with sensorineural hearing loss.

Prospectus for the Future

Ophthalmology has experienced significant advances in imaging modalities that evaluate the retina. Optical coherence tomography (OCT) is one such technique that provides high-resolution images of retina and optic nerve. Cross section images of the retina, optic nerve, and peripapillary areas are produced. It is helpful at detecting macular disease that is not readily detected on fundoscopic examination. In addition, OCT is helpful for monitoring disease activity in various optic neuropathies. OCT angiography is a non-invasive imaging technique that uses OCT technology to visualize retinal and choroidal vasculature. This technique assists with diagnosis and provides insight into the vascular contribution of various retinal diseases.

For a deeper discussion on this topic, please see Chapter 395, "Diseases of the Visual System," and Chapter 396, "Neuro-Ophthalmology," in *Goldman-Cecil Medicine*, 26th Edition. ❖

Dizziness and Vertigo

Jonathan Cahill

DEFINITIONS AND EPIDEMIOLOGY

Vertigo is defined as the sensation of self-motion in the absence of motion or the sensation of distorted self-motion during normal movement. Traditionally, vertigo is described as a spinning sensation, though other descriptions such as a rising, sinking, or floating sensation may also be vertiginous. Dizziness has a less specific definition and has often been further categorized into sensations of vertigo, disequilibrium, lightheadedness, or presyncope. Patients with dizziness frequently describe multiple different and simultaneous symptoms, and their descriptions of symptoms are frequently inconsistent, which makes accurate diagnosis challenging. Throughout this chapter, the terms *vertigo* and *dizziness* will be used almost interchangeably.

Dizziness is a very commonly reported symptom. As a chief complaint, dizziness accounts for 3% of adult primary care clinic visits and 4% of adult emergency department visits. Approximately 30% of the general population reports having had some type of bothersome dizziness.

THE VESTIBULAR SYSTEM AND BRAIN STEM CIRCUITRY

The sense of balance is maintained by a complicated network of afferent (vestibular, visual, and proprioceptive) and efferent (motor, cerebellar, and oculomotor) systems. The vestibular system consists of the vestibular labyrinth in the temporal bone of the inner ear and its projections to the vestibular portion of the eighth cranial nerve. The eighth cranial nerve projects to the vestibular nuclear complex in the brain stem, which in turn projects widely to the cerebellum, other brain stem nuclei, thalamus, and cerebral cortex.

The paired vestibular systems (left and right) maintain balanced tonic input to the brain. Perturbation of any portion of the circuit by focal lesions or aberrant stimulation can lead to dizziness. The connection of the vestibular system to the oculomotor system, demonstrated by the vestibulo-ocular reflex (VOR), is vital in maintaining clear vision during movement. In many cases, vestibular system abnormalities can be detected by examination of eye movements and the VOR. Nystagmus, alternating fast and slow rhythmic eye movements, is a characteristic sign of vestibular system dysfunction. The type and pattern of nystagmus can assist in more accurately localizing the vestibular disorder. [Table 115.1](#) summarizes common patterns of nystagmus observed in patients with vestibular disorders.

DIFFERENTIATING CENTRAL FROM PERIPHERAL

Most causes of dizziness and vertigo are benign. But it is important to consider the rare more serious causes, such as brain stem infarct or a posterior fossa mass, and to understand the strengths and limitations

of available diagnostic testing. The goal of most diagnostic tests is to differentiate causes of vertigo localized to the peripheral (e.g., vestibule, labyrinth, or vestibular nerve) or central (e.g., vestibular nuclear complex, other brain stem connections, cerebellum) vestibular systems.

Computed tomography (CT) scan of the brain is sensitive to rule out acute intracerebral hemorrhage but has limited sensitivity for other etiologies of vertigo. The contents of the posterior fossa (brain stem, cerebellum, and supporting structures) are not well imaged with CT. Furthermore, acute intracerebral hemorrhage commonly presents with additional symptoms and signs and is rarely confused for the other etiologies considered here. Magnetic resonance imaging (MRI) of the brain has better sensitivity for acute ischemic stroke, but in the posterior fossa MRI can miss 15% to 20% of acute ischemic strokes, especially in cases of small (<1 cm) infarctions and when MRI imaging is performed within 24 to 48 hours of symptom onset.

In cases of acute onset dizziness and vertigo, the acute vestibular syndrome, a three-step bedside oculomotor examination is more sensitive than MRI for acute ischemic stroke. The Head-Impulse—Nystagmus—Test-of-Skew (HINTS) examination can be performed in less than 1 minute and can lead to accurate diagnosis in many cases. [Table 115.2](#) summarizes the possible findings of the HINTS examination. It is important to recognize that the HINTS examination findings can only be interpreted when the examination is performed in symptomatic patients.

CLINICAL PRESENTATION PATTERNS

For patients presenting with dizziness, the traditional approach had been to specify the nature or quality of the dizziness as vertigo, imbalance, lightheadedness, or presyncope. The differential diagnosis would then be informed by the specific symptom type. This approach, however, does not lead to accurate diagnosis in many cases and has been replaced by a focus on the timing and triggers of symptoms, rather than the quality of dizziness.

There are four patterns of dizziness presentation: (1) acute persistent, (2) episodic-spontaneous, (3) episodic-triggered, and less commonly, (4) chronic/progressive. It is important to note that no pattern is definitively associated with a particular diagnosis but that the examination and additional testing can be used to home in on a specific disorder and rule out others.

The three most common peripheral vestibular disorders can be thought of as prototypes for most pathology involving the peripheral vestibular system. Each of these three disorders (vestibular neuronitis, Meniere's disease, and benign-paroxysmal positional vertigo [BPPV]) can be diagnosed using the tests described previously and after consideration of possible red flag symptoms. The timing of symptom onset and the triggers of symptoms are the most important features to consider. [Table 115.3](#) summarizes the symptom onset, triggers, and

TABLE 115.1 Nystagmus Patterns

	Pattern	Localization	Principal Causes
Spontaneous	Unidirectional, horizontal > torsional Downbeat, upbeat, or pure torsional	Vestibular nerve, less commonly brain stem Brain	Vestibular neuronitis, less commonly stroke Stroke, brain stem mass, brain stem demyelination
Gaze-evoked (Video 115.1)	Unidirectional (Video 115.2) Bidirectional	Vestibular nerve Brain	Vestibular neuronitis Stroke, cerebellar syndrome, medication side effect
Positional	Burst of upbeat torsional with Dix-Halpike maneuver Horizontal with supine positional testing Persistent downbeat	Semicircular canal of labyrinth Semicircular canal of labyrinth, less commonly brain stem Brain	Benign-paroxysmal-positional vertigo (BPPV) (Video 115.3) BPPV, brain stem lesion Chiari malformation, cerebellar degeneration

TABLE 115.2 HINTS Examination

	Technique	Findings Suggestive of Central Etiology	Findings Suggestive of Peripheral Etiology
Head-Impulse	Patient attempts to maintain visual fixation while the examiner quickly turns the patient's head 5-10 degrees horizontally	Normal fixation, no corrective saccade (rapid eye movements that change the point of fixation)	Abnormal corrective horizontal saccade when the head is turned toward the affected ear
Nystagmus	Extraocular movements examined for nystagmus	Direction changing nystagmus, pure vertical nystagmus	Unidirectional horizontal nystagmus, with some rotary component, worst with gaze in the direction of the fast phase nystagmus
Test-of-Skew	Alternate eye cover testing while patient maintains fixation	Vertical skew with corrective saccade upon uncovering of the eye	Normal, no skew or corrective saccade

TABLE 115.3 Acute Persistent, Episodic-Spontaneous, and Episodic-Triggered Acute Vestibular Syndromes

	Acute Persistent	Episodic-Spontaneous	Episodic-Triggered
Primary consideration	Vestibular neuronitis	Meniere's disease	BPPV
Key features	Constant vertigo, unidirectional horizontal nystagmus, HINTS suggestive of peripheral etiology	Vertigo lasting hours, no specific triggers, unilateral auditory symptoms	Positionally triggered, brief (<1 min) attacks, upbeat torsional nystagmus
Other considerations	Stroke, metabolic disorder, brain stem lesion (mass, demyelination)	TIA, vestibular migraine, panic/anxiety	Orthostatic hypotension
Red flags	Abnormal neurologic examination, HINTS suggestive of central etiology	HINTS (during symptoms) suggestive of central etiology	Prolonged duration of symptoms. Neurologic symptoms other than vertigo.

examination findings for these three common presentations of the acute vestibular syndrome.

DIFFERENTIAL DIAGNOSIS

For vestibular syndromes, the determination of a peripheral or central etiology and the pattern of presenting symptoms serve as the framework for generating the differential diagnosis. In addition to the peripheral and central causes of vertigo and dizziness considered here, there are several other general medical conditions that can present with symptoms mimicking a vestibular syndrome. And despite careful history, examination, and diagnostic testing selection, many cases of dizziness and vertigo remain idiopathic.

The three common causes of a peripheral vestibular disorder (see Table 115.3) are vestibular neuronitis, Meniere's disease, and BPPV. Vestibular neuronitis, caused by a viral infection of the vestibular

nerve, typically presents with abrupt onset vertigo (acute-persistent pattern) and nausea, most commonly lasting for several days. The vertigo attacks of Meniere's disease are shorter in duration, typically hours, and accompanied by nausea and prominent auditory symptoms of hearing loss, ear fullness, and tinnitus. The auditory symptoms of Meniere's disease become more prominent as the disease progresses and can occur outside of specific vertigo attacks. Meniere's disease attacks occur without provocation (episodic-spontaneous), unlike the attacks of BPPV (episodic-triggered). BPPV is caused by otoliths entering the semicircular canals of the inner ear and causing aberrant stimulation of the vestibule and vestibular nerve. In BPPV, sudden movement of the head, such as rolling over in bed or turning one's head to the side, can provoke severe vertigo and nausea, which lasts typically for less than 1 minute if the head is held still. Despite the short duration of vertigo in BPPV, the symptoms can be severe and disabling.

Fig. 115.1 Repositioning treatment for benign paroxysmal positional vertigo designed to move endolymphatic debris out of the posterior semicircular canal (PSC) of the right ear and into the utricle (UT). The patient is seated, and the patient's head is turned 45 degrees to the right (A). The head is then lowered rapidly to below the horizontal (B). The examiner shifts hand positions (C), and the patient's head is rotated rapidly 90 degrees in the opposite direction, so it now points 45 degrees to the left, where it remains for 30 seconds (D). The patient then rolls onto the left side without turning the head in relation to the body and maintains this position for another 30 seconds (E) before sitting up. The treatment is repeated until nystagmus is abolished. The procedure is reversed for treating the left ear. (Modified from Foster CA, Baloh RW: Episodic vertigo. In Rakel RE, editor: *Conn's Current Therapy*, Philadelphia, 1995, WB Saunders.)

Central causes of vertigo include numerous pathologies that cause structural or functional disturbance of the brain stem and cerebellum. For acute vestibular syndromes, ischemic stroke and/or transient ischemic attack (TIA) should be considered, especially in cases where the HINTS examination is concerning or there are other neurologic symptoms or signs in addition to vertigo and dizziness. Migraine may be one of the most common central causes of vertigo, with up to 40% of migraine patients reporting some accompanying vertigo with their migraine attacks. Both vestibular migraine and migraine with brain stem aura can have vertigo as a prominent symptom, though it is usually not the lone symptom. Space occupying lesions in the brain stem or cerebellum (neoplasm, abscess) should be considered in patients with risk factors. And unlike acute ischemic stroke, which can be missed by MRI up to 20% of the time, mass lesions of the brain stem or cerebellum will typically be seen on MRI. Hydrocephalus, which can be readily diagnosed on CT or MRI imaging, may cause symptoms of dizziness, but more typically it would present with a gait ataxia in the absence of dizziness. Degenerative disorders of the cerebellum can cause vertigo, but the pattern of symptoms would not be confused with that of stroke or other AVS.

A wide array of other general medical conditions can cause dizziness or vertigo as well. Dizziness as a side effect of medications is probably

the most common. Dizziness can also be a prominent symptom of panic and anxiety. Symptomatic anemia can cause lightheadedness and dizziness. And following significant head trauma, a post-traumatic dizziness can last for several weeks.

TARGETED TREATMENT

Because most causes of vertigo are benign and the symptoms typically resolve spontaneously in hours to days, conservative treatments are most often appropriate. Symptomatic relief of vertigo can be achieved with antihistamines, benzodiazepines, or antiemetics, but their side effects in the long term and in older patients limit their use. More specific, targeted treatment to the underlying cause of vertigo is preferable.

Vestibular rehabilitation as directed by a physical therapist is the most helpful treatment for prolonged vertigo, such as with vestibular neuronitis. Meniere's disease is commonly treated with a low salt diet or diuretics to reduce the frequency of attacks. The Epley maneuver (Fig. 115.1) for repositioning semicircular canal otoliths is highly effective for BPPV, especially in the most common circumstance where the posterior semicircular canal is affected. For

central causes of vertigo, both stroke and migraine have specific treatments proven to be effective as both abortive and preventative therapies.

Disorders of the Motor System

Ruth B. Schneider, Adolfo Ramirez-Zamora, Christopher G. Tarolli

INTRODUCTION

The motor system is broadly divided into the pyramidal and extrapyramidal systems. The pyramidal system functions to execute motor activity, while the extrapyramidal system provides feedback to the pyramidal system, allowing selection of wanted patterns of movement and suppression of unwanted patterns. The pyramidal system is a two-neuron system, which originates in the primary motor cortex of the frontal lobes and, with white matter projections, coalesces to form the internal capsule; it then traverses the brain stem (as the cerebral peduncles in the midbrain, the basis pontis in the pons, and the pyramids in the medulla where the majority of neurons decussate to form the corticospinal tracts) and ultimately synapses on the lower motor neurons in the anterior horn of the spinal cord. The extrapyramidal system consists primarily of the basal ganglia and the cerebellum and provides coordinating and integrating information to the pyramidal tract system under the influence of various afferent feedback loops. The components and pathways of the basal ganglia (Fig. 116.1) and cerebellum (Fig. 116.2) influence and modulate voluntary motor activity of the motor cortex.

Disorders of the motor system affect the components of the pyramidal and extrapyramidal systems. The approach to the patient with motor dysfunction depends on the ability to accurately localize the neuroanatomic region affected through a careful history and focused examination. Disorders of the pyramidal system (central and peripheral) will be described in other chapters of this text (Chapters 109, 119, 123, and 125). Here, we will focus on disorders of the extrapyramidal system, which present with a variety of disorders of movement.

INTRODUCTION TO MOVEMENT DISORDERS

Movement disorders are a heterogeneous group of disorders associated with basal ganglia dysfunction. Movement disorders refer to a broad group of conditions leading to involuntary or abnormal movement as a prominent feature. In contrast to most seizures, the involuntary movements occur when the patient is conscious but are absent during sleep (with very few exceptions).

Movement disorders can be classified as either hyperkinetic or hypokinetic. Hyperkinetic phenomena include tremor, chorea, dystonia, tics, myoclonus, and other involuntary movements (Table 116.1). Hypokinetic disorders encompass the parkinsonian disorders characterized by a paucity of spontaneous movement (akinesia), slow movements (bradykinesia), and low amplitude movements (hypokinesia). The term bradykinesia is commonly used to encompass all three of these phenomena. While this classification strategy is a valuable means for approaching the patient with abnormal movements,

many movement disorders display a combination of both hyperkinetic and hypokinetic phenomena. Idiopathic Parkinson's disease is the prototypical hypokinetic movement disorder, but it is associated with the hyperkinetic phenomenon of tremor in over 60% of patients. Similarly, Huntington's disease, a traditionally hyperkinetic disorder, is associated with bradykinesia.

Parkinsonism

Parkinsonism is characterized by bradykinesia, rigidity, tremor, and postural instability. It can be caused by a wide variety of degenerative disorders, medications, toxins, and systemic diseases. Table 116.2 summarizes the differential diagnosis of parkinsonism.

Idiopathic Parkinson's Disease

Idiopathic Parkinson's disease (PD), which is the most common cause of parkinsonism, is a progressive, neurodegenerative disorder characterized by a constellation of motor and nonmotor symptoms. The prevalence of PD increases with age and it affects approximately 1% to 2% of individuals over the age of 60. Beyond advancing age, some risk factors for PD include male sex, pesticide exposure, solvent exposure, and family history of PD. The motor symptoms of PD result from the selective loss of dopaminergic neurons in the substantia nigra-pars compacta that project to the striatum. The pathological hallmark of PD is the presence of eosinophilic cytoplasmic neuronal inclusions known as Lewy bodies containing α -synuclein.

Clinically, PD is most commonly recognized by its motor phenomena: rigidity, bradykinesia, rest tremor, and postural instability. Functionally, patients may describe difficulty with fine motor tasks (such as doing buttons), difficulty getting dressed, trouble getting up from a chair, a lack of facial expression, changes in speech (softening or hoarseness), decreased arm swing, poor balance, or tremor at rest or when holding a newspaper. Motor symptoms typically present unilaterally and remain asymmetric over time. Parkinsonian gait is characterized by a flexed and stooped posture, with a slow shuffling quality and decreased stride length and heel strike. Patients can also display festination, a phenomenon in which the stooped posture and hypometric stepping results in the center of gravity being located in front of the feet. Some experience freezing of gait, which refers to a brief and sudden inability to initiate or continue walking. Nonmotor manifestations include autonomic dysfunction (orthostatic hypotension, constipation, urinary symptoms, and impaired temperature regulation), psychiatric features (depression, anxiety, apathy, and psychosis), cognitive changes (mild cognitive impairment and dementia), sleep disorders (insomnia, excessive daytime sleepiness, restless legs syndrome, rapid eye movement [REM] sleep behavior disorder), and a myriad

Fig. 116.1 Anatomy of the basal ganglia and their connections. The feedback loop proceeds from cerebral prefrontal areas to the basal ganglia and eventually back from the basal ganglia to the thalamus to the motor cortex. This ultimately regulates the descending corticospinal motor system. *ACH*, Acetylcholine; *DA*, dopamine; *GABA*, γ -aminobutyric acid; *GLU*, glutamate; *GP*, globus pallidus (e, external; i, internal); *SN*, substantia nigra (c, compacta; r, reticulata); *VL*, ventrolateral. Fig. 116.2 Corticocerebellar loop. The major cerebellar input is from the spinocerebellar tract. Outflow is to the motor cortex via the mesencephalon and thalamus.

of other symptoms (pain, sexual dysfunction, vision changes, fatigue, micrographia, and decreased sense of smell).

PD is a clinical diagnosis based on the presence of gradual progression of characteristic motor symptoms and signs as well as a robust and sustained response to levodopa therapy. While the diagnosis of PD is made on the basis of the presence of a characteristic motor syndrome, it is now recognized that there are earlier stages of PD: preclinical

PD (neurodegeneration in the absence of symptoms or signs) and prodromal PD (symptoms and signs, often nonmotor, insufficient to meet diagnostic criteria). Certain “red flags” on history or examination might suggest an atypical or secondary cause of parkinsonism (Table 116.3). Dopamine transporter (DaT) SPECT imaging can assist in distinguishing neurodegenerative forms of parkinsonism from drug-induced parkinsonism and essential tremor with parkinsonian features. The dopamine transporter is responsible for re-uptake of dopamine into presynaptic terminals and is, therefore, an indirect measure of nigro-striatal neuronal density. In PD, nigro-striatal neurons are lost asymmetrically; on dopamine transporter imaging, this is characterized by asymmetric reduction in dopamine transporter signal in the striatum. With drug-induced parkinsonism and essential tremor, dopamine transporter imaging is normal. Dopamine transporter imaging does not distinguish PD from other degenerative forms of parkinsonism.

PD is a slowly progressive disorder associated with accumulating disability. No medications have been proven to slow progression; however, exercise may slow the progression of disease. Treatments of the motor symptoms can reduce disability and improve function. The mainstay of treatment is levodopa, the precursor to dopamine, given with a dopa-decarboxylase inhibitor (e.g., carbidopa) to maximize CNS penetration of levodopa and minimize systemic side effects. Other symptomatic treatments stimulate dopamine receptors in the brain (dopamine agonists) or inhibit the breakdown of levodopa and dopamine (monoamine oxidase type B inhibitors and catechol-O-methyltransferase inhibitors). This approach to symptom management is effective early in the course of the disease; however, as the disease continues to progress, it may be complicated by the development of motor complications, including motor fluctuations and dyskinesias (which manifest as chorea and/or dystonia). Surgical approaches to treatment of motor complications include deep brain stimulation (DBS) and continuous intestinal infusion of levodopa-carbidopa. Unfortunately, some motor features, such as postural instability, are

TABLE 116.1 Definition of Common Movement Phenomena

Movement	Definition
Parkinsonism	Generic term referring to some combination of features including a paucity of spontaneous movement (akinesia), slow movements (bradykinesia), and low amplitude movements (hypokinesia) as well as tremor (at rest), rigidity, and postural instability.
Tremor	Rhythmic oscillatory movement of a body part. Rest tremor occurs at rest. Action tremor encompasses postural tremor (present during maintenance of a posture), kinetic tremor (which occurs with voluntary movement), and intention tremor (when the tremor worsens upon approaching a target).
Chorea	Irregular, purposeless, abrupt, rapid, brief, arrhythmic, unsustained movements that flow randomly from one part of the body to another.
Dystonia	Sustained or intermittent muscle contractions causing abnormal, often repetitive movements, postures, or both. Dystonic movements are typically patterned, twisting, sustained at the peak of the movement, and may be tremulous.
Tics	Abrupt, usually brief, suppressible, “jerky” and often repetitive and stereotyped movements, which vary in intensity and are repeated at irregular intervals. Key features of tics are the presence of a premonitory urge that is usually temporarily relieved following the movement.
Ataxia	Impairment in coordination of voluntary movement, which may manifest as incoordination of limb movements, gait impairment, eye movement abnormalities, or speech impairment.
Akathisia	Sensorimotor disorder defined by a subjective sense of restlessness affecting all or part of the body with a marked difficulty staying still.
Myoclonus	Simple, rapid, involuntary movement causing movement of a part of the body across a joint. While it can be similar in appearance to a tic, myoclonus is typically a simpler movement fragment and is not associated with a premonitory urge or post-movement sense of relief.

TABLE 116.2 Differential Diagnosis of Parkinsonism

Degenerative/inherited causes	Idiopathic Parkinson’s Disease

unresponsive to medical or surgical therapy. Rehabilitative therapies play an important role throughout the disease course.

A number of monogenic causes of Parkinsonism have been identified. Mutations in α -synuclein (*SNCA*) and leucine-rich repeat kinase 2 (*LRRK2*) are associated with autosomal dominant parkinsonism. Autosomal dominant causes account for less than 2% of all adult-onset Parkinson’s disease cases with higher frequencies in certain populations due to founder effects. Autosomal recessive monogenic causes include mutations in genes encoding parkin (*PRKN*), PTEN-induced kinase 1 (*PINK1*), and DJ-1 (*PARK7*) and are relatively common in familial cases with onset before the age of 45. Mutations in glucocerebrosidase (*GBA*) are the most commonly identified mutations in PD. An improved understanding of these genetic causes suggests an important role of impairment in lysosomal pathways and protein degradation in PD pathogenesis.

Atypical Parkinsonism

The atypical parkinsonian or “Parkinson plus” syndromes refer to a heterogeneous group of sporadic neurodegenerative disorders characterized by parkinsonism, reduced or absent response to dopaminergic therapy, and characteristic nonmotor features. The most common are

the synucleinopathies: multiple system atrophy and dementia with Lewy bodies; and the tauopathies: progressive supranuclear palsy and corticobasal syndrome.

Multiple system atrophy (MSA), formerly termed olivopontocerebellar degeneration, striatonigral degeneration, or Shy-Drager syndrome, is a neurodegenerative syndrome characterized by prominent autonomic dysfunction in combination with parkinsonism and/or cerebellar ataxia. MSA has an estimated prevalence of 2 to 5/100,000. Current nomenclature subdivides patients with MSA based on their predominant motor feature: MSA with predominant parkinsonism (MSA-P) and MSA with predominant cerebellar ataxia (MSA-C), but a mixed phenotype is common. Bradykinesia and rigidity are prominent features of the parkinsonism in MSA-P, though these tend to be symmetric, compared to the asymmetry of early idiopathic PD. Both forms of MSA have prominent autonomic dysfunction manifesting as orthostatic hypotension, urinary retention, delayed gastrointestinal motility, or erectile dysfunction in men. Patients may have a transient response to dopaminergic therapy for motor symptoms, though it is often incomplete; limited interventions are available for management of the associated ataxia. Symptomatic therapy can be utilized to manage orthostatic hypotension, constipation, and urinary symptoms

TABLE 116.3 “Red Flags” in the Diagnosis of Parkinson’s Disease

Clinical or Historical “Red Flag”	Suggested Diagnosis
Early postural instability and falls	PSP, MSA, CBD, DLB, vascular
Early dysphagia	PSP, CBD
Early or spontaneous hallucinations	DLB
Early dementia or dementia predating PD	DLB
Early or severe dysautonomia	MSA
Pyramidal tract and/or cerebellar signs	MSA
Antipsychotic exposure	Tardive or drug-induced
Acute onset and/or non-progressive	Vascular

CBD, Corticobasal degeneration; *DLB*, dementia with Lewy body; *MSA*, multiple system atrophy; *PSP*, progressive supranuclear palsy.

(see Chapter 112). Death typically occurs around 6 to 8 years after the onset of motor symptoms, most often due to respiratory dysfunction or complications of swallowing difficulties.

Dementia with Lewy bodies (DLB) is characterized by the presence of parkinsonism, early dementia (preceding or within 1 year of the onset of motor symptoms), spontaneous visual hallucinations, and fluctuating levels of alertness. Unlike Alzheimer disease, DLB tends to affect visuospatial and executive domains of cognitive function with relative sparing of memory early in the course. The motor symptoms of DLB may be indistinguishable from PD, and patients can have a reasonable response to dopaminergic therapy; however, cautious use is appropriate, given the risk for worsening psychotic symptoms. Patients are also characteristically sensitive to antipsychotics, though atypical antipsychotics with low potency D2 receptor blockade (quetiapine, clozapine, pimavanserin) can generally be used to manage psychotic symptoms. Rivastigmine and other cholinesterase inhibitors are frequently used to treat the cognitive symptoms of PD; these may also offer some benefit for the treatment of hallucinations.

Progressive supranuclear palsy (PSP) is characterized by eye movement abnormalities, early postural instability and falls, axial parkinsonism, dysphagia, dysphonia, and dementia. The supranuclear palsy refers to the characteristic eye movement abnormalities in PSP with a vertical greater than horizontal gaze palsy and preserved oculocephalic reflex; early ocular features can include delayed saccadic initiation (rapid eye movement to focus of interest), slowed vertical eye movements, and the loss of the fast phase of optokinetic nystagmus. There is prominent axial parkinsonism in PSP with truncal rigidity and hyperextension and relatively symmetric appendicular bradykinesia and rigidity; these are typically unresponsive to dopaminergic therapy. Patients may also have prominent dystonia, including frontalis dystonia with associated lid lag giving patients a characteristic surprised appearance. PSP can be rapidly progressive with death often within 5 years of motor symptom onset related to dysphagia, falls, or complications of dementia.

Finally, corticobasal syndrome (CBS) is a rare and heterogeneous disorder characterized by the presence of strikingly asymmetrical parkinsonism, dystonia, and/or myoclonus with associated cortical signs including upper motor neuron features, apraxia, neglect, cortical sensory changes (e.g., agraphesthesia), alien limb phenomena, and dementia. Patients may additionally have oculomotor features that overlap with progressive supranuclear palsy or cognitive features that overlap with frontotemporal dementia. The disease is rapidly progressive, and treatment is symptomatic; motor features do not typically respond to dopaminergic therapy.

Secondary Parkinsonism

There are many causes of secondary parkinsonism, including medications, toxins, and cerebrovascular disease (see Table 116.2).

Medications associated with parkinsonism include any medication that reduces dopaminergic tone in the brain, either through direct blockade of postsynaptic dopamine receptors (e.g., antipsychotics and certain antiemetics) or through depletion of presynaptic dopamine stores (e.g., vesicular monoamine transporter-2 inhibitors). Metoclopramide, a medication commonly used to treat gastroparesis, is a frequent cause because its dopamine blocking effects may be overlooked. Although classically characterized by symmetrical parkinsonism and absence of rest tremor, drug-induced parkinsonism can be clinically indistinguishable from PD. Hyposmia, which is common in PD, may be a helpful clue in distinguishing between drug-induced parkinsonism and PD but it should be recalled that hyposmia is also common among the elderly population. Treatment consists of withholding the offending agent, recognizing that it may take months for the symptoms to resolve. Even then, patients exposed to dopamine blocking agents may develop a tardive parkinsonism (i.e., a drug-induced parkinsonism that persists even after the offending agent is removed). DAT SPECT imaging can be useful in distinguishing drug-induced or tardive parkinsonism from a neurodegenerative parkinsonism.

Cerebrovascular disease is a common cause of secondary parkinsonism. Tremor is uncommon in vascular parkinsonism; lower extremity bradykinesia and gait difficulties dominate the clinical picture. Patients may have a history of clinical strokes with acute deteriorations followed by plateaus; however, many patients have vascular risk factors and a history of gradual decline. Neuroimaging is helpful in these cases.

Tremor

Tremor is characterized by a rhythmic oscillatory movement of a body part. Tremor is classified based on location and state (rest or action). Rest tremor is present when the affected body part is fully supported and not actively contracting; however, it is absent during sleep. Types of action tremor include postural tremor, kinetic tremor, and intention tremor. Postural tremor is present during maintenance of a posture against gravity, such as when extending the arms horizontally. Kinetic tremor is present with voluntary movement of the body part. An intention tremor refers to worsening of tremor on approach of a target (e.g., finger to nose) and is characteristic of cerebellar disease. Tremor has multiple etiologies, including medications, alcohol and drug intoxication and withdrawal, systemic disease (e.g., hyperthyroidism), structural brain lesions, or as a component of a neurodegenerative disease.

Essential Tremor

Essential tremor is among the most common movement disorders and the most common cause of tremor. Essential tremor has a worldwide prevalence of 2% to 4% with increasing incidence with aging. While essential tremor is often familial with an apparent autosomal dominant pattern of inheritance, no causative genetic mutation has

TABLE 116.4 Treatment Options for Essential Tremor

First line	Propranolol Primidone
Second line	Topiramate Zonisamide Benzodiazepines Other β -blockers
Medication failure	Gabapentin/Pregabalin Botulinum toxin injections Deep brain stimulation

been identified, and there are other non-monogenic causes of essential tremor. Cerebellar dysfunction has been implicated in the pathogenesis of essential tremor. Clinically, it is a heterogeneous disorder characterized by relatively symmetric 4- to 12-Hz postural and kinetic tremor of the upper extremities. It may cause functional impairment (e.g., difficulty with handwriting, drinking, or using utensils) and may even be disabling. Involvement of the head and voice are common. Tremor tends to improve with alcohol ingestion. Cognitive dysfunction, psychiatric manifestations (e.g., depression, anxiety), and balance impairment can also be seen. Mild parkinsonian features (e.g., tremor at rest, rigidity with activation) may develop and can make distinguishing incipient PD challenging. Propranolol and primidone are first-line treatments for essential tremor and are of similar benefit (Table 116.4).

Other Tremors

Beyond essential tremor and parkinsonian tremor, there are a number of other less common etiologies of tremor and tremor syndromes. All individuals may have some fine physiologic shaking of the hands or fingers with posture or action. At times when this tremor becomes visibly or functionally notable, it is termed enhanced physiologic tremor. Enhanced physiologic tremor is most commonly due to an underlying physical or psychological stressor. Common causes include anxiety, hyperthyroidism, excessive caffeine intake, stimulant or corticosteroid use, beta agonist use (e.g., albuterol), and valproic acid use among other medications (Table 116.5). Appropriate screening for medications and contributing medical or psychiatric causes should be undertaken in anyone presenting with suspected enhanced physiologic tremor. Enhanced physiologic tremor may be clinically indistinguishable from mild or early essential tremor. If no causative etiologies can be identified or mitigated, the approach to treatment is similar with β -blockers such as propranolol being used most commonly.

Tremor is also commonly seen in association with other movement phenomena including dystonia and cerebellar features. Dystonic tremor is irregular and is associated with abnormal posturing. Cerebellar tremor is an intention tremor that is characteristically low frequency, high amplitude, and worsens as one approaches a target. The distribution of tremor is dependent upon the cause with common locations of both dystonic and cerebellar tremors including the head/neck, trunk, and limbs. The presence of dystonia or cerebellar features is necessary to diagnose a dystonic or cerebellar tremor, and treatment typically focuses on management of the alternative movement. These movements and their associated differential diagnoses are discussed elsewhere in this chapter.

Chorea

Chorea is characterized by purposeless, abrupt, rapid, brief, arrhythmic, unsustained movements that flow randomly from one part of the body to another. The term “choreoathetosis” describes the combination of

TABLE 116.5 Medications Associated With Tremor

Asthma Medications	Neuroactive Medications
β -Agonists (albuterol)	Lithium carbonate
Theophylline	Stimulants (prescribed and illicit)
Antiseizure Medications	Selective serotonin reuptake inhibitors

Carbamazepine	Levothyroxine
Immunomodulators	Caffeine
Corticosteroids	
Cyclosporine	
Tacrolimus	

chorea and athetosis, a slow form of chorea manifested by writhing movements predominantly involving distal extremities. *Ballism* is a severe form of chorea with large amplitude, flinging movements usually affecting the proximal musculature. Chorea is often associated with a variety of secondary clinical features detailed in Table 116.6.

The differential diagnosis for chorea is broad, reflecting a wide variety of processes affecting the basal ganglia network and specifically the striatum. Generally, chorea either represents the primary manifestation of an inherited disorder or is acquired secondary to basal ganglia insults due to various comorbid medical conditions, medications or toxins, or structural abnormalities. Table 116.7 summarizes the differential diagnosis of chorea categorized by genetic and acquired causes.

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant, progressively disabling, and fatal neurodegenerative disease; it is the most common cause of inherited adult-onset chorea. The causative mutation is an expansion of an unstable cytosine-adenine-guanine (CAG) trinucleotide repeat of the IT-15 gene (also known as the HTT or HD gene) on the short arm of chromosome 4, which results in production of abnormal *huntingtin* protein. The neuropathology of HD is characterized by selective neuronal vulnerability, particularly involving the caudate and putamen of the striatum. Microscopically, the pathologic hallmark of the disease is the preferential loss of medium-sized spiny neurons projecting from the striatum to the external pallidum.

The motor symptoms of HD may start at any age, with the peak incidence between 35 and 40 years of age with death occurring 10 to 20 years after development of manifest symptoms. Age of onset and rate of progression of the disease are inversely associated with CAG repeat length with the longest repeats associated with juvenile-onset disease and a more rapid disease progression.

HD is characterized clinically by the triad of a movement disorder, progressive cognitive decline (dementia), and psychiatric features. Chorea is the prototypical motor manifestation of HD occurring in 90% of patients. Other motor manifestations include dystonia, bradykinesia, and rigidity. Cognitive impairment is invariable in HD and typically progresses from selective deficits in psychomotor, executive, and visuospatial abilities to more global impairment with higher cortical functions usually spared. Psychiatric manifestations include depression, irritability, apathy, anxiety, and obsessive-compulsive symptoms.

The juvenile variant of HD, in which motor symptoms start before age 20, typically has an akinetic-rigid phenotype and only rarely chorea; patients may also have seizures. Paternal inheritance of the HD gene is the rule for onset before the age of 10 and paternal inheritance predominates (about 3:1 paternal:maternal) for onset before the age of 20. This can be explained by a phenomenon called anticipation; the

TABLE 116.6 Secondary Features Associated With Chorea

Athetosis	Slow, writhing movements of distal limbs
Ballism	Rapid, flinging movements of proximal limbs
Parakinesis	Incorporation of an involuntary movement into a voluntary movement (e.g., crossing and uncrossing of legs, adjusting glasses)
Motor impersistence	Inability to maintain tongue protrusion, “milk maid’s grip”
Partially suppressible	Brief ability to voluntarily reduce the severity of movements
Deep tendon reflex changes	“Hung up” or “pendular” reflexes
Gait disorders	Irregular or dancelike gait

CAG trinucleotide repeat is unstable and with paternal transmission the number of repeats tends to expand.

Treatment of HD is currently symptomatic. Vesicular monoamine transporter-2 inhibitors and antipsychotic drugs can be used for the management of chorea. No disease modifying treatments have been identified; *huntingtin* lowering approaches are currently under study.

Other Chorea

Beyond HD, the differential diagnosis of chorea remains quite broad with other inherited etiologies and a number of acquired causes (see [Table 116.7](#)). Approximately 10% of individuals with an autosomal dominant HD-like disorder will not carry the causative mutation for HD. Among these “phenocopies,” only a small minority will have an identifiable genetic mutation. The most

common genetic causes in the Caucasian population include spinocerebellar ataxia (SCA) 17, Friedreich’s ataxia, HD-like 2, and familial prion disease (HD-like 1). Alternative diagnoses include dentatorubropallidolusian atrophy (DRPLA), SCA 1-3, Wilson’s disease (described elsewhere in this chapter), neuroacanthocytosis syndromes, and neuroferritinopathy. Young-onset, non-progressive chorea, particularly in the setting of a family history and the absence of cognitive or behavioral changes, should raise concern for benign hereditary chorea, caused by a mutation in the *NKX2* gene; beyond chorea, the condition is associated with an increased risk of pulmonary and thyroid cancers.

Medication side effects are likely the most common acquired and overall cause of chorea. Levodopa-induced dyskinesias can be seen in patients with degenerative parkinsonian syndromes, and tardive

dyskinesia can be encountered in patients on chronic antidopaminergic therapy. These entities are described elsewhere in the chapter.

Sydenham chorea is the most common acquired cause of chorea in children and follows a throat infection with group A streptococcus. Chorea typically develops within a few weeks of the pharyngeal infection, though can be delayed by more than 6 months. Though the chorea may be generalized, the face and tongue are most commonly involved. Psychiatric symptoms are also common and can include irritability, emotional lability, or obsessive-compulsive symptoms. Various biomarkers including elevated antistreptolysin O (ASO) and anti-deoxyribonuclease B titers are associated with Sydenham chorea but are not required to make a diagnosis. The behavioral and motor symptoms associated with Sydenham disease are typically mild and self-limited. Symptomatic treatment of chorea can be considered; corticosteroids may also be considered in moderate to severe cases and likely shorten the duration of symptoms. Chorea is a major criterion for acute rheumatic fever, and all patients with suspected Sydenham chorea should be evaluated for carditis. Definitive antibiotic therapy to treat the GAS pharyngeal infection is recommended even if there are no ongoing signs or symptoms of pharyngitis. Chronic prophylactic antibiotic therapy is recommended for all patients with Sydenham chorea until age 21; treatment for 10 years or until the age of 40 is generally recommended in those with residual cardiac disease following rheumatic fever.

Other acquired forms of chorea include chorea gravidarum in pregnancy, paraneoplastic chorea, and autoimmune etiologies. Paraneoplastic chorea is most commonly associated with CRMP-5 antibodies in the setting of small-cell lung cancer. Autoimmune causes of chorea include the antiphospholipid antibody syndrome and systemic lupus erythematosus. In these cases, identification of the underlying etiology and initiation of appropriate therapy represent the definitive management.

Wilson's Disease

Wilson's disease (WD) is a rare, autosomal recessive disorder of impaired copper metabolism resulting in copper accumulation, neurologic dysfunction, and hepatic dysfunction. Typically, neurologic symptoms in WD begin in the second or third decade although late onset can occur. Patients develop a variety of abnormal movements including chorea, dystonia, parkinsonism, and tremor. The most common form of tremor in WD is an irregular, and somewhat jerky, dystonic tremor. A classical "wing-beating tremor" or "flapping tremor" in combination with dysarthria strongly suggests the diagnosis of WD. Dysarthria is frequently combined with slow tongue movements and orofacial dyskinesia including "risus sardonicus," which is characterized by involuntary grimacing with the mouth open and the upper lip contracted. Beyond abnormal movements, patients may also have seizures, cognitive impairment, and psychiatric features including abnormal behavior (typically increased irritability or disinhibition), personality changes, anxiety, and depression.

WD can present with acute liver failure or chronic liver disease that may clinically be indistinguishable from other hepatic conditions. The absence of clinical or biochemical evidence of liver disease does not exclude WD. A history of jaundice, a positive family history of neuropsychiatric disease, and increased sensitivity to neuroleptics can be diagnostic clues for WD in such patients. Untreated it is invariably fatal; early treatment is associated with better clinical outcomes; therefore, a high level of suspicion should be maintained. Diagnosis is confirmed by the presence of Kayser-Fleischer corneal rings in the setting of increased urinary copper excretion or elevated copper on liver biopsy. Bilateral symmetric high signal intensity in the putamen, caudate, thalamus, and midbrain on T2-weighted MR images can be seen

and the classic imaging sign is the "face of the giant panda" (Fig. 116.3). Serum ceruloplasmin is usually low in symptomatic patients, but this is not definitive, and confirmatory testing with ophthalmologic screen, 24-hour urinary copper, liver biopsy, or genetic testing for homozygous mutations in the *ATP7B* gene is necessary. Treatment consists of drugs that facilitate copper excretion, such as zinc, and the copper chelators D-penicillamine, trientine, and tetrathiomolybdate.

Drug-Induced Movement Disorders

The term *tardive dyskinesia* (TD) was initially coined to describe patients with rhythmic, repetitive (stereotypic), persistent movements after long exposure to antipsychotic drugs. Over time, other abnormal, persistent, involuntary movements have been reported after exposure to these drugs and other dopamine receptor blocking agents (DRBAs). Because of differences in treatment and approach, it is helpful to use the term TD to refer to the classic description of rhythmic, repetitive, stereotypic movements of the face, mouth, and tongue manifesting as lip smacking, chewing motions, and tongue protrusion. The term *tardive syndrome* more broadly refers to other phenomena, including rocking movements, tremor, myoclonus, and other forms of dystonia. Akathisia refers to the inability to remain still with an urge to move, giving the appearance of restlessness. It is a sensory phenomenon and a common and disabling form of tardive syndrome. Common movements seen in patients include repetitive self-touching, marching in place, rocking from one leg to the other, pumping the legs up and down, and crossing and uncrossing the legs.

TD and tardive syndromes are characterized by the late appearance of abnormal movements after prolonged exposure to a DRBA. Whenever the diagnosis is suspected, a careful and comprehensive review of treatment history should be done. Risk factors for the development of tardive syndromes include advancing age, female gender, and the use of high-potency antipsychotics. While removal of the offending agent is critical to prevent worsening, symptoms might persist in up to two thirds of patients and treatment can be challenging. Dopamine depleting agents can be considered for treatment and two vesicular monoamine transporter-2 inhibitors have recently been approved for the treatment of TD.

Dystonia

Dystonia is a heterogeneous group of disorders that are defined by sustained or intermittent muscle contractions causing abnormal, often repetitive movements, postures, or both. Dystonic movements are typically patterned, twisting, and may be tremulous.

Dystonia may involve nearly any region of the body, emerge at any age, appear static or progressive, and can co-occur with other neurologic or medical problems. The classification of dystonia is challenging. Newer classification systems address the different clinical manifestations with four dimensions: body region affected, age at onset, temporal aspects, and any associated symptoms. Classification according to the presence or absence of associated features addresses whether dystonia occurs by itself (isolated dystonia, previously known as primary dystonia) or is part of a more complex syndrome that combines other features (combined dystonia, previously known as secondary dystonia or dystonia-plus). This new classification system provides a more clinically useful approach for diagnosis than previously used strategies.

Adult-onset focal dystonias are by far the most common. Cervical dystonia is the most common type of focal dystonia, followed by focal dystonias involving the face and jaw muscles (blepharospasm, oromandibular dystonia or the combination); laryngeal and limb dystonias are rare. Adult-onset limb dystonias are usually task-specific with dystonic contraction only occurring during specific voluntary actions (e.g., writer's cramp, musician's dystonia). However, this task

Fig. 116.3 Representative MRI findings of different movement disorders. (A) “Hot cross bun” in multiple system atrophy (MSA) (*black arrows*). (B) Marked cerebellar and vermis atrophy in spinal cerebellar atrophy (SCA) 6 (*white arrows*). (C) “Hummingbird” sign in progressive supranuclear palsy (PSP) due to prominent midbrain atrophy (*black arrowheads*). (D) “Face of giant panda” sign in Wilson’s disease (*white arrowheads*).

specificity may be lost over time and even occur at rest. Focal adult-onset limb dystonia that is not task specific can be the earliest manifestation of parkinsonism and Parkinson’s disease.

Recent advances in our understanding of the genetics of dystonia syndromes allow for unique classification and prognosis. Mutations in the *TOR1A* gene (*DYT1*) encoding torsinA are the most common cause of early onset generalized dystonia. Patients present with childhood-onset limb dystonia that often progresses to generalized dystonia within a few years. *DYT1* is an autosomal dominant disorder with reduced penetrance (30%).

Dopa-responsive dystonia is a rare but important cause of childhood onset dystonia. It is inherited in autosomal dominant fashion with reduced penetrance (30%) with females more commonly affected than males. It is characterized by lower extremity dystonia, parkinsonism, and diurnal variability with the symptoms worsening as the day progresses and improving with sleep. As the name suggests, it is

exquisitely sensitive to levodopa therapy. The condition is often misdiagnosed and untreated; therefore, patients with childhood-onset dystonia should have a trial of levodopa. Other autosomal dominant disorders characterized by dystonia include myoclonus dystonia syndrome and rapid-onset dystonia parkinsonism. In addition, multiple other genetic causes of dystonia have been identified.

Treatment of dystonia consists of a combination of oral medications including anti-epileptics, anticholinergics, benzodiazepines, GABAergic drugs, and botulinum toxin injections for focal or segmental dystonia. Deep brain stimulation is commonly used for refractory cases.

Tics and Tourette Syndrome

Tics are rapid, repetitive, nonrhythmic, and typically briefly suppressible movements or vocalizations associated with a premonitory urge to perform the action and a post-event sense of relief. Tics are quite

common, affecting up to 20% of school-age children, though the vast majority will have transient tics, lasting less than 12 months. Tics are broadly subdivided into motor tics, which involve movement of one or more parts of the body or musculature, and vocal tics, which involve creation of a sound. These can be further subdivided into simple tics (e.g., excessive blinking, head turning, grunting, and throat clearing) and complex tics (e.g., jumping, moving, and complex vocalizations or patterns of movement).

Tourette syndrome (TS) is the most common chronic tic disorder and involves a combination of motor and vocal tics, present daily, and for at least 1 year. Patients may have comorbid psychiatric diagnoses including attention-deficit/hyperactivity disorder, obsessive-compulsive disorder, or anxiety, which are often more disabling than the tics themselves. Tics commonly improve in late adolescence and in the majority of individuals there is partial or complete resolution of symptoms by adulthood. Treatment of tics can be considered when they are bothersome, functionally impairing, or causing harm to the individual. A combination of behavioral approaches (comprehensive behavioral intervention for tics), oral medications (α -adrenergic agonists, antipsychotics, and vesicular monoamine transporter-2 inhibitors), and botulinum toxin injections can be effective at minimizing the impact of symptoms.

Paroxysmal Dyskinesias

The paroxysmal dyskinesias are a group of rare hyperkinetic movement disorders characterized by recurrent, stereotyped episodes of abnormal involuntary movements (most commonly dystonia, chorea, or a combination of both). The three classically recognized types, paroxysmal kinesigenic dyskinesia (PKD), paroxysmal non-kinesigenic dyskinesia (PNKD), and paroxysmal exercised-induced dyskinesia (PED), were defined on the basis of triggers. Several causal genetic mutations have recently been identified. However, cases may also be secondary to structural abnormalities, and seizures should always be considered in the differential. PKD episodes are triggered by sudden movement, are often preceded by a premonitory sensation, last seconds, and occur with high frequency. The most common genetic cause is a mutation in the *PRRT2* gene. PKD is typically responsive to low-dose carbamazepine. PNKD episodes are triggered by caffeine, alcohol, and stress, may be preceded by a premonitory sensation, last minutes to hours, and occur less frequently than PKD episodes. The most common genetic cause is a mutation in the *MR-1* gene. Treatment of PNKD includes avoidance of identified triggers and treatment with benzodiazepines. With both PKD and PNKD, onset typically occurs in childhood and boys are more likely to be affected. PED episodes are triggered by sustained exercise, last minutes to hours, and typically involve the lower extremities. The most common genetic cause is a mutation in the *SLC2A1* gene and when such a mutation is identified, symptoms may be responsive to the ketogenic diet.

Restless Leg Syndrome

Restless leg syndrome (RLS) is a common sensorimotor disorder that predominantly, but not exclusively, affects the legs. RLS is characterized by an urge to move the legs, predominantly when at rest, accompanied by leg discomfort that improves with ambulation. There are diurnal fluctuations with symptoms typically present initially only at night. The prevalence of RLS is variable and highest among European populations (5% to 12%). It is strongly heritable, with one half of patients having at least one affected first-degree relative. The three conditions most strongly associated with RLS are pregnancy, iron deficiency, and end-stage renal disease. Most patients with RLS also have periodic limb movements of sleep, which are periodically recurring limb movements that occur during sleep.

Although the mechanism of the disease is incompletely understood, a hypodopaminergic pathology is suspected in RLS based on the clinical observation that dopaminergic medications improve symptoms. Treatment includes the use of nonpharmacologic strategies like exercise and removal of offending drugs (e.g., antidepressants). Iron replacement should be undertaken when indicated. If medical management is needed, dopamine agonists or α -2-delta calcium-channel ligands (gabapentin, pregabalin, and gabapentin enacarbil) can be considered as first-line treatment. The use of opioids and/or benzodiazepines can be entertained in certain refractory cases.

Cerebellar Ataxias

The ataxias are a heterogeneous group of conditions reflecting impaired cerebellar function or impairment in cerebellar afferent and efferent pathways. Clinically, patients may present with incoordination, disorganized gait, poor balance, falls, dysarthria, impaired hand coordination, tremor, swallowing difficulties, and eye movement abnormalities. Comprehensive assessment is critical in elucidating potential etiologies and must include an understanding of the rate of onset/progression, ascertainment of family history, thorough examination for specific diagnostic signs, and brain magnetic resonance imaging (MRI). The presence of associated neurologic features can be useful for differentiating ataxic etiologies and guiding additional investigations. Structural lesions affecting the cerebellum or its connections can present with ataxia including abnormalities of brain development, stroke, tumor, infection, trauma, and inflammatory and demyelinating diseases. [Table 116.8](#) summarizes the differential diagnosis of the ataxic disorders divided by genetic and acquired causes.

Inherited/Genetic Ataxias

Progressive ataxia in coordination and gait disturbance are the cardinal features of the inherited ataxias. Autosomal dominant SCAs may present with a pure cerebellar syndrome or be associated with parkinsonism, spasticity, cognitive, or behavioral features. They are usually adult-onset disorders with variable genetic mutations, including trinucleotide repeats, mutations in noncoding regions, and point mutations. Genetic testing is available for many of the common spinocerebellar ataxias and new mutations are being identified in a rapid and ongoing basis. Currently there are no treatments to address disease progression and symptomatic treatment is limited.

The fragile X mental retardation (*FMR1*) gene contains a CCG trinucleotide repeat expansion of greater than 200 in the fully penetrant mutation associated with mental retardation in boys. Recently a premutation associated with repeats of 55-200 in the *FMR1* gene has been found to be the cause of the adult-onset neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS). Clinically, affected males have a progressive cerebellar tremor and ataxia. Fragile X-associated tremor/ataxia syndrome has been under-recognized and may be the most common genetic cause of late-onset ataxia. Treatment is largely symptomatic and the disease results in progressive disability.

Autosomal recessive ataxias are rare conditions with onset in childhood. Friedreich ataxia (FA) is the most common and best characterized of these disorders. It results from an unstable GAA expansion on chromosome 9. Clinically it is characterized by childhood-onset gait ataxia and clumsiness. The ataxia reflects a combination of spinocerebellar degeneration and peripheral sensory loss. Overt weakness secondary to pyramidal tract dysfunction is a late complication. Non-neurologic manifestations include cardiomyopathy, diabetes mellitus, and skeletal deformities, which add to the morbidity and mortality of the disease. Since identification of the mutation, late-onset forms of the disease with less systemic involvement and milder symptoms have

TABLE 116.8 Differential Diagnosis of Cerebellar Ataxia

Genetic disorders	Autosomal dominant	Spinocerebellar ataxias
		Episodic ataxia
		DRPLA

Neoplastic	Primary and metastatic tumors	
	Paraneoplastic (anti-Hu/Yo/Ri)	
Miscellaneous	MSA-cerebellar	
		Multiple sclerosis

CJD, Creutzfeldt-Jakob disease; *DRPLA*, dentatorubropallidolysian atrophy; *MSA*, multiple system atrophy; *PML*, progressive multifocal leukoencephalopathy.

been identified. Therefore, Friedreich ataxia should be considered in the differential of adult-onset sporadic ataxias.

Ataxia with vitamin E deficiency is a childhood-onset ataxia with a Friedreich ataxia phenotype. Treatment with high-dose vitamin E may slow the progression of neurologic symptoms. Ataxia with vitamin E deficiency should be considered in any child with signs and symptoms of Friedreich ataxia that do not carry the Friedreich ataxia mutation. Abetalipoproteinemia and Refsum disease may resemble Friedreich ataxia and because of the availability of directed testing, they should be considered in the differential. Mitochondrial disorders, ataxia telangiectasia, and ataxia with oculomotor apraxia are other common causes of early-onset ataxia with cerebellar atrophy.

Sporadic/Acquired Ataxias

Insidious onset of cerebellar ataxia without a family history can be a diagnostic challenge. Alcohol abuse, toxins, chronic infections, multiple system atrophy, and mitochondrial disorders are diagnostic considerations. Sporadic autoimmune ataxias amenable to treatment include glutamic acid decarboxylase (GAD) ataxia and steroid-responsive encephalopathy associated with autoimmune thyroiditis.

Acute or subacute onset ataxia is most often associated with cerebrovascular disease, demyelinating illness, or direct or indirect effects of cancer. Paraneoplastic cerebellar degeneration is one of the more common paraneoplastic syndromes usually associated with gynecologic, breast, lung cancer, or lymphoma. A variety of antineuronal antibodies have been implicated; however, anti-Hu/Yo/Ri are most frequently seen. The cerebellar syndrome often predates the identification of the cancer. Treatment of the underlying cancer and plasma exchange are sometimes beneficial.

Vitamin B₁₂ and vitamin E deficiency secondary to malabsorption can present with ataxic gait as a result of posterior column sensory deficits. In the appropriate clinical situation, Wernicke encephalopathy due to thiamine deficiency needs to be considered as an acute cause of gait ataxia.

Superficial siderosis is characterized by deposition of free iron and hemosiderin along the pial and subpial structures of the brain and spinal cord, resulting in damage to the cerebellar cortex, cochlear nerves, cerebral cortex, and spinal cord. Patients present with the triad of sensorineural hearing loss, cerebellar ataxia, and spasticity.

Functional Movement Disorders

Functional movement disorders (FMD), which fall into the broader category of functional neurologic disorders, are a heterogeneous group of abnormal involuntary movements that do not adhere to the physiologic characteristics of the other movement phenomena described in this chapter. FMD have traditionally been considered *conversion disorders*, where the body converts an underlying psychological stressor into a physical symptom. However, while there is clearly a link between psychological stressors and prior trauma with the development FMD, this traditional understanding is likely an oversimplification of the pathophysiology, which is not well understood. The prevalence of FMD is not well established, though it has been reported to be as high as 10% of patients seen in movement disorders specialty clinics.

Patients with FMD can present with movements that mimic any of the phenomena described in this chapter (e.g., tremor, dystonia, myoclonus). However, the examination will also typically demonstrate features inconsistent with other causes and suggestive of FMD, including variability (e.g., in the distribution, type of movement, amplitude), entrainment (where the frequency of the abnormal movement entrains to match that of an alternative volitional movement), and distractibility. Abrupt onset of symptoms, the presence of a triggering event, and rapid onset may also be suggestive of a diagnosis of FMD. A clinical diagnosis of FMD can be made based on the presence of these typical features. Electrodiagnostic testing can be helpful in identifying functional tremor and functional myoclonus.

Management of FMD can be challenging but generally starts with patient and family education and requires a multidisciplinary approach. Cognitive-behavioral therapy with counseling is the best evidence-based approach for the management of FMD. Rehabilitative therapies have a role for most patients. Pharmacotherapy has a limited role in the management of FMD though can be useful in the treatment of any comorbid psychiatric conditions.

Acknowledgment

We gratefully acknowledge the contributions of the previous-edition chapter author, Kevin Biglan, to this chapter.

Congenital, Developmental, and Neurocutaneous Disorders

Kristin A. Seaborg, Jennifer M. Kwon

INTRODUCTION

This chapter describes some important congenital nervous system malformations, neurodevelopmental disorders, and neurocutaneous syndromes. Advances in imaging and molecular genetic testing have improved our understanding of these disorders. Neuroimaging facilitates early diagnosis and management of malformations of the brain and spinal cord. Advances in genetic sequencing and microarray analysis are improving our understanding of single-gene disorders, such as fragile X syndrome and neurofibromatosis, as well as genetically complex disorders, such as autism and attention-deficit/hyperactivity disorder (ADHD).

CONGENITAL MALFORMATIONS

Malformations of the central nervous system develop during fetal life. [Table 117.1](#) summarizes the timeline of early neural and cortical development and the defects that may occur during these stages. Malformations developing early in embryogenesis can be more severe than those arising after the basic structures of the nervous system are in place.

Disorders of Dorsal Induction

Definition/Embryology

Dorsal induction is when neural tube closure occurs at 18 to 26 days post-conception. The central portion closes first, then the rostral and caudal portions. Failure to completely close the neural tube can occur anywhere along the neuro axis, leading to neural tube defects (NTDs) in 6.5/10,000 live births, the prevalence varying by geography, and genetic and environmental factors. Use of folic acid at the time of conception and during pregnancy can significantly reduce NTD rates.

If the rostral end of the neural tube fails to close, anencephaly can result, characterized by incomplete development of the brain and skull, and affected infants may not survive. If the caudal end of the neural tube fails to close, the result is spina bifida, described next.

Spina Bifida

Definition/epidemiology. Failure of complete closure of the caudal end of the neural tube during the 24th to 26th days post-conception results in spina bifida, the most common type of NTD, occurring in 3.5 of 10,000 live births. Abnormal caudal closure with overlying bony and skin defects can cause “open” NTDs, such as myelomeningocele (MMC). MMC is the most severe form of spina bifida and is characterized by the protrusion of the spinal cord and meninges through a defect in the vertebral column. “Closed” defects of the caudal spinal cord, or spina bifida occulta, are associated with malformation of one or more vertebrae and typically have limited neurologic symptoms.

Pathology. The deficits associated with meningocele are not only secondary to the abnormal caudal closure of the neural tube but also from the ongoing exposure and chemical damage of the neural tube contents to amniotic fluid, trauma, and leakage of CSF. CSF leak through the open meningocele impairs rostral vesicle expansion, leading to underdevelopment of the posterior fossa with cerebellar tonsil herniation into the upper spinal canal, called the Arnold-Chiari or Chiari 2 malformation.

Clinical presentation. Many of the stigmata of MMC can be detected on first trimester fetal ultrasound. MMC causes severe distal spinal cord dysfunction, including paralysis and sensory loss in the lower extremities as well as bowel and bladder dysfunction. Progressive loss of neurologic function and development of congenital clubfoot is commonly observed during pregnancy. Nearly all children with MMC have a Chiari 2 malformation and obstructive hydrocephalus.

Children with spina bifida occulta, or a “closed” caudal neural tube defect, may have symptoms including lower extremity spasticity and bladder abnormalities and the overlying skin may show nevi, lipomas, abnormal dimples, or whorls of hair. The most common location for spina bifida is within the lumbosacral region.

Diagnosis. Prenatal diagnosis of MMC cannot be reliably determined by ultrasound until the second trimester of pregnancy. Maternal serum testing for α -fetoprotein (AFP), which is secreted from an open spinal dysraphism (incomplete fusion), can be done in conjunction with second trimester ultrasound. Further evaluation of specific characteristics of the fetal anomaly can be done with fetal MRI.

Treatment/prognosis. Previously, infants born with MMC had surgical closure of the defect within the first 2 days of life to minimize neurologic complications. In 2011, the Management of Meningocele Study (MOMS) demonstrated that prenatal surgery for MMC repair decreased the rate of enlarged cerebral ventricles and ventriculoperitoneal shunting by 1 year of age by 42% and improved the rate of independent ambulation by 21%. This study represented a turning point in management of MMC and subsequently led to affected fetuses with normal karyotype, isolated spinal bifida with upper border between T1 and S1, and evidence of hindbrain herniation to be referred for prenatal closure of MMC during the second trimester of pregnancy.

Chiari Malformation Type I

Definition/epidemiology. Though not technically a disorder of ventral induction or a neural tube defect, Chiari I malformation (CM1) is the consequence of similar pathologic processes occurring during formation of the posterior fossa. CM1 is characterized by cerebellar tonsils that are downwardly displaced more than 5 mm past the foramen magnum. CM1 is much more common (1/1000 births) than Chiari 2 and associated with fewer neurologic sequelae.

TABLE 117.1 Stages of Prenatal Neural Development (Simplified)

	Stage	Structures Forming	Post-Conceptual Age	Anomalies Seen ^a
Neural tube, brain vesicle development	Dorsal induction	Neural tube closure	18-26 days (3-5 weeks)	Anencephaly, spina bifida, myelomeningocele, Chiari 2 malformation
	Ventral induction	Brain vesicle and face development	5-10 weeks	Holoprosencephaly, agenesis of the corpus callosum, septo-optic dysplasia
Cortical development	Proliferation	Development of neuroblasts and glioblasts	2-4 months (neuroblasts)	Microcephaly, megalencephaly
	Migration	Formation of six cortical layers	Peak occurrence at 2-4 months, though occurs from 8 weeks to 8 months	Lissencephaly, periventricular heterotopias
	Post-migrational organization	Cortex formed		Polymicrogyria, schizencephaly

^aSome anomalies (such as microcephaly, polymicrogyria) can arise from different stages. So even though it may seem intuitive to think of microcephaly as a disorder of neuronal proliferation, there are some forms of microcephaly that develop well after migration.

Pathology. CM1 results from underdeveloped bones of the skull base and reduced volume of the posterior fossa. This leads to displacement of cerebellar tonsils into the spinal canal. Obstruction of CSF outflow through the tight foramen magnum may lead to development of fluid-filled cavities in the spinal cord called syringomyelia (see later). Symptoms can occur with compression of brain stem structures.

Clinical presentation. The clinical presentation of CM1 is variable. Eighty percent of patients report occipital headaches or posterior neck pain. Younger patients can have symptoms from compression of the brain stem, including disordered sleep, vertigo, dysphagia, tinnitus, and ocular symptoms. Some CM1s are found incidentally during MRI evaluation for other reasons. Incidentally found CM1s are less likely to develop syringomyelia, intractable symptoms, or progressive neurologic findings (10%).

Diagnosis/differential. MRI is the most effective method for diagnosis. CSF flow studies may be helpful to establish clinical significance of the CM1. Since any cause of increased intracranial pressure can lead to tonsillar herniation, it is important to exclude idiopathic intracranial hypertension and CNS mass lesions.

Treatment. Asymptomatic patients without syringomyelia may be managed by observation. If patients have severe headaches, neurologic deficits, or syringomyelia, posterior fossa decompression with or without duraplasty is indicated to reestablish CSF flow across the craniovertebral junction.

Prognosis. CM1 is generally not disabling and outcome after surgical decompression leads to resolution of clinical symptoms in over 80% of patients. For symptomatic patients, posterior fossa bone-only decompression without dural opening is associated with a lower rate of complications.

Syringomyelia

Definition/epidemiology. Syringomyelia or syrinx is a cystic cavitation in the parenchyma of the spinal cord or is a dilation in the central spinal canal (hydromyelia). The estimated prevalence of 8/100,000 is likely an underestimate. Syrinx is a common and important neurologic sequela of CM1 in up to 30 to 70% of pediatric patients.

Pathology. Syringomyelia may occur as either a congenital or acquired condition. Congenital syrinx is associated with a neural tube defect and forms during embryogenesis. Acquired syringomyelia is caused by disruption of the normal CSF circulation and is seen with CM1, tethered cord syndrome, spinal cord tumors, or trauma.

Clinical. The classic presentation is a dissociated sensory loss (loss of pain and temperature sensation with preservation of light touch and proprioception) in the neck, arms, or legs. A cervical lesion produces a capelike dissociated sensory loss of the arms and shoulders, atrophy of the hands and arms, with increased tone in the legs. Scoliosis is a common finding in patients with a terminal syrinx.

Diagnosis/differential. Diagnosis is confirmed by MRI, which will also differentiate syrinx from neoplasms, infections, and other spinal cord lesions. MRI of the lumbo-sacral spine should be included to rule out tethered cord.

Treatment. Surgical correction of the cause—CM1, CM2, neoplasm, tethered cord—is the most effective way to treat syringomyelia. A small syrinx may be an asymptomatic incidental finding on MRI and can be observed without intervention.

Prognosis. Syringomyelia is most often a chronic, slowly progressive condition with periods of symptom exacerbation and remission. Patients typically experience symptomatic improvement after corrective surgery. Conservative treatment without surgical correction may be considered in young children and asymptomatic patients.

Disorders of Ventral Induction

Definition/Epidemiology

Ventral induction is the second phase of central nervous system development; the brain vesicles and the face begin to form between the fifth week after conception and mid-gestation. Insults during this phase affect brain and facial development.

Common malformations that arise during this period include holoprosencephaly (HPE), agenesis of the corpus callosum (ACC), agenesis of septum pellucidum, and septo-optic dysplasia (SOD). ACC is most commonly seen. The prevalence in the general population is 0.7% and higher in those with developmental disabilities. The estimated incidence of HPE and SOD are both 1 in 10,000.

Pathology/Embryology

Ventral induction ensues with the cleavage and formation of three primary brain vesicles: prosencephalon, mesencephalon, and rhombencephalon. By embryonic day 49 or gestational week 8, the prosencephalon cleaves into the telencephalon and diencephalon and then the telencephalon subsequently divides into two hemispheres.

Abnormal prosencephalon cleavage leads to HPE, a spectrum of abnormalities ranging from lobar HPE (cortex with a single ventricle)

Fig. 117.1 Semilobar HPE. MRI (sagittal T1 image taken at midline paired with an axial FLAIR image whose location is indicated by the scout line) of 13 day old with hypotelorism and microcephaly. There is presence of partial fusion of the frontal lobes with lack of interhemispheric fissure/falx and septum pellucidum. The body and genu of corpus callosum is likewise poorly formed. There is appropriate separation of the thalami.

to semilobar and lobar HPE (cerebral hemispheres are mostly separated except for the frontal lobes) (Fig. 117.1). In all cases, there is some fusion between the two cerebral hemispheres, often accompanied by facial anomalies. ACC and SOD represent more discrete abnormalities localized to specific midline structures and occur later in prosencephalic development.

Clinical Presentation

Children with HPE, ACC, and SOC have varying degrees of developmental disability and other congenital anomalies. Because prosencephalon cleavage occurs at the same time as facial formation, facial anomalies ranging in severity can occur, including hypotelorism, solitary median incisor, cleft palate, proboscis, or cyclopia.

The clinical spectrum of SOD includes optic nerve hypoplasia, pituitary hypofunction, and midline brain abnormalities. Individuals

with SOD often present for evaluation of visual abnormalities, poor growth, hypoglycemia, or precocious puberty. Seizures and developmental delay are the most common neurologic manifestations of SOD.

ACC may occur either in isolation or in association with other congenital syndromes. When present in isolation, individuals with ACC may be neurologically intact. If associated with other brain malformations, there may be developmental delay and intellectual disability.

Diagnosis/Differential

Neuroimaging is the primary method for diagnosing HPE, ACC, and SOD. The diagnosis of HPE can be made by prenatal ultrasound between 10 and 14 weeks' gestation. Ophthalmology exam can detect hypoplastic optic nerves in SOD. Because HPE, ACC, and SOD are associated with a number of genetic syndromes, genetic testing is indicated to guide management.

TABLE 117.2 Complications and Management of Severe Neurologic Impairment

Complication	Management
Epilepsy	Antiepileptic medications, vagal nerve stimulation, ketogenic diet
Dysphagia	Thickened feeds or enteral feeds via G tube
Respiratory insufficiency	Positive pressure ventilation while asleep, tracheostomy and mechanical ventilation if necessary
Spasticity	Physical therapy, intramuscular or intrathecal baclofen, oral benzodiazepines
Musculoskeletal	Serial monitoring for neuromuscular scoliosis, hip dislocations, and joint contractures. Often requires orthopedic surgeries.
Cognitive impairment	Individualized education plans, therapies

Treatment

Surgical treatment can improve craniofacial anomalies (e.g., cleft lip, choanal atresia [blockage of the back of the nasal passages]) in HPE and hormone replacement can treat pituitary insufficiency in SOD. [Table 117.2](#) shows additional complications and management of the associated complications of severe neurologic impairment.

Prognosis

Prognosis for affected individuals depends on the degree of medical impairment and associated comorbidities. Most fetuses with alobar HPE die perinatally, but those with semilobar and lobar HPE have improved survival with aggressive management of associated problems such as dysphagia and epilepsy.

Children with SOD have variable outcomes depending on the presence of comorbid brain abnormalities. Prognosis for individuals with ACC depends upon whether ACC is an isolated defect (excellent prognosis) or associated with a neurologic or genetic syndrome.

Malformations of Cortical Development**Definition/Epidemiology**

Malformations of cortical development (MCD) are a group of disorders that are characterized by disrupted migration and organization of neuronal progenitor cells, resulting in the abnormal appearance of cortical sulci and gyri.

The primary categories of MCD include lissencephaly (refers to smooth appearance of the brain surface), polymicrogyria, schizencephaly, focal cortical dysplasia (FCD), and periventricular nodular heterotopia. The recognized incidence of MCD is increasing with the use of MRI in children with epilepsy and congenital neurologic deficits. It is estimated that 25% to 40% of medication-resistant childhood epilepsy is secondary to MCD. The more severe forms of lissencephaly occur in approximately 1.2/100,000 births. All other forms of MCD are more common than lissencephaly.

Pathology

Neuronal migration is a complex, highly regulated process integral to formation of normal cortical architecture that occurs throughout gestation but peaks from 2 to 4 months. More than 100 genes play various roles in neuronal migration.

Schizencephaly is characterized by the presence of a cleft in the brain that extends from the surface of the pia mater to the cerebral ventricles that may occur as a consequence of a defect in neuronal migration, a genetic mutation, or a structural CNS insult in utero.

Focal cortical dysplasia (FCD) is typically the least severe type of MCD and often is clinically silent until patients present with focal seizures. FCD most often occurs as a postmigrational defect leading to cortical disorganization and focal lesions.

Clinical Presentation

MCD can have highly variable clinical presentations depending on post-conceptual timing of cortical disruption and degree of cortical involvement. Lissencephaly has a severe presentation with marked motor disability and seizures, including infantile spasms. Polymicrogyria and schizencephaly, depending on the extent and location, can have less severe presentations. Most children with severe MCD present early in infancy with microcephaly, seizures, feeding difficulties, and developmental delays. The most common presentation of FCD is onset of focal seizures in early childhood.

Diagnosis/Differential

Neuroimaging is the primary method of diagnosing all types of MCD. Moderate- to high-resolution MRI scans are used for diagnosis in infants and young children. Prenatal ultrasound or fetal MRI may identify early features of some MCD. Most MCD are associated with genetic syndromes and warrant further genetic testing.

Treatment

Seizures are treated with antiepileptic medications and, when indicated, epilepsy surgery. Severe neurologic impairment leads to other complications (see [Table 117.2](#))

Prognosis

Children with severe lissencephaly syndromes have a severe course and high mortality rates. Long-term prognosis for all other types of MCD depends on the degree of neurologic impairment and underlying etiology.

DEVELOPMENTAL DISORDERS**Autism Spectrum Disorder****Definition/Epidemiology**

Autism spectrum disorder (ASD) is characterized by impaired social communication and interactions and restricted and repetitive behaviors. Approximately 1 in 69 children are affected by ASD with an incidence four times higher in boys than girls. The early symptoms of ASD can be identified between 1 and 3 years of age.

Pathology

A combination of genetic and epigenetic factors are thought to increase the risk of developing ASD. Many genetic syndromes, such as fragile X syndrome and Rett syndrome (see later), have autistic features as part of their clinical presentation. In addition, environmental factors such as advanced maternal or paternal age, maternal diabetes mellitus, or low birthweight increase the risk of ASD.

Clinical Presentation

The early symptoms of ASD are apparent during early childhood and a reliable diagnosis can be obtained by age 2 years. Patients usually present with delayed language development or language regression and limited social interaction. Children with ASD have impaired joint attention and often display repetitive, stereotypic behaviors.

Diagnosis/Differential

Several rating scale instruments and standardized interview tools have been developed to help diagnose ASD. The most commonly used tools

are the Autism Diagnostic Observation Schedule (ADOS) and the Autism Diagnostic Interview-Revised (ADI-R). Both use standardized questions and observation scores based on the DSM-5 criteria for ASD.

Treatment

Prompt diagnosis and early initiation of intensive behavioral interventions such as applied behavioral analysis (ABA) and early childhood therapies are among treatments for ASD. In addition, some individuals with ASD require treatment for comorbid ADHD, anxiety, or epilepsy.

Prognosis

In 2014, a review of all studies examining the effectiveness of ABA intervention demonstrated that ABA delivered over an extended time leads to improvement in cognitive ability, language, and adaptive skills. Approximately 10% of children with ASD may develop skills for independent living and work. Early diagnosis and prompt referral to intensive ABA therapy are associated with improved prognostic outcomes.

Attention-Deficit/Hyperactivity Disorder

Definition/Epidemiology

ADHD is a common neurodevelopmental disorder occurring in 5% of children and 2.5% of adults. It is three times more common in males than females and often associated with additional neurodevelopmental and psychiatric disorders. ADHD is marked by inattention, impulsivity, and hyperactivity causing impaired functioning.

Pathology

There are no consistent pathologic brain findings or neurotransmitter abnormalities found in individuals with ADHD. However, ADHD is a highly heritable disorder. Several genetic disorders are associated with ADHD, including fragile X syndrome and 22q11 microdeletion (DiGeorge syndrome).

Environmental factors are known to play a role. Low birthweight, prematurity, and in utero exposure to maternal cigarette smoking, alcohol, and illicit substances are associated with a higher ADHD risk.

Clinical Presentation

Patients with ADHD typically present before age 12 years with complaints of 6 months or more of developmentally inappropriate behaviors, hyperactivity, inappropriate inattention, and impulsivity resulting in significant impairment in at least two different settings (e.g., home, school, work, or with peers).

On neuropsychiatric testing, patients with ADHD often have deficits in response inhibition, vigilance, working memory, and planning. These patients often struggle in school and have a history of behavioral outbursts due to poor impulse control.

Diagnosis/Differential

The diagnosis of ADHD can be made with the help of standardized rating scales that assess for symptoms of inattention, hyperactivity, and impulsivity in several different settings. The Vanderbilt Assessment Scale and Connors' Parent and Teacher Rating Scales are examples of standardized tools that help distinguish ADHD from inattention due to learning disability, hearing impairment, or mood disorders.

Treatment

Stimulant medications such as methylphenidate and amphetamines are the primary class of medication used in ADHD. They can improve cognition, executive and nonexecutive function, and memory. Other nonstimulant medications such as atomoxetine, guanfacine, and clonidine can be used when stimulant side effects are bothersome or when comorbid treatment of anxiety or sleep disorders is desired.

Prognosis

ADHD generally responds to treatment but there are often residual school difficulties. Core symptoms of childhood ADHD generally persist into adulthood, leading to higher risk of adverse occupational, economic, and social outcomes. Improvement in symptoms depends on age at diagnosis, associated intellectual disability, and effectiveness of clinical follow-up.

Rett Syndrome

Definition/Epidemiology

Rett syndrome is an X-linked dominant disorder caused by a mutation of the methyl-cytosine binding protein (MECP2), a transcriptional repressor. It is the second most common cause of severe intellectual disability in girls after Down syndrome, affecting 1 in 9000 to 10,000 girls. In boys, MECP2 mutations are lethal or result in severe encephalopathy.

Pathology

The loss of MECP2 function prevents regulation of gene expression during critical developmental periods in infancy.

A few patients who meet clinical criteria for Rett syndrome do not have MECP2 mutations. Other genes, such as *CDKL5*, *FOXG1*, and *MEF2C*, have been associated with Rett syndrome, and, like MECP2, encode proteins that are essential for early brain development.

Clinical Presentation

Patients with classic Rett syndrome develop normally during their first 6 to 18 months and then have stagnation in development, followed by loss of communication skills and deceleration in head growth. Other findings are "wringing" hand movements at midline, hyperventilation, air swallowing, abdominal distension, and chronic constipation. Between 60% and 80% develop seizures.

Diagnosis/Differential

Diagnosis can be confirmed by MECP2 mutational testing. As noted previously, other genes can cause Rett or Rett-like syndrome. Angelman syndrome, mitochondrial disorders, and neuronal ceroid lipofuscinosis may also present similarly.

Treatment

Girls with Rett syndrome usually require a multidisciplinary approach to address the complications associated with their severe neurologic impairment (see [Table 117.2](#)). Comorbidities often seen in Rett syndrome include seizures, spasticity with joint contractures, and prolonged QTc interval.

Prognosis

Most girls survive into adulthood but will not acquire speech or functional skills and will remain dependent for their care.

Fragile X Syndrome

Definition/Epidemiology

Fragile X syndrome (FXS) is an X-linked disorder caused by expanded CGG triplet repeats in the first exon of the fragile X mental retardation gene (*FMR1*). An X-linked recessive disorder, girls can be symptomatic though they may have milder intellectual disability compared to boys. FXS is the most common single-gene cause of inherited cognitive disability and affects 1.4/10,000 females and 1.9/10,000 males. The prevalence of the female carrier status is estimated to be as high as 1 in 250 to 300.

Pathology

A normal *FMRI* gene contains between 6 and 44 CGG trinucleotide repeats and produces fragile X mental retardation protein (FMRP), which is important in brain development. Affected individuals have greater than 200 repeats, which causes silencing of *FMRI* gene transcription with loss of FMRP.

Clinical Presentation

Boys with FXS typically have moderate to severe cognitive disability and typical facies with relative macrocephaly, long and narrow face, high-arched palate, and prominent ears. Other physical features include pubertal macro-orchidism, joint hypermobility, hypotonia, and pes planus.

Some with FXS have comorbid epilepsy, with onset between 2 and 10 years of age. Other common findings are sleep disturbances, anxiety, and ADHD. Approximately 30% of males and 25% of females with fragile X have a comorbid diagnosis of autism.

Individuals with the “premutation” range of 55 to 200 CGG repeats often develop ataxia, tremor, and cognitive dysfunction in adulthood at a median age of onset of 60 years (fragile X associated tremor/ataxia syndrome or FXTAS).

Diagnosis/Differential

Diagnosis is confirmed by identifying increased CGG repeats in the *FMRI* gene. Other conditions can be mistaken for FXS, including Sotos syndrome, Prader-Willi syndrome, and Klinefelter syndrome. Adult-onset disorders presenting like FXTAS include parkinsonism, other ataxia syndromes, and tremor.

Treatment

Treatment focuses on management of comorbid conditions such as epilepsy, autism, ADHD, and disordered sleep. Use of stimulants or selective serotonin reuptake inhibitors (SSRIs) may effectively decrease inattention, hyperactivity, and psychiatric symptoms. Behavioral and educational services validated for autism are helpful in FXS. Earlier diagnosis and earlier developmental interventions may improve outcomes.

Prognosis

Patients with FXS respond to training and education over time, but their intellectual disability may make it difficult for them to live independently. FXTAS is associated with gradual and progressive neurologic deterioration over many years.

NEUROCUTANEOUS DISORDERS

Neurocutaneous disorders are congenital, often hereditary disorders characterized by pathognomonic cutaneous and central nervous system lesions that uniquely distinguish each disease. Many neurocutaneous disorders are associated with abnormal, noncancerous growth of tissues, often in a disorganized manner. Here we discuss neurofibromatosis 1 and 2 and tuberous sclerosis complex.

Neurofibromatosis 1

Definition/Epidemiology

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder caused by mutations in the *NF1* gene on chromosome 17. NF1 is characterized by altered skin pigmentation, tumors, and abnormalities of bones, connective tissue, and brain (Fig. 117.2). It is the most common neurocutaneous disorder, occurring in 1/2500 to 1/3000 individuals worldwide.

Fig. 117.2 Multiple café-au-lait spots in a child with neurofibromatosis type 1. (From Shah KN: The diagnostic and clinical significance of café-au-lait macules, *Pediatr Clin N Am* 57:1131-1153, 2010, Fig. 3.)

Pathology

The *NF1* gene codes for neurofibromin, which regulates tissue growth and tumor formation, explaining the occurrence of cutaneous neurofibromas, plexiform neurofibromas, and gliomas in NF1. Malignant tumors can occur secondary to malignant transformation of previously benign tumors. Approximately 50% of NF1 cases are due to spontaneous mutations.

Clinical Presentation

Patients can present with NF1 variably. All NF1 patients can be diagnosed before 20 years of age based on clinical criteria shown in Table 117.3. Patients can have learning disabilities, macrocephaly, and epilepsy. Important complications of NF1 include scoliosis, gastrointestinal neurofibromas, pheochromocytomas, and renal artery stenosis.

Diagnosis/Differential

The diagnostic criteria outlined previously are highly sensitive and specific. *NF1* DNA testing for mutations in *NF1* can confirm the diagnosis. Schwannomatosis and neurofibromatosis type 2 may be mistaken for NF1.

Treatment

Regular multidisciplinary surveillance is recommended with frequent skin exams and assessment of neurocognitive development. Ophthalmology exams are strongly recommended until age 8 years because the risk of optic pathway gliomas is highest during this time. Many optic pathway tumors can be followed conservatively without surgery unless there are visual changes, when treatment with chemotherapeutic agents is recommended.

Large cutaneous neurofibromas and smaller fibromas can be removed but often recur. Subcutaneous plexiform neurofibromas grow along nerves and extend into surrounding tissue, causing pain or deformities. They have a high lifetime risk of malignant transformation and should be excised if possible. Drugs that target the biological pathways involved in tumor growth are being actively investigated.

Neurofibromatosis 2

Definition/Epidemiology

Neurofibromatosis type 2 (NF2) is a rare autosomal dominant adult-onset disease affecting 1/33,000 individuals and characterized by bilateral vestibular schwannomas and nonmalignant brain tumors.

TABLE 117.3 NIH Diagnostic Criteria for NF1 and NF2

NF1	NF2
<p>Clinical diagnosis based on presence of two of the following:</p> <ol style="list-style-type: none"> 1. Six or more café-au-lait macules over 5 mm in diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals 2. Two or more neurofibromas of any type or one plexiform neurofibroma 3. Freckling in the axillary or inguinal regions 4. Two or more Lisch nodules (iris hamartomas) 5. Optic glioma 6. A distinctive osseous lesion such as sphenoid dysplasia or thinning of long bone cortex, with or without pseudarthrosis 7. First-degree relative (parent, sibling, or offspring) with NF1 by the above criteria 	<p>The criteria are met by an individual who satisfies condition 1 or 2:</p> <ol style="list-style-type: none"> 1. Bilateral masses of the eighth cranial nerve seen with appropriate imaging techniques (e.g., CT or MRI) 2. A first-degree with NF2 and either: <ol style="list-style-type: none"> a. Unilateral mass of the eighth cranial nerve, or b. Two of the following: <ul style="list-style-type: none"> • Neurofibroma • Meningioma • Glioma • Schwannoma • Juvenile posterior subcapsular lenticular opacity

Pathology

The *NF2* gene on chromosome 22q12 is a tumor suppressor gene so mutations lead to loss of the protein merlin and a predisposition for tumor formation. Approximately 50% with NF2 have sporadic mutations.

Clinical Presentation

NF2 is characterized by multiple nonmalignant nervous system tumors including meningiomas, ependymomas, and gliomas. Bilateral vestibular schwannomas are the characteristic tumors of NF2, affecting 95% of patients. NF2 is typically diagnosed around 20 to 30 years with the onset of hearing loss and identification of unilateral or bilateral vestibular schwannomas.

Individuals with NF2 can have café au lait lesions, but rarely in the size or numbers noted in NF1. Many with NF2 have ophthalmologic findings including cataracts, retinal changes, and amblyopia.

Diagnosis/Differential

Like NF1, patients with NF2 are initially diagnosed based on highly specific clinical criteria (see Table 117.3). Molecular testing can confirm the diagnosis.

NF2 is frequently misdiagnosed as NF1, especially if there are café-au-lait spots. Patients with NF2 may also be misdiagnosed as having an isolated meningioma or unilateral vestibular schwannoma if other findings are not sought.

Treatment

Removal of the schwannomas and other tumors is usually indicated later in life when the tumors are larger and causing significant symptoms. There may be postsurgical complications and tumors may recur.

While traditional treatment has focused on surgical interventions, as described in NF1, attention has turned to development of drugs targeting tumor growth pathways.

Tuberous Sclerosis Complex

Definition/Epidemiology

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder of early cellular differentiation, proliferation, and migration. TSC results in hamartomatous lesions involving multiple organs at different stages. The incidence of TSC is 1/6000. Mutations in two genes, *TSC1* and *TSC2*, are known to cause TSC in the majority of cases, and about 70% of cases are sporadic.

Pathology

TSC1 and *TSC2* are on different chromosomes but both encode proteins (hamartin and tuberlin, respectively) that act as tumor suppressors, inhibiting the mammalian target of rapamycin (mTOR) pathway, which is essential in cell growth and proliferation. Mutations of these genes lead to unregulated growth and proliferation.

Clinical Presentation

The skin findings of TSC are common. Ninety percent have hypomelanotic macules, or “ash leaf spots.” Facial angiofibromas are benign 1- to 5-mm dome-shaped skin-colored papules that first appear between 2 and 5 years of age. Shagreen patches are large plaques in the lumbosacral region with an “orange-peel” texture to the skin and are specific to TSC.

CNS involvement affects almost all individuals with TSC. Common conditions are epilepsy, autism, developmental delay, and intellectual disability. Brain imaging may reveal subcortical tubers, subependymal nodules, and subependymal giant cell astrocytomas (SEGAs) in some. Forty percent to 50% of infants develop a severe form of seizures called infantile spasms.

Diagnosis/Differential

The diagnosis of TSC is confirmed by identifying a pathogenic mutation of *TSC1* or *TSC2*. Because 10% to 25% of affected patients have no mutation, identified clinical criteria have been established as well.

The spectrum of tumors seen in TSC may also be seen in isolation. Biopsy may be needed to distinguish facial angiofibromatosis from acne and other skin lesions.

Treatment

Treatment is primarily directed toward the sequelae of TSC-associated conditions. Several studies have shown that infants with TSC and infantile spasms have a superior response to treatment with vigabatrin.

SEGAs are typically slow growing, benign lesions that may be monitored with serial neuroimaging if asymptomatic. However, SEGAs located near the foramen of Monro can lead to obstructive hydrocephalus. Surgical intervention with gross total resection may be curative, but treatment with mTOR inhibitors such as everolimus is often helpful.

Prognosis

TSC associated with *TSC1* mutations is more often familial and has a milder clinical phenotype. Patients with *TSC2* mutations are more

likely to have a sporadic mutation with more severe clinical complications. The variability in outcome depends on the extent and type of presenting symptoms. Patients with refractory seizures, developmental delays, and CNS lesions have a poorer prognosis. The development of renal angioliopomas, especially multiple tumors, is also associated with poorer outcome.

Sturge-Weber Syndrome

Definition/Epidemiology

Sturge-Weber syndrome (SWS) is a vascular malformation syndrome characterized by vascular lesions of the skin, brain, and eyes. It occurs in 1/20,000 to 1/50,000 live births with no clear evidence of heritability. SWS is the third most common neurocutaneous syndrome after NF1 and TSC.

Pathology

SWS is caused by somatic mutations in the *GNAQ* gene that plays an important role in vascular development. The gain-of-function mutation in *GNAQ* is found in affected tissues associated with vascular lesions. Leptomeningeal vascular malformations are ipsilateral to the port-wine birthmark and are associated with cortical injury secondary to venous stasis and insufficient tissue perfusion.

Clinical Presentation

SWS is characterized by leptomeningeal angiomas of the posterior hemisphere, facial cutaneous vascular malformations known as port-wine birthmarks, choroid angioma of the eye, seizures, and glaucoma.

Diagnosis/Differential

The diagnosis is usually made by observing a port-wine birthmark in the distribution of the ophthalmic branch of the trigeminal nerve, with neuroimaging confirmation of the intracranial abnormality. While 10% to 35% of children with a facial port-wine birthmark on the forehead or upper eyelid will have SWS, as many as 80% of children with a port-wine birthmark do not have intracranial lesions. SWS should be distinguished from other disorders involving abnormal intracranial vessels and seizures, including moyamoya disease, other vascular malformations, and tuberous sclerosis.

Treatment

Aggressive treatment of seizures with antiepileptic medications and consideration for surgical excision of epileptogenic areas may be indicated. Facial birthmarks may be treated with laser ablation for cosmetic purposes. Careful screening and treatment for glaucoma is necessary.

The use of daily aspirin to prevent strokes is controversial.

Prognosis

Prognosis for patients with SWS depends on the degree of underlying intellectual and developmental disability, control of seizures, and extent of visual impairment usually due to glaucoma.

Cerebrovascular Disease

Mitchell S. V. Elkind

INTRODUCTION

Stroke is a major public health problem throughout the world due to its high prevalence and mortality and its association with significant disability among survivors. Stroke is the fifth leading cause of death in the United States and a leading cause of death in other countries, particularly in Asia. It is the leading cause of serious disability and results in enormous costs measured in both health care dollars and lost productivity. Major strides have been made in understanding the epidemiology, etiology, and pathogenesis of cerebrovascular disease, which have led to dramatic change in the approach to diagnosis and treatment of stroke in the past decade.

DEFINITIONS AND EPIDEMIOLOGY

The term *cerebrovascular disease* encompasses a host of disorders that share pathology localized to the vessels of the brain and spinal cord, including ischemic stroke, transient ischemic attack (TIA), intracerebral hemorrhage (ICH), subarachnoid hemorrhage (SAH), cerebral venous and sinus thrombosis, and disorders of the vessels themselves unassociated with cerebral injury (Table 118.1). Strokes, the major type of cerebrovascular disease, may be classified as either ischemic (i.e., due to lack of blood flow) or hemorrhagic. With widespread use of sensitive brain imaging, such as diffusion-weighted MRI (DWI), cerebral injury from ischemia can be seen among patients whose symptoms last only a few minutes. The definition of a transient ischemic attack has thus evolved from one in which symptoms lasted less than 24 hours, to one in which the duration of symptoms is not as relevant, and the focus is instead on whether there is evident brain injury on imaging (or pathology in those instances in which a patient dies). A definition from an expert panel in 2013 defined an *ischemic stroke* as “an episode of neurological dysfunction caused by focal cerebral, spinal, or retinal infarction.” A *stroke due to ICH* was defined as “rapidly developing clinical signs of neurologic dysfunction due to a focal collection of blood within the brain parenchyma or ventricular system which is not due to trauma.”

Because advanced imaging techniques permit the detection of abnormalities consistent with infarction or microhemorrhage that are unassociated with any clinical symptoms, the current definitions distinguish between “stroke,” which involves clinical symptoms, and “cerebral infarction” and “microhemorrhages” (or “microbleeds”), which need not be associated with symptoms of cerebral injury. So-called “silent strokes,” however, are not so silent; they can be associated with cognitive decline, dementia, gait disorders, functional disability, and an increased risk of clinical strokes. Because subclinical infarcts are approximately five times more common than clinically evident strokes, including them (and microbleeds) within the rubric of *cerebrovascular*

disease substantially increases the recognized burden of cerebrovascular pathology.

Ischemic strokes may be further classified into etiologic subgroups, based on the mechanism of the ischemia and the type and localization of the vascular lesion. Cardioembolism as the source occurs in 15% to 30% of cases, large vessel atherosclerotic infarction varies from 14% to 40%, and small-vessel lacunar infarcts account for 15% to 30%. Stroke from other determined causes, such as arteritis or dissection, account for less than 5% of cases. In 30% to 40% of ischemic infarcts the cause cannot be determined. Intracranial hemorrhage may also be subdivided into subtypes, based on the site and vascular origin of the blood: subarachnoid, when the bleeding originates in the subarachnoid spaces surrounding the brain; and intracerebral, when the hemorrhage is into the brain parenchyma. Other forms of intracranial bleeding, such as subdural hemorrhage and epidural hemorrhage, are generally associated with trauma and not usually considered manifestations of stroke.

In the United States, there are 6.4 million stroke survivors (prevalence of 3%), and there are approximately 600,000 new (incident) and 200,000 recurrent strokes per year. Of these strokes, about 87% are ischemic infarctions, 10% primary hemorrhages, and 3% SAHs. Among adults age 65 to 74, stroke incidence is 670 to 970/100,000 per year. Stroke incidence rates are approximately twice as high for African Americans as for white individuals. In northern Manhattan, Caribbean Hispanic individuals had an incidence rate intermediate between that of white individuals and African Americans. Temporal trends in stroke incidence suggest that stroke incidence and mortality rates have declined since 1950; however, disparities in stroke incidence and mortality have persisted. Stroke rates in the young have also increased. From 1995 to 2012, stroke hospitalization rates for men age 18 to 44 years have doubled. Overall, due to the graying of the global population and the increased prevalence of stroke risk factors in younger people, the mean global lifetime risk of stroke has increased almost 9% over the past 25 years (through 2016) to 25%, meaning that 1 in 4 people will experience a stroke at some point during their lifetime.

Stroke incidence increases with age, but strokes do occur in young adults and children and may be missed if the diagnosis is not considered. Although stroke incidence rates are higher for men than women at most ages, among young adults the rates are similar or higher among women, probably related to pregnancy, hormonal contraception, and other hormone-related differences. At older ages, incidence rates among women are again greater, and because women tend to live longer than men, overall about 55,000 more women than men have a stroke each year.

MODIFIABLE RISK FACTORS

Well-established modifiable stroke risk factors include hypertension, cardiac disease (particularly atrial fibrillation), diabetes,

TABLE 118.1 Common Forms of Cerebrovascular Disease

Ischemic cerebrovascular disease
Symptomatic
• Ischemic stroke
• Cerebral infarction
• Spinal cord infarction
• Retinal infarction
• Transient ischemic attack
• Transient monocular blindness (<i>amaurosis fugax</i>)
Asymptomatic
• Cerebral infarction/spinal cord infarction/retinal infarction
Hemorrhagic cerebrovascular disease
• Intracerebral hemorrhage
• Subarachnoid hemorrhage
• Intraventricular hemorrhage
• Subdural hemorrhage
• Epidural hemorrhage
• Cerebral microbleeds
Other forms of cerebrovascular disease
• Cerebral vein thrombosis
• Dural sinus thrombosis
Disorders of cerebral autoregulation
• Posterior reversible encephalopathy syndrome
• Hypertensive encephalopathy
• Reversible cerebral vasoconstriction syndrome
Vascular abnormalities
• Aneurysms
• Arteriovenous malformations
• Cavernous malformations
• Fibromuscular dysplasia

hyperlipidemia, cigarette use, physical inactivity, alcohol abuse, asymptomatic carotid stenosis, and a history of TIAs (Table 118.2).

Hypertension is the most powerful modifiable stroke risk factor and is associated with both ischemic and hemorrhagic strokes. Risk of stroke decreases with lower systolic and diastolic blood pressures, and this graded decrement in risk persists down to levels as low as 115/75 mm Hg. There is no clearly defined threshold level below which stroke risk levels off.

Cardiac disease is associated with an increased risk of ischemic stroke. Atrial fibrillation (AF) is the cardiac disease most often associated with stroke risk and accounts for up to 24% of cerebral infarction in the elderly. Other cardiac diseases, including valvular heart disease, myocardial infarction (MI), coronary artery disease (CAD), and congestive heart failure (CHF) are also associated with stroke risk. Recent evidence also suggests that other atrial arrhythmias, such as paroxysmal supraventricular tachycardia, may also increase risk of stroke, even in the absence of atrial fibrillation. Other possible sources of cardiac emboli include patent foramen ovale, aortic arch atherosclerotic disease, atrial septal aneurysms, and valvular strands.

Hyperlipidemia is a stroke risk factor, though its relationship to stroke is more complicated than for heart disease, primarily because of the many types of stroke. Lipid abnormalities, such as elevations in low-density lipoprotein (LDL) and decreased levels of high-density lipoprotein, are strongly associated with ischemic stroke of atherosclerotic origin. Somewhat paradoxically, however, low levels of LDL are associated with an increased risk of hemorrhagic stroke.

TABLE 118.2 Stroke Risk Factors

Nonmodifiable risk factors	Age
	Sex
	Race/ethnicity
	Family history
	Genetic disorders
Well-established modifiable risk factors	Hypertension/blood pressure
	Diabetes mellitus/hyperglycemia
	Cardiac disorders
	Atrial fibrillation
	Valvular heart disease
	Recent myocardial infarction
	Cardiomyopathy/heart failure
	Bacterial endocarditis
	Hyperlipidemia
	Cigarette smoking
	Carotid stenosis
	Transient ischemic attack (TIA)
	Physical inactivity
	Hypercoagulable states (e.g., antiphospholipid antibody syndrome, cancer-associated hypercoagulopathy)
	Alcohol abuse
	Substance abuse (e.g., cocaine, intravenous drug abuse)
Other potential risk factors	Migraine
	Sleep apnea
	Cardiac disorders
	Paroxysmal supraventricular tachycardia
	Patent foramen ovale/atrial septal aneurysm
	Aortic atheroma
	Atrial cardiopathy
	Infections (e.g., varicella zoster virus, influenza)
	Inflammation
	Others

The role of alcohol as a stroke risk factor also depends on stroke subtype, as well as the quantity consumed. Alcohol consumption has been shown to be a risk factor for both ICH and SAH in a linear fashion, whereas a J-shaped relationship exists between alcohol and ischemic stroke, such that modest consumption (up to two drinks daily in men, and one daily in women) may be protective against stroke and heavy consumption (five or more drinks per day) increases risk.

Asymptomatic carotid artery disease, particularly with 70% or greater stenosis, is associated with increased stroke risk (approximately 2% per year). The risk of stroke also depends, however, on the rate of progression of the stenosis, collateral circulation, and the stability of the atherosclerotic plaque.

TIAs are a strong predictor of subsequent stroke. The first several days after a TIA have the greatest stroke risk, with clinical series demonstrating a 5% risk at 2 days and 10% risk at 90 days. Patients with transient monocular blindness (*amaurosis fugax*) have a better outcome than those with hemispheric ischemic attacks. The stroke risk after TIA depends on the underlying cause of the ischemia, including the presence and severity of underlying atherosclerotic disease or AF. Age, hypertension, the presence of diabetes, clinical syndromes including aphasia and hemiparesis, and duration of at least 10 minutes

predict TIA patients at higher risk of stroke. Patients with TIA with evidence of infarction on MRI are also at higher risk. Other potential stroke risk factors include migraine, oral contraceptive use, drug abuse, sleep apnea, infection, and inflammation.

PATHOLOGY

Understanding the pathology of cerebrovascular disease requires an appreciation of the vascular anatomy of the brain, the vascular pathologies that can affect brain vessels, and the response of brain tissue to ischemia and hemorrhage.

Clinical Implications of Vascular Anatomy

The brain is perfused by four major vessels, the paired carotid and vertebral arteries. These originate extracranially as branches off the aorta and great vessels and course through the neck and base of the skull to reach the intracranial cavity (Fig. 118.1). The carotid and its branches constitute the anterior circulation and the vertebral arteries and its branches the posterior circulation. Anterior and posterior circulations communicate with one another through the posterior communicating arteries. The left and right sides of the anterior circulation communicate with each other through the anterior communicating artery. The major vessels at the base of the brain and these communicating vessels constitute the circle of Willis, the anastomotic network that allows for collateral blood flow when individual vessels are stenotic or occluded. Because variants in the circle of Willis are common, collateral flow may not be sufficient in many cases of blockage, and the risk of ischemic stroke therefore depends on a patient's individual anatomy.

The right common carotid artery usually begins as a branch from the innominate artery, whereas the left common carotid artery originates directly from the aortic arch. The common carotid arteries bifurcate into the internal and external carotid arteries, usually at the level of the fourth cervical vertebra. The internal carotid arteries have no branches in the neck and face and enter the cranium through the carotid canal. There are four main segments of each internal carotid artery: cervical, petrous, cavernous, and supraclinoid. The siphon is the term used to describe the hairpin turn made by the cavernous and supraclinoid segments, and it is at this level that the ophthalmic artery originates, providing the first major branch of the internal carotid artery and supplying blood flow to the optic nerve and retina. Thus, internal carotid artery disease commonly causes ocular ischemia, leading to a transient ischemic attack (*amaurosis fugax*) or infarction of the optic nerve or retina, a warning sign of impending cerebral stroke. The internal carotid arteries then give off the superior hypophyseal, posterior communicating, and anterior choroidal arteries, before terminating intracranially by dividing into the middle and anterior cerebral arteries. In addition to the eye, the paired carotid systems supply approximately 80% of the hemispheric blood flow, including the frontal, parietal, and anterior temporal lobes. In up to 15% of individuals, the posterior cerebral artery (PCA) also arises directly from the internal carotid artery (the so-called fetal origin PCA), so that the entire hemisphere including the occipital lobe is supplied by the internal carotid artery. The anterior choroidal artery supplies a number of structures in addition to the choroid plexus, including the inferior portion of the posterior limb of the internal capsule, the hippocampus, and portions of the globus pallidus, posterior putamen, lateral geniculate, amygdala, and ventrolateral thalamus.

The middle cerebral artery (MCA) is the largest branch of the internal carotid artery. Its first portion, or stem, is often referred to as the M1 segment, and this usually bifurcates into superior and inferior divisions or, less often, trifurcates into three major divisions (upper, middle, and lower). The MCA stem gives rise to the medial and lateral

Fig. 118.1 Coronal view of the extracranial and intracranial arterial supply to the brain. Vessels forming the circle of Willis are highlighted. *A*, Artery; *ACA*, anterior cerebral artery; *AICA*, anterior inferior cerebellar artery; *Ant Comm*, anterior communicating artery; *CCA*, common carotid artery; *ECA*, external carotid artery; *ICA*, internal carotid artery; *MCA*, middle cerebral artery; *PCA*, posterior cerebral artery; *PICA*, posterior inferior cerebellar artery; *Post Comm*, posterior communicating artery; *SCA*, superior cerebellar artery. (Modified from Lord R: Surgery of occlusive cerebrovascular disease, St. Louis, 1986, Mosby.)

lenticulostriates, which supply the extreme capsule, claustrum, putamen, most of the globus pallidus, part of the head and the entire body of the caudate, as well as the superior portions of the anterior and posterior limbs of the internal capsule. The divisions of the MCA supply almost the entire lateral cortical surface of the brain, including the insula, operculum, and frontal, parietal, temporal, and occipital cortices.

The anterior cerebral artery (ACA) also has a proximal, or A1, segment, which ends at the junction with the anterior communicating artery. The ipsilateral ACA then continues as the distal, or A2, segment. An important branch is the recurrent artery of Heubner, which supplies the head of the caudate nucleus, and several cortical branches supply the medial and orbital surfaces of the frontal lobe.

The vertebral arteries generally originate from the subclavian arteries, course through the transverse foramina of the cervical vertebrae, pierce the dura, and enter the cranial cavity through the foramen magnum. The two vertebral arteries join to form the basilar artery at the level of the pontomedullary junction. Anterior and posterior spinal arteries and the posterior inferior cerebellar artery (PICA), which supplies the inferior surface of the cerebellum, arise from the distal segments of the vertebrals. The lateral medulla is supplied by the multiple, perforating branches of PICA or the direct penetrating branches of the vertebral artery. Occlusion of the distal vertebral artery may, therefore, cause infarction of the lateral medulla (Wallenberg syndrome), characterized by vertigo, imbalance, Horner syndrome, dysphagia, and sensory loss.

After originating as the union of the right and left vertebral arteries, the basilar artery travels up the ventral pons. Paramedian and

circumferential penetrating arteries exit the basilar to dive into the pontine parenchyma. Proximally, the basilar gives off the paired anterior inferior cerebellar arteries (AICAs), and more distally the superior cerebellar arteries (SCAs); these perfuse the ventrolateral aspect of the cerebellar cortex. An internal auditory (labyrinthine) artery arises either directly from the basilar or from the AICA to supply the cochlea, labyrinth, and part of the facial nerve. Ischemia in the basilar territory may, therefore, cause hearing loss and vertigo, sometimes as an isolated symptom.

The basilar artery terminates in the right and left posterior cerebral arteries (PCAs). A series of penetrators arise from the posterior communicating and posterior cerebral arteries to supply the hypothalamus, dorsolateral midbrain, lateral geniculate, and thalamus. The posterior cerebral artery supplies the inferior temporal lobe and the medial and inferior surfaces of the occipital lobe. In some patients a single large penetrating vessel at the midline of the terminal basilar artery may supply medial aspects of both thalami (the artery of Percheron); emboli occluding this vessel may, therefore, cause bilateral thalamic infarcts, with a decrease in alertness and vertical gaze abnormalities, without significant motor deficit.

The brain's anastomotic network includes not only the connections through the circle of Willis, but also intercommunicating systems extracranially and more distal connections intracranially through meningeal anastomoses that cover the cortical and cerebellar surfaces (pial-pial collaterals). These networks all protect the brain from ischemia by providing alternative routes to circumvent obstructions in the main arteries.

Venous anatomy is more variable than arterial. Superficial veins drain into the transverse, superior sagittal, and cavernous sinuses. The deep venous drainage is via the great vein of Galen, which drains into the straight sinus, and in turn drains into the torcula along with the sagittal sinus. Blood drains from the torcula to the transverse sinus, then to the sigmoid sinus, and thereafter the jugular vein. Anterior venous drainage is via the cavernous sinus, which communicates with the contralateral cavernous sinus, the transverse sinus via the superior petrosal sinus, and the inferior petrosal sinus, which drains directly into the jugular bulb.

Vascular Pathogenesis

There are multiple mechanisms leading to brain ischemia. Hemodynamic infarction occurs as a result of reduced perfusion, usually in the setting of arterial stenosis due to atherosclerosis. In some cases, stenosis may be due to arterial dissection, vasculitis, fibromuscular dysplasia, or other arteriopathies. Embolism occurs when a thrombus originating from a more proximal source (e.g., arterial or cardiac) travels through the arteries and occludes a cerebral artery. Paradoxical embolism occurs when a thrombus crosses from the venous circulation to the left side of the heart through a patent foramen ovale or, less commonly, an intrapulmonary arteriovenous shunt. Other particles that may embolize include neoplasms, fat, air, or other foreign substances. Air emboli can follow injuries or procedures involving the lungs, the dural sinuses, or jugular veins. Fat embolism usually results from a bone fracture. Septic emboli arise from bacterial endocarditis.

Intracranial hemorrhage results from the rupture of a vessel anywhere within the cranial cavity. Intracranial hemorrhages may be classified by location (e.g., extradural, subdural, subarachnoid, intracerebral, intraventricular), by the type of ruptured vessel (e.g., arterial, capillary, venous), or by cause (e.g., primary, secondary). Trauma is often involved in the generation of extradural hematoma from laceration of the middle meningeal artery or vein, and subdural hematomas from traumatic rupture of veins that traverse the subdural space.

Intracerebral, or intraparenchymal, hemorrhage is characterized by bleeding into the substance of the brain, usually originating from a small penetrating artery. Hypertension has been implicated as the cause of weakening in the walls of arterioles and the formation of microaneurysms (i.e., Charcot-Bouchard aneurysms). The most common sites for hypertensive arterial hemorrhage are the putamen, pons, cerebellum, and thalamus. Blood under arterial pressures destroys or displaces brain tissue. Amyloid angiopathy, due to the vascular deposition of β -amyloid protein similar to that seen in Alzheimer disease has been implicated as an important cause of lobar hemorrhage in elderly patients. Other causes of intracerebral hemorrhage include arteriovenous malformations, infectious aneurysms, cavernous angiomas, moyamoya disease, bleeding disorders, anticoagulation, illicit drug abuse, trauma, and tumors.

Subarachnoid hemorrhage occurs when blood is localized to the surrounding membranes and cerebrospinal fluid. It is most frequently caused by leakage of blood from a cerebral aneurysm. The combination of congenital and acquired factors leads to a degeneration of the arterial wall and the release of blood, under arterial pressures, into the subarachnoid space and cerebrospinal fluid. Aneurysms may be distributed at different sites throughout the base of the brain, particularly at the origin or bifurcations of arteries of the circle of Willis. Other secondary causes that may lead to SAH include trauma, arteriovenous malformations, bleeding disorders or anticoagulation, amyloid angiopathy, or cerebral sinus thrombosis.

The most common intrinsic disorder of the cerebral blood vessels is atherosclerosis, which shares similarities in pathology with atherosclerosis throughout the body. Arteriosclerotic plaques may develop at any point along the carotid artery and the vertebrobasilar system, but the most common sites are the bifurcation of the common carotid artery, the origins of the MCAs and ACAs, and the origins of the vertebral from the subclavian arteries (Fig. 118.2). In the past it was thought that intracranial atherosclerotic disease required significant stenosis (>50%) to cause symptoms. However, recent pathologic and radiologic studies provide evidence that substenotic lesions can also cause strokes due to plaque rupture and acute thrombosis, as is the case elsewhere in the body.

Small-vessel disease refers to the occlusion of a penetrant branch of a larger artery, usually due to microatheroma or to lipohyalinosis, a degenerative disorder of the vessel characterized by deposition of fatty and proteinaceous material. Hematologic disorders and coagulopathies, including leukemia, Waldenström's macroglobulinemia, polycythemia, primary and secondary antiphospholipid antibody syndrome, and genetic defects of the coagulation cascade, may also lead to occlusive thrombi and emboli.

The cerebral circulation differs from the systemic circulation in some important ways. The brain is protected by the anastomoses described previously. In addition, *cerebral autoregulation* maintains a constant cerebral perfusion pressure over a range of systemic blood pressures (Fig. 118.3). Cerebral arterioles have a well-developed muscular coat that allows constriction in response to increased blood pressure and dilation with hypotension. The arterioles are also exquisitely sensitive to changes in peripheral arterial concentrations of carbon dioxide (P_{aCO_2}) and oxygen (P_{aO_2}). When the partial pressure of CO_2 decreases, such as during hyperventilation, the arterioles constrict and blood flow is reduced. In healthy individuals, cerebral autoregulation maintains a constant cerebral blood flow over mean arterial pressures of 60 to 140 mm Hg. In patients with chronic hypertension, the autoregulatory curve is shifted to the right, so that even minor reductions in blood pressure may not be tolerated. At blood pressures above these limits, moreover, as in severe hypertension, autoregulatory capacity may be overwhelmed, leading to breakthrough edema and hemorrhage.

Fig. 118.2 Sites of predilection for atheromatous plaque. (From Caplan LR: *Stroke: a clinical approach*, ed 2, Boston, 1993, Butterworth-Heinemann.)

Fig. 118.3 Autoregulatory cerebral blood flow (CBF) response to changes in mean arterial pressure in normotensive and chronically hypertensive persons. Note the shift of the curve toward higher mean pressures with chronic hypertension. (From Pulsinelli WA: *Cerebrovascular diseases-principles*. In Goldman L, Bennett JC, editors: *Cecil textbook of medicine*, ed 21, Philadelphia, 2000, Saunders, p 2097.)

In the setting of infarction or hemorrhage, cerebral autoregulation is also impaired, resulting in cerebral dependence on systemic blood pressure to maintain adequate perfusion. Thus, decreasing the blood pressure in the setting of acute ischemia may be hazardous.

Specific disorders may originate from autoregulatory dysfunction: posterior reversible encephalopathy syndrome (PRES) and the reversible cerebral vasoconstriction syndrome (RCVS). In posterior reversible encephalopathy syndrome, there is loss of autoregulatory control with leakage of fluid across the blood-brain barrier, primarily in the posterior regions of the brain. Patients present with elevated blood pressures, headaches, seizures, and loss of visual function. Reversible cerebral vasoconstriction syndrome, a recently recognized syndrome, remains incompletely characterized, and shares features with posterior reversible encephalopathy syndrome. The two disorders overlap in 10% or more of cases. Patients with RCVS are typically young women who present with acute, severe headache, have minimal or no neurologic deficits, and may have evidence of non-aneurysmal, superficial SAH as well as vasospasm of the cerebral arteries. Sympathetic innervation of the vessels is also less in the posterior circulation than anteriorly, leading to a reduced ability of the posterior circulation to adapt to changes in blood pressure, and may contribute to the propensity for edema to form in the occipital lobes during hypertensive crises.

In addition, focal cerebral activity, such as occurs when activating brain regions responsible for moving a limb, is accompanied by increased metabolic activity in the appropriate region, and is accommodated by slight increases in local blood flow and oxygen delivery. Exploitation of this increased local energy demand and delivery is what allows imaging of functional brain activity using MRI, which can detect subtle changes in regional cerebral blood flow. These changes in blood flow are mediated by the neurovascular unit, a complex structure characterized by the local interaction of neural, glial, and vascular elements in the brain. Intracerebral capillaries also lack adventitia, with astrocytes serving as the vascular component of the neurovascular unit. Tight junctions at the capillary level play an important role in the blood-brain barrier, which limits permeability between the vascular compartment and the brain tissue.

Injury to Brain Tissue

The adult brain weighs about 1500 g, or 2% of total body weight, but accounts for 20% of the total body oxygen consumption. Because the brain cannot store much energy, dysfunction results after only a few minutes of deprivation when either oxygen or glucose content is reduced below critical levels. In the resting state, normal total cerebral blood flow is 50 mL/min per 100 g of brain tissue.

Neuronal dysfunction occurs at cerebral blood flow levels below 50 mg/dL, and irreversible neuronal injury begins at levels below 30 mg/dL. Both the degree and duration of reductions in cerebral blood flow are related to the likelihood of permanent neuronal injury. When blood supply is completely interrupted for 30 seconds, brain metabolism is altered; after 1 minute, neuronal function may cease. After 5 minutes, anoxia initiates a chain of events that may result in cerebral infarction; however, if oxygenated blood flow is restored quickly enough, the damage may be reversible, as with a TIA.

Research into the cellular basis of cerebral ischemia has led to the concept of the "ischemic cascade." As perfusion of the brain decreases, a chain of events at the neuronal level begins with failure of the membrane sodium/potassium (Na/K) pump, the depolarization of the neuronal membrane, the release of excitatory neurotransmitters such as glutamate and glycine that hyperstimulate their receptors, and the opening of calcium channels. Calcium enters the neuron through various voltage-sensitive and receptor-mediated channels (e.g., the N-methyl-D-aspartate receptor). The influx of calcium is at the root of further neuronal injury, leading to damage to organelles and further destabilization of neuronal metabolism and function. These events may lead to neuronal death, which may be delayed, even after

restoration of blood flow, and are a target of experimental neuroprotective strategies.

Recent research has distinguished between the “core” infarct and an “ischemic penumbra,” or shadow. The core represents a central region of necrosis, or tissue that dies very quickly after blood flow ceases. The penumbra represents the surrounding region of brain tissue, in which neurons are dysfunctional but potentially salvageable. Recanalization of occluded vessels with blood flow into infarcted tissue, particularly when delayed, results in “reperfusion injury.” Increased use of MRI has shown that petechial hemorrhagic infarction is very common, occurring in the majority of strokes, even when not suspected clinically.

CLINICAL PRESENTATION

The signs and symptoms of strokes are varied and depend on the type of stroke, the region of the nervous system affected by the lack of flow or hemorrhage, and the patient’s handedness (Table 118.3). In general, embolic ischemic strokes are characterized by the sudden onset of a neurologic deficit, usually painless. Thrombotic strokes may have a stuttering or progressive course due to fluctuating hypoperfusion and gradual occlusion. Arterial dissections, as well as hemorrhages, are more often associated with headaches than ischemic stroke of other causes. Hemorrhagic strokes and large hemispheric infarcts can lead to decrease in consciousness due to increased intracranial pressure.

Most emboli occur in the territory of the MCAs. Lesions of the dominant (almost always left) hemisphere are characterized by variable combinations of right hemiparesis, right hemisensory loss, right visual loss, impaired gaze to the right side of space, and language disturbance. When the superior division of the MCA is affected, the language impairment is predominantly motor: the patient either cannot speak or produces sparse, agrammatic speech, despite an ability to fully comprehend spoken and written material. When the inferior division is affected, the patient may produce fluent, prosodic (normal stress and intonation), but nonsensical speech and be unable to follow instructions. Larger infarcts of the dominant hemisphere produce a total loss of language function, leaving the patient mute and uncomprehending.

Lesions of the nondominant (right) hemisphere produce deficits of the left side of the body. Language is preserved but the patient may demonstrate impaired attention, particularly to the left side of space; fail to appreciate the presence of people or objects to their left; and may even fail to recognize the left side of their own body (asomatognosia). This neglect phenomenon may extend even to a lack of awareness of any deficit of function on their part (anosognosia). These patients may thus be found at home, lying on the floor paralyzed yet unaware that anything is the matter; their unawareness can delay their presentation to the hospital for treatment and similarly limit their participation in rehabilitation. Lesions in the right hemisphere may also cause dysprosody, the nondominant equivalent of aphasia, which is characterized by a lack of the emotional and gestural components of speech, despite preservation of its semantic content; many of these patients have a flat affect or appear to be depressed.

Infarcts in the territory of the anterior cerebral arteries often cause weakness limited to the legs, due to location of the representation of the legs in the medial part of the hemispheres. They may have incontinence, lack initiative (abulia), and have gaze palsies. In some cases their deficits may be more extensive and mimic those of MCA infarctions. Posterior cerebral artery infarcts lead to visual loss, often without any motor deficit. With involvement of the medial temporal lobes supplied by the PCAs, there may also be behavioral disturbances, including delirium and amnesia.

Brain stem infarcts cause specific syndromes due to the affected neural pathways and nuclei. Midbrain infarcts often produce vertical gaze deficits and impaired consciousness if the reticular activating system is involved.

TABLE 118.3 Clinical Manifestations of Ischemic Stroke

Occluded Vessel	Clinical Signs
ICA	Ipsilateral blindness (variable), MCA syndrome
MCA	Contralateral hemiparesis, hemisensory loss (face or arm more than leg) Aphasia (dominant) or anosognosia (nondominant) Homonymous hemianopsia (variable)
ACA	Contralateral hemiparesis, hemisensory loss (leg more than arm) Abulia (especially if bilateral)
VA or PICA	Ipsilateral facial sensory loss, hemiataxia, nystagmus, Horner syndrome Contralateral loss of temperature or pain sensation Dysphagia
SCA	Gait ataxia, nausea, vertigo, dysarthria
BA	Quadriparesis, dysarthria, dysphagia, diplopia, somnolence, amnesia
PCA	Contralateral homonymous hemianopsia, amnesia, sensory loss

ACA, Anterior cerebral artery; BA, basilar artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery; VA, vertebral artery.

Many cerebral infarctions do not cause weakness and may therefore be missed by the less astute clinician who assumes that a stroke always leads to paralysis. These syndromes include fluent (or Wernicke) aphasia, cortical visual loss, and Wallenberg syndrome (lateral medullary syndrome caused by occlusion of the vertebral or posterior inferior cerebellar artery). Because the inferior division of the MCA supplies the lateral temporal lobe and parietal lobes, including the Wernicke area, occlusion of that vessel may cause a prosodic, fluent speech with multiple paraphasic errors and poor comprehension, while sparing the motor strip in the frontal lobe. Emboli traveling up the basilar artery may lead to significant infarction in the territory of both PCAs, causing complete blindness, sometimes without awareness of the deficit on the part of the patient, due to infarction of both occipital lobes (the “top of the basilar syndrome”). Behavioral abnormalities, memory loss, and eye movement abnormalities may also occur, due to involvement of the medial temporal lobe structures and the midbrain eye movement centers. Small emboli to branches of the superior division of the MCA may cause focal weakness of the hand, particularly fine finger movements, simulating a peripheral compression neuropathy.

In patients presenting with dizziness, it is particularly difficult to distinguish stroke from vestibular neuronitis or Meniere’s disease (see Chapter 115). The presence of a normal head-thrust test, skew deviation, or direction-changing nystagmus are all signs of stroke, rather than a peripheral cause. Patients in the emergency ward should not be discharged until they can walk without imbalance; patients with nausea and vomiting due to cerebellar infarction may develop fatal brain stem compression due to swelling (so-called “fatal gastroenteritis”).

The signs and symptoms of *subarachnoid hemorrhage* differ from other stroke types due to the absence of focal deficits. Instead, patients present with abrupt onset of severe headache (i.e., “the worst headache of my life”), vomiting, altered consciousness, and sometimes coma, typically without localizing signs.

Thrombosis of cerebral veins or the larger draining dural sinuses present with a combination of headache due to elevated intracranial pressure, seizures, and focal deficits due to hemorrhage. Rarely the

Fig. 118.4 Early signs of infarction on computed tomography of the brain. (A) Hyperdense middle cerebral artery sign (*red arrow*), and (B) hypoattenuation of the left caudate and lentiform nuclei, loss of the insular ribbon, and sulcal effacement (*outlined in red*).

syndrome of *thunderclap headache*, or sudden severe headache without any focal signs similar to that occurring in SAH, may be due to venous thrombosis. Occlusion of the cerebral venous sinuses may occur in association with hyperviscosity or a hypercoagulable state, including pregnancy or hormonal contraceptive use. Imaging findings include bilateral hemorrhagic infarctions in a parasagittal distribution and extensive white matter edema. Contrast-enhanced CT may demonstrate the *empty delta* sign, indicating a filling defect in the sagittal sinus. Magnetic resonance venography (MRV) and T1-weighted MRI images confirm the presence of thrombus; cerebral angiography is seldom needed to confirm the diagnosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The potential benefit of thrombolytic therapy within 4.5 hours of onset of acute ischemic stroke requires urgent differentiation of ischemic stroke from hemorrhage and other causes of sudden neurologic symptoms. Headache, vomiting, seizures, and coma are more common in hemorrhagic stroke, though these are never reliable enough to preclude imaging. The distinction is straightforward in most cases once a head CT is performed. The hyperdense signal of blood in the parenchyma on CT almost invariably distinguishes hemorrhage from ischemia. In exceptional cases the typical hyperdensity of ICH is absent owing to severe anemia or to its subacute state, during which blood may be indistinguishable from brain tissue. Certain imaging findings on initial CT further support a presumed diagnosis of infarction, such as a hyperdense vessel sign indicative of thrombus in the vessel, or loss of the gray-white junction and sulci in the cortex, and loss of the demarcation of the insular cortex and deep gray nuclei, both of which are early indicators of ischemia and edema (Fig. 118.4). CT angiography often identifies the site of vascular occlusion.

Imaging in the setting of suspected acute ischemia does not definitively diagnose ischemia but rather excludes hemorrhage; if clinical symptoms are consistent with cerebral ischemia, then thrombolytic treatment is indicated within the appropriate time window. Primary stroke centers must perform and interpret CT scans within 30 minutes of the arrival of a patient with suspected stroke. MRI can also effectively

exclude acute hemorrhage, and diffusion-weighted imaging sequences are more sensitive to the earliest changes of ischemia (Fig. 118.5), but the speed and availability of CT make it the initial imaging modality of choice at most centers. MRI scanning may then be used to provide additional information. Specific MRI sequences have greater sensitivity to blood than CT and may identify hemorrhagic infarction missed by CT.

Clinical features at stroke onset may suggest a subtype of cerebral infarction but require confirmatory laboratory data. Cerebral embolism is suggested by sudden onset and a syndrome of circumscribed focal signs attributable to cerebral surface infarction, such as pure aphasia or pure hemianopia. Unless the source of embolization is obvious on hospital admission, blood cultures, electrocardiographic monitoring, and echocardiography are indicated.

A diagnosis of atherosclerotic infarction is suggested if there were previous TIAs, particularly when the symptoms are stereotypical. Doppler ultrasonography, CT angiography or magnetic resonance angiography can usually identify the stenosis. In equivocal cases, conventional angiography may be needed. Small penetrating vessel infarcts, or *lacunar infarcts*, usually spare cortical functions, such as language and cognition, but cause loss of elementary neurologic function, such as strength, sensation, and coordination. Up to 25% of patients with lacunar infarcts have large-vessel disease or a cardioembolic source, so it is important to carry out a complete etiologic evaluation in all stroke patients.

Up to 50% of patients with transient deficits lasting less than 24 hours have evidence of infarction on imaging, and the risk of stroke and other vascular events is as high after TIA as after completed stroke. In the acute setting, when decisions about thrombolysis must be made, it is virtually impossible to know which patients with ischemia will have symptoms resolve without infarction (thus, having a TIA) and which will have a completed infarction. Patients with either stroke or TIA need immediate attention to secondary prevention strategies. In terms of choosing treatments, the important issue is to identify the cause of the cerebral ischemia, rather than its duration. Entities other than cerebral ischemia can masquerade as strokes and TIAs. Among patients diagnosed with stroke in emergency departments, 20% or

Fig. 118.5 Magnetic resonance imaging scan of the brain of the same patient shown in Fig. 118.4. (A) Diffusion-weighted image shows bright signal in the left middle cerebral artery territory. (B) Apparent diffusion coefficient shows dark signal in the same area, confirming acute infarction.

more have a stroke *mimic*, including seizure, migraine, systemic infection, brain tumor, and toxic-metabolic encephalopathy. Other sources of misdiagnosis are listed in Table 118.4.

In patients with a prior history of cerebral infarct or hemorrhage, new *metabolic derangements*, including infections, may precipitate a recrudescence of the original stroke syndrome. Hypoglycemia, hyponatremia, urinary tract infection, pneumonia, and initiation of a psychotropic medication can each precipitate this phenomenon. The patient returns to normal over hours to days when the new insult is treated or reversed. Such metabolic and infectious causes of neurologic deterioration should be excluded in patients with a history of earlier brain injury before diagnosing a new stroke. Focal signs may also occur with metabolic disturbances in patients without prior history of stroke.

External signs of injury are usually present in brain *trauma*, but they need not be present after acceleration-deceleration injury, such as from a motor vehicle accident. The most frequent sites of brain contusions are the frontal and temporal poles, which are not typical locations for strokes.

Seizures may occasionally complicate acute stroke, but they may also mimic stroke. Unlike stroke, seizures are often characterized by obtundation, an amnesic state, clonic activity, incontinence, or tongue biting. The postictal deficit, often called a *Todd paralysis*, resembles stroke because weakness or language and other cortical deficits may occur. The deficits after seizure usually resolve within hours after the seizure but occasionally persist for up to a week, making the distinction from stroke difficult. Seizures may also develop months or years after an infarct or hemorrhage, and the postictal state in these patients may recapitulate the initial stroke syndrome.

Migraine with persistent aura often mimics stroke or TIA. Aura alone, without headache (i.e., acephalgic migraine), is sometimes experienced by those who previously suffered from migraine with aura. Migraine aura typically produces a visual disturbance that marches across the vision of both eyes as an advancing, enlarging blind spot that takes 20 to 30 minutes to resolve. Subsequent unilateral, pounding headache suggests the diagnosis but may not occur. Less often, migrainous auras take the form of sensory symptoms. The speed of the march is generally slower than the rapid spread of symptoms in stroke.

As many as 10% of *brain tumors* present with acute transient symptoms reflecting intratumoral hemorrhage or focal seizures. Seizures

TABLE 118.4 Stroke Mimics and Differential Diagnosis

Common Mimics

Metabolic encephalopathy (e.g., hypoglycemia, hyponatremia)
Systemic infection
Seizure
Migraine
Brain tumors

Other Mimics

Transient focal neurologic symptoms associated with amyloid angiopathy
Positional vertigo
Cardiac events
Syncope
Trauma (especially acceleration-deceleration without evidence of external injury)
Subdural hematoma
Herpes simplex virus encephalitis
Transient global amnesia
Dementia
Demyelinating disease
Cervical spine disease/radiculopathy/fracture
Myasthenia gravis
Parkinsonism
Hypertensive encephalopathy
Conversion disorder
Intoxication/substance abuse

often precede focal signs. Imaging usually demonstrates an enhancing mass even when symptoms are mild.

TREATMENT

Stroke prevention and treatment are directed toward: (1) preventing the first stroke (primary prevention); (2) limiting damage from the stroke; (3) optimizing functional recovery following stroke; and (4)

avoiding recurrence (secondary prevention). Specific measures for treatment and prevention depend on the patient's risk factors and stroke mechanism. The diagnostic evaluation of the stroke patient dictates optimal therapy.

Primary Prevention of Stroke

Randomized trials have demonstrated that specific interventions prevent first stroke among patients with specific risk factors (Table 118.5). Treatment of hypertension, for example, is associated with up to a 45% reduction in the risk of stroke. Among patients with atrial fibrillation, the use of warfarin is associated with a 60% to 70% relative reduction in risk of stroke, though younger patients without any accompanying heart disease, hypertension, or diabetes may be managed with antiplatelet agents alone. Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, or statins, have been shown in some primary prevention studies, and in studies of patients with heart disease, to reduce the risk of a first stroke as well as that of heart disease. The effects on stroke risk are more modest than the effects on heart disease, possibly reflecting the greater heterogeneity among causes of stroke compared to heart disease. For patients with asymptomatic carotid stenosis of at least 60%, carotid endarterectomy reduces the risk of stroke, though the effect is much more modest than in symptomatic patients, and the number of patients needed to treat to prevent one stroke is greater. Because many of the large randomized trials of endarterectomy for asymptomatic patients were conducted in the era before the current recommended use of statins and antiplatelet agents, it is no longer clear that surgery is superior to medical therapy. New trials are therefore addressing medical versus surgical and endovascular treatment in patients with asymptomatic stenosis.

Antiplatelet therapy is not of established benefit for prevention of a first stroke. In a large primary prevention study, for example, aspirin use was associated with an increased risk of both ischemic and hemorrhagic stroke, despite reducing the risk of ischemic heart disease. However, other studies have shown that aspirin reduces the risk of ischemic stroke among women over the age of 45.

The Mediterranean diet also protects against cardiovascular disease, including stroke. It is characterized by high intake of fruits, vegetables, and legumes; olive oil as the principal source of fat; moderate consumption of fish and poultry, with minimal intake of red meat and dairy; and an option of mild to moderate consumption of red wine, mostly with meals. Compared to a low-fat diet, this combination of nutrients decreased 5-year stroke risk by approximately 30% in a randomized trial.

Observational studies provide evidence that certain behaviors prevent stroke. Smoking cessation leads to a reduction by 5 years in stroke risk to levels similar to nonsmokers. Consumption of alcohol in moderation, up to two drinks daily for men and one daily for women, is associated with a lower level of stroke risk than in those who do not drink. Physical activity, weight loss when appropriate, and management of diabetes are also recommended.

Acute Treatment of Ischemic Stroke

For patients with ischemic stroke evaluated within 3 hours of symptom onset with no evidence of hemorrhage on a brain CT or MRI, recombinant tissue plasminogen activator (rt-PA), a thrombolytic agent, improves functional outcomes at 3 months compared to placebo. Among the 624 ischemic stroke patients treated within 3 hours in the original landmark study, the proportion of patients achieving normal or near-normal neurologic and functional status by 3 months was significantly higher among those receiving rt-PA, though there was no definite benefit at 24 hours. The proportion of patients who achieved independence in their performance of activities of daily living was

TABLE 118.5 Evidence-Based Primary Prevention of Ischemic Stroke

Risk Factor	Treatment
Hypertension	Anti-hypertensives
Myocardial infarction	HMG-CoA reductase inhibitors
Hyperlipidemia	HMG-CoA reductase inhibitors
Atrial fibrillation	Anticoagulation (warfarin, other agents)
	Left atrial exclusion (selected patients)
Diabetes mellitus/vascular disease	ACE inhibitor
Diabetes mellitus type II, obesity	Metformin
	Bariatric surgery
Asymptomatic carotid stenosis (60-99%)	Carotid endarterectomy
Diet	Mediterranean diet
High vascular risk populations	Antiplatelet therapy
	HMG-CoA reductase inhibitors

HMG-CoA, Hydroxymethylglutaryl-coenzyme A.

increased from 38% to 50%, an absolute benefit of 12%. The absence of an immediate (24-hour) benefit, coupled with the finding of a benefit at 3 months, is consistent with the hypothesis that thrombolytic treatment works to reduce the size of the infarct penumbra by reperfusing tissue before permanent infarction of the entire territory occurs, despite some irreversible injury to a core component.

Patients treated with rt-PA had a 10-fold increase in incidence of hemorrhagic conversion of the infarction (from 0.6% in placebo-treated patients to 6.0% in rt-PA-treated patients). Overall, however, the rates of neurologic deterioration and mortality within the first day after stroke were similar between the groups. Rt-PA was approved for patient use by the US Food and Drug Administration (FDA) in 1996, and it is now considered standard of care for ischemic stroke patients presenting within 3 hours. Specific guidelines for eligibility and exclusion must be met when using rt-PA to reduce the risk of complications (Table 118.6).

Because of the potential to reduce cerebral perfusion below the limits permitted by autoregulation in the setting of acute brain injury, current guidelines recommend that blood pressure not be reduced acutely after ischemic stroke, and systolic blood pressure levels as high as 220 mm Hg are allowed. Before and following thrombolytic treatment, however, systolic blood pressure should be kept below 180 mm Hg to reduce the risk of hemorrhagic conversion. In addition, antiplatelet and anticoagulant medications must be withheld for 24 hours after rt-PA.

Subsequent meta-analyses and individual trials have demonstrated that the benefit of thrombolytic therapy decreases as the time interval between symptom onset (the presumed beginning of ischemia) and treatment increases, but that the therapeutic time window persists as long as 4.5 hours after stroke in selected patients (i.e., those under age 80 years without a combined history of prior ischemic stroke and diabetes mellitus).

In considering the duration of stroke symptoms, neurologists use the time that the patient was last known to be well as the time of onset of the stroke, rather than the time that the patient was discovered to have stroke symptoms. Because stroke is usually painless, patients may not be aware of the onset of symptoms. In patients with aphasia, anosognosia, or diminished consciousness, the patient may not be able to provide details regarding the time of onset of their symptoms, and a witness is required. In patients who wake with stroke,

TABLE 118.6 Eligibility and Exclusion Criteria for Treatment of Acute Ischemic Stroke With Intravenous Rt-PA**Eligibility**

Age ≥ 18 years
 Diagnosis of ischemic stroke causing measurable neurologic deficit
 Well-documented onset of symptoms <4.5 hours before beginning treatment

Major Exclusion Criteria

Stroke or head trauma within the preceding 3 months
 Major surgery within the preceding 2 weeks
 History of intracerebral hemorrhage
 Systolic blood pressure >185 mm Hg
 Diastolic blood pressure >110 mm Hg
 Rapidly improving or minor neurologic symptoms and signs
 Symptoms suggestive of subarachnoid hemorrhage
 Gastrointestinal or urinary tract bleeding within 3 weeks
 Arterial puncture at a noncompressible site within 1 week
 Platelet count $<100,000/\text{mm}^3$
 INR >1.7

Relative Exclusion Criteria (Must Weigh Risks and Benefits)

Seizure at stroke onset
 Myocardial infarction within 6 weeks
 Infective endocarditis
 Hemorrhagic eye disorder
 Blood glucose <30 mg/dL (2.7 mmol/L)
 Blood glucose >400 mg/dL (21.6 mmol/L)
 Patients requiring very aggressive therapy for blood pressure reduction

moreover, it is difficult if not impossible to determine the time at which the symptoms started, and so the time that the patient went to bed is usually considered the starting point of the time window to decide eligibility for thrombolytic therapy. Recent clinical trials, however, provide evidence that when advanced imaging techniques are used, patients can be selected for treatment with intravenous rt-PA up to 9 hours after last known well. In one study, when the MR DWI showed changes consistent with ischemia but the fluid attenuated inversion recovery (FLAIR) sequences did not, the duration of ischemia was presumed to be less than 4.5 hours, and patients were considered eligible for randomization to rt-PA or placebo; among those treated with IV rt-PA, outcomes were significantly better. Another trial used the mismatch between areas of permanent injury and those of diminished perfusion, representing “at risk” tissue, from CT or MRI, to establish an ischemic penumbra that could be salvaged up to 9 hours after onset.

Interventional techniques to revascularize occluded vessels have also been demonstrated to benefit selected patients with ischemic stroke. For patients with MCA occlusions presenting up to 6 hours after symptom onset, there is evidence that intra-arterial thrombolytic agents delivered via catheter into the face of the occluding thrombus can improve functional outcomes, despite an increase in risk of hemorrhage similar to that seen with intravenous rt-PA. More recently, the FDA has approved the use of mechanical devices called stent-retrievers specifically engineered to facilitate clot extraction in the setting of ischemic stroke in the middle cerebral artery in selected patients. These devices, used during an angiographic procedure, provide a wire mesh that can surround the thrombus in the vessel and then be used to pull the clot out. They may be used up to 24 hours after stroke onset and

can achieve a recanalization rate of up to 80%. Patients are selected for the procedure by using infarction-perfusion mismatch imaging to identify those with areas of uninfarcted, salvageable brain tissue. Meta-analyses of several randomized trials in these patients have shown marked benefits, with about two to three patients needed to treat to achieve clinically significant functional improvement.

Treatment with heparin and various heparinoids for acute stroke are not of benefit and are not recommended in acute stroke. In some patients with massive hemispheric strokes, surgical decompression (hemicraniectomy) can be life-saving with acceptable functional outcomes, particularly for younger patients.

Since stroke is characterized by a cascade of events that can cause further neuronal injury for hours or days after stroke, experimental animal stroke studies have tested strategies that might limit this injury (i.e., neuroprotection), including drugs targeting *N*-methyl-D-aspartate (NMDA) receptors, glycine receptors, calcium channels, adhesion molecules, free radicals, albumin, inflammation, and membrane constituents. However, none of these have been of benefit in human clinical trials.

Treatment of Intracerebral Hemorrhage

Treatment of ICH is primarily supportive. Many patients require management in the intensive care setting to manage elevated blood pressure and secondary complications, such as respiratory failure, aspiration, and hemodynamic instability in severely neurologically compromised patients. In many cases, patients also require management of intracranial pressure using osmotic agents, such as mannitol or hypertonic saline, or therapeutic hyperventilation. In some patients, surgical evacuation of hematomas may be life-saving, although trials have thus far failed to show that most ICH patients benefit from surgical decompression. Among more than 1000 participants randomized in a large international study, there was no evidence of benefit of surgical over medical therapy, apart from a potential benefit in the subgroup of patients with small superficial hemorrhages. Most hemorrhages that occur deep within the hemispheres probably cause the majority of their damage immediately after the ictal hemorrhage, so that evacuation does not save tissue and may introduce further damage.

One of the major recent insights into the pathogenesis of cerebral injury associated with ICH has been the recognition that a large proportion of hemorrhages continue to expand during the early hours after onset. As a result, there has been increased interest in the use of prothrombotic agents to reduce this expansion and to limit secondary cerebral injury. Though preliminary studies on the potential benefits of infusing factor VII as a prothrombogenic agent showed promise, subsequent and more definitive studies did not confirm a benefit in the majority of patients, although it remains possible that subgroups of patients, including those with warfarin-associated hemorrhage, may benefit.

For cerebellar hemorrhages, surgical decompression may be life-saving, and it is essential to recognize the signs and symptoms of incipient brain stem compression and herniation (i.e., headache, vertigo, nausea, vomiting, and truncal ataxia without focal weakness, declining sensorium, and gaze-palsy). Neuroimaging studies that support the need for surgical decompression include hematoma greater than 3 cm, fourth ventricular shift, cisternal obliteration, and ventricular enlargement. Lumbar puncture is contraindicated with ICH, particularly with cerebellar hemorrhages, because life-threatening tonsillar herniation and midbrain compression may occur. Great caution must be taken in these patients subjected to ventriculostomy for the purposes of reducing intracranial pressure because upward cerebellar herniation may occur.

The management of aneurysmal SAH is complicated, and recurrent bleeding risks and mortality are high. Antifibrinolytic agents, such as ϵ -aminocaproic acid, used to preserve the thrombus around

an aneurysm and thereby prevent rebleeding, have been unsuccessful. Therefore, definitive therapy is elimination of the ruptured aneurysm. This may be accomplished surgically or with interventional embolization techniques, such as with coils deposited in the aneurysm. Even after securing the aneurysmal site of bleeding, however, several other complications may ensue, of which vasospasm leading to cerebral infarction is one of the most common. Vasospasm appears to represent a reaction of the blood vessels to the blood in the surrounding subarachnoid space. Transcranial Doppler screening may be used daily to detect early changes of vasospasm; continuous EEG monitoring and multimodality monitoring of vital signs are other emerging ways to detect cerebral dysfunction while still reversible. The calcium-channel antagonist nimodipine, which crosses the blood-brain barrier, has become standard of care in SAH patients for up to 3 weeks after hemorrhage. It improves outcomes, although it is not clear that this is through a reduction in vasospasm, as originally hypothesized. Hydration, hyperosmolar therapy, hypertensive therapy, and angioplasty of vascular spasm may also be used to reduce risk of infarction. Other complications of SAH include cerebral edema, seizures, ventricular dilatation, the syndrome of inappropriate ADH secretion (SIADH), and cardiac failure. Hydrocephalus may require ventricular shunting.

Rehabilitation and Recovery

A team approach to stroke rehabilitation, starting with a stroke recovery unit with experienced physiatrists and physical therapists, has proven beneficial for the optimum recovery of patients. A specialized stroke unit is particularly helpful in avoiding complications such as infections, contractures, and decubiti, and in maximizing independence for patients. Speech and occupational therapists help patients improve their swallowing, communication, and daily living skills.

Constraint-induced therapy is a specific type of physical therapy that involves having a hemiparetic patient wear a large mitt to prevent use of the unaffected limb for several hours daily, forcing the patient to use the affected limb for most tasks. In a randomized trial, constraint-induced therapy with intensive task-directed therapy was associated with functional improvement compared to standard physical therapy. It remains unclear, however, whether the use of constraints or the intensive nature of the therapy itself was responsible for the improvements in function. Intensive task-directed therapy is both difficult for the patient and expensive, however, and may not be practical for large numbers of patients. Recent studies have suggested that home therapy, guided by therapists using videoconferencing with patients (i.e., “telerehabilitation”) may be more feasible for patients.

Depression is a frequent accompaniment of stroke, reflecting both the physical disability and altered brain chemistry. Depression may respond to selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants. Escitalopram administered prophylactically to stroke patients was effective in preventing the development of depression, though other studies have not confirmed this. There is also evidence from other trials that SSRI treatment facilitates functional recovery after stroke.

Secondary Stroke Prevention

The optimal secondary prevention strategy for an individual patient depends on the stroke mechanism. For stroke or TIA caused by carotid stenosis of 70% or more of the vessel diameter, carotid endarterectomy (CEA) by a skilled surgeon with an acceptable complication rate (<5%) is preferable to medical therapy in good surgical candidates. For patients at high risk of surgical complications, including those over age 80, those with cardiac or pulmonary disease, or those with radiation-induced arteriopathy, stenting reduces the risks of cardiac

complications. Trials that tested whether carotid angioplasty and stenting are more effective or safer than carotid endarterectomy in patients at low surgical risk have not demonstrated any benefit over open surgery. Among patients with symptomatic intracranial stenosis (lesions not amenable to surgery), a recent randomized trial demonstrated that best medical therapy, including aggressive risk factor control, was associated with a lower recurrence risk.

Anticoagulation is indicated in patients with definite cardioembolic sources of stroke, such as mechanical valves or atrial fibrillation. In patients with atrial fibrillation, anticoagulation with warfarin was superior to aspirin, with a relative risk reduction of about 68%. Recommended options for secondary prevention among patients with atrial fibrillation now include warfarin with an INR between 2.0 and 3.0, or use of one of the newer antithrombotic agents, such as dabigatran, rivaroxaban, edoxaban, or apixaban, which are associated with a lower risk of bleeding complications. For patients who cannot tolerate anticoagulants because of a risk of ICH or bleeding elsewhere, newer treatment modalities, including interventions to exclude the left atrial appendage from the circulation using a device delivered endovascularly has been approved after a clinical trial demonstrated that it was as effective at preventing stroke as anticoagulation with warfarin, with a low risk of bleeding or other complications.

Recent evidence suggests that some patients with unexplained stroke may have cardiac emboli from conditions related to atrial dysfunction but without frank atrial fibrillation; this entity has been labelled *atrial cardiopathy* and may be detected using cardiac biomarkers such as an enlarged heart on echocardiography, frequent ectopy on monitoring, P wave abnormalities on the electrocardiogram, or serum biomarkers. An ongoing clinical trial is testing whether patients with unexplained stroke and atrial cardiopathy would benefit from anticoagulation just as patients with atrial fibrillation do.

Other causes of cardiogenic emboli require different treatments. Closure of patent foramen ovale using umbrella-like devices has now been shown in several randomized trials to reduce the risk of recurrent stroke in selected patients (younger patients without other stroke risk factors). Among patients with patent foramen ovale, there is limited evidence that anticoagulation is any more effective than antiplatelet agents such as aspirin, and anticoagulation is not routinely recommended in the absence of a known hypercoagulable disorder or evidence of thrombi elsewhere. Infected prosthetic valves need replacement if emboli persist on antibiotics, there are large valvular vegetations, or if patients develop heart failure. Emboli from myxomatous tumors of the atria frequently require surgical removal of tumor. The need for anticoagulation among patients with other less well-established sources of emboli, such as calcific valvular disease or aortic arch plaque, is unproven, and current guidelines do not support its use in this setting.

All patients with ischemic stroke without a definite indication for anticoagulation, and in whom no contraindication is present, should receive long-term antiplatelet therapy, which reduces the risk of recurrence by 20% to 25%. Agents currently approved for this purpose include aspirin, dipyridamole, and clopidogrel, a thienopyridine derivative ADP receptor inhibitor. Head-to-head trials have failed to demonstrate a benefit of one of these agents over another; the combination of aspirin and dipyridamole was more effective than either agent alone, but long-term treatment with the combination of aspirin and clopidogrel was no more effective than aspirin alone and increased the risk of significant bleeding. More recent trials suggest that there may be benefit to the combination of aspirin and clopidogrel when used for up to approximately 30 days after stroke or TIA. The benefits to dual antiplatelet agents after about 30 days, however, are outweighed by the increased risk of significant bleeding. Aspirin doses as low as 30 mg

daily appear effective and have fewer side effects, such as gastrointestinal bleeding, than higher doses, although there is some evidence that the efficacious dose of aspirin may depend on body weight. The FDA recommends doses between 50 and 325 mg daily for stroke prevention.

Clinical trials provide evidence for increased use of anti-hypertensive agents in patients with stroke and TIA. There are theoretical concerns about lowering blood pressure in patients with existing cerebrovascular disease due to the possibility that in patients with arterial disease of cerebral vessels and reduced autoregulation, a reduction in blood pressure could worsen perfusion and precipitate clinical events or affect cognition. Randomized trials provide evidence, however, that blood pressure reduction among patients with cerebrovascular disease reduces risks of recurrent stroke by 28% independently of a history of hypertension. Guidelines currently focus on the use of blood pressure agents to achieve recommended target blood pressure levels, rather than on specific agents, which should be individualized depending on a patient's comorbidities.

Trials using hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, or statins, among cardiac and other vascular disease high-risk patients have demonstrated benefits in stroke risk reduction. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial provided more direct evidence of the benefit of statin therapy in secondary prevention of stroke among patients presenting with stroke or TIA. SPARCL randomized patients with recent stroke or TIA to atorvastatin 80 mg daily or placebo. Over 5 years, atorvastatin reduced the risk of the primary outcome, recurrent stroke, from 13.1% to 11.2%, an absolute risk reduction of about 2%. More recently, the Treat Stroke to Target trial demonstrated that among patients with ischemic stroke and atherosclerotic disease, those treated to an LDL level of less than 70 mg/dL had a lower risk of recurrent cardiovascular events.

Among those with diabetes, diet and exercise, oral hypoglycemic drugs, and insulin are recommended to obtain glycemic control. Although glycemic control reduces risks of microvascular complications, the benefit in reducing macrovascular complications is less certain. In one trial, tight glycemic control of a prospective cohort of newly diagnosed diabetics was not found to significantly reduce stroke risk. The peroxisome proliferator-activated receptor- γ (PPAR- γ) agonist pioglitazone, a potent insulin-sensitizing agent, was shown in another trial to reduce risk of recurrent stroke among patients with stroke or TIA and insulin resistance, although an increase in weight gain and fractures has limited its use. Recent evidence also suggests that bariatric surgery, a way to reduce obesity and treat the metabolic syndrome, reduces risks of cardiovascular events, including stroke.

Behavioral risk factors are difficult to control but are also important. Smoking is addictive, and cessation may necessitate psychologic counseling and medical aids, such as nicotine patches or varenicline. Physical activity should be encouraged, because a sedentary lifestyle is associated with elevations in blood pressure and stroke risk. Alcohol consumption in excess of two drinks daily should be discouraged, though there is evidence that moderate alcohol consumption may have protective effects against stroke risk. It should be noted, however, that there is only limited evidence that control of these risk factors reduces recurrent stroke risk.

PROGNOSIS

The immediate period after an ischemic stroke carries the greatest risk of death, with fatality rates ranging from 8% to 20% in the first 30 days. Age and stroke severity are the most important predictors of prognosis. Case fatality rates are worse for hemorrhagic strokes, ranging from 30% to 80% for intracerebral hemorrhage and 20% to 50% for subarachnoid hemorrhage.

Stroke survivors continue to have a 3- to 5-fold increased risk of death, compared with the age-matched general population. Annual aggregate estimates of death have been 5% for minor stroke and 8% for major stroke. Survival is influenced by age, hypertension, cardiac disease, and diabetes. Patients with lacunar infarcts appear to have a better long-term survival than do those with the other infarct subtypes.

Recurrent stroke is frequent. The immediate period after a stroke carries the greatest risk for early recurrence; rates range from 3% to 10% during the first 30 days. Thirty-day recurrence risks vary by infarct subtypes; the greatest rates are in patients with atherosclerotic infarction and the lowest rates in patients with lacunes. After the early phase, the risk of stroke recurrence continues to threaten the quality of life of a stroke survivor. Long-term stroke recurrence rates range in different studies from 4% to 14% per year, with aggregate annual estimates of 6% for minor stroke and 9% for major stroke. These rates have been decreasing with the advent of the improved protection strategies outlined previously. Recurrent stroke contributes to the burden of dementia and functional decline after stroke. Importantly, cardiac events are also increased in stroke survivors, and pose a major threat of death.

Traumatic Brain Injury and Spinal Cord Injury

Geoffrey S.F. Ling, Jeffrey J. Bazarian

INTRODUCTION

Traumatic brain injury (TBI) and traumatic spinal cord injury (TSCI) are leading causes of traumatic death and disability. It is estimated that almost 60 million people worldwide sustain a TBI each year. According to the World Health Organization, TBI is projected to become the third largest cause of disease burden worldwide by the year 2020. In the United States, TBI results in over 2.5 million emergency department (ED) visits; the vast majority (over 80%) are mild TBI or concussion. However, approximately 52,000 patients in the United States die from severe TBI as a direct consequence, making it the leading cause of traumatic death and disability. Furthermore, yearly, about 11,000 patients are severely disabled by TSCI. The vast majority are due to falls, motor vehicle accidents, sports-related occurrences, and assaults. Among the almost 5.5 million TBI and TSCI survivors, most require prolonged rehabilitation.

TYPES OF INJURY

Certain lesions require neurosurgical intervention while others do not. TBI conditions for which emergency neurosurgery is needed are penetrating wounds, intracerebral hemorrhage with mass effect including subdural and epidural blood, and bony injury such as displaced fracture and vertebral subluxation. However, focal, hypoxic-anoxic, diffuse axonal and diffuse microvascular injuries typically do not require surgery.

MANAGEMENT

Traumatic Brain Injury

Patients with mild TBI typically recover quickly and fully. To optimize outcome, it is critical to first remove the TBI victim from play or work to prevent further injury. Diagnosis of mild TBI or concussion begins simply with identifying affected patients. This is often difficult because these patients suffer transient alteration of consciousness with only a minority completely losing consciousness. Most have memory impairment. As a result, patients are typically unaware that they are injured. Thus, it is important that colleagues, coaches, athletic trainers, parents, and other observers have a heightened suspicion when a potential head injury event occurs. If so, then a sideline point-of-injury screening tool should be administered, such as the standardized assessment of concussion (SAC) or sports concussion assessment tool version 5 (SCAT 5). SAC is a neuropsychological battery that tests orientation, immediate memory, concentration, and memory recall. An abnormal score is less than 25. If the SAC score is abnormal, the patient is at high risk for having suffered a concussion and thus should be brought

to medical attention for further evaluation, diagnosis, and treatment. The SCAT-5 includes the SAC and also other neurologic tests such as balance.

In the early stage of management, it is important that patients at risk of having incurred a mild TBI or concussion have a provider skilled in managing TBI perform a detailed history, physical examination, and neurologic examination, especially assessment of cognitive function. The history should determine the duration of altered sensorium, amnesia or loss of consciousness a patient may have suffered.

The decision to obtain neuroimaging is based on the index of suspicion of intracranial hemorrhage or skull fracture. Both CT and MRI are inadequate in ruling out mild TBI, which is a clinical diagnosis. If a patient lost consciousness or has persistent altered mentation, abnormal Glasgow Coma Score (GCS), focal neurologic deficit or is clinically deteriorating, then neuroimaging should be obtained.

In general, patients with mild TBI do not require hospitalization; almost all do well after adequate convalescence. It is essential that patients have adequate time for recovery; they should not return to play or work until fully recovered. A second head injury before full recovery may be catastrophic due to the “second impact syndrome” (SIS), which leads to worse clinical outcome, including death.

The patient must be allowed to rest with minimal cognitive burden. There are no specific medications to foster recovery. Treatment is focused on ameliorating symptoms according to published evidence-based guidelines, such as VA/DoD Clinical Practice Guidelines for the Management of Concussion/mild TBI. In general, headache, the most common complaint, can be treated with acetaminophen or a nonsteroidal anti-inflammatory agent. Triptans can be considered if there are features of migraine. Dizziness can be treated with physical therapy. Meclizine should be reserved only for symptoms that are severe enough to impair activities of daily function. Insomnia can be treated with proper sleep hygiene. A sedative can be used acutely and should be limited to non-benzodiazepine agents such as zolpidem. Visual and auditory symptoms should be evaluated by appropriate medical specialists.

The patient is able to return to play or work after at least 24 hours of recovery and when cleared to do so by an advanced practice health care provider experienced in the management of concussion. In many states, statutes specify these requirements. In general, patients are able to return to play when their symptoms no longer require treatment. At this point, many practitioners will subject the patient to provocative testing such as having the patient perform exertion (e.g., run) followed by cognitive testing. If this does not cause symptoms to recur and the patient performs well cognitively, then he/she is allowed to return to full activity.

For moderate to severe TBI the initial care goals are the “ABCs” of airway, breathing, and circulation. Next is “D” for disability

TABLE 119.1 Glasgow Coma Score

Best Eye Response	Best Verbal Response	Best Motor Response
1 = No eye opening	1 = No verbal response	1 = No motor response
2 = Eye opening to pain	2 = Incomprehensible sounds	2 = Extension to pain
3 = Eye opening to verbal command	3 = Inappropriate words	3 = Flexion to pain
4 = Eyes open spontaneously	4 = Confused	4 = Withdrawal from pain
	5 = Orientated	5 = Localizing pain
		6 = Obeys commands

GCS = Eye Response + Verbal Response + Motor Response.

(neurologic). Every patient should undergo a detailed neurologic examination to ascertain the level of neurologic disability. An initial GCS should be assigned to each patient. The GCS (Table 119.1) categorizes patients with TBI and provides a quantifiable measure of impairment.

Patients with severe TBI are those who present with GCS scores of eight or less. To optimize outcome, medical management should adhere to currently accepted clinical guidelines such as the Brain Trauma Foundation “Clinical Guidelines for Severe TBI.” An important early intervention is airway protection, usually by endotracheal intubation. If elevated intracranial pressure (ICP) is suspected, elevate the patient’s head to 30° and keep it midline, ideally with a rigid neck collar (at least until the cervical spine can be evaluated for stability). Mannitol should be given intravenously at a dose of 0.5 to 1.0 g/kg. Hyperventilation may also be used with a goal of P_{CO_2} 34 to 36 mm Hg. ICP should be kept less than 20 mm Hg with the cerebral perfusion pressure (CPP) greater than 60 mm Hg. A head CT without contrast should be done as soon as possible to identify lesions that will require surgery and to determine the extent of injury.

If ICP remains poorly controlled, one can consider administering an intravenous bolus of 23% hypertonic saline (50 cc) followed by continuous infusion of 2% or 3% hypertonic saline (75 to 125 cc/hr) through a central venous catheter. If these interventions are unsuccessful, pharmacologic coma or surgical decompression should be considered. Pharmacologic coma can be induced with pentobarbital. This is given as a loading dose of 5 mg/kg intravenously, followed by an infusion of 1 to 3 mg/kg/hr. Alternatively, propofol can be used, which is administered as a loading dose of 2 mg/kg intravenously, followed by an infusion up to 200 µg/min. Continuous EEG monitoring is helpful as the limit of drug induced coma is achieving ICP control or cerebral electrical burst-suppression. Persistently elevated ICP after all these efforts is ominous. Consideration should be given to frontal or temporal lobe decompression and hemicraniectomy.

To meet CPP goals, patients must first be adequately hydrated. The goal of TBI fluid management is to increase the osmolar gradient between systemic vasculature and brain, not dehydration. For this purpose, hyperosmolar intravenous solutions are used, such as normal saline. Other options are hypertonic saline (e.g., 3% sodium solutions). If meeting CPP goals is difficult with intravenous fluids alone, vasoactive pharmacologic agents such as norepinephrine and phenylephrine can be administered. These two agents are preferred because they are considered to have the least effect on cerebral vasomotor tone. Since barbiturates and propofol are myocardial depressants, aggressive cardiovascular management will probably be necessary when pharmacologic coma is induced.

Agitation can be treated with dexmedetomidine, lorazepam or haloperidol. If inadequate, then infusions of midazolam or propofol may be used. Pain should be controlled. Acetaminophen and nonsteroidal anti-inflammatory agents are adequate for mild discomfort. However, for moderate to severe pain, narcotic analgesics such as fentanyl or morphine should be used. A benefit of opioids is that they can be reversed by naloxone to allow reassessment of neurologic status.

Hypoxia, seizures, and fever must be avoided. Maintaining P_{O_2} at approximately 100 mm Hg is sufficient. An antiepileptic drug (AED), such as phenytoin or levetiracetam, is administered for the first 7 days after injury as it will reduce early onset seizures. After 7 days it should be stopped. It can be restarted if seizures recur. Fever should be reduced with antipyretics such as acetaminophen, using a cooling blanket if needed. Other important management considerations include prevention of gastric stress ulcer, deep vein thrombosis (DVT), and decubitus ulcers. Feeding should be instituted as soon as practical to maintain nutrition.

After the initial few hours, efforts should be made to reduce hyperventilation, which is indicated only for initial emergency management. After 12 hours, metabolic compensation negates the ameliorative effects of respiratory alkalosis caused by the hypocapnic state induced by hyperventilation.

Repeated neurologic examination and continuous ICP and CPP measurement are indicated. Generally, the peak period of cerebral edema is from 48 to 96 hours after TBI. Thereafter, the edema resolves spontaneously and clinical improvement should follow.

A complication of TBI is post-concussive syndrome (PCS). Diagnosis can be made using the Post-Concussion Symptom Scale (PCSS) and Graded Symptom Checklist (GSC). The most common symptoms of PCS are headache, difficulty concentrating, appetite changes, sleep abnormalities, and irritability. PCS has a variable presentation and duration depending on the patient and the severity of TBI. In general, PCS lasts for a few weeks post-injury. However, uncommonly, it can persist beyond a year or more. Treatment is symptomatic. For headache, nonsteroidal anti-inflammatory agents, migraine drugs, and biofeedback can be effective. For cognitive dysfunction, neuropsychological testing may be helpful in determining appropriate intervention, which may include cognitive-behavioral therapy.

Traumatic Spinal Cord Injury

The emergency management of traumatic injury to the spinal cord has greatly improved with adherence to the American Association of Neurological Surgeons “Guidelines for the Management of Cervical Spine and Spinal Cord Injuries.” Therapy begins with the “ABCs” of airway, breathing, and circulation. A secure airway is absolutely vital. In patients suffering from high cervical lesions, spontaneous ventilation will be lost. Lesions below C5 may also impair ventilatory capability. If the airway or ventilatory efforts are compromised, emergency intubation is required. In a patient in whom cervical spine trauma has not been assessed, the preferred method is nasotracheal intubation using fiberoptic guidance. Other approaches are nasotracheal (blind) or orotracheal intubation, so long as cervical spine alignment is maintained by traction.

Maintaining intravascular volume is essential in TSCI. Hypotension may be due to either neurogenic shock or hypovolemia. For neurogenic shock, vasopressive pharmacologic agents such as phenylephrine may be needed. If tachycardia is present, then hypovolemia is the more likely etiology and fluid resuscitation with normal saline is the appropriate initial management.

After addressing the “ABCs,” a neurologic history and examination should be obtained. An accompanying TBI must be considered. Up to 50% of TSCI patients have an associated TBI. Neuroimaging is

often indicated, but not all patients need radiographic study. A normal neurologic assessment obviates the need for imaging studies. However, a complaint of burning hands or of pain over the spine, numbness, tingling or weakness indicates spinal cord injury. A detailed neurologic examination is needed to identify the level of the injury and the completeness of any deficits and to document the degree of neurologic dysfunction at the earliest time possible. The level of the injury is the lowest spinal cord segment with intact motor and sensory function. The prognosis for neurologic improvement is better if the lesion is incomplete rather than complete. Following the acute injury, serial examinations must be made frequently.

If spinal cord injury is suspected, the patient should be immediately and appropriately immobilized with a rigid collar or backboard or both. Radiologic evaluation should begin with plain radiographs of the bony spine. Abnormalities on radiographs should lead to further neuroimaging. Bony vertebrae should be examined with CT and the spinal cord with MRI. Intervertebral and paravertebral soft tissue are best studied with MRI. A chest radiograph should also be obtained in order to visualize the lower cervical and thoracic vertebrae. Presence of a pleural effusion in the setting of a possible thoracic spine injury suggests a hemothorax.

If the C-spine radiographs are normal but the patient complains of neck pain, then ligamentous injury may be present. Ligamentous injury is evaluated by flexion-extension C-spine radiographs. However, in the acute period, pain may prevent an adequate study. These patients should be kept in a rigid cervical collar for a few days until the pain and neck muscle spasm resolves. At that time, imaging may be performed. If abnormal, the patient will need surgical evaluation.

Spinal Cord Syndromes

There are three main spinal cord syndromes: anterior cord, Brown-Sequard, and central cord. Anterior cord syndrome is associated with deficits referable to bilateral anterior and lateral spinal cord columns. There is loss of touch sensation, pain, temperature, and motor function below the level of the lesion. The posterior column functions of proprioception and vibratory sensation remain intact. In Brown-Sequard syndrome, the deficits are due to injury to a lateral half of the cord. There is functional loss of ipsilateral motor, touch, proprioception and vibration, and contralateral pain and temperature. Central cord results in a “man in a barrel” syndrome: motor paralysis of both upper extremities with sparing of the lower extremities. Weakness is greater proximally than distally. Pain and temperature sensations are generally reduced but proprioception and vibration are spared.

Spinal Shock

Spinal shock may occur after acute injury causing a temporary loss of spinal reflexes below the level of injury. Neurologic examination will reveal loss of muscle stretch reflexes, bulbocavernosus reflex (testing anal sphincter tone in response to stimulating the glans penis or clitoris), and the anal wink. In high cervical injuries, the lower reflexes (bulbocavernosus and anal wink) may be preserved. There may also be the “Schiff-Sherrington” phenomenon, in which reflexes are affected above the level of injury. Additionally, there may be loss of autonomic reflexes leading to neurogenic shock, ileus, and urinary retention.

Acute and Subacute Management

In the intensive care unit, the patient will need continued treatment. TSCI patients require close cardiovascular and respiratory monitoring. Other issues are genitourinary, bowel, infectious disease, nutrition, skin, and prophylaxis against ulcers and deep vein thrombosis formation.

Patients suffering from spinal cord injury are at risk for neurogenic shock and dysautonomia with resulting peripheral vasodilation and hypotension. Lesions at T3 or above compromise sympathetic tone

with hypotension accompanied by bradycardia: the classic neurogenic shock triad of bradycardia, hypotension, and peripheral vasodilation.

Dysautonomia is treated by ensuring adequate circulating volume. The goal is to fluid resuscitate to a euvoletic state. Blood can be used if the patient is anemic (i.e., hematocrit less than 30). If blood is not required, then either colloid (e.g., albumin solutions) or crystalloid (e.g., normal saline) may be used. Central venous pressure (CVP) should be maintained at 4 to 6 mm Hg. Hypervolemia should be avoided, as this will exacerbate peripheral edema. Once an adequate circulating volume has been achieved, vasopressive agents can be used (e.g., phenylephrine, norepinephrine or dopamine). The mean arterial pressure (MAP) should be 85 mm Hg or greater. Symptomatic bradycardia can be treated with atropine.

Patients with TSCI are at risk for ventilatory compromise. Patients whose injuries are at C5 or higher typically require mechanical ventilation with an appropriate tidal volume (6 to 10 mL/kg), F_{IO_2} and mandatory machine driven rate. The F_{IO_2} inspired oxygen concentration should give a P_{O_2} between 80 and 100 mm Hg. The rate should be set to give a P_{CO_2} of 40 mm Hg. Positive end-expiratory pressure (PEEP) should also be used to minimize atelectasis. If the patient does not show signs of ventilatory recovery within 2 weeks of intubation, a tracheostomy should be considered. Lesions below C5 may also be associated with inadequate spontaneous ventilation. Mid-cervical lesions may be associated with intact but compromised diaphragm function. If suspected, a “sniff” test under fluoroscopy can be performed to determine if both hemidiaphragms are functioning properly. If not, intubation/tracheostomy with volume-controlled ventilation may be needed. If intact, then pressure support (PS) ventilation sufficient to maintain an appropriate tidal volume with oxygenation and PEEP should be set as described previously.

Patients with cervical lesions at C6 and below, including the thoracic cord, do not require mechanical ventilation. However, their ventilatory effort may be inadequate because the thoracic cord innervates intercostal muscles, which are accessory muscles of respiration. Such patients have decreased cough and inability to increase ventilation when needed, leading to atelectasis and inability to clear secretions, which can cause pneumonia. Such patients need assistance with clearing their airway: chest percussion, suctioning, and encouragement in coughing.

Thromboembolic disease is a leading cause of morbidity and mortality in patients with TSCI: up to 80% will develop DVT without prophylaxis. All patients with TSCI should receive anticoagulation and have mechanical compression devices applied to their legs. As soon as possible, sequential compression devices (SCD) or compression stockings should be placed on patients. As soon as hemostasis is assured, low-molecular-weight heparin (LMWH) should be initiated. Unfractionated heparin may also be used in conjunction with SCD but LMWH is preferred. An inferior vena cava filter may be placed in those patients in whom anticoagulation therapy is contraindicated but should not be the primary means of preventing DVT.

Mid-low thoracic spinal cord injury can lead to ileus. A nasogastric tube should be placed to decompress the stomach. Parental nutrition should be started as soon as possible. Enteral feeding should be delayed until gastrointestinal motility returns, usually 2 to 3 weeks. Pharmacologic agents that promote motility are metoclopramide, erythromycin, and cisapride. Gastric ulcer should be prevented with medication: H2 receptor antagonists, proton pump inhibitors, antacids or sucralfate. Pancreatitis and trauma-related bowel perforation occur: loss of abdominal muscle tone and visceral sensation may mask usual clinical findings of pain, guarding, or rigidity.

Bladder tone may be lost due to spinal shock. A Foley catheter should be placed and maintained for a minimum of 5 to 7 days to

TABLE 119.2 American Spinal Injury Association Impairment Scale

Grade	Injury Type	Definition
A	Complete	No motor or sensory function below the lesion
B	Incomplete	Sensory but no motor function
C	Incomplete	Some motor strength (<3)
D	Incomplete	Motor strength >3
E	None	Sensory & motor normal

drain the bladder and to evaluate circulatory volume and renal status. Once spinal shock resolves, autonomic dysreflexia may occur from bladder distention: skin flushing and hypertension. Clinical examination by palpation and percussion will reveal a distended bladder, which can be treated with intermittent catheterization or bladder training. Phenoxybenzamine may be helpful in this condition. Urinary tract infection is a significant risk of Foley catheters and should be monitored for, particularly if spinal cord injury affects normal sensation.

Nutrition should be given. Until enteral feeding can begin, parenteral nutrition should be used. A caloric level of 80% of the Harris-Benedict prediction should be used for quadriplegic patients. The full Harris-Benedict predicted amount should be used for patients with thoracic spine injuries and below. Skin care is essential to prevent decubitus ulcers. Mechanical kinetic beds, regular log rolling (every 2 hours), and padded orthotics are all useful in minimize this complication.

Orthotics, physical therapy, and occupational therapy (for cervical cord injury) are useful. Therapy should begin as soon as the spine is stabilized, with the goal of minimizing contractures and beginning the rehabilitation. Once therapy begins, energy expenditure will increase requiring additional nutrition. If intermittent compression devices need to be removed during therapy, heparin dose may need to be increased.

PROGNOSIS

Traumatic Brain Injury

The most useful prognostic indicator following TBI is the neurologic exam at presentation. Clearly, the better the neurologic exam, the higher the likelihood of improved recovery. The initial GCS score is a very reliable prognostic indicator. The lower the initial GCS score, the less likely it is that a patient will have meaningful neurologic or functional recovery. However, some patients with very low presenting GCS scores can have a meaningful recovery.

Traumatic Spinal Cord Injury

For TSCI, the completeness of the injury is the most useful prognosticator. The American Spine Injury Association Impairment Scale grades spinal cord injury on the basis of completeness (Table 119.2). A grade “A” or complete motor and sensory deficit below the lesion is the most ominous prognosis. If such a lesion persists greater than 24 hours, there is little reasonable likelihood of meaningful recovery. On the other hand, partial injuries, even severe, have substantial probability of recovery.

FUTURE

TBI and TSCI are serious neurologic conditions with significant implications on society. Prevention remains the most effective way of reducing the incidences of these diseases. Introduction of practice guidelines have contributed to improved outcome from TBI and TSCI. Sadly, morbidity remains a serious problem. Medical management is largely confined to supportive efforts primarily directed towards minimizing secondary injury, optimizing perfusion and oxygenation, and preventing nonneurologic morbidity. Surgical intervention helps restore structural stability, minimize further injury, and reduce the lesion. However, neither reverses neuronal death nor fully prevents secondary injury processes. There are significant medical research efforts to improve our understanding of the pathogenesis of these diseases and find ways to mitigate them. As new pharmacologic, medical, and surgical approaches are introduced, there will be increasing opportunities to restore these patients.

Epilepsy

Andrew S. Blum

DEFINITIONS AND EPIDEMIOLOGY

Epileptic seizures are defined as transient signs and/or symptoms, often including changes in behavior, due to abnormal neuronal activity (often excessively synchronous) in the brain. A wide range of symptoms accompanies seizures depending upon the CNS networks involved, including involuntary movements, abnormal sensations and behaviors, and impaired consciousness.

Seizures often occur amidst many acute medical or neurologic illnesses that compromise brain function (Table 120.1). Common secondary causes of seizures include metabolic derangements (e.g., hypoglycemia or hyponatremia), intoxications (e.g., alcohol, cocaine), withdrawal states (e.g., alcohol, benzodiazepine), acute traumatic brain injury, and hypoxic-ischemic conditions (e.g., cardiac arrest, embolic stroke). Such *provoked* seizures are usually self-limited and generally do not recur after the underlying disorder abates. Thus, provoked seizures do not constitute epilepsy.

Epilepsy, by contrast, is a chronic CNS disease characterized by a predisposition to *spontaneous* epileptic seizures. The diagnosis of epilepsy is applied when there are at least two unprovoked seizures occurring longer than 24 hours apart or one unprovoked seizure and a presumed high probability of further seizures based upon additional data, such as an epileptiform electroencephalography (EEG) or brain imaging revealing a likely structural substrate for recurrent seizures. Individuals with epilepsy have increased seizure susceptibility (lowered seizure threshold). Epilepsy represents a highly heterogeneous set of distinct epilepsy syndromes, with differing etiologies. Genetic factors and prior CNS injury (of diverse mechanisms) account for many of the causes of epilepsy. There have been successive efforts to classify both seizures and epilepsies over the past 5 decades. Classification of epilepsy syndromes depends upon many factors, including seizure type, etiology, genetics, EEG findings, neuroimaging, and response to therapy. The diagnosis of epilepsy encompasses its neurobiological, cognitive, psychological, and social consequences.

Epilepsy presents a host of challenges for patients and their families. Most seizures in people with epilepsy occur unpredictably. This aspect worsens quality of life for patients with epilepsy. When functionally impairing seizures occur during waking hours (diurnal seizures), then activity restrictions may ensue, including restriction from driving, operating heavy machinery, climbing heights, and unobserved swimming or bathing. These activity restrictions erode independence. The psychological impact of intermittent involuntary loss of bodily control and its aftermath, and the dependence imposed by activity restrictions contribute to the increased incidence of comorbid depression and anxiety in people with epilepsy (up to 50%).

In many people with epilepsy, seizures predominate in sleep due to increased synchronization of neuronal activity. Seizures that occur exclusively in sleep constitute nocturnal epilepsy. In women with

epilepsy (WWE), seizures sometimes occur more often during the week around menses or at ovulation (catamenial epilepsy). Sleep deprivation, alcohol consumption, intercurrent infections, certain medications, and marked emotional stress can further lower the seizure threshold and increase the risk of seizures in people with epilepsy (see Table 120.1).

As indicated earlier, provoked seizures are highly prevalent, accompanying many acute medical or neurologic conditions. Ten percent of the population in developed countries will have a seizure at some time during their lifetime. In contrast, approximately 1% of the population has current epilepsy (prevalence) and 3% to 4% have epilepsy at some time during their life (lifetime prevalence). In the United States, there are approximately 125,000 new cases of epilepsy diagnosed each year (incidence). Epilepsy occurs across the age spectrum. However, its incidence and prevalence are biphasic, more common in childhood (primarily because of perinatal injury, infections, and genetic factors) and with advancing age (because of stroke, tumors, and dementia) (Fig. 120.1). In developing countries, the frequency of epilepsy is higher, largely due to the increased burden of CNS infections such as neurocysticercosis.

PATHOLOGY

Prior to the 1990s, the underlying cause of a patient's epilepsy was frequently unsolved. The advent of MRI and, more recently, genetic and immunologic investigations has substantially improved our ability to identify the causes of many epilepsies. About 70% of adults and 40% of children with new-onset epilepsy have focal onset seizures, usually implying a focal cerebral injury or lesion. In parallel with the diversity of seizure types and epilepsies, there is a similarly wide variety of epilepsy-associated pathologies. The most common lesions are hippocampal sclerosis, neuronal and glial tumors, vascular malformations, neuronal migration disorders (e.g., cortical dysplasia), hamartomas, encephalitis, paraneoplastic and related autoimmune mechanisms, cerebral trauma, embolic stroke, and hemorrhage.

Hippocampal sclerosis (sometimes referred to as mesial temporal sclerosis) remains one of the more common and distinctive pathologies and can occur in isolation or secondary to another coincident epileptogenic lesion (dual pathology). It consists of loss of pyramidal cells and gliosis in several hippocampal subfields. Hippocampal sclerosis is associated with temporal lobe epilepsy and often with short-term memory dysfunction. The group of neuronal migration disorders has also been brought to light with wider use of brain imaging, especially MRI. Focal cortical dysplasia (FCD) represents one of the more common examples of such pathologies. These involve zones of dystrophic gray matter located out of place such as in the subcortical white matter, often with distorted neuronal architecture. Microscopy sometimes reveals atypical cells that exhibit both glial and neuronal markers (e.g.,

TABLE 120.1 Causes of Symptomatic Seizures***Acute Electrolyte Disorders**

Acute hyponatremia (<120 mEq/L)
 Acute hypernatremia (>155 mEq/L)
 Hyperosmolality (>310 mOsm/L)
 Hypocalcemia (<7 mg/dL)
 Hypomagnesemia (<0.8 mEq/L)
 Hypoglycemia (<30 mg/dL)
 Hyperglycemia (>450 mg/dL)

Drugs

Quinolone antibiotics, isoniazid, carbapenems, penicillins (in renal insufficiency)
 Theophylline, aminophylline, ephedrine, phenylpropanolamine, terbutaline
 Tramadol, lidocaine, meperidine (in renal insufficiency), fentanyl
 Tricyclic antidepressants (especially clomipramine), bupropion, clozapine, neuroleptics
 Cyclosporine, chlorambucil
 Cocaine (crack), phencyclidine, amphetamines; alcohol withdrawal, benzodiazepine and barbiturate withdrawal

Central Nervous System Disease

Hypertensive encephalopathy, eclampsia
 Hepatic and uremic encephalopathy
 Sickle cell disease, thrombotic thrombocytopenic purpura
 Systemic lupus erythematosus
 Meningitis, encephalitis, brain abscess
 Acute head trauma, stroke, brain tumor

*The metabolic derangements and drugs listed in here also lower the seizure threshold in people with epilepsy.

balloon cells of type IIb FCDs). Not all patients with cerebral lesions develop epilepsy nor do all lesions in a single patient equally contribute to the epileptic phenotype; how or why a particular lesion becomes epileptogenic remains poorly understood.

Hereditary influences have long been associated with epilepsy. During the past several decades, many gene mutations have been linked with specific epilepsy syndromes, including those with either focal or generalized seizure types. Many such gene mutations affect ion channel proteins, which, not surprisingly, lead to neuronal dysfunction and epilepsy. These have been collectively termed channelopathies. Two important examples of channelopathies are genetic (generalized) epilepsy with febrile seizures plus (GEFS+) and Dravet syndrome. These genetically related syndromes have markedly different phenotypes. GEFS+ is typically associated with a partial loss of function mutation in the voltage-gated sodium channel gene, *SCN1A*, whereas a complete loss of function mutation in the same gene results in Dravet syndrome. Less commonly, mutations in the other ion channel genes can also lead to the same phenotypes. GEFS+ can begin at any age, although it is usually evident in childhood, with various seizure types in different affected family members; some have febrile seizures after age 6 years (febrile seizures plus), whereas others may have myoclonic, absence, or partial seizures. In contrast, Dravet syndrome typically presents at 6 to 8 months of age with prolonged hemi-clonic seizures associated with an intercurrent fever. Children with Dravet syndrome often develop cognitive deficits, spasticity or ataxia, and occasionally nocturnal clonic seizures plus other seizure types.

The newly recognized group of paraneoplastic and autoimmune epilepsies constitute a very different etiologic process and pathology. These conditions arise either in the context of a systemic malignancy

Fig. 120.1 Etiology of epilepsy, according to age, in all newly diagnosed cases in Rochester, Minnesota, 1935-1984. (Modified from Hauser WA, Annegers JF, Kurland LT: Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984, *Epilepsia* 34:453-468, 1993.)

that triggers an aberrant immune attack on specific CNS targets or arise spontaneously (autoimmune). In many cases, MRIs may show multifocal signal changes in various cortical and limbic CNS regions. These syndromes can increasingly be diagnosed by serum or CSF assays for specific antibodies reactive to specific CNS antigens. Some antigens are intracellular (e.g., Hu), while others are membrane bound (e.g., the NMDA receptor).

CLASSIFICATION AND CLINICAL MANIFESTATIONS

Seizures

Various classification strategies have been used over decades to help sort out the diversity of seizure types and epilepsies. In 2017, the International League Against Epilepsy (ILAE) published their most recently revised seizure and epilepsy classification, which makes salient changes to its predecessors, including changes to core terminology. The new system offers important advantages, but since several terms from earlier systems persist in common clinical use, this section will occasionally reference both sets of terms, new and old, where felt helpful.

Seizure classification will be addressed first. Seizures are classified by their clinical symptoms and signs. The manifestations of a seizure depend upon whether its onset includes broad bilateral cortical regions or only a part of the cerebral cortex and reflect the functions of the involved cortical areas and the subsequent pattern of spread within the brain. Seizures are now initially subdivided into three broad types: those with onset limited to a specific region of cerebral cortex (*focal seizures*), those with onset involving the cerebral cortex diffusely and bilaterally (*generalized seizures*), and a new third group in the 2017 classification for *seizures of unknown onset*. (Note that in the 1981 classification, focal seizures were also called partial seizures. The term

TABLE 120.2 Localization of Seizures by Symptoms and Ictal Manifestations

Locus	Manifestation
Temporal Lobe	
Uncus/amygdala	Foul odor
Middle/inferior temporal gyrus	Visual changes: micropsia, macropsia
Parahippocampal-hippocampal area	Déjà vu; jamais vu
Amygdala-septal area	Fear, pleasure, anger, dreamy sensation
Auditory association cortex	Voices, music
Insular, anterior temporal cortex	Lip smacking, drooling, abdominal symptoms, cardiac arrhythmia
Frontal Lobe	
Motor cortex	Contralateral clonic movements of face, fingers, hand, foot
Premotor cortex	Contralateral arm extension, hypermotor behaviors
Language areas	Speech arrest, aphasia
Lateral cortex	Contralateral eye deviation
Bifrontal	Absence-like seizure
Parietal lobe cortex	Sensory symptoms
Occipital lobe cortex	Visual hallucinations (often in color), teichopsias, metamorphopsias

“partial seizure” has been set aside in the updated version, though this descriptor is still frequently encountered in practice.) Among focal seizure types, the next criterion relates to the retention or impairment of awareness. (In the 1981 version, “simple partial seizure” was used to indicate a *focal seizure with retained awareness*, the currently used term. Similarly, a “complex partial seizure” in 1981 parlance now corresponds to a *focal seizure with impaired awareness*.)

The next criterion relates to specific focal seizure related symptoms, motor or nonmotor, that predominate early on (Table 120.2), reflecting the distinct functions of the various CNS regions that are engaged. Focal seizures are dynamic, with evolving patterns of spread within the brain. Thus, focal seizures with preserved awareness (previously “simple partial seizures” or “auras”) often progress into more widespread focal seizures with impaired awareness (previously “complex partial seizures”) and can spread further still to become *focal to bilateral tonic-clonic seizures* in the 2017 nomenclature (previously “secondarily generalized tonic-clonic seizures”).

Generalized seizures at onset are subdivided into those with motor or nonmotor symptoms. Seizures of unknown onset are also subdivided in similar fashion. If the information is insufficient or if the seizure can't be classified, then it can be designated as “unclassified.”

In an individual, seizures are typically stereotyped, although some patients have more than one seizure type and a specific seizure type often has varying intensities. The behaviors that occur during the seizure are termed the *seizure semiology*. The seizure itself is referred to as the *ictus* and the period of the actual seizure is termed the *ictal phase*. The period after the seizure has ended until the patient is fully recovered is the *postictal phase* (usually minutes to hours, but occasionally days to rarely 1 to 2 weeks) and the time between seizures (which can be seconds to years) is the *interictal phase*. Most routine outpatient EEGs are performed during the interictal phase. Long-term video-EEG monitoring, however, may also record examples of the ictal and early postictal phases. Specific seizure types are further illustrated later, followed by a description of several attendant epilepsy syndromes.

Focal Seizures

In some focal seizures, the abnormal neuronal firing may be so confined to a small non-eloquent patch of cortex that there is no clinical manifestation of the seizure, which can only be detected with EEG. This is termed a *subclinical* or *electrographic seizure*.

Focal Seizures With Preserved Awareness (Previously Simple Partial Seizures)

This seizure type occurs when the electrical discharge involves a small but clinically functional area. This manifests as a symptom without impairment of consciousness. The symptom may be a sensation, an autonomic symptom (e.g., nausea or other epigastric sensation), abnormal thought (e.g., fear, déjà vu), or involuntary movement. This type of seizure is also commonly called an *aura* and can serve as a warning symptom to the patient that a more intense seizure may follow. Auras occur in about 60% of patients with focal epilepsy. During a focal seizure with preserved awareness, the patient can interact normally with the environment except for any limitations imposed by the seizure itself on specific functions. Thus, some subdivide this category into subgroups with impairment (e.g., a jerking limb) or without impairment (e.g., only an internal sensation). Those focal seizures with preserved awareness but with impairment may be more apt to impede safe driving.

Focal Seizures With Impaired Awareness (Previously Complex Partial Seizures)

The degree of impaired awareness within this category varies considerably. The patient's eyes are almost always open during the ictus. The eyes may close after the seizure ends and the patient typically experiences some degree of postictal confusion, fatigue, and sometimes headache (often ipsilateral to the seizure focus). Focal seizures with impaired awareness typically last 1 to 2 minutes with a postictal state lasting a few minutes up to several hours. The specific signs and symptoms that occur during such a focal seizure characteristically reflect the location of seizure onset (see Table 120.2). The location of the focus is important because it can predict the nature of the pathology and directs diagnostic testing. As well, surgical treatment options are largely governed by the location of the seizure focus.

Focal to Bilateral Tonic-Clonic Seizures (Previously Secondarily Generalized Tonic-Clonic Seizures)

A focal-onset seizure that spreads throughout the brain leading to a convulsion is termed a *focal to bilateral tonic-clonic seizure*. Typically, the tonic phase consists of extensor posturing lasting 20 to 60 seconds followed by progressively longer periods of CNS inhibition manifesting as the clonic phase that lasts up to another minute before resolving. In some patients, a few clonic jerks precede the tonic-clonic sequence; in others, only a tonic or clonic phase occurs.

As a focal seizure transitions into a bilateral tonic-clonic seizure, the arm contralateral to the seizure focus may extend first, while the ipsilateral arm flexes at the elbow. This is termed the *figure-4 sign* and can aid in lateralization of the seizure focus. A loud *tonic-cry* may occur at the onset of a convulsion as air is forcibly expelled through tightly contracted vocal cords. The eyes are open and commonly described to roll upward. During a convulsion, breathing stops and cyanosis may develop. Foaming at the mouth may occur. Oral trauma, especially tongue laceration, is typical; this most commonly affects the lateral aspect of the mid-tongue. Urinary incontinence is common. Fecal incontinence is less so. First aid involves turning the patient onto their side as the seizure ends to allow saliva to drool from the mouth, decreasing the likelihood of aspiration. The tonic-clonic phase rarely lasts longer than 2 minutes, though witnesses commonly describe such

convulsions as lasting 5 to 10 minutes or even longer. The CNS mechanisms that terminate such seizures are a matter of great research interest. Failure of seizure termination leads to convulsive status epilepticus. The postictal phase is marked by a transient deep stupor, followed in 15 to 30 minutes by a lethargic, confused state. Occasionally, this period of immediate post convulsive stupor is accompanied by profound suppression of EEG activity (postictal generalized EEG suppression, PGES). As recovery progresses, many patients complain of headache, muscle soreness, mental dulling, lack of energy, or mood changes lasting hours to days. Rarely, patients may report feeling not fully back to normal for 1 to 2 weeks. Convulsions result in many striking, transient physiologic changes, including hypoxemia, lactic acidosis, elevated catecholamine levels, and increased serum concentrations of creatine phosphokinase, prolactin, corticotropin, and cortisol. Complications include oral trauma, vertebral compression fractures, shoulder dislocation, aspiration pneumonia, and, very rarely, sudden death, which may relate to acute pulmonary edema, cardiac arrhythmia, or respiratory failure. Recent research has explored whether transient PGES may predict a greater risk of sudden unexplained death in epilepsy (SUDEP). The contributors and mechanisms of SUDEP are still incompletely understood.

Focal seizures of all intensities may be followed by transient neurologic dysfunction reflecting postictal depression of the epileptogenic cortical area. Thus, focal weakness may follow a focal motor seizure or numbness may follow a sensory seizure. These reversible neurologic deficits are collectively referred to as *Todd paralysis* and last minutes to hours, rarely more than 48 hours. Examination of a patient immediately after a seizure may show transient focal abnormalities that help implicate the site or side of seizure origin.

Generalized Seizures

Generalized seizures begin diffusely and involve both cerebral hemispheres simultaneously from the outset. Generalized seizures should be distinguished from focal to bilateral tonic-clonic seizures because, while in many instances they have similar clinical features, they may respond better to different treatments. These are subdivided into motor and nonmotor categories.

Nonmotor generalized seizures include *typical absence seizures* (historically termed “petit mal”). These occur mainly in children and are characterized by sudden, momentary lapses in awareness with

staring. Sometimes eye fluttering occurs with a slight loss of neck tone. Many absence seizures last less than 15 seconds. If the absence lasts longer than 20 seconds, automatisms are usually present, making differentiation from focal seizures with impaired awareness and motor automatisms difficult. The EEG has a characteristic pattern of generalized 3-per-second spikes and slow waves (Fig. 120.2) during a typical absence seizure. Behavior and awareness typically return to normal immediately after the seizure ends. There is no postictal period and usually no recollection that a seizure occurred.

Atypical absence seizures somewhat clinically resemble typical absence seizures (discussed previously). These also involve staring or mental slowing but instead are associated with a slower generalized spike and slow wave discharge (2.5 Hz or less) on EEG. Also, atypical absence seizures may last longer than typical absence seizures, up to many minutes. Fluctuating levels of awareness, gradual onset and offset, and occasional hypotonia are notable features of atypical absence seizures that differentiate them from typical (3 Hz) absence seizures.

Among the motor group of generalized onset seizures, several patterns will be highlighted, including myoclonic, tonic-clonic, tonic, and atonic seizures. *Myoclonic seizures* manifest as rapid, recurrent, brief muscle jerks that can occur unilaterally or bilaterally, synchronously or asynchronously, without loss of consciousness. Myoclonic seizures may affect the limbs, face, eyes or eyelids and may be of variable amplitude. Myoclonic seizures have a corresponding discharge on EEG. Other types of noncortical myoclonus that lack an EEG correlate, such as benign nocturnal (hypnic) jerks, or subcortical and spinal myoclonus, are not considered epileptic seizures. Repeated myoclonic seizures may crescendo and evolve into a generalized tonic-clonic seizure (called myoclonic-tonic-clonic seizures). Although myoclonic seizures can occur at any time, clusters of such shortly after awakening are typical.

Generalized onset tonic-clonic seizures may begin with a few myoclonic jerks or abruptly with a tonic phase lasting 20 to 60 seconds, followed then by a clonic phase of similar duration, then by a postictal state. Although there are usually no focal features, head turning occasionally occurs; this movement does not suggest a specific localization. If the onset of this seizure type is missed, it is often impossible to clinically distinguish a generalized onset tonic-clonic seizure from a focal to bilateral tonic-clonic seizure.

Fig. 120.2 Absence (petit mal) epilepsy. The electroencephalogram shows the typical pattern of generalized 3-Hz spike-wave complexes associated with a clinical absence seizure.

Tonic Seizures, Atonic Seizures, and Epileptic Spasms

Generalized onset *tonic seizures* are characterized by a sudden marked increase in tone, usually involving bilateral limbs and torso. They are more apt to occur during sleep and are typically brief, under 20 seconds. If standing, these seizures may lead to falls with associated injuries, including head injuries. Generalized onset *atonic seizures* are denoted by a sudden loss of tone affecting the head, limbs or torso. If standing, the patient may fall due to loss of tone, with associated risk of injuries. Head protective gear may be helpful. Such seizures are brief, usually less than 15 seconds. They are often referred to as drop attacks or drop seizures. *Epileptic spasms* are very brief attacks that may cluster and are classically denoted by sudden flexion of the trunk and simultaneous flexion or extension of the limbs. Epileptic spasms manifest as flexor or extensor tonus, myoclonus, or a mixed pattern. The spasms last 1 to 20 seconds each and often occur in clusters for up to 20 minutes. Epileptic spasms often occur in infancy with several forms of early life epilepsies (see later).

EPILEPSIES

Epilepsy classification is governed by the seizure type(s) expressed by that form of epilepsy. This is primarily driven on clinical grounds but is supported by EEG findings, imaging or other metrics. The epilepsies are now divided into four major categories: focal epilepsy, generalized epilepsy (also known as idiopathic or genetic generalized epilepsy), combined generalized and focal epilepsy, and unknown epilepsy. Within each category are epilepsy syndromes. Reflex epilepsy syndromes may reside in either the generalized or the focal epilepsies. Epilepsy syndromes involve a cluster of features such as seizure types, EEG findings, imaging findings, age of onset, prognosis, comorbidities, family history, and genetics. Epilepsy etiology is a major feature in epilepsy classification. There are six main etiologies: structural, genetic, infectious, metabolic, immune, and unknown. Examples of structural epilepsies include post-stroke epilepsy, post-traumatic, tumor-related, postinfectious, and cortical maldevelopment. Genetic causes of epilepsy are being rapidly discovered. While some do run in pedigrees, many are found *de novo* in the affected patient. Absence of a clear family history does not exclude a genetic etiology. One family of genetic causes relates to channelopathies, or mutations in ion channels or receptors that regulate neuronal excitability. Another subset refers to gene mutations that disrupt neural development. Another subset relates to genes that disrupt metabolism (e.g., glucose transporter, or mitochondrial genes). The immune etiologies are some of the most recently recognized. Assays for various autoantibodies targeting distinct CNS antigens, both intracellular and cell surface, are becoming more commonplace in the work-up of certain acquired epilepsies. While some of these conditions are paraneoplastic in nature, others are more purely autoimmune in origin. These often have seizures as one principle facet of a symptom complex, which may also include neuropsychiatric, dystonic, or cognitive symptoms. These may be quite fulminant in presentation (e.g., the anti-NMDA receptor antibody syndrome). Some examples of common, distinctive, or illustrative epilepsy syndromes follow.

Focal Epilepsy

Focal epilepsies are characterized by recurrent focal seizures. As discussed previously, six etiologic categories aid our understanding of the epilepsies and are germane to classification. One group of self-limited focal epilepsies is thought to be due to genetic developmental anomalies that manifest in childhood and remit during puberty. Among the several syndromes of this type, the most common is *childhood epilepsy with centrotemporal spikes* (previously called benign epilepsy with centrotemporal spikes [BECTS] or benign rolandic epilepsy [BRE]).

Seizures usually begin between the ages of 3 and 12 years in an otherwise normal child. The seizures are focal and consist of brief hemifacial motor or sensory events with preserved awareness. Typically, there is twitching of one side of the face, speech arrest, drooling, and paresthesias of the face, gums, tongue, or inner cheeks. The affected child often points to their face and goes to a parent and holds on until it is over; the child then quickly resumes normal activity. Seizures may progress to include hemiclonic movements or hemitonic posturing. Focal to bilateral tonic-clonic seizures occasionally occur, usually during sleep. The parents may report only the convulsions, as the focal onset can be missed unless the child is carefully questioned. The EEG reveals distinctive, stereotyped epileptiform discharges over the central and midtemporal regions that are dramatically activated by sleep with a normal underlying background. Prognosis for this syndrome is good, as it is for most of the other self-limited focal epilepsy syndromes; the seizures disappear and the EEG normalizes by mid to late adolescence. Outcome is unaffected by treatment, but antiepileptic drugs (AEDs) can prevent recurrent attacks.

Another example within this group is the Panayiotopoulos syndrome (also known as early onset occipital epilepsy). This self-limited syndrome is associated with focal autonomic seizures, classically involving pallor, hypersalivation, and vomiting, occasionally with eye deviation and tonic-clonic activity. Most seizures arise from sleep, often within the first hour of sleep. Seizures are lengthy, 20 to 60 minutes. The EEG in the Panayiotopoulos syndrome shows high amplitude and sleep activated, unilateral or bilateral occipital spikes. Seizures may continue for 2 to 3 years after presentation but then abate. Prognosis is good.

Many focal epilepsies can be understood by their specific locale of focal seizure onset. Temporal lobe epilepsy is an example, as is frontal lobe epilepsy. Within each of these designations, one may be able to define the epilepsy further, as in mesial temporal lobe epilepsy, or supplementary motor frontal lobe epilepsy. Distinct etiologies may account for individual forms but the seizure semiology may be similar if the seizure onset zone is shared. For instance, a structural mesial temporal lobe epilepsy secondary to a ganglioglioma may involve identical seizures as would hippocampal sclerosis associated with long-standing mesial temporal lobe epilepsy. These acquired focal epilepsies are often classified based upon the cerebral lobe involved during the initial phase of the seizure. Temporal lobe epilepsy is the most frequent, followed by frontal, then by rarer cases of parietal and occipital lobe epilepsies. Most cases of focal epilepsy entail a single seizure focus. However, the focus can sometimes involve a large, multilobar circuit. Some patients have multiple foci, each associated with a different seizure semiology.

Temporal lobe epilepsy (TLE) is the most common epilepsy syndrome of adults, accounting for at least 40% of epilepsy cases. There is a history of childhood febrile seizures in a subset. Most patients have focal onset seizures with impaired awareness, some of which evolve to focal to bilateral tonic-clonic seizures. Medial temporal lobe seizures involve the hippocampus and/or amygdala. A rising epigastric sensation or vague cephalic sensation is the most commonly reported aura. Less frequently, the classical symptoms of a foul smell, *déjà vu*, or other stereotyped altered thinking may occur. Olfactory auras have been called uncinat seizures because of their origin in or near the uncus of the medial temporal lobe. In lateral (neocortical) temporal lobe seizures, language impairment (dominant hemisphere), recurring vocalizations (nondominant hemisphere), eye blinking, or formed visual or auditory hallucinations can occur. As a temporal lobe seizure spreads to involve the dominant temporal lobe or bilateral temporal lobe structures, including the limbic system, the seizure evolves to impair awareness. A blank stare is often described by witnesses. Automatic motor behaviors, termed *automatisms*, are common in seizures that

involve the limbic system (usually in the temporal lobe). Automatism include orolimentary signs (e.g., lip-smacking, repetitive swallowing) and repetitive hand movements (manual automatism).

Frontal lobe epilepsy (FLE) can be more difficult to diagnose because the scalp EEG may be normal or not reveal a classic epileptic discharge, even with ictal recordings. There are at least four different premotor frontal lobe seizure semiologic patterns, with differing localization. *Supplementary motor seizures* (superior frontal gyri, posterior aspect) consist of contralateral versive posturing of the head and arms in a so-called “fencer posture”; the contralateral arm is extended, the head is turned strongly to that side, and the ipsilateral arm is flexed and held either up above the head or across the chest. *Lateral frontal seizures* manifest as contralateral head and eye deviation. *Hypermotor seizures* (frontal, poorly localized) consist of wild asynchronous movements and are often confused with psychogenic nonepileptic attacks. Almost all hypermotor seizures last less than 40 seconds and typically occur one to five times per night during sleep and less often during waking. *Frontal absence seizures* are rare and due to diffuse, bisynchronous frontal epileptic activity. These consist of staring and mimic typical or atypical absence seizures. Seizures arising in the posterior frontal lobe motor cortex (precentral gyrus) are classically clonic with a Jacksonian march.

Reflex epilepsies are distinguished by seizures that are precipitated by a specific stimulus such as touch, a musical tune, a specific movement, reading, flashing lights, or certain complex visual images. Apart from the photosensitive response in juvenile myoclonic epilepsy (see later), which is relatively common, reflex seizures are rare and are classified as a type of parietal or occipital lobe epilepsy because these regions mediate sensory functions.

Focal post-traumatic epilepsy is a common etiologic type of structural epilepsy. The likelihood of developing post-traumatic epilepsy relates directly to the severity of the head injury. The relative risk for developing epilepsy after a penetrating wound to the brain (e.g., bullet or shrapnel) is up to 600 times that of the general population. Severe closed head injuries result in epilepsy in 20% of patients. Severe closed head injuries are defined by the presence of intracranial hemorrhage of various types, unconsciousness or amnesia lasting more than 24 hours, or persistent abnormalities on neurologic examination, such as hemiparesis or aphasia. Although most patients with epilepsy following severe traumatic brain injury develop seizures within 1 to 2 years of their head injury, new-onset epilepsy may appear after 20 years or longer from the insult. Mild closed head injuries (uncomplicated brief loss of consciousness, no skull fracture, absence of focal neurologic signs, and no contusion or hematoma) may minimally increase the risk of seizures. Post-traumatic epilepsy is always focal or multifocal.

Idiopathic or Genetic Generalized Epilepsy

Both terms, “idiopathic” and “genetic,” for this subset of the generalized epilepsies have advocates and critics among experts. *Idiopathic* in this context is meant to imply “self or genetic” in origin. Genetic often suggests that these forms of epilepsy are inherited and track within a family tree. However, often there is no helpful family history and so some of these instances probably arise *de novo* in affected individuals. The idiopathic (or genetic) generalized epilepsies (IGEs) are likely polygenic, resulting from a combination of mutations and polymorphisms in genes involved in thalamocortical circuitry. Different members within a family carrying these traits often exhibit dissimilar phenotypes. However, only rare IGE genes have been identified. A person with IGE has a 10% chance of passing the condition to a child. Most people with IGE have normal intelligence. Four entities comprise this group and are described later.

Childhood absence epilepsy (CAE; pyknolepsy, petit mal epilepsy) begins between 4 and 10 years of age with a peak at 7 years. Children with CAE have frequent absences (often dozens per day) and are sometimes initially thought to have attentional problems or to be day-dreamers. The absences occur throughout the day. Some children with CAE have occasional generalized tonic-clonic seizures (GTCs). CAE is usually self-limited and seizures and EEG abnormalities resolve by young adulthood in most. The absence seizures of CAE are typically provoked by hyperventilation, a useful procedure in the office setting and during an EEG. The ictal EEG findings of CAE include abrupt and bilaterally synchronous 3-Hz spike and wave discharges, lasting 4 to 20 seconds with loss of responsiveness. Interictal EEGs show brief generalized spike and wave discharges in isolation or in brief bursts lasting a few seconds. Occipital intermittent rhythmic delta activity (OIRDA) is a less frequent finding.

Juvenile myoclonic epilepsy (JME) begins between ages 5 to 34 years old, with peak onset in the mid-teens, and is highly prevalent. JME exhibits a distinctive age-related expression of diverse seizure types, some of which have a clear nonrandom relationship to the sleep-wake cycle. As the name suggests, myoclonic seizures are a core feature; essentially all with JME have myoclonic seizures, though they may be occasionally subtle. Clusters of myoclonic seizures occur most commonly in the morning, usually soon after awakening. The clustered myoclonic seizures typically persist for up to 30 minutes. Myoclonic jerks predominantly affect the arms and last less than 1 second each. Consciousness is preserved with these events. Affected patients may often fail to mention their morning jerks unless specifically asked. Generalized tonic-clonic seizures often occur as well, often arising a bit later in adolescence or into the early 20s. This seizure type often brings the patient to neurologic attention. In JME, GTC seizures are more common after sleep deprivation or alcohol consumption the prior night. People with JME are usually photosensitive. That is, the seizures and EEG discharges are activated by flickering lights between 5 to 20 Hz (*photoparoxysmal* or *photoconvulsive* responses). This is a type of reflex seizure. Between 20% and 40% of patients with JME also have absence seizures. Absences in JME arise several years prior to the appearance of myoclonic seizures. The EEG in JME is like that of CAE, but the generalized discharges are slightly faster (classically 4 to 6 Hz) and often have polyspike components over a normal waking background rhythm. Unlike CAE, seizures in JME persist into adulthood and can be lifelong.

Less common IGE phenotypes include *juvenile absence epilepsy (JAE)* and epilepsy with *generalized tonic-clonic seizures alone (EGTCS)*. In JAE the predominant seizure type is absence with peak onset in the early teenage years and, unlike CAE, persists into adulthood. Absences are numerous. GTC seizures occur frequently as well, but myoclonic seizures are less common in JAE. In EGTCS, the predominant seizure type is a GTC seizure. These GTCs often occur within 1 to 2 hours of awakening but can occur anytime. EGTCS arises between 5 and 40 years of age, most often in the teens, and is not a self-limited epilepsy.

Combined Generalized and Focal Epilepsy

This category includes those epilepsies in which patients may have both focal and generalized seizures. Similarly, EEGs of these patients may exhibit both focal and generalized epileptiform patterns. This new epilepsy category includes a subgroup presently called developmental and epileptic encephalopathies, that were previously termed the symptomatic generalized epilepsies (ILAE, 1989 classification). Individuals with these epilepsies have multifocal or diffuse brain dysfunction since early in life. There is an associated encephalopathy with variable developmental delay. Important examples of the developmental and epileptic encephalopathies are Lennox-Gastaut syndrome (LGS), infantile spasms, and Dravet syndrome.

LGS is a more common form of combined generalized and focal epilepsy. LGS presents from 2 to 10 years of age. It is characterized by the presence of multiple seizure types, usually a combination of tonic or atonic seizures, myoclonic seizures, and atypical absences, and with a characteristic EEG pattern of 2.5 Hz or slower generalized spike and slow wave discharges, in the setting of intellectual disability. Sixty percent have preexisting encephalopathy and developmental delay and up to 25% had infantile spasms earlier in their course. Tonic-clonic and focal seizures also occur. Sleep EEG recordings reveal bursts of diffuse 10- to 20-Hz rhythms with or without coincident tonic seizures. LGS is a chronic condition requiring supervision; many patients ultimately live in group homes. If drop seizures are present, and the patient is ambulatory, a protective helmet should be considered.

Infantile spasms are often a precursor to LGS. Infantile spasms usually begin during the first year of life, rarely beyond 18 months. *West syndrome* is the combination of epileptic spasms in infancy, hypsarrhythmia (a chaotic, disorganized epileptiform EEG pattern), and arrest of psychomotor development. The term infantile spasms is often used synonymously with West syndrome. Numerous etiologies can give rise to infantile spasms. Diagnostic evaluation may uncover an etiology in up to two thirds of cases. Common etiologies include CNS malformations such as cortical dysplasia, neurocutaneous disorders such as tuberous sclerosis complex, various metabolic disorders of infancy (e.g., phenylketonuria), congenital infections, genetic causes (e.g., chromosomal disorders, specific genetic abnormalities), plus other peri- and postnatal CNS insults. Infantile spasms have a poor prognosis with over 90% developing intellectual disability and most progressing to LGS; a small percent of usually cryptogenic cases have a more favorable outcome.

Dravet syndrome (previously severe myoclonic epilepsy of infancy) is both a genetic epilepsy and a developmental and epileptic encephalopathy. Children with Dravet syndrome have refractory epilepsy including multiple seizure types. Seizures commonly present within the first year of life, rarely during the second year. Affected children have normal development up to their presentation with seizures but then experience neurodevelopmental delay. Their initial seizure is typically a prolonged febrile tonic-clonic seizure, either unilateral or bilateral. More often, this is in the context of a febrile illness or recent vaccination, or less frequently with bathing. No precipitants are found in one third. Within weeks to months of this first seizure, more seizures follow, febrile or afebrile, often including bouts of status epilepticus. These may include hemiclonic seizures amongst others; these can even alternate sides. Seizures can be readily triggered by a variety of stimuli. Treatment-resistant seizures are accompanied by psychomotor impairment beginning months after the sentinel seizure. Cognitive, behavioral, language, gait, and other motor impairments accrue. EEGs show both focal and generalized epileptiform patterns and may vary with age. Mutations in the voltage-gated sodium channel, alpha-1 gene (SCN1A) are responsible for this syndrome in 70% to 80% of cases. Recognition of Dravet syndrome is important because voltage-gated sodium channel blocking AEDs (e.g., lamotrigine, phenytoin) can cause clinical deterioration, whereas others are particularly beneficial (e.g., topiramate, levetiracetam, valproate, benzodiazepines).

Other Seizure Conditions

Febrile seizures affect 3% to 5% of children younger than the age of 6 years. About 30% of children have more than one episode; recurrence is more likely if the first seizure occurs before 1 year of age or there is a family history of febrile seizures. Several distinct gene mutations predispose to febrile seizures. Although most affected children have no long-term consequences and appear to outgrow this age-restricted trait, febrile seizures increase the risk of later epilepsy. This risk is low

for most children (2% to 3%) but increases to 10% to 15% in those with prolonged or focal febrile seizures (*complicated febrile seizures*), a family history of nonfebrile seizures, or neurologic abnormalities that predate their first febrile seizure.

DIAGNOSIS

Accurate diagnosis is the cornerstone of epilepsy care. The diagnostic evaluation has three objectives: (1) to determine whether the patient's spell(s) are epileptic seizures, (2) to identify a specific underlying cause, and (3) to establish if the seizures are provoked and isolated, or if epilepsy is present and, if so, to determine the type of epilepsy, ideally the specific epilepsy syndrome.

History and Examination

The patient's and witnesses' descriptions of the events are central to diagnosis. The patient's recall of their seizure may be spotty due to associated amnesia surrounding the episode, and so the witnesses' descriptions are often more helpful. Attention should be paid to details of the patient's behavior before, during, and after the seizure. The setting of the seizure can suggest acute causes such as drug withdrawal, CNS infection, trauma, stroke, or other contributing or provoking factors. Recent-onset seizures in an adult may suggest a new intracranial process. A prior history of seizures suggests epilepsy. Any focal feature before, during, or after the seizure may suggest a possible structural brain lesion requiring appropriate investigation. The pattern of the seizures and the patient's age are often important clues to the seizure and epilepsy type.

The physical examination is normal in most patients with epilepsy. Examination should seek overt or subtle focal neurologic signs: slight unilateral lower facial paresis, clumsy fine finger movements, or mild hyperreflexia. These can be present in patients with epilepsy with a contralateral seizure focus. Careful skin examination is indicated to detect features of neurocutaneous syndromes such as a facial port-wine stain involving the upper eyelid in Sturge-Weber syndrome, hypopigmented macules (ash-leaf spots), shagreen patch (pink, elevated skin nodules with "orange peel" appearance found in the lumbar area), facial angiofibromas in tuberous sclerosis, and café-au-lait spots and axillary freckling in neurofibromatosis. Asymmetry in the size of the hands, feet, or face may signify a long-standing abnormality of the cerebral hemisphere contralateral to the smaller side. Absence seizures can be triggered during an office examination in untreated children with CAE with hyperventilation for 2 to 3 minutes.

Laboratory Tests—EEG

EEG is the most helpful diagnostic test for seizures and epilepsy. EEG findings help confirm the diagnosis, classify the seizures, identify the epilepsy syndrome, and impact therapeutic decisions. Epilepsy remains a largely clinical diagnosis, informed by EEG and other test findings. In combination with suitable clinical findings, *epileptiform* EEG discharges, termed *spikes* or *sharp waves*, strongly support a diagnosis of epilepsy. In patients with recurrent seizures, focal epileptiform discharges are consistent with epilepsies with focal onset seizures, whereas generalized epileptiform activity usually indicates a generalized form of epilepsy (associated with seizures of generalized onset). Most EEGs are obtained between seizures, and such interictal abnormalities alone cannot prove or disprove a diagnosis of epilepsy. Up to 50% of patients with epilepsy show epileptiform abnormalities on their initial EEG. The chance of capturing epileptiform activity is enhanced by sleep deprivation the night before the test, which increases the likelihood of recording drowsiness and light sleep during the EEG. Serial EEGs also increase the yield of a positive test. Some neurologists rely

on prolonged EEG monitoring studies to record much more data including more sleep samples. Supplemental T1 and T2 electrodes can occasionally benefit the yield of the EEG. A small proportion of patients with epilepsy have normal interictal EEGs despite all efforts to record an abnormality.

The interpretation of the interictal EEG is confounded by two factors. Epileptiform discharges occur in about 2% of normal people; many of these may be asymptomatic markers of a genetic trait, especially in children. Also, the interpretation of the EEG is subjective. Normal benign variant waveforms and artifacts can be occasionally misinterpreted as epileptiform activity and erroneously considered to indicate seizure susceptibility.

Epilepsy can be definitively established by recording a characteristic ictal discharge during a representative clinical attack. This is uncommon during routine EEGs but can often be accomplished with *video-EEG long-term monitoring (LTM)*. This can be performed in the outpatient setting (ambulatory video-EEG LTM) or in the inpatient setting at many epilepsy centers throughout the world. The inpatient setting permits AED tapering as needed in a safe setting to increase the odds of eliciting one or more seizures for characterization, whereas this is not the case for ambulatory LTM. Inpatient video-EEG monitoring is indicated in people who have ongoing seizures despite treatment with appropriate AEDs. About one third of patients admitted for LTM are found not to have epilepsy. The majority of these patients have psychogenic nonepileptic attacks. A much smaller subset of patients with nonepileptic seizures have other physiologic mimics of epileptic seizures (e.g., certain movement disorders). In the approximately 30% of people with treatment-resistant epilepsy (those with seizures despite trials of multiple AEDs, alone or in combination), inpatient video-EEG monitoring to more precisely define the seizure focus is a critical step toward determining candidacy for various epilepsy surgery options. Phase I LTM involves scalp EEG recordings. A subset of patients require phase II LTM studies in which electrodes are neurosurgically implanted in or on the brain to more precisely localize the seizure onset zone and map critical functional cortical regions nearby. Recently, stereotactically placed depth leads have been gaining popularity for such investigations in many tertiary epilepsy centers in the United States.

Laboratory Tests—Neuroimaging

Brain MRI complements EEG findings by identifying structural pathology that is causally related to the development of epilepsy. MRI is the best test to detect epileptogenic cerebral lesions including hippocampal sclerosis, neuronal migration disorders, tumors, focal atrophy, arteriovenous malformations, and cavernous malformations. It is important to obtain a complete imaging study that includes T1-weighted, T2-weighted, and inversion-recovery sequences in coronal and axial planes. Contrast can also be helpful for some epilepsy pathologies. Imaging in the coronal plane perpendicular to the long axis of the hippocampus has improved detection of hippocampal atrophy and increased T2 signal, findings that correlate with the pathologic finding of hippocampal sclerosis and an epileptogenic temporal lobe. Additional sequences that should be routine include T2-weighted gradient echo (GRE), to detect hemosiderin indicating prior hemorrhage associated with vascular malformations or trauma, and diffusion-weighted images (DWI) for cytotoxic edema, sometimes present with acute cerebral injury from prolonged seizures or status epilepticus. In 2019, many tertiary centers in the United States offered 3T MRI. This provides improved resolution over lower strength MRIs and can aid in detecting smaller lesions such as very small cortical dysplasias.

An MRI should be obtained in all patients with suspected epilepsy with the exception that many pediatric epileptologists view MRI as

optional for patients with definite childhood epilepsy with centrotemporal spikes or definite generalized genetic epilepsies (e.g., CAE and JME). CT scan with contrast is an alternative study for those who cannot have MRI but has lower resolution than MRI for detecting small lesions. Any patient with seizures and abnormal neurologic findings or focal slow-wave abnormalities on EEG should have neuroimaging. Repeat neuroimaging should be considered if there is an unexplained change in seizure pattern, to evaluate for a new lesion, or in those with possible low-grade neoplastic lesions.

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) use physiologically active, radio-labeled tracers to image the brain's metabolic activity and are useful adjunctive imaging methods for certain patients seeking a surgical treatment option for their epilepsy. SPECT is most useful when an ictal and interictal study are combined to identify an extratemporal seizure focus. Abnormalities on PET or SPECT can be present when brain MRI is normal and thus add value in that scenario. PET has been most useful in treatment-resistant, MRI-negative, temporal lobe epilepsy.

Other Tests

Routine blood tests rarely offer diagnostic assistance in otherwise healthy patients with epilepsy. Serum electrolytes, liver function tests, and complete blood count are useful with acute new-onset seizures and as baseline studies before AED therapy is started. A mildly increased serum WBC count without a marked "left shift" is a common, but nonspecific, transient finding after convulsive seizures or status epilepticus. Serum CPK can also transiently increase postictally but is also nonspecific and no longer commonly obtained outside of the setting of suspected myonecrosis or rhabdomyolysis. Adolescents and adults with unexplained seizures should be screened for substance abuse (especially cocaine) with blood or urine studies. Genetic testing should be considered in specific cases with suspected phenotypes, especially if a positive genetic test would alter therapy, such as in SCN1A-associated epilepsies (e.g., Dravet syndrome). Lumbar puncture is indicated if there is a suspicion of meningitis, encephalitis, autoimmune or paraneoplastic process, or a CNS glucose transporter abnormality. Repeated generalized seizures and status epilepticus can increase cerebrospinal fluid protein measures slightly and produce a mild pleocytosis for 24 to 48 hours; cerebrospinal fluid pleocytosis should be attributed to seizures only in retrospect after excluding an intracranial inflammatory process. An electrocardiogram (ECG) should be obtained in any young person with a first generalized seizure if there is a family history of arrhythmia, sudden unexplained death, or episodic unconsciousness. An ECG should also be obtained in any patient with a personal history of cardiac arrhythmia or valvular disease.

DIFFERENTIAL DIAGNOSIS

Not every paroxysmal event is a seizure, and misidentification of other conditions leads to ineffective, unnecessary, and potentially harmful treatments plus delay to reach the correct diagnosis. Misdiagnosis accounts for a subset of patients who have not responded to AED treatment. The conditions confused with epilepsy depend on the age of the patient and the nature and circumstances of the attacks (Table 120.3). Nonepileptic paroxysmal disorders that are confused with epileptic seizures have sudden, discrete abnormal behaviors, variable responsiveness, changes in muscle tone, and various postures or movements.

Psychogenic nonepileptic seizures (PNES) frequently are misdiagnosed as intractable epilepsy in adults. PNES are felt to be due to unconscious emotional conflicts impacting the patient's physical state, mimicking a seizure (i.e., a somatoform manifestation of psychologic distress). Roughly 10% of patients with PNES also have epilepsy.

TABLE 120.3 Nonepileptic Episodic Disorders That May Resemble Seizures

Movement disorders: tic disorders, subcortical myoclonus, paroxysmal choreoathetosis, episodic ataxias, hyperekplexia (startle disease)
Migraine: confusional, vertebrobasilar, visual auras
Syncope (particularly convulsive syncope)
Behavioral and psychiatric: psychogenic nonepileptic seizures, hyperventilation syndrome, panic/anxiety disorder, dissociative states
Cataplexy (usually associated with narcolepsy), parasomnias
Transient ischemic attack (especially aphasic or limb-shaking)
Alcoholic blackouts
Hypoglycemia

Definitive diagnosis requires video-EEG documentation, although a history of atypical and nonstereotyped attacks, emotional or psychological precipitants, psychiatric illness, lack of response to AEDs, and repeatedly normal interictal EEGs suggests PNES as an alternate consideration. A substantial fraction of patients with PNES have experienced prior physical or sexual abuse. PNES are more common in females than in males and occur across a broad range of ages.

Panic attacks (anxiety attacks) with hyperventilation can superficially resemble focal seizures with affective, autonomic, or special sensory symptoms. Hyperventilation typically causes perioral and fingertip tingling. Prolonged hyperventilation results in muscle twitching or spasms (tetany); affected patients may faint.

Syncope refers to the symptom complex associated with a transient reduction in global cerebral perfusion associated with cardiovascular dysfunction. Loss of consciousness typically lasts only a few seconds, uncommonly a minute or more, and recovery is usually rapid. If the cerebral ischemia is sufficiently severe, the syncopal episode may include tonic posturing of the trunk or clonic jerks of the arms and legs and even incontinence (*convulsive syncope*). Convulsive syncope is a form of syncope, not seizure; it is a frequent mimic of epileptic seizures.

Some forms of *migraine* can be mistaken for seizures, especially if the headache is atypical or mild and/or when confusion occurs. The visual aura, present in some migraineurs, is typically black, gray, and white; a colored aura more often indicates an epileptic seizure. Basilar artery migraine, usually in children and young adults, can include lethargy, mood changes, confusion, disorientation, vertigo, bilateral visual disturbances, and loss of consciousness. This uncommon form of migraine may also mimic a seizure.

TIAs can occasionally mimic seizure and vice versa. The postictal phase of a seizure can be quite stroke-like in nature and typically resolves as do TIA-related symptoms. Seizures involving the language cortex often produce speech arrest—aphasia—as is more commonly encountered in association with TIA/stroke.

TREATMENT

If the cause of a provoked seizure is corrected, AEDs are usually not necessary. Adults with a single, unprovoked seizure and normal clinical, EEG, and imaging findings frequently do not have subsequent seizures. AEDs are usually not indicated if only one seizure has occurred in those instances. However, patients with abnormal focal findings on neurologic exam or abnormal radiologic or EEG findings are at higher risk for repeated seizures and may therefore be more often recommended AED treatment. In individual patients, social considerations may dictate treatment after a single seizure. Patients who have had repeated unprovoked seizures (>24 hours apart) are recommended for AED prophylaxis.

Medication Therapy

The goal in epilepsy care is complete seizure freedom. In the United States, as of 2019, there were 22 AEDs in standard use for epilepsy with several other medications sometimes used adjunctively. There is no ideal AED; all have potential toxic side effects and idiosyncratic reactions. For over one half of people with epilepsy, the appropriate AED for their type(s) of seizures can be highly effective and well tolerated. However, for 25% to 30% of people with epilepsy, no AED alone or in combination is completely effective (termed treatment-resistant or medically refractory epilepsy). Once the seizure type and epilepsy syndrome are determined, an initial and, if needed, subsequent AED, should be chosen based on both anticipated efficacy and toxicity profiles. All AEDs can cause sedation, cognitive dysfunction, and/or incoordination in some patients, especially at high blood levels. Various rare, sometimes life-threatening, reactions can occur with all the AEDs. Some common scenarios follow.

Genetic Generalized Epilepsy (CAE, JME, and Others)

- In all genetic generalized epilepsies, valproate or lamotrigine are first-line agents and result in complete seizure control in 85% to 90% of patients.
- Valproate may promote weight gain in many patients and has been associated with hair loss in approximately 5%. It causes tremor in many in a dose-related manner. It poses an increased risk of teratogenicity relative to other AEDs. It can be associated with hyperammonemia and rare thrombocytopenia and liver function test abnormalities.
- Lamotrigine has a small but significant risk of a severe rash (e.g., toxic epidermal necrolysis, Stevens Johnson syndrome [SJS]) for about the first several months after initiation. A slow dose escalation substantially lowers this risk. Much less severe allergic reactions (e.g., rash) can occur in 3% to 5%. Lamotrigine's metabolism is substantially inhibited by valproate, so in combination, lower doses of lamotrigine are required. Occasionally lamotrigine worsens myoclonus, but it is effective in most cases of JME.
- Second-line options include clobazam, topiramate, levetiracetam, and zonisamide. Levetiracetam is often used as an early option for JME, given its efficacy in myoclonic seizures.
- In childhood absence epilepsy with exclusively absence seizures, ethosuximide should be the first treatment choice. If any convulsions have occurred, valproate or lamotrigine should be used.
- If there is a history of more than 5 minutes of crescendo absences or myoclonus (often described as a “foggy” state) culminating in a convulsion, then oral benzodiazepines (lorazepam or diazepam) can occasionally help abort the cluster and prevent an impending convulsion.
- Absences and myoclonus can be exacerbated by carbamazepine, oxcarbazepine, and GABAergic compounds including gabapentin, pregabalin, and tiagabine. These AEDs should be avoided in the genetic generalized epilepsies.

Focal Epilepsy

- Almost all of the AEDs (except ethosuximide) can be effective in focal epilepsy. The choice of the first AED should be mainly guided by individualized side effect considerations, teratogenicity where appropriate, and pharmacokinetics.
- Phenytoin remains one of the most commonly used AEDs in focal epilepsy in developed countries. Patients presenting with initial seizures or status epilepticus to the emergency room are commonly “loaded” intravenously with phenytoin and subsequently continued. However, phenytoin has substantial short- and long-term

toxicity and its levels are difficult to regulate due to saturation kinetics and multiple drug interactions. Its toxicities include hirsutism, coarsening of features, and gingival hyperplasia, especially in children and adolescents. Long-term risks include osteomalacia, peripheral neuropathy, and cerebellar degeneration with risk of permanent incoordination. Peak level toxicities include nystagmus, ataxia, lethargy, and, if the level rises above 50, acute cerebellar degeneration and cardiac arrhythmias. Phenytoin poses an allergic risk to a subset, including the rare risk of SJS.

- Carbamazepine, oxcarbazepine, topiramate, levetiracetam, lamotrigine, and zonisamide are currently used as first-line therapy for partial seizures. Carbamazepine and oxcarbazepine can cause hyponatremia and allergic reactions, rarely severe in type (SJS). Topiramate can lead to weight loss but also has undesirable dose-dependent cognitive side effects and predisposes to renal stones (1%). Levetiracetam can cause undesirable mood changes, sometimes only transiently, sedation, and rare allergic risk, but is usually well tolerated. Lamotrigine needs to be titrated slowly due to its allergic risk (discussed previously). Zonisamide, which also can cause weight loss and predisposes to renal stones, has a long half-life (48 to 72 hours) so is a good option for less consistently compliant patients or those less successful with more than once-daily dosing. It can cause allergic reactions (including rarely severe ones).
- Patients of Asian ancestry should be tested for the HLA-B*1502 allele and patients of Northern European ancestry tested for the HLA-A*3101 allele prior to initiating treatment with carbamazepine, oxcarbazepine, and eslicarbazepine. Patients with these alleles are at increased risk of SJS and toxic epidermal necrolysis when exposed to these drugs.
- Adjunctive treatments for focal seizures include clobazam, valproate, pregabalin, lacosamide, gabapentin, perampanel, and primidone. The proportion of gabapentin that is absorbed decreases with increasing dose, limiting its effectiveness. For most, pregabalin may be a better choice.
- Phenobarbital is the most widely used AED in the world due to its low cost. However, it causes sedation, cognitive impairment, and poses a risk of bone loss and therefore should probably be avoided except in difficult to control epilepsy. The exception is in neonatal seizures where it remains one of the most commonly accepted AEDs.

Developmental and Epileptic Encephalopathies

- All AEDs have a role in the treatment of this category of epilepsies, but seizure freedom is rarely achieved. At a minimum, control of the more severe seizures, including drop seizures and convulsions, should be a central goal of therapy. AED polytherapy is usually required.
- Valproate is commonly the initial medication instituted.
- Added efficacy can occur with clobazam, lamotrigine, topiramate, levetiracetam, rufinamide, and zonisamide.
- Felbamate may be effective, but its use should be limited to epileptologists due to its significant risk of fatal aplastic anemia and liver failure.
- The vagus nerve stimulator (see later) has a specific role in reducing the severity of seizures in these conditions.
- Dravet syndrome and possibly the related syndrome of GEFS+ respond best to topiramate, levetiracetam, and benzodiazepines. Some voltage-gated sodium channel blocking AEDs, including lamotrigine and phenytoin, worsen Dravet syndrome.

Dosing of AEDs must be done with great care. Only a few AEDs are safe to load or start at a full therapeutic dose. Most should be started with a gradual dose escalation. Management guidelines are: (1) the type of seizures and epilepsy should be defined and the preferred medication for such should be given in usual starting doses and then increased until seizure control is complete or side effects occur (Table 120.4); (2) If seizures persist despite toxic levels, or if major side effects occur, another AED should be tried; (3) Do not stop one agent until another has been added (overlap during transitions). Otherwise, status epilepticus may occur; (4) If seizures persist after one to two AEDs have been given to toxic levels, consider referral to a specialized epilepsy center for further evaluation and treatment; (5) Toxic levels of some AEDs (e.g., phenytoin and carbamazepine) can cause seizures; (6) Extended release and longer acting AEDs are preferred for most patients; (7) Patients should be counseled to adhere to the medication regimen. Pill boxes should be encouraged. Medication noncompliance is a leading cause of poor seizure control.

Epilepsy Surgery

In most patients, epilepsy is controlled with AEDs. When seizures cannot be controlled by adequate trials of two appropriate single agents and/or by the combination of two agents, the epilepsy is termed

TABLE 120.4 Frequently Prescribed Antiepileptic Drugs

Nonproprietary AED Name	Adult Total Dose Per Day	Dose Frequency (in Hours)	"Therapeutic" Concentrations
Carbamazepine	600-1400 mg	6-8 (12 for sustained release)	4-12 µg/mL
Clobazam	10-40 mg	12	Unknown
Ethosuximide	500-1500 mg	8-12	40-100 µg/mL
Gabapentin	900-3600 mg	6-8	2-20 µg/mL
Lacosamide	200-600 mg	12	Unknown
Lamotrigine ^a	100-800 mg	12	2-18 µg/mL
Levetiracetam	500-3000 mg	12	10-45 µg/mL
Oxcarbazepine	900-2400 mg	8-12	10-35 µg/mL
Phenobarbital	60-240 mg	24	15-40 µg/mL
Phenytoin	200-600 mg	24	10-20 µg/mL
Pregabalin	100-600 mg	12	Unknown
Topiramate	50-400 mg	12	2-20 µg/mL
Valproate	500-5000 mg	8 (12-24 for sustained release)	50-125 µg/mL
Zonisamide	100-600 mg	24	10-40 µg/mL

^aSlow initial dose titration mandatory for lamotrigine and often indicated for other agents. Daily dose targets are adjusted depending on co-administered AEDs.

treatment resistant (or *medically refractory*), a situation encountered in 25% to 30% of patients with epilepsy. Such patients are at risk for many consequences: inability to drive; stigmatization by schools, employers, and society; and threats to personal educational and occupational goals, possible cognitive or memory loss over time, plus seizure-related morbidity and mortality including risk of SUDEP. In appropriately selected cases, epilepsy surgery can abolish seizures with restoration of normal neurologic function. The accurate localization of a safely resectable seizure focus requires intensive investigation at a specialized epilepsy center.

A variety of surgical approaches are presently available. These range from lesionectomies, to lobectomies, to (rarely) hemispherectomies. Palliative approaches such as transection of the corpus callosum can help those with drop attacks. The surgical options are tailored to the needs of each individual patient, depending on the nature of their epileptogenic lesion and proximity to cortical regions that cannot be resected without causing unacceptable neurologic deficits (so-called “eloquent cortex”). Recently, laser-mediated ablative techniques have permitted surgical approaches for certain pathologies, with much less risk to the surrounding normal brain near the surgical target. Laser interstitial thermal therapy (LITT) can permit smaller surgical approaches, shorter inpatient stays, and faster postoperative recoveries. Outcomes seem to approach those of conventional resective approaches, though longer-term outcome data are still needed.

Dietary Therapy

The *ketogenic diet* is a very high fat diet with markedly restricted carbohydrates and adequate protein carefully designed to cause a ketotic state, while still supplying adequate nutrition. It is mainly used in children with developmental and epileptic encephalopathies who have an unsatisfactory response to AED treatment. The ketogenic diet can be effective in these most refractory forms of epilepsy, resulting in seizure freedom in 15% to 20%. However, the diet is hard to maintain and requires a dedicated, cooperative caregiver and a specially trained dietician.

The *modified Atkins diet* (MAD) and *low glycemic-index diet* are scaled-down versions of the ketogenic diet with mainly carbohydrate restriction. These diets are more palatable than the ketogenic diet and can be tolerated by adults. The slight ketosis achieved sometimes results in dramatic seizure reduction in many forms of epilepsy.

Neurostimulators

The *vagal nerve stimulator* (VNS) is a surgically implanted device. The stimulating electrode is placed on the left vagus nerve in the neck. The current version of this device has three treatment modes. Routine round-the-clock stimulation occurs intermittently according to programmed settings. Standard settings deliver stimuli lasting 30 seconds every 5 minutes. However, one can program the VNS to deliver stimuli in a more rapid cycling pattern (greater duty cycle) and/or alter the intensity of the stimulation by modifying other parameters. Swiping a magnet over the device gives an extra “on-demand” stimulation that can sometimes abort a seizure. A third mode called autostimulation delivers stimulation based upon detected tachycardias of sufficient magnitude, since a significant percentage of seizures foster an associated tachycardia. Preapproval studies found that approximately 45% of recipients had a greater than 50% reduction in their seizure frequency (the responder rate) and seizure intensity was also often decreased in many. Postapproval long-term follow-up studies suggest an even more robust response to VNS therapy.

Deep brain stimulation (DBS) of bilateral anterior nuclei of the thalami also has been approved in the United States since 2018 for treatment-resistant epilepsy involving bilateral limbic regions. Like the VNS, this method also relies on preset, round-the-clock, intermittent

stimulation to modulate the epileptic circuitry and decrease seizure burden. Studies show that it can lead to a 60% responder rate with several years of follow-up.

Another newer strategy for medically refractory focal epilepsy is *responsive neurostimulation* (RNS), approved in the United States since 2013. Chronically implanted electrodes at or near the seizure foci are used to rapidly detect seizure onset and treat the seizure and its supporting circuitry within seconds by delivering electrical stimulation directly to the seizure focus. This method can use implanted depth electrodes or strips of electrodes to access either cortical or deeper targets (e.g., hippocampi) and provides a means to treat patients with greater than one seizure focus, thereby offering a non-resective option for patients who would not otherwise be appropriate resective surgical candidates. Detection and stimulation algorithms are tailored to the patient’s electrocorticography samples collected over time to improve its performance. Studies have reported a 72% responder rate with 5-year follow-up.

All three neuromodulatory methods appear to variably thwart seizures as they initiate and spread and, perhaps more importantly, gradually reduce the propensity of the epileptic circuitry to generate seizures. These treatments seem to improve clinical outcomes in a slower manner than is commonly seen with AEDs. However, unlike AEDs, the neuromodulatory treatments so far appear to exhibit sustained improved outcomes over years, do not seem to lose efficacy, are nonseminating, and spare neurocognitive function versus most resective surgical methods.

The process by which tertiary epilepsy programs assess the candidacy of medically refractory patients for the above dietary, surgical, or neuromodulatory methods involves careful analysis of several streams of clinical data. Patients’ EEG and LTM results are aligned with their brain imaging and neuropsychological test results. Concordant data more strongly implicate the localization of the seizure focus or foci. This is then matched with the most appropriate treatment options in a highly individualized manner.

Status Epilepticus

Status epilepticus can occur with focal or generalized seizure types and is defined as prolonged or rapidly recurring seizures without full intervening recovery. *Acute repetitive seizures* are defined as a cluster of seizures over minutes to hours with intervening recovery.

Convulsive status epilepticus is a medical emergency. Prolonged and continuous generalized convulsive epileptic activity can lead to irreversible brain injury. The most frequent cause is abrupt withdrawal of AEDs (e.g., noncompliance) in a person with epilepsy. Other precipitants include acute withdrawal from alcohol, benzodiazepines or barbiturates, cerebral infections such as encephalitis, trauma, hemorrhage, and brain tumor.

Nonconvulsive status epilepticus includes two main types. *Focal status epilepticus* (also known as complex partial status epilepticus) may resemble a sustained confusional state often associated with motor and autonomic automatisms. Some instances produce bizarre behaviors or stupor. These bouts can even last for hours or days. Occasionally, this is preceded by an overt convulsive seizure that may have incompletely resolved, with or without AED treatment. This can be diagnostically challenging, as the semiology overlaps with a myriad of other forms of encephalopathy or delirium. EEG is crucial for diagnosis and shows nearly continuous epileptiform activity predominating in a brain region or regions, often the temporal lobes.

The other main form of nonconvulsive status epilepticus is *absence status epilepticus* (or *petit mal status*). This resembles focal status epilepticus and consists of a similar confusional state with some automatisms. EEG reveals continuous runs of generalized 3- to 4-Hz spike and slow wave activity. This usually occurs in children or young adults with known absence epilepsy.

With the current widespread use of ICU EEG monitoring in neurocritically ill patients, there is a burgeoning subset whose EEGs show less sustained and less rapid epileptiform discharges than in typical status epilepticus, though often periodic and abundant, with a waxing and waning quality. Such epileptiform discharges may be lateralized or generalized. These patterns fall short of the status epilepticus patterns described previously but may follow recent bouts of status epilepticus, as they resolve. Recently, these patterns have been categorized as falling within the “ictal-interictal continuum.” Their clinical significance is less clear and is a current focus of investigation.

Focal motor status epilepticus (or *epilepsy partialis continua*, [EPC]) ranges from highly focal, clonic movements of the face or hand to jerks involving a limb or half the body. The clonus frequency can vary from 0.3 to 3.0 Hz. It is less common. Causes include stroke, trauma, neoplasm, encephalitis, and marked hyperglycemia (e.g., glucose > 450 mg/dL as in nonketotic hyperglycemic states) and in Rasmussen encephalitis, a very rare, usually pediatric epilepsy syndrome. Status epilepticus related to profound hyperglycemia can produce refractory focal status epilepticus that often resolves once hyperglycemia is corrected.

Postanoxic myoclonic status epilepticus is often accompanied by generalized polyspike and slow wave epileptiform discharges on EEG but may be less responsive to common AED treatments for status epilepticus. It typically reflects significant and extensive cortical injury, often associated with a poor prognosis.

Once status epilepticus is diagnosed, treatment is urgent. The longer status epilepticus lasts, the more difficult it is to terminate and the more likely it is to cause brain damage. Aggressive therapy is mandatory for convulsive status epilepticus (Table 120.5). If initial therapy is

not rapidly effective, anesthetic agents requiring intubation and ventilation should be used within an hour of onset. Focal status epilepticus can also result in permanent neuronal injury and should also be treated expeditiously, although therapeutic choices are often made to try to stop focal status epilepticus with agents that do not cause respiratory depression to avoid intubation. Absence status is unlikely to result in permanent sequelae and usually responds promptly to benzodiazepine treatment. Investigation into the cause of status epilepticus should be undertaken during its treatment and continued after seizures stop.

GENETIC COUNSELING AND PREGNANCY

Heredity

Patients with epilepsy should be advised about the hereditary risks to their children, although in most people with epilepsy, it does not influence their decision about having children. The most common genetic generalized epilepsies have complex inheritance patterns with about 10% of children of an affected parent developing seizures. There are over 200 mendelian-inherited syndromes with epilepsy, all rare. Screening for genetic causes of epilepsy has become more useful for certain subgroups of patients, particularly those with unknown etiology under the age of 2 years. Gene microarray assays have become more effective tools and have added to older less precise genetic assays such as karyotype or FISH assays. Genetics counselors provide valuable diagnostic and educational assistance in the care of patients who may have a genetic form of epilepsy or who may have specific concerns about the potential risk for their children.

TABLE 120.5 Treatment of Convulsive Status Epilepticus

Time (Min)	Steps
0-5 (Stabilize, ABCs)	Give O ₂ ; ensure adequate ventilation Monitor: vital signs, ECG, oximetry, seizure duration Establish intravenous access; Obtain finger stick blood glucose level, If <60 mg/dL, then: Adults: 100 mg thiamine IV, then 50 mL D50W IV Children ≥2 years: 2 mL/kg D25W IV Children <2 years: 4 mL/kg D12.5W IV Collect complete blood cell count, electrolytes, Ca, Mg, toxins, and AED levels
5-20 Initial therapy (benzodiazepine)	Choose one of the following 3 options: 1. Intravenously administer lorazepam 0.1 mg/kg/dose, max: 4 mg/dose, may repeat dose once, or 2. Intravenously administer diazepam 0.15-0.2 mg/kg/dose, max: 10 mg/dose, may repeat dose once, or 3. Intramuscularly administer midazolam 10 mg for >40 kg, 5 mg for 13-40 kg, single dose. If none of the above are available, then choose one of the following: 1. IV phenobarbital 15 mg/kg/dose, single dose. Note that IV phenobarbital following a benzodiazepine ventilatory assistance is usually required. 2. Rectal diazepam 0.2-0.5 mg/kg, max: 20 mg/dose, single dose 3. Intranasal midazolam, buccal midazolam
20-40 (Second therapy)	If status epilepticus persists, administer one of the following: 1. IV fosphenytoin ^a 20 mg PE/kg, max: 1500 mg PE/dose, 1 dose 2. IV valproic acid 40 mg/kg, max: 3000 mg/dose, 1 dose 3. IV levetiracetam 60 mg/kg, max: 4500 mg/dose, 1 dose If none of the above are available, and if not already given, administer IV phenobarbital 15 mg/kg, max dose. (Alternative to fosphenytoin above, may use phenytoin at 1 mg/kg/min up to 50 mg/min max rate in adults in a proximal IV. Monitor carefully for hypotension, arrhythmia, local extravasation.)
40-60 (Third therapy)	If the seizures do not stop after the above, choices include repeating second-line therapies not previously given, or intravenous anesthetic doses of thiopental, midazolam, or propofol, with intubation and with continuous EEG monitoring. Vasopressors or supplemental IV fluids are often necessary.

ABCs, Airway, breathing, and circulation; AED, antiepileptic drug; ECG, electrocardiogram; EEG, electroencephalograph.

^aAlways dosed in phenytoin-equivalents (PE).

Teratogenicity

Children of mothers taking AEDs have a birth defect rate of 2% up to 9%, which is up to five times that of the general population. However, seizures, especially convulsive seizures, also pose a substantial risk to both the mother and fetus. Thus, AEDs should not be stopped during pregnancy. There is significant variation in the relative teratogenic risk of the available AEDs and in their specific effects on fetal development. Two AEDs, valproate and carbamazepine, have been incriminated in neural tube closure defects. Since the neural tube closes by 28 days of fetal development, this defect develops before the mother may be aware that she is pregnant. Phenytoin, phenobarbital, primidone, and topiramate have been associated with a spectrum of neurodevelopmental abnormalities. Topiramate has been associated with higher risk of low birthweight and increased oral cleft risk. Large registries suggest that the newer AEDs have less teratogenic risk, but the data are incomplete for some of these newer AEDs. Lamotrigine and levetiracetam are presently associated with the lowest rates of major congenital malformations in these registries (approximately 2%). By contrast, valproate has the worst profile with an approximately 9% incidence. Use of two or more AEDs (polytherapy) increases the teratogenic risk. Pregnancies in women with epilepsy should be planned. During the year prior to conception, an attempt should be made to minimize the teratogenic potential of the AED regimen by considering a change to AEDs with significantly superior teratogenic risk where appropriate, to monotherapy from polytherapy, or tapering off AEDs, if there are reasons to believe that seizures will not recur (see later). The lowest effective dose of the AEDs should be used, but this must be balanced with the risk of breakthrough seizures. Folic acid deficiency is an established risk factor for neural tube defects in the general population. There is little evidence that additional folic acid in a well-nourished woman with epilepsy decreases the AED effects on neural tube closure. However, it is shared practice to advise women with epilepsy of childbearing age to take supplemental folic acid (1 mg per day) as prophylaxis against neural tube defects. Once pregnancy is planned or recognized, the dose of folic acid is commonly increased to 4 mg per day.

Management During and After Pregnancy

Women with epilepsy have generally a 1- to 1.7-fold increased rate of complications of pregnancy, including prematurity, preeclampsia, preterm labor, placental abruption, fetal death, bleeding, and poor fetal growth, except for a 10-fold higher rate of maternal mortality than the general population. They should be managed as high-risk pregnancies. High-quality level 2 ultrasound (and possibly 3D ultrasound), maternal serum α -fetoprotein level (elevated in neural tube closure defects), and amniocentesis for chromosomal analysis are used to identify fetal malformations.

During pregnancy, AED serum levels decrease due to increased hepatic and renal clearance and increased plasma volume. The free fraction of highly protein-bound AEDs (e.g., phenytoin and valproate) typically increases due to decreased albumin concentration and increased competition for binding sites by sex steroids. Thus, it is essential to monitor AED levels (free levels for highly protein-bound AEDs) prior to conception and at regular intervals throughout pregnancy (generally every 4 weeks). Hormonal changes associated with pregnancy lead to progressive induction of hepatic glucuronidation pathways that dramatically reduce lamotrigine levels, sometimes requiring doubling or even tripling the lamotrigine dose over the course of pregnancy to maintain prepregnancy levels. In light of these expected AED level changes, it is very helpful to have prepregnancy baseline AED levels, especially those corresponding to periods of good seizure control, in women aiming for pregnancy.

Emesis, a common problem during early pregnancy, can result in missed and partial doses of AEDs. The pregnant woman should be instructed to retake a full or partial dose of her AEDs if vomiting occurs after medications are taken. After the child is born, the dose of AEDs should be tapered to prepregnancy doses over 3 to 6 weeks, beginning approximately 3 days postpartum, but the duration of taper may vary according to the AED's route of clearance (renal or glucuronidation pathways—3 weeks; cytochrome pathways—6 weeks). The AED levels can be checked 1 to 2 weeks after completing the taper to confirm they are at the patient's baseline. In general, breast-feeding is not contraindicated in women taking AEDs.

During the postpartum period the mother with epilepsy may be at increased risk of seizures, especially if her seizures are activated by sleep deprivation. To lessen this risk, a support person should perform at least one of the newborn's nighttime feedings. Patients whose seizure semiology would put the infant at risk (e.g., dropping or excessively clutching the baby) require childcare modification and/or supervision.

PSYCHOSOCIAL CONCERNS

Ongoing epileptic seizures often have major emotional consequences for the patient and family. Comorbid depression is present in up to 30% to 50% of patients with refractory epilepsy and 20% of patients with controlled epilepsy. Anxiety disorders accompany epilepsy in 15% to 20%. Both are often unrecognized and untreated. In people with epilepsy, quality of life impairment better correlates with depression than with seizure frequency. The unpredictable nature of seizures and the necessary activity restrictions cause dependence, decreased self-worth, embarrassment, stigma, underemployment, and helplessness. Reduced libido and hyposexuality are common in patients with epilepsy and often unrecognized.

Family dynamics may also be disrupted by the presence of epilepsy. Patients and their families often fear seizures (seizure phobia). Family members may think their loved one is dying when they convulse, especially for the first time. Patients with epilepsy are helped most by seizure freedom, but reassurance and optimistic support from family and friends aids immeasurably. Once seizure control is achieved, people with epilepsy should be encouraged to live as normal and full a life as possible, using common sense as a guide. Although activity restrictions may eventually be lifted, patients with past epilepsy (with the exception of CAE and childhood epilepsy with centrottemporal spikes, which completely remit) should be advised to avoid head contact sports and activities or occupations that may prove catastrophic were a seizure to recur (e.g., swimming alone, working at great heights, weapon use).

All states grant automobile driver's licenses to patients with epilepsy provided that no seizures impairing consciousness or bodily control have occurred for specified periods of time (typically 3 months to 1 year). Life and health insurance policies can generally be obtained. The American with Disabilities Act (ADA) provides protection from loss of employment on the basis of disability and this pertains to those with epilepsy. Reasonable accommodations to patients should be made in the workplace setting, although there are several important caveats to these rules. Epilepsy foundations and local social service organizations can assist patients with case coordination, including social and vocational concerns.

PROGNOSIS

Two thirds of those with epilepsy achieve a 5-year remission of seizures within 10 years of diagnosis. About half of these patients can eventually become seizure-free without AEDs. Factors favoring remission include specific genetic generalized forms of epilepsy, a normal neurologic

examination, and onset in early to middle childhood (excluding neonatal seizures). Approximately 30% of patients continue to have seizures and never achieve a permanent remission despite one or more AEDs. Such treatment-resistant (or medically refractory) patients should be evaluated at an epilepsy center to ensure diagnostic accuracy and to explore the full gamut of available treatments. Seizures are occasionally associated with significant morbidity and mortality. Injuries due to seizures are common. These can include traumatic injuries such as lacerations and fractures, head injuries, aspiration, drowning, and burns, among others. Such injuries can infrequently be life-threatening. Accidental deaths related to seizures (e.g., motor vehicle collisions) further increase the death rate. Aspiration with convulsions is common but can be prevented by turning the head to one side as the convulsion ends. A growing literature suggests that some types of repeated seizures, especially prolonged seizures and status epilepticus, may be associated with certain forms of cognitive decline such as memory impairment, over the lifetime of a patient.

SUDEP occurs in approximately 1 per 1000 patients per year, taking all forms of epilepsy together. In the most refractory epilepsies, the SUDEP rate may approach 10 per 1000 patients per year. SUDEP may result from transient autonomic nervous system dysfunction, which may occur during or immediately after an unwitnessed seizure (often during sleep) with resultant cardiac arrhythmia or respiratory dysfunction (central and/or peripheral forms of apnea). Suffocation can occur after an unwitnessed convulsion if the patient is prone with face down in a pillow or bedding. Whether some patients have a still unknown genetic predisposition toward SUDEP is a current active area of investigation, as are new monitoring technologies to help detect nocturnal seizures or their autonomic sequelae and alert caregivers.

DISCONTINUING ANTIEPILEPTIC DRUGS

Many patients with epilepsy become seizure-free on AED therapy for an extended time. Some patients can successfully discontinue AEDs without relapse. Successful drug withdrawal is most likely with shorter duration of epilepsy before achieving remission, with a longer seizure-free interval before antiseizure drug withdrawal (minimum of 2 years is advised but many advocate for at least 5 years), fewer seizures before achieving remission (≥ 10 carries higher relapse risk), history of a self-limiting epilepsy syndrome (e.g., absence epilepsy, childhood epilepsy with centrotemporal spikes), and no epileptiform abnormalities on EEG before withdrawal. Other factors of possibly lesser statistical import that may also increase the risk of relapse upon AED taper include an abnormal neurologic exam, brain MRI revealing a pertinent structural correlate, intellectual disability, family history of epilepsy, history of multiple seizure types, or if seizure control was difficult to establish and required polytherapy. Ultimately, this decision is highly

individualized as the perceived burden of continuing AED treatment versus the impact of a seizure relapse may vary among individual patients with differing goals and life circumstances.

Central Nervous System Tumors

Bryan J. Bonder, Lisa R. Rogers

DEFINITION/EPIDEMIOLOGY

Central nervous system (CNS) tumors are of two types, primary or metastatic. Primary tumors arise from a variety of cell types within the parenchyma of the brain, spinal cord or the meninges. Metastatic tumors result from spread of systemic cancer to the brain, spinal cord, or meninges and represent the majority of central nervous system tumors. This chapter reviews both primary and metastatic brain tumors.

The incidence of primary malignant and nonmalignant brain tumors in the United States increases with age and is 5.65/100,000 in persons age 0 to 14, 11.2/100,000 in persons age 15 to 39, and 44.47/100,000 in persons older than 40. High-grade gliomas and meningiomas are the most common types of adult primary brain tumors. Meningiomas are the most common benign intracranial tumor and account for approximately one third of benign brain tumors. The incidence of primary CNS lymphoma (PCNSL) is increasing in all age groups, accounted for only in part by CNS lymphoma associated with HIV and immunocompromised states such as solid organ transplant.

Brain metastases are one of the most common neurologic complications of cancer with an incidence of up to 17%. Because incidence rates are based on tumor registries and many patients with brain metastasis do not undergo surgery, they may be underrepresented in these statistics.

Primary brain tumors are the second most common cancers in children. Medulloblastomas are the most common malignant pediatric brain tumor. In the United States, approximately 300 new cases of pediatric medulloblastomas are diagnosed each year. The cause of most primary CNS tumors is unknown. Aside from exposure to ionizing radiation, no environmental agents are known to be causative. Hereditary syndromes that are associated with an increased risk of CNS tumors include neurofibromatosis 1 and 2, tuberous sclerosis, von Hippel-Lindau disease, Li-Fraumeni syndrome, and Turcot syndrome, but these account for less than 1% of primary CNS tumors. Although the chromosomal abnormalities associated with many of these syndromes are known, the specific mechanisms leading to CNS neoplasia have not been defined.

PATHOLOGY

The most recent World Health Organization classification from 2016 defines brain tumors based on the cell of origin and molecular signature and includes a grading system, which is of use in predicting the biological behavior of the tumor. Most adult primary brain tumors are of neuroepithelial origin and result from neoplastic transformation of astrocytes, oligodendrocytes, or ependymocytes. Astrocytomas are the most common primary parenchymal brain tumor in adults. Meningiomas derive from arachnoidal cap cells in the meningeal

covering of the brain. They most frequently occur in older adults. Common locations of meningioma are the cerebral convexity, falx and parasagittal area, olfactory groove, sphenoid wing, and posterior fossa. They are comprised of heterogeneous histopathology patterns, and careful neuropathological assessment is needed for accurate grading.

Primary central nervous system lymphoma is a rare form of non-Hodgkin's lymphoma, typically of B cell origin. It presents within the white matter of the cerebral hemispheres, often in a periventricular location, and is often multiple.

Brain metastasis develops when tumor cells gain access to the systemic circulation and embolize to the brain. Metastases occur most commonly from solid tumors arising in the breast, lung, kidneys, colon, and skin (melanoma). Lung cancer, both non-small and small cell type, is one of the most common tumors to metastasize to the brain and constitutes up to 50% of cases of brain metastasis. In women, breast cancer is the most common source. Malignant melanoma is a less common systemic cancer but carries a high risk of brain metastasis; up to 50% of stage IV melanoma patients develop brain metastasis.

Medulloblastomas are of primitive neuro-ectodermal origin and are highly cellular. Homer Wright rosettes (arrangement of tumor cells around a central area filled with neurofibrillary processes) can be identified in resected specimens in up to 40% of cases. Medulloblastomas are grade IV tumors as they are invasive and rapidly growing, with a tendency to disseminate through the cerebrospinal fluid (CSF).

CLINICAL PRESENTATION

Symptoms and signs caused by brain tumors typically result from compression or invasion of adjacent neural tissue by the tumor or from vasogenic edema resulting from disruption of the blood-brain barrier which can be caused by cerebral vessel compression/invasion from tumor or from "leaky" blood vessels present within the tumor. Neovascularization associated with tumor growth is typically comprised of embryonic vessels that lack a normal blood-brain barrier. Because of the uncompromising rigidity of the cranial vault, both histologically benign and malignant tumors may cause symptoms, even when they are small. Symptoms caused by low-grade primary brain tumors tend to be slowly progressive whereas those in mid- and high-grade histology are acute or subacute (over weeks to months). The exception is the clinical presentation of a low-grade glioma with seizure. Metastatic tumors often present in a subacute fashion but may present acutely when hemorrhage into the tumor occurs. Hemorrhage into metastatic brain tumors is most common with renal cell, lung, papillary thyroid carcinomas, melanoma, and choriocarcinomas.

The clinical symptoms and signs depend on the location of tumor. In most pediatric patients with brain tumors, tumors arise in the posterior fossa and result in diplopia, ataxia, dysphagia, or nausea/vomiting. Most adult brain tumors arise in the cerebral hemispheres and

present with symptoms and signs related to the supratentorial structure involved: unilateral limb weakness, aphasia, and speech abnormality or memory loss are common. Tumors in either location may present with generalized symptoms arising from increased intracranial pressure or meningeal irritation. Headache occurs in up to two thirds of patients as a presenting sign. There are no unique characteristics to this headache, but useful clinical clues include a new or different headache pattern, a progressively worsening headache, and one that occurs at night or on awakening. The pain may localize to the side of the tumor in patients with supratentorial tumors, whereas patients with infratentorial tumors frequently describe pain in the retro-orbital, retroauricular, or occipital region. Other generalized symptoms include changes in mood or personality, a decrease in appetite, and nausea. Projectile vomiting, while common in children with posterior fossa tumors, is rare in adults. Meningiomas generally grow slowly; they may also be found incidentally during the evaluation of unrelated neurologic symptoms. Seizures may develop over the course of the illness in up to 15% of patients with any type of primary tumor, often in association with tumor progression.

DIAGNOSIS/DIFFERENTIAL

All patients suspected of having a brain tumor should undergo a contrast-enhanced magnetic resonance imaging (MRI) brain scan. If MRI is not available or is contraindicated because of a non-MRI-compatible pacemaker or other condition, brain computed tomography (CT) with contrast should be obtained. Brain MRI is preferred because it is more useful in imaging the temporal and posterior fossae and it is more sensitive in detecting the extent of parenchymal involvement by tumor of any type. In addition, advanced sequences such as diffusion, perfusion, and spectroscopy can add to the diagnostic accuracy of imaging. Vasogenic edema resulting from leakage of intravascular fluid through a disrupted blood-brain barrier is easily visible on MRI.

High-grade gliomas typically appear as irregularly shaped contrast-enhancing masses surrounded by edema. Central necrosis is characteristic of glioblastoma (Fig. 121.1). Anaplastic gliomas appear similarly, except for less frequent regions of necrosis. Although there are exceptions, most low-grade gliomas do not enhance after intravenous contrast injection (Fig. 121.2). Meningiomas typically demonstrate smooth and homogeneous enhancement originating from the extra-axial space and may also compress adjacent brain. Primary CNS lymphomas typically present as multiple contrast-enhancing lesions within the white matter but in rare instances do not show contrast enhancement. Brain metastases are often located at the gray-white junction of the brain and demonstrate homogeneous enhancement or peripheral enhancement surrounding a necrotic or cystic center. When solitary, a brain metastasis cannot be accurately distinguished from other neoplasm or nonneoplastic entities. Medulloblastomas are usually large by the time they are identified and demonstrate homogeneous enhancement within or superior to the floor of the fourth ventricle (Fig. 121.3). They are often accompanied by hydrocephalus. The desmoplastic variant of medulloblastomas can be located lateral to the fourth ventricle.

The differential diagnosis of contrast-enhancing lesions includes brain abscess, but infection is a consideration only in rare clinical situations. Diffusion-weighted magnetic resonance images can be useful in distinguishing tumor from infection. Low-grade gliomas can be misdiagnosed as cerebral infarction, especially on brain CT. Periventricular enhancement in PCNSL can sometimes be confused with active multiple sclerosis lesions or with brain metastasis. Dural pathologies such as sarcoidosis, meningeal infection, or dural metastasis can mimic a meningioma. Posterior fossa ependymomas in children can mimic medulloblastomas.

Fig. 121.1 Contrast-enhanced T1-weighted MRI demonstrates irregular contrast enhancement with central necrosis in the left temporal lobe. There is adjacent vasogenic edema and mass effect on midline structures characteristic of a high grade glioma.

Fig. 121.2 Coronal T-weighted MRI following contrast injection in a low-grade astrocytoma shows low signal intensity and no contrast enhancement, typical of a low-grade glioma.

Leptomeningeal metastasis can be suspected in cancer patients with multiple cranial nerve deficits, asymmetrical limb weakness, unexplained headaches or seizures. Evaluation typically includes imaging of the entire neuraxis with contrast-enhanced MRI. Leptomeningeal tumor will appear as diffuse or nodular enhancement arising from the leptomeninges of the brain or spinal cord. Cranial nerves, when involved, may enhance and appear thickened. The diagnosis can be made by MRI in the appropriate clinical setting, but definitive diagnosis is established by demonstration of tumor cells in cytology examination of CSF. In patients with lymphoma, flow cytometry is preferable to cytology. A large volume (>10 mL) lumbar puncture is frequently

Fig. 121.3 Contrast-enhanced T1-weighted MRI shows a large enhancing tumor in the midline of the cerebellum with compression of the fourth ventricle.

required in order to make the diagnosis. If the initial cytology is negative and suspicion is high, additional lumbar puncture can be considered. Findings of elevated CSF protein and white blood cell count or low glucose should raise suspicion.

In the majority of cases, biopsy or resection is the preferred method to establish the histology and grade of primary brain tumors. Exceptions include patients suspected to have PCNSL; a search for malignant cells in the CSF or by vitreous biopsy can be attempted to avoid surgery. Additionally, surgery is typically avoided in brain stem gliomas because the MRI appearance is characteristic and biopsy is considered dangerous.

TREATMENT

Surgical resection is the initial goal for most patients with benign and malignant primary brain tumors. Surgical resection provides tissue for analysis and often relieves neurologic symptoms; maximal surgical resection, when feasible, improves outcome. One exception is PCNSL, in which clinical deterioration can result from resection. Biopsy alone is adequate unless significant symptoms of mass effect from the tumor are present. In addition, small meningiomas can often be observed.

Standard therapy for newly diagnosed glioblastoma is maximal resection and focal external beam radiation of 60 Gy in combination with temozolomide followed by adjuvant temozolomide for 6 months. In a prospective randomized trial of newly diagnosed glioblastoma patients, the median survival with radiation and temozolomide was 14.6 months versus 12.1 months with radiation alone. In addition, the 2-year survival rate was superior with the combined regimen (26.5%) versus radiation alone (10.4%). O-6-methylguanine DNA methyltransferase (MGMT) is a DNA repair gene that reduces the efficacy of temozolomide and other DNA-damaging treatments for cancer. Methylation of the MGMT promoter in tumor tissue silences this gene and results in improved survival in glioblastoma. There is evidence that tumors harboring isocitrate dehydrogenase (IDH) 1 and 2 mutations are correlated with a superior outcome compared with wild-type IDH. The discovery of molecular “drivers” may lead to identification of additional targets for therapy. New approaches using next-generation sequencing and DNA-methylation fingerprinting are being evaluated in trials of glioblastoma.

The introduction of “targeted agents” that are designed to deactivate oncogenic pathways or angiogenesis is a major advance in cancer treatment. Bevacizumab, a monoclonal antibody to vascular endothelial growth factor, is associated with a high response rate and reduction in neurologic symptoms in recurrent glioblastoma, although the effect on overall survival is not significant. Because current treatment results are unsatisfactory, it is suggested that patients with glioblastoma be referred for clinical trial.

Anaplastic gliomas, most commonly anaplastic astrocytoma and anaplastic oligodendroglioma, are treated by maximal surgical resection, followed by focal external beam radiation in association with chemotherapy. However, there is increasing reliance upon the molecular markers of MGMT and IDH1 status to predict survival and to dictate the utility of adding chemotherapy in poor prognosis patients. One type of anaplastic glioma exquisitely sensitive to chemotherapy is the anaplastic oligodendroglioma with co-deletions of 1p and 19q.

The long-term progression-free survival and overall survival of low-grade glioma (grade 2) patients is better than those with glioblastoma or anaplastic glioma, but malignant transformation occurs in up to 50% of such patients and close monitoring with serial MRIs is required. Most patients with low-grade gliomas should be treated initially with maximal safe surgical resection. When grade 2 patients undergo resection, adjuvant therapy with radiation and chemotherapy is reserved for those who are older than 40 years of age or in whom the resection was subtotal. Characterizing low-grade gliomas by molecular markers such as IDH1 and chromosomal analysis for co-deletion of 1p and 19q mutations and (IDH) mutation predicts prognosis. Regardless of the treatment modality selected, serial monitoring for progression with regular MRIs is indicated. If there is disease progression or recurrence, repeat surgery, RT, and chemotherapy are all potential options depending on individual patient characteristics.

The type of therapy selected for a meningioma depends on patient characteristics, tumor features, potential for harm if untreated, and consideration of side effects of the treatment. Maximal surgical resection is important to reduce the risk of relapse. When complete removal is not possible, radiation therapy should be considered post-operatively, especially for grade 2 tumors. Radiation therapy is recommended regardless of the extent of resection for malignant (grade 3) meningiomas. Chemotherapy for this disease has not been proven to be effective.

Symptoms and imaging abnormalities associated with PCNSL often improve with the administration of corticosteroids because of the cytotoxic effects of steroids on lymphoma cells. However, administration of steroids before brain biopsy reduces the yield of tissue biopsy and can confound diagnosis. Therefore, delaying steroids prior to surgery is appropriate in suspected PCNSL because resection is often associated with neurologic deterioration and because there is no clear evidence that resection improves prognosis. A high-dose methotrexate-based regimen incorporating an alkylating agent and rituximab is the preferred induction therapy. Consolidation therapy may include other chemotherapies or low-dose whole brain radiation. High-dose radiation following chemotherapy should be avoided because of the risk of white matter damage. Up to a quarter of patients have ocular or CSF involvement at the presentation of CNS lymphomas, and staging by performing lumbar puncture and consultation with ophthalmology is appropriate prior to beginning therapy.

Contemporary management of brain metastases is individualized and is often best accomplished by a multidisciplinary team including medical oncology, neuro-oncology, radiation oncology, and neurosurgery. Initial systemic evaluation for a suspected new brain metastasis should include contrast-enhanced CT scans of the chest, abdomen, and pelvis and additionally a mammogram if the patient is female. If

the lesions are multiple and the underlying diagnosis is not known, tissue from the safest and most readily accessible site should be obtained. Standard therapy for patients with a single brain metastasis is complete resection if the tumor is resectable and the patient has a good performance status and has limited extracranial disease. Some patients with limited systemic cancer show a survival benefit with resection of up to three metastatic tumors. Resection is typically followed by whole brain radiation or stereotactic surgery to the tumor margin. Radiosurgery to all lesions, avoiding resection, is also an option. The addition of whole brain radiation therapy (WBRT) after resection or radiosurgery provides better control of tumor in the brain but does not result in increased survival, and its use should be determined based on the individual clinical circumstances.

Patients presenting with more than three brain metastases should be considered for WBRT. Novel approaches to preserving memory in patients undergoing WBRT include sparing the hippocampus during radiation and/or adding memantine. If the patient does not receive WBRT, close observation with periodic MRI scans is indicated to assess for recurrence at the original site or at other sites in the brain. A variety of systemic treatments show therapeutic efficacy in newly diagnosed and recurrent brain metastasis, depend upon the sensitivity of the brain metastasis to the agent. Examples include small molecule targeted agents for non-small cell lung cancer, immunotherapy for malignant melanoma, and chemotherapy with or without targeted agents for breast cancer.

Leptomeningeal metastasis is treated based on the underlying pathology and the performance status of the patient. Options include radiation to symptomatic sites or bulky disease in the brain or spine on MRI, systemic chemotherapy, or intrathecal chemotherapy.

The extent of resection is prognostic in medulloblastomas. Staging evaluations for the extent of disease include postoperative MRI of the brain and spine and lumbar CSF sampling. Prospective randomized trials and single-arm trials suggest that adjuvant chemotherapy administered during and after craniospinal radiation improves the progression-free survival and overall survival in both average and poor risk groups. The therapy for children younger than 3 years of age excludes craniospinal radiation therapy because of the long-term deleterious effects and includes surgery and chemotherapy alone. Distinct subgroups of medulloblastomas have been identified, and profiling of these subgroups reveals distinct genomic events, some of which represent actionable targets for therapy.

Vasogenic edema associated with parenchymal and meningeal tumor causes neurologic symptoms and signs and can be life-threatening. Treatment with corticosteroids often reduces edema and improves neurologic function. Dexamethasone is the preferred steroid because of its long half-life and low mineralocorticoid activity. Patients with symptoms related to vasogenic edema often improve within 48 hours of dexamethasone administration. Doses used for treatment of tumor-related edema are typically 4 to 24 mg/day of dexamethasone given in divided doses (two to four times daily). Because steroids can be associated with a variety of adverse effects, the lowest dose and duration of administration should be sought. In patients with severe neurologic signs related to brain edema, an intravenous bolus of 10 mg dexamethasone should be considered. If the neurologic signs are life-threatening, including signs of brain herniation, mannitol and dexamethasone should be administered and urgent neurosurgical consultation obtained. Seizures should be aggressively managed with antiepileptic drugs. Liver nonenzyme-inducing antiepileptic drugs (e.g., phenytoin) are favored because of a better safety profile than liver enzyme-inducing drugs and because of the lack of interaction with other medications prescribed to treat the tumor, including steroids and chemotherapy. Prophylactic antiepileptic

drugs are generally not recommended for patients with a primary or metastatic brain tumor. One exception is melanoma brain metastases in which patients with multiple supratentorial brain metastases, especially those with hemorrhage, have a high risk of seizures.

PROGNOSIS

The grade of glioma, performance status, and age are important predictors of prognosis. Glioblastoma has the worst prognosis, with a median survival of just over 1 year even with aggressive therapy. Favorable prognosis patients can live more than 2 years. Data from the nationwide Surveillance, Epidemiology, and End Results registry identified an overall median survival of 15 months and 42 months for patients with anaplastic astrocytomas and anaplastic oligodendrogliomas, respectively. This analysis did not include the status of 1p19q chromosomal loss, and the more favorable survival of patients with co-deletions was thus not demonstrated. Low-grade gliomas have a median survival of approximately 5 years, but there is individual variation depending on age, size of tumor, and extent of resection. The incorporation of molecular markers will allow for more specific prognostication in these tumors.

Recurrence rates in meningioma depend upon grade and vary from greater than 25% in grade 1 to greater than 90% in grade 3. Risk factors for recurrence include incomplete resection, higher tumor grade, young age, specific subtypes, brain infiltration, and high proliferative rate.

Median survival in PCNSL has improved with the introduction of high-dose methotrexate regimens in contrast to whole brain radiation that was used decades ago. Depending upon a variety of clinical factors, most importantly age and performance status, it ranges from 1 to 8 years. Elderly patients (>70 years) fare the worst.

Performance status, age, status of the extracranial tumor, and number of brain metastases are some of the factors that predict prognosis in patients with brain metastasis. The prognosis of patients with brain metastases has become increasingly individualized. As newer targeted therapies become available, the particular genetic mutations driving the cancer are also becoming important for determination of prognosis. The median survival ranges from 3 to 6 months in patients with multiple metastases treated with whole brain radiation therapy. Patients with a single metastasis with limited extracranial disease who undergo surgical resection and whole brain radiation therapy have significantly improved survival (40 weeks) as compared with those who undergo whole brain radiation therapy alone (15 weeks). Importantly, the improved survival is accompanied by a longer period of functional independence.

The 5-year progression-free survival in medulloblastomas is 70% to 85%. However, more than one third of patients experience recurrence, and there is no standard therapy at the time of recurrence. Median survival after recurrence is usually less than 1 year.

The advent of molecular markers in the diagnostic evaluation of primary brain tumors, especially gliomas, has significantly altered the approach to predicting prognosis and treatment response. In addition, multi-institution trials have provided robust information regarding the optimal therapy for subgroups of glioma, subdivided by important clinical factors such as patient age, performance status, degree of surgical resection, and incorporation of molecular markers. It is anticipated that prospectively designed trials, stratified on these factors, will yield additional information to aid the clinician in treatment recommendations. Significant advances in the treatment of systemic cancer are providing additional therapies when those cancers spread to the central nervous system.

Demyelinating and Inflammatory Disorders

Anne Haney Cross

INTRODUCTION

In demyelinating CNS disorders, previously normal myelin is lost due to an acquired, typically inflammatory disease. The prototypic CNS demyelinating disorder is multiple sclerosis (MS). Other disorders of this type include neuromyelitis optica (NMO), acute disseminated encephalomyelitis (ADEM), acute transverse myelitis (TM), and optic neuritis (ON).

MULTIPLE SCLEROSIS

Definition/Epidemiology

Recent data indicate that MS affects between 600,000 and 900,000 people in the United States and over 2.3 million worldwide. Though presumed to be autoimmune, its exact etiology is still not fully understood. MS begins as a relapsing remitting disease in greater than 80% of patients and ultimately becomes progressive in greater than 50% of patients with untreated relapsing-remitting MS (RRMS). Progressive MS patients accumulate neurologic disability unassociated with relapses (although relapses may be superimposed). MS is more common in females, with the current female to male ratio in North America and in Europe estimated at 2:1 to 4:1. An exception is primary progressive MS (see Clinical Presentation), where the female to male ratio is 1:1.

MS is most common in persons of northern European ancestry. Recent genome-wide association studies indicate that many genes affect the risk of MS, although most confer only a small risk of disease (odds ratios less than 1.5). Alleles within the HLA-DR region (DRB1*15:01 > DRB1*13:03 > DRB1*03:01) are the most well established and confer the greatest risk with odds ratios between 1.5 and 4 for most populations of northern European ancestry.

Environmental factors can confer risk for MS, including modifiable factors such as low vitamin D blood level, high body mass index during adolescence/young adulthood, and smoking cigarettes. Seropositivity to the Epstein-Barr virus increases the risk of MS; a symptomatic case of infectious mononucleosis confers greater risk than seropositivity alone. Though relatively high at 1/1000 to 1/500, MS incidence appears to be relatively stable in North America, the United Kingdom, and Europe. Incidence of MS may be increasing in several regions where MS was not previously prevalent, such as Iran, Turkey, Sicily, and South Africa. These reports of increasing incidence may reflect a real increase, improved recognition, or both.

Pathology

Classically, MS causes demyelinating CNS white matter lesions with relative sparing of axons. The most common pathology of active lesions in white matter is perivascular mononuclear cell infiltration

(monocyte/macrophages, lymphocytes), with a variable presence of antibody and activated complement. Acutely active white matter lesions display blood-brain barrier breakdown, manifest on MRI by gadolinium enhancement. Despite its categorization as a “white matter disease,” gray matter is also damaged in MS. Gray matter MS lesions have been under-recognized because they are difficult to see by MRI and are often not appreciated pathologically without special stains. Such gray matter lesions may occur in the deep gray structures such as the thalamus and in the cerebral cortex. Cortical gray matter lesions can be subpial, extend into cortex from underlying white matter (leukocortical), or wholly within the cortex (intracortical). Cortical lesions are characterized by activated microglia and relatively fewer infiltrating lymphocytes and macrophages than white matter MS lesions. Ectopic lymphoid tissue containing components of secondary lymphoid tissues (B cells, follicular helper T cells, dendritic cells, CXCL13) has been observed in meninges of people with MS, especially those with progressive MS, and is associated with poor prognosis.

Clinical Presentation

MS may manifest with a variety of symptoms and signs. Common presentations include: optic neuritis, diplopia (often caused by internuclear ophthalmoplegia due to a propensity of MS to affect the medial longitudinal fasciculus), other brain stem syndromes, partial transverse myelitis, sensory disturbances, and weakness. Less frequent presentations include seizures, cognitive problems, bladder control problems, and pain. Pain in MS is often of a burning, tingling, or electrical nature. Clinically isolated syndrome (CIS) refers to a single attack that is likely due to CNS demyelination. CIS may be acute or subacute in onset and may involve a single or more than one CNS region. CIS presentations may look identical to MS attacks, but a formal diagnosis of MS cannot be made without dissemination of lesions in space and time. New MS diagnostic criteria allow positive spinal fluid findings (CSF-restricted oligoclonal bands) to substitute for dissemination in time. Ultimately, most CIS patients with typical demyelinating syndromes develop MS. In one study, over 85% of CIS patients with even one silent abnormality on brain or spinal cord magnetic resonance imaging (MRI) eventually developed clinically definite MS.

Three main clinical subtypes of MS are defined based on clinical course: relapsing remitting, secondary progressive, and primary progressive. RRMS is characterized by clinical stability between individual attacks from which the person may or may not fully recover. Secondary progressive MS (SPMS) patients have gradual neurologic deterioration and may also have superimposed attacks (“active” SPMS). Secondary progressive MS develops following an initial relapsing-remitting course in a substantial proportion of individuals with RRMS. This proportion may be declining with the advent of disease-modifying therapies.

TABLE 122.1 The 2017 Revised McDonald Criteria

Clinical ^a	Lesions With Objective Clinical Evidence	Additional Data Needed for MS Diagnosis
≥2 attacks	≥2	None
≥2 attacks	1 lesion, plus clear cut historical evidence of a prior attack in a different anatomic location	None
≥2 attacks	1	DIS demonstrated by an additional clinical attack implicating a different anatomic location, or >1 new T2w lesion in at least one other region typical of MS (periventricular, cortical or juxtacortical, brain stem/cerebellar, spinal cord)
1 attack	≥2 lesions	DIT demonstrated by a 2nd clinical attack, or new T2w and/or gad+ lesion on follow-up MRI, or simultaneous presence of gad+ and nonenhancing lesion on MRI at any time, or positive cerebrospinal fluid findings (oligoclonal bands restricted to CSF)
1 attack	1 lesion (CIS)	DIS demonstrated by a 2nd clinical attack implicating a different CNS region, or ≥1 new T2w lesion in MS-typical region of CNS; DIT demonstrated by a 2nd clinical attack plus either new T2w MRI lesion or CSF-restricted oligoclonal bands
Gradual neurologic progression suggestive of MS (PPMS)	1 year or more of disease progression plus two of three of following criteria: evidence for DIS in the brain based on ≥1 T2w lesions characteristic of MS, evidence of DIS in the spinal cord based on ≥2 T2w cord lesions, positive CSF (elevated IgG index or oligoclonal bands not present in serum)	

^aThese criteria were developed in Caucasian adults aged 18 to 50 years with CIS presentations typical of CNS inflammatory demyelinating disease. Care should be taken when applying these criteria to persons not fitting this description. Alternative diagnoses that might better explain the disorder must always be considered and reasonably excluded.

DIS, Dissemination in space; *DIT*, dissemination in time.

Modified from Thompson AJ, Banwell BL, Barkhof F, et al: Diagnosis of multiple sclerosis: 2017 revisions of the McDonald Criteria, *Lancet Neurol* 17:162–173, 2018.

About 10% of MS patients have primary progressive MS (PPMS), which from onset is characterized by gradual downhill progression without any clinical attacks. The International Advisory Committee on Clinical Trials of MS has proposed additional clinical descriptors that include disease activity (based on relapse rate and new imaging findings) and progression over the prior year.

Diagnosis

The diagnosis of MS requires dissemination of CNS disease in time and in space, and no other disease should provide a better explanation. MRI, spinal fluid analyses, evoked potentials (EPs) and ocular coherence tomography (OCT) are tools that may aid in the diagnosis. The latest McDonald criteria (Table 122.1) allow CSF-restricted oligoclonal bands to substitute for dissemination in time in the diagnosis of MS in the setting of a CIS typical of demyelination. The new diagnostic criteria allow more rapid diagnosis of MS and earlier treatment.

MRI

The finding of classic imaging features on brain and spinal cord MRI greatly aids the certainty of diagnosis. MS lesions are characterized by increased intensity on T2-weighted (T2w) and T2-FLAIR (fluid attenuated inversion recovery) images (Fig. 122.1A). Lesions are usually ovoid and often localize to the periventricular or juxtacortical regions, the corpus callosum, the brain stem, and the cervical spinal cord. On sagittal images, lesions in the corpus callosum are usually flame-shaped (Fig. 122.1C). On T1w images, MS lesions may be isointense or hypointense. T1w hypointensity in a chronic inactive lesion denotes underlying tissue damage, including axonal loss (Fig. 122.1D). Enhancement of lesions following administration of gadolinium containing contrast agents indicates blood-brain barrier breakdown; such a lesion is considered to be active (Fig. 122.1B). Enhancing lesions are also often T1w hypointense, but this hypointensity resolves more than 50% of the time. A ring pattern (often an incomplete ring) of

enhancement is common. Most enhancing MS lesions display no mass effect. Occasional “tumefactive” MS lesions are difficult to distinguish from tumors and may require biopsy.

Spinal Fluid Analysis

Evidence of increased intrathecal immunoglobulin synthesis is present in more than 90% of people with MS. Elevated concentrations of CSF IgG and IgM, CSF-restricted oligoclonal bands of immunoglobulin (Fig. 122.2), and a high intrathecal IgG synthesis rate are seen. The IgG index, which is derived from the ratio of CSF to serum IgG and takes BBB integrity into account, is elevated in MS. A mild lymphocytic pleocytosis is frequently seen in CSF during MS relapses.

Evoked Potentials

EPs detected by surface electrode recording were used in the past to detect subclinical demyelination in the brain stem (auditory EPs), spinal cord (somatosensory EPs), and optic nerves (visual EPs). The advent of high-resolution MRI has led to far less use of EPs to aid MS diagnosis.

Optical Coherence Tomography

OCT is a safe and rapid means to image the retina and detect evidence of prior optic neuritis. OCT uses infrared light to measure thickness of the retinal nerve fiber layer (RNFL), which contains axons that form the optic nerve. A thinned temporal region of the RNFL can be used as evidence of prior subclinical optic neuritis.

Differential Diagnosis

The diagnosis of MS requires the exclusion of diseases that might better explain the clinical scenario. The differential diagnosis of MS is broad (Table 122.2). Some diseases that can mimic MS have relapses and others display progressive courses. “Red flags” that are atypical for MS, such as systemic (arthritis, rash, mouth or genital sores, or pulmonary) symptoms, bilateral hearing loss, peripheral neuropathy, or

Fig. 122.1 (A) Axial fluid-attenuated inversion recovery (FLAIR) image of the brain from a person with MS revealing classical periventricular and deep white matter high-signal intensity lesions. (B) Axial T1-weighted image following gadolinium contrast administration in the same patient as A. Enhancing lesions after gadolinium contrast administration, indicating loss of integrity of the blood-brain barrier that is seen with active MS lesions. One enhancing lesion in the right parietal region is ring enhancing. (C) Sagittal FLAIR image of the brain of a person with MS demonstrating classical flame-shaped pericallosal lesions radiating outward from the ventricle. (D) Axial T1-weighted image showing areas of T1 low signal intensity (“black holes”).

Fig. 122.2 Isoelectric focusing gel of cerebrospinal fluid (CSF) and serum of a patient with multiple sclerosis. The CSF (*upper lane*) shows oligoclonal bands cathodal to the pH 8.0, which are not seen in the serum (*lower lane*).

atypical age of onset (early childhood or after age 50) should lead the clinician to seek further support for the diagnosis of MS.

Prognosis of Multiple Sclerosis

MS is highly variable. It is occasionally “benign,” in which case the disease has little impact on quality of life. It can also be severe with considerable disability or early death. Most people with MS fall in between these extremes. It is currently not possible to predict the future course of MS in an individual patient with full accuracy. Poor prognostic indicators at onset of MS include primary progressive course, male gender, frequent attacks, prominent motor or cerebellar findings, and high initial MRI lesion burden. Expected lifespan of people with MS is reduced overall by 7 to 14 years. Suicide rate is 1.7 to 7.5 times that of the general population. The use of disease modifying therapies likely improves not only relapse rate but also long-term disability and even mortality. In one non-randomized study, early initiation of disease modifying therapies within a year of symptom onset was associated with better long-term outcomes.

TABLE 122.2 Differential Diagnosis of Demyelinating Diseases

Disease Category ^a	Examples of Disorders ^b
Immune-mediated/autoimmune	Multiple sclerosis, neuromyelitis optica (NMO), anti-MOG disorder, acute demyelinating encephalomyelitis (ADEM), idiopathic optic neuritis, CRION, idiopathic transverse myelitis, Behçet's disease
Infectious	Progressive multifocal leukoencephalopathy (PML), HTLV-I, HIV, CNS abscess, Lyme disease, Whipple disease, neurosyphilis
Metabolic	Vitamin B ₁₂ , vitamin E or copper deficiency, central pontine and extrapontine myelinolysis
Neurodegenerative	Spinocerebellar ataxias, spine disease (e.g., compressive cervical spondylopathy, central canal stenosis)
Rheumatologic	Sarcoidosis, systemic lupus erythematosus, antiphospholipid antibody syndrome, Sjögren's syndrome
Genetic disorders	Adrenoleukodystrophy/adrenomyeloneuropathy, hereditary spastic paraparesis, CADASIL (a hereditary stroke disorder), Leber optic neuropathy, Perlezeus-Merzbacher, Wilson's disease
Neoplastic/paraneoplastic	CNS lymphoma, meningeal carcinomatosis, paraneoplastic CRMP-5 IgG, anti-amphiphysin-1 Abs
Vascular	CNS vasculitis (e.g., giant cell arteritis, primary CNS vasculitis), spinal dural fistula, Susac syndrome
Iatrogenic	TNF inhibitors, CNS irradiation, immune checkpoint inhibitors

^aSeveral of the disorders listed could be placed in more than one category.

^bThis list is not comprehensive.

❖ For a deeper discussion of these topics, please see Chapter 383, "Multiple Sclerosis and Demyelinating Conditions of the Central Nervous System," in *Goldman-Cecil Medicine*, 26th Edition.

Treatment

MS treatment can be divided into three categories: treatment of symptoms (e.g., spasticity, fatigue, or depression), treatment of acute relapses, and disease modifying therapies. The following discussion will be limited to the latter two categories. However, [Table 122.3](#) lists some frequent MS symptoms and their therapies.

Relapses that alter function or cause severe pain are usually treated with corticosteroids. Severe relapses are often managed with high-dose corticosteroids, such as intravenous methylprednisolone at 500 to 1000 mg daily for 3 to 5 days, followed by a short oral taper. Lower dosed corticosteroid courses may be used for mild relapses. Blood pressure, serum electrolytes and glucose, and patient mood should be monitored during corticosteroid therapy. Based on the multicenter Optic Neuritis Treatment Trial (ONTT), this regimen will lead to more rapid recovery from the attack but is unlikely to alter the degree of eventual recovery.

For severe relapses that do not respond to high-dose IV corticosteroids, a small randomized study showed that plasma exchange can be effective. Rapid functional improvement in over 40% of patients occurred with early initiation of plasma exchange. Subjects in this trial likely included patients with NMO and ADEM, in addition to MS.

MS is one of only a handful of chronic neurologic disorders with effective disease modifying therapies. The beta-interferons (BIFNs) and glatiramer acetate (GA) are US Food and Drug Administration (FDA)-approved for the treatment of patients with relapsing forms of MS to decrease the frequency of clinical exacerbations and delay the accumulation of physical disability. The BIFNs and GA all reduced annualized relapse rate by about 30% in early pivotal studies. Most have been shown in randomized trials to delay progression to definite MS in those with CIS who are at high risk for developing MS.

As of mid-2020, 19 different disease modifying therapies, plus several generics versions of these, with 10 different mechanisms of action are available for MS ([Table 122.4](#)). The approved agents have distinct risk profiles. As there are currently no biomarkers that direct the choice of disease modifying therapies for an individual patient, selection of the disease modifying therapy for an individual is based on disease course and severity, comorbidities, and patient preferences.

Five BIFNs are approved for use in relapsing MS and CIS in the United States. They differ in dosage, mode of administration, side

TABLE 122.3 Selected MS Symptoms and Their Management

Symptom/Sign	Treatment(s)
Stiffness/cramps/spasms/spasticity	Baclofen, tizanidine
Fatigue	Amantadine, modafinil, armodafinil
Depression	Selective serotonin reuptake inhibitors, cognitive behavioral therapy
Pain/paresthesias/trigeminal neuralgia	Gabapentin, carbamazepine, oxcarbazepine, pregabalin, amitriptyline
Gait impairment	Fampridine SR
Nystagmus, with visual impairment	Gabapentin
Dizziness/vertigo	Meclizine, dimenhydrinate, benzodiazepines
Urinary urgency/incontinence/neurogenic bladder	Mirabegron, oxybutynin, tolterodine, other anticholinergics, BOTOX injection
Impotence/erectile dysfunction	Sildenafil, tadalafil, testosterone supplementation if low
Tonic spasms	Phenytoin, carbamazepine

effects, and incidence of neutralizing antibody induction. Three are identical to human BIFN-1a. Polyethylene glycol has been covalently attached to one of the three for longer duration of effect. The other two are BIFN-1b, which differs by one amino acid from BIFN-1a. BIFNs are immunomodulators whose exact mechanism of action in MS is not fully established. BIFN therapy is associated with increased circulating soluble VCAM-1, and increased IL-10, an immunoregulatory cytokine. Hepatic transaminases and CBC should be monitored in those taking BIFNs. Common side effects include a "flu-like" feeling for several hours after a dose, which can be lessened by nonsteroidal anti-inflammatory medications or acetaminophen. BIFNs are administered by injection and, as with any injectable drug, skin infection can occur. Although the risk of taking BIFNs during pregnancy and lactation are thought to be minimal, it is recommended that BIFNs be discontinued before conception.

Glatiramer acetate is given as a subcutaneous injection at 20 mg per day or 40 mg three times per week. This drug is a random polymer of four amino acids that are abundant within myelin basic protein, a major protein in CNS myelin. It is considered immunomodulatory not immunosuppressive, although its mechanism of action is not

TABLE 122.4 Disease Modifying Medications for MS

Drug (Brand Name), Dosing	Approved	MS Indication	Mechanism of Action
Interferon- β -1b (Betaseron, Extavia), 250 μ g SQ qod	1993, 2009	RRMS, CIS	Inhibits "pro-inflammatory" cytokines, such as interferon (IFN)- γ , tumor necrosis factor- α , and lymphotoxin. Increases IL-10. Adhesion molecule and class II MHC induction reduced.
Interferon- β -1a (Avonex) 30 μ g IM weekly	1996	RRMS, CIS	
Interferon- β -1a (Rebif) 22 or 44 μ g SQ 3 \times /wk	2002	RRMS	
Interferon- β -1a (Plegridy) 125 μ g SQ every 14 days	2014	Relapsing forms of MS	
Glatiramer acetate (Copaxone) 20 mg SQ daily, or 40 mg SQ 3 \times /wk	1996, 2014	RRMS, CIS	Alters T cell cytokine profile toward that of Th2 immunomodulatory cells
Mitoxantrone (Novantrone) 12 mg/m ² IV q 3 months	2000	Worsening RRMS, relapsing SPMS, PRMS	Anthracenedione chemotherapeutic agent
Natalizumab (Tysabri) 300 mg IV q 4 weeks	2004/2006 (removed briefly from market)	Relapsing forms of MS	Monoclonal antibody targeting the alpha-4-integrins, part of the VLA-4 adhesion molecule
Fingolimod (Gilenya) 0.5 mg po daily	2010	Relapsing MS, including children	Modulates sphingosine 1-phosphate receptors 1,3,4, and 5; lymphocytes unable to migrate out of lymphoid tissue. May have direct effects in CNS.
Teriflunomide (Aubagio) 7 mg or 14 mg po daily	2012	Relapsing MS	Inhibits dihydroorotate dehydrogenase, thus inhibiting proliferation of activated lymphocytes
Dimethyl fumarate (Tecfidera) 240 mg po BID;	2013	Relapsing forms of MS, including active SPMS and CIS	Activates nuclear factor erythroid 2-related factor 2 (Nrf2) pathway that enhances response to oxidative stress
Diroximel fumarate (Vumerity) 231 mg po BID;	2020		
Monomethyl fumarate (Bafiertam) 95 mg po BID	2020	Relapsing forms of MS	Monoclonal antibody that lyses cells expressing CD52
Alemtuzumab (Lemtrada) IV infusion	2014		
Ocrelizumab (Ocrevus) IV infusion 600 mg every 24 weeks	2017	Relapsing forms of MS, primary progressive MS	Lytic monoclonal antibody targeting B cells expressing CD20
Oral cladribine (Mavenclad) 1.75 mg/kg po yearly \times 2	2019	Relapsing forms of MS, including active SPMS	Cytotoxic to T and B lymphocytes through impairment of DNA synthesis
Siponimod (Mayzent) usually 2 mg po daily;	2019	Relapsing forms of MS, including active SPMS and CIS	Modulates sphingosine 1-phosphate receptors 1 and 5, lymphocytes are unable to migrate out of lymphoid tissue. May have direct effects in CNS.
Ozanimod (Zeposia) 0.92 mg po daily	2020		
Ofatumumab (Kesimpta) 20 mg SQ monthly	2020	Relapsing forms of MS, including CIS and active SPMS	Human lytic monoclonal antibody targeting B cells expressing CD20

fully understood. Glatiramer acetate has no known drug interactions. Laboratory monitoring is not needed. Side effects include injection site reactions and a tachycardia reaction that occurs infrequently and seemingly randomly, but always soon after an injection. Lipoatrophy at injection sites may develop with prolonged use. Glatiramer acetate is considered the safest MS disease modifying therapy to use in women who may become pregnant. No increase in risks for malformations or fetal/neonatal toxicity or pregnancy loss has been noted in those who were exposed to branded glatiramer acetate, although exposure has been mostly limited to the first trimester.

Mitoxantrone is an anthracenedione chemotherapeutic agent that is FDA approved for secondary progressive MS, progressive relapsing MS, or worsening relapsing-remitting MS. It is administered by IV infusion every 3 months. Due to dose-limiting cardiotoxicity and drug-induced leukemia (the latter in approximately 1% of MS patients receiving it), mitoxantrone is rarely used any more.

Natalizumab is a humanized monoclonal antibody targeting the α -4-integrins, part of the VLA-4 adhesion-related heterodimer. The dose is 300 mg infused intravenously every 4 weeks. A 2-year phase 3 trial of natalizumab showed 68% reduction in annualized relapse rate, 42% reduction in sustained disability, and over 90% reduction in gadolinium-enhancing lesions compared with placebo. Natalizumab was temporarily removed from the market in 2005 due to its association with progressive multifocal leukoencephalopathy

(PML), a severe and sometimes fatal viral disorder caused by the JC virus. Because of its association with PML, this drug is recommended mainly in cases of an inadequate response or intolerance of an alternative MS therapy. Patients should be tested for serum antibodies to the JC virus prior to initiating therapy with natalizumab and, if positive, treatment should proceed with caution. Enrollment in a risk-mitigation program is required, and the drug can only be infused at a certified infusion center. Infusion reactions are not uncommon, and neutralizing antibodies to natalizumab develop in some patients. It is not recommended that natalizumab be used during pregnancy or during breast-feeding.

Fingolimod, an oral disease modifying therapy, is indicated for those with relapsing forms of MS, including CIS, RRMS, and active SPMS MS patients 10 years of age and older. This daily 0.5-mg capsule reduces annualized relapse rate in adults with RRMS by about 50% and disability progression by about 25% versus placebo. Fingolimod modulates sphingosine 1-phosphate receptors 1, 3, 4, and 5 and is believed to work in relapsing MS primarily by the sequestration of lymphocytes in secondary lymphoid tissues. Fingolimod affects several organ systems. Adverse effects include macular edema, pulmonary dysfunction, bradycardia, and increased infection rate (including opportunistic infections such as herpetic and cryptococcal infections and PML). Patients who are varicella zoster virus antibody-negative should be vaccinated prior to initiation. Fingolimod is contraindicated

in the setting of recent myocardial infarction, stroke, uncontrolled heart failure, unstable angina, stroke, transient ischemic attack, or if baseline QTc interval on ECG is 500 ms or greater. Fingolimod can interact with a number of other drugs; it should not be initiated in those taking class IA and class III antiarrhythmic drugs. Medical monitoring for potential bradycardia for at least 6 hours after the first dose is required. Fingolimod may cause fetal harm. Women of childbearing age should use contraception during fingolimod use and for 2 months after its discontinuation.

Siponimod is a second-generation sphingosine 1-phosphate receptor modulator that was FDA-approved in 2019 for adults with relapsing forms of MS, including active SPMS, RRMS, and CIS. Siponimod is more specific than fingolimod, primarily modulating sphingosine 1-phosphate receptors 1 and 5. The maintenance dose is 2 mg per day by mouth but should be reduced to 1 mg/day for those with CYP2C9*1/*3 or *2/*3 genotype, and it is contraindicated for those who are CYP2C9*3/*3 homozygous. In a study of SPMS patients who were notably older (mean age 48 years) and more disabled (median EDSS 6.0) compared with most other MS clinical trials, siponimod reduced 3-month confirmed disability progression by a statistically significant 21% ($P = 0.013$) versus placebo. First-dose monitoring should be done in people with sinus bradycardia, first- or second-degree atrioventricular block, history of myocardial infarction or heart failure. Women of childbearing age who take siponimod should undergo effective contraception, as siponimod has potential for a serious risk to the fetus. Several other sphingosine 1-phosphate receptor modulators are currently being studied in MS.

Ozanimod is a second-generation sphingosine 1-phosphate receptor 1 and 5 modulator that was FDA-approved in 2020 for adults with relapsing forms of MS. In two trials enrolling over 800 subjects with active relapsing MS each, ozanimod was compared to BIFN 1a 30 g IM weekly, showing 48% and 38% relative reductions (each $P < 0.0001$) in annualized relapse rate versus active comparator. As with fingolimod and siponimod, patients should have baseline bloodwork to include CBC and liver function tests, an electrocardiogram to assess for preexisting conduction abnormalities, and baseline and follow-up ophthalmic assessments to assess for macular edema. If live attenuated vaccine immunizations are needed (such as for varicella zoster), these should be administered at least 1 month prior to starting ozanimod (or fingolimod or siponimod). Several other sphingosine 1-phosphate receptor modulators are currently being studied in MS with at least one of these expected to be approved in 2021.

Teriflunomide is a once-daily oral tablet of 7 mg/day or 14 mg/day. Two phase 3 studies in patients with relapsing forms of MS found that the 14-mg/day dose significantly reduced annualized relapse rate by over 30% and disability progression by around 30%. The 7-mg dose had a lesser beneficial effect. Teriflunomide can cause hepatotoxicity, and liver blood work monitoring should continue monthly for 6 months after initiation. Based on animal data, teriflunomide may cause major birth defects and thus pregnancy must be avoided during treatment. If necessary, teriflunomide can be rapidly eliminated from the body using cholestyramine; otherwise, it persists for long periods. Teriflunomide may reactivate latent tuberculosis, is associated with peripheral neuropathy, and can increase blood pressure. Teriflunomide is closely related to the drug leflunomide, approved for rheumatoid arthritis in 1998.

Dimethyl fumarate is an oral medication taken twice daily and is indicated for all relapsing forms of MS. In phase 3 trials, it reduced MS relapse rates by 44% to 53% and improved MRI outcomes. The white blood cell count may drop and should be monitored. In late 2014, the FDA issued a warning regarding the association of PML with this medication, and since then over 20 people have developed PML in

the setting of dimethyl fumarate use. The risk of PML may be greater in those with persistent low lymphocyte counts and those over age 50. Adverse effects include flushing, gastrointestinal side effects, and rash. Dimethyl fumarate should be discontinued prior to conception. Several related fumarates with improved side effect profiles are under investigation for use in MS.

Diroximel fumarate and *monomethyl fumarate* are two second generation oral fumarates each approved in 2020 by the FDA for relapsing forms of MS. These oral fumarates have similar efficacy and safety to dimethyl fumarate, but fewer gastrointestinal side effects.

Alemtuzumab is a lytic monoclonal antibody targeting cells expressing CD52, which includes T and B lymphocytes, monocytes, and other mononuclear white blood cells. In the United States, it is indicated for people with relapsing forms of MS and, because of its health risks, is reserved for those with inadequate response to two or more disease-modifying drugs for MS. In the CARE-MS I and II studies in RRMS patients, alemtuzumab infusions were compared to 44 µg BIFN-1a given subcutaneously three times per week. Patients treated with alemtuzumab had a lower annualized relapse rate (by 49% and 53.8%) and disability progression (by 28% and 42%). Alemtuzumab leads to a profound drop in the white blood cell count, which may last for months or even years. In trials, secondary autoimmune diseases developed in a sizeable proportion of alemtuzumab-treated subjects, with autoimmune thyroid disease being most common. Alemtuzumab may increase risk of malignancies, including thyroid cancer, melanoma, and lymphoproliferative disorders. Infusion reactions are common and can be life-threatening. Alemtuzumab is available only through clinicians and infusion centers that have been certified to use it. Women of childbearing potential should use effective contraceptive measures when receiving a course of alemtuzumab and for 4 months following that course of treatment.

Ocrelizumab is a fully humanized lytic monoclonal antibody targeting CD20, a cell surface antigen found on B lymphocytes. Ocrelizumab was FDA-approved in 2017 for patients with relapsing or primary progressive forms of MS. Ocrelizumab is given as an intravenous infusion of 600 mg every 24 weeks. In the phase 3 studies, those in the ocrelizumab group had almost 50% reduction in annualized relapse rate and a 40% reduction in 12-week confirmed disability progression compared to relapsing MS patients given subcutaneous BIFN-1a at 44 micrograms three times per week. In the phase 3 ORATORIO study in primary progressive MS, those receiving ocrelizumab had 24% reduction in 3 month confirmed progression versus placebo. Side effects include infusion reactions, increased infection rate (including herpetic infections) and a possible increased risk of cancers, including breast cancer. Patients should screen negative for hepatitis B before commencing use of ocrelizumab. Risks associated with ocrelizumab in pregnant women are unclear, but transient B cell depletion and lymphocytopenia have been reported in infants born to mothers exposed to other anti-CD20 antibodies during pregnancy. Being of immunoglobulin G1 subtype, ocrelizumab is expected to cross the placental barrier. Women of childbearing potential should use contraception while receiving ocrelizumab and for 6 months after the last infusion.

Ofatumumab is a human monoclonal antibody that targets and lyses cells expressing CD20. It is administered monthly, subcutaneously. In two clinical trials of over 900 relapsing MS patients each, ofatumumab was compared to teriflunomide 14 mg/day po. Annualized relapse rate reductions of 51% and 59% (both $P < 0.001$) were observed in the ofatumumab groups relative to teriflunomide groups. The combined studies showed ofatumumab to confer a 34.4% relative reduction in three-month confirmed disability progression ($P = .002$) versus teriflunomide. Potential risks and side effects are similar to those for

ocrelizumab and include infections, injection reactions, and reduced response to vaccinations.

Oral cladribine was approved by the FDA in 2019 for the treatment of relapsing forms of MS in adults, including RRMS and active SPMS. This drug is recommended for patients who have had an inadequate response to, or are unable to tolerate, an alternative disease-modifying treatment of MS. Oral cladribine is a purine antimetabolite that destroys certain immune cells. It is given at a cumulative dosage of 3.5 mg/kg divided into two treatment courses at 1.75 mg/kg per treatment course given a year apart. Oral cladribine may increase the risk of malignancy, and it is contraindicated in those with concurrent malignancy. Patients should be screened for HIV, tuberculosis, and hepatitis B and C prior to use. Varicella zoster virus antibody-negative persons should be vaccinated before initiation. Oral cladribine is contraindicated in pregnant or breast-feeding women and in both women and men of reproductive potential who do not plan to use effective contraception because of risk of fetal harm.

NEUROMYELITIS OPTICA SPECTRUM DISORDER (DEVIC DISEASE)

Definition/Epidemiology

Neuromyelitis optica spectrum disorders (NMOSD) comprise a spectrum of inflammatory CNS disorders causing both demyelination and necrosis that are clinically characterized by attacks of optic neuritis and longitudinally extensive TM that are not necessarily concurrent. Only rarely is NMOSD monophasic. In most cases serum autoantibodies to the aquaporin 4 (AQP4) water channels are found. AQP4 channels are strongly expressed by astrocytes. AQP4 is also expressed outside of the CNS in the kidney, stomach, and other tissues, but curiously no pathology has been recognized in the non-CNS organs expressing AQP4.

NMOSD is much less common than MS, with estimates by the Guthy-Jackson Charitable Foundation of 15,000 patients in the United

States. It is even more female-preponderant than MS, with female to male ratio estimated at 7:1. Children and adults both develop NMO. Unlike MS, NMO is *not* associated with HLA-DRB1*15:01, and it affects those of Asian, African, Hispanic, and Polynesian ancestry disproportionately.

Clinical Presentation

NMO presents clinically as an acute attack of optic neuritis and/or TM; it often takes a relapsing course. Gradually progressive NMO is exceedingly rare (helping to distinguish progressive MS from NMO). Other autoimmune diseases often occur together with NMOSD including Sjögren's syndrome, systemic lupus erythematosus, Hashimoto disease, and myasthenia gravis.

Diagnosis/Differential

In 2004, researchers first reported the presence of a serum IgG autoantibody targeting aquaporin 4 in NMO. NMO-IgG/AQP4-IgG is highly specific (>90%) and moderately sensitive (\approx 75%) for NMOSD. Fulfilling two out of three of the following criteria is reported to be 99% sensitive and 90% specific in the setting of optic neuritis and TM: (1) longitudinally extensive spinal cord lesion, which is greater than or equal to three segments in length (Fig. 122.3); (2) NMO-IgG (anti-AQP4) positivity; and (3) brain MRI not typical or diagnostic for MS.

For a deeper discussion of these topics, please see Chapter 383, "Multiple Sclerosis and Demyelinating Conditions of the Central Nervous System," in *Goldman-Cecil Medicine*, 26th Edition.

Pathology

Histopathologic changes in NMOSD are mostly in the spinal cord and optic nerves; the brain is less involved. Lesions affect both white and gray matter. In the brain, lesions are most common in the hypothalamus and around the fourth ventricle. NMO lesions center on blood vessels where IgG, IgM, and complement activation products are seen. The vessels are abnormally thickened and hyalinized. Active

Fig. 122.3 (A) Sagittal T2w image of the upper spinal cord in a 37-year-old female with NMO. She developed quadriplegia over several days and was AQP4-IgG seropositive. Two years later she had right eye optic neuritis, which left her with visual acuity of only 20/200. The spinal cord lesion (*arrows*) had mild mass effect and was contiguous over six vertebral segments. (B) Sagittal T2w image of the upper spinal cord in a 24-year-old male with MS shows a lesion (*arrow*) in the posterior cord at C2. This patient had moderate vibration loss in the legs but was otherwise asymptomatic.

NMO lesions show infiltration by mononuclear cells (lymphocytes, monocytes), neutrophils, and eosinophils. Older lesions display demyelination, axon loss, and death of oligodendroglia and neurons. Accumulating data indicate that AQP4-IgG itself is pathogenic, causing complement- and antibody-mediated damage.

Treatment

Acute relapses are treated with high-dose corticosteroids. If these are not quickly effective, plasma exchange is performed. Although NMO is rare, several multicenter randomized, controlled trials of disease-modifying therapies have been completed recently with notably positive results.

Eculizumab, a monoclonal antibody that inhibits the complement cascade, was compared to placebo in a randomized, double-blind, multicenter trial in adult NMOSD patients. The trial was stopped early when it showed that relapses occurred in only 3% in the eculizumab group versus 43% in the placebo group (hazard ratio, 0.06; 95% confidence interval, 0.02 to 0.20; $P < 0.001$). Upper respiratory tract infections and headaches were more common in the eculizumab group and a death from pulmonary empyema occurred in this group.

Inebilizumab, a monoclonal antibody to CD19 that depletes B cells, was compared to placebo in adults with NMOSD in a randomized, double-blind, multicenter study. Primary end point was time to onset of an NMOSD attack. This study too was stopped before complete enrollment because of a clear demonstration of efficacy. Twelve percent of 174 participants receiving inebilizumab had an attack versus 39% those receiving placebo (hazard ratio 0.272 [95% confidence interval 0.150 to 0.496]; $P < 0.0001$). Serious adverse effects were no higher in the active treatment group than in the placebo group.

Satralizumab, a monoclonal antibody targeting the IL-6 receptor and thereby inhibiting IL-6 activity, has been reported to show positive results in NMOSD, particularly in those with positive anti-AQP4 antibodies. Notably, beta-interferons are *not* effective for NMOSD and may actually increase the rate of attacks.

Prognosis

NMOSD typically displays worse outcomes than MS. Seropositive NMO patients tend to have more frequent and severe relapses than AQP4-IgG negative patients. The death rate in a retrospective study covering 1950 to 1997 was over 30%. Less than 10% mortality was reported in a more recent retrospective study of Caucasian NMO patients. Death is often due to respiratory failure.

ANTI-MYELIN OLIGODENDROCYTE GLYCOPROTEIN DISORDER

A CNS demyelinating disease identified by its association with serum antibodies to the CNS myelin component, myelin oligodendrocyte glycoprotein (MOG), was recently described. Diagnosis is based on positive serum IgG1 antibodies to MOG using cell-based assays, as well as the absence of anti-AQP4 antibodies, and absence of CSF-restricted oligoclonal bands. Anti-MOG disorder shares features with both MS and classical NMO. Anti-MOG disorder occurs in children and adults and affects males and females in similar proportion. In adults, anti-MOG disorder is often characterized by optic neuritis and transverse myelitis (which may occur separately), but the disease is usually less severe than AQP4 antibody positive NMOSD and is often monophasic. An acute disseminated encephalomyelitis-like presentation is common in children. The spectrum of anti-MOG disorder is still being determined, as is the optimum treatment strategy.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

ADEM is an acute, inflammatory, presumed immune-mediated disorder of the CNS that is encountered primarily in children but may occur in adults. An antecedent viral infection or vaccination is common. ADEM presents with multifocal neurologic symptoms and signs. These can include encephalopathy, which may manifest as reduced level of consciousness (even coma) or as behavioral changes (e.g., confusion or irritability). Fever is common. Seizures, optic neuritis, and spinal cord involvement can all occur. Males and females are about equally affected. ADEM is usually monophasic, although relapsing ADEM has been described. On MRI, both white and gray matter CNS regions are affected. Gray matter involvement can include the basal ganglia, a region not typically affected in MS. The periventricular white matter region is often spared, unlike MS. When present, enhancement with gadolinium occurs in all lesions simultaneously. CSF often shows pleocytosis and an elevated protein but no infection. Findings typical of MS, such as oligoclonal bands, are unusual. No randomized prospective treatment trials for acute disseminated encephalomyelitis are reported. Intravenous methylprednisolone followed by a prednisone taper is typically administered with usually good response. Over 80% of cases recover. Because ADEM is only rarely recurrent, long-term immunomodulatory/immunosuppressive therapy is not indicated. A rare hemorrhagic form of ADEM (Weston Hurst syndrome) is more severe and can lead to death or severe disability.

ACUTE TRANSVERSE MYELITIS

TM is an inflammatory spinal cord syndrome presenting with abrupt or subacute onset of motor and/or sensory loss below a specific spinal level. Control of bladder and bowel is often affected, as is autonomic function below the level. Back pain and paresthesias may be prominent. Many cases of acute TM are idiopathic, but treatable causes must be ruled out. An urgent MRI with and without gadolinium should be obtained to look for compressive etiologies needing immediate treatment. After a compressive etiology has been ruled out, a lumbar puncture to assess CSF for cell count, glucose, and protein and cultures and PCRs for infectious causes should be done. The usual tests for MS should be performed, and CSF should be analyzed for evidence of neoplastic cells. Serum AQP4-IgG, anti-MOG using cell-based assays, paraneoplastic panels, and chest CT should be considered. CSF may also be tested for NMO-IgG, angiotensin converting enzyme, and paraneoplastic antibodies when no etiology is forthcoming.

Acute TM can be the presenting episode for MS (in which case the TM is generally incomplete and asymmetrical) or NMO (where the TM affects ≥ 3 spinal cord segments). Acute TM can also be caused by spinal cord infarction due to occlusion of the anterior spinal artery. Infections by viruses can cause acute or subacute TM. The most common viruses associated with acute TM are varicella zoster, herpes virus type 2, and cytomegalovirus. The retroviruses HTLV-I and HIV can each cause a myelopathy that is usually subacute. West Nile virus can cause a myelopathy that resembles poliomyelitis, with flaccid paralysis due to infection and death of anterior horn cells. Subacute TM may be caused by vitamin B₁₂ or copper deficiency or infiltrating or compressive syndromes such as tumors or abscesses. Nitrous oxide anesthesia can precipitate an acute-onset myelopathy in the case of borderline vitamin B₁₂ deficiency. Rheumatologic disorders such as Sjögren's disease, systemic lupus erythematosus, and Behçet's disease can all cause TM. Paraneoplastic syndromes associated with anti-CRMP-5 and anti-amphiphysin can cause a tract-specific myelopathy. The history and physical examination should be performed with these disorders in mind.

Treatment is determined by the most likely etiology. Idiopathic TM is treated much like TM in MS or NMO, with intravenous methylprednisolone at 500 mg to 1000 mg/day, usually followed by a short oral prednisone taper. When response to intravenous methylprednisolone is suboptimal, plasma exchange should be considered.

IDIOPATHIC ACUTE OPTIC NEURITIS

Inflammatory demyelinating optic neuritis can occur as part of MS or NMO, or as an idiopathic entity. Classically, optic neuritis presents over hours with loss of vision together with pain exacerbated by eye movement. Vision loss may range from subclinical to frank blindness. Color vision and contrast sensitivity are disproportionately affected. On examination, a relative afferent pupillary defect is seen in unilateral optic neuritis. Acute demyelinating optic neuritis is often retrobulbar without papillitis. On MRI, the optic nerve can be swollen and enhance after gadolinium contrast. After recovery from the acute episode, the optic disk may appear pale, and the relative afferent pupillary defect may persist. Transient worsening of vision when the body temperature rises due to exercise or fever (Uhthoff phenomenon) may occur following recovery. The differential diagnosis includes other causes of acute monocular or binocular vision loss, such as Leber hereditary optic neuropathy, giant cell arteritis, and acute nonarteritic anterior ischemic optic neuropathy.

The Optic Neuritis Treatment Trial studied patients with acute optic neuritis (either idiopathic or due to MS) who were randomized to one of three treatments, intravenous methylprednisolone versus oral prednisone taper versus oral placebo. Visual acuity initially recovered faster in the intravenous methylprednisolone group, but by 6 months later there was no difference among the three groups. Recovery of vision was good. Patients from this trial were examined 10 years later and acuity in the affected eyes was 20/20 or better in 74% and less than 20/200 in only 3%. However, recurrence of optic neuritis was common and had occurred in either eye in 35% of the patients. Recurrences were more frequent in those who had MS than in those with idiopathic optic neuritis ($P < .001$).

CHRONIC RELAPSING INFLAMMATORY OPTIC NEUROPATHY

First described in 2003, chronic relapsing inflammatory optic neuropathy (CRION) is an inflammatory optic neuropathy characterized

by acute relapses, often with more severe visual loss than idiopathic optic neuritis or optic neuritis associated with MS. CRION can commence at any age and has been described worldwide. Prevalence rates and epidemiology are still unclear. As in other types of optic neuritis, eye pain at onset is frequent. Five diagnostic criteria for CRION have been suggested: (1) optic neuritis with at least one relapse, (2) visual loss, (3) AQP4-IgG seronegativity, (4) contrast enhancement on MRI of acutely inflamed optic nerve, and (5) response to immunosuppressive treatment and relapse on withdrawal. Other diseases that might present similarly, such as sarcoidosis and giant cell arteritis, should be ruled out. Acute CRION is treated similarly to other causes of optic neuritis, with high-dose methylprednisolone. Relapses are common upon corticosteroid discontinuation. Successful long-term treatment with “steroid sparing” agents such as methotrexate, azathioprine, or mycophenolate mofetil has been reported. The underlying pathology is not yet known, but the disease appears inflammatory based on clinical presentation, imaging, and specific medication response. Eventual visual outcomes are often poor. One report indicated that visual acuity was less than 20/200 in one third of CRION patients.

Neuromuscular Diseases: Disorders of the Motor Neuron and Plexus and Peripheral Nerve Disease

Carlayne E. Jackson, Ratna Bhavaraju-Sanka

INTRODUCTION

Neuromuscular diseases are classified into four groups, according to which portion of the motor unit is involved (Table 123.1). Motor neuron and peripheral nerve diseases are considered in this chapter; myopathies are considered in Chapter 124, and neuromuscular junction diseases are considered in Chapter 125. The symptoms and signs of the neuromuscular diseases are at times indistinguishable. However, some useful general rules apply to assist with localization based on the distribution of weakness, presence or absence of sensory symptoms, reflex abnormalities, and specific associated clinical features (Table 123.2).

Electromyography and Nerve Conduction Studies

Electromyography (EMG) and nerve conduction studies can also be useful diagnostic tools in localizing the lesion in a patient with a suspected neuromuscular disease. The measurement of electrical activity arising from muscle fibers is performed by inserting a needle electrode percutaneously into a muscle. Normal muscle is electrically silent at rest. Spontaneous activity during complete relaxation occurs in myotonic disorders, in inflammatory myopathies, and in denervated muscles. Spontaneous activity of a single muscle fiber is called a *fibrillation*, and such activity of part of or an entire motor unit is called a *fasciculation*. In myotonia, repeated muscle depolarization and contraction occur despite voluntary relaxation. Abnormalities in motor unit potentials occur during the course of denervation; with the development of reinnervation, the remaining motor units increase in amplitude and become longer in duration and polyphasic (E-Fig. 123.1). Conversely, in muscle diseases such as the muscular dystrophies and other diseases that destroy scattered fibers within a motor unit, the motor unit action potentials are of lower amplitude and shorter duration and are polyphasic. A reduced recruitment (interference) pattern from maximum voluntary effort occurs in denervation. Conversely, in patients with primary muscle disease, submaximal voluntary effort produces a full recruitment pattern despite marked weakness.

Nerve conduction is studied by stimulating a peripheral nerve (e.g., the ulnar) with surface electrodes placed over the nerve or muscle. The resulting action potential is recorded by electrodes placed over the nerve more proximally in the case of large sensory nerve fibers and over the muscle distally in the case of motor nerve fibers in a mixed motor sensory nerve. For sensory nerves, the sensory nerve action potential (SNAP) is quantitated, and for motor nerves, the compound muscle action potential (CMAP) is quantitated. Abnormalities in sensory and motor nerve studies are suggestive of a peripheral neuropathy while abnormalities in motor nerve studies with normal sensory studies can indicate a myopathy, motor neuronopathy, pure motor neuropathy or radiculopathy.

DISEASES OF THE MOTOR NEURON (ANTERIOR HORN CELL)

Amyotrophic Lateral Sclerosis

Definition and Epidemiology

The most common *acquired* motor neuron disease, amyotrophic lateral sclerosis (ALS), is a progressive, typically fatal disorder. The incidence is approximately 2 to 5 per 100,000 population, and there is a slight male predominance. The peak age of onset is in the sixth decade, although the disease can occur at any time throughout adulthood. The cumulative lifetime risk is about 1 in 400. Epidemiologic studies have incriminated risk factors for ALS including exposure to insecticides, smoking, participation in varsity athletics, and military service in the Gulf War. The cause of ALS is largely unknown, with 95% of cases considered “sporadic,” and 5% related to an autosomal dominant disease (familial ALS [FALS]). FALS is an adult-onset disease that is clinically and pathologically indistinguishable from sporadic ALS. FALS is caused by mutations in many genes, including the *C9orf72*, *SOD1*, *TARDBP*, *FUS*, *ANG*, *ALS2*, *SETX*, and *VAPB* genes. Mutations in the *C9orf72* gene are responsible for 30% to 45% of FALS in the United States and Europe. Mutations in *C9orf72* also cause sporadic ALS (E-Table 123.1).

Pathology

ALS results from degeneration of the cortical motor neurons originating in layer five of the motor cortex and descending via the pyramidal tract (resulting in upper motor neuron signs and symptoms) and from degeneration of the anterior horn cells in the spinal cord and their brain stem homologues innervating bulbar muscles (resulting in lower motor neuron signs and symptoms) (Table 123.3).

Clinical Presentation

Clinical symptoms relating to the upper motor neuron degeneration include loss of dexterity, slowed movements, muscle weakness, stiffness, and emotional lability. Signs on neurologic examination that confirm an upper motor neuron lesion include pseudobulbar affect, pathologic hyperreflexia, spasticity, and extensor plantar responses (Babinski sign). Lower motor neuron signs and symptoms caused by anterior horn cell degeneration include weakness, muscle atrophy, fasciculations, and cramps. Fasciculations in the absence of associated muscle atrophy or weakness are usually benign and may be aggravated by sleep deprivation, stress, and excessive caffeine ingestion. Muscle weakness in patients with ALS usually begins distally and asymmetrically and may manifest as a monoparesis, hemiparesis, paraparesis, or quadriplegia. It may also be limited initially to the bulbar region, resulting in difficulty with swallowing, speech, and movements of the

face and tongue. For unclear reasons, ocular motility is spared until the very late stages of the illness. Bowel and bladder function and sensation remain spared throughout the course of the disease although patients may develop symptoms of bladder urgency. Up to 60% of patients with ALS may also have a component of frontotemporal dementia characterized by executive dysfunction, poor insight, personality changes (disinhibition, impulsivity, apathy), abnormal eating habits, poor hygiene, and language dysfunction.

Diagnosis/Differential

The diagnosis of ALS remains one of “exclusion,” in which other potential causes must be ruled out through a variety of neuroimaging, laboratory, and electrodiagnostic investigations (E-Table 123.2). For example, compression of the cervical spinal cord or cervicomedullary junction from tumors or cervical spondylosis can produce weakness,

atrophy, and fasciculations in the upper extremities and spasticity in the lower extremities, closely resembling ALS.

Treatment

Specialized multidisciplinary clinic referral should be considered for patients with ALS to optimize health care delivery and prolong survival. The first US Food and Drug Administration (FDA)–approved therapy for ALS was riluzole 50 mg twice per day, which in clinical trials prolonged survival by 2 to 3 months. The mechanism of this effect is not known with certainty; however, riluzole may reduce excitotoxicity by diminishing presynaptic glutamate release. Edaravone was also recently FDA approved based on studies suggesting a slowing of the rate of functional decline by 33% (measured by the ALS Functional Rating Scale-Revised). Initiation of noninvasive ventilation (NIV) on a spontaneous timed mode has also been shown to prolong survival up to 20 months, to slow the rate of forced vital capacity (FVC) decline (level B) and to improve quality of life. NIV should be initiated when the FVC is less than 50%, the maximal inspiratory pressure is less than –60 cm, or when patients report symptoms that suggest nocturnal hypoventilation (daytime fatigue, frequent arousals, supine dyspnea, morning headaches). A cough-assist device can be used to assist with clearing upper airway secretions and has been shown to minimize the risk of pneumonia in clinical trials. A percutaneous gastrostomy (PEG) tube should be considered for prolonging survival and stabilizing body weight in patients with impaired oral food intake. Symptomatic therapy for spasticity, pseudobulbar affect, muscle cramping, and sialorrhea is also essential in maintaining patient dignity and quality of life (Table 123.4). Augmentative speech devices can assist patients with communication and computer access.

TABLE 123.1 Classification of Neuromuscular Diseases

Site of Involvement	Typical Examples
Anterior Horn Cell	
Without upper motor neuron involvement	Spinal muscular atrophy Progressive muscular atrophy Bulbospinal muscular atrophy Poliomyelitis West Nile virus
With upper motor neuron involvement	Amyotrophic lateral sclerosis Primary lateral sclerosis
Peripheral Nerve	
Mononeuropathy	Carpal tunnel syndrome Ulnar palsy Meralgia paresthetica
Multiple mononeuropathies	Mononeuritis multiplex (e.g., polyarteritis nodosa), leprosy, sarcoidosis, amyloidosis
Polyneuropathies	Diabetic neuropathy Charcot-Marie-Tooth disease Gullain-Barré syndrome
Neuromuscular Junction	
	Myasthenia gravis Lambert-Eaton syndrome
Muscle	
	Duchenne muscular dystrophy Dermatomyositis

TABLE 123.3 Symptoms and Signs Associated With Amyotrophic Lateral Sclerosis

Symptoms	Signs
Upper Motor Neuron Degeneration	
Loss of dexterity	Pathologic hyperreflexia
Slowed movements	Babinski response
Weakness	Hoffman response
Stiffness	Jaw jerk
Pseudobulbar affect	Spasticity
Lower Motor Neuron Degeneration	
Weakness	Muscle atrophy
Fasciculations	Fibrillation potentials on electromyography
Cramps	Neurogenic atrophy on muscle biopsy

TABLE 123.2 Clinical Features of the Neuromuscular Diseases

Clinical Feature	Anterior Horn Cell	Peripheral Nerve	Neuromuscular Junction	Muscle
Distribution of weakness	Asymmetrical limb or bulbar	Symmetrical, usually distal	Extraocular, bulbar, proximal limb	Symmetrical, proximal limb
Atrophy	Marked and early	Mild, distal	None (or very late)	Slight early; marked later
Sensory involvement	None	Dysesthesias, loss of sensation	None	None
Reflexes	Variable (depending on degree of upper motor neuron involvement)	Decreased out of proportion to weakness	Normal in myasthenia gravis, depressed in Lambert-Eaton syndrome	Decreased in proportion to weakness
Characteristic features	Fasciculations, cramps	Combined sensory and motor abnormalities	Fatigability	Usually painless

E-Fig. 123.1 Motor unit potentials. The shaded muscle fibers are functional members of the motor unit; the axon, which enters from the upper left, branches terminally to innervate the appropriate muscle fibers. The motor unit action potential produced by each motor unit is seen at the upper right; its duration is measured between the two small vertical lines. The normal-appearing but unshaded fibers belong to other motor units. (A) The normal situation, with five muscle fibers in the active unit. (B) In this myopathic unit, only two fibers remain active; the other three (shrunken and unshaded) have been destroyed by a muscle disease. (C) Four fibers that belonged to other motor units and had been denervated have now been reinnervated by terminal axon sprouting from the healthy motor unit. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another. (From Griggs RC, Bradley WG: Approach to the patient with neuromuscular disease. In Isselbacher KJ, Braunwald E, Wilson JD, et al, editors: Harrison's textbook of internal medicine, ed 13, New York, 1994, McGraw-Hill, p 2364.)

E-TABLE 123.1 Hereditary Motor Neuron Diseases

	Locus	Gene
Autosomal Dominant		
ALS 1	21q	Superoxide dismutase
ALS 4	9q34	Senataxin
ALS 6	16p11	<i>FUS</i>
ALS 8	20q	Vesicle-associated protein B
ALS 9	14q11	Angiogenin
ALS 10	1p36	<i>TDP-43</i>
ALS 11	6q21	<i>FIG4</i>
ALS 12	10p15	<i>OPTN</i>
ALS 13	12q24	Ataxin-2

E-TABLE 123.2 Differential Diagnosis and Diagnostic Evaluation for Patients With Suspected Motor Neuron Disease

Differential Diagnosis	Diagnostic Evaluation
Toxins—Lead, Mercury	24-hr urine collection for heavy metals
Metabolic Disorders	
Hypoglycemia	Serum chemistry
Hyperparathyroidism	Parathyroid hormone level, calcium
Hyperthyroidism	Thyroid function studies
Paraneoplastic Disorder	MRI scan, anti-Hu antibody
Immunologic Mechanism	Complete blood count, sedimentation rate, anti-nuclear antibody, rheumatoid factor, serum protein electrophoresis, anti-GM1 antibodies
Vitamin/Mineral Deficiencies	Copper, vitamin B ₁₂ , folate levels
Bacterial/Viral Infection	HIV, HTLV-1, Lyme titers, CSF exam/culture
Structural Lesion	
Cervical spondylosis	MRI of brain and cervical spine
Chiari malformation or syrinx	
Spinal cord arteriovenous malformation	
Parasagittal or foramen magnum tumor	

TABLE 123.4 Symptom Management for Motor Neuron Diseases**Respiratory Insufficiency**

Noninvasive ventilation
Cough-assist devices

Dysarthria

Augmentative speech device

Dysphagia

Percutaneous endoscopic gastrostomy (PEG) placement
Suction machine

Sialorrhea

Amitriptyline 25-75 mg qhs
Glycopyrrolate 1-2 mg q8h
Botulinum toxin

Spasticity

Baclofen 10-20 mg QID
Dantrium 25-100 mg QID

Pseudobulbar Affect

Serotonin reuptake inhibitors
Amitriptyline 25-75 mg QHS
Dextromethorphan/quinidine 20/10 mg BID

Weakness

Ankle-foot orthosis
Wheelchair
Elevated toilet seat

Prognosis

Mean survival from onset of symptoms is 2 to 5 years, with 10% of patients surviving beyond 10 years. The majority of deaths are related to respiratory muscle failure and aspiration pneumonia.

Other Acquired Motor Neuron Diseases

Other motor neuron diseases involve only particular subsets of motor neurons (Table 123.5). Progressive muscular atrophy (PMA) is a pure lower motor neuron disease that accounts for 8% to 10% of patients with motor neuron disease. Weakness is typically distal and asymmetrical, and bulbar involvement is rare. Patients with PMA generally have a better prognosis than those with ALS, with a survival of 3 to 14 years. Primary lateral sclerosis (PLS) is a pure upper motor neuron syndrome in which patients demonstrate either a slowly progressive spastic paralysis or dysarthria. This is a rare disorder, accounting for 2% of all motor neuron cases. Survival is generally years to decades.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a hereditary form of motor neuron disease in which only the lower motor neuron is affected. It is an autosomal recessive disorder that may begin in utero, in infancy, in childhood, or in adult life and represents the first class of neurologic disorders in which a developmental defect in neuronal apoptosis most likely produces the disease. The most common forms of SMA are due to a defect in the survival motor neuron 1 (*SMN1*) gene localized to 5q11.2-q13.3. All affected individuals with SMA have mutations in both copies of the *SMN1* gene causing little or no SMN (survival motor neuron) protein production from this gene. The *SMN2* gene can help replace some of the missing SMN protein. Patients who have multiple copies of the *SMN2* gene are usually associated with later onset and less severe disease. Nusinersen was recently approved for intrathecal use and has been shown to significantly slow functional decline and increase life expectancy. It is an antisense oligonucleotide targeted to increase the proportion of *SMN2* mRNA transcripts, leading to

Spinal muscular atrophy
Type I: Infantile onset (Werdnig-Hoffmann disease)
Type II: Late infantile onset
Type III: Juvenile onset (Kugelberg-Welander disease)

^aItalicized disorders are hereditary.

translation of more full-length SMN protein. In May of 2019 the FDA also approved onasemnogene abeparvovec-xioi (Zolgensma), the first gene therapy to treat children less than 2 years of age with SMA.

Bulbospinal muscular atrophy (BSMA) or Kennedy disease is an X-linked recessive disorder in which the mean age at onset is 30 years; the range is from 15 to 60 years. BSMA is a trinucleotide repeat disorder with a CAG expansion encoding for a polyglutamine tract in the first exon of the androgen receptor gene, on chromosome Xq11-12. The mechanism by which disruption of the androgen receptor gene alters the function of bulbar and spinal motor neurons is not known. An inverse correlation exists between the number of CAG repeats and the age of onset of the disease. Affected individuals exhibit chin fasciculations, midline furrowing and atrophy of the tongue, and proximal weakness. Dysphagia and dysarthria are common, and up to 90% of patients demonstrate gynecomastia and infertility. Two findings distinguishing this disorder from ALS are the absence of upper motor neuron signs and in some patients the presence of a subtle sensory neuropathy.

DISORDERS OF THE BRACHIAL AND LUMBOSACRAL PLEXUS

The roots within the cervical, lumbar, and sacral regions organize into the cervical, lumbar, and sacral plexuses before giving rise to individual peripheral nerves. Diseases of these plexuses (plexopathies) tend to be *focal* in symptoms and signs, whereas many diseases of the peripheral nerves and muscles are *generalized*.

Brachial Plexopathy

The brachial plexus is constituted by mixed nerve roots from C5 to T1 that fuse into upper, middle, and lower trunks above the level of the clavicle and redistribute into lateral, posterior, and medial cords below that landmark (E-Fig. 123.2). Symptoms include weakness, pain, and sensory loss in the shoulders or arms. Upper trunk lesions may be due to birth injury, trauma, and idiopathic brachial plexitis (see later). Lower trunk lesions may result from birth injury, malignant tumor invasion, thoracic outlet syndrome, or as a complication of sternotomy. If the entire plexus is involved, radiation injury, trauma, and late metastatic disease are the most common causes.

E-Fig. 123.2 The brachial plexus is comprised of mixed nerve roots from C5 to T1 that fuse into upper, middle, and lower trunks above the level of the clavicle and redistribute into lateral, posterior, and medial cords. (From Morton D, Peterson KD, Albertine KH: *Gray's dissection guide for human anatomy*, ed 2, Philadelphia, 2006, Churchill Livingstone.)

Acute Autoimmune Brachial Neuritis

Acute autoimmune brachial neuritis (or neuralgic amyotrophy or Parsonage-Turner syndrome) is characterized by the abrupt onset of severe pain, usually over the lateral shoulder, but at times extending into the neck or entire arm. The acute pain generally subsides after a few days to a week; by this time, weakness of the proximal arm becomes apparent. The serratus anterior, deltoid, and supraspinatus are the most commonly affected muscles, but other muscles of the shoulder girdle may also be affected. In rare cases, most of the patient's arm and even the ipsilateral diaphragm are involved. Sensory loss is usually slight and generally involves the axillary nerve distribution. Weakness lasts weeks to months and will be accompanied by severe atrophy of the shoulder girdle. No therapy has been shown to alter or shorten the clinical course, although steroids and analgesics may reduce pain. Most patients recover within several months to 3 years. The disorder frequently follows an upper respiratory infection or an immunization, but in many instances no antecedent illness occurs. It is bilateral in one third of cases but is always asymmetrical; it may recur in 5% of patients. Recurrent brachial plexopathies that are painless may be related to an autosomal dominant disorder with mutation in the *SEPTIN9* gene on chromosome 17q25 or hereditary neuropathy with liability to pressure palsies (HNPP), caused by a deletion or point mutation of PMP-22 protein (chromosome 17p).

Lumbosacral Plexopathy

The lumbosacral plexus is formed from the ventral rami of spinal nerves T12 to S4. These divide within the plexus into ventral and dorsal branches that form the femoral, sciatic, and obturator nerves. The plexus is located within the substance of the psoas major muscle. Clinical features include proximal pain and weakness in anterior thigh muscles (femoral) or posterior thigh muscles and the buttocks. Bowel and bladder dysfunction may also occur. Diabetes, malignant invasion, radiation therapy, infection (herpes zoster), psoas abscess, trauma, and retroperitoneal hemorrhage are common causes. An autoimmune form is much less frequent than brachial neuritis.

DISORDERS OF THE PERIPHERAL NERVES

Definition and Epidemiology

Peripheral neuropathy refers to a large group of disorders that can produce focal (mononeuropathy or multiple mononeuropathies) or generalized nerve dysfunction (polyneuropathies) (Table 123.6). Peripheral neuropathies are prevalent neurologic conditions, affecting 2% to 8% of adults, with the incidence increasing with age. They range in severity from mild sensory abnormalities, found in up to 70% of patients with long-standing diabetes, to fulminant, life-threatening paralytic disorders such as Guillain-Barré syndrome (GBS) or acute inflammatory demyelinating polyradiculoneuropathy (AIDP).

Mononeuropathies are disorders in which only a single peripheral nerve is affected. The most common cause is nerve entrapment such as median nerve compression resulting in carpal tunnel syndrome or peroneal nerve injury causing foot drop (Table 123.7). When more than one peripheral nerve is involved, the term *mononeuropathy multiplex* or *multiple mononeuropathies* is often used. Multiple mononeuropathies are most commonly seen in diabetes mellitus and vasculitis but also occur in leprosy, vasculitis, sarcoidosis, hereditary neuropathy with predisposition to pressure palsies, and amyloidosis.

Polyneuropathies are a group of disorders affecting the motor, sensory, and autonomic nerves. These disorders may predominantly affect the nerve axon (axonal neuropathies), myelin sheath (demyelinating neuropathies), or the small- to medium-sized blood vessels supplying

TABLE 123.6 Classification and Causes of Peripheral Neuropathy

Type of Neuropathy	Examples
Mononeuropathies	
Compressive	Carpal tunnel syndrome, ulnar palsy
Hereditary	Hereditary neuropathy with predisposition to pressure palsies
Inflammatory	Bell's palsy
Multiple mononeuropathies	Vasculitis (mononeuritis multiplex), diabetes, leprosy, sarcoidosis, amyloidosis
Polyneuropathies	
Hereditary	Charcot-Marie-Tooth disease, familial amyloid polyneuropathy
Endocrine	Diabetes, hypothyroidism
Metabolic	Uremia, liver failure
Infections	Leprosy, diphtheria, human immunodeficiency virus, Lyme disease
Immune mediated	Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy
Toxic	Lead-, arsenic-, alcohol-, drug-induced
Paraneoplastic	Lung cancer

the nerves (vasculitic neuropathies). The clinical features of the polyneuropathies reflect the pathology of the underlying process.

Pathology

In the symmetrical *axonal* polyneuropathies, the underlying pathology is usually a slowly evolving type of axonal degeneration that involves the ends of long nerve fibers first and preferentially. With time, the degenerative process involves more proximal regions of long fibers, and shorter fibers are affected. This pattern of distal axonal degeneration or *dying back* of nerve fibers results from a wide variety of metabolic, toxic, and endocrinologic causes.

In the *demyelinating* polyneuropathies, the underlying pathology involves the myelin sheath. Demyelination of a peripheral nerve at even a single site can block conduction, resulting in a functional deficit identical to that seen after axonal degeneration. In contrast to repair by regeneration, however, repair by remyelination can be rapid. Autoimmune attack on the myelin sheath occurs in the inflammatory demyelinating neuropathies (GBS/AIDP and chronic inflammatory demyelinating polyneuropathy [CIDP]) and some neuropathies associated with paraproteinemias (see later). Inherited disorders of myelin such as Charcot-Marie-Tooth (CMT) disease comprise the other major category of demyelinating neuropathies. Other causes include toxic, mechanical, and physical injuries to nerves. Although these examples have nearly pure demyelination, many neuropathies have both axonal degeneration and demyelination. This mixed pathologic abnormality reflects the mutual interdependency of the axons and the myelin-forming Schwann cells. Vasculitic neuropathies occur as a result of disease of the small or medium-sized blood vessels that leads to ischemia and infarction of isolated peripheral nerves. The term *mononeuritis multiplex* is also used to describe this clinical situation, in which there is multifocal involvement of individual nerves.

Clinical Presentation

The clinical picture of an *axonal* polyneuropathy includes early loss of muscle stretch reflexes at the ankle and weakness that initially involves the intrinsic muscles of the feet, the extensors of the toes, and the dorsiflexors at the ankle. The motor signs are usually mild in

TABLE 123.7 Common Mononeuropathies

	Precipitating Factors	Motor Signs and Symptoms	Sensory Signs and Symptoms	Treatment
Median Nerve Entrapment at the wrist (carpal tunnel syndrome)	Repetitive wrist flexion or sleep	Weakness in thenar muscle	Numbness, tingling, and/or pain in thumb, index finger, middle finger, and medial half of ring finger. Tinel and Phalen signs	Neutral wrist splint, carpal tunnel injections or surgery
Ulnar Nerve Entrapment at the elbow	External compression in condylar groove, fracture of humerus	Weakness or atrophy of the interossei and thumb adductor	Sensory loss in the little finger and contiguous half of the ring finger	Elbow pads; ulnar nerve transposition or decompression of cubital tunnel
Radial Nerve Entrapment at the spiral groove	Prolonged sleeping on arm after drinking excessive amounts of alcohol: "Saturday night palsy"	Wrist drop with sparing of elbow extension; weakness of finger and thumb extensors	Sensory loss on dorsum of hand	Spontaneous recovery; wrist splint
Femoral Nerve	Abdominal hysterectomy, hematoma, prolonged lithotomy position, diabetes	Weakness and atrophy of quadriceps	Sensory loss in anterior thigh and medial calf	Physical therapy
Lateral Femoral Cutaneous Nerve Meralgia paresthetica	Obesity, pregnancy, diabetes, constrictive belts	None	Sensory loss, pain, or tingling over anterolateral thigh	Weight loss; spontaneous recovery
Peroneal Nerve Entrapment at the fibular head	Habitual leg crossing, knee casts, prolonged squatting, profound weight loss	Weakness of ankle dorsiflexors or evertors and toe extensors	Sensory loss in anterolateral leg and dorsum of foot	Ankle-foot orthosis; remove source of compression
Sciatic Nerve	Injection injury, fracture or dislocation of hip	Weakness of hamstrings, ankle plantar flexors or dorsiflexors	Sensory loss in buttock, lateral calf, and foot	Ankle-foot orthosis; physical therapy
Tibial Nerve Entrapment in tarsal tunnel	External compression from tight shoes, trauma, tenosynovitis	None	Sensory loss and tingling in sole of foot	Tarsal tunnel injection, eliminate source of compression, medial arch support

contrast to the sensory abnormalities, which may include numbness, tingling, and burning sensations (dysesthesias). The sensory symptoms usually begin symmetrically in the toes and feet and then ascend proximally to the legs in a "stocking" distribution. When the sensory abnormalities reach the level of the knees, the symptoms begin in the hands, in a "glove" distribution. Truncal and abdominal dysesthesias may develop once the sensory abnormalities ascend to the level of the elbows.

The prominent clinical feature of an acquired *demyelinating* polyneuropathy is weakness that affects not only the distal muscles but also the proximal and facial muscles. Unlike in an axonal neuropathy, sensory loss is rarely the presenting symptom. Patients generally have diffuse hyporeflexia or areflexia.

Vasculitic neuropathies typically present with acute or subacute asymmetrical, predominantly distal weakness and sensory loss associated with severe pain.

Diagnosis/Differential

Neuropathic disorders can be broadly divided into those that are acquired and those that are hereditary (Table 123.8). Acquired disorders are the more common and have many causes: metabolic or endocrine disorders (diabetes mellitus, renal failure, porphyria); immune-mediated disorders (GBS, CIDP, multifocal motor neuropathy, anti-myelin-associated glycoprotein neuropathy); infectious causes (human immunodeficiency virus [HIV], Lyme disease, cytomegalovirus [CMV], syphilis, leprosy, diphtheria); medications (HIV drugs, chemotherapies); environmental toxins (heavy metals); or paraneoplastic processes. Diabetes mellitus and alcoholism are the most common causes of polyneuropathy in developed countries. As many as one third of acquired neuropathies are cryptogenic in which the etiology can never be identified. Causes of mononeuritis multiplex include systemic vasculitis (rheumatoid arthritis, systemic lupus erythematosus, Wegener granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa) and primary peripheral system vasculitis (25% of cases).

TABLE 123.8 Hereditary Neuropathic Disorders

	Inheritance Pattern	Genetic Defect	Clinical Features
Hereditary sensorimotor neuropathies	AR, AD, or X-linked	See E-Table 123.4	Pes cavus, distal atrophy and weakness, hammer toes
Familial amyloid polyneuropathy	AD	Transthyretin Gelsolin Apolipoprotein A1	Pain, autonomic dysfunction, carpal tunnel syndrome, heart failure.
Fabry disease	X-linked	α -Galactosidase	Cardiac ischemia, renal disease, stroke, cutaneous angiokeratomas, cornea verticillata
Tangier disease	AR	Apolipoprotein A	Low HDL levels, orange tonsils
Refsum disease	AR	Phytanic acid oxidase	Retinitis pigmentosa, cardiomyopathy, deafness, ichthyosis

AD, Autosomal dominant; AR, autosomal recessive; HDL, high-density lipoprotein.

TABLE 123.9 Differential Diagnosis of Neuropathic Disorders Based on Symptoms

Motor Symptoms Only	Sensory Symptoms Only	Autonomic Symptoms
Porphyria	Cryptogenic sensory polyneuropathy	Amyloid neuropathy
Charcot-Marie-Tooth	Metabolic, drug-related, or toxic neuropathy	Diabetic neuropathy
Chronic inflammatory demyelinating polyneuropathy	Paraneoplastic sensory neuropathy	Fabry disease
Guillain-Barré syndrome		Guillain-Barré syndrome
Lead neuropathy		Hereditary sensory or autonomic neuropathy
Motor neuron disease		Porphyria

Because of the many causes, it is important to approach the patient with neuropathy systematically, beginning with the patient's history and physical examination. It is essential to determine which nerves are involved (motor, sensory, or autonomic) and in what specific combination (Table 123.9). Small-fiber neuropathies often manifest with unpleasant or abnormal sensations such as a burning pain, electric shock-like sensations, cramping, tingling, pins and needles, or prickly feelings such as the limb "feeling asleep." Large-fiber neuropathies can manifest as numbness, tingling, or as gait ataxia. Symptoms suggesting motor nerve involvement include muscle weakness that typically involves the distal foot muscles. Autonomic nerve involvement is suggested by symptoms of orthostatic hypotension, impotence, cardiac arrhythmia, or bladder dysfunction.

The distribution of muscle weakness is important. In axonal neuropathies, the weakness predominantly involves the distal lower extremity muscles, and in demyelinating neuropathies the weakness can involve both proximal and distal muscles as well as facial muscles. Most neuropathies result in *symmetrical* weakness. If asymmetry is present, motor neuron disease, radiculopathy, plexopathy, compressive mononeuropathies, or mononeuritis multiplex should be considered. The intensity and distribution of painful dysesthesias can also be informative. Although many axonal neuropathies are associated with a burning sensation in the feet, pain as the chief complaint suggests specific causes of neuropathy (Table 123.10). A neuropathy that manifests with acute, asymmetrical weakness and severe pain suggests vasculitis.

In patients with severe, asymmetrical proprioceptive deficits, with sparing of motor function, the site of the lesion is usually the sensory neuron/dorsal root ganglion. This specific syndrome has a relatively limited differential diagnosis, including paraneoplastic process with anti-Hu antibodies, Sjögren's syndrome, cisplatin toxicity, vitamin B₆ toxicity, and HIV infection.

Most neuropathies are relatively insidious in onset, particularly those associated with metabolic or endocrine disorders. Acute neuropathies may be caused by a vasculitic process, toxin exposure, porphyria, or GBS. GBS

is commonly preceded by a viral illness, immunization, or a surgical procedure. The neurologic history must thoroughly explore potential toxic exposures such as prior medications and alcohol use (E-Table 123.3).

Because many neuropathies are hereditary, it is essential to obtain a detailed family history, specifically inquiring about a history of gait instability, use of adaptive equipment, or skeletal deformities of the feet. Hereditary neuropathies may be autosomal recessive, autosomal dominant, or X-linked. In some situations, it may be helpful to actually examine family members because the severity of disease may vary considerably from one generation to the next. The most common hereditary neuropathy is Charcot-Marie-Tooth disease (see later).

A complete neurologic examination should always be performed in a patient complaining of numbness. If the patient shows evidence of upper motor neuron involvement in addition to the sensory loss, vitamin B₁₂ or copper deficiency should be considered, even in the absence of apparent anemia. An elevated methylmalonic acid or homocystine level can also help confirm the diagnosis of B₁₂ deficiency in patients

E-TABLE 123.3 Etiology of Neuropathic Disorders: Toxic Agents

AXONAL			DEMYELINATING	MIXED
Sensory	Sensory & Motor	Motor		
Chloramphenicol	Acrylamide	β -bungarotoxin	Buckthorn	Amiodarone
Doxorubicin	Alcohol (Ethanol)	Botulism	Chloroquine	Diethylene glycol
Ethambutol	Allyl chloride	Gangliosides	Diphtheria	Ethylene glycol
Ethionamide	Arsenic	Latrotoxin	FK506 (Tacrolimus)	l,l'-Ethylidenebis (tryptophan)
Etoposide (VP-16)	Carbon disulfide	Black widow	Hexachlorophene	Gold Hexacarbons
Flecainide	Chlorophenoxy	Lead	Procainamide	n-Hexane

	Vinca alkaloids			

TABLE 123.11 Peripheral Neuropathy Laboratory Studies

Standard Tests	Tests Indicated in Selected Cases
B ₁₂	Anti-Hu antibody
Complete blood count (CBC)	ESR, ANA, RF, SS-A, SS-B
Glucose tolerance test	Genetic studies for Charcot-Marie-Tooth
RPR	Human immunodeficiency virus (HIV)
Chem 20	Lyme antibody
Serum protein electrophoresis (SPEP) and immunofixation electrophoresis (IFE)	Phytanic acid Copper level
Thyroid function tests	24-hr urine for heavy metals
Nerve conduction studies or electromyogram (EMG)	Quantitative sensory testing Lumbar puncture Nerve biopsy Skin biopsy Tilt table testing

with borderline levels. The presence of weakness and upper motor neuron signs without associated sensory loss suggests ALS.

If the neuropathy is associated with mental status abnormalities, then pyridoxine intoxication or deficiencies of thiamine, niacin (“dementia, diarrhea, dermatitis”), and vitamin B₁₂ should be considered in the differential diagnosis. Lyme disease (see [Chapter 90](#)) may result in both peripheral nervous system symptoms (facial nerve palsies, paresthesias, weakness) and central nervous system symptoms (dementia, headache). Acquired immunodeficiency syndrome (AIDS) can also affect both the central and the peripheral nervous systems. GBS and CIDP usually occur at the time of HIV seroconversion, whereas sensory neuropathy, mononeuritis multiplex, and CMV polyradiculopathy generally occur in the context of low CD4 counts in the later stages of the disease. Older antiretroviral drugs (e.g., stavudine) were associated with a significant rate of neuropathy.

Once a preliminary differential diagnosis is developed based on the history and neurologic examination findings, laboratory studies can confirm the diagnosis. Laboratory tests to identify potentially treatable causes of neuropathy are included in [Table 123.11](#). Additional studies can be ordered based on the suspected diagnosis. An impaired glucose tolerance test is found in more than half of patients with cryptogenic sensory peripheral neuropathy and is more sensitive than tests of fasting glucose or hemoglobin A_{1c} (HbA_{1c}). In a patient with acute, asymmetrical weakness and sensory loss, screening for an inflammatory process (ESR, ANA, RA, SS-A, SS-B) is appropriate. In addition, genetic testing is now available for most patients with CMT disease. If a monoclonal protein is identified on serum protein electrophoresis, a skeletal survey, urine immunofixation electrophoresis, and bone marrow biopsy should be ordered to rule out an underlying lymphoproliferative disorder. If the patient has a monoclonal protein associated with autonomic dysfunction, congestive heart failure, or renal insufficiency, a biopsy (rectal, abdominal fat, or sural nerve) should be considered for diagnosis of amyloidosis. Amyloidosis can be acquired or familial with mutations in the transthyretin (TTR) gene. CIDP can be associated with a monoclonal gammopathy, and in this situation patients should be treated with immunosuppressive therapy. Monoclonal gammopathies observed in patients with an axonal peripheral neuropathy are frequently benign (monoclonal gammopathy of unknown significance) and do not necessarily warrant therapy.

A lumbar puncture is indicated only if an acquired demyelinating neuropathy such as GBS or CIDP is being considered. In these cases,

one expects to find an “albuminocytologic dissociation” with an elevation in cerebrospinal fluid (CSF) protein and a relatively normal white blood cell (WBC) count. If the CSF WBC count is greater than 50, Lyme disease, HIV-associated disease, or a paraneoplastic process must be considered.

Electrodiagnostic studies consisting of nerve conduction testing and EMG can be a helpful extension of the physical examination. These studies are useful in defining whether the neuropathic process is caused by a primarily axonal or demyelinating process. In general, axonal degeneration decreases the amplitude of the compound muscle action potential out of proportion to the degree of reduction in peripheral nerve conduction velocity, whereas demyelination produces prominent reduction in conduction velocities. Nerve conduction testing can help determine, in the case of a demyelinating neuropathy, whether the process has an acquired or hereditary cause. A uniform slowing of nerve conduction usually suggests a hereditary cause while focal demyelination causing conduction block suggests an acquired demyelinating neuropathy. Electrodiagnostic studies can identify subclinical neuropathy (in patients receiving potentially neurotoxic medications) and can quantitate the extent of axon loss. Finally, these studies can localize the lesion in the case of radiculopathies, dorsal root ganglionopathies, plexopathies, and multiple mononeuropathies.

Sensory nerve biopsies should be obtained for diagnosis of a vasculitic neuropathy because treatment involves potentially toxic medications. Performing a muscle biopsy in addition to the nerve biopsy may improve the diagnostic yield and should be considered because the inflammation is random and focal and easily missed. Nerve biopsies are not indicated in “cryptogenic” neuropathies, diabetic neuropathy, or motor neuron disease. If nerve conduction studies are normal, skin biopsies allow quantification of the number of intraepidermal nerve fibers. A length-dependent decrease in the number of these fibers can help confirm a small-fiber neuropathy.

Treatment

Despite a very thorough history, examination, and laboratory studies, the cause of as many as one third of neuropathies remains unknown. In this situation, the focus of management is pain control. Patients with neuropathy frequently report a burning, searing, and aching sensation in their feet and hands that interferes with sleep. Neuropathic pain is difficult to treat but may respond to various medications having different mechanisms of action ([Table 123.12](#)). It is important to “start low and taper slow” and to treat for a minimum of 4 weeks before concluding that an agent is ineffective. In patients with a vasculitic neuropathy, therapy with corticosteroids in addition to a cytotoxic agent can stabilize and, in some cases, improve the neuropathy.

Prognosis

Peripheral neuropathies caused by axonal degeneration are generally progressive unless the underlying cause can be identified and treated. Recovery from axonal degeneration requires nerve regeneration, a process that often requires 2 to 3 years. Prognosis of demyelinating and vasculitic neuropathies is extremely variable, depending on the cause.

COMMON MONONEUROPATHIES

Common mononeuropathies are explored in [Table 123.7](#).

Carpal Tunnel Syndrome

Carpal tunnel syndrome results from compression of the median nerve at the wrist as it passes beneath the flexor retinaculum. Precipitating factors include activities that require repetitive wrist movements:

TABLE 123.12 Symptomatic Treatment for Neuropathic Pain**Tricyclic Antidepressants**

Amitriptyline 10-150 mg qhs
 Nortriptyline 10-150 mg qhs
 Imipramine 10-150 mg qhs
 Desipramine 10-150 mg qhs
 Venlafaxine 75-225 mg qd

Anticonvulsants

Gabapentin 300-1200 mg tid
 Carbamazepine 100-200 mg tid
 Topiramate 150-200 mg bid
 Duloxetine 60-120 mg qd
 Pregabalin 150-600 mg qd
 Sodium valproate 250-500 mg bid

Alternative Treatments

Tramadol 50-100 mg qid
 Lidoderm patches
 Capsaicin cream
 Transcutaneous nerve stimulation
 Acupuncture

mechanical work, gardening, house painting, and typing. Predisposing causes include pregnancy, diabetes, acromegaly, rheumatoid arthritis, chronic renal failure, thyroid disorders, and primary amyloidosis.

Symptoms usually begin in the dominant hand but commonly involve both hands over time. Patients typically report numbness, tingling, and burning sensations in the palm and in the fingers supplied by the median nerve: the thumb, index finger, middle finger, and medial one half of the ring finger. Some patients report that all fingers become numb. Pain and paresthesias are most prominent at night and often interrupt sleep. The pain is prominent at the wrist but may radiate to the forearm and occasionally to the shoulder. Shaking the hand relieves both pain and paresthesias. Percussion of the median nerve at the wrist provokes paresthesias in a median nerve distribution in 60% of patients (Tinel sign), and flexion of the wrist for 30 to 60 seconds provokes pain or paresthesias in 75% of cases (Phalen sign).

The diagnosis is based on clinical symptoms and signs. Electrodiagnostic studies may demonstrate prolongation of the sensory or motor latencies across the wrist in up to 85% of patients. In more severe cases, EMG may demonstrate evidence of denervation in the abductor pollicis brevis.

Treatment initially includes avoidance of repetitive wrist activities and the use of a neutral wrist splint. If these conservative measures fail, injections of lidocaine and methylprednisolone can be given into the carpal tunnel or surgical treatment by section of the transverse carpal ligament can effectively decompress the nerve. Indicators that have been shown to predict failure with conservative management include age older than 50, disease duration longer than 10 months, constant paresthesias, and a positive Phalen sign in less than 10 seconds.

Ulnar Palsy

The ulnar nerve may become entrapped at the elbow because of external compression in the condylar groove. Injury may also occur years after a malunited supracondylar fracture of the humerus with bony overgrowth. Contrary to the findings in carpal tunnel syndrome, muscle weakness and atrophy characteristically predominate over sensory symptoms and signs. Patients notice atrophy of the first dorsal

interosseous muscle and difficulty performing fine manipulations of the fingers. Numbness of the little finger, the contiguous one half of the ring finger, and the ulnar border of the hand may be present. Ulnar nerve compression can be confirmed with electrodiagnostic studies demonstrating slowed motor conduction velocity across the elbow. Treatment includes the use of elbow pads to avoid compression or surgical procedures including transposition of the ulnar nerve or decompression of the cubital tunnel.

Peroneal Neuropathy

The peroneal nerve can become compressed as it wraps around the fibular head and passes into the fibular tunnel between the peroneus longus muscle and the fibula. Compression may occur as a result of habitual leg crossing, prolonged bed rest, knee casts, prolonged squatting, anesthesia, or profound weight loss. The nerve can also be compressed as a result of Baker cysts, fibular fractures, blunt trauma, tumors, or hematomas at the knee. Symptoms include “foot drop” with selective weakness of the ankle dorsiflexors and evertors as well as the toe extensors. Reflexes remain normal, and sensory loss generally involves the anterolateral leg and dorsum of the foot. Electrodiagnostic studies demonstrate slowing of the peroneal conduction velocity across the fibular head and may demonstrate denervation if axonal injury is present. Compressive injuries usually resolve spontaneously within weeks to months. Magnetic resonance imaging (MRI) and surgical exploration should be considered if symptoms are progressive.

SPECIFIC ACQUIRED POLYNEUROPATHIES**Guillain-Barré Syndrome: Acute Inflammatory Demyelinating Polyneuropathy**

Since the advent of polio vaccination, GBS has become the most frequent cause of acute flaccid paralysis throughout the world. GBS is an immune-mediated disorder that follows an identifiable infectious disorder in approximately 60% of patients. The best-documented antecedents include infection with *Campylobacter jejuni*, infectious mononucleosis, CMV, herpesvirus, and mycoplasma. *C. jejuni* is often associated with more severe axonal cases.

The initial symptoms of GBS often consist of tingling and pins-and-needles sensations in the feet and may be associated with dull low-back pain. By the time of presentation, which occurs hours to 1 to 2 days after the first symptoms, weakness has usually developed. The weakness is usually most prominent in the legs, but the arms or cranial musculature may be involved first. Muscle stretch reflexes are lost early, even in regions where strength is retained. Cutaneous sensory deficits (loss of pain and temperature) are relatively mild; however, large-fiber functions (vibration and proprioception) are more severely impaired. Other clinical features include pain (20%), paresthesias (50%), autonomic symptoms (20%), facial weakness (50%), ophthalmoparesis (9%), bulbar weakness, and respiratory failure (25%). Symptoms associated with GBS typically evolve over a 2- to 4-week period, with approximately 90% of patients showing no evidence of progression beyond 4 weeks. For this reason, patients who are seen within several weeks from onset continue to require hospitalization for close observation. Respiratory muscle strength should be monitored with bedside measurements of the FVC and negative inspiratory function (NIF). Intubation should be initiated when the FVC falls below 15 mL/kg or NIF is less than -20 cm of H₂O.

Treatment may include either intravenous gammaglobulin (0.4 g/kg/day \times 5 days) or plasmapheresis—the exchange of the patient’s plasma for albumin (200 mL/kg over 7 to 10 days). Clinical studies have confirmed equal efficacy between these two therapies, with no additional benefit conferred with combination therapy. Corticosteroids are

not effective in GBS. Indications for therapy include inability to ambulate independently, impaired respiratory function, or rapidly progressive weakness.

Clinical features predicting a poor prognosis or prolonged recovery time include rapidly progressive weakness, need for mechanical ventilation, and low-amplitude CMAPs. The mortality rate remains 5% to 10%, usually due to respiratory complications, cardiac arrhythmia, or pulmonary embolism. With appropriate supportive care and rehabilitation, 80% to 90% of patients recover with little or no disability.

Chronic Inflammatory Demyelinating Polyneuropathy

CIDP has been considered the “chronic form” of GBS, because by definition the symptoms must progress for at least 8 weeks. The clinical features include proximal and distal weakness, areflexia, and distal sensory loss. Autonomic dysfunction, respiratory insufficiency, and cranial nerve involvement can occur but are much less common than in GBS. Treatment for CIDP includes the use of oral immunosuppressive agents such as prednisone, cyclosporine, mycophenolate mofetil, and azathioprine. Intravenous immune globulin and plasmapheresis are also indicated for severe or refractory cases.

Diabetic Neuropathy

Diabetes mellitus is the most frequent cause of peripheral neuropathy worldwide. The diabetic neuropathies take many clinical forms, including symmetrical polyneuropathies and a wide variety of individual plexus or nerve disorders.

Diabetes mellitus often causes a slowly progressive, distal, symmetrical sensorimotor polyneuropathy (DSPN). DSPN is uncommon at the time of diagnosis of diabetes, but its prevalence increases with duration of diabetes with a lifetime prevalence of 55% for type 1 and 45% for type 2. The precise pathogenesis is not defined, but, similar to the ocular and renal complications, diabetic neuropathy can be reduced in incidence and in severity by maintaining blood glucose levels close to normal.

Initial symptoms may consist of numbness, tingling, burning, or prickling sensations affecting the feet and toes. Mild distal weakness and gait instability may subsequently develop. The sensory symptoms can then slowly progress to involve a “stocking-glove pattern.” The small-fiber dysfunction often produces spontaneous neuropathic pain in which unpleasant sensations can be evoked by normally innocuous stimuli, such as the bed sheets on the toes at night. Continuous burning or throbbing pain may occur, and prolonged walking is often distressing. In severe cases, patients may develop foot ulcers in insensitive areas that necessitate amputation. Autonomic dysfunction is also frequently associated with DSPN including impotence, nocturnal diarrhea, sweating abnormalities, orthostatic hypotension, and gastroparesis.

Other less common neuropathies associated with diabetes include cranial neuropathies (the sixth, third, and rarely fourth nerves), mononeuropathies, mononeuropathy multiplex, radiculopathies, and plexopathies. Diabetic amyotrophy (also known as *diabetic lumbosacral polyradiculoplexopathy*) is a distinctive disorder characterized by severe thigh pain followed by proximal greater than distal lower extremity weakness that progresses over a period of months. The onset is invariably unilateral, but the condition may progress to involve both lower extremities. Physical therapy and effective pain management are essential; treatment with immune modulators is controversial.

Toxic-Induced Neuropathies

Toxic neuropathies constitute a large number of disorders caused by alcohol, drugs, heavy metals, and environmental substances (see [E-Table 123.3](#)). The majority of toxic neuropathies manifest as a distal

sensorimotor axonal neuropathy that chronically progresses over time unless the offending agent is eliminated. Clinical evaluation should focus on the temporal relationship between exposure and the onset of sensory or motor symptoms as well as symptoms of systemic toxicity.

Critical Illness Polyneuropathy

Critical illness polyneuropathy (CIP) is a common cause of failure to wean from a ventilator in a patient with associated sepsis and multiorgan failure. Clinical features include generalized or distal flaccid paralysis, especially involving the lower extremities, depressed or absent reflexes, and distal sensory loss with relative sparing of cranial nerve function. The diagnosis can be confirmed with nerve conduction studies showing evidence of a severe, generalized axonal neuropathy. CSF protein should be normal and, in addition to conduction studies, distinguishes CIP from GBS.

SPECIFIC HEREDITARY POLYNEUROPATHIES

Charcot-Marie-Tooth Disease

CMT identifies a group of heritable disorders of peripheral nerves that share clinical features but differ in their pathologic mechanisms and the specific genetic abnormalities ([E-Table 123.4](#)). CMT is the most common heritable neuromuscular disorder, with an incidence of 17 to 40 cases per 100,000.

CMT disease usually manifests during the first to second decades with symptoms related to insidious foot drop: frequent tripping and inability to jump well or run as fast as other children. Over time, distal upper extremity weakness develops, resulting in difficulty with buttoning, handling keys, and opening jars. Examination reveals distal weakness and wasting of the intrinsic muscles of the feet, the peroneal muscles, the anterior tibial muscles, and the calves (“inverted champagne bottle” legs). A variable degree of impaired large-fiber sensory function is reflected in reduced vibratory sensation at the toes. Muscle stretch reflexes are lost, first at the ankles. Typically, a foot deformity exists, with high arches (pes cavus) and hammer toes, reflecting long-standing muscle imbalance in the feet. Most patients with CMT disease have nearly normal occupational and daily activities, and they have a normal life span. Although no specific treatment has been developed, the foot drop can be treated by appropriate bracing of the ankle with ankle-foot orthoses. Genetic counseling and education of affected patients and their families are important, both for reassurance and to preclude unnecessary diagnostic evaluation of affected members in future generations.

Demyelinating forms of CMT are classified as CMT1 and axonal forms as CMT2. CMT is usually transmitted as an autosomal dominant trait; however, X-linked dominant transmission is responsible for approximately 10% of cases. Rare autosomal recessive forms are designated CMT4, and these patients tend to have an earlier onset and more severe phenotype. CMT1A is the most common form and accounts for 90% of CMT1 and 50% of all CMT cases. CMT1A is associated with the 17p11.2-p12 duplication in the *PMP22* gene expressed by Schwann cells. A deletion or a point mutation of the *PMP22* gene produces a different phenotype, HNPP, which is characterized by recurrent episodes of focal entrapment with attacks of weakness and numbness in the peroneal, ulnar, radial, and median nerves (in descending order of frequency) or in a brachial plexus distribution.

FAMILIAL AMYLOID NEUROPATHIES

Amyloid neuropathy is an autosomal dominant disorder caused by extracellular deposition of the fibrillary protein amyloid in peripheral nerve and sensory and autonomic ganglia, as well as around blood

Toxic neuropathies constitute a large number of disorders caused by alcohol, drugs, heavy metals, and environmental substances (see [E-Table 123.3](#)). The majority of toxic neuropathies manifest as a distal

E-TABLE 123.4 Charcot-Marie-Tooth Disease

Disorder	Locus/Protein	Inheritance	Usual Onset	Specific Clinical Features

vessels in nerves and other tissues. The age of onset varies from 18 to 83 years. In all forms of amyloidosis, the initial and major abnormalities affect the small sensory and autonomic fibers. Involvement of small fibers responsible for pain and temperature sensibilities leads to loss of the ability to perceive mechanical and thermal injuries and to an increased risk of tissue damage. As a result, painless injuries present a major hazard of this disorder; in advanced stages, they can lead to chronic infections or osteomyelitis of the feet or hands and the necessity for amputation. Amyloid deposition in the heart can lead to cardiomyopathy. Mutations in transthyretin, apolipoprotein A1, or gelsolin are responsible. Early recognition is essential, as liver transplantation has been shown to halt disease progression. Recently, the FDA approved two new medications, inotersen and patisiran, for treatment of transthyretin-associated familial amyloid polyneuropathy.

Muscle Diseases

Johanna Hamel, Jeffrey M. Statland

INTRODUCTION

Skeletal muscle fibers are the effector cells of the nervous system, turn thoughts into actions, and are the means by which we interact with our environment. Myopathies are primary diseases of the muscle and can be both inherited and acquired (Table 124.1). Myopathies can result in weakness and muscle wasting, myalgias, cramps, muscle breakdown, or contractures. Inherited disorders affect muscle proteins involved in transmission of signals from the neuromuscular junction, proteins involved in energy production or metabolism, or structural proteins that anchor and transmit force from the contractile apparatus to the extracellular matrix. They do this either by mutations directly to the muscle proteins or by mutations altering cell regulation of transcription or splicing. Acquired myopathies are caused by external factors and can be due to metabolic derangements, toxic exposures or drugs, infections, or autoimmune dysfunction often resulting in inflammation in the muscle. Acquired myopathies can improve with treatments geared towards eliminating or ameliorating the precipitating factors.

With recent advances in our understanding of the genetic and molecular mechanisms in hereditary myopathies, coupled with advances in drug development targeting DNA and RNA, efforts to develop targeted therapies for hereditary muscle diseases accelerated and increased exponentially. The first treatment targeting the underlying genetic mechanism of a muscle disease (Duchenne muscular dystrophy) was approved by the US Food and Drug Administration (FDA) in 2016. Many more disease-specific treatments targeting genetic mechanisms of muscle diseases are currently in clinical trials with a subset expected to become available to patients in the future. This change in paradigm, from supportive to disease-modifying therapies, targeting patients' DNA or RNA that will alter the trajectory of progression, will change the landscape of how we care for patients with muscle diseases. One technology worth mentioning here due to imminent clinical trials and the possibility for transformational change in inherited myopathies is systemic gene replacement therapies. The three concepts that make up systemic gene therapy are: (1) the vector, which is a virus, serotypes of which can specifically target muscle or the heart; (2) the construct, which is the gene that will be packaged into the virus vector; the size can be limited by the capsid size, and so for large genes like dystrophin new engineered genes (i.e., microdystrophin) are used; and (3) the promoter, the on and off switch for the gene, which can also be tissue specific. The first such systemic gene replacement therapy was approved for spinal muscular atrophy, and several companies have phase 3 studies starting for muscular dystrophies. With these fundamental advances on the horizon, early recognition and diagnosis of these rare diseases will be important to achieve the greatest benefit from these treatments. Physicians administering the therapies not only need to be familiar with the disease and its complications but with molecular and genetic mechanisms that are being targeted. These advances provide abundant opportunities and challenges.

ORGANIZATION AND STRUCTURE OF NORMAL MUSCLE

Each muscle is enclosed in a connective tissue sheath made up of collagen and extracellular matrix proteins called the epimysium, which merges at either end to form the tendons, which attach muscle to bone. The epimysium divides internally into the perimysium, which separates the muscle into individual bundles of muscle fibers called fascicles. The endomysium surrounds and provides support for the individual fibers. Each muscle fiber is a single multi-nucleated syncytial cell and can be as long as 10 cm. On cross section, muscle fibers appear polygonal in shape and in adults range from 40 to 80 micrometers in diameter. Medium size arterioles and veins run in the perimysium, with capillaries between the individual muscle fibers. On hematoxylin and eosin stains, cytoplasm appears pink and the nuclei blue (Fig. 124.1A). Each individual muscle fiber has multiple nuclei, which are found beneath the sarcolemma membrane on the periphery of the cell.

The plasma membrane around the muscle fiber is called the sarcolemma, and inside there are a large number of myofibrils made of thick (myosin) and thin (actin) filaments, which make up 70% to 80% of the volume of the cell, and when activated, create force. Electrochemical signals carry the signal from the nerve, through the neuromuscular junction, into the muscle fiber along the sarcolemma and t-tubule system. Muscle ion channels line this network and carry electrochemical signals. Mitochondria and enzymes involved in glycolysis and fatty acid metabolism provide energy for muscle. A network of proteins, the dystrophin-glycoprotein complex (DGC), anchors the myofibrils to the subsarcolemma cytoskeleton and connects to the extracellular matrix (Fig. 124.2). Many inherited myopathies are caused by mutations in these ion channels, metabolic enzymes, or structural anchoring proteins.

SYMPTOMS OF MUSCLE DISEASE

The most common symptom of a patient with muscle disease is a loss of function caused by weakness (for an overview of symptoms see Table 124.2). Other common symptoms, like fatigue, exercise intolerance or myalgias (muscle pain), are less specific than muscle weakness. Muscle cramping is more commonly caused by disorders of the nerves, and not the muscle.

EXAMINATION

The physical examination uses a standard modified Medical Research Council scale of motor strength to determine the pattern and degree of involvement of various muscles (Table 124.3). But just as important as isolated strength testing are functional

TABLE 124.1 Overview of Myopathies**Hereditary Myopathies**

 Systemic illness/infectious myopathies
 Toxic/drug-induced myopathies

motor tasks, particularly in children. Muscles should be inspected for atrophy or hypertrophy and range of motion around the joints for evidence of tendon contractures. Ten broad patterns of muscle weakness occur in myopathies (Table 124.4). Most myopathies have the proximal, limb-girdle pattern. There are other, highly distinctive, patterns. Weakness that is asymmetric and includes the face, proximal arms and shoulders, and distal lower extremities is characteristic of facioscapulohumeral muscular dystrophy. Weakness that starts in the distal finger flexors (patients cannot curl fingers when making a fist) and proximal lower extremities (the quadriceps) is virtually pathognomonic for sporadic inclusion body myositis. A patient in middle age who presents with ptosis and difficulty swallowing is highly characteristic for oculopharyngeal muscular dystrophy.

Fig. 124.1 Muscle biopsies hematoxylin and eosin staining. When assessing the health of muscle tissue, the pathologist evaluates the size, shape and internal architecture of muscle fibers, presence of inflammation and mitochondrial dysfunction, and amount of connective tissue. In a chronic myopathic muscle, the muscle fibers are typically more variable in size, rounded, and have central nuclei. Connective tissue can be increased. In an active myopathy, necrotic fibers undergoing phagocytosis and regenerating fibers can be seen. (A) **Normal adult muscle**, medium power. Notice polygonal muscle fibers arranged in fascicles with blue staining nuclei on the periphery. A small arteriole is visible (*white arrow*). (B) **Chronic myopathy**, Duchenne muscular dystrophy low power. Note the variability in fiber size with rounding of fibers, increase in connective tissue, and fatty deposition. (C) **Acute myopathy**, necrotizing myopathy with HMGCR antibodies. Necrotic fiber (*white arrow*) undergoing phagocytosis and regenerating fiber (*) with plump nuclei. Examples for disease characteristic findings on muscle pathology. (D) **Centronuclear congenital myopathy**. The NADH reaction shows numerous fibers with spoke-like, radial projections with central nuclei. Also notable fiber size variability, identified as moderate type 1 fiber atrophy on other stains. (E) **Dermatomyositis** on low power. Notice the prominent pathognomonic per fascicular atrophy (*white arrow*) of fibers, and perivascular inflammatory infiltrates.

Fig. 124.2 The dystrophin-glycoprotein complex. Muscle structural proteins connect the contractile apparatus to the internal cytoskeleton and the extracellular matrix. Mutations in proteins from the extracellular matrix to the anchoring proteins, which connect the extracellular matrix to the internal cytoskeleton, and mutations to proteins, which attach the internal cytoskeleton to the contractile apparatus, are all involved in the inherited muscular dystrophies and myopathies.

DIAGNOSTIC TESTING

The work-up of a patient with a suspected myopathy is a staged process, outlined in [Table 124.2](#). A useful initial laboratory test is the serum creatine kinase (CK), which is elevated commonly in acquired and often in inherited myopathies. Despite the obvious localizing value of elevated muscle enzymes it is important to remember not all elevations in serum CK are due to myopathy and a normal CK does not exclude a myopathy ([Table 124.5](#)). Furthermore, CK levels can vary depending on physical activity, gender, and race.

Electrodiagnostic testing can help distinguish between neurogenic and myopathic causes for weakness (see [Table 124.2](#)). Genetic testing is the initial test when a specific hereditary disease is suspected. Muscle biopsies can be important in patients whose family history and physical examination does not suggest a particular myopathic diagnosis and can help resolve variants of uncertain significance on genetic testing. Characteristic morphologic changes (see [Fig. 124.1](#)) are hallmarks of the congenital myopathies (e.g., centronuclear myopathy in [Fig. 124.1D](#)), inflammatory myopathies (dermatomyositis in [Fig. 124.1E](#)), and metabolic myopathies (glycogen storage disorders), but most myopathies result in nonspecific muscle changes, which confirms the localization (muscle), but not the cause.

INHERITED MYOPATHIES

Muscular Dystrophies

The muscular dystrophies are inherited myopathies characterized by progressive weakness. Typically the muscular dystrophies are divided

into the dystrophinopathies, the myotonic dystrophies, facioscapulo-humeral muscular dystrophy, Emery-Dreifuss muscular dystrophy, and the limb-girdle dystrophies ([Tables 124.6, 124.7, and E-Table 124.1](#)). The limb-girdle muscular dystrophies (LGMD) are a diverse group of diseases due to mutations in more than 20 genes. The LGMDs are inherited in either autosomal dominant or recessive fashion and present anywhere from childhood after achieving independent walking to later in life, with elevated CK and proximal muscle weakness (see [E-Table 124.1](#)). Another group of patients who have dystrophic changes in the muscle from birth, often with accompanying changes in the brain on MRI, include congenital muscular dystrophies (see [Table 124.7](#)). The traditional distinction between dystrophies and other inherited myopathies is becoming blurred as our genetic understanding advances because mutations for different diseases are often allelic.

Dystrophinopathies

Definition and Epidemiology

Dystrophinopathies are X-linked recessive disorders resulting from mutations of the large dystrophin gene located at Xp21. The incidence of Duchenne muscular dystrophy is 1 in 5300 male births; one third of the cases result from a new mutation. Becker muscular dystrophy is a milder form of dystrophinopathy and is less common than the Duchenne form, with an incidence of 5 per 100,000.

Genetics and Pathology

The majority of patients have deletions or duplications in the dystrophin gene. In the remaining patients, mutations can be small insertions

TABLE 124.2 Evaluation for a Patient With Suspected Myopathy

Feature	Description
History	
Age of onset	Congenital, childhood, adult
Acute/subacute or chronic	Hereditary myopathies are usually chronic with gradual onset, acquired myopathies can occur more acutely
Progressive or episodic	Dystrophies are usually progressive; congenital static; metabolic/channelopathies episodic
Triggers	Exercise, foods, temperature
Myotonia	Delayed relaxation of muscle: e.g., difficulty letting go when shaking hands, opening doorknobs, myotonia can also affect tongue movements (speech) and chewing. Myotonia improves with repetition (warm-up phenomenon) and gets worse in cold temperature.
Family History	
	It can be helpful to draw out a pedigree to determine the pattern of inheritance, which can be dominant, recessive, or no family history. Questions about whether family members require assistive devices to walk or wheelchairs, and asking about extra-muscular manifestation of muscular dystrophies can be useful, specifically as diseases may not have been recognized.
Weakness on Exam	
Proximal	Difficulty lifting objects, climbing stairs, getting up from chair, scapular winging, waddling gait, Gower sign
Distal	Difficulty making a tight fist, fastening buttons, opening jars, wrist drop, foot drop
Facial	Difficulty squeezing the eyes shut, transverse smile, inability to pucker or blow out cheeks, inability to whistle
Oculopharyngeal	Ptosis, restricted extra-ocular movements, coughing after drinking, and difficulty swallowing
Respiratory	Shortness of breath with activity, with lying flat, use of accessory muscles
Other Features	
Myotonia	Action Myotonia: Delayed hand opening after making a tight fist, or eye opening after tight closure Percussion Myotonia: With percussion of the extensor digitorum muscle in the forearm, the finger extensors relax with delay. Same can be observed with percussion of the thenar eminence
Cardiac	Cardiac conduction defects, cardiomyopathy
Multiorgan involvement	E.g., joint deformities, skin (rash), GI symptoms, eye (cataract), hearing loss, CNS involvement
Laboratory	
Creatine kinase (CK)	Dystrophies/inflammatory myopathy increased >10× normal; congenital 3–5× normal; metabolic >10× normal during attacks
Thyroid/Parathyroid	High TSH, low T4, low PTH, Ca ²⁺
Antibodies	Patients with myositis: Myositis specific antibodies: Anti-Jo-1, antisynthetase antibodies, signal recognition particle (SRP) antibodies, Mi-2 antibodies, anti hPMS-1, anti-MDA-5 antibody, anti-p140, anti-p155/140. Inclusion Body myositis: Cytoplasmic 5'-nucleotidase 1A (cN1A) Patients with proximal muscle weakness of unknown etiology or necrotizing myopathies: Antibodies to 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR)
Genetic Testing	
	Patients with family history and/or examination suggestive of a hereditary myopathy. A positive test can be confirmatory and avoid additional diagnostic testing.
Electrodiagnostic Studies	
	Nerve conduction studies are typically normal in muscle diseases. On electromyography, irritated muscle shows fibrillations and positive sharp waves; myopathic motor units are brief, low amplitude, and polyphasic; electrical myotonia is a repetitive muscle fiber potential discharge with waxing and waning frequency and amplitude with characteristic sound similar to an accelerating, decelerating motorcycle engine.
Muscle Biopsy	
	Chronic: Changes in muscle fiber shape and composition of fiber types, central nuclei, increased amount of connective tissue Acute: Necrotic muscle fibers, regenerating fibers Other: Presence of inflammatory cells, number or morphology of mitochondria, or abnormal deposits of fat or glycogen

or deletions, point mutations, or splice site variants. Dystrophin is a large subsarcolemmal cytoskeletal protein that, along with the other components of the dystrophin-glycoprotein complex, provides support to the muscle membrane during contraction. Mutations in dystrophin can result in a spectrum of dystrophin dysfunction, from a severely truncated protein that is rapidly degraded, as in Duchenne muscular dystrophy, to a semi-functional protein still expressed such as in the milder form, Becker's muscular dystrophy, or mild dysfunction such as in female carriers. Muscle biopsies are typically not required for diagnosis (example depicted in Fig. 124.1B).

Clinical Presentation

Duchenne muscular dystrophy manifests as early as age 2 to 3 years with delays in motor milestones and difficulty running. Patients can have marked pseudo-hypertrophy of the calf muscles. And when asked

to get up from the floor, boys use a Gower maneuver (use hands to push up). The average age of diagnosis is around 4 years of age. The proximal muscles are the most severely affected, and the course is relentlessly progressive. Patients begin to fall frequently by age 5 to 6, have difficulty climbing stairs by age 8 years, and are usually confined to a wheelchair in their early teens. Patients have a reduced life expectancy due to cardiac (dilated cardiomyopathy) and respiratory muscle weakness. The average IQ of boys with Duchenne muscular dystrophy is low, reflecting central nervous system involvement.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical history, physical examination, serum CK, and is confirmed by genetic testing. Other differential considerations are congenital myopathies, muscular dystrophies, and limb-girdle muscular dystrophies.

Treatment

Care for children with Duchenne muscular dystrophy involves a multidisciplinary team along with pulmonologists, orthopedists, and cardiologists, with monitoring of cardiac and respiratory function as well as scoliosis. Prednisone and deflazacort (a synthetic derivative of prednisolone) improve strength and motor function, pulmonary function, and prolong the ability to walk and survival in children with Duchenne muscular dystrophy.

About 15% of patients with Duchenne muscular dystrophy carry a mutation on exon 51. Eteplirsen is a drug that binds to exon 51 and

induces “exon skipping,” resulting in production of a truncated, but potentially functional dystrophin protein. The drug was approved in the United States by the FDA in 2016 and current trials are carried out to demonstrate a clinical benefit. Subsequently, two therapies were approved for patients with pathogenic variants on exon 53 (about 8% of patients with Duchenne muscular dystrophy). These therapies, golodirsen and vitolarsen, target RNA and result in exon 53 skipping. Ataluren is approved in countries outside of the United States for children with nonsense mutation. The drug allows read-through of premature stop mutations with the goal to produce a more functional dystrophin protein but with mixed results on functional outcome measures. Continued efforts and studies focus on strategies to make the cell produce some form of dystrophin, by targeting RNA or utilizing gene therapy targeting DNA. While these therapies will likely change the trajectory of DMD and care practices, new challenges will arise, such as costs, access (due to the genetic variability of DMD, therapies will target a subset of patients), duration of effect, and long-term safety concerns.

There are no guidelines for the treatment of Becker muscular dystrophy and clinical presentation is highly variable, but monitoring for cardiac and respiratory involvement is warranted. Some female carriers of dystrophin mutations may become symptomatic later in life and may have severe cardiomyopathy.

Prognosis

Patients with Duchenne muscular dystrophy die of respiratory complications in their 20s unless they are provided with respiratory support. Emerging targeted therapies will likely change this trajectory. Congestive heart failure and arrhythmias can occur late in the disease.

TABLE 124.3 Modified Medical Research Council Motor Strength Testing Scale

Grade	Degree of Strength
5	Normal strength through entire range of motion and against resistance
5–	Equivocal, barely detectable weakness
4+	Able to move against gravity and resistance, but examiner can break
4	Able to move against gravity and some resistance
4–	Able to resist gravity but only minimal resistance
3+	Able to overcome gravity and transient resistance, but then quickly gives out
3	Able to overcome gravity but no resistance
3–	Able to resist gravity but not through full range of motion
2	Able to move through range of motion with gravity eliminated
1	Trace muscle contraction
0	No contraction

TABLE 124.4 Characteristic Patterns of Muscle Weakness and Associated Myopathies

Pattern	Weakness	Diseases
Proximal limb-girdle	Symmetrical, pelvic and shoulder girdle muscles. Distal muscles to lesser extent. ±Neck flexor/extensor	Nonspecific: Duchenne muscular dystrophy; limb-girdle muscular dystrophy; inflammatory myopathies; Myopathy with HMGCR antibodies; myotonic dystrophy type 2
Distal	Symmetrical, distal upper or lower extremity. Proximal muscles to lesser degree	Nonspecific: Miyoshi myopathy (calves); Welander myopathy (wrist and finger extensors); Nonaka and Markesbery/Udd myopathy (tibialis anterior); rule out neuropathy
Proximal arm/distal leg	Scapuloperoneal distribution: periscapular muscles (proximal arm) and anterior compartment distal leg (tibialis anterior). Scapular winging. Can be asymmetrical.	When face involved highly suggestive of facioscapulohumeral muscular dystrophy; with elbow contractures Emory-Dreifuss dystrophy; scapuloperoneal dystrophies; certain limb-girdle dystrophies; congenital myopathies
Distal arm/proximal leg	Distal forearm muscles (distal finger flexors) and proximal leg (quadriceps). Other muscles variable. Often asymmetrical.	Highly suggestive of sporadic inclusion body myositis; also consider myotonic dystrophy type 1 with distal leg, neck flexion, respiratory and facial weakness
Ptosis ± ophthalmoparesis	Restriction of eye movements often without diplopia. Often with pharyngeal weakness and variable extremity weakness.	Ocular and pharyngeal weakness highly suggestive of oculopharyngeal muscular dystrophy; mitochondrial myopathies
Neck extensor weakness	Neck extensors, “dropped head syndrome.” Variable neck flexor. ±Extremity weakness.	Inflammatory myopathies, in isolation consider isolated neck extensor myopathy; rule out amyotrophic lateral sclerosis and myasthenia gravis
Bulbar weakness	Tongue and pharyngeal weakness	Certain myopathies (e.g., oculopharyngeal muscular dystrophy); significant overlap with neuromuscular junction and motor neuron disease
Episodic pain, weakness, and myoglobinuria	May be triggered by exercise or metabolic stress	Metabolic myopathies; may also occur in deconditioning
Episodic weakness delayed or unrelated to exercise	May be triggered by food, stress, rest after exercise	Characteristic of periodic paralyses
Stiffness and decreased ability to relax	May be episodic, triggered by cold	Characteristic of myotonic disorders

Modified from Jackson CE, Barohn RJ: A pattern recognition approach to myopathy, *Continuum (Minneapolis)* 19(6 Muscle Diseases): 1674-1697, 2013.

Myotonic dystrophies are the most common muscular dystrophies in adults of European ancestry with autosomal dominant inheritance. There are two types of myotonic dystrophy, type 1 (DM1) and type 2 (DM2). The frequency of DM1 in Europe is estimated at 1 in 8000. While DM1 and DM2 are equally frequent in Europe, DM2 seems less common in the United States.

Genetics and Pathology

DM1 is caused by a CTG repeat expansion on the *DMPK* gene whereas DM2 is caused by a CCTG repeat expansion on the *CNBP* gene. Both diseases share the same mechanism of RNA toxicity. Expanded CUG/CCUG repeats accumulate in nuclear foci and sequester important proteins that typically regulate RNA splicing. Loss of function of these proteins results in missplicing of various RNAs of multiple genes, resulting in wide transcriptome changes and multisystemic disease. In DM1, some but not all of the variability in age of symptom onset is explained by repeat length, with earlier onset typically associated with greater disease severity and longer repeat length. The CTG repeat is unstable and increases in somatic tissue throughout a person's life (somatic instability) and tends to increase from generation to generation (anticipation). Genetic testing confirms the diagnosis and muscle biopsies are not required but characteristic findings

TABLE 124.6 Prevalent Muscular Dystrophies

Disease	Inheritance	Mutations	Age of Onset	Phenotypes	Treatment
Dystrophinopathies	X-linked recessive	Xp21; ~75% deletion or duplication	Duchenne diagnosis by age 4; Becker variable	Limb-girdle pattern. Duchenne: severe progressive and life limiting. Becker: progressive but not as severe, more variable. Calf pseudo-hypertrophy; isolated cardiomyopathy.	For Duchenne: Prednisone (or deflazacort), Eteplirsen, golodirsen, and viltolarsen; surveillance for respiratory, cardiac, and orthopedic problems
Myotonic dystrophy type 1	Autosomal dominant	19q13; CTG expansion >50 repeats	Any age with marked variability; congenital at birth	Marked clinical variability but typically muscle weakness and wasting affecting face, neck flexion, respiratory and distal muscles (finger flexion, ankle dorsiflexion); myotonia; temporal wasting, frontal balding; multisystemic disease manifestations (e.g., with cognitive deficits, hypersomnolence, cataracts); cardiac conduction deficits	Mexiletine for symptomatic myotonia; yearly surveillance for ocular and respiratory involvement and cardiac conduction deficits
Myotonic dystrophy type 2	Autosomal dominant	3q13; CCTG expansion >75 repeats	30s and older	Limb-girdle pattern; myalgia; myotonia; multi-system involvement (e.g., cataracts, cardiac conduction deficits); diabetes	Mexiletine for symptomatic myotonia; surveillance for ocular, cardiac, and respiratory involvement
Facioscapulothoracic muscular dystrophy	Autosomal dominant	95%: 4q35 (F5HD1), 5% digenic mutation affecting methylation (F5HD2)	Any age	Scapuloperoneal pattern with facial involvement; can have marked asymmetry; significant axial involvement	Screening for extramuscular manifestation
Emery-Dreifuss muscular dystrophy	X-linked recessive; autosomal dominant or recessive	~70% Xq28 Emerin or FHL1 mutation; 1q21 lamin A/C, both dominant and recessive mutations reported	Joint contractures childhood; progressive weakness 20s–30s	Scapuloperoneal pattern; early joint contractures, particularly at elbows, marked cardiac involvement	Yearly surveillance for cardiac and respiratory involvement; orthopedic evaluation for symptomatic contractures
Oculopharyngeal muscular dystrophy	Autosomal dominant and recessive	14q11 PABPN1 GCG repeats >11 repeats	40s (range 20s–60s)	Ptosis dysphagia; limb-girdle pattern weakness	Swallow study; blepharoplasty for ptosis, cricopharyngeal myotomy for severe swallowing difficulty

TABLE 124.7 Congenital Muscular Dystrophies

Name/AKA	Gene	Inheritance	Phenotype	CNS Involvement
Merosin-deficient	6q22; laminin alpha-2	Autosomal recessive	Hypotonia; contractures; scoliosis or rigid spine; respiratory involvement; external ophthalmoplegia	MRI diffuse white matter changes; 20%–30% seizures
Bethlem myopathy/ Ullrich muscular dystrophy	21q22; 2q37; COL6 (collagen 6 spectrum disorders)	Autosomal dominant or recessive	Hypotonia; contractures; distal joint laxity; keloid; respiratory involvement	
Dystroglycanopathy	9q34 (POMT1); 14q24 (POMT2); 9q31 (fukutin); 19q13 (FKRP); 22q12 (LARGE); 1q32 (POMGnT1); 7p21 (ISPD)	Autosomal recessive	Spectrum of disorders but characteristic intellectual, eye, and brain involvement; motor early death, to acquiring ambulation	Walker-Warburg syndrome: severe eye involvement, cobblestone lissencephaly, hypoplastic cerebellum and brain stem. Muscle eye brain syndrome: common eye involvement, pachygyria/polymicrogyria, hypoplastic cerebellum and brain stem. Fukuyama: mild eye involvement, cortex mild changes, hypoplastic cerebellum but normal brain stem
SEPN1-related myopathy	1q36 (SEPN1)	Autosomal recessive	Cervicoaxial weakness, rigid spine syndrome, early nocturnal hypoventilation, medial thigh wasting	
LMNA related	1q22 (lamin A/C)	Autosomal dominant and recessive	Cervicoaxial weakness, dropped head, rigid spine syndrome, respiratory and cardiac involvement	

include pyknotic clumps (result of severe fiber atrophy), ring fibers, and type 1 fiber predominance.

Clinical Presentation

DM1 is one of the most variable monogenetic diseases and can present at any age. The wide spectrum of disease ranges from infants with hypotonia, respiratory weakness, and clubfeet at birth (congenital myotonic dystrophy) to late onset of disease at old age with minimal symptoms or signs. Typical features include facial weakness with temporalis muscle wasting, frontal balding, ptosis, and neck flexor weakness. Speech can be dysarthric with bulbar weakness resulting in dysphagia. Inspiratory (difficulty lying flat) and expiratory (weak cough) muscle weakness may be present. Extremity weakness usually begins distally and progresses slowly to affect the proximal limb-girdle muscles. In conjunction with myotonia (see Table 124.2), this phenotype is nearly pathognomonic of DM1. DM2 is considered milder because age of onset occurs typically in the late 30s and there is no congenital or childhood form of the disease. The pattern of weakness predominantly affecting proximal muscles and less facial involvement is different than in DM1. Pain is commonly described by patients with DM2. Both disorders affect multiple organ systems, such as early cataracts (<55 years), cardiac conduction abnormalities, and smooth muscle involvement with symptoms mimicking irritable bowel syndrome. *DMPK* is expressed in the brain and patients with DM1 can experience cognitive deficits including visuospatial and executive dysfunction, apathy, as well as hypersomnolence, which can be one of the most bothersome symptom in some individuals. Central nervous system involvement is thought to be less severe in DM2.

Diagnosis and Differential Diagnosis

The diagnosis is based on clinical examination, demonstration of myotonia clinically and electromyographically, and is confirmed by genetic testing. The classic phenotype and multisystemic presentation typically distinguishes myotonic dystrophy from other adult onset muscular dystrophies and non-dystrophic myotonic disorders.

Treatment

Annual surveillance for cardiac (ECG) and respiratory involvement (pulmonary function testing) is recommended. A sleep study can identify the presence of sleep apnea. Noninvasive ventilation is recommended for respiratory weakness and sleep apnea. With advanced heart block, a pacemaker may need to be placed. Mexiletine, a type IB anti-arrhythmic medication, effectively treats myotonia but is contraindicated in patients with severe arrhythmia. There is currently no treatment to halt disease progression but many therapies targeting the toxic RNA or releasing the sequestered proteins are under investigation.

Prognosis

Patients with DM1 have a reduced life expectancy due to respiratory and cardiac involvement, which on average appears to be less severe in DM2.

Facioscapulohumeral Muscular Dystrophy

Definition and Epidemiology

Facioscapulohumeral muscular dystrophy (FSHD) is the second most common adult muscular dystrophy with an estimated prevalence of 1:15,000.

Genetics and Pathology

FSHD is caused by *DUX4* expression, a gene that is typically silenced but is toxic to muscle when expressed. *DUX4* is expressed when the segment on chromosome 4q35 carrying the gene is hypomethylated. In most patients hypomethylation occurs due to a deletion/contraction of the segment on 4q35 (FSHD1), but in about 5% of patients it is caused by a mutation in a different gene regulating methylation (FSHD2). Both forms are clinically indistinguishable. FSHD1 has an autosomal dominant inheritance whereas FSHD2 as a digenic disease requires mutations on two genes, and sporadic occurrences occur in both. Muscle biopsy is typically not required for the diagnosis but shows nonspecific myopathic changes and inflammatory infiltrates in up to 30% of biopsies.

E-TABLE 124.1 Limb-Girdle Muscular Dystrophies—Abbreviated List

Nomenclature	Mutation	Age	CK	Phenotypic Characteristics (in Addition to Limb-Girdle Pattern Weakness)	
				Surveillance	
D1 DNAJB6-related	DNAJB6	1–5th decade	Normal to 5×	Legs > Arms	Dysphagia
D2 TNPO3-related	TNPO3	1–5th decade	Normal to 2900	Legs > Arms	Respiratory weakness
D3 HNRNPDL-related	HNRNPDL	2–5th decade	Normal to 9×	Proximal > distal	Cataracts
D4 calpain3-related	CAPN	Age of onset > R1	High in most	Great variability	
D5 collagen 6-related	COL6A1, COL6A2, COL6A3	Variable	Normal to 1700	Joint laxity, contractures IP joint medial 4 fingers, keloid formation	Restrictive lung disease, conduction abnormalities
R1 calpain3-related	CAPN	2–40s	Normal to 80×	Scapular winging; paraspinal involvement/scoliosis	Most common form
R2 dysferlin-related	DYSF	Teens to 20s	High: 10× to 72×	Allelic with distal myopathies	Respiratory weakness later in disease
R3 α -sarcoglycan related	R3 SGCA	3–15	>10×	Mild to severe phenotype; contrac- tures/scoliosis; calf pseudo- hypertrophy	Respiratory and cardiac involvement; orthopedics
R4 β -sarcoglycan related	R4 SGCB				
R5 γ -sarcoglycan related	R5 SGCG				
R6 δ -sarcoglycan related	R6 SGCD				
R7 telethonin-related	TCAP	9–15	3×–30×	Tibialis anterior affected in some	Cardiac involvement
R9 FKRP-related	FKRP	1st–20s	High: 10× to 30×	Proximal > distal	Respiratory weakness, cardiomyopathy
R12 anoctamin 5-related	ANO5	Variable: 1–7th decade	Typically high: up to 150×	Mild forms can have high CK with normal strength	Cardiac involvement
R22 collagen 6-related	COL6A1, COL6A2, COL6A3	2–4 years	1.5×	Proximal and distal, Contractures	Respiratory weakness

D, Dominant; *R*, recessive.

Other recessive mutations: LGMD R8 TRIM 32-related, LGMD R10 titin-related, LGMD R11 POMT1-related, LGMD R13 Fukutin-related, LGMD R14 POMT2-related and others.

Clinical Presentation

Although FSHD can affect people at all ages, most patients present in their late teens or early twenties with weakness in a characteristic pattern, often with dramatic side-to-side asymmetry: typically first in the face, shoulders, and arms, and later involving the trunk and distal lower extremities. Patients are unable to squeeze their eyes shut, have a transverse smile, scapular winging, loss of proximal muscle mass with often preserved forearm muscles, and a positive Beevor sign (movement of the umbilicus up or down when asked to tense the abdominal muscles). Extramuscular manifestations of FSHD are rare: retinal vascular changes, which can occasionally lead to symptomatic retinal vasculopathy termed Coat syndrome, high-frequency hearing loss, and atrial arrhythmias.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical examination and family history and is confirmed by genetic testing. The differential diagnosis includes other myopathies such as inclusion body myositis, limb-girdle muscular dystrophies and acid maltase deficiency.

Treatment

There are currently no pharmacologic disease-modifying therapies available. However, several therapy approaches are being studied with the unifying goal to suppress DUX4. One drug is currently being tested in a multisite clinical trial. In the interim, treatment is supportive with ankle bracing and assistive devices. In selected patients surgical fixation of the scapular can improve function. Monitoring for retinal disease, hearing loss, and respiratory function is indicated.

Prognosis

FSHD is not life limiting, but approximately 20% over the age of 50 will require a wheelchair.

CONGENITAL MYOPATHIES

Congenital myopathies are defined by their appearance on biopsy (E-Table 124.2; and see Fig. 142.1C) and have a large number of genetic mutations associated with them. They are usually present at birth with hypotonia and subsequent delayed motor development. If the child survives the perinatal period, most congenital myopathies are relatively nonprogressive and may not be diagnosed until the second or third decade. Clinical findings common in the congenital myopathies are reduced muscle bulk, slender body build, a long and narrow face, skeletal abnormalities (high-arched palate, pectus excavatum, kyphoscoliosis, dislocated hips, and pes cavus), and absent or reduced muscle stretch reflexes.

METABOLIC MYOPATHIES

Metabolic myopathies are muscle diseases due to mutations in enzymes responsible for energy production including glycogen, lipid, and mitochondrial metabolism (E-Table 124.3). Classically, these disorders present in older children or adults with episodes of exercise intolerance, muscle cramping, myalgia, and recurrent rhabdomyolysis associated with myoglobinuria. Newborns and infants can present with severe multisystem disorders that are often fatal.

Glucose and Glycogen Metabolism Disorders

Definition and Epidemiology

Glucose, and its storage from glycogen, is essential for the short-term, predominantly anaerobic energy requirements of muscle (see E-Table 124.3). Disorders of glucose and glycogen metabolism (called glycogenosis) have two distinct syndromes: (1) static symptoms of fixed weakness without exercise intolerance or myoglobinuria and (2) dynamic

symptoms of exercise intolerance, pain, cramps, and myoglobinuria. Acid maltase deficiency (Pompe disease) is an example of the first and is treatable with enzyme replacement therapy, which is life extending for the childhood variant. McArdle disease is an example of the second. The incidence varies between region and ethnic group. For example, acid maltase deficiency has an incidence as high as 1:14,000 in African Americans. The prevalence of McArdle disease is approximately 1:100,000.

Genetics and Pathology

All are due to mutations in enzymes responsible for glucose or glycogen metabolism. Muscle biopsies usually show subsarcolemmal accumulation of glycogen.

Clinical Presentation

Acid maltase disease typically has a severe infantile form with respiratory and cardiac involvement and a slowly progressive adult myopathy, which can present with respiratory muscle weakness as the initial symptom. McArdle disease presents with severe episodes of muscle cramping and contractures associated with exercise and a fixed myopathy later in life. Many patients note a “second wind” phenomenon, which means that after a brief period of rest patients can resume physical activity with improved tolerance.

Diagnosis and Differential Diagnosis

Diagnosis is made by characteristic appearance on muscle biopsy with subsequent study of the enzyme activity or by searching for specific genetic mutations. The differential diagnosis includes other glycogen storage disorders, disorders of lipid metabolism, or mitochondrial disorders.

Treatment

The only glycogen storage disorder with a therapy approved by the FDA is enzyme replacement for infantile or adult-onset acid maltase deficiency. Therapies targeting the genetic mechanism of acid maltase deficiency are expected to enter clinical trials in the near future.

Prognosis

The spectrum is wide from severe fatal infantile diseases to milder symptoms in adults.

DISORDERS OF FATTY ACID METABOLISM

Disorders of lipid metabolism differ from glucose and glycogen disorders in that the metabolic derangement is in the enzymatic breakdown of fatty acids (see E-Table 124.3). Many present in childhood with episodes of encephalopathy precipitated by fasting with hypoketotic hypoglycemia. Serum fatty acid profiles often show reduced carnitine and increased longer chain fractions, depending on whether the mutation is in very long chain, long chain, or medium chain fatty acid metabolism. Adults typically show exercise intolerance and myoglobinuria and may develop a mild limb-girdle pattern myopathy. The most prevalent disorder of fatty acid metabolism is carnitine palmitoyltransferase II (CPT II) deficiency. This disease ranges from a lethal neonatal form to an adult form with muscle pain and recurrent myoglobinuria, often precipitated by exercise, febrile illness, or fasting. The diagnosis is usually made by detection of reduced CPT II activity in skeletal muscle with confirmatory genetic testing.

MITOCHONDRIAL MYOPATHIES

Definition and Epidemiology

Mitochondrial myopathies can present at any age, with varying degrees of severity or weakness, affect multiple organ systems, and have any

E-TABLE 124.2 Congenital Myopathies

Pathologic Finding	Associated Genes	Phenotype	Surveillance
Central core, multicore	19q13 RYR1 (ryanodine receptor); 1q36 SEPN1; 14q11 MYH7	Limb-girdle pattern weakness; scoliosis; respiratory involvement; malignant hyperthermia susceptibility	Caution with anesthesia
Nemaline rod	Sarcomeric thin filament genes: 1q42 ACTA1; 1q21 TPM3; 9p13 TPM2; 2q23 NEB; 19q13 TNNT1; 14q13 CFN2; 3p22 KCHL40	Limb-girdle pattern, hypotonia, absent tendon reflexes, facial weakness, neck flexors	Respiratory involvement; independent ambulation by 18 months predictive of survival
Centronuclear	Myotubular: Xq28 XMTM1; 19p13 DNM2; 12q21 MYF6; 2q14 BIN1; 19q13 RYR1; 2q31 TTN	Limb-girdle pattern; hypotonia; respiratory involvement; cardiac rarely	Respiratory involvement
Fiber type disproportion (type 1)	See nemaline rod; plus Xq13, 1p36 SEPN1	Limb-girdle pattern, scoliosis, hypotonia, respiratory involvement	Respiratory involvement
Reducing body	Xq26 FHL1	Limb-girdle pattern, scoliosis, hypotonia, respiratory involvement	Respiratory involvement; cardiac late
Sarcotubular Myofibrillar	9q31 TRIM32 Desmin-storage: 2q35 Desmin; 11q22 alpha beta crystalline; 5q31 myotilin; 10q23 ZASP; 2q32 filamin C; 10q25 BAG3	Limb-girdle pattern, scapular winging Limb-girdle pattern, cardiomyopathy	Cardiac involvement

E-TABLE 124.3 Selected Metabolic Myopathies

Class	Name	Enzyme/Gene	Phenotype	Testing
Glycogen Storage				
Type II	Pompe disease	Acid maltase/ <i>GAA</i> , 17q21	Infantile: Hypotonia, cardiomegaly, hepatomegaly, fatal in 1st year without treatment. Adult: Limb-girdle weakness, respiratory failure	Muscle biopsy with non-rimmed vacuoles and PAS positive material. Decreased enzyme activity in muscle, lymphocytes, or fibroblasts.
Type III	Cori-Forbes disease	Debrancher/ <i>AGL</i> , 1p21	Infantile: Hypotonia. Adult: Limb-girdle pattern with distal weakness, respiratory involvement	Muscle biopsy PAS positive glycogen deposits. Decreased enzyme activity in fibroblasts or lymphocytes.
Type IV	Andersen disease	Branching/ <i>GBE1</i> , 3p12	Infantile: Hypotonia. Adult: Limb-girdle pattern, ± distal	PAS-positive, diastase-resistant filamentous polysaccharides (polyglucosan bodies); decreased enzyme activity in skin fibroblasts, muscle or liver
Type V	McArdle disease	Myophosphorylase/ <i>PYGM</i> , 11q13, recessive	Infantile: Profound weakness. Adult: Exercise intolerance, cramps, fatigue, limb-girdle pattern, second wind phenomenon, CK elevated >90%	Electrically silent muscle contractions; subsarcolemmal glycogen deposits; decreased enzyme activity from muscle
Type VII	Tarui disease	Phosphofructokinase/ <i>PFKM</i> , 12q13	Childhood: Cramps, fatigue, exercise intolerance	Accumulation of free glycogen in muscle; hemolytic anemia; enzyme deficiency in muscle, erythrocytes
Lipid Metabolism				
	Carnitine palmitoyltransferase II deficiency	CPT II, 1p32	Neonatal/infantile: Severe, fatal. Adult: Exercise or illness related, cramping, recurrent myoglobinuria, usually no fixed weakness	Low total serum carnitine; increased acylcarnitine fraction; reduced enzyme activity in skeletal muscle
	Very long chain acylcoenzyme A dehydrogenase deficiency	ACADVL, 17p13	Childhood: Nonketotic hypoglycemia can have severe form with cardiomyopathy. Adult: Rare, exercise/fasting induced myalgias or myoglobinuria	Reduced VLCAD activity in fibroblasts; increased lipid staining in muscle

Continued

E-TABLE 124.3 Selected Metabolic Myopathies—cont'd

Class	Name	Enzyme/Gene	Phenotype	Testing
	Long chain acylcoenzyme A dehydrogenase deficiency	ACADL, 2q34	Infancy: Failure to thrive, nonketotic hypoglycemia, cardiomegaly, encephalopathy. Adult: Myopathy with cramps and myoglobinuria	Reduced total and free carnitine levels; increased long chain acylcarnitine esters; reduced enzyme activity in fibroblasts
	Medium chain acylcoenzyme A dehydrogenase deficiency	ACADM, 1p31	Infancy: Failure to thrive, nonketotic hypoglycemia, cardiomegaly, encephalopathy. Adult: Mild myopathy later in life	Reduced total and free carnitine; decreased enzyme activity in lymphocytes, fibroblasts, and liver; excess lipid in muscle
Mitochondrial				
	Myoclonic epilepsy associated with ragged red fibers (MERRF)	Mitochondrial mutations, ≈80% m.8344 A>G	Mean onset 20s, epilepsy, myoclonus, ataxia, dementia, short stature, optic atrophy, Wolff Parkinson White syndrome	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS)	Mitochondrial mutations, ≈80% m.3243 A>G	Onset variable, normal psychomotor development, then episodes of encephalopathy, migraine, seizures, stroke-like symptoms, anorexia and vomiting, short stature, deafness, myopathy with exercise intolerance	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Mitochondrial neurogastrointestinal encephalopathy (MNGIE)	Genomic mutations, TYMP, 22q13	Onset variable mostly <20 years, visceral neuropathy (gastroparesis, obstipation, diarrhea), ptosis, external ophthalmoplegia, sensory > motor neuropathy, hearing loss	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Kearns-Sayre syndrome	Single large mitochondrial deletion (≈80%); also individual mutations	Onset <20 years; external ophthalmoplegia; pigmentary degeneration of retina; heart block; myopathy	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Leigh syndrome	Many genes nuclear (complex I-IV); SURF-1, 9q34; mitochondrial	Typical: Onset 1st year; hypotonia; episodic vomiting, ataxia; encephalopathy; hearing loss; visual loss; death often within 2 years of onset	Muscle normal histology but COX negative; elevated lactate (CSF > blood); MRI high T2 in lentiform and caudate nuclei
	Progressive external ophthalmoplegia (PEO)	Nuclear: POLG 15q25; ANT1 4q35; Twinkle 10q23; POLG2 17q. Mitochondrial: deletions or depletion	Onset variable typically >20 years; ptosis; ophthalmoparesis often without double vision; plus syndromes have myopathy and variable organ involvement	Muscle biopsy ragged red fibers; genetic testing or mitochondrial sequencing

GAA, Acid α -glucosidase; *GBE1*, glycogen branching enzyme 1.

 pattern of inheritance (see E-Table 124.3). Mutations affect enzymes necessary for normal mitochondrial function and can be mitochondrial or nuclear. The overall prevalence for mitochondrial disorders is thought to be approximately 1:8500; however, the prevalence of individual mitochondrial syndromes is much lower and ranges from just a handful of cases, to 1 to 6 per 100,000.

Genetics and Pathology

Mutations can occur in both mitochondrial DNA (in which case inheritance is maternal) and nuclear DNA (autosomal dominant, recessive, or X-linked). Mitochondrial disorders produce biochemical defects proximal to the respiratory chain (involving substrate transport and usage) or within the respiratory chain. On muscle biopsy, muscle fibers contain abnormal mitochondria. Pathologically, these fibers have a “ragged red” appearance on biopsy stains (trichrome) and fail to react for cytochrome C oxidase.

Clinical Presentation

Despite the diversity, certain patterns are characteristic for mitochondrial disorders, including slowly progressive myopathy and myalgias, which worsen with exertion or illness, and ptosis and/or ophthalmoplegia. E-Table 124.3 lists common clinical mitochondrial syndromes.

Diagnosis and Differential Diagnosis

The diagnosis is based on clinical history with recognition of multisystemic involvement, serum lactate levels, which can be elevated at rest, and characteristic findings on muscle biopsy. Diagnosis is confirmed by mitochondrial or nuclear genetic testing.

Treatment

Treatment is largely supportive and includes identification of other multisystem involvement, including diabetes, cardiac and ophthalmologic involvement, and hearing loss. Many agents have been tried in mitochondrial diseases, including coenzyme Q10, creatine, and carnitine. Aerobic exercise may reduce fatigue and improve muscle function, although there are no large trials of efficacy for either supplements or exercise.

Prognosis

The severity and prognosis depend partially on the load of abnormal mitochondrial DNA as well as the degree of multisystem involvement. Certain clinical syndromes with more predictable prognosis have been described (see E-Table 124.3).

MUSCLE CHANNELOPATHIES

The muscle channelopathies are a spectrum of disorders due to mutations in muscle ion channels commonly divided into the nondystrophic myotonias and periodic paralyses. Most are inherited in an autosomal dominant fashion, with episodic symptoms, often triggered by temperature or certain foods.

Nondystrophic Myotonias

Definition and Epidemiology

Nondystrophic myotonias are due to dysfunction of sodium or chloride channels resulting in hyperexcitable muscle and myotonia. The overall worldwide prevalence for nondystrophic myotonias is 1:100,000.

Genetics

Nondystrophic myotonias are caused by mutations in the muscle chloride (CLCN1) or sodium (SCN4A) channel genes causing alterations of depolarization and hyperpolarization of the muscle fiber membrane.

Clinical Presentation

As the name implies, patients have myotonia (see Table 124.2). Chloride channel mutations have a characteristic warm-up of myotonia with repetition. Sodium channel myotonias typically have more eye closure myotonia and can demonstrate a paradoxical worsening of myotonia with activity (paramyotonia). Symptoms usually start in the first decade, and patients can have a characteristic muscular build.

Diagnosis and Differential Diagnosis

Diagnosis is based on family history, clinical examination, and electrodiagnostic testing. It is confirmed by genetic testing. The differential diagnosis includes myotonic dystrophy and secondary causes of myotonia (other myopathies and drugs associated with myotonia—e.g., statins, fibric acid derivatives, and colchicine).

Treatment

Treatment for nondystrophic myotonias consists of non-mutation-specific sodium-channel blockade: mexiletine, a class IB antiarrhythmic, is the first-line therapy, but ranolazine, phenytoin, procainamide, and flecainide can be considered. Certain sodium-channel myotonias respond to the carbonic anhydrase inhibitor acetazolamide.

Periodic Paralyses

Definition and Epidemiology

The periodic paralyses are disorders that present with episodic weakness often triggered by exercise or food. Overall prevalence for the primary periodic paralyses varies between conditions from 1:100,000 to 1:1,000,000.

Genetics and Pathology

Periodic paralysis is caused by mutations in the calcium (CACN1A5), sodium (SCN4A), and potassium-channel (KCNJ2) genes that result in depolarized but inexcitable sarcolemma and episodes of paralysis. Hyperkalemic periodic paralysis is due to sodium-channel mutations that lead to persistent inward sodium current causing both myotonia and paralysis. Hypokalemic periodic paralysis can be caused by calcium-, sodium-, and potassium-channel mutations and is due to an anomalous gating pore current that, in low potassium conditions, produces a depolarizing current larger than hyperpolarizing potassium currents. Andersen-Tawil syndrome is due to loss of function in a potassium inward rectifier.

Clinical Presentation

Common to all are attacks of weakness first presenting in childhood or early adulthood, often brought on by rest after exercise, or in the mornings, and associated with changes in extracellular potassium. Hyperkalemic periodic paralysis is associated with either high or normal extracellular potassium, triggered by potassium-rich foods. In hypokalemic periodic paralysis attacks are associated with low extracellular potassium and are triggered by carbohydrates, stress, alcohol, or rest after exercise. Andersen-Tawil syndrome is characterized by the clinical triad of attacks of flaccid paralysis, dysmorphic features (wide-set eyes, narrow mandible, low-set ears, bent fifth finger, and common origin for the second and third toes), and polymorphic ventricular tachyarrhythmias.

Diagnosis and Differential Diagnosis

Diagnosis is based in family history and clinical history, supported by electrodiagnostic testing and confirmed by genetic testing.

Treatment

In all of the periodic paralyses disorders mild exercise at onset of weakness can abort attacks of paralysis. Treatment for acute attacks

consists of carbohydrates (hyperkalemic periodic paralysis) or potassium supplementation (hypokalemic periodic paralysis). Prophylactic treatment for all the periodic paralyses consists of carbonic anhydrase inhibitors.

ACQUIRED MYOPATHIES

Unlike the inherited myopathies, the acquired myopathies are typically secondary to another process: toxic, autoimmune, inflammatory, or infectious. Pathologic changes can be distinctive and are not due to mutations in muscle-related proteins. Clinically, symptoms appear acutely or subacutely.

Inflammatory Myopathies

The idiopathic inflammatory myopathies can be divided into dermatomyositis/polymyositis and sporadic inclusion body myositis (Table 124.8).

Dermatomyositis/Polymyositis

Definition and epidemiology. Dermatomyositis/polymyositis (DM/PM) are acquired idiopathic diseases of muscle characterized by inflammation and variable symmetrical proximal muscle weakness, associated with elevated serum creatine kinase and irritable features on electromyography. The overall annual incidence is approximately 1 in 100,000.

Pathology. Dermatomyositis shows a pathognomonic pattern on muscle biopsy of perifascicular atrophy and perivascular inflammatory infiltrates and positive pericapillary membrane attack complex staining (see Fig. 124.1D). In contrast, polymyositis shows endomysial inflammatory infiltrates with invasion of non-necrotic fibers.

Clinical presentation. Dermatomyositis can occur at any age with an acute to insidiously progressive onset of symmetrical proximal muscle weakness with characteristic skin changes, which include heliotrope rash, shawl sign (maculopapular violaceous rash in V-shape around neck), Gottron nodules (erythematous papular rash on the extensor surfaces of the hands or fingers), and mechanic's hands (dry, cracked skin on the dorsal or ventral hands). In contrast, polymyositis is largely a diagnosis of exclusion, occurring in adults without associated skin changes. Myalgias are more common in polymyositis. Both DM/PM can be associated with respiratory weakness, interstitial lung disease, difficulty swallowing, or cardiomyopathy. Both DM/PM can be associated with underlying malignancy (dermatomyositis more frequently than polymyositis), so screening for malignancy is recommended especially in patients over age 40.

Diagnosis and differential diagnosis. Diagnosis is based on clinical history and examination findings in conjunction with irritable

changes on electromyography (e.g., fibrillation potentials and positive sharp waves) and characteristic muscle biopsy. In about 30%, both DM/PM can be associated with myositis specific autoantibodies (see Table 124.2). Antibodies can help define a clinical syndrome and guide treatment. For example, patients with anti-Jo-1 antibodies can have interstitial lung disease and methotrexate may need to be avoided due to pulmonary toxicity. Patients may be at higher risk to develop malignancy with antibodies to transcription intermediary factor (TIF)-1gamma (anti-p155, anti-p155/140) and to nuclear matrix protein (NXP)-2 (anti-MJ or anti-p140). Muscle biopsy can help differentiate from other inflammatory myopathies associated with systemic disease (e.g., sarcoidosis).

Treatment. For both DM/PM the first line of treatment is prednisone. Steroid-sparing immunosuppressive therapies (e.g., methotrexate, azathioprine) are often added for those patients requiring long-term therapy in order to reduce the required dose of prednisone or to replace prednisone completely. In patients who do not respond to conventional therapy or have severe symptoms, intravenous immunoglobulin is used. Rituximab may also be effective.

Prognosis. Most patients respond to immunosuppressive therapies.

Sporadic Inclusion Body Myositis

Definition and epidemiology. Sporadic inclusion body myositis (s-IBM) is an idiopathic, slowly progressive muscle condition in older adults (occurring in more men than women), associated with inflammation and characteristic pathologic changes on muscle biopsy. It is the most common inflammatory muscle disease in patients over 50, affecting 3.5 per 100,000.

Pathology. Muscle biopsies resemble polymyositis with endomysial inflammatory infiltrates and invasion of non-necrotic fibers. Distinctive for IBM are vacuoles rimmed by mitochondria, secondary mitochondrial changes, and electron microscopy, which shows 15- to 18-nm tubulofilamentous inclusions.

Clinical presentation. S-IBM causes slowly progressive, often asymmetric weakness. It occurs usually after 50 years of age in an initially distinctive pattern, including distal forearm muscles (distal finger flexors) and quadriceps wasting and weakness. This can progress to involve almost any muscle and can affect swallowing in up to 70% of patients.

Diagnosis and differential diagnosis. Diagnosis is based on clinical history and examination and characteristic muscle pathology. In clinically challenging cases autoantibody levels directed against cytoplasmic 5'-nucleotidase 1A (anti-cN1A) can be helpful, with an estimated specificity around 90%. The main differential diagnosis is other idiopathic inflammatory myopathies or late-onset inherited

TABLE 124.8 Idiopathic Inflammatory Myopathies

Myopathy	Sex	Typical Age at Onset	Pattern of Weakness	Creatine Kinase	Muscle Biopsy	Response to Immunosuppressive Therapy
Dermatomyositis	Women > men	Childhood and adult	Proximal > distal, respiratory weakness, dysphagia	Increased (up to 50× normal)	Perifascicular atrophy, inflammation, complement deposition on capillaries	Yes
Polymyositis	Women > men	Adult	Proximal > distal	Increased (up to 50× normal)	Endomysial inflammation; invasion of non-necrotic fibers	Yes
Sporadic inclusion body myositis	Men > women	Elderly (>50 yr)	Proximal and distal; predilection for finger and wrist flexors, knee extensors	Increased (<10× normal)	Endomysial inflammation, rimmed vacuoles; electron microscopy: 15- to 18-nm tubulofilaments	No

myopathies. The prominent hand weakness can be misinterpreted as neurogenic (e.g., amyotrophic lateral sclerosis) and electrodiagnostic studies can help differentiate the two.

Treatment. Unlike the other inflammatory myopathies, IBM does not respond to immunosuppression. Treatment is supportive.

Prognosis. Most patients with s-IBM progress to needing a wheelchair over 10 to 15 years. Swallowing difficulty can be life-threatening.

Myopathy With HMGCR Antibodies

Patients typically present with proximal greater than distal symmetric weakness and myalgia. Most patients, but not all, report concurrent or prior exposure to statins. The CK is usually high. EMG can show muscle fiber irritability with myotonic discharges. Laboratory testing is positive for autoantibodies against 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR). Muscle biopsy shows a necrotizing myopathy. Treatment includes discontinuation of statin therapy and corticosteroids or IVIG. With early recognition and treatment, patients can recover markedly.

Infectious Myositis

An acute viral myositis can occur in the setting of viral infections. Patients develop muscle pain, proximal weakness, and elevated CK levels. The disorder is self-limited but when severe can be associated with myoglobinuria and occasionally with renal failure.

An inflammatory myopathy can occur in the setting of human immunodeficiency virus infection, either in early or in later acquired immunodeficiency syndrome. The clinical presentation resembles polymyositis. The patient's condition may improve with corticosteroid therapy. The disorder must be distinguished from the toxic myopathy caused by zidovudine, which responds to dose reduction. Although rarely seen, tuberculosis can present with muscle abscess (pyomyositis) either in the setting of pulmonary or disseminated disease or in isolation.

Myopathies Caused by Endocrine and Systemic Disorders/Corticosteroid Myopathy

Thyroid studies should be part of the evaluation in any adult with muscle weakness. Patients with hyperthyroidism often have some degree of proximal weakness but this is rarely the presenting manifestation of thyrotoxicosis. Hypothyroid myopathy is associated with proximal weakness and myalgias, muscle enlargement, slow relaxation of the reflexes, and marked (up to 100-fold) increase of the serum CK level.

Excess corticosteroids can result from endogenous Cushing's syndrome; however, muscle weakness is rarely the presenting manifestation of Cushing's syndrome.

The most common endocrine myopathy is an iatrogenic **corticosteroid myopathy**, due to exogenous glucocorticoid administration. CK is typically low or normal and EMG normal. Muscle biopsy can show type 2 fiber atrophy. Therapy consists of reducing the corticosteroid dose to the lowest possible level, exercise, and adequate nutrition.

Toxic Myopathies

Many drugs, for example hydroxychloroquine, have been associated with muscle damage, proximal weakness, elevated CK levels, myopathic EMG readings, and abnormalities on muscle biopsy. Symptoms generally improve after stopping the medication.

Critical illness myopathy, also termed acute quadriplegic myopathy, develops in a patient in the intensive care setting and is often discovered when a patient is unable to be weaned off a ventilator. The cause of the diffuse weakness is the prolonged daily use of either high-dose intravenous glucocorticoids or nondepolarizing neuromuscular blocking agents, often both. Patients often have had sepsis and multiorgan failure. The diagnosis of critical illness myopathy is often clinical but can be confirmed by muscle biopsy, which shows the loss of myosin-thick filaments on electron microscopic examination. Treatment is discontinuation of the offending agents and early intensive physical therapy.

Neuromuscular Junction Disease

Emma Ciafaloni

Neuromuscular junction diseases are caused by abnormal neuromuscular transmission of the action potential from the nerve terminal to the muscle, and they can be autoimmune (myasthenia gravis, Lambert-Eaton syndrome), hereditary (congenital myasthenic syndromes), or toxic (botulism, organophosphate intoxication).

MYASTHENIA GRAVIS

Definition/Epidemiology/Pathology

Myasthenia gravis (MG) is a rare autoimmune disease caused by antibodies against the postsynaptic acetylcholine receptors (AChR Ab) in the neuromuscular junction. All ages are affected but incidence is higher in women younger than 40 and in men older than 50. Prevalence is approximately 20 in 100,000. Transient neonatal MG occurs in about 12% of newborns of myasthenic mothers and is caused by transplacental passive transfer of antibodies from the mother to the fetus. Thymoma is found in 10% of patients with MG and thymic hyperplasia is present in 65%.

Clinical Presentation

MG is characterized by fluctuating, fatigable weakness either isolated to the ocular muscles (ocular MG) or involving ocular as well as limb, bulbar, and respiratory muscles (generalized MG). The majority of patients present first with ocular symptoms (blurred vision, double vision, droopy eyelids), but about 15% of cases present with bulbar symptoms first (dysarthria, dysphagia, shortness of breath) or limb weakness. Ptosis is usually asymmetric. Myasthenia crisis is a true neurologic emergency that occurs in 15% to 20% of patients and consists of severe dysphagia or respiratory failure requiring ventilator support and/or tube feeding in an ICU setting.

Diagnosis and Differential Diagnosis

The diagnosis of MG is based on a combination of clinical history, physical examination, and confirmatory tests. The ice pack test is a simple and relatively sensitive test to differentiate ptosis caused by MG from other causes of ptosis. In this test an ice pack is applied to the ptotic eye for 2 minutes and an improvement of 2 mm or more in ptosis supports MG.

Edrophonium chloride (Tensilon) is a short-acting acetylcholinesterase inhibitor administered intravenously to demonstrate symptom improvement in patients with MG. A positive Tensilon test is defined as an unequivocal improvement in strength in an affected muscle after 2 to 5 minutes from administration of 2 mg incremental doses up to 10 mg. Atropine should be available during a Tensilon test because bradycardia and hypotension are possible side effects. Edrophonium testing can be positive in other disorders.

Electrodiagnostic testing with 3 Hz repetitive nerve stimulation (RNS) demonstrates a compound muscle action potential

(CMAP) decrement more than 10% in about 50% to 75% of patients with generalized MG but is abnormal in less than 50% of patients with purely ocular symptoms. Single fiber electromyography (SFEMG) is the most sensitive test in the diagnosis of MG and reveals increased jitter and blocking in 99% of patients with generalized MG and in 97% of those with purely ocular MG when a weak muscle is tested. SFEMG is usually available only in specialized EMG laboratories.

Serum antibody testing for AChR Ab (binding antibody) is positive in about 80% of patients with generalized MG and 50% of patients with purely ocular symptoms. Muscle specific tyrosine kinase (Anti MuSK) antibody is detected in a portion of seronegative patients, more frequently women.

Chest CT should be performed to rule out thymoma, found in approximately 10% of seropositive myasthenic patients. Thyroid function should be evaluated because thyroid disease is commonly associated with MG. Electrodiagnostic and serum antibody testing help with differentiating MG from motor neuron disease, Lambert-Eaton myasthenic syndrome (LEMS), and Guillain-Barré syndrome (GBS).

Treatment

Pyridostigmine 30 to 60 mg every 4 hours improves symptoms in most patients with MG; it is used alone to treat purely ocular and generalized cases with only minimal or mild weakness, or in combination with immunosuppressant drugs in patients with more severe manifestations. Prednisone is effective in improving muscle weakness in a short period of time, but long-term use is associated with side effects. Azathioprine and mycophenolate mofetil are used for long-term treatment and as steroids-sparing agents. Eculizumab is a complement inhibitor recently approved for patients with generalized MG with positive AChR antibody. Plasmapheresis and IVIG are used for cases with severe bulbar or generalized weakness, respiratory crisis, and in refractory patients who do not respond to oral immunomodulating medications. Thymoma resection is indicated in all patients with MG and thymoma. Thymectomy is also recommended in patients with nonthymomatous autoimmune MG to increase the probability of remission or improvement. Thymectomy is usually not recommended in patients over age 60. Some medications may exacerbate the symptoms of MG or precipitate the initial signs and symptoms of the disease (Table 125.1).

Prognosis

Most patients with MG who are optimally treated experience improvement or remission of their symptoms. About 10% of patients with MG experience refractory symptoms despite optimal treatment. Mortality is currently less than 5%.

TABLE 125.1 Drugs to Be Avoided or Used With Caution in Myasthenia Gravis

- D-penicillamine
- Penicillins
- Telithromycin
- Interferon- α
- Aminoglycoside antibiotics
- Fluoroquinolones
- Nitrofurantoin
- Tetracyclines
- Sulfonamides
- Botulinum toxin
- Magnesium, magnesium salts contained in some laxatives and antacids
- Neuromuscular blocking agents such as succinylcholine and vecuronium should only be used by an anesthesiologist familiar with MG
- Quinine, quinidine or procainamide
- β -blockers (propranolol; timolol maleate eyedrops)
- Calcium-channel blockers
- Iodinated contrast agents
- Checkpoint inhibitors: pembrolizumab
- Anesthetics: Methoxyflurane, succinylcholine

LAMBERT-EATON MYASTHENIC SYNDROME

Definition/Epidemiology/Pathology

LEMS is an acquired, presynaptic neuromuscular transmission disorder caused by antibodies against the P/Q type voltage-gated calcium channel (VGCC). P/Q VGCC antibodies cause reduced Ca^{2+} influx into the presynaptic nerve terminal, resulting in decreased acetylcholine release and neuromuscular transmission failure. LEMS is associated with cancer, usually small cell lung carcinoma, in 60% of cases. LEMS may predate tumor detection by up to 3 years. LEMS is very rare and more common in men (3:1).

Clinical Presentation

LEMS should be suspected whenever the triad of muscle weakness, dry mouth, and decreased or absent reflexes is present. Patients have fluctuating weakness and fatigability of proximal limb and trunk muscles, with the lower limbs more severely affected than the upper ones. Difficulty walking is a common symptom. Dysphagia, dysarthria, and ocular symptoms (ptosis, blurred vision, and diplopia) are less common than in MG. Tendon reflexes are hypoactive or absent and may increase following short exercise of the muscle. Autonomic manifestations (dry mouth, impotence, decreased sweating, orthostatic hypotension, and slow pupillary reflexes) occur in 75% of patients.

Diagnosis and Differential Diagnosis

Serum antibodies against P/Q VGCCs are found in nearly all cases of paraneoplastic LEMS and in about 90% of non-paraneoplastic cases. Electrodiagnostic testing can help confirm the diagnosis by demonstrating reduced CMAP amplitudes in distal hand muscles; CMAP facilitation of at least 100% after 10" maximal voluntary contraction or high frequency RNS (post-tetanic facilitation); and CMAP decrement greater than 10% with low frequency RNS. Patients diagnosed with LEMS should be screened and monitored with chest CT for lung cancer, especially if they are smokers and over age 50. LEMS and MG can be differentiated with electrodiagnostic and antibody testing.

Treatment

Symptomatic treatment with 3,4 diaminopyridine (3,4-DAP) 5 to 10 mg every 3 to 4 hours and up to a maximum daily dose of 80 to 100 mg is most effective in improving muscle strength in patients with LEMS. Side effects at doses up to 60 mg per day are rare. Acral and perioral paresthesias occur within minutes from a dose and resolve in about 15 minutes. It is contraindicated in patients with seizures. Pyridostigmine 60 mg every 4 hours is also used to improve symptoms. In patients in whom symptoms are not adequately controlled with 3,4-DAP and pyridostigmine, immunomodulation with prednisone, azathioprine, or mycophenolate mofetil is used. Severe weakness is treated with plasmapheresis or IVIG. The underlying cancer should be treated.

Prognosis

In paraneoplastic LEMS the prognosis is determined by the underlying cancer. The presence of LEMS in patients with small cell lung cancer (SCLC) is associated with longer survival from the malignancy. Non-paraneoplastic LEMS, when optimally treated, has an excellent prognosis and normal life expectancy, although patients may continue to experience various degrees of muscle weakness.

BOTULISM

Definition/Epidemiology/Pathology

Botulism is a rare, potentially lethal, paralytic illness caused by the neurotoxin produced by the anaerobic, spore-forming bacterium *Clostridioides botulinum*. Botulinum toxin blocks voluntary and autonomic cholinergic neuromuscular junctions by binding irreversibly to the presynaptic nerve endings where it inhibits the release of acetylcholine. Human forms of the disease include food-borne botulism most commonly caused by home-canned food, wound botulism with most cases occurring among "black tar" heroin users, and infant botulism occurring usually in the second month of life due to intestinal colonization. Outbreaks of food-borne botulism occur in prison inmates due to ingestion of pruno, an alcoholic drink made illicitly in prison. About 145 botulism cases are reported each year in the United States; approximately 15% are food-borne, 65% are infant, and 20% are wound botulism.

Clinical Presentation

The disease is characterized by symmetric descending flaccid paralysis starting with blurred or double vision, ptosis, dysphagia, dry mouth, dysarthria, and muscle weakness. Symptoms usually start 18 to 36 hours after ingesting contaminated food.

Botulism should be suspected in any infant with poor feeding and sucking, constipation, dilated pupils, weak cry, poor tone, and respiratory distress. Sensory examination and mental status are normal.

Diagnosis and Differential Diagnosis

All suspected cases of botulism need to be reported to public health authorities immediately. Local health department and CDC laboratories can confirm the diagnosis by detecting the toxin in serum, stool, or gastric or wound aspirate specimens. Electrodiagnostic testing can also confirm the diagnosis by demonstrating persistent post-tetanic facilitation of CMAP of at least 20%, a decremental response greater than 10% with slow RNS, and increased jitter and blocking on SFEMG. Electrodiagnostic tests are also helpful in differentiating botulism from Guillain-Barré syndrome and myasthenia gravis.

Treatment

Prompt intensive care support with mechanical ventilation and parenteral feeding as needed are crucial in reducing mortality. Timely

administration of equine antitoxin within the first 24 hours may arrest the progression of paralysis and decrease the duration of illness. The antitoxin is provided by the CDC through the local health departments. Children younger than 12 months old should not be fed honey because it can contain *Clostridioides botulinum*.

Prognosis

The proportion of patients with botulism who die has fallen from 50% to between 3% and 5% in the past 50 years. Recovery of muscle strength may take several months. Mortality in untreated botulism is 60%.

ORGANOPHOSPHATE POISONING

Organophosphorus compounds (OPs) are used as pesticides and developed for chemical warfare. Exposure to even small amounts of an OP can be fatal and death is usually caused by respiratory failure. OPs cause inhibition of acetylcholinesterase (AChE) resulting in accumulation of acetylcholine at the cholinergic receptor sites, producing continuous stimulation of cholinergic fibers throughout the nervous system. A combination of an antimuscarinic agent (e.g., atropine), AChE reactivator, such as one of the pyridinium oximes (i.e., pralidoxime, trimedoxime, obidoxime, and HI-6), and diazepam are used for the treatment of OP poisoning in humans.

Geriatrics

126 The Aging Patient, 1126

The Aging Patient

Laura A. Preville, Mitchell T. Heflin, Harvey Jay Cohen

INTRODUCTION

The aging of the world's population compels all health care team members to gain competency in geriatrics, the clinical science of assessment, prevention, and treatment of illness in older adults. A basic grasp of geriatrics requires understanding at epidemiologic, biologic, and clinical levels. The provider must appreciate the impact of aging on presentation of and predisposition to certain conditions, must identify goals of care, and must select appropriate treatment strategies. Moreover, care of older adults demands a multifaceted approach, accounting for individual, family, and community resources. Finally, the practice of geriatrics requires an appreciation for systems of care that include interprofessional teams working in a variety of settings ranging from home to hospital to long-term care to community settings. This chapter will provide an introduction to geriatrics and the essentials of caring for older adults.

Over the last century, the number of Americans over the age of 65 years increased from 3 million to nearly 51 million in 2016, accounting for 16% of the population. During the same period the population over age 85 grew rapidly, expanding from 100,000 in 1900 to nearly 6.4 million in 2016. By 2030, the number of adults over age 65 will likely reach 74 million, or 21% of the total population. Ten million of those people will be over age 85 (Fig. 126.1). A report from the National Institute on Aging and the US State Department points out that this phenomenon is not isolated to the United States. Around the globe, the percentage of the population over 65 years of age will increase by 25% to 50% over the next 25 years and by 140% in developing nations.

EPIDEMIOLOGY OF AGING

Most experts believe that the rapid growth of the population of older adults reflects the many health care successes of the twentieth century. Fries, in his landmark paper, attributes the extension of the human lifespan to "the elimination of premature death, particularly neonatal mortality." Improvements in other aspects of public health, including adequate nutrition and housing, safe drinking water, immunizations, and antibiotics, have led to lower rates of mortality throughout childhood and early adulthood, affording an opportunity for more people to survive to late life. Examination of survival curves across the twentieth century demonstrates a marked change in the shape of the overall graph from nearly linear in 1900 to rectangular in the 1990s, with much of the mortality compressed into late life (Fig. 126.2). However, despite advances in public health, life expectancy at birth continues to vary by race and gender and social drivers of health affect the ability to achieve old age for many. As of 2016, the greatest average life expectancy at birth by ethnicity was in Hispanic females compared to non-Hispanic

black males who average 10 years fewer (E-Fig. 126.1). Although the overall average population life expectancy at birth rose dramatically in the 20th century from 47 years to nearly 77 years with up to 10% of the birth cohort surviving to age 95, the maximum lifespan defined as the age of the oldest surviving humans has remained remarkably stable at around 114 years. 

THE BIOLOGY OF AGING

The relatively static nature of the maximum lifespan reflects the human body's limits at the cellular, tissue, and organ level in dealing with the stresses of aging. Across cell types and organ systems, certain consistent age-related alterations in physiologic function exist. Variability in tissue and organ function decreases, as evidenced by less fluctuation in heart rate or hormone secretion. Organ systems also exhibit predictable declines in function over time Table 126.1. These changes are most evident at times of stress, and ultimately these systems are slower to react and recover. The overall result is an impaired ability to deal with any demands within a narrow range. This progressive restriction in the capacity to maintain homeostasis can be depicted as a steady tapering in the reserve available in multiple organ systems as time progresses (Fig. 126.3). In this situation an individual may function within the normal range in the absence of crisis, but stress such as acute illness may exceed his or her capacity to restore function and recover health. The result at best may be a decline in health and ability, and at worst, death.

THEORIES OF AGING

Scientific research provides a number of plausible theories of aging, which can be grouped into two major categories. *Error or damage theories* propose that aging occurs because of persistent threats from damaging agents derived from environmental stressors and an ever-declining ability to respond to or repair this damage. *Program theories* postulate that genetic and developmental factors most significantly determine the biologic life course and the maximal age of the organism. In actuality, biologic aging may reflect a complex combination of many types of events. In a landmark paper outlining specific "Hallmarks of Aging," Lopez-Ortin suggests nine possible molecular or genetic mechanisms through which physiologic systems age. This section provides an introduction to some of these theories (Fig. 126.4). The end of the chapter also describes the emerging field of geroscience related to these criteria.

The free radical theory of aging proposes that oxidative metabolism results in an excess of highly reactive byproducts, called *oxygen free radicals*, which damage proteins, DNA, and lipids. Molecular injury eventually leads to cell dysfunction and ultimately to tissue and organ

Fig. 126.1 Population age 65 and over and age 85 and over, selected years, 1900-2014, and projected years, 2020-2060. Federal Interagency Forum on Aging-Related Statistics, Washington, D.C., 2016, U.S. Government Printing Office.)

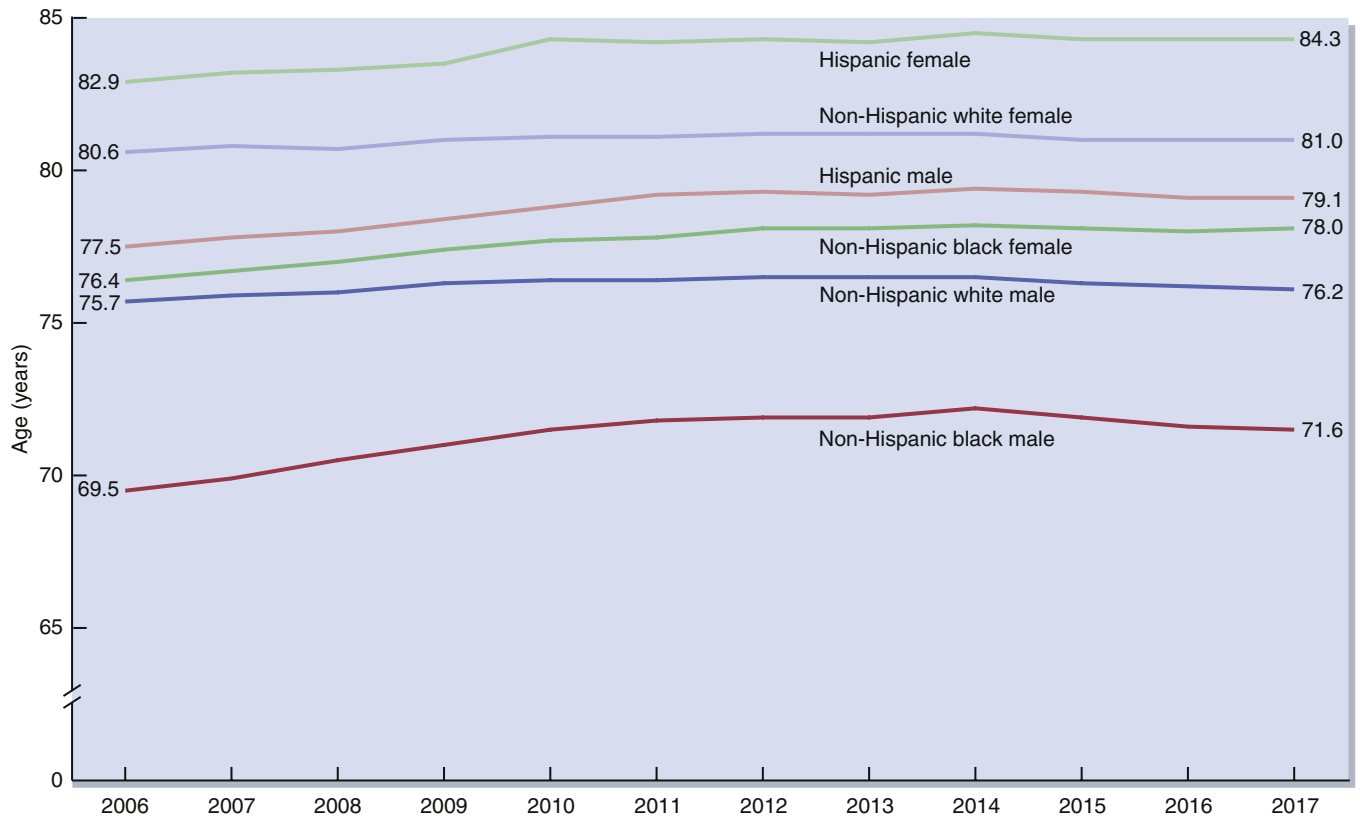

Fig. 126.2 Survival function for SSA population. Population survival curves based on period life tables for: 1900, 1950, 2000 and projected years 2050 and 2100. (From Bell, F.C. and Miller, M. L. Actuarial Study No. 120. Life Tables for the United States Social Security Area 1900-2100. [2005]. https://www.ssa.gov/oact/NOTES/as120/LifeTables_Body.html.)

disrepair. A second theory asserts that the accumulation of glucose-related molecules on proteins contributes to their dysfunction and degradation. These “glycosylated” molecules become more abundant over time and lead to impaired function at the tissue and organ level. Theory proponents point to the many chronic problems that routinely arise in patients with diabetes mellitus as proof of the significance of this phenomenon.

A different line of reasoning asserts that human lifespan and aging result from genetic-based timing mechanisms. Older theories suggest

that evolutionary pressures are biased for traits that promote health and reproduction in early adulthood, possibly at the expense of health and function in late life. Furthermore, little selective pressure exists against negative traits that emerge in late life, leaving humans prone to the ill effects of aging. Geneticists have identified, among species of fruit flies and certain nematodes, specific genes that result in a significant prolongation in the organism’s lifespan. Further exploration of specific modification to gene expression, also called epigenetics, has led to improved understanding of the influence of environmental factors

E-Fig. 126.1 Life expectancy at birth, by Hispanic origin, race, and sex: United States, 2006–2016. (From National Vital Statistics Reports, Volume 68, Number 4. United States Life Tables, 2016.)

TABLE 126.1 Changes in Physiologic Function With Age

Organ System	Age-Related Decline in Function
Special senses	Presbyopia Lens opacification Decreased hearing Decreased taste, smell
Cardiovascular	Impaired intrinsic contractile function Increased ventricular stiffness and impaired filling Decreased conductivity Increased systolic blood pressure Impaired baroreceptor function
Respiratory	Decreased lung elasticity Decreased maximal breathing capacity Decreased mucus clearance Decreased arterial P_{O_2}
Gastrointestinal	Decreased esophageal and colonic motility
Renal	Decreased glomerular filtration rate
Immune	Decreased cell-mediated immunity Decreased T-cell number Increased T-suppressor cells Decreased T-helper cells Loss of memory cells Decline in antibody titers to known antigens Increased autoimmunity
Endocrine	Decreased hormonal responses to stimulation Impaired glucose tolerance Decreased androgens and estrogens Impaired norepinephrine responses
Autonomic nervous	Impaired response to fluid deprivation Decline in baroreceptor reflex Increased susceptibility to hypothermia
Peripheral nervous	Decreased vibratory sense Decreased proprioception
Central nervous	Slowed speed of processing and reaction time Decreased verbal fluency Increased difficulty learning new information
Musculoskeletal	Decreased muscle mass

P_{O_2} , Partial pressure of oxygen.

such as chronic inflammation that impact gene expression and ultimately lifespan.

Study of the enzyme telomerase has also generated much interest among theorists on aging. In a process called apoptosis, cells undergo programmed death to be replaced by younger cells. These divisions and replacements are limited by the number of generations intrinsic to a specific cell line (the Hayflick phenomenon). As telomeres located on the ends of chromosomes are depleted, cell aging and demise eventually occur. The enzyme telomerase prevents telomere shortening and may increase a cell's number of allotted replications and thereby extend the lifespan of the organism. Of course, this advantage must be weighed against the price of "immortality," namely the increased risk of malignancy. Both apoptosis and cellular senescence are considered protective mechanisms against malignancy. The accumulation of senescent cells contributes to the biology of aging through secretion of various proteins that serve as inhibitory factors for halting cellular growth and division. In this way, regenerative capacities diminish when senescent cells shift the balance of cellular communication.

Fig. 126.3 Relative decline by organ system. (From Khan SS, Singer BD, Vaughan DE. [2017]. Molecular and physiological manifestations and measurement of aging in humans. *Aging Cell*, 16[4], 624-633.)

ASSESSMENT OF FRAILTY

Biologic changes of aging portend the increased vulnerability of humans to illness and functional decline in late life—a state commonly referred to as “frailty.” The definition of frailty moves beyond traditional components of chronologic age, comorbidity, and disability to identify a unique clinical entity with independent predictive capacity. Two prevailing models of frailty have emerged—one focused more exclusively on a set of physiologic changes occurring in a cyclical pattern (the frailty phenotype) and the other that includes measures of both physiologic markers as well as disease burden (cumulative deficit frailty). System-specific changes over time lend a specific phenotype of frailty, including weight loss, weakness, poor endurance, slowness, and inactivity. Frailty, defined as three or more of these phenotypic conditions, independently predicts falls, declines in mobility, loss of ability to perform activities of daily living (ADLs), hospitalization, and death. This definition seems to provide a defined link between aging-related disease and disability and, perhaps, a target for interventions to prevent the onset of functional decline.

Alternatively, the impact of multiple external factors over time allows “deficits to accumulate” and impact multiple facets of overall health, cognitive, psychological, and physical function (Fig. 126.5). Many believe that the phenotypic model remains difficult to recognize or measure in the clinical setting. The other definition conceives of frailty as a result of accumulation of problems (or deficits) that ultimately exceeds an individual's ability to maintain function and health. This count of deficits generates an index predictive of disability and death. To some degree both models capture different aspects of complex and heterogeneous phenomena of vulnerability to declines in health and function with aging.

CLINICAL CARE OF OLDER ADULTS

Caring for older adults requires a strong foundation in the basics of internal medicine or family medicine integrated with an appreciation for the complexity and heterogeneity of the impact of aging on health and well-being. The clinician must possess strong diagnostic skills, given that older adults may have unique presentations or multiple comorbid conditions and functional decline. In addition, the clinician must monitor for a number of nonspecific conditions, such

Fig. 126.4 The hallmarks of aging. (From López-Otín C, Blasco MA, Partridge L, et al [2013]. The Hallmarks of Aging. *Cell*, 153[6], 1194-1217.)

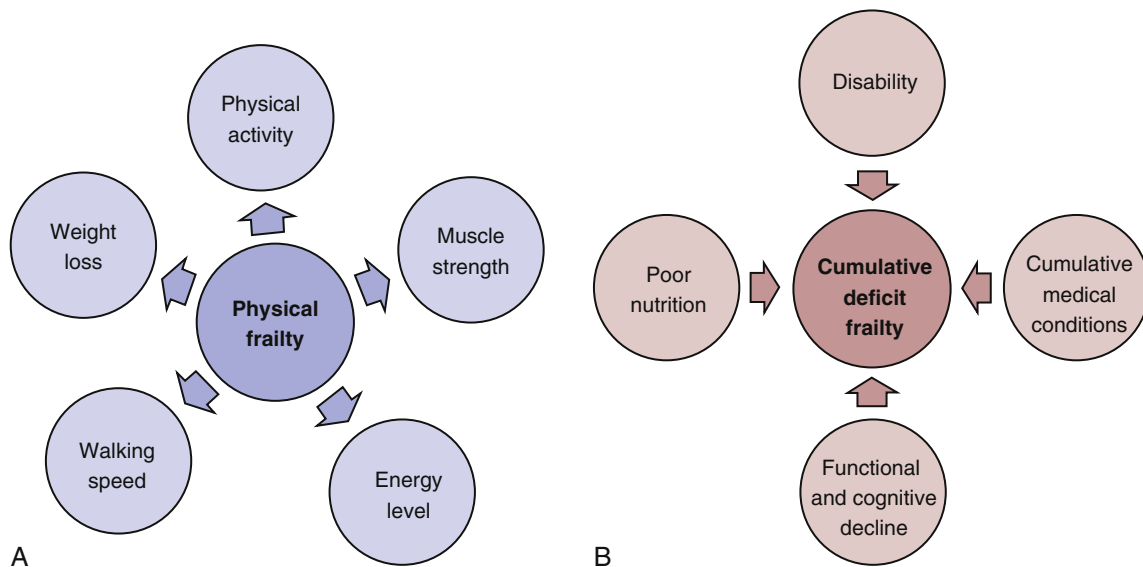

Fig. 126.5 Two major frailty theories. (A) Physical frailty or phenotypic frailty and (B) cumulative deficit frailty. (From Walston, J, Bandeen-Roche, K, Buta, B, et al. TABLE 126.2 The Geriatric 5-M's

Mind	Mentation, dementia, delirium, depression
Mobility	Impaired gait and balance, fall injury prevention
Medications	Polypharmacy, de-prescribing, optimal prescribing, adverse medication effects and medication burden
Multi-Complexity	Multi-morbidity, complex bio-psycho-social situations
Matters Most	Each individual's own meaningful health outcome goals and care preferences

as problems with mobility, mood, or mentation that affect self-care capacity and safety. Treatment strategies present unique challenges as well, often requiring a balance of pharmacologic and nonpharmacologic interventions with careful consideration of the individual's goals for care. Tinetti and colleagues capture these tenants of geriatrics as the five M's: "Mind, Mobility, Medications, Multi-complexity, and Matters Most to Me" (Table 126.2). This section presents the core components of the comprehensive assessment of the older patient.

COMORBID CONDITIONS, FUNCTION, AND LIFE EXPECTANCY

With advancing age and declines in reserve, older adults experience high rates of chronic illness and often related functional decline. Eighty percent of those over age 65 years have at least one chronic illness, and 50% have two or more comorbid conditions. Some of these conditions contribute directly to increased rates of mortality, including the leading causes of death among older adults—heart disease, cancer, stroke, lung disease, and Alzheimer's disease. Many common diseases, however, primarily threaten function and result in disability and institutionalization. Arthritis, hearing loss, and vision impairment are all important problems in this respect. The presence of multiple comorbid conditions compounds the disabling effects of individual diseases and further complicates management. In the era of evidence and guidelines, a clinician caring for a patient with several common chronic conditions, such as diabetes mellitus, coronary artery disease, and osteoporosis, may feel compelled to prescribe six or seven medications to remain in compliance with current recommendations. This practice can result in "polypharmacy" (described later), adding significant cost to the patient with limited accounting for risks, benefits, and individual preferences. In addition to considering the discrete management of individual diseases, care of the older adult requires assessment of the overall impact of treatment on symptoms, function, and life expectancy. To address this common clinical challenge, the American Geriatrics Society maintains publication of guiding principles on care of older persons with multiple comorbid conditions that highlights the importance of accounting for complex interactions between conditions, risks, and benefits of various treatment options, overall prognosis, and patient goals and preferences.

Function, defined formally by Reuben et al., is "a person's ability to perform tasks and fulfill social roles across a broad range of complexity"—more succinctly, self-care capacity. Assessing this ability provides the clinician with a means of understanding the impact of illness, assessing quality of life, identifying care needs, and estimating progress and prognosis. Comprehensive assessment of function should include questions about self-care capacity as well as objective measures of cognition and mobility (see later sections for details about the latter two). Self-care capacity is most often divided into basic, instrumental, and advanced ADLs. Basic ADLs include those actions that maintain personal health and hygiene, including transferring, bathing, toileting, dressing, and eating. Instrumental ADLs (IADLs)

include activities necessary for living independently, specifically driving or using public transportation, cooking, shopping, managing medications and finances, using the telephone (or other communication device), and doing housework. Advanced ADLs include social or occupational functions associated with activities such as hobbies, employment, or caregiving. Approximately 30% of adults over age 65 and 78% of those over age 85 have difficulty with IADLs or one or more basic ADLs. Predictably, as the incidence of disability rises, so does the rate of dependence and placement in skilled facilities. Long-term care in skilled facilities increases from 2% among those aged 65 to 74 to 14% among those older than 85 years. Impairment in ADLs is also associated with an increased risk of falls, depression, and death in the affected elder. Among older adults the assessment of self-care capacity provides key health status information independent of age and comorbid conditions.

For clinicians, navigating the myriad options for management of multiple chronic conditions requires individualized assessment of risks, benefits, and specific goals of various therapies. Estimates of life expectancy, integrating the impact of age, comorbid illness, and function, have been generated to assist in medical decision making. These estimates assist clinicians in predicting median survival and thus can help in estimating the potential life remaining, which can impact treatment decision making (E-Fig. 126.2). For example, the options offered to a frail 85-year-old man with less than 3 years left to live may be quite different from those presented to his healthy counterpart of the same age with a median life expectancy of 5 to 7 years. In addition, any decision should take into account the individual patient's goals and preferences. A variety of prognostic tools exist to assist clinicians with estimating survival in different populations and care circumstances (Table 126.3). These tools can be accessed online in an interactive fashion for clinicians at <http://eprognosis.ucsf.edu/>.

PRESENTATION OF DISEASE IN THE OLDER ADULT

Competent care of the frail older adult starts with recognition of disease, even in the absence of signs and symptoms typically present in younger people. Presentation of disease among older adults may differ dramatically from that expected in younger patients; manifestations of distress may be subtle or nonspecific, and improvement is less obvious and slower. These phenomena occur for a number of reasons. As noted previously, older adults experience high rates of comorbid illness, which may confound the clinician's ability to diagnose a problem accurately. For example, a patient with heart disease and chronic obstructive pulmonary disease who visits the office because of dyspnea may be experiencing a flare of his or her pulmonary disease or an atypical presentation of ischemic heart disease or both. Reporting of symptoms may also be affected by psychosocial factors, including limited access to the health care system, cognitive problems, or minimization of symptoms as "normal aging." Likewise, health care professionals may minimize complaints by older adults with complex medical illness or frail health.

Variable presentations for certain conditions can be seen in older adults (Table 126.4). Hyperthyroidism can manifest with apathy, malaise, depression, and fatigue, while lacking classic symptoms of tremor, tachycardia, or sweating. It can also manifest with heart failure and is highly prevalent among older adults with new-onset atrial fibrillation. Likewise, older patients with hypothyroidism may atypically demonstrate failure to thrive, weight loss, cognitive decline, or depression. In the presence of infection, older adults may not reliably mount fever or experience localized symptoms. Studies have demonstrated that lowering the threshold definition of fever can improve the diagnostic utility of body temperature as a sign of bacterial infection. Although

E-Fig. 126.2 Upper, middle, and lower quartiles of life expectancy for women (A) and men (B) at selected ages. (Adapted from Walter LC, Covinsky KE: Cancer screening in elderly patients: a framework for individualized decision making, JAMA 285:2750-2756, 2001.)

TABLE 126.3 Clinical Decisions Influenced by Life Expectancy

Life Expectancy	Clinical Decision Examples
Short-term, <2 years	Minimize major, invasive surgical procedures Discuss goals of care and when to consider hospice care Discontinue statin therapy
Mid-term, 2–3 years	Aggressive blood pressure and lipid management in the setting of diabetes less likely to prevent microvascular complications
Long-term	Discontinue colon cancer screening if <7 years Limited benefit to A _{1c} target <8.0% if <5 years Discontinue prostate cancer screening if <10 years Limit breast cancer screening if <5 years

Adapted from Yourman LC, Lee SJ, Schonberg MA, et al. Prognostic indices for older adults: a systematic review. *JAMA*. 2012;307(2):182-192.

chest pain remains the most common and important symptom of ischemic heart disease, dyspnea in the absence of chest pain is a commonly reported symptom, particularly in older adults and those with multiple comorbidities.

In truth, any medical illness may manifest nonspecifically among older adults, particularly those in frail health. Nonspecific symptoms related to an underlying illness include changes in mentation, difficulty with balance and falls, new urinary incontinence (UI), and a general change in functional ability. These presentations are often referred to as the “geriatric syndromes” and are detailed later. A lack of understanding of how disease presentation differs among older adults can lead to delays in diagnosis and treatment and result in worse outcomes. Research indicates that altered presentation predicts not only suboptimal care, but future functional decline and increased mortality.

MEDICATIONS

Medication-related problems are very common in older adults. In the United States, outpatients over age 65 take a median of four prescription medications daily, and nearly 40% are on five or more. Although medications may be indicated for specific medical conditions, use of multiple medications or polypharmacy increases the risk for drug-drug interactions and associated adverse drug events. Altered pharmacokinetics and pharmacodynamics contribute to adverse drug events, which are a common cause of hospitalization and morbidity in older persons. It is for this reason that certain medications can be considered “potentially inappropriate” in older adults. Common changes in pharmacokinetics include changes in body composition, with increased fat stores and decreased body water. Fat-soluble medications, such as benzodiazepines, have a prolonged duration of effect because of this phenomenon. Age-related declines in glomerular filtration rates result in decreased clearance of many medications, including such drugs as gabapentin, nitrofurantoin, and direct oral anticoagulants. Accurate calculations of creatinine clearance will inform drug choice and dosing and improve prescribing safety. Pharmacodynamic changes include decreased sensitivity to certain commonly prescribed drugs, such as β -blockers, and increased sensitivity to other agents, such as narcotics and warfarin.

Given the risks of medication use in older adults, health care professionals and systems must employ strategies to improve both the effectiveness and safety of prescribing as well as when to “de-prescribe” certain medications. Evidence-based recommendations include the following:

TABLE 126.4 Presentations of Disease in Older Adults^a

Diagnosis	Potential Presenting Symptoms and Signs
Myocardial infarction	Altered mental status Fatigue Fever Functional decline
Infection	Altered mental status Functional decline Hypothermia
Hyperthyroidism	Altered mental status Anorexia Atrial fibrillation Chest pain Constipation Fatigue Weight gain
Depression	Cognitive impairment Failure to thrive Functional decline
Electrolyte disturbance	Altered mental status Falls Fatigue Personality changes
Malignancy	Altered mental status Fever Pathologic fracture
Pulmonary embolus	Altered mental status Fatigue Fever Syncope
Vitamin deficiency	Altered mental status Ataxia Dementia Fatigue
Fecal impaction	Altered mental status Chest pain Diarrhea Urinary incontinence
Aortic stenosis	Altered mental status Fatigue

^aThis table represents only a limited list of select disease processes and presentations; it is not meant to serve as an exhaustive reference for use during patient care activities.

- Maintain an up-to-date medication list, including over-the-counter medications and herbal supplements.
- Comprehensively review medications at each visit with special attention at the time of transitions between care settings (e.g., after hospitalization). A clear indication for each medication, and documentation of response to therapy (particularly for chronic conditions) should be included.
- Assess for duplication and drug-drug or drug-disease interactions. Using a drug information database will help with this process.
- Assess adherence and affordability and inquire about the patient’s system for administering medications (e.g., a pillbox).
- Assess for specific classes of medications commonly associated with adverse events: antiplatelet agents, anticoagulants, analgesics

(particularly narcotics and nonsteroidal anti-inflammatory drugs [NSAIDs]), antihypertensives (particularly angiotensin-converting enzyme [ACE] inhibitors and diuretics), insulin and hypoglycemic agents, and psychotropics.

- Be suspicious that new symptoms arise from adverse effects of current drugs, not new disease.
- Minimize or avoid use of anticholinergic medications, which present specific risks.

In addition to following these general principles, prescribing clinicians also benefit from consulting lists of potentially inappropriate medications. The Beers List of Potentially Inappropriate Medications (PIMs) provides an evidence-based guide to drugs that should be avoided if possible or used with caution in older adults. A clear and rational approach to prescribing and ongoing management of medications that accounts for indication, interactions, and adherence may reduce the risk of common adverse events.

COGNITION

Dementia

The prevalence of dementia increases with age, with estimates ranging from 20% to 50% after age 85. The most common forms of dementia include Alzheimer's disease, Lewy body dementia, and vascular dementia. The latter is commonly present in combination with Alzheimer's disease in a condition termed *mixed etiology dementia*. Dementia is characterized by impairment in one or more cognitive domains severe enough to disrupt function or occupation. Mild cognitive impairment (MCI) is present when an individual has discernible cognitive limitations without apparent deficits in IADLs. Patients with MCI develop dementia at a rate of approximately 15% per year. Dementia is associated with a higher risk of falls, functional impairment, institutionalization, and death. Caregivers of demented individuals also face increased rates of stress and health problems. Clinicians diagnose dementia through symptom and functional history (often including the input of caregivers), cognitive assessment, and physical examination. A number of instruments, including the MOCA (see [Chapter 110](#)), clock-drawing test, and the Mini-Cog, are validated screening tools. The time-tested Mini Mental State Examination (MMSE) offers an assessment of multiple cognitive domains but does not provide adequate measure of executive function. It is also prone to lack of sensitivity in individuals with high premorbid intelligence and lack of specificity in those with low levels of education. Validated assessments of executive function include the clock-drawing test, verbal fluency test, and the Trail Making test part B. Instruments also exist for collecting data regarding patient function from a relative or caregiver. In patients suspected of having dementia, personal safety with respect to firearms, driving, and the home environment should be assessed. A careful medication review and physical examination, including vital signs, complete neurologic assessment, including gait and balance, are, of course, essential in evaluating for dementia to reveal findings that point to a specific cause.

Delirium

The differential diagnosis for cognitive problems other than dementia is broad, and includes delirium, mood disturbance, and drug effects. The differentiation of dementia and delirium may present the most significant challenge, particularly in hospitalized elders ([Table 126.5](#)). Delirium is characterized as an abrupt change in global cognitive function, whereas dementia is chronic and affects specific cognitive domains over time. Differentiation often hinges on history, which may be lacking at presentation. Delirium, sometimes called “altered mental status,” affects more than 2 million hospitalized persons each year. Its incidence is variably estimated at 25% to 60% among patients

TABLE 126.5 Features of Delirium Versus Dementia

Feature	Delirium	Dementia
Onset	Acute	Insidious
Course	Fluctuating, lucid at times	Generally stable
Duration	Hours to weeks	Months to years
Alertness	Abnormally low or high	Usually normal
Perception	Illusions and hallucinations common	Usually normal
Memory	Immediate and recent impaired	Recent and remote impaired
Thought	Disorganized	Impoverished
Speech	Incoherent, slow, or rapid	Word-finding difficulty
Physical illness or medication causative	Frequently	Usually absent

in acute care settings and results in extra hospital days and related expenditures. Delirium is also associated with prolonged hospital stay, increased costs, increased readmission rates to the hospital (12% to 65% at 6 months), higher in-hospital and 1-year mortality, and incident dementia. The Confusion Assessment Method (CAM) offers a validated framework for identifying delirium (<https://consultgeri.org/try-this/general-assessment/issue-13.pdf>). Per the CAM, delirium is likely present if the patient has both an acute onset of confusion with fluctuating course and inattention and either disorganized thinking or altered level of consciousness. According to Inouye and colleagues, key vulnerability factors for delirium include older age, cognitive impairment, comorbid illness, and impairments in vision and hearing. Precipitating factors related to acute illness include hypoxia, electrolyte abnormalities, dehydration, and malnutrition as well as medications and alcohol withdrawal. Delirium can also be a presenting sign for a number of serious medical conditions (see [Table 126.2](#)). Although treatment of delirium is difficult and revolves around the underlying medical issues, controlled trials have demonstrated that a multimodal intervention is effective in reducing rates of delirium in high-risk patients. There is evidence that the use of physical restraints in combative or confused older adults leads to increased morbidity and mortality. Nonpharmacologic management strategies include reorientation and preservation of sleep patterns, family or caregiver presence at the bedside, and early mobilization. “Chemical restraint” use, such as prescribing low dose antipsychotics, similarly has limited benefit. The use of pharmacologic agents, specifically neuroleptics, should be reserved for patients in whom nonpharmacologic strategies do not help and the patient presents a risk of harm to self or others.

MENTAL HEALTH

Older adults commonly experience depressive symptoms, with prevalence estimates as high as 15% to 19% among those over age 75, although in community-dwelling elders, major depressive disorder is actually less common than in younger adults. The presence of comorbid illness and grief often confound the presentation of depression. As a result, it can remain undetected despite its significant adverse impact on quality of life, morbidity, and mortality. Suicide rates are almost twice as high among older persons when compared with the general population, with the rate highest for white men over 85 years of age. Among older adults, depression can present with cognitive, functional, or sleep problems, as well as complaints of fatigue or low energy. Several instruments have been developed and validated for

screening for depression in elders. Asking two simple questions about mood and anhedonia (“Over the past 2 weeks have you felt down, depressed, or hopeless?” and “Over the past 2 weeks have you felt little interest or pleasure in doing things?”) may be as effective as using longer instruments. Longer screening questionnaires, such as the Geriatric Depression Screen (GDS) or Patient Health Questionnaire (PHQ-9), are also useful tools in the ambulatory setting. Any positive screening test result should trigger a full diagnostic interview. When screening for depression in elders, it is particularly important to have systems in place to provide feedback of screening results, a readily accessible means of making an accurate diagnosis, and a mechanism for providing treatment and careful follow-up. Randomized trials indicate that the addition of counseling to pharmacologic therapy confers additional benefit for older, frail patients with depression. Anxiety is more common than depression among older adults and may similarly result in physical and cognitive symptoms, insomnia, agitation, psychosis, and isolation. Clinicians should consider a diagnosis of generalized anxiety, panic, or agoraphobia in older adult patients with any of these symptoms.

SLEEP

Sleep disorders are present in more than 50% of older adults and have a negative impact on health and quality of life. Sleep disorders or disturbance are associated with cognitive impairment, poor health status, functional decline, and increased mortality. This may stem in part from changes in sleep structure with aging such as decreased deep (stage N3) sleep, longer sleep latency, and decreased sleep efficiency. Moreover, a variety of comorbid factors present in later life have adverse effects on sleep quality, including medical conditions, medications, psychosocial factors, and disruptive or disabling symptoms such as pain or nocturia. This includes drug and alcohol use as well as use of prescription and over-the-counter sedative hypnotics, which can cause sleep fragmentation and rebound insomnia. Additionally, medications commonly prescribed for insomnia, such as benzodiazepines and non-benzodiazepine hypnotics, are linked with cognitive impairment and falls. The mainstay of treatment for insomnia among older adults is careful attention to addressing the variety of comorbid factors and behaviors that lead to sleep disruption. The following is a sleep hygiene resource: https://www.nhlbi.nih.gov/files/docs/public/sleep/healthy_sleep.pdf. Strong evidence supports cognitive-behavioral therapy for insomnia (CBT-I) and other nonpharmacologic approaches including stimulus control, sleep restriction, and relaxation techniques. Older adults also suffer higher rates of other primary sleep disorders, including sleep apnea, periodic leg movements of sleep, and REM sleep behavior disorder. Eliciting a history of daytime somnolence and/or sleep partner complaints characteristic of these disorders should lead to completion of a diagnostic polysomnogram, which then guides initiation of appropriate therapies.

MOBILITY

Problems with mobility are common among older persons. Among those over age 65, 20% of men and 32% of women report difficulty with one or more of five specific physical activities (stooping or kneeling, reaching overhead, writing, lifting 10 pounds, or walking two to three blocks). Among these, respondents cite problems with walking most commonly. Difficulties with balance and gait present significant risks for older adults. Approximately 30% of community-dwelling elders fall each year. The annual incidence of falls approaches 50% in patients over 80 years of age. Five percent of falls in older adults result in fracture or hospitalization. According to the CDC, the rate

of deaths from falls among persons aged 65 years or older increased 31% from 2007 to 2016. Risk factors for falls include a history of falls, fear of falling, decreased vision, cognitive impairment, medications (particularly anticholinergic, psychotropic, and cardiovascular medications), peripheral neuropathy, diseases causing problems with strength and coordination, and environmental factors. Effective interventions for people with a history of falls or who are at risk for falling involve addressing multiple contributing factors. Clinicians and health care professionals should regularly inquire about recent falls or a fear of falling in older patients. For patients who report falling, the assessment should include review of circumstances of the fall(s), measure of orthostatic vital signs, visual acuity testing, cognitive evaluation, and gait and balance assessment. A brief physical examination maneuver called the “Timed get up and go” (TUG) has the patient arise from a sitting position, walk 10 feet, turn, and return to the chair to sit. A time of more than 12 seconds to complete the process, or observation of postural instability or gait impairment, suggests an increased risk of falling. Gait speed, an additional measure of mobility, predicts changes in ability and health status in older adults. Gait speed is measured over a 10-meter span with the patient walking at a comfortable pace. A speed of less than 1.0 m/sec is associated with increased mortality; 0.8 m/sec predicts difficulty navigating outside the home; and a speed of less than 0.6 m/sec predicts a high risk of falls and functional decline. For those found to be at risk for falls, providers should ask about possible causative agents and provide education about home safety. High-risk patients should be referred for evaluation by a physical therapist and consideration should be given to the utility of assistive devices and a supervised exercise program (Table 126.6).

VISION AND HEARING

Problems with vision and hearing are very common among older adults and frequently complicate the management of comorbid conditions and accelerate functional decline. Significant vision loss occurs in 16% to 18% of adults over age 65. Common causes include glaucoma, cataracts, age-related macular degeneration, and retinopathy from hypertension and diabetes. Decreased visual acuity increases fall risk and has been associated with all-cause mortality in older adults. Such problems may be detectable with regular testing via bedside tools such as the Snellen or Jaeger eye chart. Given the implications of vision loss for function and safety, a general ophthalmologic examination every 1 to 2 years is recommended for all older adults. Fortunately, many ophthalmologic centers recognize the multifaceted challenges faced by older adults with vision impairment. They offer specialized low vision clinics providing care from optometrists, occupational therapists, and social workers with a focus on improving quality of life and maintaining independence.

Hearing loss affects an estimated 40% to 66% of those over age 75. It is associated with depression, social isolation, poor self-esteem, cognitive decline, and functional disability. Pure tone audiometry is the reference standard for screening for hearing loss, but a simple whispered voice test is also highly sensitive and specific. Ideally, all older adults would undergo annual hearing screen by questionnaire and handheld audiometry. Unfortunately, the lack of reimbursement for hearing aids under most insurance plans, including Medicare, presents a major barrier for many older adults.

CONTINENCE

UI affects up to 30% of community-dwelling older adults and at least half of those residing in skilled nursing facilities. It occurs more frequently in women, but this gender disparity narrows as the rate of UI

TABLE 126.6 Recommended Components of Clinical Assessment and Management for Older Persons Living in the Community Who Are at Risk for Falling

Assessment and Risk Factor	Management
Circumstances of previous falls ^a	Change in environment and activity to reduce the likelihood of recurrent falls
Medication use <ul style="list-style-type: none"> • High-risk medications (e.g., benzodiazepines, other sleep medications, neuroleptics, antidepressants, anticonvulsives, or Class IA antiarrhythmics—including quinidine, procainamide, and disopyramide)^{a,b,c} • Four or more medications^c 	Review and reduction of medications
Vision ^a <ul style="list-style-type: none"> • Acuity <20/60 • Decreased depth perception • Decreased contrast sensitivity • Cataracts 	Ample lighting without glare; avoidance of multifocal glasses while walking; referral to an ophthalmologist
Postural blood pressure (after ≥5 min in a supine position, immediately after standing, and 2 min after standing) ^c <ul style="list-style-type: none"> • ≥20 mm Hg (or ≥20%) drop in systolic pressure, with or without symptoms, either immediately or after 2 min of standing 	Diagnosis and treatment of underlying cause, if possible; review and reduction of medications; modification of salt restriction; adequate hydration; compensatory strategies (e.g., elevating head of bed, rising slowly, or performing dorsiflexion exercises); pressure stockings; pharmacologic therapy if the above strategies fail
Balance and gait ^{b,c} <ul style="list-style-type: none"> • Patient's report or observation of unsteadiness • Impairment on brief assessment (e.g., the "get up and go" test or performance-oriented assessment of mobility) 	Diagnosis and treatment of underlying cause, if possible; reduction of medications that impair balance; environmental interventions; referral to physical therapist for assistive devices and for gait, balance, and strength training
Targeted neurologic examinations <ul style="list-style-type: none"> • Impaired proprioception^a • Impaired cognition^a • Decreased muscle strength^{b,c} 	Diagnosis and treatment of underlying cause, if possible; increase in proprioceptive input (with an assistive device or appropriate footwear that encases the foot and has a low heel and thin sole); reduction of medications that impair cognition; awareness on the part of caregivers of cognitive deficits; reduction of environmental risk factors; referral to physical therapist for gait, balance, and strength training
Targeted musculoskeletal examinations of legs (joints and range of motion) and examination of feet ^a	Diagnosis and treatment of underlying cause, if possible; referral to physical therapist for strength, range-of-motion, and gait and balance training, and for assistive devices; use of appropriate footwear; referral to podiatrist
Targeted cardiovascular examination ^b <ul style="list-style-type: none"> • Syncope • Arrhythmia (if there is known cardiac disease, abnormal electrocardiogram, and syncope) 	Referral to cardiologist; carotid-sinus massage (in case of syncope)
Home-hazard evaluations after hospital discharge ^{b,c}	Removal of loose rugs and use of nightlights, nonslip bathmats, and stair rails; other interventions as necessary

Adapted from Tinetti ME: Clinical practice. Preventing falls in elderly persons, *N Engl J Med* 348(1):42-49, 2003.

^aRecommendation of this assessment is based on observations that the finding is associated with an increased risk of falling.

^bRecommendation of this assessment is based on one or more randomized controlled trials of a single intervention.

^cRecommendation of this assessment is based on one or more randomized controlled trials of a multifactorial intervention strategy that included this component.

in men increases after age 85. The impact of UI on health ranges from increased risk of skin irritation, pressure wounds, and falls, to social isolation, functional decline, and depression. For caregivers of older adults, UI complicates physical care and can contribute to decisions for placement in skilled nursing facilities. Common comorbid conditions include diabetes mellitus, heart failure, arthritis, and dementia.

A systematic approach to the investigation of UI can often reveal a cause and potential solution. It is important to first determine if the incontinence is acute or chronic in nature. Acute causes of incontinence are often attributable to specific medical problems, including infection, metabolic disturbance, or medication effects. The mnemonic DIAPERS recalls the various potential acute causes of UI (*D*, delirium; *I*, infection; *A*, atrophic vaginitis; *P*, pharmaceuticals; *E*, excess urine output from congestive heart failure [CHF] or hyperglycemia; *R*, restricted mobility; and *S*, stool impaction). If the UI is chronic, then further history can characterize the nature of the symptoms from among four types. Urge incontinence from detrusor overactivity is the

most common type. Patients with this problem will complain of urinary frequency, nocturia, and a sudden onset of urge to void. Stress incontinence occurs with incompetence of pelvic musculature or urethral sphincter and is characterized by small amounts of leakage with laughing, sneezing, coughing, or even standing. Overflow incontinence results from urinary retention, often related to prostatic hyperplasia in men or bladder atony in patients with diabetes or spinal cord injury. Patients often have constant dribbling or leakage without a true sense of needing to void. Finally, functional incontinence results from comorbid conditions that limit a patient's ability to act on or interpret the need to void, mobility problems such as arthritis, and weakness or cognitive problems. [Table 126.7](#) describes the various types of incontinence and suggested approaches. Of course, older adults with multiple comorbid conditions often have incontinence that results from a combination of chronic and/or acute causes.

Continence problems are frequently treatable but are often not raised by patients as a concern. A targeted history and physical

TABLE 126.7 Causes, Types, and Treatment of Urinary Incontinence

Type	Definition	Cause	Treatment
Stress	Leakage associated with increased intra-abdominal pressure (coughing, sneezing)	Hypermobility of the bladder base, frequently caused by lax perineal muscles	Pelvic muscle exercise, timed voiding, α -adrenergic drugs, estrogens, surgery
Urge	Leakage associated with a precipitous urge to void	Detrusor hyperactivity (outflow obstruction, bladder tumor, detrusor instability), idiopathic (poor bladder), compliance (radiation cystitis), hypersensitive bladder	Bladder training, pelvic muscle exercise, bladder-relaxant drugs (anticholinergics, oxybutynin, tolterodine, imipramine)
Overflow	Leakage from a mechanically distended bladder	Outflow obstruction, enlarged prostate, stricture, prolapsed cystocele, acontractile bladder (idiopathic, neurologic [spinal cord injury, stroke, diabetes])	Surgical correction of obstruction, intermittent catheter drainage
Functional	Inability or unwillingness to void	Cognitive impairment, physical impairment, environmental barriers (physical restraints, inaccessible toilets), psychological problems (depression, anger, hostility)	Prompted voiding, garment and padding, external collection devices

examination can often identify the cause of UI and lead to appropriate intervention. Asking about and documenting the presence or absence of UI should be done biannually, as well as determining whether the UI, if present, is bothersome to the patient or caregiver. In addition to a history of acute and chronic causes, a targeted physical examination should include an assessment for fluid overload, genital and rectal examination, and neurologic evaluation. Urine and blood tests are indicated to evaluate for infection, metabolic causes, and renal dysfunction. In addition, for patients suspected of having urinary retention, catheterization or ultrasound can help define the postvoid residual and determine any need for catheter placement and further urologic evaluation. Many institutions now offer more specialized evaluation and care through incontinence clinics, which offer a multidisciplinary approach to management, addressing both pharmacologic and nonpharmacologic options. Effective nonpharmacologic options include scheduled toileting, bladder training, and biofeedback. Use of these strategies may avoid the use of medications with frequent adverse effects, such as anticholinergic medications for detrusor overactivity.

Like UI, fecal incontinence (FI) is an underreported and undermanaged issue among older adults with multiple factors contributing to etiology. FI is present in 45% or more of nursing home residents and is much more common in those with impaired mobility, dementia, chronic constipation or diarrhea. Ensuring prevention of constipation and associated overflow diarrhea is essential in management. Issues with muscular weakness that commonly contribute to fecal incontinence have excellent potential for treatment with specific types of physical therapy targeting pelvic floor muscles.

NUTRITION

Older adults experience high rates of malnutrition related to multiple causes, including medical illness, dental problems, or access issues related to limited mobility, cost, or cognitive problems. Approximately 15% of older outpatients and half of hospitalized elders are malnourished and have associated increases in morbidity and mortality. The utility of general laboratory testing is limited, but a combination of serial weight measurements and inquiries about changing appetite can reveal nutritional problems in the older adults. Vulnerable elders with an involuntary weight loss of 10% or more in 1 year or less should undergo further evaluation for undernutrition. This includes assessment of medical or medication-related causes, dental status, problems with acquiring or preparing food, appetite and intake, swallowing ability, and previous directions for dietary restrictions. Obese older adults suffer from high rates of malnutrition, but it is often unrecognized. They should also be screened routinely for nutrition concerns.

SOCIAL AND LEGAL ISSUES

Evaluation of the social history for older persons includes assessment of resources for direct caregiving and financial support available. These issues become particularly important for frail older adults, given their physical and economic vulnerability.

Caregiving

The clinician should always inquire about who is providing care for the older patient, including both personal care with ADLs and help with IADLs, such as transportation, medications, food preparation, finances, and housekeeping. This list should include both formal caregivers, such as home health professionals or hired aides, and informal caregivers, such as family members, neighbors, or friends. The majority of elder care provided in the United States is delivered by informal caregivers. Over 34 million people in the United States provide informal care for older adults and, of these, 15.7 million are caring for persons suffering from dementia. Seventy-five percent of informal caregivers are women and 39% are over age 65. The stress of providing daily care can have serious deleterious effects on the caregiver's health. Studies have demonstrated adverse effects on blood pressure and immune function and increased rates of cardiovascular disease and death. In addition, caregivers have alarmingly high rates of psychological illness, with symptoms of depression reported in up to 50%. This problem is particularly prevalent in those providing care for patients with dementia. The presence of mental illness further raises the risk of verbal or physical abuse or neglect of the patient. The clinician must recognize caregiver problems early and consider referral to a social worker, patient resource manager, or, when available, a geriatric assessment team. Key risk factors for caregiver stress include a frail family caregiver; a patient with cognitive impairment, emotional disturbance, substance abuse, sleep disruption, or behavioral problems; low income or financial strain; and acute illness or hospitalization. Health care professionals should recognize signs and symptoms of physical or mental strain and regularly inquire about caregiver burden with an offer to talk apart from the patient if need be.

A number of resources exist to support caregivers and provide strategies for problem solving and self-care. Community-based programs provide assistance with meals, transportation, and respite care options through volunteer organizations or subsidized programs. Counseling on both the physical and emotional aspects of care has been demonstrated to reduce health risks to the caregiver and delay institutionalization, including in-home or institutional respite stays to provide caregivers with precious time off. Studies consistently demonstrate that such services are underused by caregivers. One resource

that provides resources and supportive information about caregiving is <https://eldercare.acl.gov/Public/Resources/Topic/Caregiver.aspx#UsefulLinks>.

Mistreatment

Older adults are particularly vulnerable to mistreatment due to poor health, functional dependence, and social isolation. Mistreatment is defined as either elder abuse (harm caused by others) or self-neglect. Self-neglect is thought to be the most common form of mistreatment, but true rates are difficult to estimate. Risk factors include cognitive impairment and recent functional decline. Elder abuse has been reported in 3% to 8% of the older adult population in the United States, although this is likely an underestimate due to underreporting by patients and lack of recognition by health care providers. Abuse assumes many forms including psychological, financial, physical, sexual, and neglect. Studies have demonstrated that neglect and abuse are associated with higher rates of nursing home placement and mortality among older adults. Signs of physical abuse include contusions, burns, bite marks, genital or rectal trauma, pressure ulcers, or unexplained weight loss. Other forms of abuse may be more difficult to discern on examination but can be improved with direct questions such as “Has anybody hurt you?”; “Are you afraid of anybody?”; or “Is anyone taking or using your money without your permission?” Any suspicion of abuse or neglect should be reported to Adult Protective Services. Of note, 44 states and the District of Columbia have laws mandating reporting of suspected elder abuse and the U.S. Department of Justice has a growing network of resources (<https://www.justice.gov/elderjustice/about-eji>).

Finances

The older adult population in the United States varies widely in measures of wealth. Although the overall rate of poverty among adults over age 65 has declined over the last 50 years, 9.3% of older adults still live at or below the poverty line, and the percentage is higher among African Americans (18.7%) and Hispanic individuals of any race (17.4%). Members of the health care team including providers should screen for financial problems because these issues have direct implications for health status and well-being. Older adults with limited means are more likely to have problems affording medications, meals, and basic amenities. Referrals to community resource networks can help identify options for help with basic needs, including housing options and congregate meals. Information on agencies and services in specific locales can be identified at <https://eldercare.acl.gov/Public/Index.aspx>.

Advance Care Planning

Advance directives come in a number of different forms and serve a variety of purposes. Ideally, these documents articulate a person's preferences for care in the event of serious illness or incapacitation. Often they will describe limits on care and circumstances in which life-sustaining or restoring measures may be withheld or even withdrawn. Traditionally, advance directives have included a living will and health care power of attorney. The living will often addresses situations in which the patient has a terminal illness, persistent vegetative state, or progressive neurologic condition and can include explicit directions for care management including withdrawal or withholding of specific measures, including artificial nutrition and hydration. Living wills are ideally paired with a companion document, the health care power of attorney, which designates the person's preferred decision maker, or proxy, in the event of an incapacitating illness. For patients who have not created a health care power of attorney, typically the spouse or other first-degree relative is the default decision maker. If no proxy is designated and no next of kin is available, guardianship may be obtained.

Guardianship is a legal proceeding whereby the court appoints a surrogate decision maker. The physician's responsibility includes determination of a person's capacity for independent decision making in the event of altered sensorium or progressive cognitive impairment. This involves an assessment of his or her ability to understand the situation, ask questions, weigh options and render an opinion and, in certain situations, may require a full geriatric or neuropsychological assessment. Traditional advance directives, particularly the living will, have been criticized as having limited utility in conveying specific preferences. Recently, more detailed forms have emerged to record very specific preferences and limits for measures such as hydration, nutrition, hospitalization, and resuscitation. Examples include the Medical Orders for Scope of Treatment (MOST) and Physician's Orders for Life Sustaining Treatment (POLST) forms <https://polst.org/programs-in-your-state/>. Of course, effective completion and application of any of these forms should include a goals of care conversation conducted with the primary care provider, ideally involving family caregivers. In addition, as preferences change over time depending on health status, health care providers should encourage older adults to revisit and renew their advance directives on an annual basis.

CONTEXTS OF CARE: SPECIAL CONSIDERATIONS

The Hospitalized Patient

Millions of older adults are hospitalized in the United States each year for a variety of acute illnesses and elective procedures. Fortunately, in the United States, Medicare Part A covers much of the cost associated with acute care, including hospitalization and short-term rehabilitation. While in the hospital, however, older adults can become vulnerable to myriad complications related to both their compromised health state and problems inherent to the acute care environment itself. As noted previously, delirium afflicts hospitalized elders at a very high rate and increases risk of prolonged hospital stays, nursing home admission, and death. Hospitalized older adults also experience the effects of immobilization, with loss of muscle strength and deconditioning. Acutely, these factors increase the risk of falls and impair function and ability to provide self-care. In addition, poor oral intake may result in malnutrition, and illness-related fluid losses may cause dehydration. As a result, hypotension and protein-calorie malnutrition are common problems. Immobility and malnutrition both predispose the acutely ill patient to the development of pressure wounds, which can develop in under 2 hours. All these problems worsen in the presence of delirium or depressed mood. Environmental factors also contribute to problems, including tethers such as catheters and intravenous lines (which increase risk of falls), noisy wards, and frequent tests and procedures that further disrupt diurnal rhythms and sleep. Up to one third of hospitalized older adults experience a decline in their ability to perform ADLs in the course of their hospitalization. Patients who experience declines in function during hospitalization have higher rates of rehospitalization, prolonged institutionalization, and mortality after discharge, and many (41%) never return to their preadmission level of function. To combat these problems, some hospitals have created specialized inpatient geriatric care units, often termed *acute care for elders (ACE) units*. These units incorporate adaptations in the physical environment and specially trained staff to provide safe, patient-centered care designed to maximize restoration of function and prevent common complications of hospitalization. In randomized trials, ACE units and their consultative counterpart, the mobile ACE (or MACE), have reduced lengths of stay, improved care transitions, and lowered readmissions. Likewise, geriatric evaluation and management (GEM) units (described later) offer specialized, team-based postacute care with an emphasis on rehabilitation and return to prior level of function.

Care Transitions

As noted previously, older adults experience high rates of complications during acute illness and require prolonged periods of time and sometimes admission for rehabilitation in various types of facilities in order to recover. For this reason, management in the postacute period represents a critical and complex time. Specifically, older adults with acute illness often find themselves transferred among different care settings and providers. Nearly one quarter of hospitalized older adults are discharged to skilled nursing facilities, and another 12% are discharged with home health care. Of those discharged to skilled facilities, about one fifth will return to the hospital within 30 days. Transitions in care represent high-risk episodes, and evidence shows that patients and caregivers frequently experience miscommunication, medication errors, and missed essential laboratory tests or appointments during this period. Recent trials have demonstrated a reduction in rehospitalization through a structured discharge and transition of care plan. This includes interdisciplinary team communication, medication reconciliation before and after discharge, careful planning for laboratory and appointment follow-up, communication with patients and caregivers about expectations and preferences, and specific coaching for patients and caregivers in symptom management. More information on care management in transitions is available at www.caretransitions.org.

SYSTEMS OF CARE

Ambulatory and Home Care

The majority of care for older adults occurs in the outpatient setting. Much of the cost of this care, including visit fees, laboratory tests, radiograph studies, and vaccinations, is covered under Medicare Part B, for which patients pay a monthly premium. Outpatient visits may occur with the physician, physician assistant, nurse practitioner, or clinical nurse specialists, depending on the nature of the problem and the structure of the setting. Other key members of the care team include social workers, pharmacists, psychologists, and physical and occupational therapists. Most assessments discussed in this chapter can be performed in outpatient settings, including functional assessments, cognitive and mood screening, gait and balance assessment, medication review, eye and ear examinations, and continence evaluations. Interview of a caregiver can augment the information collected. Care in this setting can be complicated, though, by problems with transportation and ineffective or inefficient communication among multiple providers, particularly for patients with multiple specialists.

Over the last several years, home care has reemerged as an effective means of providing health care for older adults. As with the outpatient setting, Medicare Part B will reimburse providers in part for services rendered in the home. In addition, if a rehabilitative or skilled service is needed (i.e., home nursing care or home physical therapy) Medicare Part A provides coverage. Patients receiving services in the home must be “homebound,” implying that they are significantly functionally impaired and travel with assistance out of the home infrequently and usually only for medical purposes. Services rendered in the home include a full range of evaluations by teams of health care professionals depending on needs. Social workers often lead these visits and perform case management, assessing financial and other resource needs. Nurses, clinical nurse specialists, and/or nurse practitioners provide skilled services when necessary, including health education, symptom monitoring, or wound care. Physical and occupational therapy can assess mobility and home safety and greatly enhance function and independence. Furthermore, examination of a person’s home environment can reveal much about his or her safety and nutrition and can facilitate education or intervention in these areas. Physicians may serve as medical directors of such programs but may also perform visits

themselves to learn more about a given patient’s health status. If significant concerns exist about a patient’s safety, particularly in the setting of cognitive impairment, a home visit may provide information about the need for more urgent interventions, including referrals to Adult Protective Services. Research has demonstrated that coordinated home care programs can improve management of chronic disease, including dementia, diabetes mellitus, and congestive heart failure, as well as to reduce rehospitalization in patients with congestive heart failure. One home care model that began pushing the traditional boundaries of home care prior to 2001 is the hospital at home (HaH) program, which provides home-based acute care for older adults with specific illnesses identified in the ED. High quality care and patient satisfaction continue to aid in the spread of this model of care throughout the United States.

Long-Term Care

The phrase *long-term care* describes the array of services available to provide care for people with disability from chronic and acute conditions. This definition includes the services offered in the outpatient and home settings described previously. Most associate the term, however, with the system of nursing facilities providing personal and medical care for disabled adults of all ages. Skilled nursing facilities provide long-term care for those with permanent disabilities from chronic illness or short rehabilitative stays after acute illness (e.g., stroke) or procedures (e.g., joint replacement). The scope of services may also include end-of-life care in conjunction with a hospice care team. Facility staff includes licensed nurses who give 24-hour supervision, with much of the personal care provided by certified nursing assistants. Each facility also has a medical director overseeing various aspects of medical care. An attending physician, who may or may not be the medical director, performs scheduled patient visits every 30 to 60 days. Most SNFs also employ advanced practice providers (physician assistants or nurse practitioners), physical, occupational, and speech therapists for rehabilitation care, dietitians, social workers, and recreational therapists. Patients with moderate or severe dementia constitute approximately 60% of patients living in skilled nursing facilities. Although Medicare Part A provides payment for rehabilitative stays of 100 days or less (with a copayment for days 21 to 100), it does not finance long-term stays. Such patients pay out of pocket, through long-term care insurance, or through Medicaid, a joint federal and state assistance program. Medicaid constitutes between 45% and 65% of all payment sources for skilled nursing facility care in the United States.

For patients with less complex care needs, assisted living facilities or domiciliary care homes provide an alternative arrangement for long-term care. Although these facilities vary dramatically in their size and structure, most provide nonskilled care for patients who need some assistance with activities of daily living. Licensed nurses may be present during some specified periods of time, and other professions may visit the facility intermittently to provide services such as physical therapy. Assisted living facilities do not have medical directors, and patients normally continue to see a primary care provider in the outpatient setting. Unlicensed staff, including nursing aides, provide most of the personal care and assistance. Medicare does not cover the cost of assisted living. Medicaid provides some reimbursement for this type of care, but the majority of residents pay out of pocket or through other assistance programs, such as Social Security. For those with adequate means, a living option has emerged that combines independent living, assisted living, and skilled care in one location. Continuing care retirement communities allow residents to live within the same community while moving through or between levels of care. They offer residents convenient central resources, such as recreational and dining facilities, transportation, and onsite health care.

Program of All-Inclusive Care for the Elderly

In the 1970s, a group providing care for older Chinese adults in San Francisco developed a model of long-term care centered in the community. Proponents of this model, entitled the Program of All-inclusive Care for the Elderly (PACE), believed that the community (rather than the institution) provided a better location to meet the chronic care needs of older adults. From its start as a community-based effort in California, the PACE model has grown with the support of private foundations and Medicare demonstration projects; now PACE is a benefit for older adults who qualify for both Medicare and Medicaid. Reimbursement is at 95% of the cost of nursing home care in the area where the patient lives. Participants must be over 55 and certified by the state to be eligible for nursing home care. The PACE program then uses combined Medicare and Medicaid funds otherwise slated to pay for the individual's long-term care to provide care in the community. Much of it is coordinated through senior centers offering an array of resources and services, including the following:

- Adult day care, offering nursing; physical, occupational, and recreational therapies; meals; nutritional counseling; social work; transportation; and personal care
- Medical care provided by a PACE physician familiar with the history, needs, and preferences of each participant
- Home health care and personal care
- All necessary prescription drugs
- Social services
- Medical specialists such as audiology, dentistry, optometry, podiatry, and speech therapy
- Respite care

When necessary, PACE participants are admitted to the hospital or nursing home. These services are provided under the auspices of the PACE program as part of the care package, and the program bears full financial risk. The benefits of care for older adults, particularly those of limited means, appear to be substantial.

See the National PACE Association website at www.npaonline.org for more information.

Geriatric Care

In caring for frail older adults with complex care needs, consultation with a geriatrician or geriatrics-focused interprofessional team can often provide highly useful information. The team can assist in the assessment and management of the specific conditions or situations described earlier. The geriatrician can advise on appropriate level or setting of care for an older adult as difficult decisions related to treatment options in the context of limited life expectancy occur. Geriatricians complete a minimum of 1 year of fellowship after residency training in internal medicine or family practice. After training they are eligible for board certification and qualified to work in a number of different settings, including the hospital, long-term care, home care, and outpatient clinics. Comprehensive assessment by a geriatrician or geriatrics team includes components detailed previously, including evaluation of the patient's medical condition, function, and social support. Normally the consultant will work with an interprofessional team that may include a nurse case manager, physician assistant and/or nurse practitioner, social worker, physical or occupation therapist, pharmacist, psychologist, and others. The outcome of the geriatric assessment is a comprehensive plan for safely restoring the patient to optimal function with mutually agreeable and realistic goals of care.

In the setting of acute illness, geriatricians also provide important services. As described earlier, ACE units can improve patient care and prevent iatrogenic complications. Similarly, once patients are medically stable, transfer to a specialized geriatrics care unit, often termed a geriatric evaluation and management unit, may be possible in some

institutions, to provide a comprehensive medical assessment and plan for transition of care. Early consultation with a geriatrician and an interprofessional, transdisciplinary team in the acute care setting can help in the management of complex medical illness and with communication with patients and caregivers about post-hospitalization options. After hospitalization, locating facilities or services that offer comprehensive care by a geriatrician and interdisciplinary team is ideal, including a coordinated approach that uses specific strategies to manage transitions of care.

For a deeper discussion on this topic, please see Section IV, "Aging and Geriatric Medicine," in *Goldman-Cecil Medicine*, 26th Edition. ❖

FUTURE DIRECTIONS: GEROSCIENCE, AN EMERGING FIELD

Frameworks of aging theory described previously provide a foundation for the emerging field of geroscience. The nine "hallmarks of aging" (see Fig. 126.4) introduced previously are considered a theoretical framework through which to study interventions that have the potential to influence the biology of aging and delay the emergence of most chronic diseases that appear to be driven by this mechanism. Through study of molecular mechanisms of aging, evidence is increasing to suggest ways humans can influence *healthspan*, which can be thought of as an overall delay of onset of chronic disease. Caloric restriction (CR), or the purposeful reduction of food intake, is the only intervention that has been shown to reproducibly extend maximal lifespan in certain laboratory animal models. In rats, lifespan increases an average of 20 months with a 40% reduction in calories. Rhesus monkeys enrolled in a trial of caloric restriction appear to have improvements in metabolic markers and a lower disease burden than controls after 15 years but have had no definitive extension in lifespan. The mechanism is not well understood but may be metabolically mediated. In observational studies in humans, those with lower average body temperature, lower insulin levels, and higher dehydroepiandrosterone sulfate (DHEAS) levels (all changes found in calorically restricted monkeys) appeared to survive longer. Current research is focused on similarly influencing the cellular biology of healthspan in human subjects and discovering chemical agents that mimic or mediate these metabolic effects.

Emergence of Geroscience Guided Therapies

Potential molecular targets that allow for the delayed onset of human disease are well described in animal models of cardiovascular, pulmonary, and musculoskeletal systems. Animal studies have shown delayed onset of aging with inhibition of mTOR pathway in multiple species. In recent years, translational clinical trials in humans evaluating geroscience guided therapies (GGTs) have begun to occur. The trials demonstrate promise toward impacting the trajectory of certain chronic diseases. The first human trial using senolytic therapy to ablate senescent cells showed potential for improvement in physical function in people with idiopathic pulmonary fibrosis. The emergence of translational geroscience as a multidisciplinary field has the potential to influence medical practice and outcomes in the coming years.

Palliative Care

127 Palliative Care, 1141

Palliative Care

Brandon J. Wilcoxson, Erin M. Denney-Koelsch, Robert G. Holloway

INTRODUCTION

Palliative care is both a philosophy of care and an area of specialization within several medical fields. The primary goal of palliative care is to minimize suffering and to support the best possible quality of life for patients and their families. Patients with serious and debilitating illness need and deserve excellent symptom control, assistance with difficult medical decisions, effective communication and collaboration among their providers, addressing of psychosocial problems, and an empathetic presence that fosters hope and healing relationships. Palliative care affirms life by supporting the patients' goals for the future in light of a full understanding of their medical condition, potentially including their hopes for cure, life-prolongation, relief from suffering, as well as preparation for death when time is short. This process includes exploring which life goals would be left undone if treatment does not go as hoped, who should make medical decisions for the patient if decision-making capacity is lost, and what limits might be set on aggressive therapy.

Palliative care provides an organized, structured system for delivering care by an interdisciplinary team, including physicians, nurses, social workers, chaplains, and counselors, as well as other health care professionals. Palliative care should be integrated within various health care settings including the hospital, emergency department, nursing home, home care, assisted living facilities, and outpatient settings. Palliative care remains very unevenly available, so many patients and families needlessly suffer, having either no, limited, or delayed access to appropriate palliative care. There is no evidence to suggest that early integration of palliative care shortens survival, yet many patients and health care professionals share an unspoken concern that it may hasten death. This common misconception, along with the misconception that palliative care is equivalent to end-of-life care, denies patients and families access to palliative care until late in the illness trajectory. Several prospective randomized controlled trials have compared early integration of specialty palliative care with standard care. These trials, primarily conducted in patients with advanced cancer, have shown improvements in important end points, including patient quality of life, rates of depression or anxiety, patient or caregiver satisfaction, and utilization of health services at the end of life. Two trials have also reported longer survival when palliative care is proactively integrated earlier than routine referral. [Fig. 127.1](#) shows a visual concept of early integration of palliative care into a patient's disease course.

Basic palliative care should be part of the tool kit for all physicians who care for seriously ill patients. Specialty palliative care should be available for the more challenging symptom management, as well as the complex medical decision making that occurs in serious illness.

COMMON ILLNESS TRAJECTORIES AND PALLIATIVE CARE

There are four distinct trajectories of functional decline before dying ([E-Fig. 127.1](#)). These trajectories have major implications for palliative care and health care delivery. Patients and families will also have different physical, psychological, social, and spiritual needs depending on the trajectory of their illness before they die. Being aware of these trajectories can help providers deliver appropriate care that integrates both disease-directed and palliative treatments.

Trajectory 1: Short Period of Evident Decline Before Death

Cancer typifies this trajectory. Function is preserved until rather late, followed by a predictable and precipitous decline over weeks to months. The onset of decline usually suggests metastatic tumor. A more predictable decline in function can assist in anticipating care needs, transitioning away from curative treatments toward a more exclusive emphasis on palliation, and eventually into hospice care. Not all malignancies follow this trajectory (e.g., prostate, breast) and some nonmalignant conditions (e.g., rapidly progressive dementias, amyotrophic lateral sclerosis) may follow this course.

Trajectory 2: Chronic Illness With Exacerbations and Sudden Dying

Congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), end-stage liver disease, and AIDS typify this trajectory. These organ system diseases represent chronic illnesses with occasional, acute exacerbations (e.g., physiologic stress that overwhelms the body's reserves), often requiring hospital admission. Patients can have a return of function after an exacerbation, but often not to the level of their baseline. They also may die suddenly during an exacerbation, but it is difficult to predict in advance. Prognosticating is very challenging in this trajectory. When patients choose to forego or stop aggressive life support, planning for aggressive symptom relief during a future exacerbation is essential.

Trajectory 3: Prolonged Dwindling

Dementia and frailty typify this trajectory. These patients have a prolonged course of physical and/or cognitive decline and become increasingly frail. Additional diagnoses include other neurodegenerative conditions (e.g., Parkinson's disease) and patients with multiple moderate to severe comorbidities (e.g., arthritis, visual impairment, past mild strokes, diabetes with neuropathy). Gradual decline in function, weight loss, fatigue, and low levels of activity are core features. Caregiver burden is usually immense. Prognosticating survival is

Fig. 127.1 Palliative care and hospice.

difficult and complications, such as pneumonia and fractures, may be terminal events. The benefits and burdens of artificial nutrition and hydration must be balanced in the late stages.

Trajectory 4: Severe Acute Brain Injury

Sudden impairment trajectories are those that stem from sudden neurologic injury that can lead to profound cognitive and functional impairment. These include the causes of severe acute brain injury: stroke, hypoxic ischemic encephalopathy, and traumatic brain injury. The vast majority of deaths occur either early after the event, when treatments are withheld or withdrawn, or in the chronic stage in survivors who have accumulating debility. The diagnoses in this trajectory represent the leading cause of adult disability. At the extremes of impairment are chronic disorders of consciousness (vegetative and minimally conscious states) and locked-in syndrome. But there is a vast spectrum of severe impairments short of these extremes that raise questions about how to manage potentially severe debility with little or uncertain chances of improvement. This trajectory requires a health care system responsive to negotiating goals of treatment with patients and surrogates who may consider these future health states to be “worse than death.”

INTRODUCING PALLIATIVE CARE TO PATIENTS AND FAMILIES

Patients with serious, potentially life-threatening illnesses and their families are very vulnerable and initially may be frightened about the prospect of receiving palliative care. This fear develops from the association of palliative care with end-of-life care and some have even used the term “supportive care” to avoid this negative association. Such concerns, however, can be addressed by reinforcing that palliative care is intended to augment the usual treatment plan and that the integration of palliative care is designed to meet several objectives: (1) to ensure that pain and symptom control, psychosocial distress, spiritual issues, and practical needs are addressed throughout the continuum of care; (2) to make certain that patients and families obtain the information they need in an ongoing and comprehensible manner to understand their prognosis and treatment options. This process incorporates their values and preferences, and is sensitive to changes in the patient’s condition over time; (3) palliative care seeks to provide seamless care coordination across settings with high-quality communication among providers; and (4) for those patients who are not going to recover, palliative care prepares patients and families, to the extent possible, for the dying process and for death, including options for hospice care, opportunities for personal growth and bereavement support.

SUFFERING AND SYMPTOM MANAGEMENT

Palliative care aims to relieve suffering, which is defined as severe distress related to events that threaten the stability of personhood or

interconnectedness of the physical, psychological, spiritual, and social aspects of self. Beginning with simple, open-ended screening questions, such as “*In what ways are you suffering most?*” and following with more domain-related screening questions (e.g., physical, psychological, spiritual, social) may allow for more probing and multidimensional inquiries to better understand the various sources of and contributions to an individual’s suffering.

One of the first steps in the care of any seriously ill patient is to control pain and other forms of physical suffering. There are striking similarities between the burden of symptoms experienced in patients dying of cancer and noncancer conditions. Although the profile of symptoms may differ, each disease carries with it troubling symptoms that can potentially be addressed and managed.

Physical Symptoms

Pain

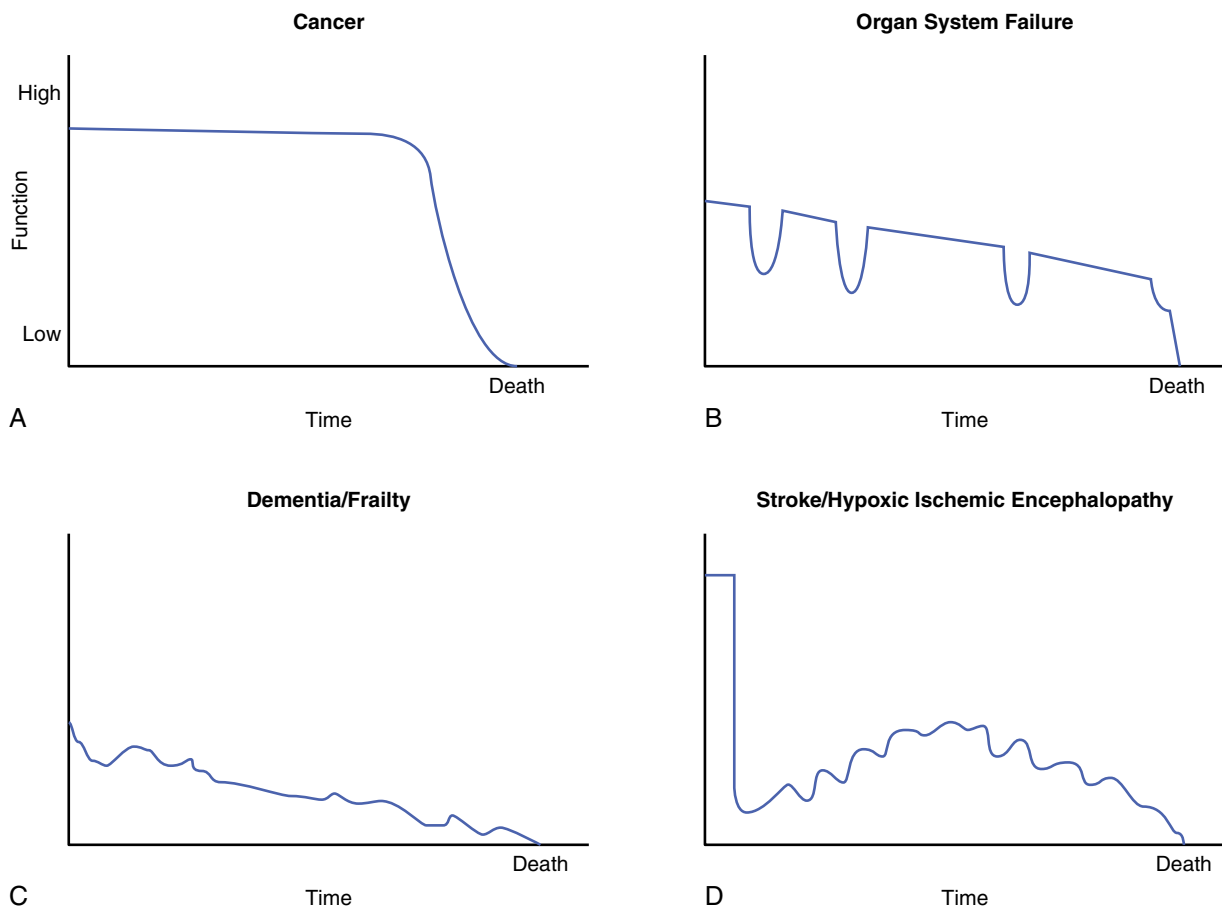

Uncontrolled pain dominates all other experiences, and most pain can be relieved using basic pain management strategies. This includes a detailed history and physical examination, categorizing the likely type or types (i.e., somatic, visceral, neuropathic) and severity (rated on a 0-10 scale) of pain, knowledge about proper opioid dosing strategies, and judicious use of consultations and invasive interventions (e.g., nerve blocks, epidural analgesia). The overarching three-tiered approach is to use nonopioids (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs) for mild pain, weak opioids (e.g., hydrocodone or codeine) for mild-to-moderate pain, and strong opioids (e.g., morphine, hydromorphone, fentanyl, methadone) for moderate to severe pain.

Developing an opioid regimen. Most seriously ill patients with chronic moderate to severe pain should be initially started on around-the-clock dosing using a short-acting opioid. Table 127.1 shows the equianalgesic dosing, usual starting doses, half-lives, and durations for the commonly available opioid agents. Once the total daily dosing has been determined (sum of all scheduled and as-needed doses), the patient may be switched to a long-acting opioid to cover the baseline requirements. As-needed opioids for breakthrough pain should be approximately 10% of the total daily dose every 1 to 2 hours orally or every 30 to 60 minutes subcutaneously or intravenously. If a patient is requiring more than four to six breakthrough doses per day, he/she should be in contact with the prescribing clinician for reevaluation of dosing. Continuous intravenous or subcutaneous infusions of opioids may be needed for rapid control of severe pain.

There are additional opioid selection recommendations for patients with renal insufficiency (avoid morphine and codeine; use hydromorphone and oxycodone with caution; methadone and fentanyl are optimal) and hepatic insufficiency (cautiously use fentanyl, hydromorphone, oxycodone, or methadone; avoid or decrease dose of morphine). Methadone is useful in palliative care because of its excellent oral bioavailability, lack of active metabolites in renal impairment, low cost, flexible route of administration (PO, IV, SC), and possible effect on both neuropathic and somatic pain. However, it does have a dose-dependent, progressively long half-life and arrhythmogenic potential; therefore, an ECG should be considered prior to starting.

Opioid adverse effects. Adverse effects with opioids exist and can be serious. Constipation occurs with all opioids, and it should be anticipated and treated by starting the patient on an appropriate bowel regimen. In refractory cases, one may consider use of methylnaltrexone, if all other methods have been exhausted.

Respiratory depression with opioid use is rare, as long as the opioid is dosed appropriately and proportionately to the severity of symptoms. Therefore, respiratory diseases, such as congestive heart failure, chronic obstructive pulmonary disease, and lung cancer should not

E-Fig. 127.1 In patients with cancer, function typically remains high until the very late stages of disease (A); this is the model of illness for which hospice care was developed. Patients with chronic organ system failure such as heart failure or obstructive lung disease are often ill for prolonged periods, with frequent exacerbations followed by recovery of function (B). Patients with dementia also follow a chronic course, with dwindling reserve over time (C). Sudden neurologic injury (stroke, hypoxic ischemic injury, traumatic brain injury) often results in a sudden decrement of well-being and function associated with a high mortality (D). Recovery is prolonged and slow with frequent setbacks and accumulating disability over time. (Modified from Murray SA, Kendall M, Boyd K, et al: Illness trajectories and palliative care, *BMJ* 330:1007-1011, 2005.)

TABLE 127.1 Equianalgesics for Adults

Pain	Medication	EQUIANALGESIC DOSE (FOR CHRONIC DOSING)		USUAL STARTING DOSES ADULT >50 KG; FOR OPIOID NAÏVE PATIENTS (♦ ½ DOSE FOR ELDERLY, OR SEVERE RENAL OR LIVER DISEASE)				Relative Generic Cost

exclude opioid use in these patients. In fact, opioids can provide these patients with the additional benefit of relieving dyspnea. Furthermore, respiratory depression is almost always preceded by sedation. Therefore, if sedation develops, decreasing the dose of the opioid usually prevents respiratory depression.

Other predictable but less common side effects include nausea, myoclonus, urinary retention, pruritus, and delirium. Some of these side effects are time-limited with initiation and can be managed by dose reduction or opioid rotation.

If patients have had severe adverse effects from opioids in the past, the particular opioid associated with the adverse effects should be avoided, and other opioids should be used with caution (start with a very low dose). To avoid precipitating adverse effects in elderly and debilitated patients, recommended starting doses should be reduced by approximately 50%. Naloxone should be rarely used unless a clear overdose is suspected or if life-threatening complications occur.

Opioid crisis and abuse. The United States is currently facing a public health crisis related to opioid abuse/misuse. According to the National Institute on Drug Abuse, in 2017, more than 47,000 Americans died as a result of an opioid overdose, including prescription opioids, heroin, and illicitly manufactured fentanyl, a powerful synthetic opioid. That same year, an estimated 1.7 million people in the United States suffered from substance use disorders related to prescription opioid pain relievers, and 652,000 suffered from a heroin use disorder. Given this escalating problem, risk factors for potential opioid abuse or misuse should be screened for, including any lifetime personal or family history of substance abuse, as well as certain psychosocial characteristics (e.g., history of psychiatric illness or poor socioeconomic status) before initiating an opioid regimen. When patients with such risk factors develop painful, potentially life-limiting medical conditions, they deserve adequate pain treatment, but with extreme caution because of the risk of reactivating or aggravating abuse behavior. If risk factors are present, special precautions should be taken to minimize the risk of abuse, including clearly defined and adhered to prescribing contracts. These contracts outline an agreement with the patient, ensuring face-to-face encounters for all renewals, placing limits on opioid dosing (max daily amount) and requiring that dose adjustments can only be made after direct conversation with the prescriber. One single prescriber should be responsible for all opioid prescriptions and renewals, and one pharmacy should be used. If clinicians are inexperienced with such prescribing or there is difficulty with contract compliance, formal consultation with specialists in palliative care and/or addiction medicine should be considered.

Evidence abounds that pain is under-treated in many medical settings, including those patients who are severely and even terminally ill (especially women, the elderly, the cognitively impaired, and those from underrepresented groups). Some under-treatment stems from fears about addiction as well as concerns about the possibility of hastening death. When patients with prior addiction problems are excluded, the incidence of new addictive behavior when opioids are used to treat pain in those with a well-defined, serious illness is rare. Similarly, there are very little data to suggest that properly prescribed opioids hasten death. In fact, current evidence supports the idea that opioids may prolong life in these patients and enhance quality of life in those with advanced illness and major pain or dyspnea.

Adjuvant analgesia. Adjuvant analgesia includes both pharmacologic and nonpharmacologic therapies that may be effective in treating pain. The World Health Organization recommends that adjuvant medications be considered in all cases of pain management. Adjuvants should be tried before opioids in cases of chronic, nonmalignant pain. For malignant, moderate to severe pain, combination therapy with an opioid and an adjuvant has been shown to

achieve better pain relief with less toxicity than continued escalation of the opioid alone. Adjuvants should be targeted to the particular type of pain (somatic, neuropathic, and visceral). For somatic pain, NSAIDs, acetaminophen, bisphosphonates, and corticosteroids have proven effective. For neuropathic pain, antidepressants (tricyclic and selective serotonin and norepinephrine reuptake inhibitors), anticonvulsants, and even topical analgesics (e.g., lidocaine patch) have provided relief. For visceral pain, anticholinergics have been used effectively. For a list of examples of commonly prescribed adjuvants, along with usual starting doses, please refer to [Table 2.3](#) in Quill et al. *Primer of Palliative Care*, 7th edition. Prescribers who are unfamiliar with the use of these medications for pain management are encouraged to consult further with specialists in palliative care or pain management.

Other Symptoms

There are numerous non-pain physical symptoms that can dominate and overwhelm the clinical picture in any given patient. These include dyspnea, nausea and vomiting, constipation, anorexia-cachexia, fatigue, bleeding, agitation, apathy, myoclonus, pruritus, and specific functional deficits. Each symptom requires a structured approach to the history and physical examination with a full exploration of the potential etiologies and treatment options informed by the prognosis and preferences of the patient and family. A few of these are discussed in more detail here, but for practical information geared toward basic management of symptoms in palliative care refer to Quill et al., *Primer of Palliative Care*, 7th ed.

Dyspnea. Dyspnea is defined by the American Thoracic society as “a subjective experience of breathing discomfort.” It is a common symptom at the end of life, experienced by patients suffering from diseases such as cancer, COPD, CHF, and pulmonary fibrosis. Dyspnea is very distressing, and when severe, requires urgent intervention.

The first step in management is identification of the underlying cause/disease, followed by treatment directed towards the particular etiology. After the underlying etiology is addressed, if dyspnea remains a prominent symptom, there are several general measures which can be done. These include reducing the need for exertion, repositioning the patient to a more upright position, keeping the compromised lung down in unilateral disease and improving air circulation by opening windows/doors or using a bedside fan.

Opioids are the preferred agents for symptomatically treating dyspnea because they effectively suppress awareness of the sensation of shortness of breath. Most routes of administration are effective except the use of nebulized opioids. There is emerging evidence that low-dose, sustained-release morphine may provide lasting relief of dyspnea, mainly in COPD patients. Some providers avoid the use of opioids for dyspnea out of fear of causing respiratory depression. However, in the absence of preexisting carbon dioxide (CO₂) retention, respiratory depression is uncommon in patients who are on carefully titrated doses of opioids.

Anxiety and dyspnea frequently exacerbate one another. It is important to treat an anxious dyspneic patient with opioids first to reduce breathlessness and then follow with a benzodiazepine if anxiety persists.

Nausea and vomiting. Nausea and vomiting are some of the most distressing symptoms for patients. Studies have shown that these symptoms are experienced by up to 78% of patients with advanced cancer at some point during their disease course. They also occur in other advanced illnesses, including end-stage cardiac, renal, and liver disease. Persistent nausea and vomiting can affect appetite, pain management, and the quality of interactions with family members or friends.

When evaluating patients with nausea and vomiting, it is important to first consider whether the symptoms are a result of intra-abdominal factors (e.g., gastroparesis, ileus, gastric outlet obstruction, bowel obstruction) or extra-abdominal factors (drugs, electrolyte abnormalities, central nervous system metastases). The goal is to identify and treat underlying reversible causes first.

In most cases, empiric pharmacologic treatment is necessary to immediately control symptoms. There are a number of pharmacologic agents that have been shown to be useful for nausea/vomiting, depending on the etiology. One of the most useful is haloperidol. When nausea and vomiting are due to increased intracranial pressure, a steroid such as dexamethasone is useful. Metoclopramide may be useful in situations of delayed gastric emptying or early satiety. When nausea and vomiting are due to inner-ear pathology or motion sickness, antihistamines can help manage vertigo.

In addition, high dosages of a combination of agents may be required for adequate control of symptoms. Treating patients with a scheduled dose of antiemetics can often prevent recurrent nausea. If the patient is too nauseated to tolerate oral medications, consider SC, IV, or PR routes.

Constipation. Palliative care patients are at particularly high risk for developing constipation due to a combination of factors, including decreased PO intake, impaired mobility and use of opioid analgesics.

Pharmacologic options for management of constipation include stool softeners (docusate sodium), stimulants (Senokot and bisacodyl), and osmotic agents (polyethylene glycol, lactulose, magnesium hydroxide, magnesium citrate). The key to adequate management of constipation in the palliative care setting is prevention, which involves initiation of a maintenance bowel regimen. If the patient has a history of constipation, the preferred maintenance regimen should be the patient's regular home regimen. If constipation has never been a problem in the past, starting with senna can be a good option. Docusate may also be used initially; however, the efficacy of docusate alone is limited, and most patients will require addition of a bowel stimulant, like senna or bisacodyl. Osmotic agents, such as polyethylene glycol or lactulose, are effective additions to most bowel regimens but may also bring about adverse effects such as bloating and flatulence. Rectal suppositories and enemas may be necessary when constipation is severe. Avoid bulk-forming agents (psyllium, methylcellulose) in palliative care patients, as these agents can lead to impactions with inadequate fluid intake.

All of the above medications may be used in combination when managing constipation. However, maximizing the dose/frequency of current bowel medications will typically provide desired effects and should be done prior to addition of other medications.

Medical Marijuana

Cannabis has several beneficial health effects although clinical data are limited because of restrictions on research.

The body contains an endogenous network known as the endocannabinoid system, which involves two receptors, CB1 and CB2. As endocannabinoids interact with these receptors, they impact many physiologic processes, including gastrointestinal (GI) function, appetite, metabolism, pain, memory, movement, immunity, and inflammation. Cannabis contains phytocannabinoids, Δ -tetrahydrocannabinol (THC) and cannabidiol (CBD), which interact with these receptors much the same way that endocannabinoids do, thereby providing the various medicinal effects that are observed with cannabis use.

THC is the primary psychoactive constituent of cannabis. Observed effects include impairments of learning, memory, spatial orientation, and attention. However, patients also report benefits including antiemetic, analgesic, and anti-inflammatory properties. CBD lacks the

THC-induced intoxicating properties, and the presence of CBD in a cannabis product is actually believed to counteract the psychosis-inducing effects of THC. CBD has reported benefits of anticonvulsant, anxiolytic, anti-inflammatory, and neuroprotective properties; however, none of these have been verified. Synthetic cannabinoids currently marketed are dronabinol, a biochemically identical form of THC, and nabilone, a THC analogue. Both can be prescribed clinically for nausea and/or vomiting, appetite stimulation, pain, and spasticity.

The National Academies of Sciences, Engineering, and Medicine (NASEM) published a comprehensive literature review on the health effects of cannabis and concluded that there is substantial evidence that cannabis is effective (1) for the treatment of chronic pain, (2) as an antiemetic in chemotherapy-induced nausea and vomiting, and (3) for muscle spasticity syndromes in MS. As far as adverse effects, the NASEM concluded that there is substantial evidence for an association between cannabis smoking and respiratory disease, motor vehicle collisions (MVCs), lower birthweight offspring, and schizophrenia or other psychoses.

Medicolegal realities surrounding medical cannabis are rapidly evolving in the United States. As of publication of this book, 33 US states and the District of Columbia have programs authorizing cannabis use for specific medical conditions. Because cannabis is illegal under federal law, clinicians cannot prescribe it and pharmacies cannot dispense it as they would with other pharmaceuticals. States require health care professionals to be registered in order to certify patients for cannabis use. Cannabis is then supplied to patients through state-licensed medical cannabis dispensaries, in various forms, including vaporized oils or plant material, sublingual tinctures, and oral capsules.

Psychological Distress

Depression, anxiety, and delirium are all common in the palliative care setting. They are frequently under-recognized and under-treated, although appropriate diagnosis and treatment can have significant improvement in a patient's quality of life.

Depression and Anxiety

Almost all patients in palliative care and their families experience normal sadness/grief as illness advances. Depression, however, is more enduring, persistent, intense, and may be associated with hopelessness, helplessness, worthlessness, and guilt. Two questions, found to have high sensitivity for depression screening, include: "Are you depressed?" and "Do you have much interest and pleasure in doing things?" A more formal exploration is indicated if the patient gives a positive answer to either of these questions. One should be cautious about overusing somatic symptoms to diagnose depression (e.g., fatigue, anorexia, sleep disturbance) because they frequently overlap with physiological changes associated with advanced disease. Terminally ill patients with depression are at higher risk of suicide and suicidal ideation, and they may have increased desires and requests for hastened death.

Anxiety symptoms may be triggered by a range of medical transitions, such as the initial diagnosis of serious illness, a recurrence of illness, treatment side effects/failure, or discussion of hospice. The patient may also have underlying fears related to their disease and end-of-life, including uncontrolled pain, isolation, abandonment, loss of control, worry about family members or even the idea of death/dying.

Regarding treatment of depression and anxiety, first recognize and address contributions from physical symptoms (e.g., uncontrolled pain), medical causes (e.g., hypothyroidism, hyperthyroidism), and medications. Effective pharmacologic and nonpharmacologic treatments exist for both depression and anxiety, though treatment selection depends on symptom intensity, patient prognosis, and treatment benefits and burdens. Other members of the interdisciplinary team

(social worker, chaplain, and psychologist) often play a critical role in assessment and ongoing management.

Delirium

Delirium, an acquired and fluctuating disorder of consciousness and cognition, occurs commonly in the palliative care setting. The level of psychomotor activity can vary from hyperactive (“agitated” delirium) to hypoactive (“quiet” delirium). Nearly 80% of the delirium in the palliative care setting is the hypoactive variant. As a result, it is often under-diagnosed or misdiagnosed as depression and fatigue. The most common causes of delirium in palliative care include medications (e.g., opioids), metabolic disorders due to progressive organ failure, and infection. Meticulous attention to the history from collateral sources (e.g., nurses, caregiver) and a detailed medication history are essential for an accurate diagnosis. While delirium may reverse if an obvious cause is identified and removed, frequently it represents an important marker of progressive illness; therefore, cognitive improvements may be transient and incomplete. In addition to etiology-specific treatment (e.g., change or stop medications, treat infection, oxygen, hydration, bisphosphonates), environmental interventions are recommended for all patients (e.g., quiet reassurance, gentle reorientation, optimize sensory input, minimize night disruptions). Pharmacologic management should be used sparingly and cautiously and may include antipsychotic medications, benzodiazepines, and psychostimulants (for the hypoactive variant). Keep in mind that benzodiazepines can sometimes have a paradoxical effect, worsening confusion and agitation in delirium.

Spiritual and Existential Suffering

Spiritual and existential distress is prevalent in patients and families with serious illness, especially at the end of life. Spirituality is about one’s relationship with and responses to transcendent questions that confront one as a human being (e.g., search for meaning and purpose in life). Religion is a set of texts, practices, and beliefs about the transcendence shared by a community. Spirituality is broader than religion. The spiritual issues of seriously ill and dying patients often center on questions of meaning, value, and relationships. Dying patients want to be assured of their value in the face of actual or perceived threats to their intactness as a human being (e.g., physical and cognitive declines, altered appearances). Spirituality can help people find hope in despair and can help restore purpose.

One of the goals of palliative care is to relieve spiritual and existential distress. Patients and families often welcome such discussions. Examples of open-ended questions to facilitate this dialogue include: “*Are you at peace with all of this?*” and “*Is faith (religion, spirituality) important to you?*” Acknowledgement and empathetic listening are the most important responses for most clinicians, as opposed to trying to provide “correct answers.”

Other strategies for fostering hope and meaning include developing caring relationships, setting attainable goals, involving the patient in the decision-making process, affirming the patient’s worth, using lighthearted humor (when appropriate), and reminiscing with life review. It is important, however, to know one’s professional boundaries and refer to chaplains or clergy from the patient’s faith traditions if questions move beyond the realm of general exploration (e.g., “*It sounds like it would be good to explore this with someone with more experience than I have. Would it be okay for me to send our chaplain in to discuss this with you?*”).

COMMUNICATION AND CARE COORDINATION

Excellent communication skills are central to palliative care, including communication with patients, family members, other physicians, nurses, and other members of the health care team. The overarching

aim is to assist the patient and family in establishing the goals of current and future treatment in a shared decision-making process.

Negotiating Goals of Care

When negotiating goals of treatment in palliative care, the focus is often to assist with the following decisions: to help decide types and aggressiveness of disease-directed therapies; to ensure optimum palliation of symptoms; to assist in hospice determinations; to discuss initiating, withholding or withdrawing therapies; to facilitate advance care planning; and to initiate surrogate decision making if the patient lacks capacity. These discussions occur at various time points in the course of advancing illness when new and important information is learned and needs to be communicated to the patient and family. The need to renegotiate goals should also be anticipated when triggers of advancing disease suggest limited life expectancy or excessive suffering. These discussions are almost always variants of “bad news” discussions.

The overall approach to communication and negotiating goals of care is standard among all patients, illnesses, and situations (Table 127.2). This includes running an effective family meeting, with or without the patient present. Initial elements include establishing the proper setting, identifying key stakeholders, and “doing your homework” (i.e., discussing potential plans with all relevant subspecialties who may have communicated with the patient and family). When the meeting begins, find out what the patient and family understand about the medical condition and ask what additional information they want to know. Keep an open mind and try to hold back on a fixed agenda (e.g., to “get the DNR” or to “stop futile care”). This allows patients and family members sufficient time to “tell their stories” and provides the context within which effective decision making can occur. In general, the more patients and families speak in the early parts of such meetings, the better.

The provider then needs to share prognostic information and discuss the benefits and burdens of the available treatment options. Alerting the patient or family of impending bad news with a warning shot (e.g., “*I am afraid I have some difficult news to share with you*”) is a useful initial communication strategy. The amount of information should be paced with frequent pauses to allow time for emotional responses. Comprehension should be frequently checked, and questions should be encouraged using an “ask-tell-ask” strategy. The skilled clinician can flexibly assess, probe, and pace the content and depth of the discussion in an emotionally responsive (acknowledge, explore, empathize, and legitimize) and culturally competent manner. This includes the ability to understand and respect diverse religious practices and differing preferences about degree of truth telling. When appropriate, the clinician should make recommendations based on scientific knowledge as well as awareness of a patient’s values and preferences and be prepared to help resolve conflicts among the patient, family members, and providers. Finally, providers need to develop strategies to preserve and potentially reframe hope, including ways to “*hope for the best*” and simultaneously “*prepare for the worst.*” Commitments to minimize suffering and to not abandon the patient and family are essential. At the end of the discussions, the provider should summarize key aspects of what was reviewed and establish a follow-up plan for future communications and treatments.

Estimating and Communicating Prognosis

A core component of information shared in the palliative care setting is prognosis. Understanding prognosis is central to making decisions (e.g., treatment, comfort measures, hospice). Prognosis is a prediction of possible future outcomes of a disease (e.g., survival, symptoms, function, quality of life, family and financial impact) with or without treatment. Most patients and families want to know prognosis. Since

TABLE 127.2 General Strategy for Communicating and Negotiating Goals of Care in Common Palliative Care Settings

Step 1	Prepare and establish setting Do not have a rigid preset agenda
Step 2	Ask patient and family what they know and understand Provide sufficient time for patients and families to “tell their story” Active listening skills
Step 3	Find out how much patient and family want to know Acknowledge and explore emotions
Step 4	Give information in small amounts, and frequently check understanding Discuss prognosis and benefits and burdens of treatment options Be mindful of overly optimistic and pessimistic predictions Be prepared to make recommendations
Step 5	Respond to emotions and empathetic response Convey honesty and reframe hope Use “I wish” statements
Step 6	Summarize, establish and implement plan, follow-up Possible time-limited trial

there are some patients and families that may not want to know prognosis or may want it communicated in a particular way, it is essential to begin by finding out what the patient and family knows and wants to know.

Inaccurate predictions may lead to poor decision making. Physicians tend to overestimate survival in patients with advanced cancer by about 30%, and the bias is more pronounced the longer the physician-patient relationship. Overly optimistic predictions can lead to overuse of ineffective or unwanted disease-directed treatment, delay in hospice referrals, false expectations, unnecessary tests and procedures, and poor symptom control. Therefore, accurately estimating and communicating prognosis is central to optimal decision making in advanced illness and at the end of life.

In advanced illnesses, common factors found to be predictive of short-term survival (i.e., less than 6 months) include performance status, anorexia-cachexia syndrome, delirium, and dyspnea. The Palliative Performance Scale can be used to measure and track a patient's functional status. It is available in a variety of websites and books. In addition to a physician's subjective predictions of survival, there exist models to assist with prognostic estimates, including generic models for particular populations (e.g., hospice enrollees) as well as disease-specific models (e.g., cancers, heart failure, liver disease, stroke, AIDS, spinal cord compression). Hospice eligibility criteria also differ for specific diseases. While not uniformly reliable, these criteria can be useful in formulating estimates where prognosis might be 6 months or less if the disease is allowed to run its natural course (a prognostic criterion). One example of this is the Functional Assessment Staging (FAST) scale used to determine hospice eligibility for Alzheimer's/dementia patients.

For an individual patient, however, prognostic uncertainty remains the rule. Therefore, it is important to integrate both evidence and experience-based medicine and present the information in formats tailored to the particular patient (verbal descriptions, numeric, frequencies, or graphics). Prognostic estimates should be bounded with ranges to convey realistic uncertainty, being sure to allow for exceptions in both directions. For example, “*in my experience, patients with your condition live on average a few weeks to a few months. It could be longer, but*

it could also be shorter.” For survival-oriented prognoses (e.g., “*How long do I have?*”), be mindful of overly optimistic prognoses, remembering to think of and convey the lower bound (e.g., “*some may live longer, but others may, unfortunately, live shorter*”). For quality of life-oriented prognoses (e.g., “*What will life be like?*”), be mindful of overly pessimistic predictions, remembering the power of adaptation and engendering hope by helping patients and families find new meaning.

END-OF-LIFE CARE

The Role of Diagnostic Tests and Invasive Procedures

Several questions should be considered in determining the appropriateness of aggressive medical or palliative interventions near the end of life: What is the goal or expected outcome of the proposed intervention? What is the probable efficacy of the intervention? What is the patient's baseline level of function and life expectancy? What are the potential side effects and burdens of the intervention? What are the patient's and family's wishes, values, and preferences?

The range of medical and palliative options available is huge, so the challenge is to determine what makes sense to enhance the well-being of each patient at their particular stage of illness. Palliative interventions range from pure symptom management and support to invasive options, such as chemotherapy, radiotherapy, surgical/endoscopic interventions, stenting procedures, thoracentesis, paracentesis, pericardiocentesis, home inotropic therapy, noninvasive ventilation, antibiotics, or transfusions. The challenge is to individualize discussions, so that patients can take full advantage of treatments that will help them meet their goals without having their experience dominated by near futile invasive treatments.

Role of Hospice

Hospice care is a specialized form of palliative care aimed at those patients and families in the terminal stages of illness. The National Hospice and Palliative Care Organization defines hospice as follows: *Considered to be the model for quality, compassionate care for people facing a life-limiting illness or injury, hospice and palliative care involve a team-oriented approach to expert medical care, pain management, and emotional and spiritual support expressly tailored to the person's needs and wishes. Support is provided to the person's loved ones as well. The focus of hospice relies on the belief that each of us has the right to die pain free and with dignity, and that our loved ones will receive the necessary support to allow us to do so.*

Since the establishment of the Medicare Hospice Benefit in 1982, use of hospice for end-of-life care has grown steadily. In 2015, more than 1.6 million patients were served by hospice programs in the United States. Cancer used to be the most common diagnosis for patients dying in hospice programs. However, in 2017, Alzheimer's disease was reported as the top principal diagnosis for hospice patients. COPD, heart failure and cancer were listed among the top five. In 2015, the median length of stay for patients in hospice was 23 days.

In most cases, hospice care is provided in the person's home. Hospice care can also be provided in freestanding hospice centers, hospitals, and nursing homes or other long-term care facilities. In order to qualify for the Medicare Hospice Benefit, two physicians must sign a statement certifying that the patient's prognosis for survival, if the disease runs its natural course, is likely to be 6 months or less. Hospice criteria exist to assist in making these determinations for common medical conditions (see section, Estimating and Communicating Prognosis). The Medicare Hospice Benefit covers most costs related to terminal care without a deductible, which includes palliative medications, nursing oversight, supplies, and bereavement care. Hospice also covers up to 2 to 4 hours of custodial caregiver services per day;

however, family and/or friends must provide the remaining care if the patient is to stay at home. Hospice can supplement care in a skilled nursing facility, but patients themselves or their insurance would be responsible for the nursing home room and board charges. The hospice benefit includes bereavement care for the family after the patient's death.

Discussing hospice with patients and families can be challenging. First, some may view the transition to hospice as a way of "giving up" or "giving in to death." It is often initially viewed as a "bad news" discussion given that patients and families need to confront the fact that disease-directed treatment is no longer effective and that prognosis is likely to be 6 months or less. Second, given the reimbursement restrictions, patients may also need to forgo particular types of treatment that are important to them (e.g., acute hospital or ICU-level care, dialysis, chemotherapy, milrinone for heart failure).

Last Hours and Days of Living

An integral aspect of palliative care is preparing and guiding the patient and caregivers through the dying process. When prognosis is measured in hours to days there are typical signs and symptoms that usually occur. Patients become weak and fatigued and gradually lose mobility. There is also a gradual and predictable decrease in food and fluid intake. Most patients do not experience hunger and thirst, and the associated mouth dryness that occurs is easily palliated with small sips or sponges of cold water. Caregivers will frequently ask about intravenous hydration. In rare instances, intravenous or subcutaneous fluids may temporarily improve mental status and energy in the final days of life. Most of the time, however, the benefits are difficult to discern and the excessive fluids may contribute to end-of-life physiologic conditions (edema, ascites, effusions, and pulmonary secretions) that do not improve longevity and may worsen comfort.

As patients become weaker, there is a predictable decrease in the level of consciousness with increasing periods of somnolence, eventually giving way to a comatose state. Education about this process should include associated changes in respiratory patterns, including prolonging periods of apnea, interspersed with episodes of hyperpnea and deep breathing (Cheyne-Stokes respirations). During this process caregivers often feel they are on a "roller-coaster ride," and gentle guidance on what to expect can allay concerns. As consciousness wanes, swallowing slows and the cough reflex weakens. As a result, saliva pools in the oropharynx and can result in noisy respiration ("death rattle"), which can usually be palliated to some degree with scopolamine (transdermal), glycopyrrolate (PO, IV, SC) or hyoscyamine (PO disintegrating tablets or sublingual solution). Families should be reminded that these symptoms are a natural part of the dying process and that persistent shortness of breath is relatively uncommon but can be treated with opiates and benzodiazepines, if needed.

As death approaches, reduced perfusion causes cooling and cyanosis of the extremities, as well as a reduced volume and darkening of the urine. Most deaths are relatively peaceful, but a few can be preceded by periods of intense agitation and restlessness (hyperactive terminal delirium). Antipsychotic medications and conventional doses of benzodiazepines can usually treat terminal delirium. Prior to and when death occurs, families should be encouraged to carry out cultural or religious rituals that are important to them. Providers should express condolences, be available for questions and responsive to intense emotional reactions that sometimes occur. A short condolence card or letter is almost always appreciated. If possible, efforts should be made to follow up with family members and caregivers deemed at risk for complicated bereavement and grief.

COMMON ETHICAL CHALLENGES IN PALLIATIVE CARE

Patient Capacity and Surrogate Decision Making

When discussing goals of care, it is essential to determine if a patient has capacity to make medical decisions. Adults are presumed to have capacity, unless determined by the court. However, many medical conditions can alter a patient's ability to make decisions for themselves (e.g., delirium, dementia, sedation). As many as 25% of adult inpatients are found to lack capacity. In order to be found to have capacity, a patient must (1) be able to comprehend the factual information about their medical condition and treatment options, (2) understand the risks and benefits of the treatment options and the consequences of that decision, (3) be able to accept or reject the proposed treatment voluntarily, and (4) provide reliable choice over time. A physician, psychiatrist, or ethics consultant may determine a patient's capacity to make a medical decision. Only a court can determine legal competence. In the event that the patient lacks capacity, a surrogate decision-maker must be consulted. This could be a health care proxy (legally designated by the patient when he/she did have capacity), a legal next-of-kin, or a court-appointed guardian. When there is question about a patient's capacity, which surrogate decision-maker is legally appropriate, or if the surrogate appears to be making decisions contrary to the patient's best interests, an ethics consultation should be obtained.

When Patients and Families Want Near Futile Treatment

The patient autonomy movement in medicine has led to patients and families taking an active role in their own medical decision making. This is generally a positive development except in two circumstances: (1) when physicians stop taking an active role using their expertise to guide patients in their decision making, thereby abdicating their professional responsibility of advocating for the best possible treatment based on the patient's medical condition and personal values, and (2) when patients or their families want and even demand near futile treatment toward the end of their lives despite physician's advice that treatment has much more burden than benefit. Physicians might try to respond to patients who want "everything" by suggesting that they want to try everything that is "more likely to help than harm," but avoid any treatment that is most likely to "do more harm than good." However, some patients and families will accept no limits on treatment no matter what the burden and the improbability of success. Of course, truly futile treatment should not be offered or provided upon request, but absolute futility has been difficult to define in many cases.

Feeding Tube Questions

Many patients gradually stop eating and drinking as a natural part of the dying process, but this can be very hard for patients and families to accept in light of fears about "starving to death" and in view of seemingly simple technologies that can potentially combat and even reverse the problem. In fact, with few exceptions, feeding tubes have not been shown to prolong life in most advanced illnesses such as metastatic cancer or advanced Alzheimer's disease. It is important to know about the exceptions (e.g., esophageal and oropharyngeal cancers, amyotrophic lateral sclerosis, acute stroke) but also to have an open discussion about the natural progression of diminished eating and drinking as many illnesses advance. If there is uncertainty about whether a particular patient might benefit from a feeding tube, and patient and family are clear about wanting to give it a try, the clinician can frame the decision as a "time-limited trial" to see how the patient tolerates tube feeding psychologically as well as physiologically in a specified time-frame. A potential framework for such a trial is that a nasogastric tube has a built-in time limit of about a month before a PEG tube needs to be inserted. Explaining to patients and families about the positive

aspects (smell, taste, and enjoyment) of natural feeding of real food, even in small amounts, may help focus the decision on important quality of life issues, rather than more technical, physiological issues.

Proportionate Palliative Sedation

Proportionate palliative sedation is the use of gradually escalating levels of sedation to help relieve intractable and distressing physical symptoms at the end of a patient's life. The goal is to achieve the lowest level of sedation that adequately relieves the patient's uncontrolled suffering, not to intentionally end a patient's life or hasten a patient's death. Although unconsciousness may eventually be the outcome of proportionate palliative sedation, this is not the intended aim.

Terminally ill patients receiving proportionate palliative sedation should have do-not-resuscitate (DNR) and do-not-intubate (DNI) orders before the treatment is initiated. Patients with capacity should provide verbal or written consent prior to initiating the process because capacity usually will be compromised once it is started. If the patient lacks capacity, the decision to initiate proportionate palliative sedation would be made by the patient's surrogate decision maker.

Medications used to achieve adequate symptom control include sedatives (lorazepam, midazolam, and phenobarbital) in the form of continuous IV infusions. Careful monitoring of the patient's level of sedation/agitation is very important in order to determine need for additional bolus doses or titration of infusion rate. A formal palliative care consult is strongly recommended to help guide this process.

Examples of conditions when proportionate palliative sedation might be initiated include agitated terminal delirium, unrelenting nausea and vomiting, intractable pain, and unrelenting dyspnea in actively dying patients who do not respond to the usual palliative treatments.

Request for Hastened Death

The prevalence of suicidal ideation and suicide attempts is higher in patients with advanced life-limiting illness compared to those without serious disease. In Oregon, where physician-assisted suicide is legally permitted (subject to safeguards), the prevalence of a patient wanting to explore a health care professional's willingness to help hasten death is about 1/50, whereas only about 1/500 die using physician-assisted suicide. The motivation behind such initial explorations may relate to relentless physical suffering, disfigurement, hopelessness, loss of dignity, fear of being a burden, or a "cry for help." Most enduring requests from patients with progressive medical illnesses, however, arise not from inadequate symptom control, but from a patient's belief about dignity, meaning, and control over the circumstances of death. Although some providers might be uncomfortable exploring such requests, before responding, a systematic approach should be used to evaluate and understand the root causes of these requests. A careful evaluation includes a precise clarification and exploration as to exactly what the patient is asking and why. Is the request based on transient thoughts about ending life (common) or a serious appeal for assistance (relatively rare)? Does the request occur in the context of intense physical suffering, psychological despair, an existential crisis, or a combination of factors? Does the patient have full decision-making capacity? Is the request proportionate to the level of suffering? Evaluating such requests can be emotionally fatiguing and conflicting, and clinicians need self-awareness in distinguishing their emotions from the patient's, including tending to one's own support by sharing the burden of such requests with trusted colleagues.

Responding to such a request should first include evaluation for potentially reversible contributions to suffering. This will often include treating physical and psychological symptoms, aggressive attempts to foster hope, consulting psychiatrists or spiritual counselors, and creative brainstorming with trusted colleagues and team members. Some

requests for hastened death persist, despite optimal palliative care. In such circumstances, the clinician should seek out a second opinion and confront the possibilities. These possibilities include withdrawal of life-sustaining interventions, palliative sedation, voluntary cessation of oral intake, and assisted suicide. As of publication, it is legal in nine jurisdictions: California, Colorado, District of Columbia, Hawaii, Montana, Maine [starting January 1, 2020], New Jersey, Oregon, Vermont, and Washington. While it is important to support the patient, the clinician must balance integrity and non-abandonment. This may include drawing specific boundaries of what the clinician can and cannot do, while still searching in earnest for a mutually acceptable solution.

PROSPECTUS FOR THE FUTURE

Palliative care became an officially recognized subspecialty within the United States in 2006. Physicians from 10 specialties can be board certified in hospice and palliative medicine, following completion of a fellowship. These specialties include: family medicine, internal medicine, emergency medicine, pediatrics, physical medicine and rehabilitation, anesthesiology, psychiatry, neurology, radiology, and surgery. As patients live longer with chronic illness, there will be an increasing need to fully integrate palliative care providers and programs within hospitals, nursing homes, and the outpatient setting; and to ensure that all primary care providers and non-palliative specialists develop the skill sets needed to provide basic palliative care. There is a compelling need for continued education and research to improve the overall palliative approach to care for everyone and to better define the optimal timing, setting, and delivery of palliative care to improve the quality of life and lessen the suffering of patients and families with advanced illness.

SECTION XIX

Alcohol and Substance Use

128 Alcohol and Substance Use, 1151

Alcohol and Substance Use

Richard A. Lange, Joaquin E. Cigarroa

ALCOHOL USE

Alcohol use is a major public health problem worldwide, accounting for 3 million deaths (5.3% of all deaths) annually. One in six US adults binge drinks (i.e., a pattern of drinking that brings a person's blood alcohol concentration to 0.08 g percent [80 mg/dL] or above, which typically happens when men consume five or more drinks or women consume four or more drinks in about 2 hours) about four times a month, consuming about seven drinks per binge. Alcohol use is the third leading preventable cause of death in the United States (exceeded only by cigarette smoking and hypertension) and claims over 88,000 lives annually, or 9.8% of all US deaths. Alcohol use accounts for 28% of all traffic-related deaths in the United States, or approximately 10,500 vehicular deaths annually, and is a major contributor to risky sexual behavior, domestic violence, homicide, and suicide. In 2010, the estimated alcohol-related costs in the United States were \$249 billion, 77% of which was attributable to binge drinking. These costs resulted from losses in workplace productivity, health care expenditures, criminal justice costs, and other expenses.

DEFINITION AND EPIDEMIOLOGY

The American Psychiatric Association has specific criteria for the diagnosis of *alcohol use disorder*; these 11 criteria are described in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, and are listed in [Table 128.1](#). Alcohol use disorder is further characterized as mild, moderate, or severe, based on the number of criteria the individual meets; two to three criteria indicate a mild disorder, four to five criteria a moderate disorder, and six or more a severe disorder. The so-called *binge drinker* is defined as a man who typically consumes five or more drinks or a woman who consumes four or more drinks on a single occasion. Nearly 50% of alcohol use disorder risk is heritable (i.e., transmissible from parent to offspring), with the other 50% attributable to environmental factors.

In 2016, 136.7 million Americans aged 12 or older reported current use of alcohol and 65.3 million reported binge alcohol use in the past month ([Fig. 128.1](#)). This number of people who were current binge drinkers corresponds to about 1 in 4 people aged 12 or older ([Fig. 128.2](#)) and nearly half of current alcohol users. Additionally, 16.3 million reported heavy alcohol use in the past month (see [Fig. 128.1](#)), which means that 1 in 8 (12%) current alcohol users or 1 in 4 (25%) binge drinkers reported heavy alcohol use. Although the prevalence of ethanol use is highest in individuals younger than 30 years of age, survey data suggest that about two thirds of persons over age 30 consume it.

In 2016, 73% of men and 66% of women aged 18 years or older reported drinking in the past year, and 7.8% of men and 4.2% of

women were diagnosed with an alcohol use disorder. Native American individuals had the highest prevalence of alcohol use disorder (9.2%), followed by non-Hispanic white (5.9%), black (5.6%), Hispanic (5.1%), Pacific Islander (3.5%), and Asian (3.0%) individuals. Alcohol use peaks in younger adults, with those aged 21 through 25 years having the highest prevalence of past-year drinking (83%) and those aged 18 through 25 years having the highest prevalence of alcohol use disorder (11%).

PHARMACOLOGIC AND METABOLIC FACTORS

After oral ingestion, alcohol is absorbed predominantly in the small intestine, and its rate of intestinal absorption is accelerated by the simultaneous ingestion of carbohydrates and carbonated beverages. Prolonged retention of alcohol in the stomach, as occurs when food is consumed before drinking, delays alcohol absorption because absorption in the stomach is considerably slower than in the duodenum. Once in the blood, alcohol equilibrates rapidly across all membranes, including the blood-brain barrier, thereby accounting for the prompt onset of its euphoric effects. Maximal blood alcohol concentrations are reached 45 to 75 minutes after alcohol is ingested.

The liver metabolizes approximately 90% of ethanol to acetaldehyde via the alcohol dehydrogenase pathway; subsequently, acetaldehyde is converted by aldehyde dehydrogenase to acetate, which enters the Krebs cycle. At low or moderate serum concentrations of ethanol, the alcohol dehydrogenase pathway functions almost exclusively in metabolizing ethanol. At high concentrations, the microsomal ethanol oxidizing system (CYP2E1) contributes to metabolism. Less than 10% of ethanol is excreted unchanged through the skin, kidneys, and lungs. Elimination of alcohol from the body is affected by obesity, food intake, previous exposure to alcohol, and variability among individuals in the efficiency of the alcohol and aldehyde dehydrogenase systems. These enzymatic variations also influence a person's risk of developing an alcohol use disorder. The mechanism is thought to involve elevated acetaldehyde levels resulting from a more rapid conversion of ethanol (in cases of alcohol dehydrogenase variants with higher enzymatic activity) or slower elimination of acetaldehyde oxidation (in cases of aldehyde dehydrogenase variants with reduced enzymatic activity). Acetaldehyde causes facial flushing, nausea, and tachycardia, which make individuals reduce their intake of alcohol.

MECHANISMS OF ALCOHOL-INDUCED ORGAN DAMAGE

The major organs that are susceptible to damage by alcohol are the liver, pancreas, heart, brain, and bone ([Table 128.2](#)). Several alcohol-related

TABLE 128.1 Criteria for the Diagnosis of Alcohol Use Disorder**Two or More of the Following in the Previous 12 Months**

1. Recurrent alcohol use resulting in a **failure to fulfill major** obligations at work, school, or home
2. Recurrent alcohol use in situations in which it is physically **hazardous**
3. Continued alcohol use despite having persistent or **recurrent social or interpersonal problems** caused or exacerbated by the effects of alcohol
4. **Tolerance**, as defined by:
 - need for markedly increased amounts of alcohol to achieve intoxication or desired effect; and/or
 - markedly diminished effect with continued use of the same amount of alcohol
5. **Withdrawal**, as manifested by:
 - characteristic alcohol withdrawal syndrome; and/or
 - alcohol is taken to relieve or avoid withdrawal symptoms
6. Alcohol is often taken in **larger amounts** or over a longer period than was intended
7. Persistent desire or **unsuccessful efforts to diminish** or to control alcohol use
8. A great deal of **time** is spent in activities necessary to obtain, use, or recover from the effects of alcohol
9. Important social, occupational, or recreational **activities are relinquished or reduced** because of alcohol use
10. Alcohol use is **continued despite knowledge** of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol use
11. **Craving** or a strong desire or urge to use a specific type of alcohol

Modified from the American Psychiatric Association: Diagnostic and statistical manual of mental disorders, ed 5, Washington, D.C., 2013, American Psychiatric Press.

medical disorders are caused by various nutritional deficiencies; ethanol is deficient in proteins, minerals, and vitamins. Therefore, the initial management of the alcoholic patient must attend to suggested dietary deficiencies (e.g., thiamine) and electrolyte deficiencies, including potassium, magnesium, calcium, and zinc.

Alcohol-related liver disease is the leading preventable cause of hepatic failure in the industrialized world. Genetic factors are thought to play a role in susceptibility to this disorder, since alcoholic liver disease is more prevalent in white individuals than in other ethnic groups (despite a similar magnitude of ethanol consumption). The histopathologic features of alcoholic liver disease include fatty infiltration, hepatitis, fibrosis, and end-stage cirrhosis.

CLINICAL PRESENTATION

Acute Alcohol Intoxication

Mild ethanol intoxication produces slurred speech, ataxia, irregular eye movements, and poor coordination. Signs of central nervous system (CNS) depression and associated cerebellar or vestibular dysfunction include dysarthria, ataxia, and nystagmus. Although blood alcohol concentrations are not precisely correlated with the degree of intoxication and the clinical effect of ethanol widely varies among individuals, stupor and coma usually develop at blood concentrations approaching 400 mg/dL. Blood levels of 500 mg/dL often are fatal; however, it is important to understand that death may occur even when the blood alcohol concentration is as low as 300 mg/dL.

Fig. 128.1 Current, binge, and heavy alcohol use among persons aged 12 years or older according to the National Survey on Drug Use and Health (2016). Binge drinking is defined as males consuming five or more drinks on an occasion and for females consuming four or more drinks on an occasion. Heavy alcohol use is defined as binge drinking on 5 or more days in the past 30 days. (Substance Abuse and Mental Health Services Administration. [2017]. Key substance use and mental health indicators in the United States: Results from the 2016 National Survey on Drug Use and Health [HHS Publication No. SMA 17-5044, NSDUH Series H-52]. Rockville, MD: Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration.)

Fig. 128.2 Past month binge and heavy alcohol use among persons aged 12 years or older, by age group, according to the National Survey on Drug Use and Health (2016). Binge drinking is defined as males consuming five or more drinks on an occasion and for females consuming four or more drinks on an occasion. Heavy alcohol use is defined as having had five or more drinks on the same occasion on each of 5 or more days in the previous 30 days. (Substance Abuse and Mental Health Services Administration. [2017]. Key substance use and mental health indicators in the United States: Results from the 2016 National Survey on Drug Use and Health [HHS Publication No. SMA 17-5044, NSDUH Series H-52]. Rockville, MD: Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration. Retrieved from <https://www.samhsa.gov/data>.)

Withdrawal Syndrome (Convulsions)

Alcohol withdrawal occurs in three stages. The signs of minor withdrawal usually appear 6 to 12 hours after the discontinuation of ethanol and are caused by central adrenergic hyperexcitability; they consist of anxiety, tremors, sweating, tachycardia, diarrhea, and insomnia. Additional evidence of autonomic nervous system hyperactivity often appears within 12 to 24 hours and includes increased startle response, nightmares, and visual hallucinations. Alcohol withdrawal seizures (so-called *rum fits*) are generalized clonic-tonic convulsions that occur

TABLE 128.2 Medical Complications of Alcohol Use

Neurologic	Electrolyte or Nutritional
Encephalopathy (Wernicke, with oculomotor dysfunction; gait ataxia)	Thiamine deficiency
Marchiafava-Bignami disease (demyelination of corpus callosum)	Niacin deficiency
Central pontine myelinolysis	Folate deficiency
Cognitive dysfunction	Vitamin B ₁₂ deficiency
Amnesia (i.e., Korsakoff syndrome)	Vitamin D deficiency
Dementia	Zinc deficiency
Cerebellar degeneration	Hypokalemia
Peripheral neuropathy	Hypomagnesaemia
Seizures	Hypocalcaemia
	Ketoacidosis
	Hypoglycemia
	Hypertriglyceridemia
	Malnutrition
Hematologic	Endocrine

Gastrointestinal bleeding	Amenorrhea
Pancreatitis	Infertility
Hepatitis	
Cirrhosis	
Splenomegaly	
Cardiovascular	Miscellaneous
Hypertension	Spontaneous abortion
Cardiomyopathy	Fetal alcohol syndrome
Stroke	Increased risk of cancer (breast, oropharyngeal, esophageal, hepatocellular, colorectal)
Arrhythmias (especially atrial fibrillation)	Accidents, trauma, violence, suicide

12 to 48 hours after the discontinuation of ethanol and are estimated to occur in 2% to 5% of alcoholics.

Delirium Tremens

Delirium tremens (DTs) is characterized by delirium (a confused state with varying levels of consciousness), hallucinations, disorientation, agitation, tremor (caused by marked autonomic nervous system over activity), tachycardia, hypertension, fever, and diaphoresis. It occurs in approximately 5% of alcoholics who discontinue or decrease their alcohol use, most often in chronic heavy users with underlying neurologic damage. If unrecognized and untreated, the in-hospital mortality rate of DTs approaches 25%; with early recognition and treatment the mortality is only 1% to 4%.

TREATMENT

Intervention strategies in alcohol users are designed to modify the individual's attitudes, knowledge, and skills to prevent alcohol misuse. In the outpatient setting, increased frequency of contact between the primary care physician and the patient increases the likelihood of

TABLE 128.3 CAGE: An Alcoholism Screening Test

1. Have you ever felt you should *cut down* on your drinking?
2. Have people *annoyed* you by criticizing your drinking?
3. Have you felt *guilty* about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (i.e., as an *eye-opener*)?

detection, intervention, and prevention of heavy alcohol consumption. All scheduled office visits should include alcohol screening, assessment, and brief attempts at intervention (one or more discussions lasting 10 to 15 minutes), if indicated, as studies show that this approach decreases alcohol intake and its consequences. Behavioral or pharmacologic treatment should be considered because two thirds of treated patients have a reduction in the amount of consumption (by more than 50%) as well as the consequences of consumption (e.g., alcohol-related injury or job loss). A year after treatment, one third of patients are either abstinent or drink moderately without consequences.

Screening and Intervention Strategies

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) provides several web-based guidelines for alcohol screening during the routine health examination (www.niaaa.nih.gov). A four-step plan exists with which physicians can (1) screen patients for alcohol use, (2) assess for the presence of alcohol-related problems, (3) provide advice concerning appropriate action, and (4) monitor the patient's progress. For the current drinker, the physician should inquire about the number of drinks consumed per day, number of days per week on which ethanol is consumed, and total number of drinks consumed per month. Alcohol consumption that exceeds 14 drinks per week or three drinks per day should trigger an in-depth assessment of alcohol-related problems. The physician should ascertain if the individual is at risk for alcohol-related problems, has an existing problem, or may be alcohol-dependent. Difficulties with work-related, interpersonal, or family relationships and/or evidence of high-risk behavior despite self-reported low-risk consumption indicate that the individual is at risk for alcohol use disorder.

The CAGE questionnaire (each of the letters in the acronym refers to one of the questions) (Table 128.3) is a useful screening tool for identifying *alcohol-dependent individuals*. A positive response to two or more of the four questions is indicative of a potential alcohol problem and should prompt questions regarding the quantity and frequency of consumption.

The 2013 US Preventive Services Task Force (USPSTF) recommendation identified one-item screeners such as the Single Item Alcohol Screening Questionnaire (SASQ) and the Alcohol Use Disorders Identification Test (AUDIT) as having the best accuracy to screen for any level of *unhealthy alcohol use* among adults. The SASQ asks, "How many times in the past year have you had 5 [for men]/4 [for women] or more drinks in a day?" where one or more occasions in the previous year constitutes a positive screen. AUDIT (Table 128.4) is the most widely validated instrument for use in primary care settings. Utilizing 10 items and taking 2 to 3 minutes to complete, it is better suited to settings where visit times are longer or when it can be completed and scored before a clinician visit. Evidence supports the use of brief (1-item) instruments as initial screeners, where high sensitivity and lower specificity would be desirable, followed by a longer instrument, such as AUDIT, with greater specificity.

TABLE 128.4 Alcohol Use Disorders Identification Test (AUDIT)

Questions	No. Items/Time to Administer	Scoring Notes
1. How often do you have a drink containing alcohol? 0. Never 1. Monthly or less 2. Two to four times a month 3. Two so three times a week 4. Four or more times a week 2. How many drinks containing alcohol do you have on a typical day when you are drinking? 0. 1 or 2 1. 3 or 4 2. 5 or 6 3. 7 to 9 4. 10 or more 3. How often do you have six ^a or more drinks on one occasion? 0. Never 1. Less than monthly 2. Monthly 3. Weekly 4. Daily or almost daily 4. How often during the last year have you found that you were not able to stop drinking once you had started? (<i>same options as #3</i>) 5. How often during the last year have you failed to do what was normally expected from you because of drinking? (<i>same options as #3</i>) 6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session? (<i>same options as #3</i>) 7. How often during the last year have you had a feeling of guilt or remorse after drinking? (<i>same options as #3</i>) 8. How often during the last year have you been unable to remember what happened the night before because you have been drinking? (<i>same options as #3</i>) 9. Have you or someone else been injured as a result of your drinking? 0. No 1. Yes, but not in the last year 2. Yes, during the last year 10. Has a relative or friend or a doctor or other health worker been concerned about your drinking or suggested you cut down? (<i>same options as #9</i>)	10 items 2–5 min	Scoring: ≥ 8 considered a positive screen for hazardous or harmful drinking. In general: Scores between 8 and 15 are most appropriate for simple advice focused on the reduction of hazardous drinking Scores between 16 and 19 suggest brief counseling and continued monitoring Scores of 20 and above clearly warrant further diagnostic evaluation for alcohol dependence

^aThe US version asks about five or more drinks, reflecting standard drink sizes in the United States.

On physical examination, evidence of alcoholic liver disease may be exhibited as jaundice, hepatomegaly, palmar erythema, male gynecomastia, spider angiomas, and ascites. The serum γ -glutamyltransferase concentration typically is elevated in individuals who drink excessively.

Low-Risk Drinking

A standard drink contains 12 g of alcohol, an amount similar to that found in one 12-oz bottle of beer or wine cooler, one 5-oz glass of wine, or 1.5 oz. of distilled (e.g., 80 proof) spirits. In men older than age 64 years and in women older than 21 years, the limit for moderate drinking is one drink per day. For younger men, moderate drinking is defined as no more than two drinks per day. For the same amount of ingested ethanol, women and older adult men achieve a higher blood concentration of ethanol than younger men owing to their smaller volume of body water. A reasonable blood alcohol level should not exceed 50 mg/dL.

A blood-alcohol level as low as 80 mg/dL may exceed the legal definition for driving under the influence (DUI) or driving while intoxicated (DWI). In national surveys, the strategy of the *designated driver*

appears to be effective at preventing unsafe driving by drinkers at risk for DWI. Complete abstinence is recommended for people with a history of alcohol use disorder, other serious medical conditions (e.g., liver disease), and pregnancy.

Nonpharmacologic Therapies

Psychosocial interventions efficacious in treating heavy alcohol use or alcohol use disorder include brief interventions, motivational enhancement therapy, cognitive-behavioral therapy, behavioral approaches, family therapies, and 12-step programs (the recovering alcoholic moves through 12 specific steps aided by his or her attendance at regular meetings within a self-help peer group). Although these therapies provide similar efficacy, brief interventions—which are commonly 15 to 20 minutes long—are most practical in outpatient medical settings. When more intensive psychosocial therapy is needed, it may be most feasible for a therapist trained in the specific method to provide it in concert with a medical practitioner who can prescribe an alcohol treatment medication.

Considerations for Drug Interventions

Three medications are approved by the US Food and Drug Administration (FDA) to treat alcohol use disorders: disulfiram, naltrexone (oral and long-acting injectable formulations), and acamprosate. Medications are prescribed to less than 9% of patients who are likely to benefit from them, despite their inclusion in clinical practice guidelines as first-line treatments for moderate to severe alcohol use disorder. Medications should be administered in conjunction with psychosocial interventions to enhance treatment adherence.

Disulfiram (Antabuse) inhibits aldehyde dehydrogenase (i.e., the enzyme that converts acetaldehyde to acetate), resulting in a 5- to 10-fold increase in serum acetaldehyde concentrations when alcohol is consumed. This produces uncomfortable symptoms (e.g., facial flushing, tachycardia, nausea, vomiting, and headache), which act to deter alcohol consumption. Because of low medication compliance and limited efficacy, disulfiram is rarely prescribed.

Naltrexone is an opioid receptor antagonist. In clinical trials, a combination of naltrexone and psychosocial intervention reduced the number of drinking days, induced a longer period of abstinence from ethanol, and decreased the relapse rate in heavy drinkers when compared with psychosocial intervention alone: it reduced the likelihood of a return to any drinking by 5% and binge-drinking risk by 10%. Naltrexone is administered orally in a dose of 50 mg daily for 12 weeks, although larger doses (i.e., 100 to 150 mg daily) and a longer duration of administration may improve its success in preventing relapse. In 2006, the FDA approved a once-a-month injectable form of naltrexone (380 mg intramuscular) for the treatment of alcohol use disorders; this form appears to be more effective than the pill form at maintaining abstinence, since it eliminates the problem of medication compliance.

Naltrexone can be initiated while the individual is still drinking, thereby permitting treatment to be provided in a community-based setting without the need for enforced abstinence or detoxification. Some recovering alcoholics develop somnolence, nausea or vomiting when naltrexone is initiated. Because hepatic toxicity may occur at high doses (≥ 300 mg), periodic testing of liver function is recommended. Naltrexone is contraindicated in subjects receiving opioids, given that opiate withdrawal is an unintended adverse effect of the drug.

Acamprosate (Campral), a structural analog of γ -amino butyric acid (GABA), decreases excitatory glutamatergic neurotransmission during alcohol withdrawal. The recommended dosage is 666 to 1000 mg 3 times daily, and its most common side effects are diarrhea and intestinal cramping. In placebo-controlled trials, acamprosate reduced relapse rates and increased abstinence from ethanol. In comparative trials, it did not appear to be as efficacious as naltrexone. Acamprosate should be used once abstinence is achieved; since it is not metabolized by the liver, it can be given safely to individuals with alcoholic liver disease.

The use of several other pharmacologic agents has been associated with a reduction in alcohol consumption, including ondansetron (a selective serotonin reuptake inhibitor), topiramate (an anticonvulsant), baclofen (a GABA agonist), sodium oxybate (the sodium salt of gamma-hydroxybutyrate), nalmefene (an opioid antagonist), and varenicline (a nicotinic acetylcholine-receptor and dopamine partial agonist), but none of these agents has been approved by the FDA for treatment of alcohol dependence.

Fetal Alcohol Spectrum Disorders

Alcohol freely crosses the placenta and is teratogenic. It is a leading preventable cause of birth defects with mental deficiency, with up to 1 in 100 children in the United States being born with fetal alcohol spectrum disorders (FASDs). The scope of disabilities and malformations varies and depends on the amount of alcohol consumed, the frequency

of exposure, the stage of fetal development when alcohol is present, maternal parity, nutrition, genetic susceptibility, and individual variation in maternal and fetal alcohol metabolism.

The term FASD is used to characterize the full range of prenatal alcohol damage, varying from mild to severe and encompassing a broad array of physical defects and cognitive, behavioral, and emotional deficits. It includes conditions such as fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBDs).

FAS, the most severe form of FASD, is characterized by (a) growth retardation (i.e., height or weight ≥ 10 th percentile); (b) neurodevelopmental abnormalities (i.e., microcephaly, hyperactivity, irritability, altered motor skills, learning disabilities, seizure disorders, and mental retardation); and (c) dysmorphic facial features (i.e., short palpebral fissures, smooth philtrum, and a thin upper lip). Children with typical dysmorphic facial features who lack the other features have partial FAS. Children with ARBDs have typical facies associated with FAS as well as anomalies in other organs (i.e., cardiac, renal, skeletal, auditory) but no growth retardation or neurodevelopmental abnormalities. Children with ARND exhibit behavioral or cognitive abnormalities in the absence of dysmorphic facial features.

Although the damage from prenatal exposure to alcohol cannot be reversed, children with FASDs benefit from early diagnosis and aggressive intervention with physical, occupational, speech and language, and educational therapies. Early recognition can also benefit the impaired mother, resulting in access to alcohol treatment and a better social situation for the entire family.

Although the recognition of FASD is important, its prevention is essential. Given that no safely established level of alcohol consumption in pregnancy exists, recommendations suggest that pregnant women maintain abstinence. In addition, women who are considering pregnancy or are already pregnant must be counseled about the effects of alcohol on the fetus.

Medical Management of Alcohol Withdrawal and Delirium Tremens

Patients admitted to a general medical hospital who have a history of heavy alcohol use have an approximately 2% to 7% chance of developing severe alcohol withdrawal syndrome (SAWS). Appropriate identification, prophylaxis, and treatment of withdrawal are essential in reducing morbidity and mortality associated with this disorder. Unfortunately, individual symptoms or signs do not effectively predict or exclude SAWS. The most effective method for predicting SAWS in acute care settings is use of a risk assessment tool that combines findings from a patient's history and clinical examination. The Prediction of Alcohol Withdrawal Severity Scale (Table 128.5) performs best for predicting the development of SAWS and requires an interview, examination (heart rate), and testing (blood alcohol).

For the patient with probable alcohol withdrawal, comorbid conditions that may coexist or mimic the symptoms of withdrawal (e.g., infection, trauma, hepatic encephalopathy, drug overdose, gastrointestinal bleeding, and metabolic derangements) should be excluded. Once this has been accomplished, the patient should be placed in a quiet and protective environment and should receive parenteral thiamine and multivitamins to decrease the risk of Wernicke encephalopathy or Korsakoff amnesic syndrome.

The Revised Clinical Institute for Withdrawal Assessment for Alcohol (CIWA-Ar) scale (available at https://umem.org/files/uploads/1104212257_CIWA-Ar.pdf), a measure of withdrawal severity, is useful in guiding symptom-triggered therapy in medically stable (i.e., non-ICU or postoperative) patients. Benzodiazepines are the only medications proved to ameliorate symptoms and to decrease the risk of

TABLE 128.5 The Prediction of Alcohol Withdrawal Severity (AW) Scale**Part A: Threshold Criteria (yes or no; no point):**

Have you consumed any amount of alcohol (i.e., been drinking) within the last 30 days? OR did the patient have a “+” BAL upon admission? IF the answer to either is YES, proceed with test:

Part B: Based on Patient Interview (1 point each):

1. Have you been intoxicated or drunk within the last 30 days?
2. Have you ever undergone alcohol use disorder rehabilitation treatment or treatment for alcoholism (i.e., inpatient or outpatient treatment programs or AA attendance)?
3. Have you ever experienced previous episodes of alcohol withdrawal, regardless of severity?
4. Have you ever experienced blackouts?
5. Have you ever experienced alcohol withdrawal seizures?
6. Have you ever experienced delirium tremens or DTs?
7. Have you combined alcohol with other “downers” like benzodiazepines or barbiturates during the last 90 days?
8. Have you combined alcohol with any other substance of abuse during the last 90 days?

Part C: Based on Clinical Evidence (1 point each):

1. Was the patient’s BAL on presentation ≥ 200 mg/dL?
2. Is there evidence of increased autonomic activity (i.e., HR > 120 /min, tremor, sweating, agitation, nausea)?

Maximum score = 10 points.

This instrument is intended as a **SCREENING TOOL**. The greater the number of positive findings, the higher the risk for the development of AWS.

A score of **>4 suggests HIGH RISK** for moderate to severe (complicated) AWS; prophylaxis and/or treatment may be indicated.

AA, Alcoholics Anonymous; AWS, alcohol withdrawal syndrome; BAL, blood alcohol level; DT, delirium tremens

Fig. 128.3 Numbers of past month prescription psychotherapeutic misusers among persons aged 12 years or older according to the National Survey on Drug Use and Health (2016). (Substance Abuse and Mental Health Services Administration. [2017]. Key substance use and mental health indicators in the United States: Results from the 2016 National Survey on Drug Use and Health [HHS Publication No. SMA 17-5044, NSDUH Series H-52]. Rockville, MD: Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration. Retrieved from <https://www.samhsa.gov/data>.)

seizures and DTs in patients with alcohol withdrawal. Typically, diazepam (5 to 20 mg), chlordiazepoxide (50 to 100 mg), or lorazepam (1 to 4 mg) is administered intravenously every 5 to 10 minutes until symptoms subside, with the last of these medications preferred in patients with advanced cirrhosis, considering that the liver minimally metabolizes it. All benzodiazepines appear to be similarly efficacious in treating alcohol withdrawal, but long-acting agents may be more effective in preventing withdrawal seizures and are associated with fewer rebound symptoms. Conversely, short-acting agents may offer a lower risk of oversedation. For the patient who is resistant to benzodiazepines, intravenous phenobarbital (130 to 260 mg administered intravenously every 15 minutes until symptoms are controlled) may be given. If the agitation is not controlled by phenobarbital, propofol (0.3 to 1.25 mcg/kg/hr for maximum 48-hour infusion) can be tried, with intubation strongly recommended.

PRESCRIPTION DRUG ABUSE

According to the 2016 National Survey on Drug Use and Health, an estimated 6.2 million Americans aged 12 years or older used prescription-type psychotherapeutic drugs nonmedically in the past month (Fig. 128.3). This estimate represents 2.3% of the population aged 12 years or older. More people in the United States now die of prescription drug overdose (i.e., the nonmedical use of prescription-type pain relievers, tranquilizers, stimulants, and sedatives) than accidental vehicular trauma.

Sedatives and Hypnotics

Benzodiazepines and barbiturates are the major sedative-hypnotic drugs among the commonly abused agents that are listed in Table 128.6. The patient with sedative-hypnotic intoxication may have slurred speech,

TABLE 128.6 Commonly Abused Drugs

Substance: Category and Name	Examples of Commercial and Street Names	How Administered ^a	Intoxication Effects and Potential Health Consequences
Cannabinoids			Euphoria, slowed thinking and reaction time, drowsiness, inattention, confusion, impaired balance and coordination, enhanced perception, cough, frequent respiratory infections, impaired memory and learning, increased heart rate, anxiety, panic attacks, tolerance, addiction
<i>Hashish</i> <i>Marijuana</i>	Boom, gangster, hash, hash oil, hemp Blunt, dope, ganja, grass, herb, joint, bud, Mary Jane, pot, reefer, green trees, smoke, sinsemilla, skunk, weed	Smoked, swallowed Smoked, swallowed	
<i>K2/Synthetic Marijuana</i>	Spice, K2, fake weed, Yucatan fire, skunk, moon rocks	Smoked, swallowed	Vomiting, agitation, hallucinations, hypertension, myocardial infarction, death, withdrawal and addiction symptoms
Sedative-Hypnotics (CNS Depressants)			Reduced pain and anxiety, feeling of well-being, lowered inhibitions, labile mood, impaired judgment, poor concentration, fatigue, confusion, impaired coordination and memory, respiratory depression and arrest, addiction
<i>Benzodiazepines (Other Than Flunitrazepam)</i>	Ativan, Halcion, Klonopin, Librium, Pro-Som, Restoril, Serax, Tranxene, Valium, Xanax, Doral; candy, downers, sleeping pills, tranks	Swallowed	Sedation, drowsiness, dizziness
<i>Flunitrazepam^b</i>	Rohypnol; forget-me pill, Mexican Valium, R2, roach, Roche, roofies, roofinol, rope, rophies, woolfies	Swallowed, snorted	Visual and gastrointestinal disturbances, urinary retention, amnesia while under drug's effects
<i>Sleep Medications</i>	Ambien (zolpidem), Sonata (zaleplon), Lunesta (eszopiclone)	Swallowed	Sedation, drowsiness, dizziness
<i>Barbiturates</i>	Amytal, Nembutal, phenobarbital, Seconal; barbs, reds, red birds, phennies, tooies, yellows, yellow jackets	Injected, swallowed	Sedation, drowsiness, depression, unusual excitement, fever, irritability, poor judgment, slurred speech, dizziness
<i>GHB^b</i>	γ -hydroxybutyrate; G, Georgia home boy, grievous bodily harm, liquid ecstasy, soap, scoop, goop, liquid X, geeb, Gina	Swallowed	Drowsiness, dizziness, nausea and vomiting, headache, loss of consciousness, hallucinations, peripheral vision loss, nystagmus, loss of reflexes, seizures, coma, death
Dissociative Drugs			Increased heart rate and blood pressure, impaired function, memory motor loss, numbness, nausea and vomiting
<i>PCP and Analogues</i>	Phencyclidine; angel dust, boat, hog, love boat, peace pill	Injected, smoked, swallowed	Possible decrease in blood pressure and heart rate, panic, aggression, violence, suicidal ideation; loss of appetite, depression
<i>Ketamine^a</i>	Ketalar SV; cat Valiums, K, Special K, vitamin K	Injected, smoked, snorted	At high doses: delirium, depression, respiratory depression and arrest, amnesia while under drug's effects
<i>Salvia Divinorum</i>	Salvia, shepherdess's herb, maria pastora, magic mint, sally-d	Chewed, smoked swallowed	
<i>Dextromethorphan (DXM)</i>	Found in some cough and cold medications: Robo, Robotripping, Triple C	Swallowed	Euphoria, slurred speech, confusion, dizziness, distorted visual perceptions
Hallucinogens			Altered states of perception and feeling, nausea, chronic mental disorders, persisting perception disorder (flashbacks)
<i>LSD</i>	Lysergic acid diethylamide; acid, blotter, cubes, microdot, yellow sunshines, blue heaven	Swallowed, absorbed through mouth tissues	LSD: flashbacks, hallucinogen persisting perception disorder LSD and mescaline: increased body temperature, heart rate, blood pressure, loss of appetite, sleeplessness, numbness, weakness, tremors, impulsive behavior, rapid shift in emotion
<i>Mescaline</i>	Buttons, cactus, mesc, peyote	Smoked, swallowed

TABLE 128.6 Commonly Abused Drugs—cont'd

Substance: Category and Name	Examples of Commercial and Street Names	How Administered ^a	Intoxication Effects and Potential Health Consequences
<i>Psilocybin</i>	Magic mushrooms, purple passion, shrooms, little smoke	Swallowed	Nervousness, paranoia, panic
Opioids and Morphine Derivatives			Pain relief, euphoria, drowsiness, respiratory depression and arrest, pinpoint pupils, nausea, confusion, constipation, sedation, unconsciousness, seizures, coma, tolerance, addiction
<i>Codeine</i>	Empirin with Codeine, Fiorinal with Codeine, Robitussin A-C, Tylenol with Codeine, OxyContin, Roxicodone, Vicodin; Captain Cody, Cody, schoolboy (with glutethimide: doors and fours, loads, pancakes and syrup)	Injected, swallowed	Less analgesia, sedation, and respiratory depression than morphine
<i>Other Opioid Pain Relievers</i> Oxycodone, hydrocodone bitartrate hydromorphone, oxymorphone, meperidine, propoxyphene	Tylox, OxyContin, Percodan, Percocet; Oxy, O.C., oxycotton, oxycet, hillbilly, heroin, percs Vicodin, Lortab, Lorcet; vike, Watson-387 Dilaudid; juice, smack, D, footballs, dillies Opana, Numorphan, Numorphone; biscuits, blue heaven, blues, Mrs. O, octagons, stop signs, O bomb Demerol, meperidine hydrochloride; demmies, pain killer Darvon, Darvocet	Chewed, injected, snorted, suppositories, swallowed	For oxycodone—muscle relaxation/twice as potent an analgesic as morphine; high abuse potential
<i>Fentanyl</i>	Actiq, Duragesic, Sublimaze; apache, China girl, China white, dance fever, friend, goodfella, jackpot, murder 8, TNT, Tango and Cash	Injected, smoked, snorted	80–100 times more potent an analgesic than morphine
<i>Heroin</i>	Diacetylmorphine; brown sugar, dope, H, horse, junk, skag, skunk, smack, white horse, China white, cheese (with OTC cold medicine and antihistamine)	Injected, smoked, snorted	Staggering gait
<i>Morphine</i>	Roxanol, Duramorph, M, Miss Emma, monkey, white stuff	Injected, smoked, swallowed	
<i>Opium</i>	Laudanum, paregoric; big O, black stuff, block, gum, hop	Smoked, swallowed	
Stimulants			Increased heart rate, blood pressure, body temperature; feelings of exhilaration, increased energy and mental alertness, tremors, rapid or irregular heart beat; reduced appetite, irritability, anxiety, panic, paranoia, violent behavior, psychosis, weight loss, insomnia, heart failure, seizures, coma
<i>Amphetamine</i>	Adderall, Biphentamine, Dexedrine; ben-nies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	Injected, smoked, snorted, swallowed	Rapid breathing, hallucinations, loss of coordination, restlessness, delirium, panic, impulsive behavior, Parkinson's disease, tolerance, addiction
<i>Methamphetamine</i>	Desoxyn; chalk, christina, cookies, cotton candy, crank, crystal, dunk, fire, gat, garbage, glass, go fast, go-go, ice, meth, no doze, no stop, pookie, rocket fuel, scooby snacks, speed, tina, trash, tweak, uppers, wash, white cross, yaba, yellow barn	Injected, smoked, snorted, swallowed	Memory loss, cardiac and neurologic damage, impaired memory and learning, tolerance, addiction, severe dental problems
<i>Methylphenidate</i>	Ritalin, Concerta; JIF, MPH, R-ball, Skippy, the smart drug, vitamin R	Injected, snorted, swallowed	Increase or decrease in blood pressure, psychotic episodes, digestive problems,

TABLE 128.6 Commonly Abused Drugs—cont'd

Substance: Category and Name	Examples of Commercial and Street Names	How Administered ^a	Intoxication Effects and Potential Health Consequences
<i>Cocaine</i>	Cocaine hydrochloride; blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow, toot	Injected, smoked, snorted	Chest pain, respiratory failure, nausea, abdominal pain, stroke, malnutrition, nasal damage from snorting
<i>MDMA^b (Methylenedioxymethamphetamine)</i>	Adam, clarity, ecstasy, Eve, lover's speed, peace, uppers, Molly	Injected, snorted, swallowed	Mild hallucinogenic effects, increased tactile sensitivity, empathic feelings, chills, sweating, nystagmus, ataxia, teeth clenching, muscle cramping, impaired memory and learning, lowered inhibition
<i>Synthetic Cathinone (Methylene-dioxypyrovalerone (MDPV), Mephedrone ("Drone," "Meph," or "Meow Meow"), and Methylone)</i>	Bath salts, drone, meph, meow meow, ivory wave, bloom, cloud nine, lunar wave, vanilla sky, white lightning, scarface	Injected, smoked, swallowed	Chest pain, paranoia, hallucinations, panic attacks, excited delirium, rhabdomyolysis, renal failure, high abuse and addiction potential
Other Compounds			
<i>Inhalants</i>	Solvents (paint thinners, gasoline), glues, gases (butane, propane, aerosol propellants, nitrous oxide), nitrites (isoamyl, isobutyl, cyclohexyl); laughing gas, poppers, snappers, whippets	Inhaled through nose or mouth	Stimulation, loss of inhibition, headache, nausea or vomiting, slurred speech, loss of motor coordination, wheezing, unconsciousness, cramps, weight loss, muscle weakness, depression, memory impairment, damage to cardiovascular and nervous systems, sudden death
<i>Anabolic Steroids</i>	Anadrol, Oxandrin, Durabolin, Depo-Testosterone, Equipoise; roids, juice, gym candy, pumpers	Injected, swallowed, topical	No intoxication effects. Hypertension, blood clotting and cholesterol changes, hostility and aggression, acne, prostate cancer, reduced sperm production, shrunken testicles, breast enlargement. In females: menstrual irregularities, beard development, and other masculine characteristics.

CNS, Central nervous system.

^aTaking drugs by injection can increase the risk of infection through needle contamination with staphylococci, human immunodeficiency virus, hepatitis, and other organisms.

^bAssociated with sexual assaults (e.g., date rape).

incoordination, unsteady gait, impaired attention or memory, stupor, and coma. The psychiatric manifestations of intoxication include inappropriate behavior, labile mood, and impaired judgment and social functioning. On physical examination, the person may have respiratory depression or even arrest, nystagmus, and hyperreflexia. Although benzodiazepines rarely depress respiration to the extent that barbiturates do (and, as a result, have a much wider margin of safety), the effects of these drugs are additive with those of other CNS depressants, such as ethanol. Chronic use may produce physical and psychological dependence and a potentially dangerous withdrawal syndrome.

Benzodiazepines potentiate the effects of GABA, which inhibits neurotransmission. They are available as short-acting agents (temazepam [Restoril] and triazolam [Halcion]), intermediate-acting agents (alprazolam [Xanax], chlordiazepoxide [Librium], estazolam [ProSom], lorazepam [Ativan], and oxazepam [Serax]), and long-acting agents (clorazepate [Tranxene], clonazepam [Klonopin], diazepam [Valium], flurazepam [Dalmane], halazepam [Paxipam], Prazepam [Centrax], and quazepam [Doral]). Flunitrazepam (Rohypnol, also known as *roach*, *rophies*, *circles*, *Mexican valium*, *forget me pill*, *wolfies*, or *rope*) is a popularly abused benzodiazepine that is not legally available in the United States but is often smuggled here from other countries. It has been implicated in cases of date rape and is known as a club drug because adolescents and young adults often use it at nightclubs and bars or during all-night dance parties called raves.

In persons with an acute benzodiazepine overdose, respiratory depression is the major danger. Flumazenil (Romazicon), a competitive antagonist of benzodiazepines, can be given intravenously for acute overdose. Although it reverses the sedative effects of benzodiazepines, flumazenil may not completely reverse respiratory depression, and it may cause seizures in patients with physical dependence or concurrent tricyclic antidepressant poisoning.

Benzodiazepine cessation may precipitate withdrawal symptoms, depending on the half-life of the specific agent, the duration of use, and the dose. Such withdrawal is characterized by intense anxiety, insomnia, irritability, perceptual changes, hypersensitivity to light and sound, psychosis, hallucinations, palpitations, hyperthermia, tachypnea, diarrhea, muscle spasms, tremors, and seizures. Withdrawal symptoms usually peak 2 to 3 days after the discontinuation of a short-acting agent and 5 to 10 days after discontinuation of a longer-acting one; however, panic attacks and nightmares may recur for months. In general, agents with shorter half-lives produce more intense withdrawal symptoms compared with agents with longer half-lives. Benzodiazepines should be discontinued gradually over a period of several weeks (e.g., 4 to 8 weeks) to prevent seizures and avoid severe withdrawal symptoms. Whether switching to a long-acting agent such as diazepam improves detoxification is unclear. Few evidence-based treatment recommendations for pharmacotherapy of benzodiazepine withdrawal are available but include antidepressant agents for depression and sleep problems,

as well as mood stabilizers, especially carbamazepine (200 mg twice per day), although empirical evidence for these approaches is limited. Propranolol can be given to decrease tachycardia, hypertension, and anxiety.

Barbiturates may be short acting (pentobarbital and secobarbital), intermediate acting (amobarbital, aprobarbital, and butobarbital), or long acting (mephobarbital and phenobarbital). The symptoms of acute intoxication with the withdrawal from barbiturates are similar to those of benzodiazepines. For acute barbiturate overdose, oral charcoal and alkalization of the urine (to a pH >7.5) with forced diuresis are effective in lowering the blood concentration. For patients with hemodynamic compromise refractory to aggressive supportive therapy, barbiturate elimination can be increased by hemodialysis or charcoal hemoperfusion. The effective treatment of withdrawal symptoms requires estimating the daily dose of the abused drug and substituting an equivalent phenobarbital dose to stabilize the patient, after which the dose of phenobarbital is tapered over 4 to 14 days, depending on the half-life of the abused drug. Benzodiazepines may also be used for detoxification, and propranolol and clonidine may help reduce symptoms.

Abuse of γ -hydroxybutyrate (GHB) has increased substantially over the last decade in the United States. This drug is abused for its sedative, euphoric, and bodybuilding effects. GHB is a metabolite of the neurotransmitter GABA, and it also influences the dopaminergic system. It potentiates the effects of endogenous or exogenous opiates. The ingestion of GHB results in immediate drowsiness and dizziness, with the feeling of a *high*. These effects can be potentiated by the concomitant use of alcohol or benzodiazepines. Similar to flunitrazepam and ketamine, GHB is a popular club drug, and it has been implicated in cases of date rape. Its street names include *G*, *liquid E*, *liquid X*, *fantasy*, *geeb*, *Georgia home boy*, *scoop*, and *grievous bodily harm*. Adverse effects that may occur within 15 to 60 minutes of its ingestion include headache, nausea, vomiting, hallucinations, loss of peripheral vision, nystagmus, hypoventilation, cardiac dysrhythmias, seizures, and coma. In rare instances, these adverse effects have led to death. The withdrawal from GHB becomes clinically apparent within 12 hours and may last up to 12 days.

Opioids

Opioids include the natural and semisynthetic alkaloid derivatives of opium as well as the purely synthetic drugs that mimic heroin. They bind to opioid receptors in the brain, spinal cord, and gastrointestinal tract; in addition, they act on several other CNS neurotransmitter systems, including dopamine, GABA, and glutamate, to produce analgesia, CNS depression, and euphoria. With continued opioid use, tolerance and physical dependence develop. As a result, the user must use larger amounts of the drug to obtain the desired effect, and withdrawal symptoms may occur if use is discontinued. Opioid misuse includes the misuse of prescription opioid pain relievers or the use of heroin. The commonly abused opioids include heroin, morphine, codeine, oxycodone (OxyContin, OxyIR, Oxecta, Roxicodone, or combination products, such as Percocet, Percodan, Tylox, Combunox), meperidine (Demerol), propoxyphene (Darvon), hydrocodone (Vicodin, Lortab, Lorcet), hydromorphone (Dilaudid), buprenorphine (Temgesic), and fentanyl (Sublimaze).

In 2016, there were 11.8 million past-year opioid misusers aged 12 or older in the United States, the vast majority of whom (97%) misused prescription pain relievers. The 2016 National Survey on Drug Use and Health reported that 53% of subjects who abused prescription pain relievers obtained them from friends or relatives (40% were given, 9% bought, and 4% stolen), and about one third (35%) indicated that they obtained pain relievers through prescription(s); only 6% were bought from a drug dealer.

Deaths from opioid overdoses have increased dramatically over the last decade. Opioids were involved in 47,600 overdose deaths in 2017

(68% of all drug overdose deaths), with synthetic opioids (other than methadone) the main driver of drug overdose deaths. Deaths involving synthetic opioids in the United States increased from roughly 3000 in 2013 to more than 30,000 in 2018. Synthetic opioids like fentanyl—which is 50 times more potent than heroin and 100 times more potent than morphine—are now involved in twice as many deaths as heroin.

Acute opioid overdose produces pulmonary congestion, with resultant cyanosis and respiratory distress, and changes in mental status that may progress to coma. Other manifestations include fever, pinpoint pupils, and seizures. Unsterile intravenous practices can lead to skin abscesses, cellulitis, thrombophlebitis, wound botulism, meningitis, rhabdomyolysis, endocarditis, hepatitis, or human immunodeficiency virus (HIV) infection. Neurologic complications from intravenous heroin use include transverse myelitis, inflammatory polyneuropathy, and peripheral nerve lesions.

For acute opioid overdose, the patient's respiratory status must be assessed and supported. Naloxone should be administered intravenously and repeated at 2- to 3-minute intervals, often in escalating doses; the patient should respond within minutes with increases in pupil size, respiratory rate, and level of alertness. If no response occurs, opioid overdose is excluded, and other causes of somnolence and respiratory depression must be considered. Naloxone should be titrated carefully, since it may precipitate acute withdrawal symptoms in opioid-dependent patients.

Withdrawal symptoms may appear as early as 6 to 10 hours after the last injection of heroin. Initially the individual often has feelings of drug craving, anxiety, restlessness, irritability, rhinorrhea, lacrimation, diaphoresis, and yawning; these signs are followed by dilated pupils, piloerection, anorexia, nausea, vomiting, diarrhea, abdominal cramps, bone pain, myalgia, tremors, muscle spasms, and, in rare cases, seizures. These symptoms and signs peak at 36 to 48 hours and then subside over 5 to 10 days, if untreated. A protracted abstinence syndrome characterized by bradycardia, hypotension, mild anxiety, sleep disturbance, and decreased responsiveness may occur for up to 5 months.

Treatment for opioid use disorder combines medication with behavioral health services, which is associated with a reduction in deaths from overdose, less opioid use and relapse, and prevention of infectious diseases. Several drugs that target the μ -opioid receptor can be used to manage opioid withdrawal: the full agonist methadone, the partial agonist buprenorphine, and the antagonist naltrexone.

Withdrawal from opioids can be managed with methadone, a long-acting synthetic agonist drug, as withdrawal symptoms of methadone develop more slowly and are less severe than those caused by heroin. Methadone is more highly regulated than the other opioid treatment drugs (i.e., classified as a schedule II substance in the United States) and is usually administered to patients via observed dosing in specialized clinics since it may be abused, diverted, or misused. Methadone can be given twice daily and tapered over 7 to 10 days. Methadone use, in both therapeutic doses and overdoses, has been associated with QTc interval prolongation and torsade de pointes, which, in some cases, has been fatal.

Buprenorphine can alleviate opioid withdrawal signs and symptoms, reduce craving, and block the subjective effects (e.g., so-called drug-liking) of other opioids. Accordingly, treatment with buprenorphine can be titrated to patients' withdrawal symptoms, yielding a well-tolerated transition to treatment. It is available in a daily mucosal formulation (which is also subject to diversion and misuse), as a subdermal implant administered every 6 months, or a monthly subcutaneously injected, extended-release formulation. It is also combined with naloxone in a formulation (Suboxone) developed to decrease the potential for abuse. This combination is available for use in two

different forms—under the tongue or in the cheek—and decreases withdrawal symptoms for about 24 hours.

Naltrexone, a long-acting opioid antagonist that blocks impulsive opioid use, is an option for maintenance treatment to prevent relapse. It can be given orally daily or via injectable depot and implantable formulations every 60 to 90 days. It should only be administered after the patient is thoroughly detoxified because it may precipitate withdrawal. Pharmacotherapy must be combined with psychotherapy and structured rehabilitation to achieve an optimal outcome.

Finally, clonidine reduces autonomic hyperactivity and is particularly effective if combined with a benzodiazepine.

Amphetamines

Amphetamines have been used therapeutically for weight reduction and treatment of attention-deficit disorder and narcolepsy. Similar to cocaine, they cause a release of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) from presynaptic neurons. In addition, however, they have neurotoxic effects on dopaminergic and serotonergic neurons. Their euphoric and reinforcing effects are mediated through dopamine and the mesolimbic system, whereas their cardiovascular effects are caused by the release of norepinephrine. Chronic use leads to neuronal degeneration in dopamine-rich areas of the brain, which may increase the risk for the eventual development of Parkinson's disease.

Amphetamines can be abused orally, intranasally, intravenously, or by smoking. The most frequently used drugs are dextroamphetamine (Dexedrine), methamphetamine (Desoxyn), and methylphenidate (Ritalin). Illicit use of amphetamines has increased substantially, in part because (a) they are easily and quickly synthesized from ephedrine or pseudoephedrine and (b) their psychotropic effects may persist for up to 24 hours. The anorexiant, phenmetrazine and phentermine, which are structurally and pharmacologically similar to amphetamine, also have been used illicitly.

Tolerance to the stimulant effects of amphetamines develops rapidly, and toxic effects can occur with higher doses. Acute amphetamine toxicity is characterized by excessive sympathomimetic effects, including tachycardia, hypertension, hyperthermia, cardiac tachyarrhythmia, tremors, seizures, and coma. The patient may experience irritability, hypervigilance, paranoia, stereotyped compulsive behavior, and tactile, visual, or auditory hallucinations. The clinical picture may simulate an acute schizophrenic psychosis. The symptoms of withdrawal are similar to those seen with cocaine (see discussion of cocaine), but the acute psychosis and paranoia are often pronounced.

The treatment of amphetamine abuse centers on a quiet environment, benzodiazepines for anxiety, and sodium nitroprusside for severe hypertension. Antipsychotics, such as haloperidol, can reduce the agitation and psychosis by blocking the effect of dopamine on the CNS receptor. Urine acidification with ammonium chloride accelerates amphetamine excretion.

ILLICIT DRUG ABUSE

Cocaine

Among individuals 12 years old or older in 2016, 1.9 million had used cocaine within the previous month, including 432,00 users of crack. Cocaine can be taken orally or intravenously; alternatively, because it is well absorbed through all mucous membranes, abusers may achieve a high blood concentration after intranasal, sublingual, vaginal, or rectal administration. Its freebase form (called *crack* because of the popping sound it makes when heated) is heat stable, and it can be smoked. Crack cocaine is considered to be the most potent and addictive form of the drug. Euphoria occurs within seconds after crack cocaine is

smoked, and is short lived. Compared with smoking crack cocaine or intravenous injection of the drug, mucosal administration results in a slower onset of action, a later peak effect, and a longer duration of action. The blood half-life is approximately 1 hour. The drug's major metabolite is benzoylecgonine, which can be detected in the urine for 2 to 3 days after a single dose.

An intense, pleasurable reaction lasting 20 to 30 minutes occurs after cocaine use, after which rebound depression, agitation, insomnia, and anorexia occur, which are then followed by fatigue, hypersomnolence, and hyperphagia (the *crash*). This crash usually lasts 9 to 12 hours but occasionally may last up to 4 days. Users often ingest the drug repetitively at relatively short intervals to recapture the euphoric state and to avoid the crash. On occasion, sedatives or alcohol are ingested concomitantly to reduce the intensity of anxiety and irritability associated with the crash. The combination of cocaine and intravenously administered heroin (so-called *speedball*, *snowball*, *blanco*, *boy-girl*, *Bombita*, *Belushi*, or *dynamite*) is often used so that the abuser can experience the cocaine-induced euphoria and then *float* down on the opiate. Unfortunately, this combination has been reported to cause sudden death. People who use cocaine in temporal proximity to the ingestion of ethanol produce the metabolite cocaethylene, which has also been implicated in cocaine-related deaths.

Cocaine blocks the presynaptic reuptake of norepinephrine and dopamine, producing an excess of these neurotransmitters at the site of the postsynaptic receptor. Thus, cocaine acts as a powerful sympathomimetic agent, resulting in tachycardia, hypertension, tachypnea, hyperthermia, agitation, pupillary dilation, peripheral vasoconstriction, and seizures. Cocaine causes potent vasoconstriction of cerebral arteries and, therefore, may result in a stroke. It is associated with myocardial ischemia and arrhythmias and, in rare cases, with myocardial infarction in young persons with normal or only minimally diseased coronary arteries. The principal mechanisms of ischemia and infarction are coronary arterial vasoconstriction, thrombosis, platelet aggregation, tissue plasminogen activator inhibition, increased myocardial oxygen demand, and accelerated atherosclerosis (Fig. 128.4).

For patients with cocaine-induced hypertension or tachycardia, labetalol and benzodiazepines are usually effective in lowering systemic arterial pressure and heart rate. Patients with acute cocaine-related myocardial infarction should receive aspirin, heparin, nitroglycerin, and, if indicated, reperfusion therapy (with a thrombolytic agent or primary coronary intervention). The use of β -adrenergic blockers should be avoided when possible, since ischemia may be worsened by unopposed α -adrenergically mediated coronary arterial vasoconstriction. Patients with a normal electrocardiogram or nonspecific changes can be managed safely with observation.

The immediate treatment of acute cocaine intoxication includes obtaining vascular and airway access, if needed, and careful electrocardiographic monitoring. Benzodiazepines can be given to control CNS agitation; haloperidol or risperidone can be used in the severely agitated patient. A supportive environment is needed, but detoxification is not required, given that few physical signs of true dependence are present.

Most chronic cocaine abusers have psychological dependence and an intense craving for cocaine. Personal and group therapies are important adjuncts to pharmacologic treatment, but relapse is common and is difficult to manage. Although no medication is FDA approved for treatment of cocaine addiction, disulfiram, modafinil, anticonvulsants (e.g., topiramate and tiagabine), serotonin reuptake inhibitors (e.g., citalopram), serotonin receptor antagonists (e.g., ondansetron), and GABA receptor agonists (e.g., baclofen) have shown some promise in promoting cocaine abstinence.

Fig. 128.4 The mechanisms by which cocaine may induce myocardial ischemia or infarction. Cocaine may cause increases in the determinants of myocardial oxygen demand when oxygen supply is limited (*top*), when intense vasoconstriction of the coronary arteries occurs (*middle*), or when accelerated atherosclerosis and thrombosis are present (*bottom*).

Cannabis

The cannabinoid drugs include marijuana (the dried flowering tops and stems of the hemp plant) and hashish (a resinous extract of the hemp plant). Marijuana is the most commonly used “illicit” drug in the United States, recognizing that it is now legalized for recreational use in many states and for medical indications in most states. In 2016, an estimated 24 million Americans had used it in the past month. Between 2007 and 2016, the rate of use increased from 5.8% to 8.9% of the U.S. population, and the number of users increased from 14.5 million to 24 million. This increase reflects the increase in marijuana use by adults aged 26 years or older and, to a lesser extent, the increase in marijuana use among young adults aged 18 to 25 years (Fig. 128.5). In 2018 about 1 in every 13 young adults (8%) aged 19 to 28 was a daily or near daily marijuana user.

Marijuana use disorder occurs when someone experiences clinically significant impairment caused by the recurrent use of marijuana, including health problems, persistent or increasing use, and failure to meet major responsibilities at work, school, or home. Approximately 4.0 million people aged 12 or older in 2016 had a marijuana use disorder in the past year, which represents 1.5% of persons aged 12 years or older.

Marijuana and hashish are among the drugs most commonly used by adolescents, with approximately one third (36%) of 12th graders admitting use at least once and 5.8% reporting that they are daily or nearly daily users. Most of their pharmacologic effects come from metabolites of δ -9-tetrahydrocannabinol, which bind to specific cannabinoid receptors located in the CNS, spinal cord, and peripheral

nervous system. The primary mode of use is smoking, with mood-altering and intoxicating effects noted within 3 minutes and peak effects in approximately 1 hour. However, vaping cannabis extracts and synthetic cannabinoids (“fake marijuana”) in electronic cigarette devices has become increasingly popular. The acute physiologic effects are dose-related and often include increased heart rate, conjunctival congestion, dry mouth, fine tremor, muscle weakness, and ataxia. Psychoactive effects include euphoria, enhanced perception of colors and sounds, drowsiness, inattentiveness, and inability to learn new facts. Tolerance and physical dependence occur, and chronic users may experience mild withdrawal symptoms of irritability, restlessness, anorexia, insomnia, or mild hyperthermia. Rarely, acute psychosis with panic reactions occurs. The treatment of withdrawal is supportive and includes reassurance; benzodiazepines may be used in severely agitated patients. Cannabinoids have been used as antiemetic agents in patients with cancer receiving chemotherapy, for weight stimulation (in patients with cancer or HIV infection), and in the treatment of glaucoma.

Severe pulmonary illnesses have been reported in hundreds of otherwise healthy young persons who have “vaped” cannabis extracts (i.e., tetrahydrocannabinol products) in e-cigarettes, with one third requiring mechanical ventilation and some experiencing death. Initial symptoms include shortness of breath, cough, chest pain fever, gastrointestinal issues (i.e., nausea, vomiting, diarrhea, and abdominal pain), and weight loss, which occurs days or weeks after vaping. Bilateral infiltrates are present on chest imaging. Although most patients (>80%) reported having used tetrahydrocannabinol products in e-cigarette

Fig. 128.5 Past-month marijuana use among persons aged 12 years or older, by age group according to the National Survey on Drug Use and Health (2016). (Substance Abuse and Mental Health Services Administration. [2017]. Key substance use and mental health indicators in the United States: Results from the 2016 National Survey on Drug Use and Health [HHS Publication No. SMA 17-5044, NSDUH Series H-52]. Rockville, MD: Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration. Retrieved from <https://www.samhsa.gov/data>.)

devices prior to the development of their severe pulmonary symptoms, a wide variety of products and devices have been reported. E-cigarette liquids and aerosols contain a variety of chemical constituents that may have adverse health effects, including propylene glycol, glycerin, hydrocarbons, nitrosamines, volatile organic chemicals, and toxic metals, flavoring compounds (i.e., diacetyl and 2,3-pentanedione), and THC-based oils and vitamin E acetate.

Synthetic marijuana is a psychoactive designer drug composed of a mixture of herbs, spices, or shredded plant material that is sprayed with synthetic chemicals that mimic the effects of cannabis when smoked or prepared as a tea. They have been sold widely in “head shops” as well as through the internet and are best known by the brand names K2 and Spice. Spice products are popular among young people; of the illicit drugs most used by high school seniors, they are second only to marijuana. Synthetic cannabis can precipitate acute psychosis or a worsening of previously stable psychotic disorders; they also may trigger a chronic (long-term) psychotic disorder among vulnerable individuals, such as those with a family history of mental illness. K2 ingestion has been associated with myocardial infarction and death. Regular users may experience withdrawal and addiction symptoms.

Hallucinogens and Dissociative Drugs

Hallucinogens (drugs that cause hallucinations) include lysergic acid diethylamide (LSD), mescaline, psilocybin, and ibogaine. *Dissociative drugs* distort perceptions of sight and sound and produce feelings of detachment (dissociation) without causing hallucinations. They include phencyclidine (PCP), ketamine, salvia, and dextromethorphan (a widely available cough suppressant).

LSD is the most potent of the hallucinogenic drugs. Although it is known to interact with serotonin receptors in the cerebral cortex and *locus ceruleus*, its precise psychoactive mechanism is unknown. Within 30 minutes of its oral ingestion, sympathomimetic effects appear,

including mydriasis, hyperthermia, tachycardia, elevated blood pressure, diaphoresis, dry mouth, increased alertness, tremors, and nausea. Within 2 hours, the psychoactive effects become apparent, with heightened perceptions (highly intensified colors, smells, sounds, and other sensations), body distortions, mood variations, and visual hallucinations. An acute panic reaction may occur, sometimes leading to self-injury or suicide. After approximately 12 hours, the syndrome begins to subside, but fatigue and tension may persist for another day. Flashbacks (brief recurrences of the hallucinations) may occur days or even weeks after the last dose but tend to disappear without treatment. Acute panic reactions are best treated in a supportive environment; benzodiazepines can be given to severely agitated patients.

PCP is a potent, addictive hallucinogen that produces a prompt stimulant effect similar to that of amphetamines, with feelings of euphoria, power, and invincibility. Patients may have hypertension, tachycardia, hyperthermia, bidirectional nystagmus, slurred speech, ataxia, hallucinations, extreme agitation, and rhabdomyolysis. With more severe reactions, patients may be brought to medical attention in a coma-like state, with open eyes and pupils that are partially dilated, a decreased pain response, brief periods of excitation, and muscle rigidity. On occasion, PCP users may have hypertensive urgency, seizures, and bizarre (often violent) behavior, which lead to suicide or extreme violence toward others. Tolerance and mild withdrawal symptoms have been seen in daily users, but the major problem is drug craving. Treatment entails a quiet environment, sedation with benzodiazepines, hydration, haloperidol for terrifying hallucinations, and suicide precautions. Continuous gastric suction and acidification of the urine with intravenous ammonium chloride or ascorbic acid may aid in the drug’s excretion, but acidification may increase the risk of renal failure if rhabdomyolysis is present.

Ketamine is a rapidly acting general anesthetic; unlike most anesthetics, it produces only mild respiratory depression and appears to stimulate the cardiovascular system. Adverse effects, including delirium

and hallucinations, limit its use as a general anesthetic in humans. Similar to PCP, ketamine is a dissociative anesthetic. In addition, it has both analgesic and amnestic properties and is associated with less confusion, irrationality, and violent behavior than PCP. Ketamine is one of the club drugs that have been implicated in date rape.

Inhalants

Of the 1.8 million people aged 12 years or older who used inhalants in the past year to get high, about 684,000 were adolescents aged 12 to 17. Because they are readily available, inhalants are often among the first drugs that adolescents use, with felt-tip pens/markers or magic markers the most common agents. The inhalants may be classified as (1) *organic solvents*, including toluene (airplane glue and spray paint), paint thinners, kerosene, gasoline, carbon tetrachloride, shoe polish, acetone (nail polish removers and Liquid Paper), xylene (permanent markers), and degreasers (dry cleaning fluids); (2) *gases*, such as butane, propane, aerosol propellants, and anesthetics (ether, chloroform, halothane, and nitrous oxide); and (3) *nitrites*, such as cyclohexyl nitrite, amyl nitrite, and butyl nitrite (room deodorizer). These substances are most often inhaled by children or young adolescents, after which they produce dizziness and intoxication within minutes. Prolonged exposure or daily use may lead to hearing loss, bone marrow depression, cardiac arrhythmias, cerebral degeneration, peripheral neuropathies, and damage to the liver, kidneys, or lungs. A characteristic “glue sniffer’s rash” around the nose and mouth is sometimes seen after prolonged use. In rare instances, death may occur, most likely from hypoxemia, cardiac arrhythmias, pneumonia, or aspiration of vomit while unconscious. Detoxification is rarely required for the patient who has abused these substances, but psychiatric treatment may be needed to prevent relapse.

Designer Drugs

The term *designer drug* refers to illicit synthetic drugs, many of which have increased potency in comparison with their parent compounds. The most common designer drugs include analogs of fentanyl, meperidine, piperazine, and methamphetamines. Several fentanyl derivatives, initially sufentanil, alfentanil, remifentanil, carfentanil and, more recently, acetylfentanyl, 6-butyrfentanyl, 4-MeO-butyrfentanyl, isobutyrylfentanyl, furanylfentanyl, α -methylfentanyl (China white), 3-methylfentanyl or TMF, p-methylfentanyl, methylacetylfentanyl, acrylfentanyl, 2-fluorofentanyl, fluoroacetylfentanyl, ocfentantanyl are illegally manufactured. These derivatives do not have recognized medical uses, are often not detected by routine drug testing, and have worsened the opioid crisis and number of drug-related deaths. Because these drugs are approximately 1000 times as potent as heroin, it is not surprising that fatal overdoses from respiratory depression have been reported.

The major meperidine derivatives are 1-methyl-4-phenyl-4-propionoxypiperidine (MPPP) and 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP), each of which produces euphoria similar to that caused by heroin. In some users, MPTP causes neuronal degeneration in the substantia nigra, which produces an irreversible form of Parkinson’s disease.

Piperazines, a new class of designer drugs of abuse, are commonly sold as party pills in the form of tablets, capsules, or powders on the drug black market and in so-called head shops or over the internet under the names of Frenzy, Bliss, Charge, Herbal ecstasy, A2, Legal X, and Legal E. 1-Benzylpiperazine (BZP) is the most prevalent of these compounds. Aside from BZP and 1-(3,4-methylenedioxybenzyl) piperazine (MDBP), the phenylpiperazine derivatives 1-(3-trifluoromethylphenyl) piperazine (TFMPP), 1-(3-chloro phenyl) piperazine (mCPP), and 1-(4-methoxyphenyl)

piperazine (MeOPP) are often abused. Because piperazines and amphetamines cause similar pharmacologic symptoms, piperazine poisoning can easily be wrongly diagnosed as amphetamine poisoning. Furthermore, piperazines are not detected by routinely used immunochemical screening procedures for drugs of abuse, but they require an appropriate toxicologic analysis (e.g., by gas chromatography-mass spectrometry). The methylenedioxy synthetic derivatives of amphetamine and methamphetamine are generally referred to as *ecstasy* and include 3, 4-methylenedioxy methamphetamine (MDMA, also known as *Adam*); 3, 4-methylenedioxy-ethylamphetamine (MDEA, also known as *Eve*); and N-methyl-1-(3, 4-methylenedioxyphenyl)-2-butanamine (MBDB, also known as *Methyl-J* or *Eden*). These drugs have CNS stimulant and hallucinogenic properties. They produce elevated mood and increased self-esteem and may cause acute panic, anxiety, paranoia, hallucinations, tachycardia, nystagmus, ataxia, and tremor. Deaths in some users have been attributed to cardiac arrhythmias, hyperthermia with seizures, and intracranial hemorrhage.

PROSPECTUS FOR THE FUTURE

Immunotherapy (i.e., vaccine development) has emerged as a promising approach to treat abuse of drugs like methamphetamine, heroin, and cocaine. By sequestering the drugs in the periphery without allowing the drug to cross the blood-brain barrier, the toxic and rewarding effects of the drugs are reduced. A novel pharmacokinetic approach to the treatment of drug toxicity involves the development of compounds that can be administered safely to humans and that accelerate the metabolism of the drug to inactive components. For example, catalytic antibodies have been developed to accelerate cocaine metabolism and are administered parentally. In experimental animals, mutations of human butyrylcholinesterase (one of the enzymes responsible for the metabolism of cocaine) accelerate cocaine metabolism and antagonize cocaine’s behavioral and toxic effects.

Coronavirus Disease 2019 (COVID-19)

Edward J. Wing

The Coronavirus Disease 2019 (COVID-19) pandemic occurred after the initial deadline for this book had passed, and as a result I have written this appendix to reflect our knowledge of COVID-19 as of October 2020. The COVID-19 pandemic burst on the world as a totally new viral respiratory infection at the end of 2019 and the beginning of 2020. Initially the virology, epidemiology, transmission, diagnosis, clinical aspects, treatment, and prevention were largely unknown. Since then the amount of scientific focus and effort on all aspects of the disease from its molecular virology to clinical understanding to vaccine and drug development has been extraordinary.

While we know much more now about the infection than initially, our knowledge and hence this appendix is still largely incomplete. The ability to recognize, diagnose, care for our patients, and prevent this virus will undoubtedly change and evolve over time. Therefore, all physicians and health care workers need to continue to update their knowledge of COVID-19 to become long-term learners concerning all aspects of the infection.

COVID-19 PANDEMIC

Infectious pandemics, usually associated with animal–human contact, have afflicted mankind for millennia. Although some infections such as malaria have probably infected primates for millions of years, most pandemic infections have occurred since the beginning of agriculture. Pandemics such as the bubonic plague, which killed from one third to one half of the population of Europe and devastated other parts of the world, and the 1918 to 1919 influenza H1N1 pandemic that killed 675,000 people in the United States and at least 50 million people worldwide, have been catastrophic. More recent pandemics have included HIV, cholera, Zika virus and other influenza strains (1957, H2N2; 1968, H3N2; 2009, H1N1pdm09). The majority of recent pandemics in this century have been due to viral infections in which animals have been either the primary or intermediate host or the vectors of the diseases. RNA viruses such as the influenza and coronaviruses that have inherent genetic instability have been particularly prominent.

Coronaviruses have been known to have natural animal reservoirs, particularly in bat populations, and to cause mild, seasonal upper respiratory disease. Four human coronaviruses—OC43, 229E, HKU1 and NL63 viral strains—have been shown to have a predilection for children under the age of 5, to cause respiratory illness, and to be transmitted similarly to influenza virus. In 2002 to 2003, a new coronavirus, SARS-CoV, derived from bat strains, was identified in China. It caused severe respiratory infection infecting more than 8000 people in 29 countries with a mortality of approximately 10%. Because of limited transmissibility, the pandemic was controlled and then eliminated with strict public health measures. In 2012, a second coronavirus, Middle East respiratory syndrome (MERS-CoV), was first recognized in Saudi Arabia and subsequently in other Middle Eastern countries. Evidence indicates that its source is camels and that close contact with

these animals is a risk for contracting the disease. Gastrointestinal and pulmonary symptoms occur. To date there have been approximately 2500 cases with a mortality rate of 34%.

In early December 2019, cases of pneumonia of unknown cause were identified in the city of Wuhan, capital city of Hubei province, China. Many of the initial cases had worked in or had close contact with wet markets that sell fresh meat, fish, and other perishable produce. The outbreak increased during December, and on December 31 the WHO was informed of an outbreak of a new cause of pneumonia. With remarkable speed, the cause was identified as a new coronavirus and the gene sequence reported from China and the WHO on January 9, 2020. The virus was named SARS-CoV-2, and the infection is referred to as COVID-19. The epidemic continued to increase in Wuhan during January 2020 and peaked in late January and early February. The high population density in Wuhan, population movements, and the lack of clarity regarding human-to-human transmission drove the epidemic. Severe overcrowding of medical facilities occurred, prompting draconian public health measures including the imposition of a *cordon sanitaire* that prevented movement in or out of Wuhan, universal and compulsory home restriction with drastic penalties for violations, suspension of public transportation, closure of entertainment venues, closure of the implicated wet markets, and compulsory mask wearing. Subsequently, the number of new cases decreased steadily so that few cases were reported after March 1 in Wuhan although cases continued to be reported in other areas of China including Beijing. The total number of confirmed cases in Mainland China as of February 11 was reported as over 72,000 although this may represent a low estimate. The overall fatality rate was reported as 2.3%, but it was soon understood that mortality rate varies based on age group, testing availability, and other factors. Vigorous public health measures as described appear to have been effective in at least limiting the number of cases in China.

Cases of COVID-19 were reported outside of China as early as January 13 in persons who had traveled from Wuhan. The first case in the United States occurred on January 19, 2020, in Snohomish County, Washington, in an individual who had recently returned from visiting family in Wuhan. The patient had gastrointestinal and respiratory symptoms with fever that persisted for 8 days, requiring treatment with oxygen and remdesivir, an experimental antiviral agent. The patient recovered without incidence. Notably, future studies demonstrated that the virus circulated on both coasts for many weeks before it was recognized.

On January 30 with cases in Asia including Japan, South Korea, Vietnam, and Singapore; in Europe including France; and in the United States, the WHO declared a global emergency. Cases were reported from Africa (first in Egypt) but remained relatively low. By March the number of cases in Europe exploded, with particularly devastating effects in Italy, Spain, France, and the United Kingdom, and the WHO labeled COVID-19 a pandemic. Health care systems were overwhelmed in northern Italy as well as other areas, and mortality

was particularly high among the elderly. By June 29 COVID-19 had occurred in over 200 countries with 10 million cases and over 500,000 confirmed deaths. By the fall of 2020 it was estimated that more than 30 million cases of COVID-19, with more than 1 million deaths, had occurred worldwide.

By the end of April 2020, the number of cases in the Americas, primarily the United States, had skyrocketed, reaching over 1 million cases with 58,000 deaths. As an early example in the United States, an outbreak of COVID-19 was identified in February 2020 in a long-term care skilled nursing facility in King County, Washington State. In the facility, 81 residents (median age 81), 48 health care workers (median age 42.5 years), and 14 visitors (median age 42.5 years) were infected. Twenty-two of the 81 residents (27%), 0 of the 48 (0%) health care workers, and 1 of the 14 visitors (7.1%) died. In addition to age and residence in a nursing home, residents had a high rate of chronic underlying conditions, including cardiovascular disease (including hypertension), renal disease, diabetes mellitus/obesity, and pulmonary disease.

By March, the epicenter in the United States was New York City and the surrounding counties where the number of cases exploded, overwhelming some medical centers and devastating nursing homes and their residents where the mortality was the greatest. By May widespread outbreaks were noted in Mid-Atlantic and New England states, Louisiana, Florida, and in West Coast states. The number of cases fell in May in the United States, most likely due to restrictive measures including school and business closings, restrictions on public events, quarantine regulations, and wearing masks. The incidence of COVID-19 began to rise again in June with outbreaks in states such as Florida and Arizona, perhaps due to relaxation of earlier restrictive public health measures. Unfortunately, in late August and September the number of deaths continued at greater than 1000/day and the number of deaths directly associated with COVID-19 in the United States reached 200,000. In the fall, with reopening schools, particularly colleges and universities, and relaxation of restrictions on businesses and entertainment venues such as restaurants and bars, the number of new cases continued to rise as did the rates of hospitalizations. Early data indicate that the age of persons infected has decreased and the severity and mortality is lower. The rise in rates among those 18 to 24 years old was particularly striking. In addition, the disproportionate impact of the pandemic on the Black and Latinx communities became apparent. As of October 15, 2020, 216,035 deaths were reported in the United States, although excess deaths possibly related to the effects of COVID-19 have been estimated to be higher.

Finally, the 2020 to 2021 influenza season will intersect with the COVID-19 pandemic in the United States this winter and spring with unknown severity. The effects of COVID-19 public health measures, vaccination rates for influenza, and the already devastating effects of COVID-19 on vulnerable populations will all influence the morbidity and mortality of the influenza season.

VIROLOGY

The COVID-19 virus is an enveloped single-stranded RNA virus with surface spike proteins, like other coronaviruses, that give the group its distinctive contour under electron microscope, hence its name “coronavirus” (“corona” means crown). COVID-19 has 79% similarity to SARS-CoV and 50% similarity to MERS-CoV based on genetic analysis. Bats are believed to be the original source of COVID-19 with perhaps an intermediate host such as the pangolin, sometimes called the spiny anteater, which is regarded as a delicacy in parts of China and sold in wet markets. Genetic mutations presumably allowed the virus to cross species and cause disease. However, the origins of the virus are not completely understood at this point.

The 180-kDa spike (S) protein binds to the peptidase angiotensin-converting enzyme 2 receptor (ACE2) on cell surfaces and mediates viral and cell membrane fusion for entry into cells. Membrane fusion also requires the interaction of other proteases, particularly transmembrane protease serine 2 (TMPRSS2), on cell surfaces. The presence of ACE2 determines cell tropism of COVID-19 and is found on epithelial cells of both the upper and lower respiratory tract. ACE2 also has a wide distribution in other tissues including vascular endothelial cells, the gastrointestinal tract, and kidney. SARS-CoV-2 virus enters cells by endocytosis, uses the cells’ own machinery to reproduce, and then is released to infect other cells. Nasal epithelial cells are infected, which in early infection may result in initial upper respiratory symptoms and anosmia. Bronchial, alveolar, and endovascular epithelial cells are also infected early, causing an inflammatory response consisting of neutrophils, T lymphocytes, macrophages and the release of cytokines including TNF- α , and IL-6. As the infection and inflammation progresses in the lungs there is interstitial thickening, pulmonary edema, activation of the coagulation pathway, and lymphocyte depletion. Further inflammation can result in fibrosis with marked compromise of pulmonary function.

PATHOLOGY

Autopsy findings demonstrate high SARS-CoV-19 titers particularly in the lung, but also in blood, liver, kidney, brain, and heart. In individuals who died of COVID-19, autopsy shows diffuse alveolar damage in all lobes but with more pronounced findings in the lower lobes. During the early phase, signs of acute alveolar damage include edema, hyaline membrane formation, and thickened alveolar septa with perivascular lymphocytic infiltration. There is severe endothelial injury associated with disrupted cell membranes and the presence of virus. Pulmonary vessels including alveolar capillaries show widespread microthrombi and vascular angiogenesis, both of which distinguish it from the pathology of severe influenza infection. In later stages there is diffuse alveolar damage, fibroblastic proliferation leading to fibrosis, pneumocyte hyperplasia and interstitial thickening, and collapsed alveoli. In some areas of diffuse alveolar damage, metaplasia or widespread fibrosis is observed.

Other findings have included bronchopneumonia; lymphocytic myocarditis and epicarditis; periportal lymphocytic infiltration with hepatic congestion and steatosis, hepatic cell necrosis, and central vein thrombosis; acute tubular injury; and thrombotic features in multiple organs including lung, heart, and kidney. Also noted are focal pancreatitis, adrenocortical hyperplasia, and lymphocyte depletion in spleen and lymph nodes. In the brain, extensive inflammation has been noted in the olfactory bulbs and medulla oblongata. It was recognized early on that severe COVID-19 could result in activation of coagulation and consumption of clotting factors resulting in diffuse intravascular coagulation. Increased coagulation can result in deep venous thrombosis and unsuspected pulmonary embolism, myocardial infarction, stroke, and vascular compromise in other organs. Thrombosis of small and mid-sized pulmonary arteries with associated infarction is found in a high percentage of cases. In addition, neutrophilic plugs have been observed composed of neutrophil extracellular traps (NETS). NETS are composed of extracellular strands of DNA from neutrophils that trap pathogens. In an autopsy series NETS have been observed with platelets, which may induce thrombus formation.

HOST DEFENSES

Host defenses against coronaviruses consist of both innate and specific immunity, but the specific mechanisms and their relative importance

have yet to be clarified. Sites of infection, particularly the lung with endothelial damage, attract immune cells including T and B lymphocytes, macrophages, and neutrophils. The immune response includes release of cytokines and inflammatory molecules including interleukins 1 and 6, interferons, TNF- α as well as antibody production of IgM and IgG, and activation of the coagulation system with increases in D-dimer and micro- and macro-thrombosis. Inflammatory markers include elevated erythrocyte sedimentation rate, C-reactive protein, ferritin, and lactic dehydrogenase. A characteristic of the inflammatory process is the destruction and apoptosis of both CD4 and CD8 T lymphocytes with resulting lymphopenia. Experimental data suggest that neutralizing antibodies directed towards the S protein afford protection after infection; thus, vaccine development has targeted the response against this protein. Recent data suggest that the specific immune response to SARS-CoV-2 consists of CD4, CD8, and antibody in a coordinated response. Lack of such a response and decreased number of T cells occur in persons over 65 and may account for greater susceptibility to the virus. It is not clear, however, whether infection itself provides long-lasting immunity, whether the presence of antibody after infection protects, whether antibody persists after infections, or what the relative importance of T-cell immunity is.

TRANSMISSION

Transmission of COVID-19 is an essential issue in determining risk for acquiring the virus. At the beginning of the pandemic, it was unclear whether transmission was airborne, through contact with infected animals or material in the wet markets of Wuhan, or by some other mechanism. The rapid spread of the infection within households, among health care workers, and the spread of the disease outside of Wuhan quickly indicated that human-to-human contact was the primary mode of transmission. It is apparent now that most transmission occurs within households, nursing homes, and other congregate settings. Within households, the greatest risk is among the elderly and spouses. Infected individuals appear to be most infectious just before or for several days after the beginning of symptoms when viral loads peak. However, patients who remain asymptomatic can also transmit the infection.

A major question has centered on the infectivity of individuals after contracting COVID-19. Reverse transcriptase-polymerase reaction (RT-PCR) tests usually become negative when an individual recovers from COVID-19 infection but may remain positive for prolonged periods. However, in the majority of cases recovery of viable virus has been shown to disappear 8 days after the onset of symptoms. Thus, in most protocols, the quarantine is stopped 10 to 14 days after the onset of symptoms.

Airborne transmission occurs when viable virus becomes airborne after an infected individual exhales, speaks, particularly in a loud voice, sings, coughs or sneezes. Infectious particles can be broadly classified as either large droplets, which are usually defined as larger than 5 micrometers, or aerosols, which are smaller particles of less than 5 micrometers. A mixture of large particles and aerosols are generated after a person coughs or sneezes. Certain medical procedures such as intubation or noninvasive positive-pressure ventilation potentially cause aerosol formation. After leaving the respiratory tract, large droplets rapidly fall to the ground—usually within 6 feet of an infected individual. Influenza is a typical pathogen transmitted primarily by large droplets. Close contact with someone who is coughing or sneezing maximizes the risk for acquiring influenza. The CDC has recently defined a close contact as “someone who was within six feet of an infected person for a cumulative time of 15 minutes or more over a 24-hour period starting from 2 days before illness onset (or for

asymptomatic patients, 2 days prior to test specimen collection) until the time the patient is isolated.”

In contrast, aerosols evaporate quickly, leaving infectious particles suspended in the air for a considerable period of time—usually hours—in closed and particularly in poorly ventilated spaces. Microbial pathogens such as tuberculosis or measles are typically spread by aerosol. These pathogens can potentially infect large numbers of people because of the airborne suspension of infectious particles. The difference between large droplet spread, such as found with influenza, and aerosols, such as found with measles, is indicated by the average number of people who are infected by an index case, which is termed the reproduction number. For COVID-19 the average reproduction number is 2 to 3, similar to influenza. Risk of transmission does vary with the type of exposure. For example, close contact exposure gives a risk of perhaps 5% whereas household contact can be as high as 40%. But brief interactions, such as while shopping, have a risk of less than 1%. For aerosol transmission, the reproduction number can be as high as 18. Thus, in an epidemic, each active measles case infects on average of 18 other individuals. Because the reproduction number for COVID-19 is low, as is the secondary attack rate, and because the evidence that masks and social distancing of 6 feet reduces incidence of disease, large droplet transmission seems the likely mode of most transmission. Also, a potential association between the size of the inoculum and the clinical presentations and outcome has been proposed and is under investigation.

Nonetheless, some data do support the possibility of aerosol transmission of SARS-CoV-2. Aerosols with SARS-CoV-2 RNA have been demonstrated experimentally and in hospitals. In addition, viable virus has been demonstrated in hospital settings. Furthermore, aerosol transmission has been suggested epidemiologically in certain situations. An outbreak in a nursing home in the Netherlands in June and July 2020 suggested aerosol transmission. In this outbreak 17 (81%) residents and 17 (50%) health care workers (who wore masks) from one of seven wards in a psychogeriatric nursing home were diagnosed with COVID-19 as confirmed by RT-PCR. All residents were diagnosed within 4 days of each other. None of the 95 residents or 106 health care workers in the six other wards was infected. Investigation of the ventilation system in this ward revealed the possibility that air was recirculated, rather than circulated to the outside, due to a recent renovation of the system. Thus, circumstantial evidence in this widespread, ward-specific outbreak over a short time suggests aerosol transmission. Other reports of short-term, extensive outbreaks in poorly ventilated venues suggest the possibility of occasional aerosol transmission. Finally, transmission by “super transmitters” has occurred when a single individual appears to infect a large number of people, well beyond the expected number of two (discussed previously). The frequency and the mechanism for transmission from these individuals remains to be clarified.

Therefore, at the time of this writing, the major route of transmission of COVID-19 during the pandemic appears to be by large droplets in situations where there is close contact without the protection of masks (see later) and over a sustained period, and not by aerosol. In certain circumstances, however, usually indoors in poorly ventilated venues, transmission by aerosols may occur.

Experimental conditions with large inocula of SARS-CoV-2 have demonstrated persistence of the virus on fomites for periods of up to 72 hours, depending on the surface and the conditions. Virus persists longer on impermeable surfaces such as steel or plastic than on permeable surfaces such as paper. More realistic conditions with lower inocula suggest survival of the viable virus for several hours. Virus has been found on numerous surfaces in hospital rooms of infected patients, although data from the United Kingdom indicate that the presence of virus as detected by RT-PCR in the air and on surfaces is

low, particularly after cleaning, and that recovery of viable virus is very low. There is little epidemiologic or clinical data at this point suggesting significant transmission through fomites, although it is certainly reasonable to keep open the possibility and act on that assumption.

SARS-CoV-2 RNA has been found in stool as might be expected with a gastrointestinal tropic virus, but there is no evidence that transmission results from contaminated water or food.

COVID-19 is much less likely to be transmitted in outside venues because of rapid dispersal of droplets and aerosols. Sunlight and ultraviolet light have been shown to rapidly inactivate the virus.

Finally, epidemiologic data suggest that masks and social distancing reduce the risk of transmission. N-95 masks provide protection for both aerosols and large droplets. Surgical masks in hospital settings have been shown to reduce the risk of transmission. Experimental data showed that surgical masks and well-fitted homemade masks with multiple layers of quilting fabric were most effective in preventing droplet and even aerosol dispersal after a cough or loud singing. Bandana and folded handkerchief masks were less effective. Although epidemiologic and experimental data support mask wearing, to date, there are very limited controlled clinical data supporting the effectiveness of masks for COVID-2.

DIAGNOSIS

To date, RT-PCR testing for COVID-19 in nasopharyngeal swabs or nasal swabs is the most common diagnostic test. Samples from saliva may be as accurate. Different gene targets are used by different manufacturers. Viral RNA is measured by the number of polymerase chain reproductive cycles and expressed as threshold (Ct). Ct values less than 40 cycles indicate that a higher number of RNA copies are in the original sample and are regarded as positive. Specificity for most tests approaches 100%. RT-PCR positivity is highest for bronchoalveolar lavage specimens followed by nasopharyngeal, nasal, and oral specimens. False-negative results may occur due to improper specimen collection or due to collection too long before or after the onset of symptoms. RT-PCR may remain positive in some patients for 6 weeks or more. However, viable SARS-CoV-2 can be detected only for the first 8 days after symptoms begin. Therefore, infectivity is presumed to be low after that point. RT-PCR may remain positive in other sites such as sputum and stool for more prolonged periods but does not seem to have clinical relevance.

One important point to remember for any test is that accuracy depends on both the pretest probability, taking into account the symptomatology, history, and local infection rates of a patient, as well as the sensitivity and specificity of a test. The sensitivity for many of the available RT-PCR tests for COVID-19 varies from 71% to 98% and depends on a number of factors, including how the specimen was collected. With a low pretest probability that a patient has COVID-19 and with a relatively low-sensitivity test, a negative result would not assure lack of disease. Thus, depending on the clinical scenario, it is important not to rule out disease if the RT-PCR is negative.

In addition to RT-PCR technology, diagnostic tests are being rapidly developed and tested. They include assays based on the following technology: antigen based, isothermal amplification (LAMP), sequencing, and CRISPR/Cas. Potential advantages of these methodologies include reduced time for results, reduced resources necessary for the test, use of saliva rather than nasopharyngeal or nasal specimens, and more accuracy.

The antibody response of infected persons is usually measured by an ELISA (enzyme-linked immunoassay) test that detects the host's specific IgM and IgG antibodies to COVID-19 virus. Uses for antibody testing include aid in diagnosing acute disease and determining

immunity after infection. Antibodies to the receptor-binding domain of S protein are the most specific and are expected to be a neutralizing antibody. IgM and IgG antibodies are usually not detected until the second or third week of illness, and conversion for most patients occurs by the third to fourth week. After that IgM antibodies begin to decline, usually disappearing by week 7, whereas IgG antibodies persist. The specificity of antibody testing may be compromised by immune responses to other coronaviruses that cause common respiratory illness. Although many serodiagnostic tests have been developed by different manufacturers, most have not undergone appropriate external validation. Therefore, the persistence of the antibody response and whether neutralizing antibodies protect and for how long are unknown at this point.

Most of the data on diagnostic tests for COVID-19 have derived from adults with symptomatic disease. It is not clear whether a similar pattern of RT-PCR and antigen positivity and antibody response will be found in other populations including immunocompromised patients, children, and asymptomatic patients.

CLINICAL ASPECTS

We don't know what percentage of patients who are infected with COVID-19 are asymptomatic. Numerous studies have suggested that a significant percentage of infected people remain asymptomatic. For example, all 217 passengers and crew members on an isolated cruise ship sailing in the South Atlantic Ocean were tested for COVID-19 and 128 (59%) tested positive. Of the positive patients, 24 (19%) were symptomatic, 8 (6%) required evacuation, and 1 patient died. The remaining 104 patients were asymptomatic. Similar data were obtained from analysis of asymptomatic infected patients in a well-publicized outbreak on a cruise ship named *Diamond Princess*. In another remarkable report in September 2020, point prevalence surveys in 33 nursing homes across Connecticut were done on 2117 residents. Six hundred and one were positive and of those 530 (88.2%) were asymptomatic at the time of testing. Sixty-two of 530 developed symptoms within 14 days of testing, and thus 468 of 601 (78%) patients with positive tests remained asymptomatic. Furthermore, population-based antibody testing suggests that a significant percentage of patients who test positive for SARS-CoV-2 antibodies were asymptomatic.

A narrative review published in the *Annals of Internal Medicine* concluded that the asymptomatic rate may be as high as 40% to 45%, and a conservative estimate may be closer to 30%. CDC estimates of asymptomatic rates have been even higher. Similar to most clinical aspects of the infection, these numbers depend on the age and comorbidities of the population. Overall, the data are preliminary; however, since reports have been retrospective, presymptomatic or minimally symptomatic disease may have been underestimated, and patient selection was not random.

Initial studies from China indicate that of the symptomatic patients, 81% had mild symptoms, 14% had severe manifestations, and 5% were critically ill. Studies on COVID-19 symptoms initially focused on hospitalized patients, although most of these findings apply to patients with mild disease as well. The incubation period for COVID-19 averages 5 days but can range from 2 to 11 days. Rarely, the incubation period can extend to 14 days or even longer. For symptomatic patients early in the disease, upper respiratory tract symptoms including rhinorrhea and nasal congestion are frequent. Initial symptoms noted in hospitalized patients are fever (initially 50% but up to 90% later), dry cough (60% to 86%) and dyspnea (53% to 80%). Other common symptoms are fatigue, myalgias, and headache. Some patients initially have gastrointestinal symptoms including nausea and vomiting and/or diarrhea (15% to 39%). As in other respiratory viruses, anosmia is

frequently reported by patients with COVID-19 (up to 64%), although it is not often the presenting symptom.

Respiratory symptoms predominate in most patients with COVID-19. Nonproductive cough, dyspnea, and at times chest pain predominate. Peripheral pulse oxygen levels are used to determine the degree of pulmonary involvement and the need for hospitalization. One phenomenon noted with some patients is lack of dyspnea despite low peripheral oxygen levels (<90). The respiratory symptoms are progressive, resulting in 17% to 35% of hospitalized patients requiring ICU care. In severe cases hypoxemia may increase in severity, requiring sequentially supplemental oxygen, noninvasive respiratory support (for example noninvasive high-flow nasal cannulas), invasive respiratory support with intubation, and in extreme cases extracorporeal membrane oxygenation (ECMO). The great majority of patients do not progress to invasive respiratory support. The entire topic of respiratory support has undergone re-evaluation and change and remains controversial.

Cough is usually nonproductive; the occurrence of productive cough, worsening respiratory function, and signs of localized pulmonary infection may indicate the onset of bacterial or in some cases fungal superinfection. However, the preemptive use of antimicrobial agents has not improved outcomes.

Chest imaging by plain radiographs and particularly chest CT typically show bilateral ground-glass opacification, consolidation, and peripheral distribution in the lower lobes that are characteristic of viral pneumonia. Plain chest films will often miss disease early. Of note, even patients with no symptoms but positive COVID-19 testing may have characteristic findings on chest CT. Laboratory investigations show blood lymphopenia and elevated erythrocyte sedimentation rate, C-reactive protein, D-dimer, lactate dehydrogenase, and ferritin. Elevated blood sugar, creatinine, and hepatic enzymes are common.

EXTRAPULMONARY MANIFESTATIONS

COVID-19 infection in severely ill patients may have protean extrapulmonary manifestations including cardiovascular, renal, gastrointestinal, neurologic, thromboembolic, and endocrine. Myocarditis, cardiomyopathy, and acute coronary syndrome with cardiac injury as detected by elevated troponin levels have been reported in as high as 20% to 30% of hospitalized patients, particularly critically ill patients. Cardiac injury may occur by direct infection of cardiac myocytes by the virus or by the inflammatory response, which can cause thrombosis and endothelialitis. Cardiac arrhythmias including new-onset atrial fibrillation and heart block have been reported in up to 17% of hospitalized patients. Congestive heart failure, especially with preserved ejection fraction and right ventricular dilation, occurs frequently in critically ill patients, complicating the interpretation of chest radiographs. Vascular instability, sepsis-like picture, and bleeding and coagulation abnormalities are also common in ICU patients. Thrombosis of both the venous and arterial systems occurs in up to one quarter of hospitalized patients and greater than one half in ICU patients.

Acute kidney injury (AKI) occurs in up to 37% of severely ill hospitalized patients with up to 14% requiring dialysis. Hematuria and proteinuria are common in severely ill patients. Pathologic studies have shown high rates of viral infection of kidney cells, presumably due to the high distribution of ACE2 in the kidney. In addition, high rates of microvascular and tubular dysfunction may contribute to AKI and impact the prognosis. Careful fluid management and use of scarce dialysis resources are particularly important. Patients who are already on dialysis before acquiring COVID-19 have a very high mortality rate.

Gastrointestinal symptoms including anorexia, diarrhea, and nausea can occur in up to one third of patients and range in series from

12% to 61%. A smaller percentage will develop vomiting and abdominal pain. Gastrointestinal manifestations including transaminitis, ileus, and mesenteric ischemia are more common in critically ill intubated patients with COVID-19 compared to matched uninfected patients.

In some patients, gastrointestinal symptoms may be the initial indications of COVID-19 and should prompt testing for the virus since delays in diagnosis have been reported. Although the virus infects gastric epithelial cells and glandular cells, which have ACE2 present, and viral shedding can be demonstrated, gastrointestinal bleeding is not common, and endoscopy should be avoided if possible in infected patients because of the risk of aerosolization of the virus.

Hepatocellular injury may occur in up to 20% of patients with severe COVID-19 but rarely results in significant hepatitis. Liver function abnormalities including bilirubin have been associated with disease severity. Abnormal liver studies may also be related to drugs, particularly certain antiviral medications, as well as severe disease-causing cytokine release and with vascular compromise. Diagnostic studies are not indicated in most cases.

Neurologic manifestations are common in hospitalized patients, including headache, dizziness, and anosmia. The nasal epithelium has a high frequency of ACE2 and is an early target for COVID-19, probably contributing to anosmia. Delirium occurs frequently, particularly in ICU patients. Acute vascular stroke, encephalopathy, and encephalitis occur in up to 8% of severely ill patients. The extent of direct viral tropism for the central nervous system has yet to be fully defined.

Endocrine abnormalities in COVID-19 center around glycemic control. Hyperglycemia is common in hospitalized patients. Patients with undiagnosed diabetes mellitus often present with hyperglycemia alone or ketoacidosis. Patients who have preexisting diabetes mellitus or obesity are at greater risk for severe disease.

Preliminary data indicate that many patients continue to have symptoms 2 to 3 months after acute infection and a syndrome of “long COVID” has been described. More recently, post-acute COVID-19 has been defined as symptoms extending beyond 3 weeks and chronic COVID-19 beyond 12 weeks. Fatigue, dyspnea, and joint and chest pain are common. Risk factors include age greater than 50 and three or more chronic medical conditions. In one study of hospitalized patients from the United Kingdom who had been discharged at least 2 to 3 months previously, 74% reported at least one symptom, including dyspnea, fatigue, and insomnia. Approximately 14% continued to have abnormal chest radiographs. Some patients who had had more severe disease continued to have abnormal pulmonary function tests. In other studies, myocarditis and myocardial injury by MRI have been described. Significant emotional health issues are not unusual.

RISK FACTORS FOR SEVERE DISEASE AND MORTALITY

Mortality rates for COVID-19 infection vary based on population characteristics, are impacted by testing availability, and have ranged from 0.1% to 2% to 3%. Calculations are complicated by estimating the number of asymptomatic infected individuals, the normal expected death rate, and the deaths due to COVID-19 not recorded. A more meaningful expression of mortality is the excess number of expected deaths, because the individuals most at risk for COVID-19 (elderly, frail, nursing home residents) have a high baseline mortality rate.

The major risk factors for acquisition of symptomatic disease, hospitalization, and mortality are advanced age, frailty, and residing in a nursing home or congregate living facility. In some series more than 90% of deaths occur in patients over the age of 65, particularly those who are frail and those living in nursing homes or the equivalent. Early

TABLE A.1 Hospitalization, Intensive Care Unit (ICU) Admission, and Case Fatality Percentages for COVID-19 Cases by Age Group of 2499 Cases: United States, February 12–March 16, 2020^a

Age	Hospitalization	ICU Admission	Case-Fatality
0–19 (123)	1.6–2.5	0	0
20–44 (705)	14.3–20.8	2.0–4.2	0.1–0.2
45–54 (429)	21.2–28.3	5.4–10.4	0.5–0.8
55–64 (429)	20.5–30.1	4.7–11.2	1.4–2.6
65–74 (409)	28.6–43.5	8.1–18.8	2.7–4.9
75–84 (201)	30.5–58.7	10.5–31.0	4.3–10.5
>85 (144)	31.3–70.3	6.3–29	10.4–27.3
Total (2449)	20.7–31.4	4.9–11.5	1.8–3.4

^aLower bound of range = number of persons hospitalized, admitted to ICU, or who died among the total in the age group. Upper bound of range = number of persons hospitalized admitted to ICU, or who died among the total in age group.

data from the CDC in [Table A.1](#) show the striking risk that age has for hospitalization, ICU admission, and fatality.

Large outbreaks of COVID-19 have occurred in nursing homes in which both staff and residents have been infected. In one CDC study from West Virginia, nursing homes with low quality ratings from Center for Medicare and Medicaid Services (CMS) were more at risk for outbreaks of COVID-19 than those with high ratings.

Early data from the CDC indicated that 37% of patients diagnosed with COVID-19 had at least one underlying health condition. In addition to age, frailty, and nursing home residence, the most common risk factors for severity and hospitalization are diabetes mellitus and obesity, cardiovascular disease (including hypertension), and chronic lung disease. Risk increases with established diabetes mellitus and increasing BMI and is also related to central obesity and metabolic syndrome. Undiagnosed diabetes mellitus is frequently uncovered and diagnosed when patients are hospitalized for COVID-19. Other chronic diseases associated with COVID-19 include immunocompromised conditions, chronic renal disease, and chronic neurologic and psychiatric disorders. Very weak data have suggested an increased risk for patients with type A blood type although this is controversial. There was initial concern that angiotensin-converting enzyme inhibitors or angiotensin-receptor blockers would increase susceptibility to COVID-19, but subsequent data indicate that use of these agents is not associated with more disease.

Minority populations in the United States have significantly greater risk for mortality from COVID-19 than other populations. For example, the age-adjusted rate for mortality for the Black population is 3.4 times and for the Latinx population is 3.3 times that of the white population. Minority populations also have increased rates of disease and hospitalization. There are multiple causes for this discrepancy including (1) workplace exposure; (2) use of public transportation; (3) poor and crowded housing; (4) underlying diabetes mellitus, obesity, and asthma; (5) congregate living settings; (6) delayed health care and lack of access to health care; and (7) distrust of the health care system. Addressing these issues is a critical priority for the equal care of all patients and for controlling the epidemic.

In addition, there is evidence that COVID-19 affects other populations at a greater rate, including those in prisons (people in prisons have 5.5 times the case rate of the general population), group homes, and those with HIV.

TREATMENT

Treatment for COVID-19 for the vast majority of patients is supportive, similar to other respiratory viral illnesses. For hospitalized

patients the primary therapy is respiratory, consisting of conventional supplemental oxygen support. Heated, humidified, high-flow nasal canula oxygen treatment or other oxygen supplementation may be necessary if standard oxygen is inadequate. If invasive ventilation is necessary, low tidal volumes and low plateau pressure are recommended. One lesson from COVID-19 is that hypoxemia is often tolerated well with various modes of supplemental oxygen and without invasive endotracheal ventilation. ECMO has been used in patients who have progressive respiratory and/or cardiovascular failure, but its effectiveness is unknown at this point. Details of ICU care and further goals of ICU care are outlined in guidelines from the Society of Critical Care Medicine, the CDC, and the National Institutes of Health.

A number of drugs in different classes are in clinical trial at this point but few at this time have been shown to be effective. The only one on which there is persuasive data from prospective randomized clinical trials (RCT) is the anti-inflammatory drug dexamethasone. It was shown to reduce mortality in the Randomized Evaluation of COVID-19 Therapy (RECOVERY) trial. Compared to control patients, a significant decrease in mortality was noted in patients on mechanical ventilation (41% vs. 29%) and those on oxygen supplementation (26% vs. 23%). Those without oxygen requirement had no benefit, but even in this situation there could be a subgroup that would benefit, and further studies are ongoing.

Antiviral drugs including remdesivir, hydroxychloroquine, azithromycin, and lopinavir are being studied but none have shown a reduction in mortality. Remdesivir was recently approved by the FDA on the basis of a study in which patients assigned to a 10-day course of remdesivir had a recovery time that was 4 days shorter compared with placebo (median, 11 vs. 15 days).

Other therapies being actively investigated in clinical trials include anti-COVID-19 antibodies, such as convalescent plasma and monoclonal antibodies, and targeted immunomodulatory drugs such as anti-IL-6 (tocilizumab), anti-IL-1, JAK inhibitors, and tyrosine kinase inhibitors. Some of these immunomodulatory drugs may have antiviral properties as well. Likewise, antiviral interferon alpha2b therapy is under active investigation. Chloroquine/hydroxychloroquine has been controversial. A systemic review in August 2020 concluded that the evidence on the benefits and harms of this drug is very weak and conflicting. Future studies should clarify what if any drugs have a significant effect on morbidity and mortality.

It is recommended that all hospitalized patients receive subcutaneous low-molecular-weight heparin to prevent thrombotic complications. Which patients need therapeutic anticoagulation is under study,

but in most centers use is based on clinical presentation, comorbidities, and D-dimer level.

Most patients hospitalized with COVID-19 have evidence of viral pneumonia but not bacterial superinfection and thus do not benefit from routine antimicrobial therapy that predisposes to bacterial and fungal superinfection from resistant pathogens.

Standard therapy for cardiac, renal, endocrinologic, hematologic, and neurologic complications is detailed in subspecialty guidelines.

VACCINES

Vaccine development is one of the highest priorities in COVID-19 research. Traditional vaccine development typically takes more than a decade to complete. The traditional process includes: discovery (2 to 5 years); preclinical including animal studies (2 years); clinical (phase 1: 2 years involving 10 to 50 people, phase 2: 2 to 3 years involving hundreds of people, and phase 3: protection studies involving thousands of subjects taking years); regulatory phase of 2 years; and manufacturing and delivery, which takes 1 to 2 years. With the COVID-19 pandemic the process was streamlined with rapid early phases producing as many candidates as possible, then clinical studies using sites across the globe, and eventually building global manufacturing capacity.

Vaccines have in general targeted the spike protein, but it is not clear what site on the molecule will be the most effective target. Types of vaccines include RNA/DNA, inactivated virus, live attenuated virus, nonreplicating vector, protein subunit, and replicating viral vector. Much attention and preliminary findings have focused on mRNA vaccines. At this writing at least eight potential vaccines are in phase 3 trials in various countries around the world.

Concerns about vaccines include the following:

1. Will the vaccine produce lasting immunity in all populations including those most at risk such as the elderly?
2. Are studies adequately addressing both short-term and long-term adverse effects?
3. Vaccines produced for other coronaviruses have shown lung toxicity, and therefore toxicity must be investigated first in animal models.
4. Will manufacturing capacity and clinical capacity be adequate and will distribution of the vaccine be equitable and target the most vulnerable populations?
5. Will people be willing to take the vaccine?
6. What will be the immune response of the vulnerable population to the vaccine? It is important to recognize that vaccines for respiratory illnesses such as influenza are only 40% to 80% effective at most.

Information about vaccines and their effectiveness and safety will be forthcoming rapidly in the next several years. Preliminary data from two phase 3 trials indicate remarkable efficacy and safety for two mRNA vaccines.

PREGNANCY AND CHILDREN

Preliminary experience from China indicated that pregnant women did not have increased risk from COVID-19 during the third trimester of pregnancy and that newborns were not at risk for infection. Data from the United States are accumulating but remain preliminary. Data from the CDC early in the epidemic indicate that pregnant women with COVID-19 may have fewer symptoms but are more likely to be hospitalized and have severe disease than pregnant women who are not infected. In a study among 598 hospitalized pregnant women with COVID-19, 55% were asymptomatic at admission. Severe illness occurred among symptomatic pregnant women including ICU

admissions (16%), mechanical ventilation (8%), and death (1%). Pregnancy losses occurred for 2% of pregnancies completed during COVID-19-associated hospitalizations and were experienced by both symptomatic and asymptomatic women. Of concern, however, are women with increased risk factors in the United States, such as glucose intolerance, diabetes mellitus, obesity, hypertension, and minority status. Data from the CDC showed that women with obesity and/or gestational diabetes were at higher risk for severe disease. A later study (PRIORITY study) compared women who tested positive for COVID-19 0 to 14 days before delivery versus those who tested negative. COVID-19 was not associated with a difference in birthweight, difficulty breathing, apnea, or respiratory infection in the first 8 weeks of life. Women infected with COVID-19 delivered 1.5 weeks earlier on average. Guidelines for the care of pregnant women and delivery have been published by the CDC and the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine, and the Society for Obstetric Anesthesia and Perinatology.

Data from the early phase of the pandemic indicate that children account for only a small portion of confirmed cases and that most cases of clinical COVID-19 in children are mild and self-limiting. Subsequent data indicate that a percentage of pediatric patients are asymptomatic. Symptomatic patients have fever and cough; a lower percentage have typical viral respiratory symptoms including nasal congestion, myalgia, fatigue, and sore throat. Less than 10% presented with gastrointestinal symptoms. Case fatality rates in children are less than 0.5% and are lower than those of seasonal influenza. Children with underlying respiratory/cardiac disease are most at risk.

Childhood multisystem inflammatory syndrome (MIS-C) was initially described in the United Kingdom as a disease having some characteristics of Kawasaki disease, a rare vasculitis of childhood that can cause coronary aneurysms, and subsequently was reported worldwide. As of mid-July 2020, approximately 1000 cases had been reported. The pathophysiology is still being defined, but most definitions include an inflammatory illness with fever and increased inflammatory markers that involve at least four organ systems including the gastrointestinal, cardiovascular, hematologic, skin, and respiratory systems and in most patients evidence of COVID-19 infection. The disease typically begins 2 to 4 weeks after COVID-19 symptoms. It occurs in previously healthy children who are older than 5 years of age, including adolescents, compared to patients with Kawasaki disease who are usually younger than 5 years. A relatively high percentage (10% to 20%) have evidence of cardiovascular involvement and coronary artery aneurysms. Treatment is anti-inflammatory agents. Most patients recover but mortality ranges as high as 2%. Further data on the epidemiology, clinical characteristics, and treatment of this rare condition are needed.

PREVENTION

It is beyond this Appendix to review the complex epidemiology and public health efforts to prevent and mitigate the COVID-19 pandemic. It was clear from the experience in Wuhan that draconian governmental action including preventing travel in and out of Wuhan, strict quarantine, wearing face masks, shutting down public transportation and public gatherings, closing businesses, and increasing medical care capacity halted the epidemic over several months. Less stringent measures have been instituted in Europe, the United States, and other parts of the world, although there has been wide variation in the extent of restrictions. Contact tracing has been practiced effectively in some countries such as South Korea, but lack of adequate testing and the high percentage of asymptomatic patients has made that impractical in many settings. What have become generally accepted as effective

measures include face masks, social distancing, and restricting social gatherings.

Many countries have seen a marked reduction in cases due to initial public health measures and have begun loosening restrictions with a resultant increase in the number of cases. Early data on resurgent COVID-19 indicate that younger age groups are more affected and that the severity and mortality are less. It is possible, however, that the infection will spread to vulnerable populations, resulting in additional waves of the pandemic that need to be addressed and controlled. Mitigation efforts do not eliminate the virus and until herd immunity is widespread (presumably higher than 40%) and effective vaccines are available, viral transmission and infection will continue.

The downside of public health restrictions has included major negative effects on people. There has been an increase in stress, mental health issues such as depression and anxiety, and unfortunately increases in drug use including alcohol. In one survey, frequency of alcohol use increased 14% overall in 2020 compared to 2019 and affected women more than men. Many patients have avoided the medical care system for acute and routine care out of fear of catching COVID-19. According to a CDC survey early in June 2020, 41% of the US population had delayed or avoided medical care during the pandemic. Care for conditions such as acute infection, acute cardiac disease, and injuries has often not been readily accessible in many locations and as a result mortality has increased for some of these conditions. Routine care including elective surgery, vaccinations, and regular medical visits have been put on hold. Economic disruption with unprecedented economic contraction, massive worldwide unemployment, supply chain disruption, business failures, and food insecurity has wreaked havoc on all countries but has disproportionately affected the poorest and most vulnerable populations. One estimate of the total cost for the United States is \$16 trillion resulting from economic disruption and medical costs. School closings and reopenings have been an extremely important issue that continues to be debated,

but the downside of school closings has been enormous, particularly for children in minority populations. The balance between restrictions for the pandemic and opening society will be an ongoing issue for the foreseeable future.
