The interest in nutrition and in food continues to be evident in the adult years. Popular literature demonstrates a growing interest in cooking, cookbooks, supermarket RDs, grocery store and farm-to-table events, and other "foodie" behavior (see Box 19-1).

Messages regarding the potential benefits and risks of certain foods and nutrients are being heard by consumers. These include messages on the negative effect of saturated fat, trans fatty acids, and sodium. According to Elizabeth Sloan, there is a re-orienting of priorities and behaviors that puts healthfulness as a major driver for both the consumer and the producer. More consumers are looking for "healthful foods" thus increasing the demand for creating and marketing foods that fit this image (Sloan, 2010). Food companies are changing products to reflect a more health-promoting choice, and restaurants are following this lead. However, a study on energy and sodium contents of menu items in U.S. chain restaurants concluded that industry marketing that indicated healthier options was balanced by

BOX 19-1 Buying the Dream

A cadre of "foodies" is developing at all age levels but is a tracked trend in the millennials; those who reached adulthood around the year 2000. Evidence of this phenomenon includes the sale of cookbooks, the number of chef and other food-centered shows on television and the Internet, and even the types of food now offered in restaurants. This interest in food has reached the big screen and TV reruns with the movie "Julie and Julia" in 2009 and "Chef" in 2014. There are Internet sites that advise on how to publish your own cookbook and many apps to download on your phone or computer related to food and nutrition. The social media site, Pinterest, has an overwhelming number of users interested in food, recipes and food culture. Popular high-end grocery stores are hiring RDN's to do store tours and cooking classes. Farm cooperatives are hiring outreach staff who may also be dietitians. Check your local area for the list of cooking classes, community kitchens, supermarket RDNs, and food demonstrations, or take a look at the number of cookbooks, food and recipe links accessible from the Web. The challenge to the nutrition and food professional is to be a player and aim to be a leader.

simultaneous less-healthy changes in menu choices. For example, as lower-calorie options were offered, the appetizer menu added more fried foods to dip in high-sodium sauces with the featured drinks. The conclusion was there was no meaningful change in energy and sodium content in main entrées in a 1-year (2010-2011) time period (Wu and Sturm, 2014).

The nutrition and dietetics professional can be a positive influence in advocating and educating for meaningful and real changes in the food supply with a focus on prevention. However, there must be a consumer-driven effort to support these changes. To be a leader, or at least a player, the nutrition and dietetics professional must be aware of community resources and influences, available food sources, and changing food behaviors.

INFORMATION SOURCES

Where consumers get their information is another factor to consider. The source and the appeal of the message affect how realistic and meaningful information is to the consumer. However, the scientific value and the application of evidence-based information vary. To the adult consumer, the promise of specific benefit is more important than the standard “it’s good for you” message, and the scientific validity of the message may not be the determining point.

Sources of information have continued to change. Traditional print sources continue to decline as digital and electronic sources increase. The 2013 Trends study noted a gain in consumers use of the internet for information of +16 points, bringing the Internet into a position similar to magazines (see Box 19-2).

Use of phones for digital applications, or “apps,” is a growing trend and so is creating, marketing, and evaluating apps. The Academy of Nutrition and Dietetics website includes ratings on apps for nutrition and dietetics as do other sites aimed at professionals and consumers. Future studies likely will look at the Internet and related links as major information sources (AND, 2014a).

Regarding believable human sources of nutrition information, health professionals, including registered dietitians, doctors, and nurses, continue to be rated as the most credible (IFIC, 2014, 2015). However, when consumers were asked about the factors that affect their willingness to believe new food and health information, others in their environment including family and friends were named as potential influencers (see Box 19-3).

Surveys have shown an increase in the number of consumers familiar with My Plate and in those who use food labels, shelf information, and other tools (AND, 2011; IFIC, 2013, 2014, 2015). Popular literature indicates a growing segment of the population interested in food, cooking, cookbooks, and “foodie” behavior. The Nutrition Facts Panel and other label information influence nutrition and food decisions, but there may be gaps in the interpretation. The growing lists of ingredients, unknown terminology, changing ingredients, and even the format can make these tools less useful. Changes in the format and content of labels as well as front-of-package systems have been

discussed for at least 10 years and are a work in progress to be released in 2015. Changes in portion size, the Nutrition Facts panel, and the front-of-package/label claims should be appearing in 2015 (U.S. Department of Health and Human Services [USDHHS] 2015; Healthfinder, January 24, 2014; Food and Drug Administration [FDA], 2014). Studies continue to indicate that consumers will use labels and would welcome a reliable front-of-package system. However, barriers continue to be related to developing a more universal system and providing the support and education important for knowledgeable consumer use (IOM, Label 2011). Although the movement for more labeling on menus has met with mixed reactions, forthcoming regulations will require additional labeling (Wu and Sturm, 2014). All of these efforts are additional pieces of what is a developing puzzle that involves actions at the state and regional level as well as from federal sources. A continuing theme is the need for an overall consumer-related valid message based on current evidence-based tools that are understandable. Also critical to the effort is credentialed food, nutrition, and health professionals who can guide consumers to sources they can easily use to validate information.

Nutrition Information and Education for Adults

Mainstream adults in reasonable health frequently are ignored as a unique segment of the population who can benefit from nutrition assessment and education. Preventive strategies are likely to be targeted to address the formative years of prenatal, infancy, childhood, adolescence, and young adulthood. The older adult group is likely to be targeted with health intervention strategies and quality-of-life messages. However, the population group in the middle of the continuum, the adult age 25 to approximately 65, is likely to be segmented in reference to a disease state, a life event, or a lifestyle choice. For example, adults are targeted as having or being at risk for diabetes or heart disease, in need of a medication, being pregnant, or being an athlete.

The adult who is not pregnant, an athlete, or “sick,” but who seeks guidance on normal nutrition or prevention of disease may be directed toward diets for chronic disease or weight loss. Such information may be a good fit when the information is based on science, but it can miss the mark on overall prevention goals. Fortunately, the guidance provided by such groups as the American Heart Association (AHA), the Academy of Nutrition and Dietetics (AND), the American Diabetes Association (ADA), and the American Cancer Society (ACS) tend to mirror the Dietary Guidelines for Americans 2010 (DGA) (USDHHS, 2010). These guidelines will continue to change with the updating of the DGA (FDA, 2015). The overall focus on diet with evolving guidelines is to emphasize quality of food choices including a

message of the role of choices of “healthy fats” (NIH, Fat 2015). Another change that will affect how the DGA will be implemented both by consumers and food producers will be the elimination of trans fats as ingredients (Health.Gov 2015).

The AHA released prevention guidelines in 2006 with a focus on improving overall health and achieving improved cardiovascular health of all Americans by 20% by 2020 (Lloyd-Jones, 2010). In November 2013 the AHA, along with the American College of Cardiology (ACC) and The National Heart, Lung, and Blood Institute (NHLBI), released four guidelines based on evidence-based reviews sponsored by NHLBI (see Chapter 33). The ACC/AHA recommendations are for a diet high in vegetables, fruits, whole grains, low-fat poultry, fish, non-tropical vegetable oils, nuts and low-fat dairy and low in sweets, sugar sweetened beverages and red meat. The DASH diet pattern or USDA food pattern (MyPlate) is recommended to achieve this diet (Eckel 2013). The 2015 DGA is consistent with the AHA/ACC and also emphasizes increasing the intake of vegetables and fruit to meet the MyPlate guidance of half the plate. A 2015 study by the Produce for Better Health Foundation noted that fruit and vegetable consumptions has declined 7% over five years (from 2009 -2014). Adults 18-44 were cited as an agegroup (along with children of all ages) as a population group showing this decrease. (PBH, 2015) Nutrition messages related to consumption of fat, choices of fat sources, and of vegetables and fruit are ones that are likely to frame the guidance provided by groups such as the American Heart Association.

Guidelines for diabetes prevention continue to be related to healthy lifestyle guidelines of the DGA (see Chapter 30). A 2014 study indicated that research will continue to explore obesity and overweight. In a Danish study the link to being obese or overweight was a factor but there was a time difference noted. The presence of overweight or obese for several years was the identified risk factor rather than the BMI or amount of weight. This led to the conclusion that focusing on small weight reduction for the total population may be more beneficial than concentrating on weight loss targeted to high-risk individuals (Vistisen et al, 2014).

Adults are prime targets for information on chronic disease prevention and weight management. However, the messages may appear to be conflicting or less sensational than advice promising quick solutions. Determining adults’ likely source of information can help the professional be the leader in delivering a validated message.

Health education and public health programs, along with improved research and care, have contributed to changes in morbidity and mortality of the adult population (CDC, 2013). U.S. adults are on a path to positive change, moving from knowledge to action (CDC, 2013). Nutrition assessment is a critical component of MNT and guidance for prevention. The nutrition and dietetics professional should either lead or be a part of lifestyle management teams. These professionals can link MNT to food, economic and social choices and can frame the guidance to be useful and achievable. Nutrition education, communication, and assessment skills add other dimensions to the goal of moving adults to action. Adults in the awareness and action stages are likely to be looking for answers, often short-term fixes or reversals of a health problem rather than more realistic long-term behavior changes. For example, adults may want to know where carbohydrates fit into the total diet and whether there are “better carbs.” What’s the message on “good” or any fat now that trans fats have been almost banned?

What is a “healthy” or “unhealthy” food or diet? Should I be buying organically grown or locally grown foods? What should I do about sodium? These are questions best addressed by skilled nutrition and dietetics professionals who can provide valid current information that answers the short-term questions but builds on long-term solutions.

Guidance based on science generally addresses total diet and lifestyle rather than single nutrients or foods. The concepts of *healthful eating*, *nutrient density*, and *nutritious food* are being debated by food and nutrition professionals as science and technology move the discussions along. The idea of expressing nutrient density using food labels is a major discussion point. Unfortunately, food and nutrition debates and new research findings, often meant to clarify the evidence, are fodder for media coverage, adding to the confusion and perception of mixed messages.

However, adults, as already mentioned, are a population group with the interest and the ability to seek out their own resources and answers. A search for information on choosing foods for health can result in evidence-based information such as the DGA, as well as questionable guidance based on single studies or product promotion. The combination of marketing and electronic media makes it easier to mix science with speculation and outright untruths. Adults with an interest in improving the nutritional quality of their diet may end up with unreliable advice pointing to quick-fix solutions.

The Wellness Years and Food Security

The adult years span a broad range chronologically and are complicated by physiologic, developmental, and social factors. Along with their genetic and social history, adults have accumulated the results of behaviors and risks from environmental factors. These factors shape the heterogeneity of the adult years. Nonetheless, the adult years are an ideal time for positive health promotion and disease prevention messages. In the transitions from early to middle adulthood, health and wellness may take on a new importance. This may be the result of a life event or education (an epiphany) that triggers awareness that being well and staying well are important. Examples include learning the results of a screening for blood pressure, cholesterol, or diabetes; facing the reality of death; the self-reflection that occurs when personal health or that of a peer or family member is in crisis; or realizing that clothes do not fit as well as they should. Regardless of the reason, the concept of wellness takes on a new meaning, and these events are teachable moments.

The Wellness Councils of America (WELCOA) describes **wellness** as a process that involves being aware of better health and actively working toward that goal (WELCOA, 2009). With this mindset, a state of wellness can exist at any age and can start at any point in a person’s life course. Wellness is more than physical health and well-being. A state of well-being includes mental and spiritual health and encompasses the ability of a person to move through Maslow’s Hierarchy of Needs (Maslow, 1970).

The ability to address nutrition needs requires **food security** (i.e., access to a safe, acceptable, and adequate source of food). Part of the issue of food security is quantity and part is quality. According to USDA data, in 2012, 85.5% of U.S. households were food secure, unchanged from 2011. Of the remaining population, 14.5% (17.6 million households) were reported as food insecure (United States Department of Agriculture [USDA], 2014b). The Food Research and Action Center (FRAC) offers similar figures, which identifies food security as a major issue in the United States (Feeding America, 2014a).

BOX 19-4 Feeding America: SNAP is Targeted to the Most Vulnerable

- 76% of SNAP households included a child, an elderly person, or a disabled person. These vulnerable households receive 83% of all SNAP benefits.
- SNAP eligibility is limited to households with gross income of no more than 130% of the federal poverty guideline. The majority of households have income well below the maximum: 83% of SNAP households have gross income at or below 100% of the poverty guideline (\$19,530 for a family of three in 2013), and these households receive about 91% of all benefits. 61% of SNAP households have gross income at or below 75% of the poverty guideline (\$14,648 for a family of three in 2013)
- The average SNAP household has a gross monthly income of \$744; net monthly income of \$338 after the standard deduction and, for certain households, deductions for child care, medical expenses, and shelter costs; and countable resources of \$331, such as a bank account.

<http://feedingamerica.org/how-we-fight-hunger/programs-and-services/public-assistance-programs/supplemental-nutrition-assistance-program/snap-myths-realities.aspx> 2013.

The current economic climate has put added emphasis on food security or access and potential population inequalities. Hispanic, Native Americans, and African Americans in all age groups are more likely to live in poverty than Caucasians and Asian Americans. Native Americans and Alaska Natives have the highest rate of poverty in the United States (U.S. Census Bureau). The highest levels of food insecurity are reported to be in African American, Native American, and Hispanic households (Coleman-Jensen et al, 2013).

The issue of quantity as well as quality and acceptability are a part of the food security discussion. It is often more expensive to eat healthy foods than less healthy, high-calorie foods. Access is a part of this. However, limited skills in the areas of wise food purchasing and food preparation coupled with limited food and equipment resources further complicate a person's ability to follow advice for a healthy lifestyle. This emphasizes the need for adult consumer education in basic food skills. Eligibility for participation in the Supplemental Nutrition Assistance Program (SNAP), formerly known as food stamps (see Box 19-4), is based on income level and aims to alleviate food insecurity. The program includes some money for nutrition education (USDA, 2014c). SNAP, like other food and nutrition assistance programs, is being reviewed and altered to not only increase access but also increase the nutrition quality and types of food offered. The fact that SNAP is a program that serves the working poor as well as those who are unemployed often is overlooked. One in 5 children will rely on SNAP at some point in their lives (see Chapter 9).

Food insecurity frames the need for guidance from nutrition and dietetics professionals on food access, acceptability, and use.

Quality of Life and Work-Life Balance

Perceptions of personal health (mental and physical) relate to views on wellness and perceptions of quality of life. **Health-related quality of life (HRQOL)** is a concept used to measure the effects of current health conditions on a person's everyday life. To capture this and create a tool for professionals, the CDC measures population HRQOL perceptions, including the perception of "feeling healthy." Using HRQOL, one can learn about how adults relate their health to their daily performance. Americans

report feeling "unhealthy" approximately 6 days a month and "healthy" or "full of energy" approximately 19 days a month; adults with the lowest income levels and more chronic diseases report more "unhealthy" days (CDC, 2011b, 2012b, 2012c). Similarly adults are being urged to set a goal of "work-life" balance. This is not a new concept and fits into the need for stress reduction and relaxation as a part of a healthy lifestyle. However, the idea of balancing work time with leisure also can be a part of the reasons adults use for not exercising, not cooking, for eating on the run, ignoring nutrition guidelines, or skipping meals. Leisure time can be interpreted as screen time, inactivity while watching activity, or social interaction, all of which are sedentary and may be accompanied by eating and drinking. Regardless of the reasons and the interpretations, the idea of work-life balance is a message that is receiving social media time and is an issue that often is related to multitasking and multiple roles adults are assuming (see Figure 19-1). In the concept of wellness or prevention, there is a mental health link as well as a potential block to leading a health-promoting lifestyle, not only for adults but also for their associates, family members, and others in their sphere of influence. The pros and cons and the potential health benefits are a topic for worksites and for dietetic and nutrition professionals (National Institutes of Health [NIH], Office of Human Resources, 2014).

The adult years offer unique opportunities to evaluate health status, build on positive factors, and change the negative factors that affect quality of life. Because adults are teachers, coaches, parents, caregivers, and worksite leaders, targeting the wellness-related attitudes and behaviors of adults potentially can have a multiplier effect. A positive wellness focus may influence the health of not only the adult but also those in his or her sphere of influence.

FIGURE 19-1 Eating quickly without attention, when stressed or when multitasking often results in poor nutritional intake in the adult years. (Copyright 2011 Photos.com a division of Getty Images. All rights reserved.)

LIFESTYLE HEALTH RISK FACTORS

Lifestyle choices, including activity, lay the framework for health and wellness. The health of people living in the United States has continued to improve in part because of education that has led to lifestyle changes. Life expectancy has continued to increase (projected at 78.7 years), and the morbidity and mortality rates from heart disease, cancer, and stroke have dropped (CDC, 2013a). Overall life expectancy for the African American population is 3.8 years less than that of the Caucasian population. This disparity is reported to be related to higher death rates from heart disease, cancer, homicide, diabetes, and perinatal conditions (CDC, 2013e).

These statistics point the way for increased emphasis on prevention and intervention initiatives in minority populations.

Even when the emphasis is on wellness and prevention, there is a strong link to risk factors that influence morbidity and mortality. In the United States the leading causes of death and debilitation among adults include (1) heart disease, (2) cancer, (3) chronic lower respiratory diseases, (4) cerebrovascular disease, (5) accidents (unintentional injuries), (6) Alzheimer's disease, (7) diabetes, and (8) nephritis, nephrotic syndrome, and nephrosis (CDC, 2014b). Chronic diseases, including heart disease, stroke, cancer, and diabetes, are among the most costly and preventable of all health problems and account for one third of the years of potential life lost before age 65 and for 75% of the nation's medical care costs (CDC, 2014b). The information quoted is for all adults, but when adjusting for age, the leading causes of death for young adults 18 to 44 are related to preventable causes, with suicide and homicide in the top three causes for adults under 34 years of age (CDC, 2013c). These health issues also have direct links to diet and lifestyle and to life cycle status. Accidents or unintentional injuries play a different role in younger adults. Accidents are the fifth leading cause of death and debilitation among all adults but moves up to first place for adults under 44 with emphasis on ages 25 to 44 (CDC, 2012e). Presumably the other leading causes of death, involving chronic diseases and those more diet related, can be important prevention teaching points at younger ages. Add to the list osteoporosis and new links to such health issues as Alzheimer's disease or arthritis as health problems that affect health care costs and loss of quality of life and that have a potential lifestyle and nutrition link (CDC, 2014d).

Overweight and obesity is either a precursor or complication in all of these diseases. The prevalence of overweight, as measured by a body mass index (BMI) of 25 or more, has increased at all ages but appears to be holding steady and even showing slight decline. It is important when looking at the overall health of adults to consider elevated BMI as a major risk factor but to move to the next phase of total assessment to identify the health profile. Hypertension, hyperlipidemia, and elevated blood glucose often are seen together with or without obesity, known as the **metabolic syndrome** (see Chapter 30). Increasing numbers of obese and overweight adults have been linked to an increase in the number of cases of metabolic syndrome. There is a genetic link to this syndrome but lifestyle is a major issue. Evidence suggests that it is possible to delay or control the risk factors associated with metabolic syndrome with lifestyle changes, including health-promoting diet and exercise patterns, with the help of health professionals (NIH, NHLBI, 2011).

Obesity and overweight directly link with calorie imbalance. An estimated less than half of U.S. adults participate in regular physical activity, with one fourth reporting no activity. Many

health risks in the adult years, including coronary artery disease, certain types of cancer, hypertension, type 2 diabetes, depression, anxiety, and osteoporosis have a relationship with lack of participation in regular physical activity and poor eating behaviors. One cannot achieve positive health without a combination of physical activity and food choices that fit personal needs for energy balance and nutrition. Note the emphasis on *personal* needs.

On the other end of the weight spectrum is chronic underweight, frequently accompanied by undernutrition. Anorexia nervosa is the extreme condition, found in both genders across the age span. An unhealthy weight or unhealthy concern about body weight not only affects overall health but in women also can affect fertility and the ability to conceive.

HEALTH DISPARITIES AND ACCESS TO CARE

Implementation of the Healthy People 2020 goals are based in part on eliminating disparities that increase the health risks for affected populations. Such disparities are related to inadequate access to a safe and affordable food supply and health care based on race, ethnicity, gender, education, income level, and geographic location. Inadequate access to care is a disparity that has a major effect on a person's wellness. Chronic diseases and obesity have been shown to be more of a burden to racial minorities and women (CDC, 2013e, 2014b). There is a higher incidence of heart disease, diabetes, and obesity or overweight in low-income, African American, and Hispanic populations (CDC, 2013e). These same population groups have limited access to preventive care, nutrition education, and guidance (USDHHS, 2011).

The Affordable Healthcare Act was passed by Congress and signed into law on March 23, 2010, by President Obama. After a Supreme Court decision on June 28, 2012, the interpretation of the law began (see Chapter 10). Implementation began slowly with a goal of access to affordable care by all. Preventive care is highlighted. For current progress, check the Health and Human Services website at <http://www.hhs.gov/healthcare/> (USDHHS, 2014).

World Health

The problems associated with chronic diseases are similar in other countries (World Health Organization [WHO], 2009). Also cited are human immunodeficiency virus, acquired immune deficiency syndrome, tuberculosis, and tropical diseases as barriers to global achievement of positive health status. Eight United Nation Millennium Development Goals seek to reduce the number of people who suffer from hunger and to increase access to safe water and sanitation (WHO, 2009). However, obesity has been cited as being of epidemic proportions globally, with at least 2.8 million people dying each year as a result of being overweight or obese.

WHO: Key Facts

- Worldwide obesity has nearly doubled since 1980.
- In 2008 more than 1.4 billion adults, 20 and older, were overweight. Of these more than 200 million men and nearly 300 million women were obese.
- 35% of adults aged 20 and over were overweight in 2008, and 11% were obese.
- 65% of the world's population live in countries where overweight and obesity kills more people than underweight.
- More than 40 million children under the age of 5 were overweight or obese in 2012.

This condition, once associated with higher-income countries, is now listed by WHO as prevalent in low and middle income countries. The growing international problem of obesity is a point for consideration and involvement (WHO Media Center, 2014).

Access to a safe and affordable food supply goes beyond the borders of the United States. The quality and quantity of that food and lifestyle factors are concerns that require more than provision of food. A newer and growing emphasis on food lifestyles is identifying “food deserts.” CDC defines **food deserts** as areas that lack access to affordable fruits, vegetables, whole grains, low-fat dairy, and other foods that make up the full range of a healthy diet (CDC, 2012d). USDA expands the definition with a focus on limited access to supermarkets, supercenters, and other sources of affordable and *healthy* foods, noting it can occur in rural or urban settings. Knowing the potential of access to healthy foods, the limitations, and working to expand this access is a critical part of assisting adults and families in meeting nutrition goals. The USDA Food Access Research Atlas is a starting point for nutrition and dietetic professionals.

Emphasis: Women’s Health

The reproductive years constitute a significant stage of a woman’s life. Many issues that affect the health of women are related to the monthly hormonal shifts associated with menses. Osteoporosis, heart disease, and some cancers are disease states that are affected by specific hormones. Pregnancy and breastfeeding have an effect on a woman’s health (see Chapter 15). Breastfeeding helps control weight, lower the risk for diabetes, and improves bone health. Therefore encouraging women to breastfeed is a potential prevention strategy for the future health of the mother and her infant.

Shifts of estrogen and progesterone hormones trigger the female reproductive cycle and affect health. Associated with menses is a complex set of physical and psychologic symptoms known as **premenstrual syndrome (PMS)**. Reported symptoms vary but are described as general discomfort, anxiety, depression, fatigue, breast pain, and cramping. Such symptoms are reported to occur approximately 1 week to 10 days before the onset of menses and increase in severity into menses. Currently, there is no single cause or intervention identified for PMS. Hormone imbalance, neurotransmitter synthesis defects, and low levels of certain nutrients (i.e., vitamin B₆ and calcium) have been implicated (NIH, Office of Dietary Supplements [ODS], 2011). A diet high in sodium and refined carbohydrates has been implicated, but the evidence is not complete enough to make recommendations (NIH, ODS, 2007). A greater emphasis on a plant-based diet of whole grains, fruits, vegetables, lean or low-fat protein sources, and low-fat dairy or soy beverages is a reasonable intervention and may cause relief in some women. Exercise and relaxation techniques have been reported as lessening the symptoms.

When menses end, either because of age or surgical removal of reproductive organs, women have unique health and nutrition concerns. Perimenopause and menopause generally begin in the late forties. However, genetics, general health, and the age that menses began can alter the timing of this marker. Typically, estrogen production decreases around age 50, when endogenous estrogen circulation decreases approximately 60%. The effects include a cessation of menses and the loss of the healthful benefits of estrogen. Even after the ovaries cease production,

a weaker form of estrogen continues to be produced by the adrenal glands, and some is stored in adipose tissue (Barrett-Connor and Laughlin, 2005).

As estrogen decreases, symptoms associated with menopause may occur. The onset of menopause and the reported side effects vary. Some women experience a gradual decline in the frequency and duration of menses, whereas others experience an abrupt cessation. The symptoms most often reported include low energy levels and vasomotor symptoms (hot flashes). Bone, heart, and brain health are affected. The decrease in circulating estrogen limits the body’s ability to remodel bones, resulting in a decrease of bone mass. Lower levels of circulating estrogen also affect blood lipid levels, increasing total cholesterol and low-density lipoprotein cholesterol levels and decreasing high-density lipoprotein (HDL) levels. Brain function, particularly memory, also is affected; negative changes may be alleviated somewhat with hormone therapy (MacLennan et al, 2006).

Managing menopause promotes emphasis on plant-based foods for the benefits of **phytoestrogens**, soluble fiber, and other components. Having sufficient calcium, vitamin D, vitamin K, and magnesium, and using the DRI as the guideline are important for protecting bone health. Although soy (isoflavones) continues to be rumored by the popular press as a way to control hot flashes, current research is not definitive. A recent study in American women published online in *Menopause* found that only women who are able to produce the soy metabolite equol get relief from hot flashes by eating soy (Newton et al, 2014). Of 357 study participants 34% were equol producers. The authors warned that a readily available test for the metabolite must be developed, and more randomized studies are needed to be able to make any recommendations that soy be a treatment for hot flashes.

Heart disease, cancer, and stroke continue to be the leading causes of death in women (CDC, 2014e). Again, although genetics are a factor, lifestyle is a major predictor and complicating factor.

Weight is a risk factor for heart disease and some cancers. Weight gain is an issue for women, with a 35% prevalence of obesity in American women aged 20 to 74 years compared with 33% in the same aged men. One-half of non-Hispanic African American women and two-fifths of Hispanic women are obese, compared with one-third of non-Hispanic white women (CDC, 2014a). Physical activity with aerobic endeavors and resistance and weight-bearing exercise is protective for bone, cardiovascular, and emotional health. The key nutrition message is one of balanced food intake with nutrient dense foods that are low in fat. However, once again personal assessment and tailoring to meet individual needs are a critical part of success in weight loss and maintenance.

Emphasis: Men’s Health

The leading causes of death among American men include heart disease, prostate and lung cancers, and unintentional injuries. For the adult man, a diet that supports reducing the risk for heart disease is especially important because men develop heart disease at a younger age than women. Regular exercise and activity are important. Along with contributing to cardiovascular health, weight-bearing exercise has a positive effect on bone health.

Another issue in adult men is iron intake. Unless adult men are diagnosed with iron deficiency anemia and require

additional iron, they should not seek additional iron from multivitamin or mineral supplements, enriched sports drinks, or energy bars. Excessive iron intake is problematic because it is an oxidant in the body; men and postmenopausal women do not have menstruation, pregnancy, or lactation to get rid of excess iron. A certain percentage of men carry the genetic variant for hemochromatosis and iron overload, and in this situation iron is particularly dangerous (see Chapter 32).

Like women, today's male population also is affected by obesity and the risk factors that come with excess weight such as diabetes, heart disease, and orthopedic problems. The American Cancer Society reports that one in seven men will have prostate cancer in his lifetime but only one in 36 will die of this disease. Obesity may play a role in these cancers. Some studies indicate that foods high in lycopene, an antioxidant found in tomatoes and other fruits and vegetables, may provide a protective role in lowering the risk factors for developing prostate cancer. Although this is still being studied, it is an emerging area for nutrition and diet in lowering risk factors and an area for dietetic and nutrition professionals to continue to explore. Such factors as how the food high in lycopene is prepared may have an effect on the usefulness of the lycopene (American Cancer Society, 2014).

INTERVENTIONS, NUTRITION, AND PREVENTION

Adults are in the ideal life-cycle phase for health promotion and disease prevention nutrition advice because of the combination of life experience and influence. This group has the potential to shape personal lifestyle choices and influence others. The tools are in place, including the DGA, My Plate, and the Nutrition Facts panel on food labels.

The vegetarian diet or a more plant-based diet and the Mediterranean diet have become popular with health and nutrition professionals and the public. Alternative patterns and resources support those who choose to be vegetarian or vegan (AND, 2009b). Both patterns are more plant based and support the recommendations of the Dietary Guidelines for Americans.

Implementation of positive choices and moving people along the continuum of a healthy lifestyle are other issues. Studies indicate consumers are aware of the concerns associated with lifestyle and diet but have a limited interest in making sustainable changes (IFIC, 2013). Consumers are aware of the implied promises for good health that come with messages from the media, friends, and health professionals; however, they are unlikely to move from awareness to action without motivation stronger than a message or promise. One perception of consumers is that eating healthful foods means giving up foods they like or having to eat foods that do not have the taste they prefer (AND, 2011). A total diet approach of making gradual changes of food and lifestyle choices may help. The Small Steps: Big Rewards Program is an example of such an approach with a goal of preventing type 2 diabetes (NIH, National Diabetes Education Program, 2006). America on the Move is another program that emphasizes achievable goals while maintaining calorie balance through small changes (America on the Move, 2014).

The steps to prevention and health promotion, even when small, are personal responsibilities that cannot be legislated. Americans have many choices: what and where they eat, where they receive their information, and what they include or exclude from their lifestyle. Adults value choice and food selection is a right, even if it leads to poor health, chronic disease, or

death. Some messages are directed at reaching adults where they live and work. For the working adult populations, much of the day is tied to a work site. There are increasing efforts in the private and public sectors to promote positive work site nutrition-related behaviors and programs.

FOOD TRENDS AND PATTERNS

Where one eats, who prepares it, and how much is consumed are patterns of behavior and choice. There is no stereotypic "adult" lifestyle. Adults may be single or partnered, with or without children, and working outside the home or at home. The sit-down family meals at home have given way to eating on the run, take-out, and drive-through. Too little time for planning or preparation and limited cooking skills can lead to reliance on processed foods, speed-scratch cooking (combining processed with fresh ingredients), or more food prepared out of the home. Today's economic climate and changing dietary recommendations present new challenges. The nutrient-dense approach is essential (Miller et al, 2009). Reaching men and women with an understandable and relevant message, especially heads of households or gatekeepers, is critical.

The **consumer price index (CPI)** estimates that Americans spend more than 52% of their food dollars away from home. This is an amount that has continued to increase and that fluctuates by month. The CPI for food measures the average change over time in the prices paid by urban consumers, using a representative market basket of consumer goods and services. The Economic Research Service (ERS) of the USDA follows these expenditures and manages the data set. This is a valuable resource for monitoring expenditures and planning for meaningful interventions (USDA, 2014a).

Changing food patterns and the use of more processed and purchased foods can result in an increase in dietary sodium, fat, and sweeteners and a decrease in use of basic foods such as fruits, vegetables, and whole grains. Portion sizes (either the amount presented or the amount eaten) replace serving sizes (what is recommended as a serving by the DGA or other source), as others determine what is considered a "meal" or "snack." Portions have continued to increase in size, as evidenced from using the tool "Portion Distortion" available at <http://hp2010.nhlbihin.net/portion/keep.htm>.

Dietary changes have affected nutrition and already are reflected in the current concerns for weight and nutrient imbalances. The DGA 2010 and My Plate (see Chapter 11) can be viewed as attempts to put more emphasis on basic foods that are nutrient dense rather than calorie dense and on total amounts of foods per day rather than numbers of servings. The most current information is reflected in the information used to shape the 2010 DGAs, but stay tuned as the 2015 DGA evolve guidance will change (Health.Gov, 2015).

Based on 2010 studies adult diets are likely to be higher in total fat than the 30% of total calories recommended in the 2010 DGA and include a predominance of carbohydrates as added sugar and refined grains. Fruit and vegetable guidelines are not being met, although increases are being noted. Although chicken and fish servings have increased, animal sources outweigh plant-based protein sources. Health guidelines continue to move in the direction of increasing plant-based foods. Key nutrients that may be in short supply are calcium, magnesium, and potassium; the antioxidants vitamins A, C, and E; and vitamin D (USDHHS, 2010). Accessing information building to the

2015 DGA (Scientific Report of the 2015 DGA Advisory Committee) will give a clearer picture (Health.gov, 2015).

NUTRITIONAL SUPPLEMENTATION

The position of the Academy of Nutrition and Dietetics (formerly the American Dietetic Association) is that the best nutritional strategy for promoting optimal health and reducing the risk of chronic disease is to choose wisely a variety of nutrient-rich foods. Additional nutrients from fortified foods and supplements help people meet their nutritional needs as specified by science-based nutrition standards such as the DRI ([AND, 2009a](#)). In making this statement, the Academy puts food first but leaves the door open for those with specific nutrient needs, identified through assessment by a dietetics or health professional, to be nutritionally supplemented.

Traditionally, one thinks of vitamins and minerals, fiber, and protein as nutrient supplements, generally in a pill, capsule, or liquid form. The DRIs are the standards used with most adults. However, food fortification is another form of nutrient supplementation. The level of fortified foods (such as “energy bars,” “sports drinks,” smoothies, or ingredients for fortification) in the marketplace puts another layer of potential nutrient sources in the mix with traditional supplements. Less traditional supplements such as herbals and other natural dietary “enhancers” are added to the array of supplements available to consumers. Information continues to build on the safety of some of the ingredients used to fortify or supplement. Examples include the 2014 report on the safety of caffeine added to foods and supplements and the ongoing updates from the NIH, Office of Dietary Supplements, and National Center for Alternative and Complementary Medicine ([IOM, 2014](#); [NIH, 2014](#); [NIH, NCACM, 2012](#)).

Either because of choice, access, or health-related issues, Americans may not meet the dietary recommendations for promoting optimal health. Several segments of the adult population fall into high-risk groups who are unlikely to meet their nutrient needs because of life stage (e.g., pregnancy), alcohol or drug dependency, food insecurity, chronic illness, recovery from illness, or choosing a nutritionally restrictive diet or lifestyle. Other persons with special needs include those with food allergies or intolerances that eliminate major food groups, persons using prescription drugs or therapies that change the way the body uses nutrients, those with disabilities that limit their ability to enjoy a varied diet, and those who are just unable or unwilling

because of time or energy to prepare or consume a nutritionally adequate diet. These adults potentially need a nutritional supplement ([AND, 2009a](#); [AND, 2013b](#); see Chapter 12).

FUNCTIONAL FOODS

Adults interested in attaining and maintaining wellness are frequently interested in altering dietary patterns or choosing foods for added health benefits. The desire for fewer calories and multiple health benefits, especially when children are in the home, is driving the growth in the U.S. functional foods market. Sloan described this drive for real-food solutions, for “healthy” foods as a reminder to consumers of the long-term value of staying healthy ([Sloan, 2012](#)). Eight of ten Americans are making an effort to eat healthfully, and 42% are concerned about the nutrient content of the foods they buy. One result is an increase in sales of functional foods and beverages. Sloan notes that young adults, ages 18 to 24, are the top users of functional foods and beverages. This increase in sales of these foods and beverages is related to the search for healthier foods from familiar staples with better health profiles as well as options for individual nutrients ([Sloan, 2012](#)).

In a 2013 position paper on functional foods, the Academy of Nutrition and Dietetics noted all food is functional at some level, but there is growing evidence of components in food beyond traditional nutrients ([AND, 2013a](#)). Examples of large classes of **functional foods** are fruits and vegetables, including legumes, flax seeds, whole grains, the oils of fish, certain spices, yogurt, nuts, and soy. These are examples of foods believed to have benefits beyond their usual nutrient value ([AND, 2013a](#); [IFIC, 2011](#)). Functional foods can include whole foods as well as those that are fortified, enriched, or enhanced by the addition of food components or nutrients. The potential benefit for health is when these foods are consumed as part of a varied diet on a regular basis.

Providing this information to the segment of the adult population who is looking for ways to enhance health not only gains the adults’ attention but also takes nutrition guidance to a higher level. Research continues to provide information on dietary patterns and components of foods that may have added benefits for health. Helping to lower blood cholesterol or control blood sugar, serving as an antioxidant or scavenger against harmful components, promoting a healthy gastrointestinal tract, or stimulating activity of detoxification enzyme systems in the liver are examples of benefits being reported and researched for validity (see *Focus On: Eating to Detoxify*).

FOCUS ON

Eating To Detoxify

By Sheila Dean, DSc, RDN, CDE, and L. Kathleen Mahan, RDN, MS

Detoxification, or “detox,” is an elusive term because it does not always mean the same thing to everyone. However, the scientific meaning for detoxification, also referred to as biotransformation, is simply the elimination of anything that is toxic or foreign to the body. Detoxification can become impaired for a variety of reasons, including poor diet, drug-induced nutrient depletion, intestinal permeability, and genetic variations that may predispose a person to poor detoxification ability.

As a result, current thinking on eating to detoxify for optimal health is based on a system of choosing foods to protect, maintain, and renew the body. The body is protected from xenobiotics (compounds foreign to the body) by natural barriers, including the GI system, the lungs, and the skin. When compounds that are potentially harmful or unknown cross these

barriers, the body’s detoxification systems, which are series of metabolic reactions, go into play, with the result of decreasing the negative impact of the xenobiotics, drugs, or toxins.

Toxins may be of external origin (also referred to as xenobiotics or exogenous toxins), such as chemicals and pollutants in the air, water, food additives, or drugs. They also may be generated internally (also referred to as endogenous toxins), as the end-products from the metabolism of hormones, bacterial byproducts, and other complex molecules. The prolonged presence of these molecules can have damaging effects on tissues or lead to undesirable imbalances.

The detoxification (also referred to as biotransformation) process occurs in two classical steps—named Phase 1 and Phase 2—each involving a battery of enzymes of broad specificity. Specifically, Phase 1 reactions are

FOCUS ON—cont'd

Eating To Detoxify

catalyzed by the cytochrome P450 (CYP450) supergene family of isoenzymes, which have very broad substrate specificity. The products generated from Phase 1 reactions are often highly volatile and reactive intermediate metabolites and/or reactive oxygen species, which may cause tissue damage. The reactions in Phase 2 generally involve conversion or conjugation of the intermediate metabolites of Phase 1. This process is facilitated by the addition of a host of nutrients including various amino acids, methyl donors, and glutathione, a tripeptide consisting of glutamic acid, cysteine, and glycine, and which acts as a powerful antioxidant. The Phase 2 reactions that require the above-mentioned nutrients include glucuronidation, sulfation, methylation, acetylation, glutathione conjugation, and amino acid conjugation to the reactive site of the final products that are then eliminated. In some cases, a toxin may be converted directly via Phase 1 or Phase 2. Although both phases have different characteristics, it is essential that they function in balance with one another to minimize the presence of intermediate metabolites and carry through an effective detoxification.

Although as much as 75% of detoxification activity occurs in the liver, much of the remainder takes place in the intestinal mucosa wall. Still, an additional small percentage occurs in other tissues. Although the liver is thought of as the detoxification site, it makes sense that the intestine also plays an important role in detoxification, because the gastrointestinal lining provides the initial physical barrier to the largest load of xenobiotics.

The potential power of these systems to protect the body is demonstrated by a closer look at the major barrier, the gut. More than half the body's lymphoid tissue surrounds the digestive tract. Gut-associated lymphoid tissue (GALT) generates almost 70% of the body's antibodies and contains the greatest number of lymphocytes in the body. It is the GALT immunoglobulins that prevent absorption of bacteria and viruses. Secretory immunoglobulin A (sIgA) is a part of the major immune system of the gut and has been reported to directly deactivate enzymes and toxins from bacteria such as *Escherichia coli*.

The mechanisms for the food and nutrient link to detoxification are being explored, but it is suggested that phytochemicals are involved, along with more traditional nutrients that build and support the enzyme systems. Isothiocyanates such as sulforaphanes found in cruciferous vegetables; organosulfuric compounds in garlic, onions, and other members of the allium family; and the components present in **prebiotics** (nondigestible food products that stimulate the growth of bacteria already present in the colon) are examples of food choices that can affect detoxification in prevention and healing. In addition, the use of **probiotics** has been suggested as a helpful dietary addition for improving barrier activity, immune health, and gut function (Martin et al, 2014).

Foods and phytochemicals that boost detoxification include the following:

- At least one cup of cruciferous vegetables (cabbage, broccoli, collards, kale, Brussels sprouts) daily for their Phase II enzyme promoting effect
- A few cloves of garlic, which also promote Phase II enzymes
- Epigallocatechin gallate (EGCG) from regular or decaffeinated green tea
- Fresh vegetable juices, including carrots, celery, cilantro, beets, parsley, and ginger
- Herbal teas containing a mixture of burdock root, dandelion root, ginger root, licorice root, sarsaparilla root, cardamom seed, cinnamon bark, and other herbs
- High-quality, sulfur-containing foods—eggs or whey protein, garlic, onions
- Limonene in citrus peels, caraway, and dill oil
- Bioflavonoids in grapes, berries, and citrus fruits that promote Phase I enzymes
- Dandelion greens to help liver detoxification, improve the flow of bile, and increase urine flow

- Celery to increase the flow of urine and aid in detoxification
- Cilantro which may help remove heavy metals
- Rosemary, which has carnosol, a potent booster of detoxification enzymes
- Curcuminoids (turmeric and curry) for their antioxidant and antiinflammatory action
- Chlorophyll in dark green leafy vegetables and in wheat grass

Putting It All Together with the Functional Medicine “4R” Program

There is a growing awareness that understanding the cause of disease at the genetic-molecular-environmental level may be just as important if not more important than disease classification. Functional medicine, an evidence-based biology systems approach, addresses this concept of underlying cause and root cause solutions. In essence, functional medicine assessment is concerned with understanding the antecedents, triggers, and mediators of dysfunction that give rise to molecular imbalances underlying the signs and symptoms of disease (Lyon, 2010).

The following is a brief adaptation of the “4R Program” that the Institute for Functional Medicine pioneered for the management of chronic disease by targeting detoxification and improving GI function.

1. REMOVE: What does this person need to have removed for healthy detoxification?

Remove focuses on eliminating pathogenic bacteria, viruses, fungi, parasites, and other environmentally derived toxic substances from the GI tract. Dietary modification is important, because foods to which a person is intolerant or allergic can exacerbate GI dysfunction and stimulate immune and inflammatory responses systemically.

2. REPLACE: What does this person need to have replaced to support normal detoxification?

Replace refers to the replenishment of enzymes and other digestive factors lacking or in limited supply in an individual's GI environment. GI enzymes that may need to be replaced include proteases, lipases, and saccharidases normally secreted by cells of the GI tract or by the pancreas. Other digestive factors that may require replenishment include betaine hydrochloride and intrinsic factor, normally produced by parietal cells in the stomach wall.

3. REINOCULATE: What does this person need to support or reestablish a healthy balance of microflora?

Reinoculate refers to the reintroduction of desirable bacteria, or “probiotics,” into the intestine to reestablish microflora balance and to limit proliferation of pathogenic bacteria and candida. Probiotics serve a variety of functions in the GI tract: they synthesize various vitamins, produce short chain fatty acids necessary for colonic cell growth and function, degrade toxins, prevent colonization by pathogens, improve epithelial and mucosal barrier function, and alter immune-regulation via stimulation of secretory IgA or reduction in TNF-alpha.

4. REGENERATE (or REPAIR): What does this person need to support healing?

Regenerate refers to providing support for the healing and regeneration of the GI mucosa. Part of the support for healing comes from removing insults that continually reinjure or irritate the mucosa, promoting the return and growth of healthy microflora. L-glutamine supplementation also has been found useful in restoring GI mucosal integrity.

Using this type of functional medicine approach may allow for a more precise and clear evaluation of all the information available to create a systematic, effective, and functional nutrition care plan for an individual that can potentially significantly alter the trajectory of health maintenance over time.

As a first step, adults who have no major health problems that would restrict food choices can benefit from guidance on meeting the recommendations of My Plate and the DGA. This guidance is based on increasing the intake of fruits, vegetables (including legumes), grains (with emphasis on whole grains), and seeds and nuts—some of the same foods known to have components that go beyond the benefits associated with major nutrients. Most of these components that are considered dietary enhancers are associated with plant foods.

Phytochemicals or **phytonutrients** (from the Greek word *phyto*, meaning “plant”) are biologically active and naturally occurring chemical components in plant foods. In plants, phytochemicals act as natural defense systems for their host and offer protection against microbial invasions or infections. They also provide color, aroma, and flavor, with more than 2000 plant pigments identified (see [Figure 19-2](#)). These include flavonoids, anthocyanins, and carotenoids. Functional foods have become a favorite topic of the consumer press who often exaggerates the benefit of the food (see [Focus On: Chocolate: A Functional Food?](#)). As part of human consumption, phytonutrients can have antioxidant, detoxification, and antiinflammatory functions in the body.

Soy is another example of a food with value beyond quality protein but like others, research is still being collected and evaluated. The potential health benefits of soy products or components of soy include the potential of reducing the risk for heart disease and certain types of cancer and reducing vasomotor symptoms (hot flashes) in menopausal females. Note that soy itself, as a plant, has no cholesterol and is a source of **isoflavones**, a **phytoestrogen** or plant estrogen. In 1999 the Food and Drug Administration (FDA) approved a food label claim for soy, addressing its potential role in reducing the risk

FIGURE 19-2 Cooking at home can be the best way to eat balanced and nutritious meals but can also be the most challenging during the adult years due to busy schedules.

FOCUS ON

Chocolate: A Functional Food?

What is there to hate about chocolate? Some people are allergic to it and some do not enjoy the flavor, but many people enjoy eating it. Chocolate can be considered a healthy food, as long as it is eaten in moderation. White chocolate is generally the cocoa butter portion with added sugar and flavorings and does not possess the same health benefits as milk or dark chocolate. Some facts about chocolate are the following:

- Chocolate is a plant food, made from beans harvested from a cocoa tree. Once the beans are removed from a pod, they are fermented, dried, roasted, and then ground. This produces a liquid, which is pressed to separate the cocoa butter from the solids. The end result is a cake that is then ground to make cocoa powder.
- Cocoa butter contains saturated fat, but research indicates the effect on blood cholesterol is neutral and may even be positive. However, it is a calorie source.
- Chocolate is a source of flavonoids, naturally occurring compounds that serve as antioxidants. Known as polyphenols, these are the same antioxidants found in tea, red wine, and some fruits and vegetables. These compounds give chocolate its rich color as well as potential health benefits. Dark chocolate has the most flavonoids.
- It is believed flavonoids help the body repair damage to the many cells and may even provide a protective shield. The cocoa in chocolate has a similar effect on blood vessels as taking small doses of aspirin. That is something to consider if you are on certain medications.
- Chocolate is also a source of plant sterols, B vitamins, magnesium, and potassium, all with potential heart health benefits.
- Chocolate can potentially improve mood because cocoa is believed to have a positive effect on boosting endorphin and serotonin levels in the brain.
- There are some potential negatives along with the potential of an allergic reaction:
 - Cocoa is a source of oxalates. For some this can be a trigger for certain types of kidney stones.
 - Caffeine is present in chocolate with dark chocolate taking the lead and milk chocolate at about one third the amount of the dark chocolate. This is a stimulant with varying effects based on your health and the amount consumed.
 - Dark chocolate is a source of tyramine, also present in red wine, some fermented and aged foods. Still under investigation but worth noting is the potential for triggering migraine headaches.
 - Chocolate is often in foods with excessive calories. Added sugar and fat in popular chocolate desserts, candies, and beverages bring to light the ongoing theme....keep the portions real for your personal needs.

of heart disease (FDA, 1999). This was reevaluated in 2013 when FDA Model guidelines noted the following:

1. 25 grams of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease.
2. Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease (FDA, 2013).

The American Heart Association continues to note the positive influences of soy with a low saturated fat, low-cholesterol diet most recently on blood pressure, but the AHA has not updated statements dating back to 2006. The statement in 2006 noted there was no position after the results of a review of 22 randomized trials on the effect of soy protein with isoflavones on serum cholesterol ([Sacks et al, 2006](#)). The committee noted that soy protein and isoflavones have not been shown to

lessen vasomotor symptoms of menopause and show no significant effects on HDL cholesterol or triglyceride levels. Foods that fit the FDA label claim for soy protein have a positive nutrition profile by virtue of the label requirements. Soy provides quality protein and provide an alternative for those limiting their animal protein intake. Soy can be used to displace animal protein and help lower intake of saturated fat, but soy is not recommended as a therapy to reduce LDL cholesterol or other cardiovascular risk factors (Lichtenstein et al, 2006). Whole soy foods continue to be a reasonable part of a diet with a role in disease prevention and health promotion (Messina et al, 2009). In addition, moderate amounts of soy foods can be part of a balanced diet even for cancer survivors (Maskarinec, 2005). The ACS concludes that cancer survivors may safely consume up to three servings daily (American Cancer Society, 2014; McCullough, 2012).

One cannot address dietary guidance without considering the issues of functional components and functional foods. Rather than isolating and promoting food components, current thinking supports the emphasis on food as a package and as a first source for nutrients and potential enhancers (see Figure 19-2). In the big picture it is the person's health status, lifestyle choices, and genetics that form his or her potential for wellness, but dietary enhancement is a tool that gains attention and helps the person move forward on the wellness continuum.

HEALTHY FOOD AND WATER SYSTEMS AND SUSTAINABILITY

This chapter began with a note that community nutrition is a constantly evolving and growing area of practice with the broad focus of serving the population at large with a thrust to be proactive and responsive to the needs of the community. Today's community and the community needs differ, but regardless of environmental, social, and geographic variations, a goal of nutrition and dietetics professionals is to promote and sustain access to a safe, affordable, and health-promoting food sources. In 2014 The Academy of Nutrition and Dietetics issued Standards of Professional Performance that addressed building and supporting sustainable, resilient, and healthy food and water systems (AND, 2014c). These standards are meant to provide guidance to Registered Dietitian Nutritionists beyond the usual safety standards. This paper identifies *sustainability* as the ability to maintain the system for the long term. *Resilience* encompasses the concept that a system can withstand interruptions. A practical example of resilience is that standards are in place for access to health-supporting and safe food and water even after a flood, natural disaster, or funding interruption. The sustainability is rooted in how the system is built, guided, and nourished. Public and private programs and resources are critical components but must meet the tests of resiliency to be sustainable to meet funding requirements. The safety, adequacy, and quality of the food and water supply along with energy sources are components that build the sustainability and the resiliency. The nutrition and dietetics professional can be a major player but must have the expertise and competency as well as the initiative to build as well as promote standards and conditions in which people can reach the goal of being healthy.

ADULT HEALTH NEXT STEPS

The objectives for this chapter are to introduce direction for the well adult. This is a segment of the population who already may be a candidate for MNT, but the intent is to focus on resources for prevention and wellness. The 2013 position of the Academy of Nutrition and Dietetics, The Role of Nutrition in Health Promotion and Chronic Disease Prevention, is a rallying point. In this position the statement is made that primary prevention is the most affordable method to prevent chronic disease (AND, 2013b). Prevention strategies may include MNT because the line between being "healthy" and being "well" relates to control, maintenance, and for the adult, taking personal responsibility for setting a path as early as possible in the life cycle.

CLINICAL CASE STUDY

Aileen is a 28-year-old woman who lives in an urban neighborhood with her husband and 12-year-old daughter. She is 5 ft, 10 in tall and currently weighs 165 pounds. In the past 2 years she has gained 10 pounds. At a recent neighborhood health fair at the YMCA, Aileen's blood glucose and blood pressure screening results were higher than they had been a year ago but were still in a good range. She has a family history of heart disease and diabetes and recognizes that her weight gain is an issue. Both she and her husband work full time, and blending their schedules with that of their daughter is hectic. Aileen does all the cooking and shopping, they have a kitchen with a range, oven, microwave, and refrigerator/freezer. She describes her food shopping habits as chaotic and last minute, often stopping at the local convenience store. They eat out (fast food or take out) for most lunches and at least two dinners a week. They have no regular activity or exercise. They have the minimum health insurance with a large copayment; thus they do not have an ongoing health care routine.

Aileen made an appointment with a locally based health care source. She asked for dietary counseling and was asked to bring a 1-day food recall for the registered dietitian. She reported the following: breakfast: egg and sausage on a bagel, coffee; midmorning: low-fat snack bar from vending machine with coffee; lunch: double burger with cheese on a bun and large fries, ketchup, and extra pickles, diet soda; dinner: frozen dinner that included chicken, rice, and corn. She had an iceberg lettuce salad with diet ranch dressing "to add something green." Beverage was a diet soda. During the evening she had a dish of chocolate ice cream and sweet tea. She reports that in her coffee she likes two packets of sugar and some nondairy creamer.

Nutrition Diagnostic Statements

1. Physical inactivity related to lifestyle issues as evidenced by no regular physical activity and a 10-lb weight gain.
2. Undesirable food choices related to high fat and low fruit and vegetable intake as evidenced by diet history revealing high-fat foods at every meal and an average of one fruit or vegetable each day. Sodium level questionable.

Nutrition Care Questions

1. What lifestyle factors and nutrition triggers are likely to be identified by the dietitian?
2. What foods should Aileen consider including in her diet to build a prevention-related meal plan?
3. Plan a meal pattern and two sample meals that illustrate your recommendations, including at least one at-home and away-from-home breakfast, lunch, and dinner.

Nutrition in Aging

Nancy S. Wellman, PhD, RDN, FAND

Barbara J. Kamp, MS, RDN

KEY TERMS

achlorhydria
activities of daily living (ADLs)
age-related macular degeneration (AMD)
cataract
constipation
dysgeusia
dysphagia
functionality
geriatrics
gerontology

glaucoma
home- and community-based services (HCBS) waivers
hyposmia
instrumental activities of daily living (IADLs)
long-term services and supports (LSS)
Minimum Data Set (MDS)
polypharmacy
pressure ulcers
presbycusis

quality of life
Resident Assessment Instrument (RAI)
sarcopenia
sarcopenic obesity
sedentary death syndrome (SeDS)
senescence
skilled nursing facility (SNF)
supercentenarians
xerostomia

THE OLDER POPULATION

Population aging, now a global phenomenon, is no longer limited to developed, higher-income countries. The World Health Organization's Global Forum on Innovations for Ageing Populations describes how quickly the older population is growing even in low- and middle-income countries and that over the next 40 years, developing countries will be home to about 80% of older adults worldwide (World Health Organization [WHO], 2013).

Today, one in seven Americans is age 65 or older. They are living longer, healthier, and more functionally fit lives than ever before. Figure 20-1 shows older adults involved in physical activities. Those born today can expect to live an average of 80 years. Women who reach age 65 can expect to live an additional 20.4 years, and men, 17.8 years. By the year 2050 the population older than age 65 will grow from approximately 44 million to 84 million, increasing from 14% to 21% of the population. The fastest-growing segment is those older than age 85, currently 6 million and increasing to 18 million in 2050. Members of minority groups also will increase from 21% to more than 39% of the older population (Colby and Ortman, 2014; Ortman et al, 2014) (see Figures 20-2 and 20-3).

By 2056, the total U.S. population 65 years and over is projected to become larger than the population under 18 years (Colby and Ortman, 2014). Even sooner, more than half of the states will double their older-than-65 population by 2030, when the oldest of the baby boomer generation enter their 80s. By 2030 the number of older adults will exceed the number of

school-age children in 10 or more states—Florida, Pennsylvania, Vermont, Wyoming, North Dakota, Delaware, New Mexico, Montana, Massachusetts, and West Virginia. A few years ago no state had more people older than age 65 than those younger than 18. Growth in the older-than-65 population will equal 3.5 times the U.S. growth as a whole. This demographic shift has enormous social, economic, and political implications (Ortman et al, 2014).

Women live longer than men. The older-than-65 female/male ratio is 129:100; it increases to 200:100 among those older than age 85. More than 71% of older men are married, whereas only 45% of older women are married (Ortman et al, 2014). Almost half (45%) of women over age 75 live alone; thus more men die married and most women die unmarried.

Classification

Everyone knows people older than themselves, but those considered “old” depends a lot on one’s own age. Youngsters consider their 20- or 30-something parents old. Today gray hair color, wrinkles, retirement, or age 65 no longer defines *old*. Yet qualifying as an “older adult” is based on the minimum eligibility age of 65 in many federal programs. The U.S. Census Bureau uses a stratified system to define this generation-spanning age group; those aged 65 to 74 are the *young old*; 75 to 84, *old*; and 85 or older, *oldest old*. Some consider today’s *new old* to be those in their 90s. The more than 100,000 centenarians alive today are no longer considered unique, and many of them still live independently (see *Focus On: Centenarians . . . Life in the Blue Zone*).

FIGURE 20-1 Active older adult fishing at 70.

FIGURE 20-2 Population ages 65 and older: 2000 to 2060.

GERONTOLOGY + GERIATRICS = THE SPECTRUM OF AGING

Gerontology is the study of normal aging, including factors in biology, psychology, and sociology. **Geriatrics** is the study of the chronic diseases frequently associated with aging, including diagnosis and treatment. Although medical nutrition therapy commonly has been practiced in hospitals and long-term care facilities, nutrition services have moved out of hospitals and into homes and communities where the focus is on health promotion, risk reduction, and disease prevention.

FIGURE 20-3 Population age 65 and over, by race and Hispanic origin, 2010 and projected 2050. Note: The term *non-Hispanic white alone* is used to refer to people who reported being white and no other race and who are not Hispanic. The term *black alone* is used to refer to people who reported being black or African American and no other race, and the term *Asian alone* is used to refer to people who reported only Asian as their race. The use of single-race populations in this chart does not imply that this is the preferred method of presenting or analyzing data. The U.S. Census Bureau uses a variety of approaches. The race group “All other races alone or in combination” includes American Indian and Alaska Native alone; Native Hawaiian and Other Pacific Islander alone; and all people who reported two or more races. Reference population: These data refer to the resident population. (U.S. Census Bureau: 2010 Census Summary File 1; Table 4. <http://www.census.gov/prod/cen2010/doc/sf1.pdf>, 2011. Accessed December 31, 2014.)

NUTRITION IN HEALTH PROMOTION AND DISEASE PREVENTION

In aging adults, nutrition care is not limited to disease management or medical nutrition therapy but has broadened to have a stronger focus on healthy lifestyles and disease prevention. Without increased emphasis on better diets and more physical activity at all ages, health care expenditures will rise exorbitantly as the population ages. Thus it is never too late to emphasize nutrition for health promotion and disease prevention. Older Americans, more than any other age group, want health and nutrition information and are willing to make changes to maintain their independence and quality of life. They often need help in improving self-care behaviors. They want to know how to eat healthier, exercise safely, and stay motivated.

Nutrition may include three types of preventive services. In *primary prevention*, the emphasis is on nutrition in health promotion and disease prevention. Pairing healthy eating with physical activity is equally important.

Secondary prevention involves risk reduction and slowing the progression of chronic nutrition-related diseases to maintain functionality and quality of life. *Functionality* as related to strength and mobility is perceived as a positive way to discuss fitness versus disability and dependence. Many community

FOCUS ON

Centenarians . . . Life in the Blue Zone

By Janice M. Raymond, CSG, RD, MS

Centenarians are the fastest growing segment of older adults in the United States and in other developed nations, including Japan. The worldwide estimate of centenarians is 450,000. The U.S. Census Bureau estimates for 2009 there are about 65,000 centenarians and more than 1 million by 2050. As with the aging population as a whole, women represent 85% of the long lived. A new group of individuals older than age 110, **supercentenarians**, have sufficient numbers to merit dedicated research.

What is known about extremely long-lived individuals? Centenarians generally have delays in functional decline. They also tend to either never develop a chronic disease or develop one late in life. Much has been written about longevity in the southern Japanese prefecture of Okinawa. The ongoing Okinawa Centenarian Study suggests that low caloric intake may produce fewer destructive free radicals. This intake plus an active lifestyle, natural ability to combat the stresses of life, and a genetic predisposition favor a healthy, functional, longer life.

The National Institute on Aging has identified communities around the world where people are living longer and living measurably better. They called these areas, where people reach the age of 100 at rates 10 times greater than in the United States, the *Blue Zones*. One such community is Okinawa. Others include the Nicoya Peninsula in Costa Rica and Sardinia in Italy. Residents of Loma Linda in California boast the longest life spans in America. They found that these groups had common characteristics related to food: very little animal protein and four to six servings of fruits, vegetables, legumes, and nuts. However, eating wisely is only part of what seems to be a prescription for long life. The people of these communities don't smoke and make regular low-intensity exercise part of their daily routine (e.g., gardening, walking). They are people who can articulate their purpose in life, are spiritually fulfilled, and have strong social networks.

In the New England Centenarian Study, independent function to at least age 90 is a predominant feature. Other important factors are that few centenarians are obese, they rarely smoke, and they consume little or no alcohol. At least 50% of centenarians have first-degree relatives or grandparents who also achieved very old age, and many have exceptionally old siblings.

dining centers funded through the Older Americans Act (OAA) Nutrition Programs attract participants through new fitness programs.

In *tertiary prevention*, care/case management and discharge planning often involve chewing and appetite problems, modified diets, and functional limitations. Complex cases often are influenced by nutrition issues that must be addressed; care managers can benefit from consulting with dietitians. In some circumstances dietitians are the case managers.

THEORIES ON AGING

Gerontologists study aging and have diverse theories about why the body ages. No single theory can fully explain the complex processes of aging ([American Federation for Aging Research, 2011](#)). A good theory integrates knowledge and tells how and why phenomena are related. Broadly, theories can be grouped into two categories: predetermined (genetic) and accumulated damage. A loss of efficiency comes about as some cells wear out, die, or are not replaced. Identification of the mechanisms that affect aging could lead to interventions that slow or alter aging. Most likely several theories explain the heterogeneity in older populations (see [Table 20-1](#)).

TABLE 20-1 Predetermination and Accumulated Damage Theories on Aging

Theory	Description
Predetermination: Built-in mechanism determines when aging begins and time of death	
Pacemaker theory	"Biologic clock" is set at birth, runs for a specified time, winds down with aging, and ends at death.
Genetic theory	Life span is determined by heredity.
Rate of living theory	Each living creature has a finite amount of a "vital substance," and, when it is exhausted, the result is aging and death.
Oxygen metabolism theory	Animals with the highest metabolisms are likely to have the shortest life spans.
Immune system theory	Cells undergo a finite number of cell divisions that eventually cause deregulation of immune function, excessive inflammation, aging, and death.
Accumulated damage: Systemic breakdown over time	
Crosslink/glycosylation theory	With time, proteins, DNA and other structural molecules in the body make inappropriate attachments, or crosslinks, to each other, leading to decreased mobility, elasticity, and cell permeability.
Wear-and-tear theory	Years of damage to cells, tissues, and organs eventually take their toll, wearing them out and ultimately causing death.
Free radical theory	Accumulated, random damage caused by oxygen radicals slowly cause cells, tissues, and organs to stop functioning.
Somatic mutation theory	Genetic mutations caused by oxidizing radiation and other factors accumulate with age, causing cells to deteriorate and malfunction.
Telomere length	Telomeres protect and cap linear chromosome ends. Short telomeres have been associated with many age-related conditions.

PHYSIOLOGIC CHANGES

Aging is a normal biologic process. However, it involves some decline in physiologic function. Organs change with age. The rates of change differ among individuals and within organ systems. It is important to distinguish between normal changes of aging and changes caused by chronic disease such as atherosclerosis.

The human growth period draws to a close at approximately age 30, when senescence begins. **Senescence** is the organic process of growing older and displaying the effects of increased age. Disease and impaired function are not inevitable parts of aging. Nevertheless, certain systemic changes occur as part of growing older. These changes result in varying degrees of efficiency and functional decline. Factors such as genetics, illnesses, socioeconomic, and lifestyle determine how aging progresses for each person. Indeed, one's outward expression of age may or may not reflect one's chronologic age, and ageist stereotypes should be eliminated (see [Figure 20-1](#)). Examples of active older adults include those surf fishing at 70, skiing expert slopes at 75, cycling 25 miles at 85, and playing league tennis at 90.

Body Composition

Body composition changes with aging. Fat mass and visceral fat increase, whereas lean muscle mass decreases. **Sarcopenia**, the loss of muscle mass, strength, and function, can be age related

and can significantly affect an older adult's quality of life by decreasing mobility, increasing risk for falls, and altering metabolic rates (Dam et al, 2014). Sarcopenia accelerates with a decrease in physical activity, but weight-bearing exercise can slow its pace. Although inactive persons have faster and greater losses of muscle mass, sarcopenia also is found in active older individuals to a lesser degree. The criteria to make a diagnosis of sarcopenia are evolving and must be validated. The evidence-based cutpoints for weakness are grip strength less than 26 kg for men and less than 16 kg for women, and for low lean mass, appendicular lean mass adjusted for body mass index less than 0.789 for men and less than 0.512 for women. Further research using these cutpoint criteria is needed, especially in populations with high rates of functional limitations (Studenski et al, 2014). The proposed term "skeletal muscle function deficit" best describes the variety of muscular conditions that contribute to clinically meaningful mobility impairment (Correa-de-Araujo and Hadley, 2014). All losses are important because of the close connection between muscle mass and strength. By the fourth decade of life, evidence of sarcopenia is detectable, and the process accelerates after approximately age 75. Prevention strategies deserve emphasis because of the strong relationships of sarcopenia to functional decline, disability, hospitalization, institutionalization, and mortality (Litchford, 2014).

Sarcopenic obesity is the loss of lean muscle mass in older persons with excess adipose tissue. Together the excess weight and decreased muscle mass exponentially compound to further decrease physical activity, which in turn accelerates sarcopenia. An extremely sedentary lifestyle in obese persons is a major detractor from quality of life.

Sedentary lifestyle choices can lead to **sedentary death syndrome (SeDS)**, a phrase coined by The President's Council on Physical Fitness. It describes the life-threatening health problems caused by a sedentary lifestyle. *Sedentary lifestyle* can be defined as a level of inactivity below the threshold of the beneficial health effects of regular physical activity or, more simply, burning fewer than 200 calories in physical activity per day. *The Surgeon General's Vision for a Healthy and Fit Nation 2010* emphasizes health consequences of inactivity as greater risk for cardiovascular disease (CVD), hypertension, diabetes, dyslipidemia, obesity, overweight, and even death (U.S. Department of Health and Human Services [USDHHS], 2010).

Few older adults achieve the minimum recommended 30 or more minutes of moderate physical activity on 5 or more days per week. About 42% of those aged 65 to 74 and 29% of those 75 and older reported that they engaged in regular leisure-time physical activity (Colby and Ortman, 2014). Inactivity is more common in older people than younger people; women often report no leisure-time activity. The American College of Sports Medicine (ACSM) position emphasizes that all older adults should engage in regular physical activity and avoid an inactive lifestyle (ACSM, 2009). The Centers for Disease Control and Prevention (CDC) quantifies the amount of exercise older adults need and the National Institute on Aging (NIA) has a guide for physical activity (CDC, 2013; NIA, 2010).

Taste and Smell

Sensory losses affect people to varying degrees, at varying rates, and at different ages (Benelam, 2009; Schiffman, 2009). Genetics, environment, and lifestyle are part of the decline in sensory competence. Age-related alterations to the sense of taste, smell, and touch can lead to poor appetite, inappropriate food choices,

and lower nutrient intake. Although some **dysgeusia** (altered taste), loss of taste, or **hyposmia** (decreased sense of smell) are attributable to aging, many changes are due to medications. Dysgeusia has been shown to be predictive of mortality in the elderly. Other causes include conditions such as Bell's palsy; head injury; diabetes; liver or kidney disease; hypertension; neurologic conditions, including Alzheimer's disease and Parkinson's disease; and zinc or niacin deficiency. Untreated mouth sores, tooth decay, poor dental or nasal hygiene, and cigarette smoking also can decrease these senses. Olfactory dysfunction is related to mortality (Jayant et al, 2014).

Because taste and smell sensation thresholds are higher, older adults may be tempted to overseason foods, especially to add more salt, which may have a negative effect in many older adults. Because taste and smell stimulate metabolic changes such as salivary, gastric acid, and pancreatic secretions and increases in plasma levels of insulin, decreased sensory stimulation may impair these metabolic processes as well.

Hearing and Eyesight

Hearing loss is the third most prevalent chronic condition in older Americans, it is the number one communicative disorder of the aged: between 25% and 40% of the population aged 65 years or older is hearing impaired (National Institute in Deafness and Other Communicative Disease [NIDCD], 2013b). The most common type of hearing loss is **presbycusis** (NIDCD, 2013a). This loss is usually greater in the high-pitched tonal range (e.g., telephone ring). The cumulative effect of exposure to daily noises such as traffic, construction, loud music, noisy office, and machines causes a change to the inner ear complex. The change occurs slowly over time, and sufferers may not be aware of the loss. The prevalence of presbycusis rises with age, ranging from 40% to 60% in patients older than 75 years to more than 80% in patients older than 85 years.

Some vitamins may play a part in hearing loss. Vitamin B₁₂, a nutrient often found to be deficient in the diets of older adults, has been associated with increased ringing in the ears, presbycusis, and reduced auditory brainstem response. Vitamin D may have an effect on hearing loss because of the role it plays in calcium metabolism, fluid and nerve transmission, and bone structure.

Age-related macular degeneration (AMD) is a disease of the retina that affects central vision and can lead to blindness in older people. AMD is the leading cause of legal blindness in Americans age 65 and older. It affects more than 1.75 million individuals in the United States. It is expected to increase to more than 5 million by 2050 (American Optometric Association [AOA], 2014). Smoking, race (it is more common in Caucasians), and family history are known risk factors (Chew et al, 2014; National Eye Institute, 2014). As the population ages, AMD is becoming a more significant public health problem. AMD occurs when the macula, the center part of the retina, degrades. The result is central vision loss. The macular pigment is composed of two chemicals, lutein and zeaxanthin. A diet rich in fruits and vegetables may help delay or prevent the development of AMD. Zinc also has been shown to decrease the risk of developing AMD. Micronutrition supplementation often is used in the treatment of AMD (Aslam et al, 2014). Finally, correcting obesity and smoking are modifiable factors that can reduce progression of AMD.

Presbyopia is a loss of elasticity in the crystalline lens that causes an inability to focus clearly at close distances and results

in the need for reading glasses. This becomes apparent around the fourth decade of life (AOA, 2014). As it worsens, poor vision interferes with shopping, cooking, and eating.

Glaucoma is damage to the optic nerve resulting from high pressure in the eye. It is the second most common cause of vision loss, affecting approximately 3 million Americans. Hypertension, diabetes, and CVD increase the risk of glaucoma.

A **cataract** is a clouding of the lens of the eye. Approximately half of Americans 65 and older have some degree of clouding of the lens. The most common treatment is surgery; the clouded lens is removed and replaced with a permanent prosthetic lens. A diet high in antioxidants, such as beta carotene, selenium, resveratrol, and vitamins C and E, may delay cataract development. Studies show that a high sodium intake may increase risk of cataract development. Ultraviolet (UV) radiation exposure is related directly to 5% of worldwide cataracts. When the UV index is 3 and above, protective sunglasses are recommended.

Immunocompetence

As immunocompetence declines with age, immune response is slower and less efficient. Changes occur at all levels of the immune system, from chemical alterations within the cells to differences in the kinds of proteins found on the cell surface and even to mutations to entire organs. The progressive decline in T-lymphocyte function and cell-mediated immunity contributes to the increased infection and cancer rates seen in aging populations. The mechanisms of age-related changes in immune function are not fully understood but likely depend on environmental factors and lifestyle choices that affect overall immune function. Maintaining good nutritional status promotes good immune function.

Oral

Diet and nutrition can be compromised by poor oral health (see Chapter 25). Tooth loss, use of dentures, and **xerostomia** (dry mouth) can lead to difficulties in chewing and swallowing. Decreases in taste sensation and saliva production make eating less pleasurable and more difficult. Oral diseases and conditions are common among Americans who grew up without the benefit of community water fluoridation and other fluoride products. However, the percentage of Americans age 65 and older who are missing all of their natural teeth (edentulous) fell from 28% in 2000 to 2003 to 26% during 2004 to 2007. Missing, loose, or decayed teeth or poor-fitting, painful dentures are common problems that make it difficult to eat some foods. People with these mouth problems often prefer soft, easily chewed foods and avoid some nutritionally dense options such as whole grains, fresh fruits and vegetables, and meats.

The nutrition-related consequences of taking five or more medications or over-the-counter drugs daily (**polypharmacy**) are significant. More than 400 commonly used medications can cause dry mouth (see Chapter 8). Preparing foods that are moisture-rich such as hearty soups and stews, adding sauces, and pureeing and chopping foods can make meals easier to eat. In addition, those with poor oral health may benefit from fortified foods with increased nutrient density (see **Focus On: Food First!**).

Gastrointestinal

Some gastrointestinal (GI) changes may be age related. Rather than ascribing any of these disorders to aging, the true clinical

cause should be determined. GI changes can negatively affect a person's nutrient intake, starting in the mouth. **Dysphagia**, a dysfunction in swallowing, commonly is associated with neurologic diseases and dementia. It increases the risk for aspiration pneumonia, an infection caused by food or fluids entering the lungs (see Chapter 34). Thickened liquids and texture-modified foods can help people with dysphagia eat safely (see The National Dysphagia Diet, Appendix 28, and appropriate levels of texture modification in Chapter 40).

Gastric changes also can occur. Decreased gastric mucosal function leads to an inability to resist damage such as ulcers, cancer, and infections. Gastritis causes inflammation and pain, delayed gastric emptying, and discomfort. These affect the bioavailability of nutrients such as calcium and zinc and increase the risk of developing a chronic deficiency disease such as osteoporosis.

Achlorhydria is the insufficient production of stomach acid. Approximately 30% of those older than age 50 have achlorhydria (Plummer, 2004). Sufficient stomach acid and intrinsic factor are required for the absorption of vitamin B₁₂. Although substantial amounts are stored in the liver, B₁₂ deficiency does occur. Symptoms, often misdiagnosed because they mimic Alzheimer's disease or other chronic conditions, include extreme fatigue, dementia, confusion, and tingling and weakness in the arms and legs (see Chapter 40). It has become common practice to use calcium carbonate antacids as a way to supplement calcium intake. This is contraindicated in the elderly who are already at risk of inadequate gastric acid.

The incidence of diverticulosis increases with age. Half of the population older than age 60 develops it, but only 20% of them have clinical manifestations. The most common problems with diverticular disease are lower abdominal pain and diarrhea (see Chapter 28).

Constipation is defined as having fewer bowel movements than usual, having difficulty or excessive straining at stool, painful bowel movements, hard stool, or incomplete emptying of the bowel. It is one of the most common disorders in the U.S. population, and its prevalence increases with age. Primary causes include insufficient fluids, lack of physical activity, and low intake of dietary fiber. Studies have also shown distinct physiologic changes affecting colonic motility occur in older people. They include myenteric dysfunction, increased collagen deposits in the left colon, reduced inhibitory nerve input to the colon's muscle layer, and increased binding of plasma endorphins to intestinal receptors.

Diminished anal sphincter pressure or degeneration of the internal anal sphincter and loss of rectal wall elasticity are age-related changes. Constipation also is caused by some medications commonly used in older people such as narcotics and antidepressants that actually slow intestinal transit. Diuretics can cause decreased stool moisture, another contributing factor in constipation (see Chapters 7 and 8).

Cardiovascular

Cardiovascular disease (CVD), including heart disease and stroke, is the leading cause of death in both genders in all racial and ethnic groups and not necessarily a disease of aging. CVD age-related changes are extremely variable and are affected by environmental influences such as smoking, exercise, and diet. Changes include decreased arterial wall compliance, decreased maximum heart rate, decreased responsiveness to beta-adrenergic stimuli, increased left ventricle muscle mass,

and slowed ventricular relaxation. Often the end result of hypertension and artery disease is chronic heart failure. One in nine hospital admissions in the United States include the diagnosis of heart failure. A low-sodium diet and fluid restriction are integral to the treatment of this condition. These necessary diet restrictions in conjunction with other side effects of heart failure often lead to decreased nutrient consumption. See Chapter 33 for discussion of the multifaceted approach required to manage CVD in older adults.

Renal

Age-related changes in renal function vary tremendously. Some older adults experience little change, whereas others can have devastating, life-threatening change. On average glomerular filtration rate, measured in creatinine clearance rates, declines by approximately 8 to 10 ml/min/1.73m² per decade after age 30 to 35. The resulting increase in serum creatinine concentrations should be considered when determining medication dosages. The progressive decline in renal function can lead to an inability to excrete concentrated or dilute urine, a delayed response to sodium deprivation or a sodium load, and delayed response to an acid load. Renal function is also affected by dehydration, diuretic use, and medications, especially antibiotics (see Chapter 35).

Neurologic

There can be significant age-related declines in neurologic processes. Cognition, steadiness, reaction time, coordination, gait, sensations, and daily living tasks can decline as much as 90% or as little as 10%. On average, the brain loses 5% to 10% of its weight between the ages of 20 and 90, but most, if not all, neurons are functional until death unless a specific pathologic condition is present (Galvin and Sadowsky, 2012).

It is important to make the distinction between normal, age-related decline and impairment from conditions such as dementia, a disease process (Galvin and Sadowsky, 2012). Memory difficulties do not necessarily indicate dementia, Alzheimer's disease, Parkinson's disease, or any mental disorder (see Chapters 40 and 41). Many changes in memory can be attributed to environmental factors, including stress, chemical exposure, and poor diet rather than to physiologic processes. Urinary tract infections are associated with changes in cognition that mimic dementia but are reversible with treatment (Beveridge et al, 2011). However, even mild cognitive impairment may affect eating, chewing, and swallowing, thus increasing the risk of malnutrition (Lopes da Silva et al, 2012).

Pressure Ulcers

Pressure ulcers, formerly called bedsores or decubitus ulcers, develop from continuous pressure that impedes capillary blood flow to skin and underlying tissue. Several factors contribute to the formation of pressure ulcers, but impaired mobility, poor circulation, obesity, and urinary incontinence are key. Older adults with neurologic problems, those heavily sedated, and those with dementia are often unable to shift positions to alleviate pressure. Paralysis, incontinence, sensory losses, and rigidity can contribute to the problem. Notably malnutrition (inadequate protein) and undernutrition (inadequate energy intake) set the stage for its development and can delay wound healing. The escalating chronic nature of pressure

ulcers in non-ambulatory or sedentary elderly requires vigilant attention to nutrition.

Several classification systems describe pressure ulcers. The four stages of pressure ulcers, based on the depth of the sore and level of tissue involvement, are described in Table 20-2. As wound nutrition tends to equal whole-body nutrition, coordinated efforts of a multidisciplinary treatment team are important. Nutrition recommendations for the treatment of pressure ulcers are as follows (Doley, 2010; Thomas, 2014; Thomas and Burkemper, 2013):

- Optimize protein intake with a goal of 1.2 to 1.5 g/kg/day. Providing protein beyond 1.5 g/kg/day may cause dehydration without increasing protein synthesis. Also, there is no likely benefit from the administration of specific amino acids.
- Meet calorie requirements at 30 to 35 kcal/kg/day.
- Assess the effect of medications on wound healing and supplement if indicated.
- Replace micronutrients if depleted—routine supplementation is not warranted. There are no demonstrated benefits from supertherapeutic doses of vitamin C and zinc.

QUALITY OF LIFE

Quality of life is a general sense of happiness and satisfaction with one's life and environment. Health-related quality of life is the personal sense of physical and mental health and the ability to react to factors in the physical and social environments. To assess health-related quality of life, common measures and scales, either general or disease-specific, can be used. Because older age often is associated with health problems and decrease in functionality, quality-of-life issues become relevant.

Depression

Psychologic changes often manifest as depression, and its extent can vary widely from person to person. Among older persons depression often is caused by other conditions such as heart disease, stroke, diabetes, cancer, grief, or stress. Depression in older people frequently is undiagnosed or misdiagnosed because symptoms are confused with other medical illnesses. Untreated depression can have serious side effects for older adults. It diminishes the pleasures of living, including eating; it can exacerbate other medical conditions; and it can compromise immune function. It is associated with decreased appetite, weight loss, and fatigue. Nutritional care plays an important role in addressing this condition (see Chapter 41). Providing nutrient- and calorie-dense foods, additional beverages, texture-modified foods, and favorite foods at times when people are most likely to eat the greatest quantity can be very effective. In that comorbidities lead to polypharmacy and concern regarding drug-drug interactions, providers may choose to omit antidepressants, which leaves the depression untreated.

Given the untoward consequences of unintentional weight loss with aging and the lack of FDA-approved medications for appetite stimulation in older adults, food and nutritional interventions along with the treatment of underlying conditions that contribute to weight loss, such as poor dentition, deserve greater attention. One, antidepressant mirtazapine (Remeron) has helped increase appetite and weight gain in depressed elderly patients. With appropriate monitoring for side effects,

TABLE 20-2 Pressure Ulcer Stages

Suspected Deep Tissue Injury

Purple or maroon localized area of discolored intact skin or blood-filled blister caused by damage of underlying soft tissue from pressure or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler compared with adjacent tissue.

Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

Stage I

Intact skin with non-blanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate “at-risk” persons (a heralding sign of risk).

Stage II

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed without slough. May also present as an intact or open or ruptured serum-filled blister. Presents as a shiny or dry, shallow ulcer without slough or bruising. This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation. Bruising indicates suspected deep tissue injury

Stage III

Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling. The depth of a stage III pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. Bone and tendon are not visible or directly palpable.

Stage IV

Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed, often include undermining and tunneling. The depth of a stage IV pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and these ulcers can be shallow. Stage IV ulcers can extend into muscle and supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis possible. Exposed bone or tendon is visible or directly palpable.

Unstageable

Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) or eschar (tan, brown, or black) in the wound bed. Until enough slough or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as “the body’s natural (biologic) cover” and should not be removed.

National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel and Pan Pacific Pressure Injury Alliance, The Prevention and Treatment of Pressure Ulcers: Quick Reference Guide, 2014 <http://www.npuap.org/wp-content/uploads/2014/08/Updated-10-16-14-Quick-Reference-Guide-DIGITAL-NPUAP-EPUAP-PPPIA-16Oct2014.pdf>

mirtazapine may be a drug of choice for older persons experiencing weight loss and depression (Rudolph, 2009).

Food and nutrition contribute to one’s physiologic, psychologic, and social quality of life. A measure of nutrition-related quality of life has been proposed to document quality-of-life outcomes for individuals receiving medical nutrition therapy. Effective strategies to improve eating and thereby improve nursing home residents’ quality of life are well established but could be more widely implemented (Bernstein et al, 2012) (see *New Directions: Culture Change*).

**NEW DIRECTION****Culture Change**

Janice L. Raymond, MS, RD, CSG

Culture Change in Long-Term Care

Pioneer Network was formed in 1997 by a small group of prominent professionals (including dietitians) working in long-term care to advocate for person-directed care. This group called for a radical change in the culture of aging so that when our grandparents, parents—and ultimately we—go to a nursing home or other community-based setting, it is to thrive, not to decline. This movement, away from institutional provider-driven models to more humane consumer-driven models that embrace flexibility and self-determination, has come to be known as the *long-term care culture change movement*. The belief is that the quality of life and living for older Americans is rooted in a supportive community and cemented by relationships that respect each individual regardless of age, medical condition, or limitations.

The mission of the Pioneer Network is to

- Create communication, networking, and learning opportunities
- Build and support relationships and community
- Identify and promote transformations in practice, services, public policy, and research
- Develop and provide access to resources and leadership

Values and Principles

- Know each person.
- Each person can and does make a difference.
- Relationship is the fundamental building block of a transformed culture.
- Respond to spirit, as well as mind and body.
- Risk taking is a normal part of life.
- Put person before task.
- All elders are entitled to self-determination wherever they live.
- Community is the antidote to institutionalization.
- Do unto others as you would have them do unto you.
- Promote the growth and development of all.
- Shape and use the potential of the environment in all its aspects: physical, organizational, psycho/social/spiritual.
- Practice self-examination, searching for new creativity and opportunities for doing better.
- Recognize that culture change and transformation are not destinations but a journey, always a work in progress. <https://www.pioneernetwork.net/>

Functionality

Functionality and *functional status* are terms used to describe physical abilities and limitations in, for example, ambulation. **Functionality**, the ability to perform self-care, self-maintenance, and physical activities, correlates with independence and quality of life. Disability rates among older adults are declining, but the actual number considered disabled is increasing as the size of the aging population grows. Limitations in **activities of**

daily living (ADLs) (toileting, bathing, eating, dressing) and **instrumental activities of daily living (IADLs)** such as managing money, shopping, telephone use, travel in community, housekeeping, preparing meals, taking medications correctly, and other individual self-performance skills needed in everyday life, are used to monitor physical function ([Federal Interagency Forum on Aging-Related Statistics, 2012](#)).

Many nutrition-related diseases affect functional status in older individuals. Inadequate nutrient intake may hasten loss of muscle mass and strength, which can have a negative effect on performing ADLs. Among the older adults who have one or more nutrition-related chronic diseases, impaired physical function may cause greater disability, with increased morbidity, nursing home admissions, or death.

Frailty and Failure to Thrive

The four syndromes known to be predictive of adverse outcomes in older adults that are prevalent in patients with frailty or “geriatric failure to thrive” include impaired physical functioning, malnutrition, depression, and cognitive impairment. Symptoms include weight loss, decreased appetite, poor nutrition, dehydration, inactivity, and impaired immune function. Interventions should be directed at easily remediable contributors in the hope of improving overall functional status. Optimal management requires a multidisciplinary multifaceted approach. Occupational therapists and speech therapists are essential to comprehensive care management. Nutrition interventions, especially those rectifying protein-energy malnutrition (PEM), are essential but often difficult to implement in an older person who is disinterested in eating. Because overall diet quality has been shown to be associated inversely with prevalent and future frailty status in a large cohort of community-living older men, more attention to the total dietary intakes when advancing age is critical ([Galvin and Sadowsky, 2012](#)). Liberalization of overly restrictive diet prescriptions is often key to improving calorie intake and dietary quality ([American Dietetic Association \[ADA\], 2010](#)).

Weight Maintenance

Obesity

The prevalence of obesity in all ages has increased during the past 25 years in the United States; older adults are no exception. Obesity rates are greater among those ages 65 to 74 than among those age 75 and older. Obesity is a major cause of preventable disease and premature death. Both are linked to increased risk of coronary heart disease; type 2 diabetes; endometrial, colon, postmenopausal breast, and other cancers; asthma and other respiratory problems; osteoarthritis; and disability ([Flicker et al, 2010](#)). Obesity causes a progressive decline in physical function, which may lead to increased frailty. Overweight and obesity can lead to a decline in IADLs.

Weight loss therapy that maintains muscle and bone mass is recommended for obese older adults because it improves physical function and quality of life and reduces the multiple medical complications associated with obesity. Lifestyle changes that include diet, physical activity, and behavior modification techniques are the most effective. The goals of weight loss and management for adults are the same for the general population and should include prevention of further weight gain, or reduction of body weight, and maintenance of long-term weight loss (see Chapter 21).

Weight loss of 10% of total body weight over 6 months should be the initial goal. After that, strategies for maintenance

should be implemented. Dietary changes include an energy deficit of 500 to 1000 kcal/day. Calorie restriction should not be less than 1200 kcal/day. It is critical for the older adult on a calorie-restricted diet to meet nutrient requirements. This may necessitate the use of a multivitamin or mineral supplement as well as nutrition education.

Being overweight after age 70 may be health protective. A study reviewed data from two long-term studies and found that adults who were overweight averaged a 13% lower risk of death from any cause over 10 years, compared with those who were normal weight ([Flicker et al, 2010](#)). Those who were underweight were 76% more likely to die (see later in this chapter), although the obese had the same mortality risk as those of normal weight. The researchers concluded that the BMI thresholds for overweight and obese may be overly restrictive for older adults. Notably, the researchers also found that being sedentary increased the risk of death in men by 28%; in women, the risk was doubled.

Underweight and Malnutrition

The actual prevalence of underweight among older adults is low; women older than age 65 are three times as likely as their male counterparts to be underweight ([Winter et al, 2014](#)). However, many older adults are at risk for undernutrition and malnutrition ([Federal Interagency Forum on Aging-Related Statistics, 2012](#)). Among those hospitalized, 40% to 60% are malnourished or at risk for malnutrition, 40% to 85% of nursing home residents have malnutrition, and 20% to 60% of home care patients are malnourished. Many community-residing older persons consume fewer than 1000 kcal/day, an amount not adequate to maintain good nutrition. Some causes of undernutrition include medications, depression, decreased sense of taste or smell, poor oral health, chronic diseases, dysphagia, and other physical problems that make eating difficult. Social causes may include living alone, inadequate income, lack of transportation, and limitations in shopping for and preparing food.

Health care professionals frequently overlook protein-energy malnutrition (PEM). The physiologic changes of aging, as well as changes in living conditions and income, contribute to the problem. Symptoms of PEM often are attributed to other conditions, leading to misdiagnosis. Some common symptoms are confusion, fatigue, and weakness. Older adults with low incomes, who have difficulty chewing and swallowing meat, who smoke, or engage in little or no physical activity are at increased risk of developing PEM.

Strategies to decrease PEM include increased caloric and protein intake. The Practice Paper for dietitians provides a variety of approaches that can be used in residential facilities ([ADA, 2010](#)). In a long-term care clinical setting oral medical nutrition supplements and enteral feedings may be considered but should be the last resort. Reliance on medical nutritional supplements actually may affect the elderly negatively. It is important that people continue to smell and chew real food.

In community settings older adults should be encouraged to eat energy-dense and high-protein foods. Federal food and nutrition services are also available for the many who reside at home (see sections below) (See *Focus On: Food First!*). Diet restrictions should be liberalized to offer more choices ([ADA, 2010](#)). Simple practical approaches, such as adding gravies and creams, can increase calories and soften foods for easier chewing.

FOCUS ON

Food First!

Digna Cassens, MHA, RDN

There are many reasons for practitioners to consider changing from the use of commercially manufactured nutritional supplements to nutrient-dense real food. Although commercial nutritional supplements are convenient to use and provide high calories and high protein, people like to eat food and drink fluids that taste good, provide a variety of flavors, and are familiar to them. Food is more than a can of soy protein with added vitamins and minerals, it is culture, tradition, and part of life celebrations. The smell of food and appearance on a plate is part of the overall eating experience.

Fortified foods at meals and snack time in lieu of commercially prepared supplements can satisfy the most demanding palate because they can be flexible and individualized. Virtually any food can be calorie enhanced; many can be protein enhanced.

Fortified food programs have been known by a variety of names: Every Bite Counts, Nutrition Intervention Program, Enhanced Food Program, Super Foods, or Food Fortification Program. Today, thanks to the Dining Practice Standards published in 2011 and adopted by the Centers for Medicare and Medicaid, **Food First!** is the term of choice for this approach. Traditionally, fortified food programs have focused on adding calories and protein to a couple of foods on the menu each day. For example, cream is added to hot cereal and powdered milk is added to milk (double-strength milk). This approach can lead to lack of variety and food fatigue. A program approach to fortifying food will provide more flexibility and ultimately be more successful.

Modified from www.flavorfulfortifiedfood.com.

NUTRITION SCREENING AND ASSESSMENT

Simple and easy-to-use nutrition screening tools have been validated (Skipper et al, 2012). However, the physical and metabolic changes of aging can yield inaccurate results. Examples are anthropometric measurements: height and weight, and BMI. A meta-analysis of BMI and all-cause mortality concluded that being overweight was not associated with an increased risk of mortality in older populations. The mortality risk increased in underweight older people, those with a BMI of less than 23 (Winter et al, 2014).

With aging, fat mass increases and height decreases as a result of vertebral compression. An accurate height measure may be difficult in those unable to stand up straight, the bed bound, those with spinal deformations such as a dowager's hump, and those with osteoporosis. Measuring arm span or knee height may give more accurate measurements (see Appendix 15). BMIs based on questionable heights are inaccurate. Clinical judgment is needed for accuracy.

The Mini Nutritional Assessment (MNA) includes two forms: a screening Short Form (MNA-SF) and the full assessment (Kaiser et al, 2009). The validated MNA-SF is the most widely used screening method to identify malnutrition in non-institutionalized older adults (see Figure 4-5). It includes six questions and a body mass index (BMI) evaluation, or a calf circumference if a BMI is not possible. The MNA-SF is being used as a screening assessment tool in long-term care and is especially useful in the short stay units.

NUTRITION NEEDS

Many older adults have special nutrient requirements because aging affects absorption, use, and excretion of nutrients (Bernstein et al, 2012). The dietary reference intakes (DRIs) separate the cohort of people age 50 and older into two groups, ages 50 to 70 and 71 and older. Based on the Healthy Eating Index, older Americans need to a) increase their intakes of whole grains, dark green and orange vegetables, legumes, and milk; b) choose more nutrient-dense forms of foods, that is, foods low in solid fats and free of added sugars; and c) lower their intake of sodium and saturated fat. Other studies show that older persons have low intakes of calories, total fat, fiber, calcium, magnesium, zinc, copper, folate, and vitamins B₁₂, C, E, and D. Box 20-1 lists the Key Recommendations for Older Adults as specified in the 2010 Dietary Guidelines for Americans. A MyPlate for Older Adults that corresponds to the 2010 Guidelines is available online (Lichtenstein, 2014).

The Mifflin-St. Jeor energy equation can be used to assess calorie needs in healthy older adults (see Chapter 2). The DRI tables (see Table 20-3 and inside cover) also can be used. DRIs for energy suggest 3067 kcal/day for men and 2403/day for

BOX 20-1 Dietary Guidelines for Americans 2010

Key Recommendations for Older Adults

- **Maintain calorie balance over the lifetime to achieve and sustain a healthy weight.** Healthy eating patterns limit intake of sodium, solid fats, added sugars, and refined grains. Increased physical activity and reduced time spent in sedentary behaviors are also desired.
- **Focus on consuming nutrient-dense foods and beverages.** A healthy eating pattern emphasizes nutrient-dense foods and beverages. Select fat-free or low-fat milk and milk products, seafood, lean meats and poultry, eggs, beans and peas, and nuts and seeds. Choose vegetables, fruits, whole grains, and milk and milk products for more potassium, dietary fiber, calcium, and vitamin D as nutrients of concern. Eat a variety of vegetables, especially dark-green and red and orange vegetables, beans and peas. Consume at least half of all grains as whole grains.
- **Nutrient needs should be met primarily through consuming foods.** When needed, fortified foods and dietary supplements may be useful in providing one or more nutrients that otherwise might be consumed in less than recommended amounts. Consume foods fortified with vi-

tamin B₁₂, such as fortified cereals, or dietary supplements. Two eating patterns that are beneficial are Vegetarian adaptations and the DASH (Dietary Approaches to Stop Hypertension) Eating Plan.

- **A healthy eating pattern should prevent foodborne illness.** Four basic food safety principles (Clean, Separate, Cook, and Chill) work together to reduce the risk of foodborne illnesses. In addition, some foods (such as milks, cheeses, and juices that have not been pasteurized, and undercooked animal foods) pose high risk for foodborne illness and should be avoided.
- **Use alcohol in moderation.** If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age.
- Individuals should meet the following recommendations as part of a healthy eating pattern while staying within their calorie needs.
- Information on the type and strength of evidence supporting the Dietary Guidelines recommendations can be found at <http://www.nutritionevidencelibrary.gov>.

TABLE 20-3 Nutrient Needs Change with Aging

Nutrient	Changes with Aging	Practical Solutions
Energy	Basal metabolic rate decreases with age because of changes in body composition. Energy needs decrease ~3% per decade in adults.	Encourage nutrient-dense foods in amounts appropriate for caloric needs.
Protein 0.8 g/kg minimum	Minimal change with age but research is not conclusive. Requirements vary with chronic disease, decreased absorption, and synthesis.	Protein intake should not be routinely increased; excess protein could unnecessarily stress aging kidneys.
Carbohydrates 45%-65% total calories Men 30 g fiber Women 21 g fiber	Constipation may be a serious concern for many.	Emphasize complex carbohydrates: legumes, vegetables, whole grains, fruits to provide fiber, essential vitamins, minerals. Increase dietary fiber to improve laxation especially in older adults.
Lipids 20%-35% total calories	Heart disease is a common diagnosis.	Overly severe restriction of dietary fats alters taste, texture, and enjoyment of food; can negatively affect overall diet, weight, and quality of life. Emphasize healthy fats rather restricting fat.
Vitamins and minerals	Understanding vitamin and mineral requirements, absorption, use, and excretion with aging has increased but much remains unknown.	Encourage nutrient-dense foods in amounts appropriate for caloric needs. Oxidative and inflammatory processes affecting aging reinforce the central role of micronutrients, especially antioxidants.
Vitamin B ₁₂ 2.4 mg	Risk of deficiency increases because of low intakes of vitamin B ₁₂ , and decline in gastric acid, which facilitates B ₁₂ absorption.	Those 50 and older should eat foods fortified with the crystalline form of vitamin B ₁₂ such as in fortified cereals or supplements.
Vitamin D 600-800 IU*	Risk of deficiency increases as synthesis is less efficient; skin responsiveness as well as exposure to sunlight decline; kidneys are less able to convert D ₃ to active hormone form. As many as 30%-40% of those with hip fractures are vitamin D insufficient.	Supplementation may be necessary and is inexpensive. A supplement is indicated in virtually all institutionalized older adults.
Folate 400 µg	May lower homocysteine levels; possible risk marker for atherothrombosis, Alzheimer's disease, and Parkinson's disease	Fortification of grain products has improved folate status. When supplementing with folate, must monitor B ₁₂ levels.
Calcium 1200 mg	Dietary requirement may increase because of decreased absorption; only 4% of women and 10% of men age 60 and older meet daily recommendation from food sources alone.	Recommend naturally occurring and fortified foods. Supplementation may be necessary. However, in older women, high intakes may be occurring with supplements.
Potassium 4700 mg	Potassium-rich diet can blunt the effect of sodium on blood pressure.	Recommend meeting potassium recommendation with food, especially fruits and vegetables.
Sodium 1500 mg	Risk of hypernatremia caused by dietary excess and dehydration Risk of hyponatremia caused by fluid retention	Newer evidence based on direct health outcomes is inconsistent with the recommendation to lower dietary sodium in the general population, including older adults, to 1500 mg per day. More research is needed.†
Zinc Men 11 mg Women 8 mg	Low intake associated with impaired immune function, anorexia, loss of sense of taste, delayed wound healing, and pressure ulcer development.	Encourage food sources: lean meats, oysters, dairy products, beans, peanuts, tree nuts, and seeds.
Water	Hydration status can easily be problematic. Dehydration causes decreased fluid intake, decreased kidney function, increased losses caused by increased urine output from medications (laxatives, diuretics). Symptoms: electrolyte imbalance, altered drug effects, headache, constipation, blood pressure change, dizziness, confusion, dry mouth and nose	Encourage fluid intake of at least 1500 ml/day or 1 ml per calorie consumed. Risk increases because of impaired sense of thirst, fear of incontinence, and dependence on others to get beverages. Dehydration is often unrecognized; it can present as falls, confusion, change in level of consciousness, weakness or change in functional status, or fatigue.

* National Research Council: *Dietary Reference Intakes for Calcium and Vitamin D*, Washington, DC, 2011, The National Academies Press.

†National Research Council: *Sodium intake in populations: assessment of evidence*, Washington, DC, 2013, The National Academies Press.

women 18 years; subtract 10 kcal/day for men and 7 kcal/day for women for each year of age older than 19 years.

The DRIs are not specific for protein in older adults. After age 65, the minimum protein requirement is 1 g protein/kg of body weight with newer evidence supporting up to 1.2 gm/kg. In those individuals with impaired renal function or long-standing diabetes, 0.8 g/kg to 1.0 g/kg may be more appropriate. Protein distribution evenly throughout the day with no single serving exceeding 30 g should be a goal.

MEDICARE BENEFITS

The federal Medicare program covers most of the health care costs of those 65 and older and persons with disabilities.

However, this federally funded health insurance program does not cover the entire cost of residential/institutional long-term care. A portion of payroll taxes and monthly premiums deducted from Social Security payments finance Medicare.

Medicare benefits are provided in four parts. *Part A* covers inpatient hospital care, some skilled nursing care, hospice care, and some home health care costs for limited periods of time. It is premium free for most citizens. *Part B* has a monthly premium that helps pay for doctors, outpatient hospital care, and some other care not covered by Part A (physical and occupational therapy, for example). *Part C* allows private insurers, including health maintenance organizations (HMOs) and preferred provider organizations (PPOs), to offer health insurance plans to Medicare beneficiaries. These must provide the same

benefits the original Medicare plan provides under Parts A and B. Part C HMOs and PPOs also may offer additional benefits, such as dental and vision care. *Part D* provides prescription drug benefits through private insurance companies.

The **2010 Affordable Care Act** (see Chapter 10) changed Medicare to include an annual wellness visit and a personalized prevention assessment and plan with no copayment or deductible. Prevention services include referrals to education and preventive counseling or community-based interventions to address risk factors. Thus expansion of medical nutrition therapy reimbursement for registered dietitians/nutritionists is likely. It will cover therapy considered reasonable and necessary for the prevention of an illness or disability as well as a broader array of nutrition counseling for chronic conditions. More universal access to nutrition services has implications for aging healthier and promoting quality of life and independence.

Medicaid, for qualified low-income individuals, finances a variety of long-term care services via multiple mechanisms, including Medicaid State Plans and **home and community-based services (HCBS) waivers**, Section 1915 (c). Both provide service to nursing home–appropriate older adults to help prevent or decrease nursing home or institutionalization. States may offer an unlimited variety of services under this waiver. These programs may provide traditional medical services (dental, skilled nursing) and nonmedical services (meal delivery, case management, environmental modifications). States have the discretion to choose the number of older persons served and the services offered.

Program of All-Inclusive Care for the Elderly (PACE) is a comprehensive managed care system for people over 55 who are nursing home eligible and who meet low income criteria. The program is funded through Medicare and Medicaid. Coordinated preventive, primary, acute and long-term care services allow older adults to remain in their homes for as long as possible (Thomas and Burkemper, 2013). The PACE model is based on the belief that it is better for the well-being of older adults with chronic care needs to be served in the community whenever possible. PACE is multidisciplinary and includes dietitian services. There are more than 100 PACE Programs nationwide.

PACE Programs and HCBS waiver reflect federal commitments to delay or avoid nursing home placement whenever possible. The U.S. Administration on Aging is now under the new umbrella of the U.S. Administration on Community Living. Terms such as “aging in community,” “communitarian alternatives,” “age-friendly living,” “care circles,” and especially “**long-term services and supports**” (LSS) (versus “long-term care”) are indicative of the transformations taking place in the more positive approaches to aging (Bernstein et al, 2012; Rudolph, 2009).

NUTRITION SUPPORT SERVICES

U.S. Department of Health and Human Services Older Americans Act (OAA) Nutrition Program

The OAA Nutrition Program is the largest, most visible, federally funded community-based nutrition program for older persons (Lloyd and Wellman, 2015). Primarily a state-run program, it has few federal regulations and considerable variation in state-to-state policies and procedures. This nutrition program provides congregate and home-delivered meals (usually

5 days per week), nutrition screening, education, and counseling, as well as an array of other supportive and health services. Although frequently called *meals on wheels*, that term accurately refers *only* to the home-delivered meals. Participants are poorer, older, sicker, frailer, more likely to live alone, be members of minority groups, and live in rural areas. The OAA Nutrition Program, available to all persons age 60 and older regardless of income, successfully targets those in greatest economic and social need, with particular attention to low-income minorities and rural populations. Unfortunately, the program reaches fewer than 5% of older Americans, and those are served an average of fewer than three meals per week because of budget constraints. However, if all states had increased by 1% the number of adults age 65 and older who received home-delivered meals in 2009, total annual savings to states’ Medicaid programs could have exceeded \$109 million (Thomas and Mor, 2013). The savings would come from decreased Medicaid spending on those with low care needs because they would no longer require nursing home care. The Nutrition Program has neither received the research or evaluation attention that a program its size deserves nor the growth in federal funding to keep pace with inflation and the growing numbers of older adults (Wellman, 2010).

More than half of the OAA annual budget supports the nutrition program, which provides about 224 million congregate and home-delivered meals to 2.5 million older adults annually (U.S. Administration on Aging, 2014). Home-delivered meals have grown to more than 61% of all meals served; almost half of the programs have waiting lists. To receive home-delivered meals, an individual must be assessed to be homebound or otherwise isolated. Home-delivered meal recipients are especially frail; half are at high nutrition risk or are malnourished and approximately one third qualify as nursing home appropriate.

At congregate sites, the nutrition program provides access and linkages to other community-based services. It is the primary source of food and nutrients for many program participants and presents opportunities for active social engagement and meaningful volunteer roles.

For the majority of program participants, the meal provides half or more of their total food for the day. Thus participants have higher daily intakes of key nutrients than similar nonparticipants. The meals are nutritionally dense per calorie and each meal supplies more than 33% of the recommended dietary allowances (an OAA requirement) and provides 40% to 50% of daily intakes of most nutrients (Lloyd and Wellman, 2015). Otherwise, inadequate nutrient intake affects approximately 37% to 40% of community-dwelling individuals 65 years of age and older (Lloyd and Wellman, 2015).

The OAA Nutrition Program is closely linked to **home- and community-based services (HCBS)** through cross-referrals within the Aging Network. Because older adults are being discharged earlier from hospitals and nursing homes, many require a care plan that includes home-delivered meals and other nutrition services (e.g., nutrition screening, assessment, education, counseling, and care planning). Many states are creating programs to provide necessary medical, social, and supportive HCBS, including home-delivered meals, nutrition education, and counseling services. States are being encouraged to help older adults and people with disabilities live in their homes and fully participate in their communities by the new U.S. Administration for Community Living (ACL). Its role is to build the

capacity of the national aging and disability networks to better serve older persons, caregivers, and individuals with disabilities.

USDA Food Assistance Programs

Several U.S. Department of Agriculture (USDA) food and nutrition assistance programs are available to older adults (Kamp et al, 2010). All USDA programs are means tested (i.e., recipients must meet income criteria). Several of these programs, for example, the Supplemental Nutrition Assistance Program (SNAP, formerly food stamps), are discussed in Chapter 9.

Commodity Supplemental Food Program

The Commodity Supplemental Food Program (CSFP) strives to improve the health of low-income Americans by supplementing their diets with nutritious USDA commodity foods. It provides food and administrative funds to states, but not all are enrolled. In states, CSFP administration may be located in diverse sites such as public health, nutrition services, or agriculture departments. Eligible populations include adults age 60 and older with incomes less than 130% of the poverty level. Local CSFP agencies determine eligibility, distribute the foods, and provide nutrition education. The food packages do not provide a complete diet but may be good sources of nutrients frequently lacking in low-income diets.

Seniors Farmers' Market Nutrition Program

The Seniors Farmers' Market Nutrition Program (SFMNP) is administered by state departments of agriculture, aging and disability services, health and human service, markets, public health, state units on aging, or state food and nutrition services. SFMNP provides coupons to low-income older individuals to purchase fresh, unprepared foods at farmers' markets, roadside stands, and community-supported agriculture programs. It provides eligible older adults with local, seasonal access to fresh fruits, vegetables, and fresh-cut herbs as well as nutrition education and information.

Medicaid and Nutrition Services

The Social Security Act suggests seven core HCBS waiver program services: case management, homemaker services, home health aide services, personal care services, adult day health, rehabilitation, and respite care. Nutrition service is not a core Medicaid service. Older persons who are eligible for nursing home placement are not usually able to shop for food, store food safely, or plan and prepare nutritionally appropriate meals. Thus a strong argument can be made to fund all or some meals and nutrition services based on health and nutrition risk criteria. However, not all states include meals or nutrition services among the specified benefits available through Medicaid waivers. Approved nutrition services include home-delivered meals, nutrition risk reduction counseling, and in some cases, nutritional supplements.

COMMUNITY AND RESIDENTIAL FACILITIES FOR OLDER ADULTS

The report *Long-term Care Services in the United States* found that about 58,500 paid, regulated long-term care services providers served about 8 million people (Harris-Kojetin et al, 2013). Long-term care services were provided by 4800 adult day services centers, 12,200 home health agencies, 3700 hospices, 15,700

nursing homes, and 22,200 assisted living and similar residential care communities. Each day, there are more than 273,200 participants enrolled in adult day services centers, 1,383,700 residents in skilled nursing facilities (SNFs), and 713,300 residents in residential care communities; in 2011, about 4,742,500 patients received services from home health agencies, and 1,244,500 patients received services from hospices.

People move to residential facilities, generally known as assisted living, when they can no longer safely live alone because they have some cognitive impairment requiring supervision or need help with ADLs because of immobility. Care is provided in ways that promote maximum independence and dignity. Assisted living care's annual cost is about half that of nursing homes (MetLife Mature Market Institute, 2012). Residents are encouraged to maintain active social lives with planned activities, exercise classes, religious and social functions, and field trips directed by the facilities. These communities are now required in some states to provide therapeutic diets but in those states without such regulation residents have difficulty getting special requirements met.

Comprehensive state regulations for food and nutrition services in assisted living care is not yet widespread, but there is early consensus of what should be regulated (Chao et al, 2009). Emphasizing that food and nutrition matter at every age, it is essential that support for nutrition and quality of life extend beyond food availability and safety. Dietitian expertise is needed for nutrition assessment and care planning to meet special needs such as type and amounts of macronutrients and micronutrients, texture modifications, and quality of food choices and presentation.

Only about 3% or 1.4 million older adults live in the approximately 15,700 nursing homes (Harris-Kojetin et al, 2013). The percentage of the population that lives in nursing homes increases dramatically with age, especially for those older than age 85. However, the overall percentage has declined since 1990, likely because of healthier aging, the federal cost-containment policy to delay residential placement in nursing homes by providing more aging services in the community, as well as the increased availability and use of hospice. The percentage increases dramatically with age, ranging from 1% for persons age 65 to 74 years to 3% for persons age 75 to 84 years and 10% for persons age 85. The average annual cost is \$90,500 (MetLife Mature Market Institute, 2012).

SNFs are federally regulated by the Centers for Medicare and Medicaid Services; assisted living centers, by each state. More residents are in SNFs for short-stay, postacute care; thus more comprehensive medical nutrition therapy is now needed. Nutritional care is directed toward identifying and responding to changing physiologic and psychologic needs over time that protect against avoidable decline.

The culture change movement in long-term care has led to the creation of the Dining Practice Standards (DPS). The DPS were published by the Pioneer Network's Dining Clinical Task Force and have been endorsed by CMS and over a dozen professional groups, including the AND. They provide evidence-based support for resident-centered dining, for liberalized diets, for the use of real food rather than medical nutritional supplements, and for the incorporation of these standards into the CMS survey process.

In 1987 Congress passed reform legislation as part of the Omnibus Reconciliation Act (OBRA) to improve the quality of

care in SNFs by strengthening standards that must be met for Medicare/Medicaid reimbursement. Since that time SNFs have been required by CMS to conduct periodic assessments to determine the residents' needs; to provide services that ensure residents maintain the highest practical physical, mental, and psychologic well-being; and to ensure that no harm is inflicted. This is accomplished using the **Minimum Data Set (MDS)**, which is part of the federally mandated process for clinical assessment of residents of LTC facilities licensed under Medicare or Medicaid. Section K of the MDS is specific to nutrition and is generally the responsibility of the dietitian to complete but can be done by nursing staff (see **Figure 20-4**). This form documents "triggers" that may place a resident at nutrition risk and therefore requires an intervention. This assessment must be

done at admission and if there is a significant change in the resident's condition such as weight loss or skin breakdown. Reassessment is required quarterly and annually. The entire process is known as the **Resident Assessment Instrument (RAI)**. It provides the individual assessment of each resident's functional capabilities and helps identify problems and develop a care plan.

High nutrition risk individuals must be identified and assessed monthly by the dietitian. High risk is defined as:

- Significant weight loss defined as 5% of body weight in 1 month or 10% of body weight in 6 months
- Nutrition support (tube feedings or parenteral nutrition)
- Dialysis patients
- Wounds or pressure ulcers

Section K		Swallowing/Nutritional Status

	2. 501 cc/day or more		

FIGURE 20-4 The Minimum Data Set, Section K version 3.0. (From the Centers for Medicare & Medicaid Services, Baltimore, MD.)

CLINICAL CASE STUDY

MF is an 86-year-old Caucasian female resident in a skilled nursing facility with unintentional weight loss. She was admitted 3 months ago from the hospital after a hip fracture. She had been residing in an independent living facility for several years. She reports she has been eating poorly because of difficulty moving around, being generally uncomfortable, and states, "If I am not active I don't need to eat so much." Intake is less than 50% of regular diet. No problems chewing or swallowing are noted after a speech language pathologist's evaluation. Admission weight was 112 pounds; current weight is 95 pounds. Self-reported height is 5'3"; Hgb/Hct, normal; total cholesterol, 135; and Mini Nutrition Assessment score, 5. Hip scans show slow fracture healing and no improvement in bone density; currently she is being supplemented with calcium 1000 mg/day and vitamin D 600 IU/day. Blood pressure, 128/80 with furosemide (Lasix); other medications are lorazepam (Ativan), fentanyl transdermal patch (Duragesic), senna (Senokot-S), docusate (Colace), and mirtazapine (Remeron).

Nutrition Diagnostic Statement

Unintentional weight loss related to food intake of less than 50% of meals with limited physical activity as evidenced by weight loss of 17 lb.

Nutrition Case Study Questions

1. Comment on the appropriateness of and use for each medication. Would you suggest any changes or additional medications?
2. What strategies could you use to help improve this resident's food and fluid intake?
3. What suggestions are appropriate to promote fracture healing and increase bone density?
4. Do you suspect that this client is constipated? What would you recommend in terms of food choices to deal with this?

Nutrition for Health and Fitness

The chapters in this section reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge to the concepts that relate nutrition, to the prevention of chronic and degenerative diseases, and to optimization of health and performance.

The relationship between nutrition and dental disease has long been recognized. In more recent decades the possibility of reducing the incidence of osteoporosis by emphasizing appropriate nutrition has accumulated supportive evidence. Medical research now shows the role of nutrition on gene expression; dietary intake can turn on or turn off the inflammatory process, a key factor in disease onset and management.

Weight management and exercise form the basis for a great deal of nutrition in health, fitness, and disease prevention. Understanding the role of nutrition in sports and in optimizing performance has led to dietary and exercise practices generally applicable to a rewarding, healthy lifestyle.

The opportunities for members of an affluent society to choose from a great variety of foods has led to an overabundant intake of energy for many individuals. Efforts to reduce body weight, widely pursued with varying degrees of enthusiasm and diligence, are often disheartening, making the knowledge presented here so important. Frustration with dieting and stress often lead to eating disorders, which are increasing in frequency and require attention and understanding from the nutrition professional.

Nutrition in Weight Management

*Lucinda K. Lysen, RDN, RN, BSN
Donna A. Israel, PhD, RDN, LPC, FADA, FAND*

KEY TERMS

abdominal fat	hyperphagia	nonexercise activity thermogenesis (NEAT)
activity thermogenesis (AT)	hyperplasia	nutritional genomics
adipocyte	hypertrophy	obesity
adipocytokines or adipokines	hypophagia	obesogen
adiposity rebound	incretin	overweight
android fat distribution	insulin	sensory-specific satiety
bariatric surgery	laparoscopic sleeve gastrectomy (LSG)	set point theory
body mass index (BMI)	lean body mass (LBM)	storage fat
brown adipose tissue (BAT)	leptin	semivolatile organic compounds (SVOCs)
comorbidities	lifestyle modification	underweight
essential fat	lipogenesis	vagus nerve
fat mass	lipoprotein lipase (LPL)	very low-calorie diet (VLCD)
fat-free mass (FFM)	liposuction	visceral adipose tissue (VAT)
gastric banding	metabolic syndrome (MetS)	white adipose tissue (WAT)
gastric bypass	morbid obesity	yo-yo effect
gastroplasty	night-eating syndrome (NES)	
ghrelin	nonalcoholic fatty liver disease (NAFLD)	
gynoid fat distribution		
hormone-sensitive lipase (HSL)		

Body weight is the sum of bone, muscle, organs, body fluids, and adipose tissue. Some or all of these components are subject to normal change as a reflection of growth, reproductive status, variation in physical activity, and the effects of aging. Consistent body weight is orchestrated by neural, hormonal, and chemical mechanisms as well as individual genetic polymorphisms that balance energy intake and expenditure within fairly precise limits. Abnormalities of these complex mechanisms can result in weight fluctuations.

On one end of the weight spectrum is underweight. Although the inability to gain weight can be a primary problem, low body weight is usually secondary to a disease state, an eating disorder, or a psychiatric disorder. In the elderly or in children, unintentional weight loss can be especially detrimental and should be addressed early to prevent malnutrition or other undesirable consequences. Most crucial is the in utero development of the fetus. Babies deprived of nutrition before birth and who have low birth weight may be primed for accelerated growth after birth when exposed to a nutrient-rich environment (which often consists of infant formula). Furthermore, inadequate passage of nutrients across the placenta and

low birth weight eventually can lead to an increased risk of developing obesity and diabetes (Apovian, 2011).

On the other end of the spectrum and more common, are the conditions of overweight and obesity.

BODY WEIGHT COMPONENTS

Body weight often is described in terms of its composition, and different models have been advanced to estimate body fat. Assessment of body composition is discussed in detail in Chapter 7. Traditionally, a two-compartment model divides the body into **fat mass**, the fat from all body sources including the brain, skeleton, and adipose tissue, and **fat-free mass (FFM)**, which includes water, protein, and mineral components (see Figure 21-1). The proportions of FFM are relatively constant from person to person.

Although *FFM* often is used interchangeably with the term lean body mass, it is not exactly the same. **Lean body mass (LBM)** is muscle. LBM is higher in men than in women, increases with exercise, and is lower in older adults. It is the major determinant of the resting metabolic rate (RMR).

FIGURE 21-1 The components of fat-free mass in the body.

It follows that a decrease in LBM could hinder the progress of weight loss. Therefore, to achieve long-term weight loss, the loss of fat mass while maintaining FFM is desirable. Water, which makes up 60% to 65% of body weight, is the most variable component of LBM, and the state of hydration can induce fluctuations of several pounds.

Body Fat

Total body fat is the combination of “essential” and “storage” fats, usually expressed as a percentage of total body weight that is associated with optimum health. Muscle and even skeletal mass adjust to some extent to support the burden of adipose tissue.

Essential fat, necessary for normal physiologic functioning, is stored in small amounts in the bone marrow, heart, lung, liver, spleen, kidneys, muscles, and the nervous system. In men, approximately 3% of body fat is essential. In women, essential fat is higher (12%) because it includes body fat in the breasts, pelvic regions, and thighs that supports the reproductive process.

Storage fat is the energy reserve, primarily as triglycerides (TGs), in adipose tissue. This fat accumulates under the skin and around the internal organs to protect them from trauma. Most storage fat is “expendable.” The fat stores in adipocytes are capable of extensive variation. This allows for the changing requirements of growth, reproduction, aging, environmental and physiologic circumstances, the availability of food, and the demands of physical activity. Total body fat (essential fat plus storage fat) as a percentage of body weight associated with the average individual is between 18% and 24% for men and 25% and 31% for women. On the other extreme, “elite fit” men are as low as 2% to 5% body fat and women 10% to 13% (Digate Muth, 2014).

Adipose Tissue Composition

Adipose tissue exerts a profound influence on whole-body homeostasis. Adipose tissue is located primarily under the skin, in the mesenteries and omentum, and behind the peritoneum. This is often referred to as **visceral adipose tissue (VAT)**. Although it is primarily fat, adipose tissue also contains small amounts of protein and water. **White adipose tissue (WAT)** stores energy as a repository for TGs, cushions abdominal organs, and insulates the body to preserve heat. Carotene gives it

a slight yellow color. **Brown adipose tissue (BAT)** can be found in a substantial proportion of adults in small amounts as well as in infants. Unlike WAT, BAT is made of small droplets and many more iron-containing mitochondria, which makes it brown. In adults, it plays a role in controlling energy expenditure. In newborns, it provides body heat. Although WAT stores energy, BAT helps regulate body temperature by regulating heat (Apovian, 2011). It is found mainly in scapular and subscapular areas.

Adipocyte Size and Number

The mature fat cell (**adipocyte**) consists of a large central lipid droplet surrounded by a thin rim of cytoplasm, which contains the nucleus and the mitochondria. These cells can store fat equal to 80% to 95% of their volume. Gains in weight and adipose tissue occur by increasing the number of cells, the size of cells as lipid is added, or a combination of the two.

Hyperplasia (increased number of cells) occurs as a normal growth process during infancy and adolescence. Cell number increases in lean and obese children into adolescence, but the number increases faster in obese children. In teens and adults, increases in fat cell size are more common, but hyperplasia also can occur after the fat content of existing cells has reached capacity.

During normal growth, the greatest percentage of body fat (approximately 25%) is set by 6 months of age. In lean children, fat cell size then decreases; this decrease does not occur in obese children. At the age of 6 years in lean children, **adiposity rebound** occurs, especially in girls, with an increase in body fat. An early adiposity rebound occurring before five and a half years old is predictive of a higher level of adiposity at 16 years of age and in adulthood; a period of later rebound is correlated with normal adult weight (Rolland-Cachera, 2005).

With **hypertrophy** (increased cell size), fat depots can expand as much as 1000 times at any age, as long as space is available. In a classic study Bjorntorp and Sjostrom (1971) demonstrated, using weight loss as a result of trauma, illness, or starvation, that fat cell size decreases but cell numbers remain the same. Although weight loss of any amount in severely obese individuals improves basic adipocyte physiology, a weight loss of at least 5% is required to decrease fat cell size (Varady et al, 2009).

Fat Storage

Most depot fat comes directly from dietary TGs. The fatty acid composition of adipose tissue mirrors the fatty acid composition of the diet. Even excess dietary carbohydrate and protein are converted to fatty acids in the liver by the comparatively inefficient process of **lipogenesis**. Under normal conditions, little dietary carbohydrate is used to produce adipose tissue; three times more energy is required to convert excess energy from carbohydrate to fat storage compared with dietary fat.

Semivolatile organic compounds (SVOCs) accumulate in adipose tissues from exposure to toxins, chemicals, and pesticides. When adipose tissue is mobilized during weight loss, SVOCs are released (see *Clinical Insight: What's in That Fat When You Lose It?*). The effect of SVOCs on the developing fetal brain is not yet known (see Chapter 15), which adds to the health concern about obese pregnant women who lose weight.

CLINICAL INSIGHT**What's in That Fat When You Lose It?****Sheila Dean, DSc, RDN, LD, CCN, CDE**

The role of toxins in obesity development and later fat loss is becoming increasingly concerning as the emerging evidence forms a plausible link between toxins and obesity. Exposure to toxins comes from two main sources: the environment (external or exogenous toxins), which includes environmental pollutants such as pesticides, industrial compounds, solvents, detergents, plasticizers, cosmetic additives, chemical additives, colorings, preservatives, flavorings, microbial toxins such as aflatoxins from peanuts, mycotoxins from molds, and bisphenol A found in plastic baby bottles, toys, and especially dental sealants; and “lifestyle chemicals,” such as alcohol, OTC drugs, and prescription drugs. It can be byproducts from food preparation such as acrylamide from French fries, nitrosamines from cold cuts and sausages, polycyclic aromatic hydrocarbons (PAHs) from charbroiled meats, trans fats from partial hydrogenation of fats and AGEs (advanced glycosylated end products) in foods in which the glucose molecule is brought to high temperatures. Toxins can also originate from the gut i.e., breakdown products of metabolism, including hormones, internal toxins such as metabolites of yeast (d-arabinitol), or gut bacteria.

Both sources of toxins can overload the body's endogenous detoxification mechanisms. When this happens, these toxins, which are often fat soluble and have an affinity for adipose tissue, are ultimately stored in the body's depot fat. This can necessitate the deposition of more fat and obesity development, or in the case of weight or fat loss, the release of these toxins can interfere with the body's functioning, placing a burden on the liver and even its ability to continue to lose more fat (Barouki, 2010; La Merrill, 2013; Tremblay et al, 2004).

Toxins alter metabolism, disrupt endocrine function, damage the mitochondria, increase inflammation and oxidative stress, lower thyroid hormones, and alter circadian rhythms and the autonomic nervous system. These all interfere with key weight control mechanisms in the body. Using a comprehensive approach to obesity, including the assessment and treatment of toxin-mediated effects can result in more effective body fat and weight management. Simple lifestyle choices, as well as medical detoxification, can reduce exposure to toxins and enhance mobilization and elimination of stored and external toxins (Hyman, 2006) (see *Focus On: Eating to Detoxify* in Chapter 19).

Lipoprotein Lipase

Dietary TG is transported to the liver by chylomicrons. Endogenous TGs, synthesized in the liver from free fatty acids (FFA) travel as part of very low-density lipoprotein particles. The enzyme **lipoprotein lipase (LPL)** moves lipid from the blood into the adipose cell, by hydrolyzing TGs into free fatty acids and glycerol. Glycerol proceeds to the liver; fatty acids enter the adipocyte and are reesterified into TGs. When needed by other cells, TGs are hydrolyzed once again to fatty acids and glycerol by **hormone-sensitive lipase (HSL)** within the adipose cell; they then are released into the circulation.

Hormones affect LPL activity in different adipose tissue regions. Estrogens stimulate LPL activity in the gluteofemoral adipocytes, and thus promote fat storage in this area for childbearing and lactation. In the presence of sex steroid hormones, a normal distribution of body fat exists. With a decrease in sex steroid hormones—as occurs with menopause or gonadectomy—central obesity tends to develop.

REGULATION OF BODY WEIGHT

Neurochemicals, body fat stores, protein mass, hormones, and postingestion factors play a role in regulating intake and weight. Regulation takes place on a short-term and a long-term basis. Short-term regulation governs consumption of food from meal

to meal; long-term regulation is controlled by the availability of adipose stores and hormone responses.

Metabolic Rate and Voluntary Activity

The resting metabolic rate (RMR) (see Chapter 2) explains 60% to 70% of total energy expenditure. RMR declines with age or with restriction of energy intake. When the body suddenly is deprived of adequate energy from involuntary or deliberate starvation, the body conserves energy by dropping its RMR as rapidly as 15% in 2 weeks.

Activity thermogenesis (AT) is the energy expended in voluntary activity, the most variable component of energy expenditure. Under normal circumstances physical activity accounts for 15% to 30% of total energy expenditure. However, all activity counts. **Nonexercise activity thermogenesis (NEAT)** is the energy expended for all activity that is not sleeping, eating, or sports-like exercise. It includes going to work, typing, doing yard work, toe-tapping, even fidgeting (see Chapter 2). NEAT and a sedentary lifestyle may have profound importance in weight management. NEAT varies as much as 2000 kcal/day between individuals (Levine, 2007). To reverse obesity, individual strategies should promote standing and ambulating for 2.5 hours per day and should also reengineer work, school, and home environments to support a more active lifestyle (Levine, 2007).

Short- and Long-Term Regulation

Short-term controls are concerned primarily with factors governing hunger, appetite, and satiety. Satiety is associated with the postprandial state when excess food is being stored. Hunger is associated with the postabsorptive state when those stores are being mobilized. Physical triggers for hunger are much stronger than those for satiety; it is easier to override the signals for satiety.

When either overfeeding or underfeeding occurs, younger individuals exhibit spontaneous **hypophagia** (undereating) or **hyperphagia** (overeating) accordingly. Older individuals do not have the same responsiveness; they are more vulnerable to unexplained weight losses or gains because they are unable to control spontaneous, short-term changes in food intake.

Long-term regulation seems to involve a feedback mechanism in which a signal from the adipose mass is released when “normal” body composition is disturbed, as when weight loss occurs. **Adipocytokines or adipokines** are proteins released by the adipose cell into the bloodstream that act as signaling molecules. Younger persons have more responsiveness to this feedback than older adults do (see Table 21-1 and *Focus On: Signals from a Host of Hormones*).

Set Point Theory

Fat storage in non-obese adults appears to be regulated in a manner that preserves a specific body weight. In animals and humans, deliberate efforts to starve or overfeed are followed by a rapid return to the original body weight, a “set point.” According to the **set point theory**, body weight remains remarkably stable from internal regulatory mechanisms that are genetically determined. Emerging evidence from the bariatric surgery experience suggests that this drastic approach to weight loss may result in a new set point by altering anatomy and physiology (Farias 2011). More research is needed to establish definitively that there is a set point for weight.

TABLE 21-1 Regulatory Factors Involved in Eating and Weight Management

Brain Neurotransmitters	Characteristics and Function
Norepinephrine and dopamine	Released by the SNS in response to dietary intake; mediates the activity of areas in the hypothalamus that govern feeding behavior. Fasting and semi-starvation lead to decreased SNS activity and increased adrenal medullary activity with a consequent increase in epinephrine, which fosters substrate mobilization. Dopaminergic pathways in the brain play a role in the reinforcement properties of food.
Serotonin, neuropeptide Y, and endorphins	Decreases in serotonin and increases in neuropeptide Y have been associated with an increase in carbohydrate appetite. Neuropeptide Y increases during food deprivation; it may be a factor leading to an increase in appetite after dieting. Preferences and cravings for sweet, high-fat foods observed among obese and bulimic patients involve the endorphin system.
CRF	Involved in controlling adrenocorticotrophic hormone release from the pituitary gland; CRF is a potent anorexic agent and weakens the feeding response produced by norepinephrine and neuropeptide Y. CRF is released during exercise.
Orexin (hypocretin)	Orexin is a neurotransmitter produced by the hypothalamus that has a weak resemblance to secretin produced in the gut and is an appetite stimulant and central regulator of glucose and energy homeostasis.
Gut Hormones	Characteristics and Function
Incretins	Gastrointestinal peptides increase the amount of insulin released from the beta cells of the pancreas after eating, even before blood glucose levels become elevated. They also slow the rate of absorption by reducing gastric emptying and may directly reduce food intake. Incretins also inhibit glucagon release from the alpha cells of the pancreas. (See GLP-1 and GIP)
CCK	Released by the intestinal tract when fats and proteins reach the small intestine, receptors for CCK have been found in the gastrointestinal tract and the brain. CCK causes the gallbladder to contract and stimulates the pancreas to release enzymes. At the brain level, CCK inhibits food intake.
Bombesin	Released by enteric neurons; reduces food intake and enhances the release of CCK.
Enterostatin	A portion of pancreatic lipase involved specifically with satiety after the consumption of fat.
Adiponectin	An adipocytokine secreted by the adipose tissue that modulates glucose regulation and fatty acid catabolism. Levels of this hormone are inversely correlated with BMI. The hormone plays a role in metabolic disorders such as type 2 diabetes, obesity, and atherosclerosis. Levels drop after gastric bypass surgery for up to 6 months (Couce et al, 2006).
Glucagon	Increased secretion of glucagon is caused by hypoglycemia, increased levels of norepinephrine and epinephrine, increased plasma amino acids, and cholecystokinin. Decreased secretion of glucagon occurs when insulin or somatostatin is released.
Apolipoprotein A-IV	Synthesized and secreted by the intestine during lymphatic secretion of chylomicrons. After entering the circulation, a small portion of apolipoprotein A-IV enters the CNS and suppresses food consumption.
Fatty acids	Free fatty acids, triglycerides, and glycerol are factors that also affect uptake of glucose by peripheral tissues.
GLP-1 and GIP	Released by intestinal mucosa in the presence of meals rich in glucose and fat; stimulate insulin synthesis and release; GLP-1 decreases glucagon secretion, delays gastric emptying time, and may promote satiety; examples of incretin hormones.
Insulin	Acts in the CNS and the periphery nervous system to regulate food intake. Insulin is involved in the synthesis and storage of fat. Impaired insulin activity may lead to impaired thermogenesis. It is possible that obese persons with insulin resistance or deficiency have a defective glucose disposal system and a depressed level of thermogenesis. The greater the insulin resistance, the lower the thermic effect of food. Fasting insulin levels increase proportionately with the degree of obesity; however, many obese persons demonstrate insulin resistance because of a lack of response by insulin receptors, impaired glucose tolerance, and associated hyperlipidemia. These sequelae can usually be corrected with weight loss.
Leptin	An adipocytokine secreted by the adipose tissue, correlated with percent of body fat. Primary signal from energy stores; in obesity loses the ability to inhibit energy intake or to increase energy expenditure (Enriori et al, 2006). Compared with men, women have significantly higher concentrations of serum leptin.
Resistin	An adipocytokine expressed primarily in adipocytes; antagonizes insulin action (Goldstein and Scalia, 2007).
Ghrelin	Produced primarily by the stomach; acts on the hypothalamus to stimulate hunger and feeding. Ghrelin levels are highest in lean individuals and lowest in the obese. Increased levels are seen in people who are dieting, and suppressed levels are noted after gastric bypass, possibly counteracted by adiponectin (Couce et al, 2006).
PYY ₃₋₃₆	Secreted by endocrine cells lining the small bowel and colon in response to food; a "middle man" in appetite management. PYY seems to work opposite from ghrelin; it induces satiety.
IL-6 and TNF- α	Both are gut hormones. Cytokines secreted by adipose tissue and participate in metabolic events. Impair insulin signals in muscle and liver. Levels are proportional to body fat mass (Thomas and Schauer, 2010).
Oxytomodulin	Secreted from L-cells in small intestine in response to a meal. Exerts its biologic effects through activation of GLP-1 and glucantoin-related pancreatic peptide (GRPP) (Bray and Bouchard, 2014).
GLP-2	Produced in the L-cells of small intestines and in neurons of CNS. Is an intestinal growth factor. Inhibits gastric emptying and acid secretion while stimulating intestinal blood flow. Decreases gastric acid secretion and gastric emptying and increases mucosal growth (Bray and Bouchard, 2014).
FGF-21	Expressed in the liver and secreted mainly during faster and after feeding a ketogenic diet. Can decrease body weight without affecting food intake. Increases insulin sensitivity, decreases gluconeogenesis, and increases glucose uptake in adipocytes (Bray and Bouchard, 2014).

TABLE 21-1 Regulatory Factors Involved in Eating and Weight Management—cont'd

Other Hormones	Characteristics and Function
Thyroid hormones	Modulate the tissue responsiveness to the catecholamines secreted by the SNS. A decrease in triiodothyronine lowers the response to SNS activity and diminishes adaptive thermogenesis. Women should be tested for hypothyroidism, particularly after menopause. Weight regain after weight loss may be a function of a hypometabolic state; energy restriction produces a transient, hypothyroid, hypometabolic state.
Visfatin	An adipocytokine protein secreted by visceral adipose tissue that has an insulin-like effect; plasma levels increase with increasing adiposity and insulin resistance.
Adrenomedullin	A new regulatory peptide secreted by adipocytes as a result of inflammatory processes.

BMI, Body mass index; CCK, cholecystokinin; CNS, central nervous system; CRF, corticotropin-releasing factor; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide 1; IL-6, interleukin-6; PYY3-36, peptide YY₃₋₃₆; SNS, sympathetic nervous system; TNF α , tumor necrosis factor alpha.

See below for addition of gut hormones to chart.

FOCUS ON

Signals from a Host of Hormones

A host of hormones—insulin, leptin, adiponectin, and ghrelin, among others—communicate with the hypothalamus to control a person's intake and weight. These regulatory hormones govern feeding in response to signals originated in affected body tissues.

Insulin controls the amount of glucose in the blood by moving it into the cells for energy. Leptin, which is produced mainly by fat cells, contributes to long-term fullness by sensing the body's overall energy stores. Adiponectin is also made by fat cells and apparently helps the body respond better to insulin by boosting metabolism. Ghrelin, the hunger hormone, tells the brain when the stomach is empty, prompting hunger pangs and a drop in metabolism.

The stomach communicates with the brain via the **vagus nerve**, part of the autonomic nervous system that travels from the brain to the stomach. When filled with food or liquid, the stomach's stretch receptors send a message to the brain indicating satiety. Gastric bypass surgery reduces the stomach to the size of an egg, and triggers a sharp drop in ghrelin levels, which lessens hunger and oral intake (Blackburn, 2008). Unfortunately, traditional dieting tends to boost ghrelin levels.

WEIGHT IMBALANCE: OVERWEIGHT AND OBESITY

Overweight occurs as a result of an imbalance between food consumed and physical activity. Obesity is a complex issue related to lifestyle, environment, and genes. Environmental and genetic factors have a complex interaction with psychological, cultural, and physiologic influences. Over the years, many hypotheses have evolved to explain why some people become fat and others remain lean, and why it is so difficult for reduced-obese persons to maintain weight loss. No single theory can completely explain all manifestations of obesity or apply consistently to all persons.

Prevalence

Until recently, the United States has had the highest prevalence of obesity among the developed nations. However, increases in the prevalence of overweight and obesity have been observed throughout the world. For example, the number of overweight individuals in Germany is now the same percentage as the United States (English, Scharioth, 2011). The international trend often is called “globesity.”

The estimates of overweight and obesity among adults and children are based on measured weights and heights from the National Health and Nutrition Examination Survey (NHANES), conducted by the National Center for Health Statistics, Center for Disease Control and Prevention (see Figure 21-2). In the United States the 2009 to 2010 findings were that an estimated one third of adults and almost 20% of children were obese. The prevalence of obesity remains higher among African American and Hispanic populations (see *New Directions: Organizing to Solve the Childhood Obesity Problem “Within a Generation”*).

NEW DIRECTIONS

Organizing to Solve the Childhood Obesity Problem “Within a Generation”

Because the number of obese children in the United States has tripled since 1980, and obesity now rivals smoking as the largest cause of preventable death and disease, a new foundation was launched in the spring of 2010 to address this serious epidemic of childhood obesity (Ogden et al, 2010). This foundation, Partnership for a Healthier America, has as its mission the simple concept that children should have good, nutritious food to eat and the chance to be physically active every day to become healthy adults.

The objectives of the partnership are to support the national goal of solving the childhood obesity challenge “within a generation” set by First Lady Michelle Obama, who also serves as Honorary Chair of the organization. The Partnership brings together the public and private sectors, organizations, business and thought leaders, the media, and states and local communities to make meaningful and measurable commitments for fighting childhood obesity. The plan has four pillars:

- Offering parents the tools and information they need to make healthy choices for their children
- Introducing healthier food into the nation's schools
- Ensuring that all families have access to healthy, affordable food in their communities
- Increasing opportunities for children to be physically active, both in and out of school

The partnership will support, unite, and inspire families from every corner of the United States to implement and sustain the 4 pillar plan. The initiative was started with the *Let's Move!* Campaign. www.letsmove.gov/

The White House Task Force on Childhood Obesity—Report to the President “Solving the Problem of Childhood Obesity within a Generation” (Task Force on Childhood Obesity, Domestic Policy Council, 2010) can be accessed at www.nj.gov/health/fhs/shapingnj/pdf/wh_obesity_report.pdf.

FIGURE 21-2 CDC Obesity Prevalence Map Prevalence of obesity among U.S. adults in 2013. (Centers for Disease Control and Prevention [CDC] Behavioral Risk Factor Surveillance System Survey, 2013.)

In February 2014 a researcher for the CDC reported to the media around the world that among children 2 to 5 years old, there had been a broad decline in the obesity epidemic. The drop emerged from a major federal health survey that experts stated was the “gold standard for evidence.” Theories emerged as to why the decline happened; possibly children were consuming less refined sugar, or maybe the decline was due to the fact that more women were breastfeeding their children. However, criticism followed that the sample size was too small to validate the results (CDC, 2014; Ogden, 2010). Combined with media sensationalism, the news mistakenly sent a message that early childhood obesity numbers were finally reversing themselves when, indeed, they are not.

Genetics

Many hormonal and neural factors involved in weight regulation are determined by heredity and genetics. These include short-term and long-term “signals” that determine satiety and feeding activity. Small defects in their expression or interaction could contribute significantly to weight gain. **Nutritional genomics** is the study of the interactions between dietary components and the instructions in a cell or genome, and the resulting changes in metabolites that affect gene expression (Camp and Trujillo, 2014) (see Chapter 5).

The number and size of fat cells, regional distribution of body fat, and RMR also are influenced by genes. Studies of twins confirm that genes determine 50% to 70% of the predisposition to obesity (Prentice, 2005). Although numerous genes are involved, several have received much attention—the *Ob* gene, the *adiponectin* (*ADIPOQ*) gene, the “fat mass and obesity associated” gene or *FTO* gene, and the *beta3*-adrenoreceptor gene. The *Ob* gene produces leptin. Mutations in the *Ob* gene, leptin receptor (*LEPR*), or *ADIPOQ* genes can result in obesity or **metabolic syndrome** (**Mets**), especially if the person’s diet provides too much saturated fat (Ferguson et al, 2010). The *beta3*-adrenoreceptor gene, located primarily in the adipose tissue, is thought to regulate RMR and fat oxidation in humans. The *FTO* gene predisposes individuals to diabetes by its effect on body mass (Frayling et al, 2007).

Nutritional or lifestyle choices can activate or deactivate these obesity-triggering genes. Thus the “formula” for successful long-term weight management is likely to require the behavioral application of individual genetics. Deoxyribonucleic acid

(DNA) tests can provide predictions about an individual’s response to a particular diet (see *Clinical Insight: Low Fat vs Low Carb: The Answer May Be in Your Genes*).

CLINICAL INSIGHT

Low Fat vs Low Carb: The Answer May Be in Your Genes

While eating a low-fat diet is generally a successful strategy for weight loss and weight maintenance because of the lower calorie content, your genes may have an effect. Genetic studies now show that, for example, a person identified as obesogenic from a high-carbohydrate diet will not be as successful on a lower-fat diet as a person identified as obesogenic from high-fat diet and vice versa (Collins, 2010). However, because genetic testing is complicated, the AND Position Statement states that only advanced qualified health professionals should be interpreting the results.

In a study that did not consider genetics, researchers studied 19 obese adults in a metabolic unit (Hall 2015). They found that when given isocaloric diets, the low-fat diet resulted in more fat loss than the low-carbohydrate diet. This occurred despite the fact that only the carbohydrate-restricted diet led to decreased insulin secretion. Ultimately both diets, along with the 60 minutes per day of exercise resulted in weight loss.

Through the examination of genetic markers known to affect metabolism, exercise, and energy within the human body (expressed in organs such as the brain, stomach, muscle, pancreas, and fat tissue), insight is given into how a person processes nutrients. DNA testing provides an analysis of how the body responds to exercise and performance and gives strategies to help a person reach and maintain a healthy weight based on his or her genes (see Chapter 5).

Inadequate Physical Activity

Lack of exercise and a sedentary lifestyle, compounded by chronic overeating, are also causes of weight gain. The sedentary nature of society is a factor in the growing problem of obesity. Fewer people are exercising, and more time is being spent in low-energy, screen-watching activities such as watching television or movies, using a computer or smartphone, playing video games, and sitting in cars driving to work or events.

Inflammation

Adipose tissue actively causes secretion of a wide range of pro- and anti-inflammatory cytokines that are influenced by single-nucleotide polymorphisms in the cytokine genes. Effects include insulin insensitivity, hyperlipidemia, muscle protein loss, and oxidant stress (Grimble, 2010). Scientists have found a direct relationship between obesity and inflammatory diseases such as cardiovascular disorders, some cancers, and type 2 diabetes (Bueno et al, 2014).

Metabolic signals are triggered in the hypothalamus of obese individuals, laying the groundwork for chronic inflammation and tissue damage during a prolonged period. In mice fed a high-fat diet, the “master switch” of inflammation turns on the hypothalamus. In humans, chronic overeating “flips on” the inflammation switch, leading to weight gain and insulin resistance. In insulin-resistant individuals on a weight-loss diet, and using the drug ezetimibe (Zetia), there is a reduction in hepatic steatosis and inflammatory markers with weight loss (Chan et al, 2010).

A combined approach of diet and drug use is likely to improve health outcomes. A simple dietary change to an anti-inflammatory diet and lifestyle changes can alter obesity-related inflammation. Genotypic factors influence the effectiveness of immunonutrients; antioxidants and omega-3 polyunsaturated fatty acids decrease the intensity of the inflammatory process (Grimble, 2010) (For discussion of inflammation, see Chapter 3).

Medication Usage and Weight Gain

Although weight gain can be due to disease, therapists always should consider the possibility that the patient's medication may be contributing. This often is seen with diabetes medications, and psychotropic, antidepressant, steroid, and antihypertensive medications. The use of such medications must be considered carefully, and alternative ones with less deleterious effects selected when possible (see Chapter 8 and Appendix 23).

Sleep, Stress, and Circadian Rhythms

Shortened sleep alters the endocrine regulation of hunger and appetite. Hormones that affect appetite take over and may promote excessive energy intake. Thus recurrent sleep deprivation can modify the amount, composition, and distribution of food intake and may contribute to the obesity epidemic. It is estimated that more than 50 million Americans suffer from sleep deprivation. Others may have shift work or exposure to bright light at night, increasing the disruption of circadian rhythms and enhancing the prevalence of adiposity (Garaulet et al, 2010).

There is also a relationship between sleep, disrupted circadian rhythm, genes, and the metabolic syndrome. Stress is another factor. The cortisol hormone is released when an individual is under stress, and stimulates insulin release to maintain blood glucose levels in the "fight-or-flight" response. Thus an increase in appetite occurs. Chronic stress with constantly elevated cortisol levels can also lead to appetite changes.

Cortisol levels are typically high in the early morning and low around midnight. Individuals with **night-eating syndrome (NES)** have a delayed circadian rhythm of meal intake as a result of genetically programmed neuroendocrine factors, including altered cortisol levels (Stunkard and Lu, 2010).

Taste, Satiety, and Portion Sizes

Food and its taste elements evoke pleasure responses. The endless variety of food available at any time at a reasonable cost can contribute to higher calorie intake; people eat more when offered a variety of choices than when a single food is available. Normally, as foods are consumed, they become less desirable; this phenomenon is known as **sensory-specific satiety**. Overriding this principle is the "all-you-can-eat buffet," in which the diner reaches satiety for one food but has many choices for the "next course." Although sensory-specific satiety can promote the intake of a varied and nutritionally balanced diet, it can also lead to overconsumption.

Leptin is a hormone, made by fat cells, that decreases appetite. **Ghrelin** is a hormone that increases appetite and plays a role in body weight. Levels of leptin, the appetite suppressor, are lower in normal weight individuals and higher in the obese. However, many obese people seem to build up a resistance to the appetite-suppressing effects of leptin.

Active overeating is partly the result of excessive portion sizes that are now accepted as normal. The portions and calories that

restaurants and fast-food outlets offer in one meal often exceed a person's energy needs for the entire day. Frequent intake of energy-dense food also can be problematic.

Obesogens

Obesogens are chemical compounds foreign to the body that act to disrupt the normal metabolism of lipids, ultimately resulting in fatness and obesity (Grün and Blumberg, 2006). Obesogens can be called "endocrine disruptors" in that they alter lipid homeostasis and fat storage, change metabolic set points, disrupt energy balance, or modify the regulation of satiety and appetite to promote accumulation of fat and obesity. Examples of suspected obesogens in the environment and food supply are bisphenol A (BPA) and phthalates, which are found in many plastics used in food packaging and which migrate into foods processed or stored in them (Grün, 2010) (see *Clinical Insight: What's in that Fat When You Lose It?*).

Viruses and Pathogens

In the last two decades, at least 10 adipogenic pathogens have been identified, including viruses, scrapie agents (spongiform encephalopathies from sheep or goats), bacteria, and gut microflora. Whether "infectobesity" is a relevant contributor to the obesity epidemic remains to be determined. A human adenovirus, adenovirus-36, is capable of inducing adiposity in experimentally infected animals by increasing the replication, differentiation, lipid accumulation, and insulin sensitivity in fat cells and reduces leptin secretion and expression (van Ginnekin et al, 2009).

Gut Microflora and Diet

Research has identified a strong and complex relationship between the microflora population of the gut and food absorption. The microbes *firmicutes* and *bacteroidetes*, normally found in gut flora, are believed to have a symbiotic relationship, acting as either fattening or slimming microbiota, dependent on the person's nutritional status, food intake, and ability to absorb food. Firmicutes bacteria tend to be much more efficient at nutrient breakdown and calorie absorption than bacteroidetes, and therefore contribute to calorie absorption and the development and maintenance of obesity in individuals. A higher number of bacteroidetes, on the other hand, may help to make or keep people lean. Weight loss, then, it appears would require a higher number of bacteroidetes and a lower number of firmicutes. A number of theories attempt to explain how this complicated process works, the ecologic relationship between the two, and ways to manipulate it continue to evolve (Krajmalnik-Brown et al, 2012).

Assessment

Overweight is a state in which the weight exceeds a standard based on height. **Obesity** is a condition of excessive fatness, either generalized or localized. Overweight and obesity usually parallel each other, but it is possible to be overweight according to standards but not be "overfat" or obese. It is also possible to have excessive fatness and yet not be overweight.

Body Fatness and Circumference Measurements

Assessing body fatness or "adiposity" is explained in detail in Chapter 7. Clinically practical assessment tools are (1) the **body mass index (BMI)** or W/H^2 , in which W = weight in kg and H = height in meters, (2) the waist circumference, (3) the neck

circumference, (4) the waist-to-hip ratio, (4) waist-to-height ratio and the (5) the neck-to-waist ratio, all of which are detailed in Chapter 7.

The NIH guidelines classify individuals with a BMI of 25 as overweight and those with a BMI of 30 or more as obese (see Table 21-2). Optimal BMI for longevity varies with race, gender, and age. BMI that increases over time has a substantial effect on health outcomes (see Appendix 18).

Waist circumference of more than 40 inches in men and more than 35 inches in women signifies increased risk, equivalent to a BMI of 25 to 34. When waist circumference and percentage of fat are both high, they are significant predictors of heart failure and other risks associated with obesity. Waist circumference is a strong correlate of insulin sensitivity index in older adults; measurement of waist circumference is helpful to assess disease risk (Racette et al, 2006). Waist/hip ratio (WHR) is a measurement in which a ratio of more than 0.8 for women and 1 for men is also associated with high risk for cardiovascular events (see Chapter 7).

Deurenberg Equation

The Deurenberg equation using the BMI, age, and gender of an individual to determine body fatness is as follows (Deurenberg and Deurenberg-Yap, 2003):

$$\% \text{ body fat} = (1.2 \times \text{BMI}) + (0.23 \times \text{age in yrs}) - (10.8 \times G) - 5.4$$

$$G = 1 \text{ for male; } G = 0 \text{ for female}$$

For example if BMI = 28, age = 21 years and G = female:

$$\begin{aligned} \% \text{ body fat} &= (1.2 \times 28) + (0.23 \times 21) - (10.8 \times 0) - 5.4 \\ &= 33.6 + 4.83 - 0 - 5.4 \\ &= 33\% \end{aligned}$$

A body fat percentage of 20% to 25% or more in a male and 25% to 32% or more in a female usually is considered to be excessive and associated with the metabolic and health risks of obesity.

A Body Shape Index

Measuring BMI historically has been the most common way to assess body fat and a person's risk of weight-related health problems. Because BMI measures body fat through a formula using height and weight only, it does not account for where the weight is concentrated. Athletes, for example, could weigh more from muscle mass, and their BMI would be higher because of it. As a result, Dr. Nir Krakauer, an engineer and professor at New York

University, developed A Body Shape Index (ABSI), incorporating waist circumference (WC) as well as height and weight into one formula to determine mortality rates. ABSI has been found to be a better mortality predictor, because of the added evaluation of abdominal fat via WC, which, with age, turns from brown to white fat and becomes a measure of central adiposity as well as body shape (Krakauer and Krakauer, 2014).

Health Risks and Longevity

In general, obesity can be viewed as metabolically unhealthy. Chronic diseases such as heart disease, type 2 diabetes, hypertension, stroke, gallbladder disease, infertility, sleep apnea, hormonal cancers, and osteoarthritis tend to worsen as the degree of obesity increases (see Figure 21-3).

A subset of obese persons who are metabolically normal seems to exist. This subgroup, the metabolically healthy obese (MHO), has good levels of insulin sensitivity, and absence of diabetes, dyslipidemia and hypertension. (Boonchaya-anant and Apovian, 2014). However, they are the exception and not the rule. Estimates using mortality data from the NHANES surveys show that thousands of deaths are related to obesity. Moderately high BMI in adolescence is correlated with premature death in younger and middle-age women (van Dam et al, 2006). Increased adiposity and reduced physical activity are strong independent risk factors for death in women.

A huge study of more than 100,000 U.S. men and women age 50 and older who took part in the 9-year Cancer Prevention Study II Nutrition Cohort found that obesity is linked to death. Those individuals with very large waists (at least 47 inches in men and 43 inches in women) had twice the risk of mortality compared with those with small waists (35 inches or less for men and 30 inches or less for women). This was true at all BMIs but was strongest in women of normal weight, indicating the danger of waistline, abdominal, or visceral fat (Jacobs et al, 2010).

Several large studies have determined that the optimal BMI with the least risk for mortality is a BMI of 23 to 24.9. BMI above or below this range seems to increase mortality risk (Adams et al, 2006; Jee et al, 2006). The optimal range for longevity appears to be within the range of 20.5 to 24.9.

Nonalcoholic fatty liver disease (NAFLD) is associated with obesity and may progress to end-stage liver disease (see Chapter 29). Obesity is also a risk factor for cancer, infertility, poor wound healing, and poor antibody response to hepatitis B vaccine. Thus the costs of obesity are staggering. Health economists estimate costs of overweight and obesity to account for nearly 10% of total annual U.S. medical expenditures. The Internal Revenue Service issued a rule in 2002 qualifying obesity as a disease, allowing taxpayers to claim weight loss expenses as a medical deduction if undertaken to treat an existing disease.

The U.S. government recognizes the immense effect of obesity on the health and financial well-being of its citizens. In June 2013 the American Medical Association (AMA) finally recognized obesity as a disease classification in its own entity (AMA, 2013). Healthy People 2020 objectives also identify the implications of overweight and obesity (see Chapter 9). The objectives include targets to increase the proportion of adults who are at a healthy weight and to reduce the proportion of adults, children, and adolescents who are obese. Overweight adolescents often become obese adults; obese individuals are at increased risk for **comorbidities** of type 2 diabetes, hypertension, stroke, certain cancers, infertility, and other conditions.

TABLE 21-2 Classification of Overweight and Obesity

Classification	Body Mass Index (kg/m ²)
Underweight	<18.5
Normal	18.5-24.9
Overweight	25.0-29.9
Obesity, class I	30.0-34.9
Obesity, class II	35.0-39.9
Extreme obesity, class III	>40

From National Institutes of Health, National Heart, Lung, and Blood Institute: Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults after Mennce report, NIH Publication No. 98-4083, 1998.

Fat Deposition and the Metabolic Syndrome

Regional patterns of fat deposit are controlled genetically and differ between and among men and women. Two major types of fat deposition currently are recognized: excess subcutaneous truncal-abdominal fat (the apple-shaped **android fat distribution**) and excess gluteofemoral fat in thighs and buttocks (the pear-shaped **gynoid fat distribution**). The android shape is more common among men. Gynoid fat deposition in women during child-bearing years is utilized to support the demands of pregnancy and lactation. Women with the gynoid type of obesity do not develop the impairments of glucose metabolism in those with an android deposition (Wajchenberg 2013). Postmenopausal women more closely follow the male pattern of abdominal fat stores, sometimes referred to as “belly fat.”

Abdominal fat is an indicator of fat surrounding internal organs or visceral fat. According to a major study done through the Brigham and Women’s Hospital in Boston over 7 years and including more than 3000 people (Framingham Study patients were used), those with higher amounts of abdominal fat, versus fat in other parts of body, were found to have higher risks of cancer and heart disease (Britton et al, 2013). Many other reputable scientific studies have been performed, validating the findings repeatedly.

Reports on methods to lose abdominal or “belly” fat (reputable and unorthodox ones) have targeted the media in the recent past. Data from smaller studies show that the Mediterranean diet,

with a concentration on monounsaturated fat intake, appears to have a positive effect on diminishing belly fat; however, adequate protein intake, combined with a reduction in saturated fats, refined sugar, and calories, plus an increase in physical activity, still appear to remain the key to overall loss of body fat (Doheny, 2014).

Visceral obesity, or excessive **visceral adipose tissue (VAT)** under the peritoneum and in the intraabdominal cavity, is correlated highly with insulin resistance and diabetes. Individuals diagnosed with the metabolic syndrome (MetS) have three or more of the following abnormalities: waist circumference of more than 102 cm (40 in) in men and more than 88 cm (35 in) in women, serum TGs of at least 150 mg/dl, high-density lipoprotein (HDL) level less than 40 mg/dl in men and less than 50 mg/dl in women, blood pressure 135/85 mm Hg or higher, or fasting glucose 100 mg/dl or higher. Increased visceral fat is a risk factor for coronary artery disease, dyslipidemia, hypertension, stroke, type 2 diabetes, and MetS (Wajchenberg 2013). By the same token, VAT and low cardiorespiratory fitness (CRF) levels are associated with a deteriorated cardiometabolic risk profile. Achieving a low level of VAT and a high level of CRF is an important target for cardiometabolic health (Rhéaume et al, 2011).

Calorie Restriction and Longevity

Balancing energy intake and energy expenditure is the basis of weight management throughout life. **Lifestyle modification**,

and becoming aware of eating behavior triggers to manage them more effectively, is vital for permanent change to occur. A key recommendation is to prevent gradual weight gain over time, by making small decreases in overall caloric intake and increasing physical activity. Patterns of healthful eating and regular physical activity should begin in childhood and continue throughout adulthood. The aging process with a lower RMR introduces special challenges. Energy balance is maintained by adjusting energy intake and physical activity to prevent weight gain.

Prolonged calorie restriction (CR) increases life span and slows aging in animals. The apparent generality of the longevity-increasing effects of CR has prompted speculation that similar results could be obtained in humans. Two biomarkers of longevity—fasting insulin level and body temperature—have been noted to be decreased by prolonged CR in humans (Heilbronn et al, 2006). Proponents of CR for anti-aging believe that cutting calorie intake reduces aging and chronic disease development. In rodents with Alzheimer’s disease, heart disease, and stroke, decreased deterioration of nerves and increased nerve creation also was demonstrated with calorie restriction. (Mayo Clinic, 2010).

Whether CR can slow the aging process in humans, however, remains an important question (Fontana, 2009). Unless clinical studies provide clear evidence of its utility, the wider use of CR in the human population cannot be justified, based on current data. On the other hand, the randomization of humans to CR may not be ethical, making it difficult to study its effect on individuals (Adomaityte et al, 2014).

Weight Discrimination

Widespread bias and discrimination based on weight have been documented in education, employment, and health care. Like other forms of prejudice, this stems from a lack of understanding of the chronic disease of obesity and its medical consequences. The vast majority of the U.S. does not consider obesity a protected class and therefore weight-based employment discrimination does not have a basis for a legal claim (Pomeranz JL 2013). Overweight children experience adverse social, educational, and psychologic consequences as a result of weight bias. There are automatic negative associations for obese people among health professionals, exercise science students, and obese individuals themselves. It is essential to break down the barriers caused by ignorance and indifference. Patient support groups help to correct the negative effect of this type of discrimination.

MANAGEMENT OF OBESITY IN ADULTS

The management of obesity has evolved over the years. Initially, clinicians focused entirely on weight loss, and little was known about weight maintenance. Treatment also has evolved. Years ago, an energy-restricted diet was the only treatment. Eventually, lifestyle modifications were added. The importance of developing physical activity behaviors is recognized as an essential ingredient for weight maintenance during and after weight loss. Today, a chronic disease-prevention model incorporates lifestyle interventions and interdisciplinary therapies from physicians, dietitians, exercise specialists, and behavior therapists.

Goals of Treatment

The goal of obesity treatment should focus on weight management and attaining the best weight possible in the context of

overall health. Achieving an “ideal” body weight or percentage of body fat is not always realistic; under some circumstances, it may not be appropriate at all. Depending on the type and severity of the obesity and the age and lifestyle of the individual, successfully reducing body weight varies from being relatively simple to being virtually impossible.

Maintaining present body weight or achieving a moderate loss is beneficial. Obese persons who lose even small amounts of weight (5% to 10% of initial body weight) are likely to improve their blood glucose, blood pressure, and cholesterol levels.

Despite the recognition that modest weight loss is beneficial and may be more achievable, obese persons usually have self-defined goal weights that differ considerably from that suggested by professionals. Therefore, health professionals must help their patients accept more modest, realistic weight loss goals. For example, actuarial tables support no benefit and possible harm from weight loss after age 65. In fact, in the obese elderly, sarcopenia (loss of muscle mass) is the greatest predictor of disability along with the inability to perform daily activities.

Rate and Extent of Weight Loss

Reduction of body weight involves the loss of protein and fat in amounts determined to some degree by the rate of weight reduction. A drastic reduction in calories resulting in a high rate of weight loss can mimic the starvation response. Tissue response to starvation is one of adaptation to an anticipated period of deprivation. The classic starvation studies done by Keys (1950) found that during the first 10 days of a fast and after depletion of glycogen stores, approximately 8% to 12% of the energy expenditure is from protein, and the balance is from fat. As starvation progresses, up to 97% of energy expenditure is from stored TGs. Metabolic aberrations during starvation include bradycardia, hypotension, dry skin and hair, easy fatigue, constipation, nervous system abnormalities, depression, and even death.

Mobilizing fat, with more than twice the kilocalories of protein, is more efficient and also spares vital LBM. Steady weight loss over a longer period favors reduction of fat stores, limits the loss of vital protein tissues, and avoids the sharp decline in RMR that accompanies rapid weight reduction. Calorie deficits that result in a loss of approximately 0.5 to 1 lb per week for persons with a BMI of 27 to 35, and 1 to 2 lb per week for those with BMIs greater than 35, should continue for approximately 6 months for a reduction of 10% of body weight (Academy of Nutrition and Dietetics [AND], formerly the American Dietetic Association [ADA], 2010). For the next 6 months the focus changes from weight loss to weight maintenance. After this phase, further weight loss may be considered.

Even with the same caloric intake, rates of weight reduction vary. Men reduce weight faster than women of similar size because of their higher LBM and RMR. The heavier person expends more energy than one who is less obese and loses faster on a given calorie intake than a lighter person. Many obese persons who fail to lose weight on a diet actually consume more energy than they report and overestimate their physical activity levels.

Lifestyle Modification

Behavior modification is the cornerstone of lifestyle intervention. It focuses on restructuring a person’s environment, nutrient intake, and physical activity by using goal setting, stimulus

control, cognitive restructuring, and relapse prevention. It also provides feedback on progress and places the responsibility for change and accomplishment on the patient.

Stimulus control involves modification of (1) the settings or the chain of events that precede eating, (2) the kinds of foods consumed when eating does occur, and (3) the consequences of eating. Patients are taught to slow their rate of eating to become mindful of satiety cues, and reduce food intake. Strategies such as putting down utensils between bites, pausing during meals, and chewing for a minimum number of times are some ways to slow the eating process.

Problem solving is the process of defining the intake problem, generating possible solutions, evaluating and choosing the best solution, implementing the new behavior, evaluating outcomes, and reevaluating alternative solutions if needed.

Cognitive restructuring teaches patients to identify, challenge, and correct the negative thoughts that frequently undermine their efforts to lose weight and keep it off. A cognitive therapy program that underscores the inextricable connection between emotions and eating, and how to manage that connection successfully using positive long-term mental strategies has been developed and found useful (Beck et al, 2011).

Self-monitoring with daily records of place and time of food intake, as well as accompanying thoughts and feelings, helps identify the physical and emotional settings in which eating occurs. Physical activity typically is recorded in minutes or calories expended. Self-monitoring also gives clues to the occurrence of relapses and consequent guilt and how they can be prevented.

A comprehensive program of lifestyle modification produces a loss of approximately 10% of initial weight in 16 to 26 weeks, as revealed by a review of recent randomized controlled trials (RCTs), including the Diabetes Prevention Program. Long-term weight control is facilitated by continued patient-therapist contact, whether provided in person or by telephone, mail, text messaging, or email. Multiple strategies for behavioral therapy often are needed (AND, 2010).

Technology shows promise as a delivery mechanism. Email and phone consults appear to be viable methods for contact and support as part of structured behavioral weight loss programs. Future treatment methods may include augmenting behavioral interventions with specific stimulus controls, self-monitoring with mobile device apps, pharmacotherapy, targeted educational interventions from the Internet, meal replacements, and telephone interventions. Nontraditional behavioral interventions for children and culturally sensitive interventions for racial and ethnic minority populations are needed.

Dietary Modification Recommendations

Weight loss programs with any degree of success integrate food-choice changes with exercise, behavior modification, nutrition education, and psychologic support. When these approaches fail to bring about the desired reduction in body fat, medication may be added. For **morbid obesity** (BMI of 40 or greater), surgical intervention may be required.

Weight loss programs should combine a nutritionally balanced dietary regimen with exercise and lifestyle modification. Selecting the appropriate treatment strategy depends on the goals and health risks of the patient. Treatment options include the following:

- A low calorie, macronutrient adjusted eating plan, increased physical activity, and lifestyle modification

- A low calorie macronutrient adjusted eating plan, increased physical activity, lifestyle modification, and pharmacotherapy
- Surgery plus an individually prescribed eating regimen, physical activity, and lifestyle modification program
- Prevention of weight regain through energy intake and output balance
- Mindset interventions

Restricted-Energy Diets

A balanced, restricted-energy diet is the most widely prescribed method of weight reduction. The diet should be nutritionally adequate except for energy, which is decreased to the point at which fat stores must be mobilized to meet daily energy needs. A caloric deficit of 500 to 1000 kcal daily usually meets this goal. The energy level varies with the individual's size and activities, usually ranging from 1200 to 1800 kcal daily. Regardless of the level of CR, healthful eating should be taught and recommendations for increasing physical activity should be included.

The low-calorie diet should be individualized for carbohydrates (50% to 55% of total kilocalories), using sources such as vegetables, fruits, beans, and whole grains. Generous protein, approximately 15% to 25% of kilocalories, is needed to prevent conversion of dietary protein to energy. Fat content should not exceed 30% of total calories. Extra fiber is recommended to reduce caloric density, to promote satiety by delaying stomach-emptying time, and to decrease to a small degree the efficiency of intestinal absorption.

Calculating fat as a percentage of calories is useful. A simple rule is to divide ideal calorie level by 4 for a 25% fat intake (e.g., an 1800-kcal intake needs 450 kcal from fat, or, at approximately 9 kcal/g, approximately 50 g of fat). Giving the person the option to distribute fat grams throughout the day makes the approach more appealing, involves the person in the process, and decreases energy intake without hunger. Total calories also must be considered.

Alcohol and foods high in sugar should be limited to small amounts for palatability. Alcohol makes up 10% of the diet for many regular drinkers and contributes 7 kcal/g. Heavy drinkers who consume 50% or more of daily calories from alcohol may have a depressed appetite, whereas moderate users tend to gain weight with the added alcohol calories. Habitual use of alcohol may result in lipid storage, weight gain, or obesity (see Chapter 29).

Artificial sweeteners and fat substitutes improve the acceptability of limited food intakes for some people. There is no evidence that using artificial sweeteners reduces food intake or enhances an individual's weight loss.

Vitamin and mineral supplements that meet age-related requirements usually are recommended when there is a daily intake of less than 1200 kcal for women, and 1800 kcal for men, or when it is difficult to choose foods that will meet all nutrient needs at the restricted energy intake.

Formula Diets and Meal Replacement Programs

Formula diets are commercially prepared, ready-to-use, portion-controlled meal replacements. These meal replacements - drinks, prepackaged meals or entrees, or meal bars - can be found over the counter (OTC) in drug stores, supermarkets, and franchised weight loss centers, or in a clinical setting. The goal with use of these foods is to provide structure and replace other higher

calorie foods. Per serving, most meal replacements include 10 to 20 g of protein, various amounts of carbohydrate, 0 to 10 g of fat, up to 5 g of fiber, and 25% to 30% of recommended dietary allowances for vitamins and minerals. Usually drinks or shakes are milk (casein or whey), pea protein, rice protein, or soy based, are high in calcium, and have 150 to 250 kcal per 8 oz. They are frequently ready to use, portion controlled, or are made with a purchased powder. People who have difficulty with self-selection or portion control may use meal replacements as part of a comprehensive weight management program. Substituting one or two daily meals or snacks with meal replacements is a successful weight loss and weight maintenance strategy (AND, 2010).

Commercial Programs

Millions of Americans turn to commercial weight loss or self-help programs in search of permanent weight loss. The more calorie-restricted programs usually are supervised medically in a health care setting. The programs vary considerably but the majority are books or internet-based programs that are not medically supervised (see Table 21-3). Some require the use of proprietary prepackaged low-fat meals. Prepackaged diets appeal to some people because they allow them to avoid making choices about food. Some provide classes on self-introspection, behavior modification, and nutrition.

Use of the Internet has spawned a new generation of commercial programs. The importance of a tailored approach was the conclusion of an RCT comparing an Internet-based tailored weight management program with an information-only Internet weight management program based in an integrated health care setting (Rothert et al, 2006).

With the exception of Weight Watchers, there is not strong evidence to support the use of the major commercial and

self-help weight loss programs. The reported results are probably a best-case scenario because many studies do not control for high attrition rates. More controlled trials are needed to assess the efficacy and cost effectiveness of commercial programs. Thus it is important to evaluate all weight loss programs for sound nutritional practices. Consumers are savvy, and many programs have begun to report data on dropout or success rates, as well as weight maintenance.

Extreme Energy Restriction and Fasting

Extreme energy-restricted diets provide fewer than 800 kcal per day, and starvation or fasting diets provide fewer than 200 kcal per day. Fasting is seldom prescribed as a treatment; however, it frequently is invoked as a part of religious or protest regimen or in a personal effort to lose weight. Under these circumstances it is seldom continued long enough to produce the serious neurologic, hormonal, and other side effects that accompany prolonged starvation. More than 50% of the rapid weight reduction is fluid, which often leads to serious hypotension. Accumulation of uric acid can precipitate episodes of gout; gallstones also can occur. Also, as fat stores diminish, molecules are released that can affect further weight loss (see *Clinical Insight: What's in That Fat When You Lose It?*). Sometimes what starts as extreme energy restriction to lose weight leads to more disordered eating patterns (see Chapter 22).

Very Low-Calorie Diets

Diets providing 200 to 800 kcal are classified as **very low-calorie diets (VLCDs)**. Little evidence suggests that an intake of fewer than 800 calories daily is of any advantage. An example of a significant exception to this would be the hospitalized patient on a metabolic unit who is monitored carefully, is less than 65 years old, and has a condition such as congestive heart

failure secondary to obesity. In such a case, the immediacy of rapid weight loss is considered life saving.

Most VLCDs are hypocaloric, but relatively rich in protein (0.8 to 1.5 g/kg IBW per day). They are designed to include a full complement of vitamins, minerals, electrolytes, and essential fatty acids, but not calories, and they are usually given for a period of 12 to 16 weeks. Their major advantage is rapid weight loss. Because of potential side effects, prescription of these diets is reserved for persons with a BMI of more than 30 for whom other diet programs with psychotherapy have been unsuccessful. Occasionally VLCDs may be indicated for persons with a BMI of 27 to 30 who have one or more comorbidities, or other risk factors.

The VLCD that first became popular in the early 1970s resulted in several deaths; however, improved protein formulations have increased acceptability and safety for those with morbid obesity. VLCDs can lead to an increase of urinary ketones that interfere with the renal clearance of uric acid, resulting in increased serum uric acid levels or gout. Higher serum cholesterol levels resulting from mobilization of adipose stores pose a risk of gallstones. Additional adverse reactions include cold intolerance, fatigue, lightheadedness, nervousness, euphoria, constipation or diarrhea, dry skin, anemia, and menstrual irregularities; some of these are related to triiodothyronine (thyroid) deficiency (see Chapter 31).

Even though there are significantly greater weight losses with VLCDs in the short term, there are no significant differences in the weight losses in the long term (Tsai and Wadden, 2006). Thus there rarely seems to be reason to recommend these VLCDs over more moderate CR. For those who have lost weight on a VLCD, limiting dietary fat intake and maintaining physical activity are important factors for the prevention of weight regain. To promote better weight loss, patients should limit their fat intake to less than 30% of calories and increase activity levels.

Popular Diets and Practices

Each year, new approaches to weight loss find their way to the consumer through the popular press and media. Some of the programs are sensible and appropriate, whereas others emphasize fast results with minimum effort. Some of the proposed diets would lead to nutritional deficiencies over an extended period; however, the potential health risks are seldom realized because the diets usually are abandoned after a few weeks (see *Focus On: Eating Like a Caveman*). Diets that emphasize fast results with minimum effort encourage unrealistic expectations, setting the dieter up for failure, subsequent guilt, and feelings of helplessness about managing the weight problem.

Online commercial diet programs have grown dramatically in the past decade. A programmed approach, for people on the run who carry their phones and computers, with a product line offered and accessibility to counselors and health professionals, has made the business of diets a multibillion dollar industry. One-on-one and group online counseling, phone access to discuss weight loss progress and setbacks, and delivery of “to-your-door” foods and meals are some of the enticing aspects of joining these programs. Consumers continue to need proper guidance to separate the good, sound diet programs

EATING LIKE A CAVEMAN

The Paleo diet, also called the caveman diet or stone age diet, claims that eating like our prehistoric ancestors will make us leaner and less likely to get diabetes, heart disease, cancer, and other health-related problems. It is a high-protein, high-fiber eating plan that promises weight loss without reducing calories. Because our ancestors were hunters and gatherers (not farmers), the diet eliminates processed foods, dairy, refined sugar, potatoes, and salt and refined vegetable oils such as canola oil. Calorie counting is eliminated. The rationale for the diet rests with the belief that lean meat and high-fiber fruits and vegetables will provide the feeling of fullness and create a lack of desire to overeat.

Foods allowed include lean meats, fresh fish, fruits, vegetables, eggs, seeds, nuts, and some oils such as olive and coconut.

The diet appears adequate with the exceptions of calcium and vitamin D. These should be supplemented. The Paleo diet has been shown to be of benefit in some studies that compared it to the Mediterranean diet and low fat-high carbohydrate diets (Lindeberg, 2007). A 2-year randomized trial also found benefit in obese postmenopausal women (Mellberg, 2013).

from the bad. The diets are described at many websites (see Table 21-3).

The low-carbohydrate, high-fat diet restricts carbohydrates to less than 20% of calories (and often less than 10% in the beginning), and fat constitutes 55% to 65% of calories, with protein making up the balance. Protein obtained from animal sources means that fat, saturated fat, and cholesterol intakes are high. These diets feature high ketone production and do suppress appetite, at least initially. The initial rapid weight loss from diuresis is secondary to the carbohydrate restriction. Examples of severe carbohydrate-restricted diets include Dr. Atkin’s New Diet Revolution and The Paleo Diet.

The Zone Diet and The South Beach Diet restrict carbohydrates to no more than 40% of total calories, with fat and protein each providing 30% of total calories. This diet composition is claimed to keep insulin in check, which is blamed for fat storage. The diet includes generous amounts of fiber and fresh fruits and vegetables. There is attention to the kind of fat, with emphasis on monounsaturated and polyunsaturated fat and limitation of saturated fat. Weight loss ensues not because insulin is kept in a narrow range, but because calories are restricted.

Very low fat diets contain less than 10% of calories from fat, such as the original Dr. Dean Ornish’s Program for Reversing Heart Disease and The Pritikin Program. These diets produce rapid weight loss because they are very restrictive. A more popular variation limits fat to 20% of total energy intake. Because fat provides more than two times the energy per gram as protein or carbohydrate (9 kcal versus 4 kcal), limiting fat is the most efficient way to decrease calories.

Moderate-fat, balanced-nutrient reduction diets contain 20% to 30% of calories from fat, 15% to 20% of calories from protein, and 55% to 60% of calories from carbohydrate. *Volumetrics*, a program in this category, focuses on the energy density of foods (Rolls et al, 2005). Foods high in water content have a low energy density. These include fruits, vegetables, low-fat milk, cooked grains, lean meats, poultry,

fish, and beans. Low water-containing foods that are energy dense, such as potato chips, crackers, and fat-free cookies, are restricted.

The U.S. Department of Agriculture (USDA) supported a scientific review of popular diets to assess their efficacy for weight loss and weight maintenance, as well as their effect on metabolic parameters, mental well-being, and reduction of chronic disease. A summary is shown in Table 21-4. See Table 21-5 for popular nutritional supplements used for weight loss.

Physical Activity

Physical activity is the most variable component of energy expenditure (see Chapter 2). Increases in energy expenditure through exercise and other forms of physical activity are important components of interventions for weight loss and its maintenance. By increasing LBM in proportion to fat, physical activity helps to balance the loss of LBM and reduction of RMR that inevitably accompany intentional weight reduction. Other positive side effects of increased activity include strengthening cardiovascular integrity, increasing sensitivity to insulin, and expending additional energy and therefore calories.

Adequate levels of physical activity appear to be 60 to 90 minutes daily, as recommended by the USDA. This is also the amount of activity reported by those in the National Weight Control Registry (NWCR) who have kept off at least 10% of their weight for at least a year. Overweight and obese adults should gradually increase to these levels of physical activity. There is evidence that, even if an overweight or obese adult is unable to achieve this level of activity, significant health benefits can be realized by participating in at least 30 minutes of daily activity of moderate intensity (AND, 2010). Therefore it is important to target these levels of physical activity to improve health-related outcomes and to facilitate long-term weight control.

Aerobic and resistance training should be recommended. Resistance training increases LBM, adding to the RMR and the ability to use more of the energy intake, and it increases bone mineral density, especially for women (see Chapter 24). Aerobic exercise is important for cardiovascular health through elevated RMR, calorie expenditure, energy deficit, and loss of fat. In addition to the physiologic benefits of exercise are relief of boredom, increased sense of control, and improved sense of well-being. The whole family can get involved in pleasurable activities (see Figure 21-4).

The recommendations for exercise from the American College of Sports Medicine differ for weight loss vs weight maintenance. Physical activity <150 minutes/week has a minimal effect on weight loss. Physical activity >150 minutes/week usually results in modest weight loss (defined as ~2-3 kg), with physical activity between 225 and 420 minutes/week resulting in the greatest weight loss (5 to 7.5 kg). While research on maintaining weight indicates that moderately vigorous physical activity of 150 to 250 minutes per week at an energy equivalent of ~1200 to 2,000 kilocalories per week (about 12 to 20 miles per week of jogging or running) is sufficient to prevent weight gain (Donnelly 2009).

Pharmaceutical Management

Appropriate pharmacotherapy can augment diet, physical activity, and behavior therapy as treatment for patients with a BMI of 30 or higher or patients with 27 or higher who

TABLE 21-4 Results of U.S. Department of Agriculture Scientific Review of Popular Diets

Area	Finding
Weight loss	Diets that reduce caloric intake result in weight loss; all popular diets result in short-term weight loss if followed.
Body composition	All low-calorie diets result in a loss of body fat. In the short term, high-fat, low-carbohydrate ketogenic diets cause a greater loss of body water than body fat.
Nutritional adequacy	<ul style="list-style-type: none"> High-fat, low-carbohydrate diets are low in vitamins E and A, thiamin, B₆, and folate; and the minerals calcium, magnesium, iron, and potassium. They are also low in dietary fiber. Very-low-fat diets are low in vitamins E and B₁₂ and the mineral zinc. With proper food choices, a moderate-fat, balanced nutrient-reduction diet is nutritionally adequate.
Metabolic parameters	<ul style="list-style-type: none"> Low-carbohydrate diets cause ketosis and may significantly increase blood uric acid concentrations. Blood lipid levels decline as body weight decreases. Energy restriction improves glycemic control. As body weight declines, blood insulin and plasma leptin levels decrease. As body weight declines, blood pressure decreases.
Hunger and compliance	No diet was optimal for reducing hunger.
Effect on weight maintenance	Controlled clinical trials of high-fat, low-carbohydrate, low-fat, and very-low-fat diets are lacking; therefore no data are available on weight maintenance after weight loss or long-term health benefits or risk.

From Freedman M et al: Popular diets: a scientific review, *Obes Res* 9(Suppl 1):1S, 2001.

also have significant risk factors or disease. These agents can decrease appetite, reduce absorption of fat, or increase energy expenditure. As with any drug treatment, physician monitoring for efficacy and safety is necessary. Pharmacotherapy is not a “magic pill”; dietitians should collaborate with other health professionals regarding the use of Food and Drug Administration (FDA)-approved pharmacotherapy. Not all individuals respond, but for patients who do respond, weight loss of approximately 2 to 20 kg can be expected usually during the first 6 months of treatment. Medication without lifestyle modification is less effective.

Medications currently available can be categorized as central nervous system (CNS) acting agents and non-CNS-acting agents. The CNS-acting agents fall into the categories of catecholaminergic agents, serotonergic agents, and combination catecholaminergic-serotonergic agents. Common side effects of CNS-acting agents are dry mouth, headache, insomnia, and constipation. As of April, 2015, five long-term weight loss drugs were listed as approved by the FDA (FDA, 2015). They are: orlistat (Xenical), lorcaserin (Belviq), phentermine/topiramate (Qysmia), naltrexone-bupropion (Contrav), and liraglutide (Saxenda) (see Table 21-5 for mechanisms of action and common side effects of prescription weight loss drugs).

Catecholaminergic drugs act on the brain, increasing the availability of norepinephrine. Drug Enforcement Agency Schedule II anorexic agents such as amphetamines have a

TABLE 21-5 Nonprescription Weight Loss Products

Product	Claim	Effectiveness	Safety
Alli: OTC version of prescription drug orlistat (Xenical)	Decreases absorption of dietary fat	Effective; weight loss amounts typically less for OTC versus prescription	FDA investigating reports of liver injury, pancreatitis
Bitter orange	Increases calories burned	Insufficient reliable evidence to rate	Possibly unsafe
Chitosan	Blocks absorption of dietary fat	Insufficient reliable evidence to rate	Possibly safe
Chromium	Increases calories burned, decreases appetite, and builds muscle	Insufficient reliable evidence to rate	Likely safe
CLA	Reduces body fat and builds muscle	Possibly effective	Possibly safe
Country mallow (heartleaf)	Decreases appetite and increases calories burned	Insufficient reliable evidence to rate	Likely unsafe and banned by FDA
Ephedra (Ma Huang)	Decreases appetite	Possibly effective	Likely unsafe and banned by FDA
Green tea extract	Increases calorie and fat metabolism and decreases appetite	Insufficient reliable evidence to rate	Possibly safe
Guar gum	Blocks absorption of dietary fat and increases feeling of fullness	Possibly ineffective	Likely safe
Hoodia	Decreases appetite	Insufficient reliable evidence to rate	Insufficient information
Senna	Cathartic; causes diarrhea	Insufficient reliable evidence	Likely unsafe
Raspberry ketones	Increases lipolysis	No human studies	Likely unsafe especially for hypertensives
Qsymia, by qualified G	Phentermine increases metabolism for short term and topiramate for long term	Human studies indicate short and long term success for majority.	Not for the pregnant, caution with stroke/heart disease, glaucoma
Garcinia Cambogia	Blocks enzymes from in body which convert glucose to fat. Also increases serotonin in brain, limiting appetite and providing extra energy	Contradictory evidence	Reports of liver damage associated

FIGURE 21-4 Jogging is an excellent aerobic activity for the whole family. (Photo printed with permission from Dr. David Rivera, 2010.)

high potential for abuse and are not recommended for obesity treatment.

Serotonergic agents act by increasing serotonin levels in the brain. Two drugs in this category, fenfluramine (commonly used in combination with phentermine, known as “fen-phen”) and dexfenfluramine, were removed from the market in 1997 after concerns were raised regarding the possible side effects of

cardiac valvulopathy, regurgitation, and primary pulmonary hypertension.

The mode of action of the weight loss drug orlistat is unusual in that it inhibits gastrointestinal lipase, which reduces approximately one third the amount of fat that is absorbed from food. Depending on the fat content of a person’s diet, this lowered absorption can represent 150 to 200 kcal/day. With lowered fat-soluble vitamin absorption, supplements typically are recommended, separated from the drug dosage by 2 hours or more. A weight loss of 3 to 5 kg in orlistat-treated patients is common. Side effects are gastrointestinal: oily spotting, fecal urgency, and flatus with discharge. Health benefits include reduced low-density lipoprotein (LDL) cholesterol and elevated HDL cholesterol, improved glycemic control, and reduced blood pressure.

Other drugs targeting weight loss and obesity through the CNS pathway or peripheral adiposity signals are in early phase clinical trials. Orexin is an appetite stimulant produced by the hypothalamus. Orexin is also known as hypocretin (Tsuneki et al, 2012). The FDA-approved, OTC weight loss product Alli contains 50% of the prescription dose of orlistat and Qsymia, which is a combination of two FDA-approved drugs, phentermine and topiramate, in an extended-release formulation. OTC and natural weight-loss products hold varying degrees of efficacy (see Table 21-6).

Other Nonsurgical Approaches

The non-diet paradigm maintains that the body will attain its natural weight if the individual eats healthfully, becomes attuned to hunger and satiety cues, and incorporates physical activity. This approach focuses on achieving health rather than attaining a certain weight. Advocates for this approach promote

TABLE 21-6 Prescription Drugs Approved for Obesity Treatment*

Weight Loss Drug	Approved for	How it works	Common side effects
Orlistat Sold as Xenical by prescription; over-the-counter version sold as Alli	Xenical: adults and children ages 12 and older Alli: adults only	Blocks some of the fat that you eat, keeping it from being absorbed by your body	Stomach pain, gas, diarrhea, and leakage of oily stools Note: Rare cases of severe liver injury reported. Should not be taken with cyclosporine.
Lorcaserin Sold as Belviq	Adults	Acts on the serotonin receptors in the brain. This may help you eat less and feel full after eating smaller amounts of food.	Headaches, dizziness, feeling tired, nausea, dry mouth, cough, and constipation. Should not be taken with selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitor (MAOI) medications
Phentermine-topiramate Sold as Qsymia	Adults	A mix of two drugs: phentermine (suppresses your appetite and curbs your desire to eat) and topiramate (used to treat seizures or migraine headaches). May make you feel full and make foods taste less appealing.	Tingling of hands and feet, dizziness, taste alterations (particularly with carbonated beverages), trouble sleeping, constipation, and dry mouth Note: Sold only through certified pharmacies. May lead to birth defects. Do not take Qsymia if you are pregnant or planning a pregnancy.
Other appetite suppressant drugs (drugs that curb your desire to eat), which include phentermine benzphetamine diethylpropion phendimetrazine Sold under many names	Adults	Increase chemicals in the brain that affect appetite. Make you feel that you are not hungry or that you are full. Note: Only FDA approved for a short period of time (up to 12 weeks).	Dry mouth, difficulty sleeping, dizziness, headache, feeling nervous, feeling restless, upset stomach, diarrhea, and constipation

*Note: *Metformin*, used for type 2 diabetes, is a prescription drug which has been used by physicians as an “off-label” treatment of obesity. Historically, health care providers have had some leverage in how they may prescribe drugs approved by the FDA. For example, in treating obesity, a qualified health care provider may prescribe a drug approved for treating another medical problem, prescribe two or more drugs at the same time, and/or prescribe a drug for a longer period of time than approved by the FDA.

Adapted from www.niddk.nih.gov Mar 3, 2014.

size acceptance and respect for the diversity of body shapes and sizes. Given the evidence that a 5% to 10% loss of initial weight can result in health benefits, that many persons set weight loss goals that are unrealistic, and that fat discrimination continues to plague society, this approach may help some persons to develop a better relationship with food and a healthier perspective about their bodies.

Bariatric Surgery

Bariatric surgery is at this point considered the only long-term effective treatment for extreme or class III obesity with a BMI of 40 or greater, or a BMI of 35 or greater with comorbidities. Approximately 179,000 surgeries are done annually in the United States (Beebe 2015). **Gastroplasty** or stomach restricting procedures, decrease the amount of food entering the gastrointestinal tract. Other surgical procedures, such as Roux-en-Y, are restrictive and cause malabsorption because they also prevent food from being absorbed from the gastrointestinal tract.

Before any extremely obese person is considered for surgery, failure of a comprehensive program that includes CR, exercise, lifestyle modification, psychologic counseling, and family involvement must be demonstrated. *Failure* is defined as an inability of the patient to reduce body weight by one third and body fat by one half, and an inability to maintain any weight loss achieved. Such patients have intractable morbid obesity and should be considered for surgery.

If surgery is chosen, the patient is evaluated extensively with respect to physiologic and medical complications, psychologic problems such as depression or poor self-esteem, and motivation. Counseling sharply improves the outcomes for

diETING and drug therapy in this population (Wadden and Sarwer, 2006). Postoperative follow-up requires evaluation at regular intervals by the surgical team and a registered dietitian nutritionist (RDN). In addition, behavioral or psychologic support is necessary. Studies indicate some positive physiologic changes in liver fibrosis, BMI, branched chain amino acid production and reversal of insulin-induced increases in brain glucose metabolism (Abdenmour et al, 2014; Tuulari et al, 2013).

Gastric Bypass, Gastroplasty, Gastric Banding, and the Sleeve Gastrectomy

Gastroplasty and gastric bypass procedures reduce the amount of food that can be eaten at one time and produce early satiety (see Figure 21-5). The new stomach capacity may be as small as 30 ml or approximately 2 tablespoons. After surgery the patient’s diet progresses from clear liquid, to full liquid, to puree, soft, and finally to a regular diet as tolerated, with emphasis on protein intake (see Table 21-7). The results of gastric surgery are more favorable than those from the intestinal bypass surgery practiced during the 1970s. On average, the reduction of excess body weight after gastric restriction surgery correlates to approximately 30% to 40% of initial body weight. In addition to the greater absolute weight loss observed, the gastric bypass tends to have sustainable results with significant resolution of hypertension, type 2 diabetes mellitus, osteoarthritis, back pain, dyslipidemia, cardiomyopathy, nonalcoholic steatohepatitis, and sleep apnea. However, late complications may be seen, such as vitamin deficiencies, electrolyte problems, or even intestinal failure. Patients should be nutritionally assessed regularly (see Appendices 21 and 22).

FIGURE 21-5 Bariatric surgeries. New diagram from Dietitians in Nutrition Support newsletter Support Line, June, 2014, P 10, Vol 6, No. 3. Academy of Nutrition and Dietetics.

TABLE 21-7 Diet Progression After Gastric Bypass

Phases of Diet	Total Quantity	Typical Progression after Surgery	Sample Food Items
Liquid diet	NPO 1-2 days post surgery for stomach healing then no more than ½ cup total	2-3 days after surgery	Plain and flavored waters, broth, unsweetened juices, diet gelatin, noncarbonated noncaffeinated diet drinks, strained cream soups
Semisolids and pureed diet	Gradually increase from ½ cup to no more than 1 cup total	Day 4-5 up to 4 weeks as semi-solids are tolerated	Blenderized or pureed soft meats, fish, chicken, turkey; pureed fruits and tender vegetables; hot cereals cooked in milk; yogurt
Soft foods	Meals should be from ¾ cup to no more than 1 cup total 3 × per day	Up to 8 weeks	Foods that can be mashed with a fork, such as ground or finely diced meats, canned or soft, fresh fruit, and cooked vegetables
Regular small meals and snacks	No more than 1 cup total; meat should be no more than 2 oz 48-64 oz water not at meals and multivitamin daily is necessary	6 weeks and beyond	Firmer foods without being pureed. Avoid popcorn, nuts, meats with gristle, dried fruits, vegetables and fruits that are stringy or coarse, sodas, bread, seeds, granola.

Adapted from Mayo Clinic: *Gastric Bypass Diet: What to Eat after the Surgery* (website): <http://www.mayoclinic.com/health/gastric-bypass-diet/my00827>, 2011. Accessed April 7, 2014.

Gastroplasty reduces the size of the stomach by applying rows of stainless-steel staples to partition the stomach and create a small gastric pouch, leaving only a small opening (0.8 to 1 cm) into the distal stomach. This opening may be banded by a piece of mesh to prevent it from enlarging during the years after surgery. Vertical-banded gastroplasty is the most popular of these surgeries. In the lap-band procedure, also called **gastric banding**, the band creating the reduced stomach pouch can be adjusted so that the opening to the rest of the stomach can be made smaller or enlarged. The band, filled with saline, has a tube exiting from it to the surface of the belly just under the skin; this allows for the injection of additional fluid or reduction of fluid into the lap band. Patients who undergo the banding procedures usually do not require folic acid, iron, or vitamin B₁₂ replacements, but nutritional status monitoring on a regular basis is still recommended.

Gastric bypass involves reducing the size of the stomach with the stapling procedure but then connecting a small opening in the upper portion of the stomach to the small intestine by means of an intestinal loop. The original operation in the late 1960s evolved into the Roux-en-Y gastric bypass (RYGB). Because use of the lower part of the stomach is omitted, the gastric bypass patient may have dumping syndrome as food empties quickly into the duodenum (see Chapter 27). The tachycardia, sweating, and abdominal pain are so uncomfortable that they motivate the patient to make the appropriate behavioral changes and refrain from overeating. However, patients tend to choose liquids and weight loss can then be deterred by drinking too much calorically dense liquid like milk shakes and soft drinks. Eventually the pouch expands to accommodate 4 to 5 oz at a time. Frequently, gastric bypass surgery leads to bloating of the pouch, nausea, and vomiting. A postsurgical food record noting the tolerance for specific foods in particular amounts helps in devising a program to avoid these episodes.

Up to 16% of patients may experience postoperative complications (Beebe 2015). These include anastomotic leaks, strictures, perforation, gastric fistulas, bowel obstructions, wound infections, respiratory failure and intractable nausea and vomiting. Additionally, bypass surgery places an individual at high risk for malnutrition that requires lifelong follow-up and monitoring by the multidisciplinary team. Nutritional status should be frequently evaluated by an RDN. Monitoring should include an assessment of total body fat loss, potential anemia, and deficiencies of

potassium, magnesium, folate, and vitamin B₁₂. Ice-cube pica and iron deficiency anemia are possible (Kushner and Shanta Retelny, 2005). Supplementation is necessary. An adult vitamin-mineral supplement (one liquid or chewable tablet twice daily) containing 1200 to 1500 mg calcium citrate, 400 to 2000 IU vitamin D, 500 mcg vitamin B₁₂, 400 mg folic acid, and 65 to 80 mg elemental iron with vitamin C is suggested (Kuluck et al, 2010; Snyder-Marlow et al, 2010).

The **laparoscopic sleeve gastrectomy (LSG)** initially was used for patients with a BMI greater than 60 as a precursor to RYGB, but it is now used as a stand-alone procedure and currently is the most popular bariatric surgery in the U.S. A sleeve is created by cutting the antrum of the stomach away from the pylorus and forming a pouch around a bougie on the side of the lesser curvature of the stomach. This reduces the stomach capacity by about 80% through the removal of the fundus and body (Mechanick et al, 2013). Complications associated with the LSG can include gastric bleeding, stenosis, leak, and reflux. After resection, the greater curvature of the stomach can bleed. Treatment involves transfusion and possibly an additional laparoscopy to reinforce the bleeding area with sutures. Each case requires the surgeon's expertise to decide if a patient can resume oral intake, will need nutrition support such as enteral feedings through a jejunostomy tube, or may require parenteral nutrition. Occasionally, RYGB is necessary to resolve reflux complications (Weiner et al, 2011) (see Figure 21-5).

Liposuction

Liposuction (or liposculpture) involves aspiration of fat deposits by means of a 1- to 2-cm incision through which a tube is fanned out into the adipose tissue. The most successful operations are performed on younger persons with only small amounts of fat to be removed, where the elastic properties of the skin are able to allow tightening over the aspirated areas. It is not usually a weight-reduction technique, but rather a cosmetic surgery because usually only approximately 5 lb of fat are removed at a time. Deaths, severe infections, cellulitis, and hemorrhage have occurred with liposuction surgeries.

COMMON PROBLEMS IN OBESITY TREATMENT

The prognosis for maintaining reduced body weight is typically poor. Continued dieting, with repeated ups and downs, leads

gradually to a net increase in body fat and thus to a health risk for hyperlipidemia, hypertension, diabetes, and even osteoarthritis. Women having bariatric surgery have had lower serum (25-OH vit D) and higher parathyroid hormone (PTH). The major determinant of (25-OH vit D) and PTH was weight. Hyperparathyroidism in obesity did not indicate vitamin D insufficiency. Low (25-OH vit D) was not associated with comorbid conditions, apart from osteoarthritis (Grethen et al, 2011).

Maintaining Reduced Body Weight

Energy requirements for weight maintenance after weight reduction appear to be 25% lower than at the original weight. The net effect is that reduced-obese persons are faced with the necessity of maintaining a reduced energy intake, even after the desired weight has been lost. Whether this reduced intake must be maintained indefinitely is not known.

The NWCR consists of more than 5000 individuals who have been successful in long-term weight loss maintenance. The purpose of establishing the NWCR is to identify the common characteristics of those who succeed in long-term weight loss maintenance. There is very little similarity in how these individuals lost weight, but there are some common behaviors they all have for keeping the weight off. Lifestyle modification and a sense of self-efficacy appear to be essential. To maintain weight loss, NWCR participants report the following:

1. Eating a relatively low-fat (24%) diet
2. Eating breakfast almost every day
3. Weighing themselves regularly, usually once per day to once per week
4. Engaging in high levels (60 to 90 minutes per day) of physical activity

A national weight loss registry is contributing to our understanding of those tactics that lead to long term success. Dietary restriction of fat, frequent self-weighing and ongoing leisure time physical activity were factors associated with maintaining weight loss (Thomas, 2014). Support groups are valuable for obese persons who are maintaining a new lower weight; they help individuals facing similar problems. Two self-help support groups are Overeaters Anonymous and Take Off Pounds Sensibly. These groups are inexpensive, continuous, include a “buddy system,” and encourage participation on a regular basis, or as often as needed. Weight Watchers programs offer free lifelong maintenance classes for those who have reached and are maintaining their goal weights.

Interestingly, boring and monotonous diets can provide the strategy for reducing food intake. Diets that are repetitious (without change from meal to meal) are a useful consideration for controlling intake, because people tend to overeat when they have many mealtime choices. This can be a particular problem in a society where 1 in 3 meals is eaten away from home. Reliance on restaurants and vending trucks or machines generally offer many options, most high in calories (see *Focus On: Restaurant and Vending Machine Nutrition Labeling*).

Overall, a common sense approach is needed. Some phrases can be shared with individuals who are trying to maintain their weight loss, including the following:

1. The best diet is “don’t buy it.”
2. “Easy does it”—use moderation at all meals.
3. “Don’t drink your calories.”
4. Keep the “extras” to no more than 200 kcal per day.

FOCUS ON

Restaurant and Vending Machine Nutrition Labeling

DeeAnna Wales VanReken, MS, RDN, CD

When President Obama signed the Affordable Care Act into law in 2010, restaurant labeling laws were included as part of the legislation for health care reform (Federal Register, 2014). This public health effort has been proposed with the intent of providing consumers with the appropriate tools to make nutritious choices when dining out. The ruling will apply to chain restaurants, retail food businesses, and vending machines with 20 or more locations or units (FDA, 2014b).

The law mandates that all participants list the calorie content of menu items directly on the menu or provide the information from nutrition labels that may not be visible in vending machines. Further, if a vending machine consumer requests it, other nutrition data must also be available to them in writing. These data include total calories, fat, saturated fat, cholesterol, sodium, total carbohydrates, sugars, fiber, and total protein (FDA, 2014b). The FDA also has developed a colorful info-graphic to demonstrate basic facts about the new law, which may be posted in restaurants or on vending machines to help consumers understand the changes (FDA, 2014a).

Although it is not required, those with fewer than 20 restaurant locations or vending machines may also register voluntarily with the FDA to meet federal requirements. Although some businesses are already in compliance, restaurants will have until December 2015 and vending machines until December 2016 to fulfill the labeling agreement (FDA, 2014b). For more information, including exclusions, children’s menus, and timing of implementation of these laws, visit www.fda.gov.

Plateau Effect

A common experience for the person in a weight reduction program is arrival at a weight plateau, when weight remains at the same level for a long period. Eventually weight loss halts completely. One theory is that interim plateaus reflect a reduction of lipid in individual adipocytes to some level that signals metabolic adjustment and weight maintenance. Another theory is that there is a release of toxins from adipose tissue that acts as an endocrine disruptor and inflammatory agent and affects subsequent weight loss. To move out of this phase usually requires an increase in activity level or a change in food choices to include more fruits and vegetables which are naturally higher in detoxifying phytochemicals (see *Clinical Insight: What’s in That Fat When You Lose It?*).

Any weight loss—whether fast or slow—results in a loss of the extra muscle that has developed to support the excess adipose tissue. Because this extra LBM has contributed to an increase in metabolic rate, RMR decreases as LBM is lost. The fact that RMR decreases rapidly at the onset of a weight-reduction diet, by as much as 15% within 2 weeks, indicates that other adaptations to the lower weight and the threat of deprivation are taking place.

Other factors join to decrease RMR and limit effectiveness of the restricted energy intake. A decrease in the total kilocalories ingested results in a decrease in total energy expenditure. Because a body that weighs less requires less energy expenditure to move around, the cost of physical activity is also less. A state of equilibrium eventually is reached at which the energy intake is equal to energy expenditure. Unless a change is made in either nutritional intake or physical activity, weight loss stops at this point.

Weight Cycling

Repeated bouts of weight loss and regain, known as weight cycling or the **yo-yo effect**, occurs in men and women and is common in overweight and normal weight individuals. The effect of weight cycling appears to result in increased body fatness and weight, with the end of each cycle. There are metabolic and psychologic effects that are undesirable.

WEIGHT MANAGEMENT IN CHILDREN AND ADOLESCENTS

About one third of U.S. children ages 2 to 19 are overweight or obese (Ogden et al, 2010). Obese children are often the targets of discrimination. Childhood obesity increases the risk of obesity in adulthood. For the child who is obese after 6 years of age, the probability of obesity in adulthood is significantly greater, if either the mother or the father is obese.

The BMI tables for determining childhood obesity are available for use by health care practitioners (see Appendices 7 and 11). Children whose BMI is greater than the 85th percentile are six times more likely to be overweight later (Nader et al, 2006). In addition, children who have growth failure and undernutrition in utero or in the early years of life tend to become overweight in later childhood with subsequent risks of elevated blood pressure, lipid, and glucose levels (Stein et al, 2005). Obesity that begins in childhood tends to lead to hypertension, elevated LDL cholesterol, and TGs in adults (Thompson et al, 2007).

Children or adolescents with a body mass index (BMI) in the 85th percentile or higher with complications of obesity, or with a BMI in the 95th percentile or higher with or without complications, should be carefully assessed for genetic, endocrinologic, and psychologic conditions, and secondary complications such as hypertension, dyslipidemias, type 2 diabetes, sleep apnea, and orthopedic problems. If the complications cause serious morbidity and require rapid weight loss, referral to a pediatric obesity specialist may be necessary. Otherwise, parent and child readiness to make changes should be evaluated and eating and activity patterns carefully assessed.

Once assessment is complete, treatment can begin. The primary goal of treatment is to achieve healthy eating and activity, not to achieve an IBW. For children 7 years of age and younger, the goal is prolonged weight maintenance or slowing of the rate of weight gain, which allows for a gradual decline in BMI as children grow in height. This is an appropriate goal in the absence of any secondary complication of obesity. However, if secondary complications are present, children in this age group may benefit from weight loss if their BMI is at the 95th percentile or higher. For children older than 7 years, prolonged weight maintenance is appropriate if their BMI is between the 85th and 95th percentile and if they have no secondary complications. If a secondary complication is present, or if the BMI is at the 95th percentile or above, weight loss (about 1 lb per month) is advised.

If the weight appropriate for the child or teen's anticipated adult height has already been reached, maintenance at that weight should be the lifetime goal. The child who already exceeds an optimal adult weight can safely experience a slow weight loss of 10 to 12 pounds per year until the optimal adult weight is reached. Balanced micronutrient intake for children includes 45% to 60% of kilocalories from carbohydrates, 25% to 40% from fat, and 10% to 35% from protein. New directions

in childhood obesity research since the turn of the twenty-first century have uncovered 25 (OH)D deficiency (defined as a level less than or equal to 57 nmol/L or 20 ng/ml). This has been manifested by a lack of sun exposure and the increase in use of sunscreen—blocking the skin's absorption of ultraviolet light. Low vitamin D is predominant in obese children. The accompanying proinflammatory association with diabetes and atherogenic pathways has prompted recommendations to test kindergarten and first grade children. Children with low levels of vitamin D could have the systemic inflammatory mediators and reduced insulin sensitivity pathways inhibited by vitamin D supplementation (Reyman et al, 2014).

The child or adolescent who needs to reduce weight requires attention from family and health professionals. This attention should be directed to all the areas mentioned previously, with family modification of eating habits and increased physical activity. The program should be long term, over the entire growth period and perhaps longer (see Box 18-3: Staged Care Treatment for Overweight and Obesity in Chapter 18).

Inactivity often is coupled with sedentary hobbies, excessive TV watching, or prolonged sitting in front of a computer or game screen. However, there is a new theory that physical inactivity appears to be the result of fatness rather than its cause (Metcalf et al, 2011). This requires further research but does suggest that factors other than inactivity may be more important in obesity development in children (see *New Directions: Organizing to Solve the Childhood Obesity Problem* “Within a Generation”).

WEIGHT IMBALANCE: EXCESSIVE LEANNESS OR UNINTENTIONAL WEIGHT LOSS

Almost eclipsed by the attention focused on obesity is the need for some people to gain weight. The term **underweight** is applicable to those who are 15% to 20% or more below accepted weight standards. Because underweight is often a symptom of disease, it should be assessed medically. A low BMI (less than 18.5) is associated with greater mortality risk than that of individuals with optimal BMI (18.5 to 24.9), especially with aging and in the elderly. Undernutrition may lead to under functioning of the pituitary, thyroid, gonads, and adrenals. Other risk factors include loss of energy and susceptibility to injury and infection, as well as a distorted body image and other psychologic problems (see Chapter 22).

Cause

Underweight or unintentional weight loss can be caused by (1) inadequate oral food and beverage intake, with insufficient quantities to match activity; (2) excessive physical activity, as in the case of compulsive athletic training; (3) inadequate capacity for absorption and metabolism of foods consumed; (4) a wasting disease that increases the metabolic rate and energy needs, as in cancer, acquired immune deficiency syndrome (AIDS), or hyperthyroidism; or (5) excess energy expenditure during psychologic or emotional stress (see Chapter 22).

Assessment

Assessing the cause and extent of underweight before starting a treatment program is important. A thorough history and pertinent medical tests usually determine whether underlying disorders are causing the underweight. From anthropometric data such as arm muscle and fat areas, it is possible to determine whether health-endangering underweight really exists

(see Appendices 21 and 22). Assessment of body fatness is useful, especially in dealing with the patient who has an eating disorder (see Chapter 7 and Appendix 21). Biochemical measurements indicate whether malnutrition accompanies the underweight (see Chapter 7).

Management

Any underlying cause of unintentional weight loss or low BMI must be the first priority. A wasting disease or malabsorption requires treatment. Nutrition support and dietary changes are effective, along with treatment of the underlying disorder (see Table 21-8).

If the cause of the underweight is inadequate oral food and beverage intake, activity should be modified and psychologic counseling initiated if necessary.

Appetite Enhancers

The FDA has approved orexigenic agents that include corticosteroids, cyproheptadine, loxiglumide (cholecystokinin antagonist), megestrol acetate, mirtazapine, dronabinol, oxoglutarate, anabolic agents (testosterone or Anadrol), oxandrin, and growth hormone. Use of orexigenic agents for weight loss in seniors is saved for those whose conditions are refractory to usual treatments. One third of older adults, especially women, exhibit weight loss in combination with depression. Mirtazapine is an effective antidepressant that is well tolerated and increases appetite. It is particularly effective in elderly patients with dementia-related weight loss (Fox et al, 2009). Dronabinol is used for chemotherapy-induced nausea and vomiting in

cancer and AIDS patients; it has been shown to induce weight gain in patients with dementia.

High-Energy Diets

A careful history may reveal inadequacies in dietary habits and nutritional intakes. Meals should be scheduled and relaxed instead of hastily planned or quickly eaten. The underweight person frequently must be encouraged to eat, even if not hungry. The secret is to individualize the program with readily available foods that the individual really enjoys, with a plan for regular eating times throughout the day. In addition to meals, snacks are usually necessary to adequately increase the energy intake. High-calorie liquids taken with meals or between meals are often effective in those who have loss of appetite or early satiety. Everyday foods can be fortified to increase the calories and protein (see *Focus On: Food First!* in Chapter 20).

The energy distribution of the diet should be approximately 30% of the kilocalories from fat, with the majority from mono-unsaturated or polyunsaturated sources and at least 12% to 15% of the kilocalories from protein. A basic vitamin and mineral supplement may be encouraged. In addition to an intake according to estimated energy requirements for the present weight, 500 to 1000 extra kilocalories per day should be planned. If 2400 kcal maintains the current weight, 2900 to 3400 kcal would be required for weight gain.

The intake should be increased gradually to avoid gastric discomfort, discouragement, electrolyte imbalances, and heart dysfunction. Step-up plans are outlined in Table 21-9. In underweight children, nonnutritional factors, insufficient caloric intake, excessive nutrient losses, and abnormal energy metabolism may contribute to growth failure and morbidity. Thus adequate nutritional support should be an integral part of the management plan. Lipid-based nutrient supplements are fortified products that are often ready-to-use therapeutic foods or highly concentrated supplements that can be administered at “point of service” or emergency settings (Chaparro and Dewey, 2010).

TABLE 21-8 Nutrition Management of Unintentional Weight Loss

Concern	Tips
Anxiety, stress, depression	Antidepressants can help; monitor choice to be sure they do not contribute to weight loss.
Cancer	Gastrointestinal cancers are especially detrimental. Some treatments and medications can cause loss of appetite, as can the cancer itself.
Celiac disease	Ensure that all gluten-containing foods and ingredients are eliminated from the diet.
Changes in activity level or dietary preparation methods	Avoid skipping meals; prepare foods with high energy density.
Diabetes, new onset	See a physician; monitor medications and meals accordingly.
Dysphagia or chewing difficulties	Alter food and liquid textures accordingly to improve chewing and swallowing capability.
Hyperthyroidism	Too much thyroxine can cause weight loss.
Inflammatory bowel disease	Check medications and treatments to determine whether new choices are in order.
Intestinal ischemia	See a physician.
Medications	Some medications can cause weight loss; check with physician; add snacks or enhanced meals if needed.
Nausea and vomiting	Infections, other illnesses, hormonal changes, and some medications cause nausea and vomiting; small, frequent meals are useful; serve liquids between meals instead of with meals to reduce fullness.
Pancreatitis and cystic fibrosis	Monitor for sufficiency of pancreatic enzyme replacement.

CLINICAL CASE STUDY

Maria is a 45-year-old Latina woman who has tried numerous weight loss programs. She has followed strict diets and has never exercised in previous weight loss attempts. She takes several cardiac medications, none of which she can remember. Her blood pressure is 160/90, she is 5 ft 4 in, and she weighs 195 lb. Her lowest body weight was 130 lb at age 30, maintained for 2 years. Maria mentioned that she tried numerous diets while a teenager, when she weighed 170 lb for 3 years. What guidelines would you offer to Maria at this time?

Nutrition Diagnostic Statements

- Limited adherence to nutrition-related recommendations related to multiple failed weight loss attempts as evidenced by no change in weight
- Overweight and obesity related to excessive energy intake as evidenced by weight 70 lb over desirable weight

Nutrition Care Questions

- How would you address the concern about medications?
- What types of exercise would you be likely to discuss?
- Which macro- and micronutrients would you discuss with Maria (e.g., total fat, saturated fat, sodium, potassium, calcium)?
- How would you bring up exercise and what would you recommend for Maria?
- What would be the goals of her treatment?

TABLE 21-9 Suggestions for Increasing Energy Intake

Additional Foods	kcal	Protein (g)
Plus 500 kcal (Served Between Meals)		
A. 1 c dry cereal	110	2
1 banana	80	
1 c whole milk	159	8
1 slice toast	60	2
1 T peanut butter	86	4
Total	495	16
B. 8 saltine crackers	99	3
1 oz cheese	113	7
1 c ice cream	290	6
Total	502	16
C. 6 graham cracker squares	165	3
2 T peanut butter	172	8
1 c orange juice	122	
2 T raisins	52	
Total	511	11
Plus 1000 kcal (Served Between Meals)		
A. 8 oz fruit flavored whole milk yogurt	240	9
1 slice bread	60	2
2 oz cheese	226	14
1 apple	87	
¼ of 14-inch cheese pizza	306	16
1 small banana	81	1
Total	1000	42
B. Instant breakfast with whole milk	280	15
1 c cottage cheese	239	31
½ c pineapple	95	
1 c apple juice	117	3
6 graham cracker squares	165	
1 pear	100	1
Total	996	50
Plus 1500 kcal (Served Between Meals)		
A. 2 slices bread	120	4
2 T peanut butter	172	8
1 T jam	110	
4 graham cracker squares	110	2
8 oz fruit-flavored whole milk yogurt	240	9
¾ c roasted peanuts	628	28
1 c apricot nectar	143	1
Total	1523	52
B. 1 baked custard	285	13
Instant breakfast with whole milk	280	15
1 c dry cereal	110	2
1 banana	80	
1 c whole milk	159	8
1 c orange juice	122	
1 bagel	165	6
2 T cream cheese	199	
2 T jam	110	
Total	1510	44

Nutrition in Eating Disorders

Janet E. Schebendach, PhD, RDN,
Justine Roth, MS, RDN

KEY TERMS

anorexia nervosa (AN)

binge

binge eating disorder (BED)

bulimia nervosa (BN)

cognitive-behavioral therapy (CBT)

**Diagnostic and Statistical Manual of
Mental Disorders, 5th Edition
(DSM-5)**

**other specified feeding or eating
disorder**

purging

refeeding syndrome (RFS)

Russell's sign

Feeding and eating disorders (EDs) are characterized by a persistent disturbance of eating or eating-related behavior that results in significantly impaired physical health and psychosocial functioning. Diagnostic criteria (see [Box 22-1](#)) are published in the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5)* (American Psychiatric Association [APA], 2013). Revised DSM-5 criteria are available for anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED); new criteria have been established for avoidant/restrictive food intake disorder, other specified feeding or eating disorder, pica, and rumination disorder. However, a commonly referred to disorder is not yet clinically defined (see *Clinical Insight: Orthorexia*).

CLINICAL INSIGHT

Orthorexia

Orthorexia refers to the fixation on foods to be perfect and clean. The disorder is categorized by compulsive dieting and adherence to very strict food rules, often leading to a major disruption in one's ability to take part in everyday life (Mathieu, 2005). Steven Bratman, author of *Health Food Junkies* (Bratman and Knight, 2000), coined the term and described the disorder as an "unhealthy obsession with eating healthy food." The Greek word *ortho* refers to "correct or right," so unlike anorexia or bulimia, in which foods are often restricted or binged on, orthorexia often leads to individuals consuming food only if they believe it is wholesome and pure.

Orthorexia is not a clinically defined eating disorder and is not included in the DSM-5. Little research has been done on its prevalence rates to date. However, preliminary studies have shown prevalence rates of 6.9% for the general population and, interestingly, 35% to 58% in high-risk groups such as health care professionals (Varga et al, 2013). The desire to eat "healthy" foods is not orthorexia, rather it is an obsession with these types of foods combined with the social isolation and disordered behaviors that become dangerous, possibly leading to the development of a diagnosed eating disorder.

Anorexia Nervosa

Essential features of **anorexia nervosa (AN)** include persistent energy intake restriction; intense fear of gaining weight or of becoming fat or persistent behavior that interferes with maintenance of appropriate weight; and a disturbance in self-perceived weight or shape. Two diagnostic subtypes are restrictive eating only and restrictive eating interspersed with **purging**, and crossover between the subtypes is possible over the course of illness. The DSM-5 is the first to allow clinicians to document a severity rating for a case of AN: mild, moderate, severe, and extreme. Severity ratings are differentiated based on current body mass index (BMI, adults) or BMI percentile (children/adolescents); however, the rating may be increased at the clinician's discretion to reflect clinical symptoms, degree of functional disability, and the need for supervision. In the general population, lifetime prevalence of AN is approximately 1% in women and less than 0.5% in men (Hay et al, 2014). Presentation typically occurs during adolescence or young adulthood, but prepubertal and late-onset (after age 40) cases have been described. Although AN occurs across culturally and socially diverse populations, increased prevalence occurs in postindustrialized, high-income countries. Within the United States, prevalence appears to be comparatively low among Latinos, African Americans, and Asians; however, presentation of weight concerns among individuals with eating disorders may vary substantially across cultural and ethnic groups. Risk and prognostic factors associated with this disorder include genetic, physiologic, environmental, and temperamental characteristics (see [Table 22-1](#)). The crude mortality rate is approximately 5% per decade with death attributed to medical complications directly related to AN or suicide (APA, 2013).

Bulimia Nervosa

Essential features of **bulimia nervosa (BN)** include recurrent episodes of binge eating followed by inappropriate compensatory behaviors in an effort to prevent weight gain; and self-evaluation

BOX 22-1 American Psychiatric Association (DSM-5) Diagnostic Criteria

Anorexia Nervosa (AN)

- A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal, or for children and adolescents, less than that minimally expected.
- B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

1. Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.
2. Binge-eating/purging type: During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see below) or, for children and adolescents, on BMI percentile. The ranges below are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

Mild: BMI ≥ 17 kg/m²

Moderate: BMI 16-16.99 kg/m²

Severe: BMI 15-15.99 kg/m²

Extreme: BMI < 15 kg/m²

Bulimia Nervosa (BN)

- A. Recurrent episodes of binge eating at least once a week for three months. An episode of binge-eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. Recurrent inappropriate compensatory behaviors in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify current severity:

The minimum level of severity is based on the frequency of inappropriate compensatory behaviors (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: An average of 1-3 episodes of inappropriate compensatory behaviors per week.

Moderate: An average of 4-7 episodes of inappropriate compensatory behaviors per week.

Severe: An average of 8-13 episodes of inappropriate compensatory behaviors per week.

Extreme: An average of 14 or more episodes of inappropriate compensatory behaviors per week.

Binge Eating Disorder (BED)

- A. Recurrent episodes of binge eating. An episode of binge-eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than what most individuals would eat in a similar period of time under similar circumstances.
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).
- B. The binge-eating episodes are associated with three (or more) of the following:
 1. Eating more rapidly than normal.
 2. Eating until feeling uncomfortably full.
 3. Eating large amount of food when not physically hungry.
 4. Eating alone because of feeling embarrassed by how much one is eating.
 5. Feeling disgusted with oneself, depressed, or very guilty afterward.
- C. Marked distress regarding binge eating is present.
- D. The binge eating occurs, on average, at least once a week for 3 months.
- E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

Specify current severity:

The minimum level of severity is based on the frequency of episodes of binge eating (see below). The level of severity may be increased to reflect other symptoms and the degree of functional disability.

Mild: 1-3 binge-eating episodes per week.

Moderate: 4-7 binge-eating episodes per week.

Severe: 8-13 binge-eating episodes per week.

Extreme: 14 or more binge-eating episodes per week.

Other Specified Feeding and Eating Disorder

This category applies to presentations in which symptoms characteristic of a feeding and eating disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functions predominate but do not meet the full criteria for any of the disorders in the feeding and eating disorders diagnostic class. The other specified feeding and eating disorder category is used in situations in which the clinician chooses to communicate the specific reason that the presentation does not meet the criteria for any specific feeding and eating disorder. This is done by recording "other specified feeding or eating disorder" followed by the specific reason (e.g., "bulimia nervosa of low frequency"). Examples of presentations that can be specified using the "other specified" designation include the following:

1. Atypical anorexia nervosa: All of the criteria for anorexia nervosa are met, except that despite significant weight loss, the individual's weight is within or above the normal range.
2. Bulimia nervosa (of low frequency and/or limited duration): All of the criteria from bulimia nervosa are met, except that the binge eating and inappropriate compensatory behaviors occur, on average, less than once a week and/or for less than 3 months.
3. Binge eating disorder (of low frequency and/or limited duration): All of the criteria for binge eating disorder are met, except that the binge eating occurs, on average, less than once a week and/or for less than 3 months.
4. Purging disorder: Recurrent purging behavior to influence weight or shape (e.g., self-induced vomiting; misuse of laxatives, diuretics, or other medications) in the absence of binge eating.
5. Night eating syndrome: Recurrent episodes of night eating, as manifested by eating after awakening from sleep or by excessive food consumption after the evening meal. There is awareness and recall of the eating. The night eating is not better explained by external influences such as changes in the individual's sleep-wake cycle or by local social norms. The night eating causes significant distress and/or impairment in functioning. The disordered pattern of eating is not better explained by binge eating disorder or another mental disorder, including substance use, and is not attributable to another medical disorder or to the effect of medication.

BOX 22-1 American Psychiatric Association (DSM-5) Diagnostic Criteria—cont'd

Unspecified Feeding or Eating Disorder

This category applies to presentations in which symptoms characteristic of a feeding and eating disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for any of the disorders in the feeding and eating disorders diagnostic class. The unspecified feeding and eating disorder category is used in situations in which the clinician chooses *not* to specify the reason that the criteria are not met for a specific feeding and eating disorder, and includes presentations in which there is insufficient information to make a more specific diagnosis (e.g., in emergency room settings).

Avoidant/Restrictive Food Intake Disorder

- A. An eating or feeding disturbance (e.g., apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate nutritional and/or energy needs associated with one (or more) of the following: 1. Significant weight loss (or failure to achieve expected weight gain or faltering growth in children). 2. Significant nutritional deficiency. 3. Dependence on enteral feeding or oral nutritional supplements. 4. Marked interference with psychosocial functioning.
- B. The disturbance is not better explained by lack of available food or by an associated culturally sanctioned practice.
- C. The eating disturbance does not occur exclusively during the course of anorexia nervosa or bulimia nervosa, and there is no evidence of a disturbance in the way in which one's body weight or shape is experienced.
- D. The eating disturbance is not attributable to a concurrent medical condition or not better explained by another mental disorder. When the eating disturbance occurs in the context of another condition or

disorder, the severity of the eating disturbance exceeds that routinely associated with the condition or disorder and warrants additional clinical attention.

Pica

- A. Persistent eating of nonnutritive, nonfood substances over a period of at least 1 month.
- B. The eating of nonnutritive, nonfood substances is inappropriate to the developmental level of the individual.
- C. The eating behavior is not part of a culturally supported or socially normative practice.
- D. If the eating behaviors occurs in the context of another mental disorder (e.g., intellectual disability [intellectual developmental disorder], autism spectrum disorder, schizophrenia) or medical condition (including pregnancy), it is sufficiently severe to warrant additional clinical attention.

Rumination Disorder

- A. Repeated regurgitation of food over a period of at least 1 month. Regurgitated food may be re-chewed, re-swallowed, or spit out.
- B. The repeated regurgitation is not attributable to an associated gastrointestinal or other medical condition (e.g., gastroesophageal reflux, pyloric stenosis).
- C. The eating disturbance does not occur exclusively during the course of anorexia nervosa, bulimia nervosa, binge eating disorder, or avoidant/restrictive food intake disorder.
- D. If the symptoms occur in the context of another mental disorder (e.g., intellectual disability [intellectual developmental disorder] or another neurodevelopmental disorder), they are sufficiently severe to warrant additional clinical attention.

American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, ed 5, Arlington, Va, 2013, American Psychiatric Association.

TABLE 22-1 Risk and Prognostic Factors Associated with Anorexia Nervosa and Bulimia Nervosa

Diagnosis	Temperament	Environment	Genetic and Physiologic
AN	Obsessional traits in childhood	Cultures/settings that value thinness	First-degree biological relative with AN, BN, bipolar disorder, or depressive disorder
	Anxiety disorders	Occupations/avocations that encourage thinness, e.g., modeling, elite athletics	Higher concordance rates in monozygotic vs. dizygotic twins Functional imaging studies indicate a range of brain abnormalities but unclear if changes are primary anomalies or secondary to malnutrition
BN	Weight concerns	Internalization of thin body ideal	Childhood obesity
	Low self-esteem	Increased weight concerns	Early pubertal maturation
	Depressive symptoms	Childhood sexual abuse	Familial transmission
	Social anxiety disorder	Childhood physical abuse	Genetic vulnerabilities
	Overanxious disorder of childhood		

American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Arlington, VA, American Psychiatric Association, 2013.

that is unduly influenced by body shape and weight (APA, 2013). A binge consumption is an episode of uncontrollable eating of an excessive amount of food. Inappropriate compensatory mechanisms include self-induced vomiting, misuse of laxatives, diuretics, other medications (e.g., thyroid hormone), fasting, and excessive exercise. An individual may employ one or more methods. The DSM-5 includes four levels of severity ratings based on frequency of inappropriate compensatory behaviors: mild, moderate, severe, extreme. Although the default level of severity is

based on the frequency of these episodes, the level of severity may be increased at the clinician's discretion to reflect other symptoms and the degree of functional disability. Lifetime prevalence of BN is approximately 2% in women and 0.5% in men (Hay et al, 2014). Initial presentation typically occurs during adolescence or young adulthood; prepubertal and late onset (after age 40) cases are uncommon. Diagnostic crossover from BN to AN occurs in 10% to 15% of cases. However, individuals who crossover to AN commonly revert back to BN, and some experience

multiple crossovers between these disorders. BN occurs at similar frequencies in industrialized countries (APA, 2013). The prevalence of BN is similar among ethnic groups (APA, 2013). Risk and prognostic factors associated with BN include genetic, physiologic, environmental, and temperamental characteristics (see Table 22-1). BN is associated with a significantly elevated risk for mortality (all-cause and suicide) with a crude mortality rate of approximately 2% per decade (APA, 2013).

Binge Eating Disorder

A major change in the DSM-5 is the official recognition of **binge eating disorder (BED)** as a clinical disorder. Although BED was included in the DSM-IV (APA, 2000), those criteria were established only for research purposes. The essential feature of BED is recurrent episodes of binge eating without inappropriate compensatory measures (such as purging) intended to prevent weight gain. BED diagnostic criteria include four levels of severity ratings (mild, moderate, severe, and extreme) that are based on the frequency of binge episodes. The level of severity may be increased at the clinician's discretion to reflect other symptoms as well as the degree of functional disability. The lifetime prevalence of BED is approximately 3.5% in women and 2% in men (Hay et al, 2014). BED occurs at similar frequencies in most industrialized countries. In the United States prevalence rates appear comparable among Caucasians, Latinos, Asians, and African Americans. BED is more prevalent among individuals seeking weight loss treatment than in the general population. Crossover from BED to other eating disorders is uncommon. Binge eating disorder appears to run in families, which may reflect additive genetic influences (APA, 2013); less is known about temperamental and environmental risk and prognostic factors.

Other Specified Feeding or Eating Disorder

Other specified feeding or eating disorder applies to atypical AN (restrictive eating in the presence of normal weight), atypical BN and atypical BED (episodes are less frequent or of limited duration), purging disorder (i.e., recurrent purging in the absence of binge eating), and night eating syndrome. Treatment of subclinical AN, BN, and BED is similar to that used for full criteria presentation, but the frequency of therapeutic interventions and the treatment setting may differ. Patients with a purging disorder and night eating syndrome often benefit from psychotherapeutic approaches used in the treatment of BN and BED.

CLINICAL CHARACTERISTICS AND MEDICAL COMPLICATIONS

Although EDs are classified as psychiatric illnesses, they are associated with significant medical complications, morbidity, and mortality. Numerous physiologic changes result from the dysfunctional behaviors associated with AN, BN, and BED. Some are minor changes related to excessive or inadequate nutrient intake; some are pathologic alterations with long-term consequences; a few represent potentially life-threatening conditions.

Anorexia Nervosa

Initially, individuals with AN may simply appear underweight. As the disease progresses, patients appear increasingly cachectic and prepubescent in their appearance (see Figure 22-1). Common physical findings at this stage include lanugo (i.e., a soft,

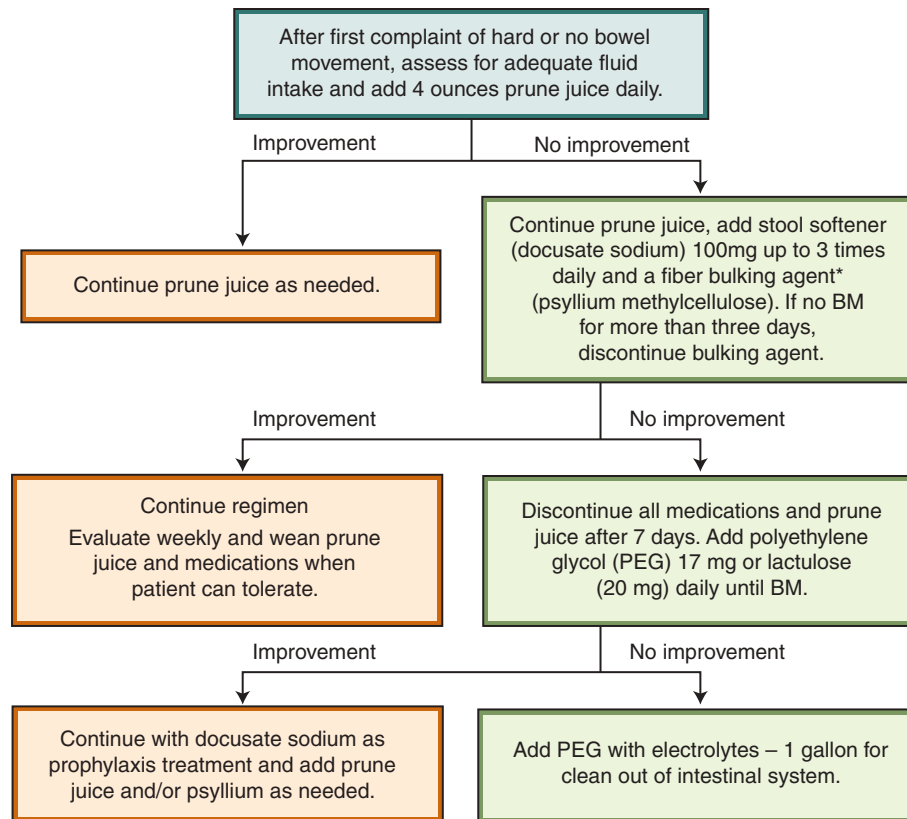

FIGURE 22-1 Physical and clinical signs and symptoms of bulimia nervosa and anorexia nervosa. *DTRs*, Deep tendon reflexes; *ECG*, electrocardiogram; *WBC*, white blood cell.

downy hair growth on the face and extremities), dry skin and hair, cold intolerance, cyanosis of the extremities, edema, and primary or secondary amenorrhea. The degree of symptomatology varies person to person and with duration of illness; for example, some women with anorexia never experience amenorrhea; others exhibit cold intolerance even before weight loss is significant.

Cardiovascular complications may include bradycardia, orthostatic hypotension, cardiac arrhythmias, and pericardial effusion. Protein-energy malnutrition (PEM) with resultant loss of lean body mass is associated with reduced left ventricular mass and systolic dysfunction; however, cardiac function is largely reversible with nutritional rehabilitation and weight restoration. Baseline deficiencies in thiamin, phosphorus, and magnesium levels in very malnourished patients may exacerbate during early refeeding and heart failure may ensue (Winston, 2012). For this reason extremely malnourished patients must be monitored closely during nutritional restoration.

Gastrointestinal complications secondary to starvation include delayed gastric emptying, decreased small bowel motility, and constipation. Complaints of abdominal bloating and a prolonged sensation of abdominal fullness complicate the refeeding process. A protocol for management of constipation during refeeding may be necessary (see Figure 22-2).

The over use of laxatives is common and are used to control weight or offset the effects of binge eating. Laxatives are among the most commonly abused substances in this population with prevalence rates ranging from 10-60% (Tozzi et al, 2006). Because of the high prevalence of laxative use it is important to be cautious when treating constipation in these individuals. Prophylactic measures during refeeding or weaning from laxative abuse may include the use of prune juice, a stool softener (docusate sodium) or a bulking agent (psyllium methylcellulose.) An example of a treatment plan for an individual in an inpatient setting is presented above. This treatment approach may be modified when treating someone with less severe eating disorder symptoms to include the addition of high fiber foods and an increase in fluid intake.

(1) Tozzi F et.al. Features associated with laxative abuse in individuals with eating disorders. *Psychosom Med* 68:470,2006.

FIGURE 22-2 Algorithm for treatment of constipation in eating disorders in an inpatient treatment setting.

Bone loss occurs frequently and bone mineral density (BMD) findings consistent with osteopenia in early illness, and osteoporosis later in the course of disease, have been described. Hormonal adaptations aimed at decreasing energy expenditure during periods of chronic energy restriction cause an uncoupling of bone formation and resorption that results in decreased bone mass (Fazeli and Klibanski, 2014). A number of therapies have been investigated to treat low bone mass in AN (i.e., oral contraceptives, physiologic estrogen replacement, insulin-like growth factor I, androgen replacement, and bisphosphonates); however, none result in normalization of BMD, and the effect of treatment on risk of fracture is unknown (Fazeli and Klibanski, 2014). Bone density of males with AN actually may be worse than their female counterparts (Mehler et al, 2011).

Women with AN have thyroid hormones levels consistent with the nonthyroidal illness syndrome: thyroxin (T_4) and triiodothyronine (T_3) are low or low normal, reverse T_3 is elevated,

and thyroid-stimulating hormone (TSH) is normal. This syndrome is likely an adaptive response to conserve energy during chronic undernutrition, and these abnormalities usually normalize with refeeding (Fazeli and Klibanski, 2014).

Hepatic changes are generally asymptomatic and self-limiting, but rare cases of severe liver damage and liver failure have been reported. Abnormalities in liver function tests may occur before refeeding and improve during nutritional rehabilitation or arise during the course of refeeding. When this occurs during refeeding, it is suggested that increased carbohydrate intake stimulates increased insulin secretion causing lipogenesis and fatty changes in the liver (Winston, 2012).

Renal complications include renal insufficiency, decreased renal concentrating ability, increased urine output, proteinuria, and hematuria. In general, these symptoms ameliorate with adequate hydration and treatment of malnutrition (Campbell and Peebles, 2014).

Hematologic abnormalities include anemia, leukopenia, and thrombocytopenia. AN patients may present with mild, moderate, or severe anemia that is frequently attributed to bone marrow failure. Iron deficiency anemia is, however, relatively uncommon (Cleary et al, 2010). In a sample of 53 severely malnourished AN patients, 83% were anemic, but only 3 (6%) were iron deficient (Sabel et al, 2013).

Bulimia Nervosa

Clinical signs and symptoms of BN are more difficult to detect because patients are usually of normal weight and secretive in behavior. When vomiting occurs, there may be clinical evidence such as (1) scarring of the dorsum of the hand used to stimulate the gag reflex, known as **Russell's sign** (see Figure 22-3); (2) parotid gland enlargement; and (3) erosion of dental enamel with increased dental caries resulting from the frequent presence of gastric acid in the mouth.

Gastrointestinal complaints are common in individuals with BN who use vomiting as a purging method. These may include sore throat, dysphagia, gastrointestinal reflux, esophagitis, mild hematemesis (vomiting of blood), and subconjunctival hemorrhage (Brown and Mehler, 2013). More serious gastrointestinal complications include Mallory-Weiss esophageal tear, rare occurrence of esophageal rupture, and acute gastric dilation or rupture. Symptoms associated with laxative misuse vary with type, dose, and duration of use. Patients may present with diarrhea, abdominal cramping, rectal bleeding, and rectal prolapse. Abuse of stimulant laxatives (i.e., those containing bisacodyl, cascara, or senna) can damage intestinal nerve fibers in the bowel wall, whereby the colon becomes increasingly dependent on these stimulants to propulse fecal material; this results in cathartic colon syndrome (Brown and Mehler, 2012). Cessation of laxatives, particularly of the stimulant type, may result in

severe rebound constipation that requires ongoing medical management.

Vomiting, laxative misuse, and diuretic misuse are associated with fluid and acid-base imbalances. Hypokalemic, hypochloremic metabolic alkalosis occurs in patients who vomit and abuse diuretics; hypokalemic, hyperchloremic metabolic acidosis occurs in patients who abuse laxatives (Winston, 2012). Hypokalemia is associated with increased risk of atrial and ventricular arrhythmias (Trent et al, 2013). Patients who abuse ipecac to induce vomiting are at risk for cardiomyopathy, sudden death, and congestive heart failure (Trent et al, 2013).

Individuals with BN may experience menstrual irregularity, leading to the mistaken belief that they are unable to conceive. Thus unplanned pregnancy can occur, with the possibility of negative outcomes such as lower birthweight and a smaller head circumference (Koubaa et al, 2013). An association between BN and miscarriage has been less consistently observed (Linna et al, 2013). It is unknown if negative outcomes are associated with malnutrition, inadequate prenatal care resulting from delayed detection of pregnancy, or another mechanism specific to bulimic behavior.

Binge Eating Disorder

The predominant feature of BED is episodes of excessive eating. In many cases, but not all, this binge eating results in overweight or obesity, yet causes greater functional impairment, decreased quality of life, and greater levels of psychiatric comorbidity than obesity without BED (Wilson, 2011). Ingestion of large amounts of food may cause considerable upper and lower gastrointestinal distress. Symptoms include abdominal pain, fullness, delayed gastric emptying, bloating, acid regurgitation, heartburn, dysphagia, nausea, diarrhea, constipation, hard or loose and watery stools, fecal urgency, fecal incontinence, and anal blockage. It may be difficult to sort out physical complications of BED that are independent of body weight status. For example, metabolic syndrome is common in obese patients with BED (Barnes et al, 2011).

TREATMENT APPROACH

Treatment of EDs requires a multidisciplinary approach that includes psychiatric, psychologic, medical, and nutrition interventions, ideally provided at a level of care appropriate to the severity of the illness. Levels of care offered by facilities in the United States include inpatient hospitalization, residential treatment, partial or day hospitalization, intensive outpatient treatment, and outpatient treatment. Treatment guidelines and policy statements on the necessary components of treatment are available from the American Psychiatric Association (APA, 2006; APA, 2012), the Society for Adolescent Health and Medicine (SAHM, 2015), the American Academy of Pediatrics (Rosen and American Academy of Pediatrics Committee on Adolescence, 2010), the Academy of Nutrition and Dietetics (Ozier et al, 2011), and the Royal Australian and New Zealand College of Psychiatrists (Hay et al, 2014).

Inpatient treatment can be provided on a psychiatric or medical unit of a general or specialty hospital and a behavioral protocol developed specifically for the management of eating-disordered patients is highly recommended. Residential treatment programs also provide 24-hour care but are less likely to admit the medically or psychiatrically unstable patient because of their location outside of a hospital setting. Partial and day hospital programs typically provide 6 to 8 hours of specialized

FIGURE 22-3 Russell's sign: calluses on the knuckles or the back of the hand resulting from repeated self-induced vomiting over a long period of time.

multidisciplinary treatment for 5 to 7 days per week, depending on an individual patient's need for supervision, and decreasing as improvement occurs. Intensive outpatient treatment programs provide several hours of multidisciplinary care each week. This may be scheduled in the late afternoon or early evening so that the patient can attend after school or work. The least intensive form of treatment is outpatient care, with separate psychotherapist, doctor, and dietitian nutritionist appointments. Because providers may be in more than one physical location, effective outpatient care will require ongoing, coordinated effort.

Standard guidelines use a variety of factors in determining the recommended care level, but the ultimate decision should be made by the health care professionals based on individual needs.

PSYCHOLOGIC MANAGEMENT

EDs are complex psychiatric illnesses that require psychologic assessment and ongoing treatment. Evaluation of the patient's cognitive and psychologic stage of development, family history, family dynamics, and psychopathologic condition is essential for the development of a comprehensive psychosocial treatment program.

The long-term goals of psychosocial interventions in AN are (1) to help patients understand and cooperate with their nutritional and physical rehabilitation, (2) to help patients understand and change behaviors and dysfunctional attitudes related to their EDs, (3) to improve interpersonal and social functioning, and (4) to address psychopathologic and psychologic conflicts that reinforce or maintain eating-disordered behaviors.

In the acute stage of illness, malnourished AN patients are obsessive and negativistic, making it difficult to conduct formal psychotherapy. It therefore is recommended that intensive, highly structured psychologic therapies be initiated after the medical and cognitive effects of acute starvation have been stabilized (Hay et al, 2014). Behavior modification protocols that link privileges and “rewards” (e.g., physical activity vs. bed rest, off-unit passes, visits from friends and family) to targeted weight gain and food intake goals are used commonly during inpatient or residential treatment (Attia and Walsh, 2009). Once acute malnutrition has been corrected and weight restoration is underway, the AN patient is more likely to benefit from psychotherapy. Psychotherapy can help the patient understand and change core dysfunctional thoughts, attitudes, motives, conflicts, and feelings related to his or her ED. Associated psychiatric conditions, including deficits in mood, impulse control, and self-esteem, as well as relapse prevention, should be addressed in the psychotherapeutic treatment plan.

No consensus has been reached on the best overall approach to psychotherapy in AN. Studies suggest that family-based therapy (FBT) is the first-line treatment for adolescents less than 19 years of age with duration of illness less than 3 years (Hay et al, 2014). If FBT is contraindicated, then enhanced cognitive behavioral therapy (CBT-E) may be an effective option for the adolescents (Dalle Grave et al, 2013). In adults with AN, CBT-E may be the best choice. FBT and CBT-E are specialized therapies that require highly trained psychotherapists. If FBT and CBT-E are unavailable, then individualized psychotherapy provided by a therapist with experience in the management of eating disorders should be initiated.

Cognitive behavioral therapy (CBT) is structured present-oriented psychotherapy that combines behavioral and cognitive

BOX 22-2 The SCOFF Questionnaire

1. Do you make yourself **Sick** because you feel uncomfortably full?
2. Do you worry you have lost **Control** over how much you eat?
3. Have you recently lost more than **One** stone (14 lb) in a 3-month period?
4. Do you believe yourself to be **Fat** when others say you are too thin?
5. Would you say that **Food** dominates your life?

* Two or more “yes” answers suggest the presence of an eating disorder. From Morgan JF, Reid F, Lacey JH: *BMJ* 4:1467, 1999.

principles. It directs the client toward modifying dysfunctional thinking and behavior (see Chapter 14). It is thought to be the best therapy option for adults with BN; however, interpersonal therapy (IPT) has also demonstrated benefits (Kass et al, 2013). Dialectical behavioral therapy (DBT), a skill-based therapy that focuses on mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness, may be helpful in BN cases in which comorbid psychiatric disorders (e.g., depression and mood disorders, personality disorders, and substance abuse disorders), self-injurious behaviors (e.g., cutting), and greater impulsivity are manifested (Berg and Wonderlich, 2013). In some instances, an antidepressant medication (typically a selective serotonin reuptake inhibitor [SSRI] such as fluoxetine) is prescribed adjunctive to psychotherapy. Technology-based interventions using smartphone applications are currently being tested in this population.

A variety of psychologic and pharmacologic interventions are used to treat BED (Wilson, 2011). CBT and IPT are efficacious treatments, with total remission of binge eating reported in greater than 50% of cases at 1-, 2-, and 5-year follow-ups. Behavioral weight loss treatment and guided self-help (using CBT-based manuals) have been used with varying degrees of success (Wilson, 2011). Pharmacotherapy with antidepressant and antiepileptic agents is less effective than psychotherapy, and when combined with psychotherapy, medications fail to augment the treatment response (Wilson, 2011).

Several validated psychologic instruments and questionnaires are available for the assessment of patients with EDs. Self-report measures may be used for screening purposes, whereas structured interviews often are used to confirm the diagnosis, or assess response to treatment. Representative instruments include the Eating Attitudes Test (Eat-26), Eating Disorder Inventory, Eating Disorder Examination, Eating Disorders Questionnaire, and the Yale-Brown-Cornell Eating Disorder Scale (APA, 2006). The SCOFF (Morgan et al, 1999), a brief and effective screening tool that is easy to administer and score, is highlighted in Box 22-2.

NUTRITION MANAGEMENT

Roles and responsibilities of the registered dietitian nutritionist (RDN) in the treatment of individuals with eating disorders include assessment, intervention, monitoring, evaluation, and care coordination. Although AN, BN, and BED have different presenting features, similarities exist in the assessment and management of these disorders.

Nutrition Assessment

Nutrition assessment should include a thorough diet history, as well as the evaluation of biochemical, energy metabolism, and anthropometric markers of nutritional status.

Diet History

The diet history should include assessment of energy; macronutrient, micronutrient, and fluid intakes; energy density; diet variety; and an evaluation of eating attitudes, behaviors, and habits (see Chapter 4). Patients with a shorter duration of illness should be queried about their premorbid diet and eating habits as this may be a useful benchmark by which to gauge recovery.

Anorexia Nervosa

Patients with restricting type AN typically eat fewer than 1000 kcal/day. Patients with binge-purge type AN have more variable diet patterns, and energy intake should be assessed across the spectrum of restriction and binge eating. The early literature often described AN patients as carbohydrate “phobic” (Russell, 1967). Recent studies report a restriction of dietary fat, with intakes substantially less than 30% of calories (Schebendach et al, 2008). Percent of calories contributed by protein may be in the average to above-average range, but adequacy of protein intake becomes marginalized as caloric intake decreases. A vegetarian diet may affect the adequacy of high-biologic value protein intake.

Inadequate calories, limited diet variety, and poor food group representation increase risk for deficient micronutrient intakes. In general, micronutrient intake parallels macronutrient intake; thus AN patients who consistently restrict dietary fat are at greater risk for diets that are deficient in essential fatty acids and fat-soluble vitamins. Based on a 30-day diet history, Hadigan et al (2000) found that more than 50% of 30 AN patients failed to meet Recommended Dietary Allowances (RDA) for vitamin D, calcium, folate, vitamin B₁₂, magnesium, copper, and zinc (see inside front cover for DRIs). Abnormal fluid balance is common, and the diet history should query patients about types, amounts, and rationale for fluid intake. Some individuals restrict fluid intake because they find it difficult to tolerate feelings of fullness afterward; others drink excessive amounts to feel full and suppress appetite. Extremes in fluid restriction or ingestion may require monitoring of urine specific gravity and serum electrolytes. Many AN patients consume excessive amounts of artificially sweetened beverages and artificial sweeteners. Use of these products should be addressed during the course of nutrition therapy.

Bulimia Nervosa

Chaotic eating, ranging from restriction to normal eating to binge eating, makes it difficult to assess total energy intake in BN. The caloric content of a binge, the degree of caloric absorption after a purge, and the extent of calorie restriction between binge episodes must be evaluated. Patients with BN assume that vomiting is an efficient mechanism for eliminating calories consumed during binge episodes; however, this is a common misconception. In a study of the caloric content of foods ingested and purged in a feeding laboratory, it was determined that, as a group, BN subjects consumed a mean of 2131 kcal during a binge and vomited only 979 kcal afterward (Kaye et al, 1993). As a rule of thumb, RDNs can estimate that approximately 50% of energy consumed during a binge is retained.

In a similar manner, patients misusing laxatives believe that catharsis will prevent the absorption of food and calories; however, laxatives do not act on the small intestine, where the majority of absorption occurs. In a laboratory study that was conducted by Bo-Linn et al (1983), two BN participants ate a standardized diet and took their regular daily dose of laxatives (35 and 50 tablets, accordingly). Results indicated that despite outputs of 4 to 6 L of diarrhea per day, these participants

BOX 22-3 Determination of Average Daily Energy Intake in the Individual with BN

1. Keep a record of patient intake for 7 days.
2. Out of the 7 days determine the number of nonbinge days (which may include restrictive and normal intake days)
3. Approximate the total caloric content for the week.
4. Determine the number of binge days.
5. Determine the approximate caloric content of the binge days and then deduct 50% of the caloric content of binges that are purged (vomited).
6. Finally, average the caloric intake over the 7-day period. Determination of this average energy intake, as well as the range of intake, will be useful information for the assessment process.

decreased calorie absorption by only 12%. Because of day-to-day variability, a 24-hour recall is not a particularly useful assessment tool. To assess energy intake, it is helpful to estimate daily food consumption over the course of a week using the method outlined in Box 22-3.

Nutrient intake in BN patients varies with the cycle of binge eating and restriction, and it is likely that overall diet quality and micronutrient intake is inadequate. A 14-day dietary intake study of 50 BN patients revealed that at least 50% of participants consumed less than two thirds of the recommended dietary allowance (RDA) for calcium, iron, and zinc on nonbinge days. Furthermore, 25% of participants still had inadequate intakes of zinc and iron when overall intake (i.e., binge and nonbinge days) was assessed (Gendall et al, 1997). Even when the diet appears adequate, nutrient loss occurs secondary to purging, thus making it difficult to assess true adequacy of nutrient intake. Use of vitamin and mineral supplements also should be determined but, once again, retention after purging must be considered.

Eating Behavior

Characteristic attitudes, behaviors, and eating habits seen in AN and BN are shown in Box 22-4. Food aversions, common in this population, include red meat, baked goods, desserts, full-fat dairy products, added fats, fried foods, and caloric beverages. Patients with EDs often incorrectly regard specific foods or groups of foods as absolutely “good” or absolutely “bad.” Irrational beliefs and dichotomous thinking about food choices should be identified and challenged throughout the treatment process.

In the assessment process, the RDN may discover unusual or ritualistic behaviors the patient practices, such as ingestion of food in an atypical manner or with nontraditional utensils; unusual food combinations; or the excessive use of spices, vinegar, lemon juice, and artificial sweeteners. Meal spacing and length of time allocated for a meal also should be determined. Many patients save their self-allotted food ration until late in the day; others are fearful of eating past a certain time of day.

Many AN patients eat in an excessively slow manner, often playing with their food and cutting it into small pieces. This is sometimes regarded as a tactic to avoid food intake, but it also may be an effect of starvation (Keys et al, 1950). Time limits for meal and snack consumption frequently are incorporated into behavioral treatment plans and family-based therapy.

Many BN patients eat quickly, reflecting their difficulties with satiety cues. In addition, BN patients may identify foods they fear will trigger a binge episode. The patient may have an all-or-nothing approach to “trigger” foods. Although the patient may

BOX 22-4 Assessment of Eating Attitudes, Behaviors, and Habits

1. Eating attitudes
 - A. Food aversions
 - B. Safe, risky, forbidden foods
 - C. Magical thinking
 - D. Binge trigger foods
 - E. Ideas on appropriate amounts of food
 - F. Refusal to eat a food item that does not have a nutrition facts label
2. Eating behaviors
 - A. Ritualistic behaviors
 - B. Unusual food combinations
 - C. Atypical use of condiments (e.g., mustard, lemon juice, vinegar) and seasonings (e.g., black pepper)
 - D. Atypical use of eating utensils and use of utensils to consume a finger food (e.g., using a knife and fork to eat a muffin)
 - E. Excessive use of artificial sweeteners
3. Eating habits
 - A. Intake pattern
 - (1) Number of meals and snacks
 - (2) Time of day, including times when eating may be restricted (e.g., patients will not permit themselves to eat before or after a certain time in the day).
 - (3) Duration of meals and snacks
 - (4) Eating environment—where and with whom
 - (5) How consumed—sitting or standing or while looking at a screen
 - B. Food group avoidance; particularly those with higher energy density
 - C. Diet variety from all food groups, including those with a low energy density content
 - D. Fluid consumption:
 - Restricted vs. excessive
 - Types: caloric, noncaloric, beverage water

prefer avoidance, assistance with reintroduction of controlled amounts of these foods at regular times and intervals is helpful.

Patients may feel a sense of shame about particular food and eating practices, so these behaviors may not be identified during the initial assessment period. The assessment process continues during subsequent meetings and, in some cases, will not be complete until the RDN has observed the patient during a meal time.

Biochemical Assessment

The marked cachexia of AN may lead one to expect many biochemical indices of malnutrition (see Chapter 7), but this is rarely the case. Compensatory mechanisms are remarkable, and laboratory abnormalities may not be observed until the illness is far advanced.

Significant alterations in visceral protein status are uncommon in AN. Indeed, adaptive phenomena that occur in chronic starvation are aimed at the maintenance of visceral protein metabolism at the expense of the somatic compartment. Although serum albumin is usually normal, when hypoalbuminemia does occur, it is associated with a poorer prognosis (Winston, 2012). A low baseline transferrin concentration that improves with weight restoration may occur. A low serum prealbumin level may be associated with the development of serious complications of refeeding (i.e., hypophosphatemia and hypoglycemia) in extremely underweight individuals (Gaudiani et al, 2014) (see Appendix 22).

Despite typical consumption of a very low-fat, low-cholesterol diet, malnourished AN patients often manifest elevated total

cholesterol, LDL cholesterol, and HDL cholesterol levels (Winston, 2012). Although the cause is unclear and cardiovascular risk is uncertain, the bulk of available evidence suggests that lipid abnormalities improve or normalize after recovery and a low-fat, low-cholesterol diet is not warranted during the weight restoration process. If hyperlipidemia predates the development of AN, or a strong family history of hyperlipidemia is identified, the patient can be reassessed after nutritional rehabilitation. Lipid profiles routinely are included in laboratory assessments; however, a fasting lipid profile is not warranted until the patient is restored to a healthy and stable body weight.

Individuals with BN also may have elevated lipid levels, but the validity of the test must be questioned if the patient is actively binge eating. Furthermore, some BN patients cannot comply with the abstinence period required for a fasting lipid profile. Patients with BN eat chaotically, consuming a high-fat, high-calorie diet during binge episodes, and a low-fat, low-calorie diet during intermittent periods of restriction. An inaccurate lipid profile may lead to the unnecessary prescription of a low-fat, low-cholesterol diet, which in turn may exacerbate binge eating episodes and reinforce an all-or-nothing approach to eating. If hyperlipidemia predates the development of BN, or if a strong family history of hyperlipidemia is identified, the patient should be reassessed after eating behavior and diet are stabilized (see Chapter 33).

Hypoglycemia results from a deficit of precursors that are needed for gluconeogenesis and glucose production. Patients with mild hypoglycemia are often asymptomatic; however, severe hypoglycemia is associated with increased risk of the refeeding syndrome (Gaudiani et al, 2014) and hospitalization may be warranted (Winston, 2012; see Chapter 13).

Vitamin and Mineral Deficiencies

Despite obviously deficient diets, surprisingly few studies address biochemical markers of micronutrient status in patients with eating disorders. The decreased need for micronutrients in a catabolic state, possible use of vitamin supplements, and the selection of micronutrient-rich foods may afford some degree of protection in low weight patients; however, the shift from catabolic to anabolic processes may precipitate micronutrient deficiencies during refeeding and weight restoration. Zinc, copper, vitamin C, vitamin A, riboflavin, and vitamin B₆ deficiencies have been reported in AN. Thiamin deficiency, prevalent among low-weight AN patients, is exacerbated by increased carbohydrate intake during refeeding, and a thiamin supplement may be warranted (Winston, 2012). Given that assays for some vitamins and trace elements may not always be readily available, and that the relationship between blood concentrations and whole-body status is unclear, it may be more practical to prescribe a prophylactic vitamin/mineral supplement during refeeding and weight restoration (Winston, 2012).

Hypercarotenemia, attributed to mobilization of lipid stores, catabolic changes caused by weight loss, and metabolic stress, may occur in AN; excessive dietary intake of carotenoids is less likely. Hypercarotenemia resolves during weight restoration and measurement of serum carotene levels is unnecessary.

Iron requirements are decreased in AN secondary to amenorrhea and the overall catabolic state. At treatment onset, the hemoglobin level may be falsely elevated as a result of dehydration resulting in hemoconcentration. Malnourished patients may also have fluid retention, and associated hemodilution may

falsely lower the hemoglobin level. In severely malnourished AN patients, iron use may be blocked. Loss of lean tissue results in decreased red blood cell mass. Iron released from red cell mass is bound to ferritin and stored. Saturated ferritin-bound iron stores increase the risk of unbound iron that may result in cell damage, and use of iron supplements should be avoided at this phase of treatment (Royal College of Psychiatrists, 2005). During nutrition rehabilitation, ferritin-bound iron is taken out of storage; this is generally adequate to meet the need for cellular repair and increased red blood cell mass. Patients should, however, be periodically reassessed for depletion of their reserve and the possible need for supplemental iron later in treatment.

Zinc deficiency may result from inadequate energy consumption and transition to a vegetarian diet. Although zinc deficiency may be associated with altered taste perception and weight loss, there is no evidence that deficiency causes or perpetuates symptoms of AN. Supplemental zinc is purported to enhance food intake and weight gain in AN patients, but there is limited evidence to support this claim (Lock and Fitzpatrick, 2009).

Inadequate calcium and vitamin D intakes are reported in AN (Marzola et al, 2013). Although these nutrients contribute to healthy bone development, their role in the cause and treatment of bone loss appears to be minimal (Fazeli and Klibanski, 2014; Mehler et al, 2011). Dual x-ray absorptiometry (DXA) to determine the degree of impaired bone mineralization is recommended in AN (see Chapters 7 and 24).

Laboratory values are not always accurate in assessing micronutrient deficiencies because blood values in many cases do not reflect the full extent of depletion of total body nutrient stores.

Fluid and Electrolyte Balance

Vomiting and laxative and diuretic use can result in significant fluid and electrolyte imbalances in patients with EDs (Trent et al, 2013). Laxative use may result in hypokalemia, and diuretic use may result in hypokalemia and dehydration. Vomiting is associated with dehydration, hypokalemia, and alkalosis with hyponatremia. Hyponatremia, another serious complication, occurs less frequently.

Urine concentration is decreased and urine output is increased in semistarvation. Edema may occur in response to malnutrition and refeeding. An increase in extracellular water frequently occurs in AN patients with a BMI less than 15 to 16 kg/m² (Rigaud et al, 2010). Although fluid retention generally dissipates with refeeding, a moderate sodium-restricted diet (4 to 5 g NaCl/day) may be helpful (Rigaud et al, 2010). Depletion of glycogen and lean tissue is accompanied by obligatory water loss that reflects characteristic hydration ratios. For example, the obligatory water loss associated with glycogen depletion may be in the range of 600 to 800 ml. Varying degrees of fluid intake, ranging from restricted to excessive, may affect electrolyte values in patients with eating disorders (see Chapter 6).

Energy Expenditure

Resting energy expenditure (REE) is characteristically low in malnourished AN patients (Kosmiski et al, 2014). Weight loss, decreased lean body mass, energy restriction, and decreased leptin levels have been implicated in the pathogenesis of this hypometabolic state. Refeeding increases and normalizes REE in AN patients. An exaggerated diet-induced thermogenesis (DIT) also has been reported during the course of refeeding, and this may pose metabolic resistance to weight gain during the course of nutritional rehabilitation in patients with AN (Kosmiski et al, 2014).

Patients with BN can have unpredictable metabolic rates. Intermittent periods of dietary restraint may result in a hypometabolic rate. However, binge eating followed by purging can increase the metabolic rate secondary to a preabsorptive release of insulin that activates the sympathetic nervous system.

Baseline and follow-up measurements of REE are useful during the nutritional rehabilitation process (Mehler et al, 2010), but access to indirect calorimetry equipment often is limited. Handheld calorimeters are readily available but data on their accuracy in this patient population are limited (Hipskind et al, 2011; see Chapter 2).

Anthropometric Assessment

Patients with AN have protein-energy malnutrition, characterized by significantly depleted adipose and somatic protein stores but a relatively intact visceral protein compartment. These patients meet the criteria for a diagnosis of severe protein-energy malnutrition. A goal of nutritional rehabilitation is restoration of body fat and fat-free mass. Although these compartments do regenerate, the extent and rate vary.

Body composition studies of eating disordered patients have used underwater weighing, dual-energy x-ray absorptiometry (DXA) equipped with body composition software, and skinfold thicknesses. Imaging techniques such as CT and MRI also have been used to obtain detailed measurements of specific regions or tissues (e.g., visceral adipose fat) or fat infiltration of tissues. Most methodologies are limited to the research setting. Bioelectrical impedance analysis (BIA) is more clinically available, but shifts in intracellular and extracellular fluid compartments in patients with severe EDs may affect the accuracy of body fat estimate (see Chapter 7 and Appendix 22).

Careful assessment and routine monitoring of body weight and stature are critical in the clinical management of patients with EDs. In AN, weight gain and then maintenance is necessary for recovery. In BN, cessation of binge eating and purging episodes is the immediate goal. In BED, cessation of binge eating is the immediate goal, and weight loss is a secondary objective.

When individual body composition data are not available, estimates of appropriate weight ranges are a substandard option. Typical methods historically used by RDNs, such as Metropolitan Life Insurance Company tables and the Hamwi method provide widely varying and empirically unsupported results.*

Use of BMI has become increasingly accepted in the management of AN patients (see Chapter 7 and Appendix 18). Four categories of BMI severity ratings, based on the World Health Organization categories for thinness in adults, have been incorporated into the DSM-5 (APA, 2013). For children and adolescents, BMI percentiles with corresponding thinness cutoffs should be used (Cole et al, 2007).

Delayed growth and stunting can occur in AN, and growth records should be obtained to determine whether linear growth has deviated from premorbid height curves. If stunting has occurred, calculation of the weight deficit should be based on the premorbid height percentile.

Because puberty and peak height velocity occur later in males than females, boys are more vulnerable to the impact of

*Hamwi Method for women: 100 lb for the first 5 feet of height plus 5 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame. For men: 106 lb for the first 5 feet of height plus 6 lb per inch for every inch over 5 feet plus 10% for a large frame and minus 10% for a small frame.

malnutrition on growth and development (Nicholls et al, 2011). Pubertal ratings (e.g., Tanner stages, see Appendices 12 and 13), a baseline bone age x-ray, growth history (i.e., carefully plotted growth charts), and parental height measurements provide information about actual versus expected development. In all age groups, height should be measured carefully using a stadiometer rather than a scale-anchored measuring rod (see Appendix 14).

The height, weight, and BMI percentile tables of the NCHS can be used to assess boys and girls up to 20 years of age (see Appendices 6, 7, 10, and 11). Expected body weight in adolescents also can be determined from weight-for-stature (defined as the median weight by sex, age, and height group) tables recently derived from NHANES II data by Golden et al (2012).

Rate of weight gain in AN may be affected by hydration status, glycogen stores, metabolic factors, and changes in body composition (see Box 22-5). Rehydration and replenished glycogen stores contribute to weight gain during the first few days of refeeding. Thereafter, weight gain results from increased lean and fat stores. A general assumption is that someone has to increase or decrease caloric intake by 3500 kcal to cause a 1-lb change in body weight, but the true energy cost depends on the type of tissue gained. More energy is required to gain fat versus lean tissue, but weight gain may be a mix of fat and lean tissues.

In adult women with AN, short-term weight restoration has been associated with a significant increase in truncal fat and central adiposity; this distribution, however, appears to normalize within 1 year of weight maintenance (Mayer et al, 2009). Short-term weight restoration in adolescent females has been associated with and without central adiposity (de Alvaro et al, 2007; Franzoni et al, 2013).

In hospitalized AN patients, an early morning, preprandial, gownned body weight measurement should be obtained every 1 to 2 days. Before weigh-in the patient should void, and urine specific gravity should be checked for dehydration or fluid loading.

BOX 22-5 Factors Affecting Rate of Weight Gain in Anorexia Nervosa

1. Fluid balance
 - A. Polyuria seen in semistarvation
 - B. Edema
 - (1) Starvation
 - (2) Refeeding
 - C. Hydration ratios in tissues
 - (1) Glycogen: 3-4:1
 - (2) Protein stores: 2-3:1
2. Metabolic rate
 - A. Resting energy expenditure (REE): Low weight: REE 30%-40% below predicted value for height, weight, age, gender
Refeeding: progressive increases in REE
Weight restoration: REE normalizes
 - B. Postprandial energy expenditure (PPEE)
Under normal metabolic conditions: PPEE approx. 10% greater than REE
In AN: PPEE may be 30%-40% greater than REE
Duration of exaggerated response varies among individuals
 - C. Respiratory quotient
3. Energy cost of tissue gained
 - A. Lean body mass (early to midtreatment)
 - B. Adipose tissue (mid- to late treatment)
4. Previous obesity associated with decreased metabolic resistance to weight gain
5. Physical activity: volitional vs. fidgeting

If the patient claims to be unable to provide a urine specimen, the physician should examine the patient to see whether the bladder is full. Patients may resort to deceptive tactics (water loading, hiding heavy objects on their person, and withholding urine and bowel movements) to make a mandated weight goal.

On an outpatient basis, a gownned weight should be obtained on the same scale, at approximately the same time of day, at least once a week in early treatment. Before informing a patient of his or her weight or weight goals, the RDN should consult with the other members of the treatment team about the pros and cons of this information on the patient's recovery.

MEDICAL NUTRITION THERAPY AND COUNSELING

Treatment of an ED may begin at one of five levels of care: outpatient, intensive outpatient, partial or day treatment, inpatient, or residential. The registered dietitian nutritionist (RDN) is an essential part of the treatment team at all levels of care; roles and responsibilities of caring for individuals with eating disorders are summarized in Table 22-2.

In AN, the chosen level of care is determined by the severity of malnutrition, degree of medical and psychiatric instability, duration of illness, growth failure, and ability to manage recovery in the home. In some instances, treatment begins on an inpatient unit but is stepped down to a less intensive level of care as weight restoration progresses. In other instances, treatment begins on an outpatient basis; however, if progress is absent or considered inadequate, care is stepped up to a more intensive level.

In BN, treatment typically begins and continues on an outpatient basis. On occasion a BN patient may be directly admitted to an intensive outpatient or day treatment program. However, inpatient hospitalization is relatively uncommon and generally is of short duration and for the specific purpose of fluid and electrolyte stabilization.

Anorexia Nervosa

Guidelines for MNT for AN are summarized in Box 22-6. Goals for nutrition rehabilitation include restoration of body weight and normalization of eating patterns and behaviors. Although MNT is an essential component of treatment, guidelines are based largely on clinical experience rather than scientific evidence.

Weight restoration is essential for recovery. The medically unstable, severely malnourished, or growth-retarded patient typically requires supervised weight gain in a specialized hospital unit or residential ED treatment program. Treatment programs often have three phases to the weight restoration process: weight stabilization and prevention of further weight loss, weight gain, and weight maintenance. Although the duration of these phases vary, the weight restoration process is typically the longest and is obviously influenced by the patient's state of malnutrition.

Treatment typically includes a targeted rate of expected weight gain. The APA recommends a weight gain of 2 to 3 lb/week during inpatient or residential treatment (APA, 2006); however, others consider this rate too conservative (SAHM, 2015, Garber et al, 2012; Katzman, 2012; Kohn et al, 2011).

Initial calorie prescriptions, and subsequent caloric adjustments, are also not widely agreed upon. Convention has been to "start low and advance slow" and to prescribe initial diets in the range of 30 to 40 kcal/kg of body weight per day (approximately 1000 to 1600 kcal/day) (APA, 2006), but this approach recently has been challenged. Whitelaw et al (2010) safely initiated weight gain using a meal-based diet that provided approximately

TABLE 22-2 Roles and Responsibilities of Registered Dietitian Nutritionists Caring for individuals with Eating Disorders

<p>Nutrition Assessment: Identify nutrition problems that relate to medical and physical condition, including eating disorder symptoms and behaviors.</p>	<p>Specific Activities: Eating patterns Core eating attitudes Core attitudes regarding body weight and shape Assess behavioral-environmental symptoms: Food restriction Binge eating Preoccupation Rituals Secretive eating Affect and impulse control Vomiting or other purging behaviors Excessive exercise Anthropometric assessment: Perform anthropometric measurements Obtain height and weight history Complete growth chart Assess growth patterns and maturation in patients ≤ age 20 years Interpret biochemical data and assess risk of refeeding syndrome Apply diagnosis, plan intervention, coordinate with treatment team</p>
<p>Nutrition Intervention: Calculate and monitor energy and macronutrient intake to establish expected rates of weight change, and body composition and health goals. Guide goal setting to normalize eating patterns for nutrition rehabilitation and weight restoration or maintenance as appropriate.</p>	<p>Ensure diet quality, regular eating pattern, increased amount and variety of foods, normal perceptions of hunger and satiety, provide suggestions about supplement use Provide a structured meal plan Provide psychological support and positive reinforcement Counsel patients and caregivers on food selection with consideration given to individual preferences, health history, physical factors, psychological factors, and resources</p>
<p>Nutrition Monitoring & Evaluation: Monitor nutrient intake and adjust as needed.</p>	<p>Monitor rate of weight gain Upon weight restoration, adjust food plan for weight maintenance Communicate progress with the treatment team Adjust treatment plan as needed</p>
<p>Care Coordination: Provide counsel to team about protocols to maximize tolerance of feeding regimen or nutrition recommendations, guidance about supplements to ensure maximum absorption, minimize drug nutrient interactions, and referral for continuation of care as needed.</p>	<p>Work collaboratively with the treatment team, delineate roles and tasks, communicate nutrition needs across treatment settings (i.e., inpatient, day patient, outpatient) Function as a resource and educator for other health care professionals and family members Advocate for evidence-based treatment and access to care</p>
<p>Advanced Training: Seek specialized training in other counseling techniques, such as cognitive behavioral therapy, dialectical behavioral therapy, and motivational interviewing.</p>	<p>Use advanced knowledge and skills relating to nutrition Seek supervision and case consultation from a licensed health professional to gain and maintain proficiency in eating disorders treatment</p>

Adapted from: Ozier AD, Henry BW: Position of the American Dietetic Association: Nutrition intervention in the treatment of eating disorders. *J Acad Nutr Diet*, 111: 1236, 2011.

1900 kcal/day. [Kohn et al \(2011\)](#) initiated refeeding using a 40% carbohydrate continuous NG tube feeding diet that provided a minimum of 2000 kcal/day. [Golden et al \(2013\)](#) safely fed hospitalized adolescents on a 1400 to 2000 kcal/day diet. After the baseline calorie prescription is implemented, progressive increases in caloric intake are needed to promote continued weight gain. This increase may be provided in increments of 100 kcal/day (for severely malnourished patients) to 500 kcal/day (for medically stable patients).

Risk of life-threatening complications associated with the **refeeding syndrome (RFS)** may present during the first few weeks of nutritional rehabilitation. Manifestations include fluid and electrolyte imbalance; cardiac, neurologic, and hematologic complications; and sudden death. Risk for the development of RFS may depend more on the degree of malnutrition rather than caloric intake and rate of weight gain ([Agostino et al, 2013](#); [Garber et al, 2012](#); [Golden et al, 2013](#); [Kohn et al, 2011](#); [Whitelaw et al, 2010](#)). A position statement of the Society for Adolescent Health and Medicine (2014) suggests that physicians should have a high

index of suspicion for the development of refeeding hypophosphatemia when severely malnourished adolescents (less than 70% median BMI) are admitted to the hospital for nutritional rehabilitation; guidelines for the interpretation of laboratory findings and phosphate replacement regimens in adolescents are provided. The National Institute for Health and Clinical Excellence (NICE) Guidelines have established two sets of criteria for the identification of adults at high risk for RFS ([NICE, 2009](#)).

At-risk individuals must be monitored carefully with daily measurements of serum phosphorus, potassium, and magnesium for the first 5 to 7 days of refeeding, and every other day for several weeks thereafter. Supplemental phosphorus, magnesium, and potassium may be given orally or intravenously. In some instances, prophylactic supplementation is provided to high-risk individuals; in other cases, supplementation is based on serum levels. Thiamin (B₁) supplementation may be required at the onset and throughout the course of nutritional rehabilitation. Plasma glucose levels must be closely monitored for hypo- and hyperglycemia ([Boateng et al, 2010](#)).

BOX 22-6 Guidelines for Medical Nutrition Therapy for Anorexia Nervosa

1. Caloric prescription
 - A. Initial prescription

Typically in the range of 30 to 40 kcal/kg/day (approx. 1000-1600 kcal/day)

Higher caloric prescriptions require careful assessment and ongoing monitoring for symptoms associated with the refeeding syndrome.

Types of feedings: whole foods, liquid supplements, tube feedings; TPN is rarely indicated.
 - B. Controlled weight gain phase:

Progressive increases in kcal prescription (e.g., 100 kcal to 200 kcal increments) to promote controlled weight gain (inpatients: 2-3 lb/wk; outpatients: minimum of 1 lb/wk)
 - C. Late treatment weight gain phase:

70 to 100 kcal/kg/day

Approx. 3000 to 4000 kcal/day for females

Approx. 4000 to 4500 kcal/day for males

If a larger energy prescription is required, the patient must be evaluated for vomiting, discarding food, excessive exercise, exaggerated postprandial thermogenesis.
 - D. Weight maintenance phase:

Adults: 40 to 60 kcal/kg/day

Children and adolescents: adjust prescription to promote normal growth and development.
2. Macronutrient intake
 - A. Protein

15% to 20% kcal

Minimum intake = RDA in g/kg ideal body weight

Promote high biologic value sources; avoid vegetarian diets
 - B. Carbohydrate

50% to 55% kcal

Decrease carbohydrate to 40% kcal if patient has an elevated blood glucose level or symptoms associated with the refeeding syndrome.

Provide insoluble fiber for treatment of constipation.
 - C. Fat

Hospitalized/day treatment patients: 30% kcal from fat

Outpatients: progressively increase dietary fat until a 30% fat kcal diet is attained.

Include sources of essential fatty acids
3. Micronutrient intake:
 - A. 100% RDA multivitamin/mineral supplement.
 - B. Avoid supplemental iron: during initial phase of refeeding and if patient is constipated.
 - C. Assess need for additional thiamin supplement.
 - D. Assess need for additional calcium supplementation.
4. Energy density
 - A. Promote intake of energy dense foods and beverages
 - B. If nutrient intake is assessed by computer analysis, calculate a Dietary Energy Density Score (DEDS): $DEDS = \text{kcal intake} / \text{weight (g) of food and beverage}$

Goal for DEDS: ≥ 1.0
5. Diet variety
 - A. Promote intake of a wide variety of foods and beverages within all food groups.
 - B. Pay particular attention to the variety of complex carbohydrates, caloric beverages, and added fats.

RDA, Recommended dietary allowance.

Later in the course of weight restoration, caloric prescriptions in the range of 70 to 100 kcal/kg of body weight per day (approximately 3000 to 4000 kcal/day) may be needed, and male patients may require as much as 4000 to 4500 kcal/day (APA, 2006). Changes in REE, DIT, and the type of tissue gained contribute to high energy requirements. Patients who require extraordinarily high energy intakes should be questioned or observed for discarding of food, vomiting, exercising, and excessive physical activity, including fidgeting.

After the goal weight is attained, the caloric prescription may be slowly decreased to promote weight maintenance. Weight maintenance requirements are generally higher than expected and are usually in the range of 2200 to 3000 kcal/day. Caloric prescriptions may remain at higher levels in adolescents with the potential for continued growth and development.

AN patients receiving care in less structured environments, such as an outpatient treatment program or a private nutrition practice, may be challenging and resistant to following formalized meal plans. A practical approach may be the addition of 200 to 300 calories per day to the patient's typical (baseline) energy intake; however, the RDN must be mindful that these patients tend to overestimate their energy intake (Schebendach et al, 2012).

Once the energy prescription is calculated, a reasonable distribution of macronutrients must be determined. Patients may express multiple food aversions. Extreme avoidance of dietary fat is common, but continued omission will make it difficult to provide concentrated sources of energy needed for weight restoration. A dietary fat intake of at least 30% of calories is recommended. This can be accomplished easily when AN patients are treated on inpatient units or in day hospital programs. On an outpatient basis, however, small, progressive increases in the dietary fat prescription may elicit more cooperation and less

resistance. Although some patients will accept small amounts of added fat (such as salad dressing, mayonnaise, or butter), many do better when the fat content is less obvious (as in cheese, peanut butter, granola, and snack foods). Encouraging the gradual change from fat-free products (fat-free milk) to low-fat products (1% or 2% milk) and finally to full-fat items (whole milk) is also acceptable to some patients.

A protein intake in the range of 15% to 20% of total calories is recommended. To ensure adequacy the minimum protein prescription should equal the RDA for age and sex in gram per kilogram (g/kg) ideal body weight (see inside front cover). Vegetarian diets often are requested but should be discouraged during the weight restoration phase of treatment.

Carbohydrate intakes in the range of 50% to 55% of calories are generally well tolerated. A lower carbohydrate diet (e.g., 40% of calories) may be indicated for a hyperglycemic patient. Constipation is a common problem in early treatment, and food sources of insoluble fiber may be beneficial (see Appendix 35 and Figure 22-2).

Although vitamin and mineral supplements are not universally prescribed, the potential for increased needs during the later stages of weight gain must be considered. Prophylactic prescription of a vitamin and mineral supplement that provides 100% of the RDA may be reasonable, but iron supplementation may be contraindicated early in treatment (Royal College of Psychiatrists, 2005). Owing to the increased risk of low BMD, calcium and vitamin D-rich foods should be encouraged; there is no consensus on the use of calcium and vitamin D supplements in this population.

Delayed gastric emptying and resultant early satiety with complaints of abdominal distention and discomfort after eating are common in AN. In early treatment intake is generally low and can be tolerated in three meals per day. However, as the

caloric prescription increases, between-meal feedings become essential. The addition of an afternoon or evening snack may relieve the physical discomfort associated with larger meals, but some patients express feelings of guilt for “indulging” between meals. Commercially available, defined-formula liquid supplements containing 30 to 45 calories per fluid ounce often are prescribed once or twice daily. Patients are fearful that they will become accustomed to the large amount of food required to meet increased caloric requirements; thus use of a liquid supplement is appealing because it can easily be discontinued when the goal weight is attained. The consumption of meals, snacks, and liquid supplements must be supervised.

Claims of lactose intolerance, food allergies, and gluten sensitivity complicate the refeeding process. These may be legitimate or simply a covert means of limiting food choice. To the extent possible, all claims should be verified by prior or current medical testing. Lactose intolerance secondary to malnutrition may occur but typically resolves during the course of weight restoration. If medically warranted, lactose-free whole milk products and the prescription of an oral enzyme supplement before meals and snacks can be easily accommodated.

Food allergies and a gluten-free diet are far more challenging. Many patients claim to be vegetarians; however, the adoption of this dietary practice usually occurs in close proximity to the onset of AN. Many treatment programs prohibit vegetarian diets during the weight restoration phase of treatment; others allow a lacto-ovo vegetarian diet. The relationship of social, cultural, and family influences and religious beliefs relative to the patient’s vegetarian status must be explored.

Institutions vary with respect to their menu-planning protocol. In some institutions the meal plan and food choices are fixed initially without patient input; as treatment progresses and weight is restored, the patient generally assumes more responsibility for menu planning. In other inpatient programs the patient participates in menu planning from the beginning of treatment. Some institutions have established guidelines that the patient must comply with to maintain the “privilege” of menu planning. Guidelines may require a certain type of milk (e.g., whole versus low-fat) and the inclusion of specific types of foods such as added fats, animal proteins, desserts, and snacks. A certain number of servings from the different food groups may be prescribed at different calorie levels.

Meal planning methods vary among treatment programs but data to suggest that one method is superior to another is lacking. Some programs use food group exchanges, others customize their approach. Regardless of the method, AN patients find it difficult to make food choices and plan menus. The RDN can be extremely helpful in providing a structured meal plan and guidance in the selection of nutritionally adequate meals and a varied diet. In a study of recently weight-restored, hospitalized AN patients, those who selected more energy-dense foods and a diet with greater variety had better treatment outcomes during the 1-year period immediately after hospital discharge, and this effect was independent of total caloric intake (Schebendach et al, 2008).

In an outpatient setting, the treatment team has less control over energy intake, food choice, and macronutrient distribution. Under these circumstances the RDN must use counseling skills to begin the process of developing a plan for nutritional rehabilitation. AN patients are typically precontemplative and, at best, ambivalent about making changes in eating behavior, diet, and body weight; some are defiant and hostile on initial presentation. Motivational interviewing and cognitive behavior

therapy techniques may be useful in the nutrition counseling of AN patients (Ozier et al, 2011); the reader is referred to Fairburn (2008) for a thorough review of CBT techniques.

Effective nutritional rehabilitation and counseling must ultimately result in weight gain and improved eating attitudes and behaviors. A comprehensive review of nutrition counseling techniques can be found in Chapter 14 and in Herrin and Larkin (2013) and Stollefson Myers (2006).

Bulimia Nervosa

Guidelines for MNT in BN are summarized in Box 22-7. BN is described as a state of dietary chaos characterized by periods of uncontrolled, poorly structured eating, followed by periods of restrained food intake. The RDN’s role is to help develop a reasonable plan of controlled eating while assessing the patient’s tolerance for structure.

During the initial onset of BN, much of the patient’s eating and purging behavior is aimed at weight loss. Later in the process, the behaviors may be habitual and out of control. Even if the patient is legitimately overweight, immediate goals must be interruption of the binge-and-purge cycle, restoration of normal eating behavior, and stabilization of body weight. Attempts at dietary restraint for the purpose of weight loss typically exacerbate binge-purge behavior in BN patients.

Patients with BN have varying degrees of metabolic efficiency, which must be taken into account when prescribing the baseline diet. Assessment of REE along with clinical signs of a hypometabolic state, such as a low T3 level and cold intolerance,

BOX 22-7 Guidelines for Medical Nutrition Therapy of Bulimia Nervosa

1. Caloric prescription for weight maintenance
 - A. If metabolic rate appears normal, provide DRI for energy (approximately 2200-2400 kcal/day).
 - B. If there is evidence of a hypometabolic rate:
 - Start at 1500 to 1600 kcal/day
 - Increase diet in 100 to 200 kcal increments until DRI for energy is attained (approximately 2000-2400 kcal/day)
 - C. Monitor body weight and adjust caloric prescription for weight maintenance.
 - D. Avoid low calorie diets as these may exacerbate bingeing and purging behaviors.
2. Macronutrients
 - A. Protein
 - (1) 15% to 20% kcal
 - (2) Minimum: RDA in g/kg of ideal body weight
 - (3) High biological value sources
 - B. Carbohydrate
 - (1) 50% to 55% kcal
 - (2) Provide insoluble fiber sources for treatment of constipation
 - C. Fat
 - (1) 30% kcal
 - (2) Provide source of essential fatty acids
3. Micronutrients
 - A. 100% RDA multivitamin/mineral supplement
 - B. Avoid supplemental iron if patient is constipated
4. Energy density
 - A. Provide foods with a range of energy densities
 - B. Provide an overall diet with an energy density of approximately 1.0
5. Diet variety
 - A. Promote intake of a wide variety of foods and beverages within all food groups

DRI, Dietary reference intake; RDA, recommended dietary allowance.

are useful in determining the caloric prescription. If a low metabolism is suspected, a caloric prescription of 1600 to 1800 calories daily is a reasonable place to start; however, this prescription should be titrated upwards, in 100 to 200 calorie increments, to stimulate the metabolic rate. Ultimately, a weight maintenance diet of 2200 to 2400 kcal/day is attainable and well tolerated. If a patient is willing and able to provide a detailed diet history or a 7-day food record, the initial caloric prescription can also be calculated by the method described in [Box 22-3](#).

Body weight should be monitored with a goal of stabilization; however, BN patients need a great deal of encouragement to follow weight maintenance versus weight loss diets. They must be reminded that attempts to restrict caloric intake may only increase the risk of binge eating and that their pattern of restrained intake followed by binge eating has not facilitated weight loss in the past.

A balanced macronutrient intake is essential for the provision of a regular meal pattern. This should include sufficient carbohydrates to prevent craving and adequate protein and fat to promote satiety. In general, a balanced diet providing 50% to 55% of the calories from carbohydrate, 15% to 20% from protein, and approximately 30% from fat is reasonable.

Adequacy of micronutrient intake relative to the caloric prescription, macronutrient distribution, and diet variety should be assessed. A multivitamin and mineral preparation may be prescribed to ensure adequacy, particularly in the initial phase of treatment.

Bingeing, purging, and restrained intake often impair recognition of hunger and satiety cues. The cessation of purging behavior coupled with a reasonable daily distribution of calories at three meals and prescribed snacks can be instrumental in strengthening these biologic cues. Many patients with BN are afraid to eat earlier in the day because they are fearful that these calories will contribute to caloric excess if they binge later. They also may digress from their meal plans after a binge, attempting to restrict intake to balance out the binge calories. Patience and support are essential in this process of making positive changes in their eating habits.

CBT is the most studied therapeutic intervention for the treatment of BN ([Hay et al, 2014](#)). When applied to an ED, CBT is typically a 20-week intervention that consists of three distinct and systematic phases of treatment: (1) establishing a regular eating pattern, (2) evaluating and changing beliefs about shape and weight, and (3) preventing relapse. When the BN patient is receiving CBT, the RDN can be instrumental in helping the patient establish a regular meal pattern (phase 1). However, the RDN and the psychotherapist must maintain active communication to avoid overlap in the counseling sessions. If the BN patient is engaged in a type of psychotherapy other than CBT, the RDN should incorporate more CBT skills into the nutrition counseling sessions ([Herrin and Larkin, 2013](#)). See [Fairburn \(2008\)](#) for guidance on CBT techniques.

Patients with BN are typically more receptive to nutrition counseling than AN patients and less likely to present in the precontemplation stage of change. Suggested strategies for nutrition counseling at the precontemplation, contemplation, preparation, action, and maintenance stages are given in [Table 22-3](#) (see Chapter 14).

Binge Eating Disorder

Strategies for treatment of BED include nutrition counseling and dietary management, individual and group psychotherapy, and medication. Some treatment programs focus primarily on nutrition counseling and weight loss. Behavioral weight loss therapy may be effective in attaining weight loss in the short term, but not

TABLE 22-3 Counseling Strategies Using the Stages of Change Model in Eating Disorders

Stage of Change	Counseling Strategies
Precontemplation	<ul style="list-style-type: none"> Establish rapport. Assess nutrition knowledge, beliefs, attitudes. Conduct thorough review of food likes and dislikes, safe and risky foods, forbidden foods (assess reason), binge and purge foods. Assess physical, anthropometric, metabolic status. Assess level of motivation. Use motivational interviewing techniques. Decisional balance: weigh costs and benefits of maintaining current status versus costs and benefits of change.
Contemplation	<ul style="list-style-type: none"> Identify behaviors to change; prioritize. Identify barriers to change. Identify coping mechanisms. Identify support systems. Discuss self-monitoring tools: food and eating behavior records.
Preparation	<ul style="list-style-type: none"> Continue motivational interviewing technique. Implement nutrition-focused CBT. Implement self-monitoring tools: food and eating behavior records. Determine list of alternative behaviors to bingeing and purging.
Action	<ul style="list-style-type: none"> Develop a plan of healthy eating. Reinforce positive decision making, self-confidence, and self-efficacy. Promote positive self-rewarding behaviors. Develop strategies for handling impulsive behaviors, high-risk situations, and "slips." Continue CBT.
Maintenance and relapse	<ul style="list-style-type: none"> Continue self-monitoring. Identify strategies; manage high-risk situations. Continue positive self-rewarding behaviors. Reinforce coping skills and impulse-control techniques. Reinforce relapse prevention strategies. Determine and schedule follow-up sessions needed for maintenance and reinforcement of positive changes in eating behavior and nutrition status.

Modified from Stollefson Myers E: *Winning the war within: nutrition therapy for clients with anorexia or bulimia nervosa*, Dallas, 2006, Helm Publishing.
CBT, Cognitive behavioral therapy.

the longer term ([Wilson, 2011](#)). Other treatment programs focus primarily on reduction of binge episodes rather than weight loss. Self-acceptance, improved body image, increased physical activity, and better overall nutrition are also goals of treatment in BED. Guided self-help CBT ([Fairburn, 1995](#)) is an effective treatment option ([Striegel-Moore et al, 2010](#)).

Monitoring Nutritional Rehabilitation

Guidelines for patient monitoring are indicated in [Box 22-8](#). The health professional, patient, and family must be realistic about treatment, which is often a long-term process. Although outcomes may be favorable, the course of treatment is rarely smooth, and clinicians must be prepared to monitor progress carefully.

Nutrition Education

Patients with EDs may appear knowledgeable about food and nutrition. Despite this, nutrition education is an essential

BOX 22-8 Patient Monitoring

1. Body weight
 - A. Establish treatment goal weight
 - B. Determine:
 - (1) Acceptable rate of weight gain in AN
 - (2) Maintenance weight in BN
 - C. Children and adolescents:
 - (1) Plot weight on NCHS weight-for-age growth chart
 - (2) Determine weight percentile
 - D. Monitor weight:
 - (1) Inpatient and partial hospitalization
 - a. Frequency: Inpatient: daily or every other day; partial hospitalization: varies with diagnosis, age of patient, phase of treatment (i.e., daily, several times per week, once per week)
 - b. Gowned
 - c. Morning weight
 - d. Preprandial
 - e. Post void
 - f. Same scale
 - g. Check urine specific gravity if fluid loading is suspected
 - h. Additional random weight checks if fluid loading is suspected
 - (2) Outpatient treatment:
 - a. Once every 1-2 weeks in early treatment, less frequently in mid- to late treatment
 - b. Gowned
 - c. Post void
 - d. Same time of day
 - e. Same scale
 - f. Check urine specific gravity if fluid loading is suspected
2. Height
 - A. Measure baseline height using a stadiometer
 - B. Children and adolescents:
 - (1) Plot height on NCHS stature-for-age growth chart
 - (2) Determine height percentile
 - (3) Assess for growth impairment
 - (4) Monitor height every 1 to 2 months in patients with growth potential
3. Body mass index (BMI):
 - A. Adults: calculate BMI
 - B. Children and adolescents:
 - (1) Calculate BMI
 - (2) Plot BMI on NCHS body mass index-for-age percentile chart
 - (2) Determine median BMI (50th percentile BMI for age and sex)
 - (3) Calculate percent median BMI [(current BMI/median BMI) x 100]
 - (4) Determine BMI z score
4. Outpatient diet monitoring
 - A. Anorexia nervosa

Daily food record to include:

 - (1) Food
 - (2) Fluid: caloric, noncaloric, alcohol
 - (3) Artificial sweeteners
 - (4) Eating behavior: time, place, how eaten, with whom
 - (5) Dietary energy density
 - (6) Diet variety
 - B. Bulimia nervosa

Daily food record to include:

 - (1) Food
 - (2) Fluid: caloric, noncaloric, alcohol
 - (3) Artificial sweeteners
 - (4) Eating behavior: time, place, how eaten, with whom
 - (5) Emotions and feelings when eating
 - (6) Foods eaten at a binge
 - (7) Time and method of purge
 - (8) Dietary energy density
 - (9) Diet variety
 - (10) Exercise

AN, Anorexia nervosa; BN, bulimia nervosa; NCHS, National Center for Health Statistics.

component of their treatment plan. Indeed, some patients spend significant amounts of time reading nutrition-related information, but their sources may be unreliable, and their interpretation potentially distorted by their illness. Malnutrition may impair the patient's ability to assimilate and process new information. Early and middle adolescent development is characterized by the transition from concrete to abstract operations in problem solving and directed thinking, and normal developmental issues must be considered when teaching adolescents with EDs (see Chapter 18).

Nutrition education materials must be assessed thoroughly to determine whether language and subject matter are bias free and appropriate for AN and BN patients. For example, literature provided by many health organizations promotes a low-fat diet and low-calorie lifestyle for the prevention and treatment of chronic disease. This material is in direct conflict with a treatment plan that encourages increased caloric and fat intake for the purpose of nutritional rehabilitation and weight restoration.

Although the interactive process of a group setting may have advantages, these topics can also be effectively incorporated into individual counseling sessions. Topics for nutrition education are suggested in [Box 22-9](#).

Prognosis

The course and outcome of AN are highly variable. Some individuals fully recover, some have periods of recovery followed by

BOX 22-9 Topics for Nutrition Education

- Guidelines for recovery: energy, macronutrient, vitamin, mineral, and fluid intakes
- Impact of malnutrition on adolescent growth and development
 - Physiologic and psychological consequences of malnutrition
 - Set-point theory and the determination of a healthy body weight
 - Impact of energy restriction on the metabolic rate
 - Ineffectiveness of vomiting, laxatives, and diuretics in long-term weight control
 - Causes of bingeing and purging, and techniques to break the cycle
 - Changes in body composition that occur during weight restoration
 - Exercise and energy balance
 - What does "healthy eating" mean to you?
 - Challenging food rules
 - Emotional undereating and overeating
 - Intuitive eating: how to get in touch with hunger and satiety cues
 - Meal planning strategies for recovery and maintenance of a healthy body weight
 - Social and holiday dining
 - Interpreting food labels
 - Strategies for food shopping

relapse, and others are chronically ill for many years ([APA, 2013](#)). Although approximately 70% of individuals with BN achieve remission, those who have not achieved remission after 5 years of illness may demonstrate a chronic course ([Keel and Brown, 2010](#)).

CLINICAL CASE STUDY 1

Anorexia Nervosa

Melissa has just been admitted to an inpatient hospital unit. She is 19 years old and reports the onset of anorexia nervosa at 12 years of age. Upon admission, Melissa's weight is 68 lb, and her height is 61 inches.

Patient began menses early at the age of 11, and because of adolescent developmental changes reported feeling uncomfortable in her body. At this time she was 58 inches and weighed 100 lb (between 50th and 75th percentile). She learned she could restrict through seeing her mom diet at home and began counting her calories. She would aim for less than 1000 calories per day and began walking for 30 to 60 minutes daily. After 6 months, halfway through her sixth grade year, Melissa had dropped to 82 pounds and did not grow in height during this time; she remained at the 25th percentile and stopped menstruating. Melissa's parents began worrying and started to adapt a Maudsley/family-based therapy approach of eating at home in which she ate all of her meals at home with them. She would continue to restrict at school and exercise as much as she could. By the age of 17 Melissa had gained back some weight and graduated from high school, weighing 105 lb with a height of 62 inches (10th percentile for weight and 10th to 25th for height).

After her first year away at college, Melissa began restricting again, this time down to approximately 500 calories per day. Her typical daily intake now is 1 cup coffee in the morning with an apple. For lunch she has salad from the dining hall with 3 ounces of sliced turkey on it and a ½ cup of brown rice with balsamic vinegar. For dinner she has two pieces of laughing cow cheese with steamed vegetables from the dining hall. If she gets hungry at night, she will have an individual bag of fat-free popcorn. She also reports 60 to 90 minutes of walking or running per day around campus or at the gym. Since her first onset of menses, Melissa was getting her period on average 2 to 3 times per year. It has now been 1 year since her last period (age 18). Melissa denies any purging or laxative abuse.

Since being in the hospital, Melissa has struggled with eating 100% of her planned meals. She reports fearing any foods high in fat such as cheese, fried foods, desserts of any kind, meat, oils, and potato chips. Melissa is refusing to drink regular milk as well. The nursing staff on the unit told you that Melissa has been consuming approximately 50% to 60% of her 1800 kcal meal plan and has not taken any of the recommended supplements.

Medical history: amenorrhea, hypokalemia

Current medications: MVI with trace minerals, thiamine daily

Inpatient calorie prescription: 1800 kcal/day

B/P: 89/58

Pulse: 58

Laboratory Values:

Test	Result	Reference Range
Sodium	129	135-147 mEq/L
Potassium	3.3	3.5-5.2 mEq/L
Chloride	94	95-107 mEq/L
Calcium	8.2	8.7-10.7 mg/dL
CO ₂	32	22- 29 mmol/L
Glucose	65	60- 69 mg/dl (fasting)
BUN	23	8-21 mg/dl
Creatinine	1.2	0.65-1.00 mg/dl
Phosphorous	3.2	2.5-4.6 mg/dl
Magnesium	2.2	1.7-2.3
Cholesterol	240	<200

Nutrition Diagnostic Statement

Underweight related to abnormal eating pattern as evidenced by a restrictive caloric intake and excessive exercise in the setting of being below 75% IBW.

Questions

1. List the essential criteria for the diagnosis of anorexia nervosa.
2. What are some behavioral or psychologic treatment approaches that could be used to help Melissa?
3. What are the significant physical findings from a nutrition-focused physical examination of Melissa? What are some other symptoms commonly seen in anorexia nervosa?
4. Assess Melissa's laboratory values and indicate what other values also may be altered in her condition.
5. What is Melissa's goal weight? How would you calculate that?
6. What are some typical reasons why Melissa may be avoiding food and losing weight?
7. What are common complications to assess for when monitoring refeeding syndrome?
8. What would be a safe and appropriate rate of weight gain for Melissa in the inpatient hospital setting?

CLINICAL CASE STUDY 2

Bulimia Nervosa

Kristin is a 34-year-old female who has come to see you in your outpatient private practice. Her chief complaint is that she feels "out of control and wants to stop bingeing."

Kristin currently is employed as a marketing director at a company in New York City. She describes her life to be very stressful: working approximately 50 to 55 hours per week in the office and has several social engagements in the evenings. She reports an "unhealthy" relationship with food since she was a teenager, when she was a "yo-yo dieter" and would take various diet pills to lose weight. Her weight as a teenager fluctuated between slightly underweight to normal. Kristin began to purge in college after some of her friends introduced her to the idea of vomiting. Later after moving to New York and becoming stressed with life events, she began to purge more often after what she describes as "binges."

Currently Kristin reports skipping breakfast most days but has a large cup of coffee, black with 5 packets of artificial sweetener. She has a snack around 10 AM of a handful of almonds and sometimes a fruit. She usually goes to the gym during her lunch hour, where she does 45 to 55

minutes of cardio. For lunch Kristin has two hardboiled eggs, a piece of toast, and diet coke. A few times per week after client lunches Kristin feels stressed that she ate "fear foods," so she binges on cookies or candy and afterward purges in her private bathroom. In the afternoon Kristin usually has another coffee or diet coke and a protein bar. After work Kristin goes home with plans of eating a normal dinner but, after ordering take out from the local Chinese, Italian, or sushi restaurant, binges on approximately 2000 to 3000 calories worth of food before purging.

Kristin has a hard time at social events that occur several times a week and binges or purges after them as well. In total Kristin estimates she is binge/purging five times per week, sometimes twice per day. Kristin is frustrated with the binge/purge cycle she is caught in and is requesting guidance for a meal plan.

Medical history: Dental caries requiring three root canals and two implants; irritable bowel syndrome with constipation

Current medications: Fluoxetine 40 mg, Colace 100 mg once daily

Height: 5'5"; weight: 138 lb

Continued

CLINICAL CASE STUDY 2

Bulimia Nervosa—cont'd

Laboratory data:

Test	Result	Reference Range
Sodium	139	135-147 mEq/L
Potassium	3.3	3.5-5.2 mEq/L
Chloride	94	95-107 mEq/L
Calcium	8.2	8.7-10.7 mg/dl
CO ₂	29	22-29 mmol/L
Glucose	85	60-99 mg/dl (fasting)
BUN	15	8-21 mg/dL
Creatinine	1.2	0.65-1.00 mg/dl
Phosphorous	3.6	2.5-4.6 mg/dl
Magnesium	2.2	1.7-2.3
Amylase	105	25-100 units/L
Cholesterol	210	<200 mg/dl
Bicarbonate	16.5	18.0-23.0 mmol/L

Nutrition Diagnostic Statement

Disordered eating pattern related to bingeing and purging as evidenced by a pattern of restrictive eating, bingeing and then self-induced vomiting.

Questions

1. What are the medical complications Kristin is experiencing secondary to her bingeing and purging? What are some others she could develop if she does not stop?
2. Discuss which laboratory values are abnormal.
3. What are your main goals for nutrition therapy while working with Kristin?
4. How might you approach meal planning with Kristin?
5. How might you help Kristin talk about her fear foods and set goals for including them in her diet without bingeing on them?
6. What techniques would be helpful for Kristin to challenge her urges to binge and purge during stressful work situations?

Nutrition in Exercise and Sports Performance

Lisa Dorfman, MS, RDN, CSSD, LMHC, FAND

KEY TERMS

actomyosin	ergogenic aid	mitochondria
adenosine diphosphate (ADP)	fat adaptation strategy	muscle dysmorphia (MD)
adenosine triphosphate (ATP)	female athlete triad (FAT)	myoglobin
aerobic metabolism	glycemic index	nutrition periodization
anabolic effects	glycogen	oxidative phosphorylation
anaerobic metabolism	glycogen loading (glycogen supercompensation)	pseudoanemia
androgenic effects	glycogenolysis	respiratory exchange ratio (RER)
anorexia athletica (AA)	glycolysis	reactive oxygen species (ROS)
athletic energy deficit (AED)	high-intensity interval training (HIIT)	sports anemia
creatine phosphate (CP)	hypohydration	The Athlete's Plate
dehydroepiandrosterone (DHEA)	human growth hormone (HGH)	thermoregulation
eating, exercise, body image (EEBI) disorders	lactic acid	VO ₂ max

Athletic performance is the culmination of genetics, proper training, adequate nutrition, hydration, desire, and rest. Understanding sport-specific physiologic requirements for training and competition is integral to obtaining sufficient energy, optimal levels of macronutrients and micronutrients, and adequate levels of fluids. Healthy eating habits and the use of supplements and sports foods may be necessary to support energy needs for training hard, achieving performance goals, and reducing the incidence of illness and injury. Energy and fuel requirements for training and competition also have to adapt for recovery between training sessions to reduce the risk of illness or injury and maintain appropriate body composition ([International Olympic Committee \[IOC\], 2011](#)).

AN INTEGRATIVE APPROACH TO WORKING WITH ATHLETES

To advance the practice of dietitians working with fitness-minded individuals, cross-disciplinary training provides a broader and more comprehensive understanding and application of the dietary needs for individuals who exercise. Exercise nutrition is not limited to exercise physiology or nutrition but considers six core areas of study including the role of optimal overall health and longevity, optimal growth, peak physiologic function, energy balance and body composition, nutrition enhancement, and safety.

Genetics and individualized differences, exercise environments, and life stress also can affect the athlete's tolerance of specific nutrients. To prevent nutrient deficiencies, dietitians must integrate anthropometric, biochemical, and dietary

data and feedback from athletes to determine whether additional factors such as gut dysbiosis, food allergies or intolerances, dietary preferences or aversions, or disease processes may affect the overall absorption, assimilation, digestions, biotransformation, and transport of specific macronutrients, micronutrients, or fluids and ultimately affect performance potential.

A comprehensive understanding of the relationship between optimal nutrition and exercise science also enables dietitians and nutrition practitioners to appreciate the importance of ensuring adequate nutrition for active individuals and to critically evaluate the validity of claims concerning nutritional supplements and special dietary modifications to enhance physique, physical performance, and exercise training responses.

BIOENERGETICS OF PHYSICAL ACTIVITY

Exercise nutrition requires essential elements from food to fuel muscle contractions, build new tissue, preserve lean muscle mass, optimize skeletal structure, repair existing cells, maximize oxygen transport, maintain favorable fluid and electrolyte balance, and regulate metabolic processes.

The human body must be supplied continuously with energy to perform its many complex functions. Three metabolic systems supply energy for the body: one dependent on oxygen ([oxidative phosphorylation](#) or [aerobic metabolism](#)) and the other two independent of oxygen (creatine phosphate and anaerobic glycolysis or [anaerobic metabolism](#)). The use of one system over the other depends on the duration, intensity, and type of physical activity.

Adenosine Triphosphate: Ultimate Energy Source

Regardless of the energy system used to generate power for exercise, the body relies on a continuous supply of fuel through **adenosine triphosphate (ATP)**, found within the mitochondria of the body. The energy produced from the breakdown of ATP provides the fuel that activates muscle contraction. The energy from ATP is transferred to the contractile filaments (myosin and actin) in the muscle, which form an attachment of actin to the cross-bridges on the myosin molecule, thus forming **actomyosin**. Once activated the myofibrils slide past each other and cause the muscle to contract.

Although ATP is the main currency for energy in the body, it is stored in limited amounts. In fact, only approximately 3 oz of ATP is stored in the body at any one time (McArdle et al, 2013). This provides only enough energy for several seconds of exercise, and yet ATP must be resynthesized continually to provide a constant energy source. When ATP loses a phosphate, thus releasing energy, the resulting **adenosine diphosphate (ADP)** is combined enzymatically with another high-energy phosphate from **creatine phosphate (CP)** to resynthesize ATP. The concentration of high-energy CP in the muscle is five times that of ATP.

Creatine kinase is the enzyme that catalyzes the reaction of CP with ADP and inorganic phosphate. This is the fastest and most immediate means of replenishing ATP, and it does so without the use of oxygen (anaerobic). Although this system has great power, it is time-limited because of the limited concentration of CP found in the muscles (see **Creatine** later in the chapter).

The energy released from this ATP-CP system will support an all-out exercise effort of only a few seconds, such as in a power lift, tennis serve, or sprint. If the all-out effort continues for longer than 8 seconds, or if moderate exercise is to proceed for longer periods, an additional source of energy must be provided for the resynthesis of ATP. The production of ATP carries on within the muscle cells through either the anaerobic or aerobic pathways.

Anaerobic or Lactic Acid Pathway

The next energy pathway for supplying ATP for more than 8 seconds of physical activity is the process of **glycolysis**. In this pathway the energy in glucose is released without the presence of oxygen. **Lactic acid** is the end product of glycolysis. Without the production of lactic acid, glycolysis would shut down. The coenzyme called nicotinic acid dehydrogenase (NAD) is in limited supply in this pathway. When NAD is limited, the glycolytic pathway cannot provide constant energy. By converting pyruvic acid to lactic acid, NAD is freed to participate in further ATP synthesis. The amount of ATP furnished is relatively small; the process is only 30% efficient. This pathway contributes energy during an all-out effort lasting up to 60 to 120 seconds. Examples are a 440-yard sprint and many sprint-swimming events.

Although this process provides immediate protection from the consequences of insufficient oxygen, it cannot continue indefinitely. When exercise continues at intensities beyond the body's ability to supply oxygen and convert lactic acid to fuel, lactic acid accumulates in the blood and muscle, lowers the pH to a level that interferes with enzymatic action, and causes fatigue. Lactic acid can be removed from the muscle, transported into the bloodstream, and converted to energy in muscle, liver, or brain. Otherwise, it is converted to glycogen. Conversion to

glycogen occurs in the liver and to some extent in muscle, particularly among trained athletes.

The amount of ATP produced through glycolysis is small compared with that available through aerobic pathways. Substrate for this reaction is limited to glucose from blood sugar or the glycogen stored in the muscle. Liver glycogen contributes but is limited.

Aerobic Pathway

Production of ATP in amounts sufficient to support continued muscle activity for longer than 90 to 120 seconds requires oxygen. If sufficient oxygen is not present to combine with hydrogen in the electron transport chain, no further ATP is made. Thus the oxygen furnished through respiration is of vital importance. Here, glucose can be broken down far more efficiently for energy, producing 18 to 19 times more ATP. In the presence of oxygen, pyruvate is converted to acetyl coenzyme A (CoA), which enters the **mitochondria**. In the mitochondria acetyl CoA goes through the Krebs cycle, which generates 36 to 38 ATP per molecule of glucose (see **Figure 23-1**).

Aerobic metabolism is limited by the availability of substrate, a continuous and adequate supply of oxygen, and the availability of coenzymes. At the onset of exercise and with the increase in exercise intensity, the capability of the cardiovascular system to supply adequate oxygen is a limiting factor, and this is largely due to the level of conditioning. The aerobic pathway provides ATP by metabolizing fats and proteins. A large amount of acetyl CoA, which enters the Krebs cycle and provides enormous amounts of ATP, is provided by beta-oxidation of fatty acids. Proteins may be catabolized into acetyl CoA or Krebs cycle intermediates, or they may be directly oxidized as another source of ATP.

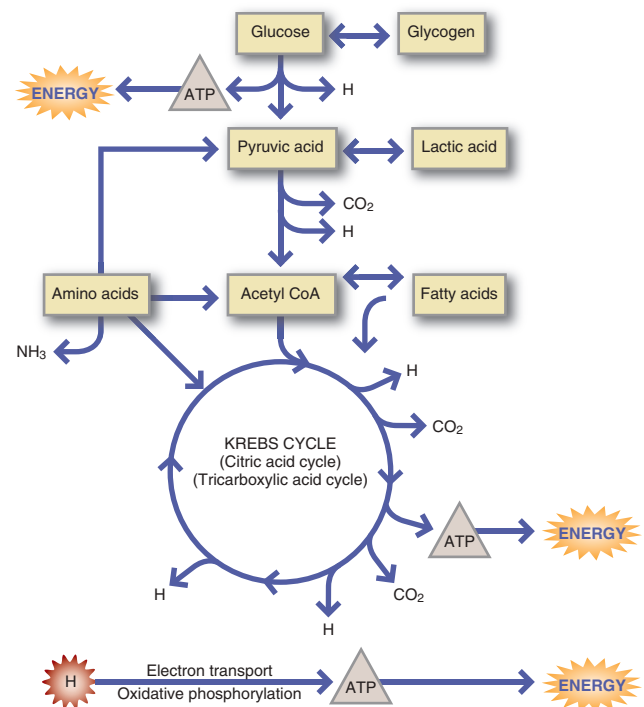

FIGURE 23-1

Energy Continuum

A person who is exercising may use one or more energy pathways. For example, at the beginning of any physical activity, ATP is produced anaerobically. As exercise continues, the lactic acid system produces ATP for exercise. If the person continues to exercise and does so at a moderate intensity for a prolonged period, the aerobic pathway will become the dominant pathway for fuel. On the other hand, the anaerobic pathway provides most of the energy for short-duration, high-intensity exercise such as sprinting; the 200-meter swim; or high-power, high-intensity moves in basketball, football, or soccer. However, all of the ATP-generating pathways are turned on at the onset of exercise.

The production of ATP for exercise is on a continuum that depends on the availability of oxygen. Other factors that influence oxygen capabilities and thus energy pathways are the capacity for intense exercise and its duration. These two factors are inversely related. For example, an athlete cannot perform high-power, high-intensity moves over a prolonged period. To do this, he or she would have to decrease the intensity of the exercise to increase its duration (see [Figure 23-2](#)).

The aerobic pathway cannot tolerate the same level of intensity as duration increases because of the decreased availability of oxygen and accumulation of lactic acid. As the duration of exercise increases, power output decreases. The contribution of energy-yielding nutrients must be considered also. As the duration of exercise lengthens, fats contribute more as an energy source. The opposite is true for high-intensity exercise; when intensity increases, the body relies increasingly on carbohydrates as substrate.

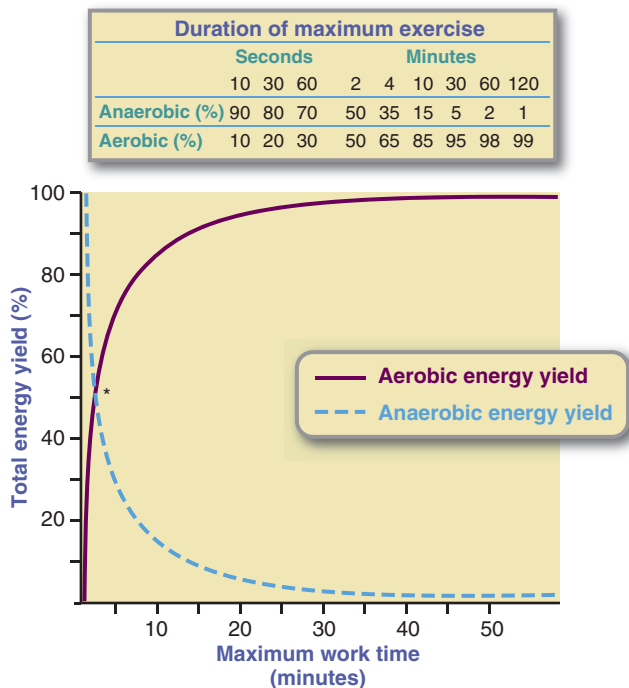

FIGURE 23-2 Relative contribution of aerobic and anaerobic energy during maximum physical activity of various durations. Note that 90 to 120 seconds of maximum effort requires 50% of the energy from each of the aerobic and anaerobic processes. This is also the point at which the lactic acid pathway for energy production is at its maximum.

FUELS FOR CONTRACTING MUSCLES

Protein, fat, and carbohydrate are possible sources of fuel for ATP generation and therefore muscle contraction. The glycolytic pathway is restricted to glucose, which can originate in dietary carbohydrates or stored glycogen, or it can be synthesized from the carbon skeletons of certain amino acids through the process of gluconeogenesis. The Krebs cycle is fueled by three-carbon fragments of glucose; two-carbon fragments of fatty acids; and carbon skeletons of specific amino acids, primarily alanine and the branched-chain amino acids. All these substrates can be used during exercise; however, the intensity and duration of the exercise determine the relative rates of substrate use.

Intensity

The intensity of the exercise is important in determining what fuel will be used by contracting muscles. High-intensity, short-duration exercise has to rely on anaerobic production of ATP. Because oxygen is not available for anaerobic pathways, only glucose and glycogen can be broken down anaerobically for fuel. When glycogen is broken down anaerobically, it is used 18 to 19 times faster than when broken down aerobically. Persons who are performing high-intensity workouts or competitive races may run the risk of running out of muscle glycogen before the event or exercise is done as a result of its high rate of use.

Sports that use the anaerobic and aerobic pathways also have a higher glycogen-use rate and, like anaerobic athletes, athletes in these sports also run the risk of running out of fuel before the race or exercise is finished. Sports such as basketball, football, soccer, tennis and swimming are good examples; glycogen usage is high because of the intermittent bursts of high-intensity sprints and running drills. In moderate-intensity sports or exercise such as jogging, hiking, aerobic dance, gymnastics, cycling, and recreational swimming, approximately half of the energy for these activities comes from the aerobic breakdown of muscle glycogen, whereas the other half comes from circulating blood glucose and fatty acids.

Moderate- to low-intensity exercise such as walking is fueled primarily by the aerobic pathway; thus a greater proportion of fat can be used to create ATP for energy. Fatty acids cannot supply all the ATP during high-intensity exercise because fat cannot be broken down fast enough to provide the energy. Also, fat provides less energy per liter of oxygen consumed than does glucose (4.65 kcal/L of O_2 versus 5.01 kcal/L of O_2). Therefore when less oxygen is available in high-intensity activities, there is a definite advantage for the muscles to be able to use glycogen because less oxygen is required.

In general, glucose and fatty acids provide fuel for exercise in proportions depending on the intensity and duration of the exercise and the fitness of the athlete. Exertion of extremely high intensity and short duration draws primarily on reserves of ATP and CP. High-intensity exercise that continues for more than a few seconds depends on anaerobic glycolysis. During exercise of low-to-moderate intensity (60% of maximum oxygen uptake [Vo_{2max}]), energy is derived mainly from fatty acids. Carbohydrate becomes a larger fraction of the energy source as intensity increases until, at an intensity level of 85% to 90% Vo_{2max} , carbohydrates from glycogen are the principal energy source, and the duration of activity is limited (see [Figure 23-3](#)).

FIGURE 23-3 Principle Energy Source and Exercise Duration.

Duration

The duration of a training session determines the substrate used during the exercise bout. For example, the longer the time spent exercising, the greater the contribution of fat as the fuel. Fat can supply up to 60% to 70% of the energy needed for ultraendurance events lasting 6 to 10 hours. As the duration of exercise increases, the reliance on aerobic metabolism becomes greater, and a greater amount of ATP can be produced from fatty acids. However, fat cannot be metabolized unless a continuous stream of some carbohydrates is also available through the energy pathways. Therefore muscle glycogen and blood glucose are the limiting factors in human performance of any type of intensity or duration.

Effect of Training

The length of time an athlete can oxidize fatty acids as a fuel source is related to the athlete's conditioning, as well as the exercise intensity. In addition to improving cardiovascular systems involved in oxygen delivery, training increases the number of mitochondria and the levels of enzymes involved in the aerobic synthesis of ATP, thus increasing the capacity for fatty acid metabolism. Increases in mitochondria with aerobic training are seen mainly in the type IIA (intermediate fast-twitch) muscle fibers. However, these fibers quickly lose their aerobic capacity with the cessation of aerobic training, reverting to the genetic baseline.

These changes from training result in a lower **respiratory exchange ratio (RER)**, (also called respiratory quotient [RQ]), which is $RQ = \text{CO}_2 \text{ eliminated} / \text{O}_2 \text{ consumed}$; lower blood lactate and catecholamine levels, and a lower net muscle glycogen breakdown at a specific power output. These metabolic adaptations enhance the ability of muscle to oxidize all fuels, especially fat.

NUTRITIONAL REQUIREMENTS OF EXERCISE

Energy

The most important component of successful sport training and performance is to ensure adequate calorie intake to support energy expenditure and maintain strength, endurance, muscle mass, and overall health. Energy and nutrient requirements vary with age, gender, weight, height, training/sport type, frequency, intensity, and duration; typical diet, diet history, history of restrictive and disordered eating; endocrine and environmental conditions such as heat, cold, and altitude. Estimating energy intake is challenging to accomplish, especially in sports that are less well studied (Driskell and Wolinsky, 2011).

Individuals who participate in an overall fitness program (i.e., 30 to 40 min/day, three times per week) can generally meet their daily nutritional needs by following a normal diet providing 25 to 35 kcal/kg/day or roughly 1800 to 2400 calories a day. However, energy requirements for athletes training 90 minutes a day has been suggested to be 45 to 50 kcal/kg/day, and in certain sports even more.

For example, the 50-kg athlete engaging in more intense training of 2 to 3 hours/day five to six times a week or high-volume training of 3 to 6 hours in one to two workouts per day 5 to 6 days a week may expend up to an additional 600 to 1200 calories a day above and beyond REE, thus requiring 50 to 80 kcal/kg/day or roughly 2500 to 4000 kcal/day. For elite athletes or heavier athletes, daily calorie needs can reach 150 to 200 kcal/kg, or roughly 7500 to 10,000 calories a day, depending on the volume and intensity of different training phases.

Estimation of Energy Requirements

Resting metabolic rate (RMR) or resting energy expenditure (REE) can be measured using indirect calorimetry or estimated by using predictive equations. Indirect calorimetry involves using a hand-held device such as the MedGem calorimeter or metabolic cart typically used in exercise physiology or research settings to measure a person's oxygen consumption to determine RMR or basal metabolic rate (BMR). Measuring RMR or BMR is more accurate than using prediction equations.

Predictive equations are used to estimate RMR/BMR when technical equipment, such as a metabolic cart, is not available. The Cunningham equation has been shown to be the best predictor of RMR or REE for active men and women followed by the Harris Benedict equation (Rodriguez et al, 2009). DeLorenzo developed an equation that also has been shown to be accurate specifically with male strength and power athletes such as those in water polo, judo, and karate (Academy of Nutrition and Dietetics [AND], 2014; DeLorenzo et al, 1999).

If the sports dietitian has body composition data including percent body fat, the REE can be calculated as shown in Box 23-1.

Once REE has been calculated, the total energy expenditure (TEE) can be estimated using energy expenditure from physical activity. Because metabolic equipment is expensive, requires considerable training to use, and is not practical outside

BOX 23-1 Calculating RMR from Body Composition Data

RMR (calories/day) = 500 + (22 × Lean Body Mass in kilograms)
 RMR = resting metabolic rate
 LBM = lean body mass

research settings, indirect methods can be employed and include heart rate monitors, pedometers, or accelerometers. Other indirect methods are to use a daily activity factor as a base to which is added calories expended in exercise, which are calculated by multiplying the calories expended per minute of exercise times the amount of time spent in that activity, known as METS, metabolic equivalent of task (Driskell and Wolinsky, 2011; see Chapter 2).

Heart rate monitoring to estimate energy expenditure is based on the assumption that there is a linear relationship between heart rate and oxygen consumption (VO_2). Pedometers measure ambulatory distance covered, which is a limitation of the method because it does not consider other types of physical activities such as weight lifting, cycling, or yoga. Accelerometers have the advantage of measuring all activities, are easy to wear, and can give feedback for long periods of time. Other personal fitness devices have been developed in recent years, although no method is as accurate as measuring directly with a metabolic cart.

A method for calculating total energy expenditure using activity factors provided is shown in [Box 23-2](#).

BOX 23-2 Calculating Daily Energy Requirements for Athletes

Cunningham Formula

RMR or REE (resting energy expenditure in kcalories/day) = $500 + [22 \times \text{Lean Body Mass (LBM) in kilograms (kg)}]$

For example:

175-pound (79.5kg) athlete with 10% body fat
 Kg of fat = weight = $79.5 \text{ kg} \times .10 = 7.9 \text{ kg fat}$.
 Lean body mass = total weight - fat weight = $79.5 - 7.9 = 71.6 \text{ kg of LBM}$
 REE = $500 + (22 \times 71.6\text{kg LBM}) = 2075 \text{ calories}$.

To Determine EEPA—Energy Expended for Physical Activity

Can use:

Calories expended in a day using: http://www.cdc.gov/nccdphp/dnpa/physical/pdf/PA_Intensity_table_2_1.pdf

Or

Can use:

Specific caloric expenditures for different weights using: <http://www.nutribase.com/exercala.htm>.

Or

Can multiply REE by the activity factor using:

1.200 = sedentary (little or no exercise)
 1.375 = lightly active (about 30 minutes of moderate training, 1 to 3 days/week)
 1.550 = moderately active (45 minutes of moderate training, 3 to 5 days/week)
 1.725 = very active (training for 1 hour, 6 to 7 days/week)
 1.900 = extra active (very hard training, including weight lifting, 2-3 days/week)

To continue the example:

The EEPA for this 175-pound athlete who is training hard would be the following:

REE (2075 kcalories) \times activity factor (1.9) = 3942 total kcalories for BEE and EEPA

To continue the example:

Thermic effect of food (TEF) = the total kcalories for REE and EEPA \times 10% = $3942 \times 0.1 = 394 \text{ kcalories}$
 Total daily energy requirements = total kcalories (3942) + TEF (394 kcalories) = 4336 kcalories.

Total daily energy requirements = 4336 kcalories

Thompson J, Manore MM. Predicted and measured resting metabolic rate of male and female endurance athletes. *J Am Diet Assoc*. 1996 Jan; 96(1):30-4.

Meeting caloric needs for many fitness-minded or elite, intensely training individuals can be a challenge regardless of the accuracy of the formulas used to predict energy needs.

For high school and college athletes, disruptive sleep patterns and accommodating academic, social, and training schedules often lead to skipped meals, high frequency of unplanned snacking, use of sport shakes and bars in lieu of whole food meals, and late-night snacking while studying, or socializing online or with friends. Adult athletes with family and work responsibilities are also meal challenged when juggling daily training schedules with carpools, work deadlines, and accommodating children's eating schedules, which ultimately can compromise the quantity, quality, and timing of meals and greatly affect energy, strength levels, and overall health.

In elite athletes, consuming enough food at regular intervals without compromising performance is challenging, particularly when athletes are traveling abroad, are at the mercy of airport food, foreign food schedules, unfamiliar training facilities, delays, and unforeseen events such as weather-postponed game and competition schedules. All athletes regardless of age and lifestyle demands can be better prepared by packing snacks and ready-to-eat meals, which are essential for keeping energy intakes adequate to support overall health and performance.

Meeting the daily energy needs and the appropriate macronutrient distribution for active individuals may necessitate the use of sports bars, drinks, and convenience foods and snacks in addition to whole foods and meals. Dietitian nutritionists should stay open minded and be flexible in accommodating lifestyles and eating behaviors when designing meal plans for maximum sport performance.

WEIGHT MANAGEMENT

Although lean body mass has been associated with positive health benefits, negative health outcomes are associated with excessive loss or gain of body mass. Although weight classifications in sports such as youth and sprint football, wrestling, lightweight crew, and boxing were designed to ensure healthy, safe, and equitable participation, few published and widely accepted weight and body composition standards exist, and the governing organizations for these sports have no mandated weight control practices. Only sprint football and wrestling consider the components of an athlete's weight and body composition as well as the safety considerations for achieving and maintaining that body size.

In 1997 specific rules and guidelines were implemented by the NCAA to ensure safe weight control practices in wrestling, applied early in the competitive season and conducted on a regular basis to ensure prevention of dehydration and other weight-cutting behaviors. In 2006 the National Federation of State High School Associations adopted similar standards for determining body weights, although they are not accepted or enforced universally.

Weight Loss

In efforts to maximize performance or meet weight criteria determined by specific sports whether it is in the case of "making a lower weight" in sports such as martial arts, sailing, rowing, or wrestling, or reaching a higher weight for power lifting, football, or baseball, many athletes alter normal energy intake to either gain or lose weight. Although such efforts are sometimes appropriate, weight reduction or weight gain programs

may involve elements of risk, especially when the pressure to lose or gain weight is expected in an unrealistically short amount of time. For some young athletes achievement of an unrealistically low weight or conversely a high weight with the use of weight gainer or other supplements can jeopardize growth and development.

The goal weight of an athlete should be based on optimizing health and performance and be determined by the athlete's best previous performance weight and body composition. Adequate time should be allowed for a slow, steady weight loss of approximately 1 to 2 pounds each week over several weeks. Weight loss should be achieved during off-season or preseason when competition is not a priority. A weight loss planning guide can be found online at the *AND Sports Nutrition Care Manual*.

The National Athletic Trainers Association (NATA) suggests the lowest safe weight should be calculated at no lower than the weight determined by the low reference body fat composition delineated by sex and age. The lowest safe weight can be defined as the lowest weight sanctioned by the governing body at which a competitor may compete (Turocy et al, 2011). When no standard exists, participants would be required to remain above a certain minimal body fat. The highest safe weight should be calculated using a value no higher than the highest end of the range satisfactory for health: 10% to 22% body fat in males and 20% to 32% in females (Turocy et al, 2011; see Table 23-1).

Weight Gain

To accomplish a healthy weight gain of lean muscle tissue, 500 to 1000 additional calories per day can be added in addition to strength training, which will dually increase muscle strength. The rate of weight gain depends on the athlete's genetic makeup, degree of positive energy balance, number of rest and recovery sessions a week, and exercise type.

WEIGHT MANAGEMENT AND AESTHETICS

Disordered Eating

Although drive, perfection, and attention to detail are the hallmarks of talented athletes, they are also some of the personality traits associated with the development of eating disorders (see Chapter 22). Disordered eating behaviors among athletes can be difficult to detect given the tendencies of athletes to maintain rigid nutritional requirements, follow intense training schedules, and push through fatigue and pain.

Disordered eating behaviors specifically in athletes have been termed **anorexia athletica (AA)**, where the ultimate goal is to perform at one's best as opposed to thinness in and of itself being the goal. Athletes who are more vulnerable to AA are those who participate in "lean-build" sports, such as cross country running, swimming, gymnastics, cheerleading, dance, yoga, and wrestling, who may think they need to be a certain

weight or body type, often far less than what it is realistic to attain and maintain to be competitive. This desire to be unrealistically light or lean may lead to restrictive eating, bingeing and purging, and excessive training far beyond what is required for their sport.

Female Athlete Triad

Chronic dieting by female athletes can lead to the **female athlete triad (FAT)**, which consists of three interrelated health disorders: low energy availability with or without an eating disorder, osteoporosis, and amenorrhea. The prevalence of FAT for athletes participating in lean-requiring versus non-lean-requiring sports has been shown to range from 1.5% to 6.7% and from 0% to 2.0% respectively (Gibbs et al, 2013). For example, it has been shown that student and professional female dancers consume only 70% to 80% of the Recommended Dietary Allowance (RDA) for total daily energy intake (Mountjoy et al, 2014).

Also known as **athletic energy deficit (AED)**, this low-energy intake can lead to an increase in bone fractures and lifelong consequences for the bone and reproductive health of developing adolescent girls. Evidence suggests it is energy availability that regulates reproductive function in women, not exercise or body composition, and that ensuring adequate calorie intake is imperative to the overall health of the athletic woman (De Souza et al, 2014). Low energy intake paired with ovarian suppression or amenorrhea has been associated with poor athletic performance.

Muscle Dysmorphia

Although many studies suggest females are more susceptible to disordered eating behaviors than males, results from descriptive data from project EAT (Eating Amongst Teens) revealed that males who consider themselves in a weight-related sport are comparative to females in the same category. In fact, as the media's portrayal of the male physique has been increasingly muscular and unattainable, men have become more dissatisfied with their bodies and more vulnerable to **eating, exercise, and body image (EEBI) disorders**.

Muscle dysmorphia (MD), also known as "bigorexia" or reverse anorexia nervosa (AN), is a disorder in which individuals are preoccupied with their bodies not being muscular enough or big enough. It is marked by symptoms that are similar to and the opposite of anorexia nervosa symptomatology (see Chapter 22).

AA and MD experience grossly distorted perceptions of their bodies, which in the case of MD, often leads to maladaptive eating, exercise and substance use behaviors, including preoccupation with diet and excessively high protein intakes. In addition there is anabolic steroid, diet pill, caffeine, and over-the-counter supplement abuse, especially of those reputed for fat burning, ergogenic, or thermogenic effects. Last, the athlete exercises excessively, especially weight lifting, in an attempt to increase body satisfaction and attain the "perfect" lean and muscular physique. As with other EEBI, MD can lead to social, occupational, and relationship impairments (see Box 23-3).

Research suggests that this preference for a muscular physique is already evident in boys as young as 6 years old and may affect up to 95% of college-age American men who are dissatisfied with some aspect of their body and up to 25% of college men engaging in negative body talk (Engeln et al, 2013; Murray et al, 2012).

TABLE 23-1 Body Fat (%) Standards by Sex and Age

Body Fat Standard	Males	Females
Lowest reference body fat for adults	5	12
Lowest reference body fat for adolescents	7	14
Healthy body fat ranges	10-22	20-32

BOX 23-3 Body Image and Eating Disorders in Athletes

Anorexia Athletica

Exercising beyond the requirements for good health
 Obsessive dieting; fear of certain foods
 Obsessive or compulsive exercising; overtraining
 Individual won't eat with teammates, tries to hide dieting
 Stealing time from work, school, and relationships to exercise
 Focusing on challenge and forgetting that physical activity can be fun
 Defining self-worth in terms of performance
 Rarely or never being satisfied with athletic achievements
 Always pushing on to the next challenge
 Justifying excessive behavior by defining self as an athlete or insisting that the behavior is healthy
 Desire to keep losing more pounds despite already low body weight
 Mood swings; angry outbursts
 Menstrual periods stop
 REF: <http://www.eatingdisorderonline.com/explain/anorexiathleticasigns.php>

Muscle Dysphoria

Primarily male eating disorder
 Getting bigger is on the mind constantly. This includes thinking about diet, working out, or appearance
 See themselves as looking small or "puny" even though they typically appear normal or very muscular to others
 Constant concerns with body fat percentage
 Hide physique with baggy clothing since never feel "good enough" and is source of shame
 Workouts take precedence over other significant events or time spent with family and friends
 Fear that missing one workout session will set them back or stymie progress
 Workout even when injured
 Common to abuse anabolic steroids to enhance their appearance
 Missing workout or eating a "forbidden" food item can trigger extreme anxiety and crush self-esteem
 Individual might add additional workout sessions, skip meals, or use some means to punish themselves for diet cheating
 Frequently accompanying symptoms of depression
 REF: <http://www.eatingdisorderonline.com/lifestyle/general/recognizing-muscle-dysmorphia-bigorexia>

MACRONUTRIENTS

According to the position of the Academy of Nutrition and Dietetics (AND), Dietitians of Canada, and the American College of Sports Medicine, most recreational athletes do not need to eat a diet that is substantially different than the U.S. Dietary Guidelines for Americans to perform optimally (Rodriguez et al, 2009; see Chapter 11). Individuals engaging in a general fitness program typically can meet their macronutrient needs by consuming a normal diet of 45% to 55% of calories from carbohydrates (3 to 5 g/kg/day), 10% to 15% from protein (0.8 to 1 g/kg/day), and 25% to 35% from fat (0.5 to 1.5 g/kg/day).

Nutrition Periodization

Athletes involved in moderate- to high-volume training need greater amounts of carbohydrates, protein, and fat to meet macronutrient needs. The composition of the athlete's diet is dependent on training phase: preseason, season, off season; sport type including intensity and duration of training; and weight and body composition goals.

Specific macronutrient recommendations should be used when counseling a competitive or elite athlete to maximize performance, a concept known as **nutrition periodization**.

TABLE 23-2 A Nutrition Periodization Program

Cycle	Training Goal/Dietary Recommendation
Preseason training	Preparation load cycles followed by recovery cycles Higher or lower energy needs depending on weight goals Greater protein needs for lean muscle mass development
Competitive season	Peak cycles with recovery; energy needs depending on expenditure; higher carbohydrate needs to support high intensity competition; protein and fat needs relative to weight maintenance, recovery and overall health
Postseason training	Active rest-transition cycle of conditioning and recovery; energy to support but not exceed needs; emphasis on more lax dietary guidelines for mental and emotional competitive break

Nutrition periodization is a term to describe dietary modification to match specific training patterns during in and off seasons as well as pre- and postcompetition periods, which are marked by different nutritional needs (Driskell and Wolinsky, 2011). Periodization involves different training cycles, including load, recovery peak, and conditioning that are implemented according to the athlete's sports demands and competition schedules (Driskell and Wolinsky, 2011; see Table 23-2).

Strategies and Tools for Eating Guides in Athletes

According to the United States Olympic Committee (USOC), sports dietitians, and other sports nutrition experts, keeping guidelines simple for athletes is imperative for compliance. See <http://www.outsideonline.com/fitness/nutrition/The-Secret-Food-of-Athletes.html>.

The USOC dietitians created **The Athlete's Plate** as a guide for eating for athletes based on easy, moderate, and hard training regimens (see Figure 23-4). This tool helps athletes who play a sport for more than 5 hours a week modify servings and portion sizes from each food group based on their training (Mettler et al, 2010).

CARBOHYDRATE

Carbohydrates are one of two main fuels used for sport activity. The first source of glucose for the exercising muscle is its own glycogen store. When this is depleted, **glycogenolysis** and then gluconeogenesis (both in the liver) maintain the glucose supply. The relationship between carbohydrate intake, muscle glycogen content, and endurance exercise capacity is well documented, and it has become widely accepted that a high-carbohydrate diet before combined with carbohydrate supplementation during prolonged submaximal exercise can postpone the development of muscular fatigue and enhance performance (Burke, 2010).

During endurance exercise that exceeds 90 minutes, such as marathon running, muscle glycogen stores become progressively smaller. When they drop to critically low levels, high-intensity exercise cannot be maintained. In practical terms the athlete is exhausted and must either stop exercising or drastically reduce the pace. Athletes often refer to this as "hitting the wall."

FIGURE 23-4 The athlete's plate adjusted to type of training and competition.

Glycogen depletion also may be a gradual process, occurring over repeated days of heavy training, in which muscle glycogen breakdown exceeds its replacement, as well as during high-intensity exercise that is repeated several times during competition or training. For example, a distance runner who averages 10 miles per day but does not take the time to consume enough

carbohydrates in his or her diet, or the swimmer who completes several interval sets at maximum oxygen consumption within hours can deplete glycogen stores rapidly.

Historically, a high-carbohydrate or **glycogen loading (glycogen supercompensation)** diet was used to guide athletes to enhance maximize glycogen stores and be able to continue endurance performance, but this approach has its benefits and drawbacks (McArdle et al, 2013).

Traditionally, the 7-day carbohydrate-loading approach combined muscle-specific depletion training with a low-carbohydrate diet for 4 days followed by a high-carbohydrate diet and little to no training for 3 days before competition. Normal muscle typically contains about 1.7 g glycogen per 100 g of muscle; supercompensation packs up to 5 g glycogen per 100 g of muscle. Although this may be beneficial for the endurance athlete training or competing over 60 minutes, it has not been shown to benefit those in higher-intensity, shorter-duration activities. The negative effects of the additional weight of 2.7 g of water for each gram of glycogen can be a hindrance to performance, making it a heavy fuel. A modified approach of gradual exercise tapering along with more modified increases in carbohydrate intake may minimize the negative outcomes associated with classical loading (McArdle et al, 2013).

Effects of Training Low, Competing High

Recent studies have investigated the impact of short-term, 1- to 2-week diet-training interventions that increase endogenous muscle glycogen and lipids and alter patterns of substrate utilization during exercise. Otherwise known as the **fat adaptation strategy** or “train low” approach, well-trained endurance athletes consume a high-fat, low-CHO diet for up to 2 weeks while undertaking their normal training and then immediately follow this by a high-carbohydrate diet and tapering of exercise 1 to 3 days before an endurance event. Research suggests that this **nutritional periodization** approach can increase the rate of fat oxidation while attenuating the rate of muscle glycolysis during submaximal exercise.

Carbohydrate Recommendations

The amount of carbohydrate required depends on the athlete's total daily energy expenditure, type of sport, gender, and the environmental conditions, with the ultimate goal of providing adequate energy for performance and recovery, and a protein sparing effect.

Recommendations should provide for daily carbohydrate intake in grams relative to body mass and allow flexibility for the athlete to meet these targets within the context of energy needs and other dietary goals. Carbohydrate intake of 5 to 7 g/kg/day can meet general training needs, and 7 to 10 g/kg/day will likely suffice for endurance athletes, although elite athletes training 5 to 6 hours a day may need as much as 12 g/kg/day or a range of 420 to 720 g of carbohydrates a day for the 60-kg athlete (AND, 2014; Driskell and Wolinsky, 2011).

Carbohydrates are especially important not only as an overall contributor to meeting daily calorie needs but also as ergogenic aids in a more time-specific approach, also known as nutritional periodization, designed to enhance and maximize performance for competition, especially more than 90 minutes in length. However, a recent meta-analysis suggests that the impact of carbohydrates on performance is subject to debate as numerous studies use fasting subjects and time-to-exhaustion test modes, which may offer a less-convincing picture,

especially with an exercise session lasting less than 70 minutes (Colombani et al, 2013).

Types of Carbohydrate

Even though the effects of different sugars on performance, substrate use, and recovery have been studied extensively, the optimal type of carbohydrate for the athlete is still subject to debate by sports performance experts (Colombani et al, 2013). The **glycemic index (GI)** represents the ratio of the area under the blood glucose curve resulting from the ingestion of a given quantity of carbohydrate and the area under the glucose curve resulting from the ingestion of the same quantity of white bread or glucose (see Appendix 37).

Studies concerning whether the GI of carbohydrate in the preexercise meal affects performance have been performed primarily in athletes in endurance sports, and are inconclusive. In one study, high-glycemic and low-glycemic carbohydrate solutions demonstrated similar performance outcome when consumed during a long distance run (Bennett et al, 2012). A preexercise low-glycemic index meal was shown to diminish increases in stress hormones and accelerate recovery. Another study also showed that compared with fasting, low- and high-GI foods consumed 3 hours before and halfway through prolonged, high-intensity intermittent exercise improved repeated sprint performance (Little et al, 2009).

Food Timing

Pre-Training Carbohydrates

The pretraining or preevent meal serves two purposes: (1) it keeps the athlete from feeling hungry before and during the exercise, and (2) it maintains optimal levels of blood glucose for the exercising muscles. A preexercise meal can improve performance compared with exercising in a fasted state. Athletes who train early in the morning before eating or drinking risk developing low liver glycogen stores, which can impair performance, particularly if the exercise regimen involves endurance training.

Carbohydrate meals before exercise can enhance liver glycogen stores. In addition to allowing for personal preferences and psychologic factors, the preevent meal should be high in carbohydrate, nongreasy, and readily digested. Fat should be limited because it delays gastric emptying time and takes longer to digest. A meal eaten 3½ to 4 hours before competition should be limited to 25% of the kilocalories from fat. Closer to the event, the fat content should be less than 25% (see Box 23-4).

Exercising with a full stomach may cause indigestion, nausea, and vomiting. Thus the pregame meal should be eaten 3 to 4 hours before an event and should provide 200 to 350 g of carbohydrates (4 g/kg) (Driskell and Wolinsky, 2011). Allowing time for partial digestion and absorption provides a final addition to muscle glycogen, additional blood sugar, and also relatively complete emptying of the stomach. To avoid gastrointestinal (GI) distress, the carbohydrate content of the meal should be reduced when the meal is close to the exercise time. For example, 4 hours before the event it is suggested that the athlete consume 4 g of carbohydrate per kilogram of body weight, whereas 1 hour before the competition the athlete would consume 1 g of carbohydrate per kilogram of body weight.

Commercial liquid formulas providing an easily digested high-carbohydrate fluid are popular with athletes and probably leave the stomach faster. Foods high in fiber, fat, and lactose cause GI distress for some (e.g., bloating, gas, or diarrhea) and

BOX 23-4 Examples of Pre-Event Meals and Snacks

For athletes who compete in events such as track or swimming meets or soccer, basketball, volleyball, and wrestling tournaments all day, nutritious, easy-to-digest food and fluid choices may be a challenge. The athlete should consider the amount of time between eating and performance when choosing foods during all-day events. Suggested pre-competition menus include the following:

1 hr. or Less Before Competition—About 100 kcal

One of these choices:

- Fresh fruit such as a banana or orange slices
- Half of a sports or breakfast bar
- ½ plain bagel or English muffin
- Crackers such as rice crackers, saltines or Melba toast
- Small box of plain cereal such as Kashi, Kind, Krispies, or Flakes
- 8-12 oz. of a sports drink such as Body Armor, Gatorade

2 to 3 Hours Before Competition—About 300-400 kcal

One of these choices:

- ½ of turkey sandwich on white bread with baked chips
- ½ bagel with low-sugar jelly and 1 banana
- 2 pancakes with lite or sugar-free syrup and berries
- 32 fluid oz. of a sports drink such as Body Armor, Gatorade, PowerBar, Endurance Sports Drink or 32 oz. endurance drink with protein such as UCAN, Endurox, or Accelerade
- 1 low-sugar smoothie with berries, banana, and 1 scoop (< or = 20 gm), of protein, either plant-based, whey or egg whites
- 1 sports energy bar, 1 cup sports drink, 1 cup water

3 to 4 Hours Before Competition—About 700 kcal

One of these selections:

- Scrambled egg whites with white toast/low-sugar jam and banana
- 1 bagel with fat free or low-fat cream cheese and low-sugar jelly and 1 banana
- 1 6-in turkey sub on Italian bread with lettuce, tomato, and mustard
- 1 3-oz grilled chicken breast with small baked potato, roll, and water
- 2 cups plain pasta with 1 plain roll
- 1 can of low fat sport shake with no more than 25 g protein, 1 sports bar, 1 banana, water

should be avoided before competition. Athletes should always use what works best for them by experimenting with foods and beverages during practice sessions and planning ahead to ensure they have these foods available when they compete.

Pre-training Fasting

Some athletes either rise too early for workouts to consume a meal or snack or feel nauseous when consuming food before exercise. Overnight fasts of 8 to 10 hours or longer are normal for most people, but not for athletes. An overnight fast causes a drop in liver glycogen, causing glycogenolysis to maintain the supply of glucose to the brain. Although a modest fall in blood sugar may not affect the average individual, it may affect the physical and cognitive performance of athletes fasting longer than 12 to 24 hours. Although some evidence suggests a metabolic advantage of endurance training in a fasted state to increase fat oxidation in trained muscles, other evidence supports the intake of nutrients, primarily carbohydrates, before, during, and after training sessions (Van Proeyen et al, 2011).

Training Fuel During Exercise

Carbohydrates consumed during endurance exercise lasting longer than 1 hour ensure the availability of sufficient amounts

FIGURE 23-5 A triathlon is a high-intensity endurance sport during which both carbohydrates and fats are used as fuels, the amount depending on the speed and length of the event. (Photo©istock.com).

of energy during the later stages of exercise, improve performance, and enhance feelings of pleasure during and after exercise (Driskell and Wolinsky, 2011). Carbohydrate feedings may not prevent fatigue but may delay it. During the final minutes of exercise, when muscle glycogen is low and athletes rely heavily on blood glucose for energy, their muscles feel heavy, and they must concentrate to maintain exercise at intensities that are ordinarily not stressful when muscle glycogen stores are full. Glucose ingestion during exercise also has been shown to spare endogenous protein and carbohydrates in fed cyclists without glycogen depletion; thus consuming an exogenous carbohydrate during endurance exercise helps to maintain blood glucose and improve performance (McArdle et al, 2013). (See Figure 23-5).

The type of carbohydrates consumed may affect performance during exercise. Recent research suggests that compared with water, a solution containing fructose attenuates thermoregulatory responses compared with glucose (Suzuki et al, 2014). However, the form of carbohydrate consumed does not seem to matter physiologically. Some athletes prefer to use a sports drink, whereas others prefer to eat a solid or gel and drink water.

If a sports drink with carbohydrates is consumed during exercise, the rate of carbohydrate ingestion should be approximately 25 to 30 g every 30 minutes, an amount equivalent to 1 cup of a 4% to 8% carbohydrate solution taken every 15 to

20 minutes. This ensures that 1 g of carbohydrate is delivered to the tissues per minute at the time fatigue sets in. It is unlikely that a carbohydrate concentration of less than 5% is enough to help performance, but solutions with a concentration greater than 10% often are associated with abdominal cramps, nausea, and diarrhea.

Combining protein and carbohydrates in a sport fluid or snack also may improve performance, muscle protein synthesis and net balance, and recovery. Amino acids ingested in small amounts, alone or in conjunction with carbohydrates before or after exercise, appear to improve net protein balance, and may stimulate protein synthesis during exercise and postexercise recovery (AIS, 2014).

Postworkout and Recovery Fuel

Dietary strategies that can enhance recovery from the negative effects of exercise can help promote effective physiologic adaptation, muscle conditioning after exercise, and enable a faster return to training. The resulting improvement in training efficiency may lead to significant performance benefits and sport career longevity by supporting repetitive training and competition and helping to maintain immune status and long-term health (Lynch, 2013).

On average, only 5% of the muscle glycogen used during exercise is resynthesized each hour after exercise. Accordingly, at least 20 hours are required for complete restoration after

exhaustive exercise, provided approximately 600 g of carbohydrates are consumed during that time. The highest muscle glycogen synthesis rates have been reported when large amounts of carbohydrates—1 to 1.85 g/kg/hr—are consumed immediately after exercise and at 15- to 60-minute intervals thereafter for up to 5 hours after exercise. Delaying carbohydrate intake for too long after exercise reduces muscle glycogen resynthesis.

Apparently the consumption of carbohydrates with a high glycemic index results in higher muscle glycogen levels 24 hours after exercise compared with the same amount of carbohydrates provided as foods with a low glycemic index (Cermak and van Loon, 2013). Adding approximately 5 to 9 g of protein with every 100 g of carbohydrate eaten after exercise may further increase glycogen resynthesis rate, provide amino acids for muscle repair, and promote a more anabolic hormonal profile (Sousa et al, 2014).

Many athletes find it difficult to consume food immediately after exercise. Usually when body or core temperature is elevated, appetite is depressed, and it is difficult to consume carbohydrate-rich foods. Many athletes find it easier and simpler to drink their carbohydrates, ingest easy-to-eat, carbohydrate-rich foods such as fruit pops, bananas, oranges, melon, or apple slices, or consume a sports recovery shake or bar.

Sports supplements may include the easy-to-carry, easy-to-consume, and easy-to-digest meal-replacement powders, ready-to-drink supplements, energy bars, and energy gels. These products are typically fortified with 33% to 100% of the Dietary Reference Intakes (DRIs) for vitamins and minerals, provide varying amounts and types of carbohydrates, protein, and fat, and are ideal for athletes on the run. They provide a portable, easy-to-consume food that can be used pericompetitively, while traveling, at work, in the car, or throughout the day at multievent meets such as in track and field, swimming, diving, or gymnastics.

Many fitness-minded and athletic individuals use these products, generally recognized as safe, as a convenient way to enhance their diets. However, if they are substituted in the place of whole foods on a regular basis, they can deprive the athlete of a well-balanced diet. They also may contain excesses of sugars, fats, and protein and banned substances such as herbs, stimulants, and other botanicals prohibited by United States Anti-Doping Agency (USADA) in and out of competition.

PROTEIN

The protein needs of athletes have been debated. The current RDA is 0.8 g/kg bodyweight, and the acceptable macronutrient distribution range for protein for people 18 years and older is 10% to 35% of total calories. Factors affecting the protein needs of athletes include age, gender, lean body mass, fitness level, training regimen, and phase of competition.

Nitrogen balance studies in endurance athletes suggest a range of 1.2 g/kg to 1.4 g/kg/day, and for strength athletes 1.2 to 1.7 g/kg/day for protein intake, with the higher end of the range recommended early in the competitive season (Phillips, 2012).

Reports of food intake in athletes and nonathletes consistently indicate that protein represents from 12% to 20% of total energy intake or 1.2 to 2 g/kg/day. The exception to the rule is small, active women who may consume a low-energy intake in conjunction with their exercise or training program. Although these women may consume close to the RDA for protein in

conjunction with the restricted energy intake, it may be inadequate to maintain lean body mass.

However, the need for protein during exercise is elevated just slightly above that for sedentary persons. Consuming more protein than the body can use is not necessary and should be avoided. When athletes consume diets that are high in protein, they compromise their carbohydrate status, which may affect their ability to train and compete at peak levels. High protein intakes also can result in diuresis and potential dehydration. Protein foods are often also high in fat, and consumption of excess protein can create difficulty in maintaining a low-fat diet.

Protein Needs for Resistance Exercise

Protein needs for resistance exercise involve maintenance (minimum protein required to accomplish nitrogen equilibrium) and the need for increasing lean tissue (positive nitrogen balance). Strategies to increase the concentration and availability of amino acids after resistance exercise such as timing of snacks and meals continue to be an area of ongoing research (Aguirre et al, 2013).

Dietary protein intake also may have a beneficial role in exercise recovery by attenuating impairments in endurance performance, which accompany intensified periods of training.

Type, Timing, and Amount of Protein for Muscle Hypertrophy

Still a hot topic among athletes and in the sports nutrition community, many factors appear to contribute to overall muscle hypertrophy. Nutritional factors that control protein synthesis during exercise are not well understood, leaving experts in discord about the type, amount, and timing of meals to enhance protein synthesis and muscle hypertrophy.

Resistance training (RT) and diet consistently appear to play a role in post-workout muscle protein synthesis. The metabolic basis for muscle growth appears to be a balance between muscle protein synthesis (MPS) and prevention of catabolism, especially the balance of myofibrillar protein or contractile protein synthesis, in which dietary protein plus exercise plays an important role. Resistance training enhances the anabolism by 40% to 100% over and above resting levels and dietary protein response for up to 24 hours when protein is consumed immediately before and at least within 24 hours after (Tipton and Phillips, 2013). This higher combined rate of protein synthesis after exercise has been shown to occur in young and elderly men.

Research suggests the anabolic response to resistance exercise, and protein ingestion works just as well with whole food proteins as with nutritional supplement proteins, although convenience often makes the difference because taking a high-protein shake or bar to training is more practical than carrying a chicken breast.

Between 20 and 25 g of a high-quality protein maximizes the response of MPS after resistance exercise, whereas no difference occurs between the ingestion of 20 g of protein and 40 g, suggesting that more is not better, at least in young, resistance-trained males. Preworkout ingestion of essential amino acids also appears to enhance the MPS response. However, more protein may be required to maximize the response of MPS when less than optimal protein sources (complete vs. noncomplete) are used in older individuals (Tipton and Phillips, 2013).

Although the inclusion of carbohydrates does not seem to have an impact on protein synthesis, it may have an impact on the prevention of breakdown. Fat content of postworkout fuel also may have a positive impact as in one study, whole milk enhanced synthesis more than skim milk did (Tipton and Phillips, 2013).

For athletes interested in muscle hypertrophy, it appears that neither the type nor the amount of protein matters if the day's total amount is within the recommended range for resistance-training athletes of 1.2 to 2 g of protein per kilogram of body weight. Research shows that a minimum of 30 g of high-quality protein at each meal that contains 2.5 g leucine per meal will optimally stimulate protein synthesis. Recent preliminary evidence suggests that leucine in addition to omega-3 fatty acid supplementation may help reduce muscle loss for acutely injured athletes (Tipton, 2013).

FAT

Even though maximum performance is impossible without muscle glycogen, fat also provides energy for exercise. Fat is the most concentrated source of food energy, supplying 9 kcal/g. Essential fatty acids are necessary for cell membranes, skin health, hormones, and transport of fat-soluble vitamins. The body has total glycogen stores (muscle and liver), equaling approximately 2600 calories, whereas each pound of body fat supplies about 3500 calories. This means that an athlete weighing 74 kg (163 lb) with 10% body fat has 16.3 lb of fat and thus carries energy worth about 57,000 calories depending on his or her metabolism. Even if this number is individualized, and not known accurately, it is still far more calories than that supplied by the athlete's glycogen stores.

Fat is the major, if not most important, fuel for light- to moderate-intensity exercise. Although fat is a valuable metabolic fuel for muscle activity during longer aerobic exercise and performs many important functions in the body, more than the usual recommended amount of fat is not indicated. In addition, athletes who consume a high-fat diet may consume fewer calories from carbohydrate, which may be detrimental to short-term performance.

The distribution of substrate in the diet also determines which substrate is used during an exercise bout. If an athlete is consuming a high-carbohydrate diet, he or she will use more glycogen as fuel for the exercise. If the diet is high in fat, more fat will be oxidized as a fuel source. Fat oxidation rates decline after the ingestion of a high-fat diet, partly because of adaptations at the muscle level, greater utilization of fat, and decreased glycogen stores as a result of lower carbohydrate intakes. Fasting longer than 6 hours optimizes fat oxidation; however, the ingestion of carbohydrates in the hours before or at the beginning of an exercise session augments the rate of fat oxidation significantly compared with fasting all the way up to the race (Volek et al, 2014; Yeo et al, 2011).

Exercise intensity and duration are important determinants of fat oxidation. Fat oxidation rates decrease when exercise intensity becomes high. A high-fat diet has been shown to compromise high-intensity performance even when a high-fat diet regimen is followed by carbohydrate loading before high-intensity performance (McArdle et al, 2013). The mode and duration of exercise also can affect fat oxidation; running increases fat oxidation more than cycling (Rosenkilde et al, 2013).

Fats, Inflammation, and Sports Injury

When athletes are injured, they want to heal and get back to training as soon as possible. Specific foods at the right time can help to provide energy for rehabilitation, rebuild strength, and ensure a complete, healthy, and faster recovery.

Stress to muscle leads to inflammation, bruising, and tissue breakdown. Failure to decrease inflammation can lead to scar tissue, poor mobility, and delayed recovery times. The inflammatory stage is affected by foods, especially by the types of dietary fat consumed. A diet high in trans fats, saturated fats, and some omega-6 vegetable oils has been shown to promote inflammation, whereas a diet high in monounsaturated fat and essential omega-3 fats has been shown to be anti-inflammatory (see Chapter 3 and Appendix 31). Monounsaturated fats such as olive, peanut, canola, and sesame oils as well as avocado oil also inhibit and reduce inflammation by interfering with proinflammatory compounds such as leukotrienes, which are produced naturally by the body. Diets supplemented with omega-3 fats have been shown to reduce postexercise delayed-onset muscle soreness and inflammation and promote healing (Jouris et al, 2011). There is also evidence to suggest a strong connection between omega-3 status and neuroprotection and supplementation to accelerate recovery from traumatic brain injury, including concussion (Michael-Titus and Priestley, 2014).

Supplemental omega-3 fat has been recommended during the inflammation stage after injury, especially when the diet is deficient. However, some concern exists regarding the sources of omega-3 fat supplements and fish oils, because some have been found to be contaminated with mercury and polychlorinated biphenyls (PCBs), toxins dangerous to humans (see *Focus On: Omega-3 Fatty Acids in Pregnancy and Lactation* in Chapter 15).

Fruits and vegetables are also good sources of alpha linolenic acid (ALA), an omega-3 fatty acid. However, the conversion in the body of ALA to the more active forms of omega-3 fatty acids, DHA and EPA, is very low. Plant-based foods rich in ALA include flaxseeds, chia seeds, walnuts, almonds, and tofu. Wheat germ, free-range beef, poultry, and some eggs are also good sources of omega-3 fats when the animals are fed omega-3 rich food (see Appendix 34).

FLUID

Maintaining fluid balance requires the constant integration of input from hypothalamic osmoreceptors and vascular baroreceptors so that fluid intake matches or modestly exceeds fluid loss (McArdle et al, 2013). Proper fluid balance maintains blood volume, which in turn supplies blood to the skin for body temperature regulation. Because exercise produces heat, which must be eliminated from the body to maintain appropriate temperatures, regular fluid intake is essential. Any fluid deficit that is incurred during an exercise session can potentially compromise the subsequent exercise bout.

The body maintains appropriate temperatures by **thermoregulation**. As heat is generated in the muscles during exercise, it is transferred via the blood to the body's core. Increased core temperature results in increased blood flow to the skin; in cool to moderate ambient temperatures, heat is then transferred to the environment by convection, radiation, and evaporation.

Environmental conditions have a large effect on thermoregulation. When ambient temperatures range from warm to hot, the body must dissipate the heat generated from exercise, as

well as the heat absorbed from the environment. When this occurs, the body relies solely on the evaporation of sweat to maintain appropriate body temperatures. Thus maintaining hydration becomes crucial when ambient temperatures reach or exceed 36° C (96.8° F). The hotter the temperature, the more important sweating is for body-heat dissipation. Exercise in the heat also affects blood flow and alters the stress response, with modest changes in circulating leukocytes and cytokines. A critical threshold for elevation of body temperature is 6° F (3.5° C), above which the systemic inflammatory response leads to heatstroke.

Humidity affects the body's ability to dissipate heat to a greater extent than air temperatures. As humidity increases, the rate at which sweat evaporates decreases, which means more sweat drips off the body without transferring heat from the body to the environment. Combining the effects of a hot, humid environment with a large metabolic heat load produced during exercise taxes the thermoregulatory system to its maximum. Ensuring proper and adequate fluid intake is key to reducing the risk of heat stress.

Fluid Balance

Body fluid balance is regulated by mechanisms that reduce urinary water and sodium excretion, stimulate thirst, and control the intake and output of water and electrolytes. In response to dehydration, antidiuretic hormone (ADH or vasopressin) and the renin-angiotensin II–aldosterone system increase water and sodium retention by the kidneys and provoke an increase in thirst. These hormones maintain the osmolality, sodium content, and volume of extracellular fluids and play a major role in the regulation of fluid balance (see Chapter 6).

Water losses throughout the course of the day include those from sweat and the respiratory tract, plus losses from the kidneys and GI tract. When fluid is lost from the body in the form of sweat, plasma volume decreases and plasma osmolality increases. The kidneys, under hormonal control, regulate water and solute excretion in excess of the obligatory urine loss. However, when the body is subjected to hot environments, hormonal adjustments occur to maintain body function. Some of these adjustments include the body's conservation of water and sodium and the release of ADH by the pituitary gland to increase water absorption from the kidneys. These changes cause the urine to become more concentrated, thus conserving fluid and making the urine a dark gold color. This feedback process helps to conserve body water and blood volume.

At the same time, aldosterone is released from the adrenal cortex and acts on the renal tubules to increase the resorption of sodium, which helps maintain the correct osmotic pressure. These reactions also activate thirst mechanisms in the body. However, in situations in which water losses are increased acutely, such as in athletic workouts or competition, the thirst response can be delayed, making it difficult for athletes to trust their thirst to ingest enough fluid to offset the volume of fluid lost during training and competition. A loss of 1.5 to 2 L of fluid is necessary before the thirst mechanism kicks in, and this level of water loss already has a serious effect on temperature control. *Athletes need to rehydrate on a timed basis rather than as a reaction to thirst, and it should be enough to maintain the pre-exercise weight.*

Imbalance between fluid intake and fluid loss during prolonged exercise may increase the risk for dehydration. Dehydration may

enhance the development of hyperthermia, heat exhaustion, and heat stroke.

Men appear to have higher sweat rates that may lead to more fluid loss during exercise compared with women. Studies also have shown that men have higher plasma sodium levels and a higher prevalence of hypernatremia than women after prolonged exercise, which suggests larger fluid losses in men. In contrast, it also is reported that women have an increased risk for overdrinking, which could lead to exercise-associated hyponatremia. This was demonstrated in a recent endurance study that compared female and male walkers. The study demonstrated a significantly larger change in body mass in men than in women, a higher incidence of dehydration in the men (27% of the men vs. 0% of the women showed postexercise hypernatremia), and a significantly lower fluid intake and higher fluid loss in the men compared with females (Eijssvogels et al, 2013).

In one study, approximately 66% of collegiate athletes, more men than women, were found to be dehydrated pretraining, which may be due to individual hydration habits, lack of hydration before early morning practices, or lack of knowledge regarding proper hydration before and after training (Volpe et al, 2009).

Although for years, studies have shown that substantial fluid and body mass losses greater than 2% of total body weight were related to an impaired exercise performance, a recent study shows otherwise (Wall et al, 2013). High-intensity prolonged exercise may increase the discrepancy between fluid intake and losses. In one study, increased body temperature and dehydration up to 3% in well-trained male cyclists, had no effect on a 25-km cycling time-trial performance in hot conditions in well-trained men who were blinded to their hydration status (Wall et al, 2013).

Daily Fluid Needs

Fluid intake recommendations for sedentary individuals vary greatly because of the wide disparity in daily fluid needs created by body size, physical activity, and environmental conditions. The DRI for water and electrolytes identifies the adequate intake for water to be 3.7 L/day for men (130 oz/day, 16 cups of fluid/day) and 2.7 L/day for women (95 oz/day, approximately 12 cups/day) (Institute of Medicine [IOM], 2005). Approximately 20% of the daily water need comes from water found in fruits and vegetables; the remaining 80% is provided by beverages, including water, juice, milk, coffee, tea, soup, sports drinks, and soft drinks. When individuals work, train, and compete in warm environments, their fluid needs can increase greatly, and this should be appreciated (McArdle et al, 2013).

Fluid Replacement

Controversy exists among experts as to how to assess fluid needs because there is no scientific consensus regarding the best method to assess hydration status. Recreational sports typically result in hypotonic fluid losses, which increase relative concentrations of blood and urine. Field measures to assess body hydration status include body mass measurements, urine specific gravity and color, and taste sensation. Each has its limitations (McArdle et al, 2013).

Several position statements and recommendations are published by a variety of professional organizations that address fluid and electrolyte replacement before, during, and after exercise. A summary of these recommendations can be found in [Box 23-5](#).

BOX 23-5 Summary of Guidelines for Proper Hydration**General Guidelines**

Monitor fluid losses: Weigh in before and after practice, especially during hot weather and the conditioning phase of the season.
 Do not restrict fluids before, during or after the event.
 Do not rely on thirst as an indicator of fluid losses.
 Drink early and at regular intervals throughout the activity.
 Do not consume alcohol before, during, or after exercise because it may act as a diuretic and prevent adequate fluid replenishment.
 Discourage caffeinated beverages a few hours before and after physical activity because of their diuretic effect.

Before Exercise

Drink approximately 400 to 600 mL (14 to 22 oz) of water or sports drink 2 to 3 hr before the start of exercise.

During Exercise

Drink 150 to 350 mL (6 to 12 oz) of fluid every 15 to 20 min, depending on race speed, environmental conditions, and tolerance; no more than 1 C (8 to 10 oz) every 15 to 20 min, although individualized recommendations must be followed.

After Exercise

Drink 25% to 50% more than existing weight loss to ensure hydration 4 to 6 hours after exercise.
 Drink 450 to 675 mL (16 to 24 oz) of fluid for every pound of body weight lost during exercise.
 If an athlete is participating in multiple workouts in 1 day, then 80% of fluid loss must be replaced before the next workout.

Electrolyte Replacement

Sodium: 0.5 to 0.7 g/L in activity longer than 1 hour to enhance palatability and the drive to drink, to reduce the risk of hyponatremia and to minimize risk of muscle cramps.

When possible, fluid should be consumed at rates that closely match sweating rate. It appears that plain water is not the best beverage to consume after exercise to replace the water lost as sweat. Although specific recommendations differ slightly, the intent is to keep athletes well hydrated (Kenefick and Cheuvront, 2012).

Electrolytes

The replacement of electrolytes as well as water is essential for complete rehydration (see Table 23-3).

Sodium

It is important to include sodium in fluid-replacement solutions, especially with excessive intake of plain water (McArdle et al, 2013) for events lasting more than 2 hours; sodium should be added to the fluid to replace losses and to prevent hyponatremia. Rehydration with water alone dilutes the blood rapidly, increases its volume, and stimulates urine output. Blood dilution lowers sodium and the volume-dependent part of the thirst drive, thus removing much of the drive to drink and replace fluid losses.

The potential benefits of temporary hyperhydration with sodium salts are important. Sodium losses can contribute to heat cramping, especially among football players. In fact, in one study, 75% of National Football League teams use pregame hyperhydration with intravenous fluid to prevent muscle cramps.

TABLE 23-3 Comparison of the Sweat Electrolyte Losses* and Sports Drink Content

Electrolyte	Sweat Loss mg/L	Standard Sport Drink mg/L	Endurance Specific Sport Drink mg/L
Sodium	900-2600	230-1700	800-1110
Potassium	150	80-125	390-650
Magnesium	8.3-14.2	0	10-815
Chloride	900-1900	0	390-1550
Calcium	28	0-100	24-275
Iron	0.1-0.4	0	0
Phosphorus	40	0	0
Zinc	0.36-0.48	0	0-5

*Dependent on exercise duration, intensity, ambient temperature, hydration status before and during exercise

Baker A: Nutrition for Sports 22: Sweat mineral losses. <http://www.arniebakercycling.com/pubs/Free/NS%20Sweat.pdf>. Accessed January 13, 2015; Kenefick RW, Cheuvront SN: Hydration for recreational sport and physical activity, *Nutr Rev* 70 (Suppl 2):S137, 2012.

Besides individual variations, the intensity and duration of workouts appear to play a role in the amount of sodium lost.

Water-soluble electrolytes such as sodium can move rapidly across the proximal intestines. During prolonged exercise lasting more than 4 to 5 hours, including sodium in replacement fluids increases palatability and facilitates fluid uptake from the intestines. Sodium and carbohydrate are actively transported from the lumen to the bloodstream.

Water replacement in the absence of supplemental sodium can lead to decreased plasma sodium concentrations. As plasma sodium levels fall below 130 mEq/L, symptoms can include lethargy, confusion, seizures, or loss of consciousness. Exercise-induced hyponatremia may result from fluid overloading during prolonged exercise over 4 hours. Hyponatremia is associated with individuals who drink plain water in excess of their sweat losses or who are less physically conditioned and produce a saltier sweat.

Potassium

As the major electrolyte inside the body's cells, potassium works in close association with sodium and chloride in maintaining body fluids, as well as generating electrical impulses in the nerves, muscles, and heart. Potassium balance is regulated by aldosterone and its regulation is precise. Although aldosterone acts on sweat glands to increase the resorption of sodium, potassium secretion is unaffected. Loss of potassium from skeletal muscle has been implicated in fatigue during athletic events. There is little loss of potassium through sweat; loss of 32 to 48 mEq/day does not appear to be significant and is easily replaced by diet.

Fluid Absorption

The speed at which fluid is absorbed depends on a number of different factors, including the amount, type, temperature, and osmolality of the fluid consumed and the rate of gastric emptying. Because glucose is absorbed actively in the intestines, it can markedly increase sodium and water absorption. A carbohydrate-electrolyte solution enhances exercise capacity by elevating blood sugar, maintaining high rates of carbohydrate oxidation, preventing central fatigue, and reducing perceived exertion (Lynch, 2013).

Early studies indicate that water absorption is maximized when luminal glucose concentrations range from 1% to 3% (55 to 140 mM); however, most sports drinks contain two to three times this quantity without causing adverse GI symptoms. To determine the concentration of carbohydrate in a sports drink, the grams of carbohydrate or sugar in a serving are divided by the weight of a serving of the drink, which is usually 240 g, the approximate weight of 1 cup of water. A 6% carbohydrate drink contains 14 to 16 g of carbohydrate per 8 oz (1 cup).

Cold water is preferable to warm water because it attenuates changes in core temperature and peripheral blood flow, decreases sweat rate, speeds up gastric emptying, and is absorbed more quickly. In one recent study, sweating response was influenced by water temperature and voluntary intake volume. Cool tap water at 60° F appeared to replace fluids better in dehydrated individuals compared with warmer fluids (Hosseini et al, 2013).

Burton showed that, although ingestion of cold beverages is preferable, an ergogenic benefit was also seen from the effect of ice slush ingestion and mouthwash on thermoregulation and endurance performance in the heat (Burdon et al, 2013). Another study compared ice slush to cold water in moderately active males while running and showed prolonged time to exhaustion and reduced rectal temperature, supporting possible sensory and psychologic effects of ice slush beverages either consumed or used as a mouthwash. Precooling with an ice slushy solution also may have more beneficial effects over cold fluid ingestion during exercise and performance (Dugas, 2011).

Children

Children differ from adults in that, for any given level of dehydration, their core temperatures rise faster than those of adults, probably because of a greater number of heat-activated sweat glands per unit skin area than in adolescents or adults. Children sweat less even though they achieve higher core temperatures. Sweat composition also differs between children and adults: adults have higher sodium and chloride concentrations but lower lactate, hydrogen, and potassium concentrations. Children also take longer to acclimate to heat than adolescents and adults (McArdle et al, 2013).

Because young children do not drink enough when offered fluids freely during exercise in hot and humid climates, and because they participate in physical activities less than 60 minutes in duration, often little attention is paid to their hydration.

Children who participate in sports activities must be taught to prevent dehydration by drinking above and beyond thirst and at frequent intervals, such as every 20 minutes. A rule of thumb is that a child 10 years of age or younger should drink until he or she does not feel thirsty and then should drink an additional half a glass (3 to 4 oz or $\frac{1}{3}$ to $\frac{1}{2}$ cup) of fluid.

Older children and adolescents should follow the same guidelines; however, they should consume an additional cup of fluid (8 oz). When relevant, regulations for competition should be modified to allow children to leave the playing field periodically to drink. One of the hurdles to getting children to consume fluids is to provide fluids they like. Providing a sports drink or slushy ice drink as described in the previous section that will maintain the drive to drink may be the key to keeping child athletes hydrated.

Older Athletes

Older, mature, or masters-level athletes are also at extra risk for dehydration and need to take precautions when exercising. **Hypohydration** (water loss exceeding water intake with a body water deficit) in older individuals can affect circulatory and thermoregulatory function to a greater extent and may be caused by the lower skin blood flow, causing core temperature to rise. Because the thirst drive is reduced in older adults, they need to drink adequately before exercise, well before they become thirsty (McArdle et al, 2013).

Hydration at High Altitudes

Unacclimated individuals undergo a plasma volume contraction when acutely exposed to moderately high altitude. This is the result of increased renal sodium and water excretion and decreased voluntary sodium and water intake. Respiratory losses are increased by high ventilatory rates and typically dry air. The result is an increase in serum hematocrit and hemoglobin, which increases the oxygen-carrying capacity of the blood, but at the cost of reduced blood volume, stroke volume, and cardiac output. Fluid requirements increase as a result. With acclimation, red blood cell production increases and plasma and blood volumes return to pre-high altitude levels.

OTHER CONSIDERATIONS

Carbohydrates

Chocolate Milk

Postexercise carbohydrate intake has been shown to augment recovery from heavy aerobic exercise. The effects of carbohydrate and protein coingestion have been investigated more recently, including the potential influences of chocolate milk.

The efficacy of carbohydrates and protein together could be due to influences on glycogen resynthesis, protein turnover, rehydration, attenuations in muscle disruption, or perhaps a combination of these factors. However, there are inconsistencies in the literature regarding the effects of carbohydrates and protein on these factors, and the mechanisms explaining potential influences after endurance exercise are not defined clearly.

Some studies report that carbohydrate and protein beverages such as chocolate milk can enhance subsequent exercise performance better than carbohydrate-only beverages, although others have reported no positive effects (Lunn et al, 2012; Peschek et al, 2013). Compared with placebo of an isocaloric carbohydrate-only beverage, chocolate milk has been shown to improve recovery from high intensity and endurance training in runners and cyclists. Postexercise chocolate milk supplementation also has been shown to improve subsequent exercise performance and muscle glycogen synthesis and provide a greater intracellular signaling stimulus for protein synthesis (Lunn et al, 2012). Chocolate milk can be an affordable recovery beverage for some athletes.

VITAMINS AND MINERALS

Micronutrients enable the use of macronutrients for all physiologic processes and are key regulators in health and work performance. Athletes who fail to consume a diet with

adequate vitamins and minerals can become deficient, which can lead to impairments in training and performance. High training volume, exercise performed in stressful conditions including hot conditions, altitude, or training with substandard diets may promote excessive losses of micronutrients because of increased catabolism or excretion (Rodríguez et al, 2009).

Training and work schedules, low-nutrient snacks, infrequent nutrient-dense meals, and overall low calorie intakes may cause inadequate intakes of vitamins and minerals. Athletes who adopt popular diets that eliminate whole food groups such as meat, dairy, grains, or fruits, as in the case of vegetarians or Paleo enthusiasts, run the risk of poor micronutrient intake. Micronutrients such as calcium, zinc, iron, vitamin B₁₂, and others will be of concern.

Description of vitamin metabolism and resulting physical performance is very limited. Assessments of vitamin intake, biochemical measures of vitamin status, and determination of resulting physical performance are required; however, very few studies have provided this information.

A 2010 report reported numerous dietary vitamin and mineral deficiencies in elite female athletes including folate (48%), calcium (24%), magnesium (19%), and iron (4%) (Heaney et al, 2010). A 2014 report also highlighted the risk of injury in female athletes with iron, vitamin D, and calcium deficiencies (McClung et al, 2014).

A 2013 study of male athletes showed significant deficiencies in vitamin A (44% of group), vitamin C (80% of group), vitamin D (92% of group), folate (84% of group), calcium (52% of group), and magnesium, (60% of group) (Wierniuk and Włodarek, 2013).

Without a doubt, impaired micronutrient status affects exercise and work performance. Some of the deficiency signs and symptoms associated with exercise have been summarized in this section (see Table 23-4).

B Vitamins

Increased energy metabolism creates a need for more of the B vitamins, including thiamin, riboflavin, niacin, pyridoxine, folate, biotin, pantothenic acid, and choline, which serve as part of coenzymes involved in regulating energy metabolism by modulating the synthesis and degradation of carbohydrates, protein, fat, and bioactive compounds.

Some athletes who have poor diets and athletes such as wrestlers, jockeys, figure skaters, gymnasts, or rowers who consume low-calorie diets for long periods of time may be prone to deficiencies. A B-complex vitamin supplement to meet the RDA may be appropriate. However, there is no evidence that supplementing the well-nourished athlete with more B vitamins increases performance.

The intake of folic acid could potentially be low in athletes whose consumption of whole grains, whole fruits, and vegetables

TABLE 23-4 Vitamin and Mineral Deficiency Signs and Symptoms Associated with Exercise

Vitamin/Mineral	Function	Deficiency Sign or Symptom	Evidence for Supplementation to Improve Performance
B ₁ Thiamin	Carbohydrate and protein metabolism	Weakness, decreased endurance, muscle wasting, weight loss, pyruvate accumulation, increased circulating lactate, fatigue, reduced performance	To correct deficiency
B ₂ Riboflavin	Oxidative metabolism, electron transport system	Altered skin and mucous membrane, and nervous system function limited	In athletes whose food availability may be at initiation of increased physical activity
B ₃ Niacin	Oxidative metabolism, electron transport system	Irritability, diarrhea	Adequate in athletes, no impact on performance
B ₆ Pyridoxine	Gluconeogenesis	Dermatitis, convulsions	Not shown effective
Folic Acid	Hemoglobin and nucleic acid formation	Anemia, fatigue	In deficiency
B ₁₂ Cyanocobalamin	Hemoglobin formation	Anemia, neurological symptoms	In deficiency
Vitamin C	Antioxidant	Fatigue, loss of appetite	In depleted states, including environmental stress, infection altitude, high temperatures, cigarette smoking; 250 or 500 mg may reduce body heat, enhance immune function & facilitate recovery from intense training
Vitamin A	Antioxidant	Appetite loss, prone to infections	No evidence to suggest supplementation even in dietary deficient athletes
Vitamin E	Antioxidant	Nerve and muscle damage	Evidence lacking; results equivocal with regard to reducing exercised-induced damage
Magnesium	Energy metabolism, nerve and muscle contraction	Muscle weakness, nausea, irritability, impaired performance	May increase muscle strength, improve cellular function; lactate and oxygen uptake shown to decrease in exhaustive rowing; those with adequate status not shown to benefit
Iron	Hemoglobin synthesis	Anemia, cognitive impairment, immune abnormalities	Equivocal results in Fe-deficient nonanemic athletes; supplementation in women with depleted serum iron but not anemic enhanced muscle function
Zinc	Nucleic acid synthesis, glycolysis	Growth retardation, appetite loss, immune abnormalities	May benefit when zinc intake suboptimal; diet intakes within 70% maintains serum levels
Chromium	Glucose metabolism	Glucose intolerance	High-intensity exercise may increase urinary loss, albeit small; supplements not shown to improve body comp or performance or strength

is low; however, folate supplementation in deficient athletes has not been shown to improve performance. A deficiency of vitamin B₁₂ could develop in a vegetarian athlete after several years of a strict vegan intake; thus a vitamin B₁₂ supplement may be warranted. However B₁₂ supplementation has not been shown to improve performance in athletes consuming adequate amounts of B₁₂.

Choline

Choline is a water-soluble nutrient typically found in foods rich in B vitamins. Choline is synthesized in the body from other nutrients and therefore is not considered essential. Some evidence suggests that choline, found in fatty foods, peanuts, dairy products, and egg yolks, is low in men and women, and is shown to decrease after certain types of strenuous exercise and this may affect performance (Penry and Manore, 2008).

Choline has been promoted to athletes to improve physical endurance by increasing fat lipolysis and acetylcholine production to increase muscle contractions and delay fatigue, although evidence does not support these claims (Castell et al, 2010).

Choline supplements may cause gastrointestinal side effects, including breakdown to trimethylamine, which leads to a fishy body odor.

Antioxidants

Antioxidants have been studied individually and collectively for their potential to enhance exercise performance or to prevent exercise-induced muscle tissue damage. Cells continuously produce free radicals and **reactive oxygen species (ROS)** as a part of metabolic processes. The rate of oxygen consumption during exercise may increase 10- to 15-fold, or as much as 100-fold in active peripheral skeletal muscles. This oxidative stress increases the generation of lipid peroxides and free radicals, and the magnitude of stress depends on the ability of the body's tissues to detoxify ROS (see Chapter 3).

Free radicals are neutralized by antioxidant defense systems that protect cell membranes from oxidative damage. These systems include catalase; superoxide dismutase; glutathione peroxidase; antioxidant vitamins A, E, and C; selenium; and phytonutrients such as carotenoids (see Chapter 3). Susceptibility to oxidative stress varies from person to person and the effect is influenced by diet, lifestyle, environmental factors, and training. Antioxidant nutrients may enhance recovery from exercise by maintaining optimal immune response, and lowering lipid peroxidation.

Although large-dose antioxidant supplementation attenuates exercise-induced reaction oxygen species (ROS) production and consequential oxidative damage, studies suggest over-supplementation may block necessary cellular adaptations to exercise (Sureda et al, 2013). In a recent study of 14 trained male runners, 152 mg of vitamin C and 50 mg vitamin E supplementation daily reduced oxidation of neutrophil proteins without inhibiting cellular adaptation to exercise. Further research is needed to assess the response to supplementation with varying degrees of exercise duration and intensity (Sureda et al, 2013). Another 2012 study showed that, although vitamin C and E supplementation may attenuate the acute exercise-induced increase in the inflammatory cytokine plasma IL-6, it does not seem to further decrease IL-6 levels after 12 weeks of supplementation combined with endurance training (Yfanti et al, 2012).

A diet rich in fruits and vegetables can ensure an adequate intake of antioxidants, and prudent use of an antioxidant supplement may provide insurance against a suboptimal diet and the increased stress from exercise.

Recent research has shown the positive benefits of phytonutrients with anti-inflammatory and antioxidant effects, especially anthocyanins found in purple and red fruits, and vegetables may help with posttraining inflammation. One review study suggests the benefits of quercetin found in red onions, blueberries, tomatoes, apples, black tea, purple grapes, and red onions. These compounds found in tart cherry juice can help to reduce inflammation, muscle damage, and oxidative stress after marathon running (Howatson et al, 2010). An unexpected effect of tart cherry juice is that it also may have a beneficial effect on sleep, which has been attributed to the high melatonin content of tart cherries (Howatson et al, 2010).

Vitamin C

Vitamin C is involved in a number of important biochemical pathways that are important to exercise metabolism. For example vitamin C is involved in the synthesis of carnitine, which transports long-chain fatty acids into the mitochondria for energy production. The effect of vitamin C supplementation on performance has received considerable attention, mainly because athletes consume vitamin C in large quantities, generally because of the volume of food they consume. Athletes generally have normal plasma vitamin C levels.

In studies in which athletes were deficient in vitamin C, supplementation improved physical performance, but a thorough analysis of these studies supports the general conclusion that vitamin C supplementation does not increase physical performance capacity in subjects with normal body levels of vitamin C. On the other hand, because exercise is a stressor to the body, some nutritionists recommend that the active individual may need more vitamin C than the DRI.

Fat-Soluble Vitamins

Vitamins A, D, E, and K have no direct role in energy metabolism; rather they play supportive roles in energy use. Vitamin A acts as an antioxidant in reducing muscle damage from exercise, whereas vitamin K functions in coagulation and bone formation.

Vitamin D

Over the past few years, vitamin D has been shown to play an increasingly important role in sports performance beyond its role in calcium absorption and use in bone formation (Todd et al, 2014). As a secosteroid hormone, upon activation to 1,25 hydroxyvitamin D₃, vitamin D responsive gene expression is altered with more than 1000 responsive genes affecting muscle protein synthesis, muscle strength, muscle size, reaction time, balance coordination, endurance, inflammation, and immunity, all of which are important to athletic performance.

Vitamin D deficiency may be more common in athletes than previously thought, especially in specific groups (Shuler et al, 2012). The prevalence appears to vary by sport, training location, and time of year and skin color (Larson-Meyer and Willis, 2010). Research has shown that more than 75% of Caucasians and 90% of African Americans and Latinos are possibly vitamin D deficient according to set values. It is possible that up to 77% of athletes who live in northern climates with little winter sunlight and who are indoor athletes, (94% of basketball players, and 83% of gymnasts) may be affected by deficiencies

BOX 23-6 Vitamin D and Athletic Performance

2,313 athletes in 23 studies – 56% were deficient
Football Players: 19.1% had adequate vitamin D levels; 50.6% had insufficient levels; 30.3% had deficient levels.

Vitamin D Potential Impact on Athletic Performance

Positive effect on muscle strength, power, and mass
Increased force and power output of skeletal muscle tissue
May influence maximal oxygen uptake (VO₂ Max)
Improved skeletal muscle function & bone strength
Potentially increased size and number of type II muscle fibers
Decreased recovery time from training
Increase testosterone production

Dahlquist DT et al: Plausible ergogenic effects of vitamin D on athletic performance and recovery, *J Int Soc Sports Nutr*, 12:33, 2015.
Farrokhyar F et al: Prevalence of vitamin D inadequacy in athletes: a systematic-review and meta-analysis, *Sports Med* 45:365, 2015.
Maroon JC et al: Vitamin D profile in National Football League players, *Am J Sports Med* 43:1241, 2015.

of vitamin D (Cannell et al, 2009). Outdoor athletes may not have an advantage over indoor athletes; in a National Football league study, 81% of Caucasian and African American players may be at risk for deficiency (see Box 23-6). Blood tests can better determine deficiency states. A measurement of 25-(OH) D levels of 50 ng/ml or less is a value used to determine those at risk.

Although the specific amount of vitamin D needed to reverse deficiency states has not been determined, partly because it depends on the extent of deficiency, athletes should be tested and guided by a health professional if diagnosed with a deficiency (see Chapter 7 and Appendices 22 and 45).

Recent research suggests supplemental vitamin D increased serum 25(OH) D concentrations and enhanced the recovery in peak isometric force after the damaging event, and attenuated the immediate and delayed increase in circulating biomarkers representative of muscle damage (ALT or AST) (Barker et al, 2013).

After a detailed assessment, recommendations for attaining and maintaining optimal vitamin D levels can be individualized to the athlete's current 25-(OH)D concentration, diet, lifestyle habits, belief system, and clinical symptoms. The recommendation for fair-skinned individuals is to obtain 5 minutes and for dark skin 30 minutes of sunlight exposure to arms, legs, and back several times a week without sunscreen (see Appendix 45). Short-term, high-dose "loading" regimens for rapid repletion under the care of a physician also may be beneficial (Todd et al, 2014).

Vitamin E

Vitamin E is used widely as a supplement by athletes who hope to improve performance. Vitamin E may protect against exercise-induced oxidative injury and acute immune response changes.

MINERALS

Although 12 minerals have been shown to be designated as essential nutrients, iron, calcium, magnesium, and copper have biochemical functions with the potential to affect performance.

Iron

Iron is critical for sport performance because, as a component of hemoglobin, it is instrumental in transporting oxygen from the lungs to the tissues. It performs a similar role in **myoglobin**, which acts within the muscle as an oxygen acceptor to hold a supply of oxygen readily available for use by the mitochondria. Iron is also a vital component of the cytochrome enzymes involved in the production of ATP. Iron adequacy can be a limiting factor in performance because deficiency limits aerobic endurance and the capacity for work. Even partial depletion of iron stores in the liver, spleen, and bone marrow, as evidenced by low serum ferritin levels, may have a detrimental effect on exercise performance, even when anemia is not present (see Chapter 32).

Sports anemia is a term applied to at least three different conditions: hemodilution, iron deficiency anemia, and foot-strike anemia. Athletes at risk are the rapidly growing male adolescent; the female athlete with heavy menstrual losses; the athlete with an energy-restricted diet; distance runners who may have increased GI iron loss, hematuria, hemolysis caused by foot impact, and myoglobin leakage; and those training with heavy sweating in hot climates. Recent research suggests that anemia may be common in female athletes, especially adolescent and premenopausal females, long-distance runners, and vegetarians, who should be screened periodically to assess their iron status.

Heavy endurance training also can cause a transient decrease in serum ferritin and hemoglobin. This condition, known as **sports or pseudoanemia** is characterized by reduced hemoglobin levels resulting from expanding blood volumes that are almost those of clinical anemia, but return to pretraining normal levels. Performance does not appear to deteriorate and the pseudoanemia may in fact improve aerobic capacity and performance (McArdle et al, 2013).

Some athletes, especially long-distance runners, experience GI bleeding that is related to the intensity and duration of the exercise, the athlete's ability to stay hydrated, how well the athlete is trained, and whether he or she has taken ibuprofen before the competition. Iron loss from GI bleeding can be detected by fecal hemoglobin assays. See *Clinical Insight: GI Issues in Athletes*.

It is possible that using serum hemoglobin as the determining factor for identifying anemic athletes who may benefit from iron supplementation with performance improvement is not the best biomarker. Nonanemic athletes (with normal serum hemoglobins) who are supplemented with iron have shown improved performance (DellaValle, 2013). Optimal levels of serum ferritin, which is the most common index of body iron status associated with performance, and thus a better marker, may also be inadequate, because athletes supplemented with iron to achieve higher than "normal" serum ferritin levels have also shown improved performance (DellaValle, 2013). Some athletes experience iron deficiency without anemia, and have normal hemoglobin levels but reduced levels of serum ferritin (20-30 ng/ml; see Chapter 7).

Athletes should be assessed for their iron status using serum hemoglobin and serum ferritin at the beginning of and during the training season. This is especially important in those suspected to have sickle cell trait (SCT), because their rate of sudden death is 10 to 30 times higher than in non-SCT athletes. Typically deaths have occurred early in the season, during exhaustive drills in hot weather without adequate warmup time (Harris et al, 2012). In 2010 the NCAA instituted a universal screening program to test for SCT in all Division I athletes; however,

in athletes at the high school level, in the NBA, NFL, Navy, Marines, and Air Force, testing is not required (Jung et al, 2011).

Although male athletes have been reported to consume at least the RDA for iron, female athletes tend to consume somewhat less for a variety of reasons, including low energy intake, lower intake of animal products, or adherence to a vegetarian or vegan diet (Woolf et al, 2009). Increasing dietary intake of iron or supplementation is the only way to replace iron losses and improve status.

Who should be supplemented and with how much iron remains to be answered. Given the evidence suggesting iron's role in overall health and physical performance, there is no debate that athletes with clinical deficiency should be identified and treated. Whether those with subclinical deficiency should be treated with iron supplementation remains controversial. Individuals with normal status typically do not benefit from supplementation, and concerns regarding unregulated doses and overload should be considered.

Calcium

Suboptimal levels of dietary calcium intake are seen in athletes. Because low levels of calcium intake have been shown to be a contributing factor in osteoporosis, young female athletes, especially those who have had interrupted menstrual function, may be at risk for decreased bone mass.

The FAT in women's athletics is discussed earlier in the chapter. Strategies to promote the resumption of menses include estrogen replacement therapy, weight gain, and reduced training. Regardless of menstrual history, most female athletes need to increase their calcium, vitamin D₃, and magnesium intake. Low-fat and nonfat dairy products, calcium-fortified fruit juices, calcium-fortified soy milk, and tofu made with calcium sulfate are good sources (see Appendices 45 and 46).

Magnesium

Magnesium is an essential mineral that supports more than 300 enzymatic reactions including glycolysis, fat and protein metabolism, and adenosine triphosphate hydrolysis, and is a regulator of neuromuscular, immune, and hormonal functions. Although hypomagnesemia has been seen in athletes possibly caused by excessive sweating while training and transient redistribution of magnesium indicating a release from one storage area to an active site, levels return to normal within 24 hours after exercise (Malliaropoulos et al, 2013).

True magnesium deficiency has been shown to impair athletic performance, causing muscle spasms and increased heart rate and oxygen consumption during submaximal exercise. For deficient athletes, supplemental magnesium has been shown to improve performance by improving cellular function, although in athletes with adequate status, performance outcomes are mixed (Kass, 2013). In one recent study with female volleyball players, magnesium supplementation improved lactic acid (does not produce any lactic acid) anaerobic metabolism, even though the players were not magnesium deficient (Setaro et al, 2013). In another study with young men participating in a strength training program for 7 weeks, daily magnesium intake of 8 mg/kg of body weight resulted in increases in muscle strength and power, whereas marathon runners with adequate stores did not seem to benefit (Moslehi et al, 2013).

COPPER

Copper is a cofactor in numerous enzymes that potentially can affect sports performance, including antioxidant defense,

CLINICAL INSIGHT

GI Issues in Athletes

Gut issues are a common problem affecting about 45% to 85% of athletes (ter Steege et al, 2012). Issues can affect the upper GI tract, such as reflux, heart burn, chest pain, nausea, vomiting, gastritis, peptic ulcers, bleeding or stitches, or the lower GI, as gas, bloating, excessive urge to defecate, diarrhea, hemorrhoids, and colitis. Changes in mechanical forces seen with running, altered GI blood flow, and GI motility, along with neuroendocrine changes from training can cause changes in GI function. In addition, pretraining and precompetition diet changes, stress, climate, dehydration, NSAID use, and bowel movements before exercise are some of the possible causes.

Assessment tools used to rule out food-related issues include (1) a thorough dietary analysis including an analysis of foods, fluids, alcohol use, and supplements consumed before, during and after training; (2) food sensitivity or allergy testing to determine whether food intolerances to gluten, lactose, or other foods or herbals exist; (3) a bowel function and chronic GI disease history; (4) a history of overall fluid intake and possible dehydration because of changes in training climate; and (5) a history of infections and antibiotic use.

A game plan including an elimination diet if necessary, specific competition day diet and fueling guidelines, and a GI healing supplementation regimen including probiotics, digestive enzymes, electrolytes, and vitamins and minerals is useful and reassuring for the athlete with GI issues (see Chapter 28).

oxygen transport and utilization, immune function, and catecholamine and connective tissue synthesis. Athletes who report persistent fatigue, frequent infections, and stress fractures should have their copper status assessed. Copper supplementation should not be undertaken without clinical justification, because it can be toxic.

ERGOGENIC AIDS

Ergogenic aids include any training technique, mechanical device, nutrition practice, pharmacologic method, or physiologic technique that can improve exercise performance capacity and training adaptations. Many athletes devote substantial time and energy striving for optimal performance and training and turn to ergogenic aids, especially dietary supplements.

The Food and Drug Administration (FDA) regulates dietary supplement products and ingredients in addition to labeling, product claims, package inserts, and accompanying literature. The Federal Trade Commission (FTC) regulates dietary supplement advertising (<http://www.fda.gov/food/dietarysupplements/>). See Chapter 12 for a definition of a dietary supplement as defined by the Dietary Supplement Health and Education Act (DSHEA) of 1994.

DSHEA protects dietary supplements from being required to demonstrate proof of efficacy or safety. Manufacturers are allowed to publish limited information about the benefits of dietary supplements in the form of statements of support, as well as so-called structure and function claims. This results in a great deal of printed material that can be confusing to athletes at the point of sale of nutritional products. In addition athletes are bombarded with advertisements and testimonials from other athletes and coaches about the effects of dietary supplements on performance.

The use of ergogenic aids in the form of dietary supplements is widespread in all sports. Many athletes, whether recreational, elite, or professional, use some form of dietary supplementation

(e.g., substances obtainable by prescription or by illegal means or others marked as supplements, vitamins, or minerals) to improve athletic performance or to assist with weight loss (Maughan et al, 2011).

According to a survey, 88% of collegiate athletes report using one or more nutritional supplements (Buell et al, 2013). A recent study found 25,000 supplement inquiries to the Resource Exchange Center (REC) of the National Center for Drug Free Sport. Among dietary supplements, inquiries for amino acids and their metabolites, vitamins and minerals, and herbal products occurred most frequently, with banned substances accounting for 30% of all inquiries submitted to the REC, and 18% of all medications searched in the database (Ambrose et al, 2013).

Surveys show reasons for supplement use are varied and differ between genders. Women athletes often take supplements for their health, or to overcome an inadequate diet, whereas men may take supplements to improve speed, agility, strength, and power and also use them to help build body mass and reduce weight or excess body fat.

A recent survey of track and field athletes competing in the world championships showed 89% of females and 83% of males reported using supplements for the following reasons: 71% to aid in recovery from training; 52% for health; 46% to improve performance; 40% to prevent or treat an illness; and 29% to compensate for a poor diet (Maughan et al, 2007).

See Table 23-5 for discussion of ergogenic aids commonly used by athletes.

TABLE 23-5 Ergogenic Aids

Ergogenic Aid	Reported Action/Claim	Research on Ergogenic Effects	Side Effects
α -Ketoglutarate	Intermediate in Krebs cycle	Some evidence as anti-catabolic after surgery; may impact mitochondrial functioning at altitude	None
ALA	Enzyme found in mitochondria involved in energy production	No studies of use in humans for sport; used in Europe with persons with diabetes to treat insulin resistance and neuropathy	None
Arginine	Protein synthesis; precursor to creatine and potential to increase GH; precursor to NO	Improves aerobic endurance performance; increases plasma nitrite, reduces O ₂ consumption during submax exercise	GI distress
Branched-chain amino acids	Decrease mental fatigue Decrease exercise-induced protein degradation and muscle enzyme release	Some evidence that decreased fatigue may occur at higher altitudes	Mild GI distress for some
EAA's	Increase strength, endurance; accelerate recovery	Limited; suggests 3-6 g of EAA's before exercise; stimulate protein synthesis	Same as protein
Glutamine	Boosts immunity; stimulates protein and glycogen synthesis	May boost immunity with branched-chain amino acids and enriched whey	None reported
HMB	Metabolite of EAA leucine; anticatabolic; enhances recovery by stimulating protein and glycogen synthesis	3 gm in 2 divided doses shown to improve performance; may increase upper-body strength and lean body mass and minimize muscle damage; decreases muscle catabolism	None reported
Carnitine	In skeletal muscle oxidizes fat and CHO during exercise; bioavailability from food poor; vegetarians have lower stores	Studies weak, no effect on performance, energy metabolism; limited stores may impact performance, supplementation may improve stores marginally	None reported
Choline	Lipolysis, weight loss, increased time to fatigue, improved work performance	Low plasma levels shown in endurance athletes, may decrease fatigue; strenuous and prolonged physical activity appears to significantly decrease circulating levels; no performance benefits in those with adequate stores	GI upset; fishy odor
Chondroitin sulfate	Builds and grows cartilage	No studies that it is effective in treating arthritis or joint damage or helps torn ligaments or cartilage.	None
Glucosamine	Serves as non-steroidal anti-inflammatory drug alternative	Readily absorbed; benefit in reducing pain and need for medication	None reported
Glycerol	Decreases heat stress, increases body fluid volume, facilitates water absorption from intestines, lowers heat stress, heart rate, body temp; enhances endurance performance in heat	Mixed—reduces heart rate, thirst sensation, improved endurance output and peak power output reported	Bloating, nausea, dizziness, light headedness
Glutamine	Conditionally essential amino acid; improves muscle recovery	Mixed, no effect on performance	None reported
Green tea extract Nitrates (beet juice)	Antioxidant; increases energy expenditure Vasodilator, reduced BP, increased performance, time to exhaustion	Limited; may increase energy expenditure Mechanism unclear, research shows it to be strong NO precursor which reduces O ₂ cost of submaximal exercise, increases mitochondrial efficiency, contractile function	Same as caffeine None reported
COQ10	Cofactor for ATP production; electron transport in mitochondria; reduces fatigue	Mixed: double-blinded, placebo, cross-over trial, 100 mg/d for 2 mo., lift loads of 75 g/kg of body weight 5x/30 s improved mean power; may improve in those with mitochondrial disorders or CoQ deficiency	

Continued

TABLE 23-5 Ergogenic Aids—cont'd

Ergogenic Aid	Reported Action/Claim	Research on Ergogenic Effects	Side Effects
Beta-alanine	As precursor to carnosine, buffer and antioxidant potential	Mixed; 4-10 weeks of supplementation can increase carnosine by 50-80%; effects seen in 30s-7min sports; acidosis during 6 minute high intensity training bout blunted w/4 weeks supplements; effects start 3-4 weeks following start of supplementation and for 1 month after D/C supplement	Skin prickling (paresthesia) when exceeding recommended dose 10mg/kg body weight)
Pyruvate	Augments endurance exercise performance; promote fat loss	Double-blind studies showed increased upper/lower body endurance performance by 20%; increased cycle ergometer time to exhaustion when diet contains adequate CHO 55%, supplement to increase pre-exercise muscle glycogen levels	None reported
Quercetin	Anti-inflammatory, anticarcinogenic, cardioprotective, neuroprotective	Mixed reduced muscle damage and body fat; increase in total time to exhaustion in badminton; no improvements in other studies	None reported
Ribose	Replenishes high-energy compounds following intense exercise; increases power	Limited; can increase exercise capacity in heart patients; no significant difference in double-blind hot environment; greater improvement in 1 rep MAX bench press; no effects on greater sprint performances	None reported
Sodium bicarbonate/sodium citrate	Buffers lactic acid production; delays fatigue	Increases body's ability to buffer lactic acid during sub max exercise for events lasting 1-7 min	Stomach distress: bloating, diarrhea; dangerous in high doses; alkalosis
Sodium phosphate	Buffer	Some; increases VO ₂ max and anaerobic threshold by 5%-10%; improves endurance	Stomach distress
Creatine	Improves strength, power and intermittent sprint performance; accelerate training recovery	Increases muscle free creatine, phosphocreatine; performance effect seen in sprint/power through endurance by enhancing muscle glycogen storage; stimulates muscle anabolism, muscle relaxation; effects may fade after 2 months supplementation; consume with CHO to increase levels to greater extent	Weight gain 0.8-2.9%; watch with weight sensitive sports; unknown long term

ALA, α -Lipoic acid; CF, cardiorespiratory fitness; EAA, essential amino acid; EP, endurance performance; GH, growth hormone; HMB, β -hydroxy- β -methylbutyrate; NO, nitric oxide.

Research suggests that all too often physically active individuals, including high-level athletes, obtain nutrition information from unreliable sources, including coaches, fellow athletes, trainers, advertisements, and the Internet rather than well-informed and educated sports dietitians, physicians, and accredited exercise professionals (Morente-Sánchez and Zabala, 2013). Information on the efficacy and safety of many of these products used by athletes is limited or completely lacking.

The biggest concern for athletes is the use of drugs prohibited in sport and the possibility that a supplement may contain something that will result in a positive drug test, which may also apply to supplemental sport food products such as drinks, shakes, and bars. In fact a wide range of stimulants, steroids, and other agents that are included in the World Anti-Doping Agency's (WADA) prohibited list have been identified in supplements. This may occur in the preparation of the raw ingredients or in the formulation of the finished product. In some cases, the amount of product may be exceptionally higher or lower than the therapeutic dose (see Table 23-6).

Sports nutritionists need to know how to evaluate the scientific merit of articles and advertisements about exercise and nutrition products so that they can separate marketing hype from scientifically based training and nutrition practices (see Chapter 12).

ERGOGENIC AIDS FOR HIGH INTENSITY EXERCISE

Beta-Alanine

Intermittent bouts of **high-intensity interval training (HIIT)** deplete energy substrates and allow for metabolite accumulation.

Studies suggest that supplementation with beta-alanine may improve endurance performance as well as lean body mass (Kern and Robinson, 2011). Because of its relationship with carnosine, beta-alanine appears to have ergogenic potential. Carnosine is believed to be one of the primary buffering substances in muscle. Although carnosine is synthesized from two amino acids, beta-alanine and histidine, its synthesis appears to be limited by the availability of beta-alanine, thus taking supplemental beta-alanine can increase carnosine levels (Danaher et al, 2014).

This proposed benefit would help increase an athlete's capacity for training and increase time to fatigue. Supplementing with beta-alanine has been associated with improved strength, anaerobic endurance, body composition, and performance on various measures of anaerobic power output.

In one study, football players participated in 5 days a week training that included repeated sprints with low work-rest ratios three times a week and Olympic power-lifting four times per week. Football players taking 1.5 g of beta-alanine plus 15 g sugar (about the amount of sugar in 8 oz of a sports drink) gained an average of 2.1 lb of lean mass compared with controls who gained 1.1 lb in the same 8-week training cycle (Kern and Robinson, 2011). Another study showed that beta-alanine can result in greater training adaptations in 3 weeks of high-intensity interval training (Harris and Stellingwerff, 2013). More research is needed to confirm the effectiveness in football players and look for any long-term consequences.

TABLE 23-6 Commonly Used Banned and Recreational Drugs Used by Athletes

Ergogenic Drug	Goals of Use	Athletic Effect	Adverse Effects
Alcohol	Reduce stress and inhibition; most widespread used drug in sport 88% intercollegiate athletes	No benefits	Dependence producing; twofold higher risk of injury; cardiovascular/liver disease; worsens left ventricular dysfunction; decreases amino acid, glucose utilization; decreases energy, hypoglycemia; dehydration; decreases skeletal muscle capillary density, cross sectional area; inhibits sarcolemmal calcium channel actions, impairs excitation-contraction coupling and diminishes performance; decreases muscle oxidative capability; compromises blood coagulation/fibrinolysis/post exercise perturbations in clotting factors; positive energy balance, obesity; increases HR and $\dot{V}O_2$, reductions in power output
Nicotine	CNS psychostimulant	Mixed: Enhances brain norepinephrine and dopamine; higher doses enhances serotonin and opiate exerting calming and depressing effect, increases pain tolerance; increases muscle blood flow, lipolysis; may improve cognitive function, learning memory and reaction time and fine motor abilities; delays central fatigue	Addictive; may lead to development of respiratory, cardio and skin diseases and tobacco-related cancers if smoked; increased heart rate and blood pressure, cardiac stroke volume and output, and coronary blood flow; increases skin temp
Tetrahydrocannabinol (marijuana, cannabis)	Diminish nerves/pre competition stress, and anxiety; relax/decrease inhibition; improve sleep	No positive effect	Increases HR and BP at rest; physical work capacity decreases by 25%; decrease in standing steadiness, reaction time, psychomotor performance
Anabolic androgenic steroids	Gain muscle mass and strength	Increase muscle mass and strength especially when combined with strength training and high protein diets	Multiple organ systems including infertility, gynecomastia, female virilization, hypertension, atherosclerosis, physeal closure, aggression, depression, suicidal ideation
Androstendione	Increases testosterone to gain muscle mass and strength	Increase muscle strength and size	Tendopathy, rhabdomyolysis; tendon rupture
DHEA	Increases testosterone to gain muscle mass and strength	No measureable effect	Increases estrogens in men; impurities in preparation
Human Growth Hormone	Increase muscle mass, strength, and definition	Decreases subcutaneous fat and increases lipolysis; increases muscle mass and strength; improves wound healing; stimulates testosterone production	Acromegaly, glucose intolerance, physeal closure, increased lipids, myopathy
Stimulants (ephedrine alkaloids, amphetamines, cocaine)	Increases weight loss; fatigue delay	Increases metabolism, no clear performance benefit although may benefit power, endurance, strength, or speed; reduces tiredness; increases alertness and aggression	Muscle and joint pain; misjudgment in time orientation; tremors; cerebral vascular accident, arrhythmia, myocardial infarction, seizure, psychosis, hypertension, death
Arimidex, (anastrozole); selective estrogen receptor modulators (SERMs) like tamoxifen	Cancer drug used to decrease estrogen levels associated with testosterone use	None; increase testosterone, luteinizing hormone secretion; increase muscle strength and size; prevent bone loss	Side effects associated with taking these agents; early fatigue; increased bone resorption and decreased BMD (hip, lumbar spine)
Ghrelin mimetics, (GHRP6 and GHRP2)	Increase GH secretion	Increase muscle mass; stimulates glycogenesis; anabolic effects on muscle mass	GH-associated side effects (see above)
Glucocorticoids	Alleviate pain; reduce tiredness	No improvement	Growth suppression, osteoporosis, avascular necrosis of femoral head; tendon or facial rupture (by local injections) osteoarthritis

Refs: Pesta, D et al 2013; Nikolopoulos, D et al 2011, Rogol A 2010; Hoffman J et al 2009.

Caffeine

Research on the physiologic benefits of caffeine on performance is extensive in areas of strength, endurance, rates of perceived effort, hydration, and recovery. The ergogenic benefits include:

- (1) affecting the central nervous system (CNS) and cognitive performance
- (2) mobilizing fat and sparing glycogen during exercise
- (3) increasing intestinal absorption and oxidation of carbohydrates

- (4) speeding up resynthesis of muscle glycogen in recovery
- (5) reducing perceived exertion and pain of training.

Caffeine is classified as an “A” level effective and safe supplement by the Australian Institute of Sports Nutrition (AIS) because a large number of studies now show that caffeine intake can enhance performance at a dose of 1 to 3 mg/kg. The plateau in dose to performance appears to occur at 3 mg/kg (AIS, 2014).

According to the AIS, there is sound evidence that caffeine may enhance the performance of endurance sports (more than

60 min), brief, sustained high-intensity sports (1 to 60 min), and the work rates and skills and concentration of teams in intermittent sports. The effect of caffeine is still unclear in skill sports involving low-intensity exercise and in single efforts involving strength or power, in which the effects appear to be small and limited to certain muscle groups.

Caffeine contributes to endurance performance, apparently because of its ability to enhance mobilization of fatty acids and thus conserve glycogen stores. Caffeine also may directly affect muscle contractility, possibly by facilitating calcium transport. It could reduce fatigue as well by reducing plasma potassium accumulation, which contributes to fatigue. An energy-enhancing effect is seen with up to 3 mg/kg body mass or about 200 mg caffeine for the 150-lb athlete (Spriet, 2014). Unwanted side effects of overconsuming caffeine that may limit performance are headaches, insomnia, GI irritation, reflux, shakiness, heart palpitations, and increased urination.

Consumer demand for caffeine has resulted in greater accessibility and acceptance of a variety of beverages beyond coffee and tea. An emerging trend in sports nutrition is the intake of caffeine-containing energy drinks and shots for performance.

The growing availability and consumption of energy drinks with caffeine among all age groups is of concern, especially among young athletes because excessive amounts of caffeine have been shown to disrupt adolescent sleep patterns, exacerbate psychiatric disease, cause physiologic dependence, increase the risk of subsequent addiction and risk-taking behaviors, raise blood pressure, and cause dehydration, vomiting, irregular and rapid heartbeat, convulsions, coma, and death. Altered sleep patterns from excessive caffeine use can lead to poor performance, delayed reaction times, and increased risk for injuries.

Energy drinks consumed with alcohol are another growing concern among health experts, and in 2010 the US Food and Drug Administration (FDA) declared caffeine an “unsafe food additive” to alcoholic beverages, effectively banning premixed alcoholic energy drinks.

HERBS

Athletes' use of herbal supplements is higher than that of the general public and may change throughout the year as athletes move through training cycles. Reasons for athletes' use of herbs range from performance enhancement to immune function improvement to prevention of illness or healing of injuries. Many studies examining the pharmacologic effects of herbs on performance have been poorly designed, conducted only in animals, or lack consistency in the herbal preparation.

Nitrates and Beet Juice

Several studies suggest that inorganic nitrates may alter the physiologic responses to exercise and enhance performance by increasing vasodilation and glucose uptake and reducing blood pressure and the O₂ cost of submaximal exercise (Cermak et al, 2012). Because the consumption of nitrate salts may result in the production of harmful nitrogenous compounds, researchers have explored using natural nitrate-rich foods such as beetroot juice and powders. A dose of dietary nitrate, approximately 0.5L of beetroot juice, has been shown to increase plasma nitrite, which peaks within 3 hours and remains elevated for 6 to 9 hours before returning to baseline (Wylie et al, 2013).

In one study, supplementing the diet with 0.5 L of beetroot juice per day for 4 to 6 days reduced the steady state cost of

submaximal exercise by 5% and extended the time to exhaustion during high-intensity cycling by 16%, which has been confirmed in other exercise populations including rowers and team sports. Although the mechanistic bases for the effects are unclear, evidence suggests mitochondrial efficiency and contractile function may be enhanced (Wylie et al, 2013).

It has been recommended to consume nitrate immediately before, during, and after long duration endurance exercise because of peak and maintenance level times. A daily dose of supplement has been shown to keep plasma nitrite elevated (Jones, 2013). Although there is a possibility that uncontrolled high doses of nitrate salts may be harmful to health, natural sources found in beetroot, spinach, lettuce, and celery are likely to promote health.

Ergogenic Aids for Muscle Building, Recovery, Antiinflammation

Amino Acids

The use of amino acids and protein by athletes is as old as the Olympic Games of ancient Greece. Athletes generally meet daily protein dietary recommendations, therefore on a dietary basis, protein or amino acid supplementation in the form of powders or pills is not necessary and should be discouraged, especially for teens and young children.

Taking large amounts of protein or amino acid supplements may be contrary to good performance and health and may lead to dehydration, hypercalciuria, weight gain, and stress on the kidney and liver. Taking single amino acids or in combination, such as arginine and lysine, may interfere with the absorption of certain other essential amino acids. An additional concern is that substituting amino acid supplements for food may cause deficiencies of other nutrients found in protein-rich foods such as iron, zinc, niacin, and thiamin.

A recent review suggests no relationship between consuming protein supplements and muscle recovery, soreness, or damage when protein supplements are consumed before, during, or after an endurance or resistance exercise training session. However some potential ergogenic effects of protein supplementation were shown in athletes who were in negative energy balance (Pasiakos et al, 2014).

Glutamine

Considered by some to be a conditionally essential amino acid, glutamine has many functions in the human body, including protein synthesis and energy source for cells in the immune system. Glutamine supplementation increases glycogen synthesis and muscle protein levels and may improve glucose utilization post-workout and increase growth hormone levels (Phillips, 2014).

Branched-Chain Amino Acids (BCAAs)

The BCAAs include leucine, isoleucine, and valine, and they make up 35% to 40% of the essential amino acids (EAAs) in the body's protein and 14% of the total AAs in muscle. To get energy, the body can break down muscle to use the BCAAs. During times of stress, BCAAs are required more than any other EAA.

BCAAs consumed before and after training have been shown to increase protein synthesis and muscle gains beyond normal adaptation. They have been reported to decrease exercise-induced protein breakdown and muscle enzyme release, a sign of muscle damage.

A combination of 3.2 g BCAA and 2.0 g taurine, three times a day, for 2 weeks before and 3 days after exercise was a useful

TABLE 23-7 Foods High in Branched-Chain Amino Acids

Branched-Chain Amino Acid	Food Sources
Leucine	Meat, dairy, nuts, beans, brown rice, soy, and whole wheat
Isoleucine	Meat, chicken, eggs, fish, almonds, chickpeas, soy protein, and most seeds
Valine	Meat, dairy, soy protein, grains, peanuts, and mushrooms

strategy reducing delayed muscle soreness (DOMS) and muscle damage (Ra et al, 2013).

Dairy products and red meat contain the greatest amounts of BCAAs with whey protein from dairy being a very concentrated source. Egg protein is also a good source (see Table 23-7).

Leucine is the most readily oxidized BCAA and is most effective at causing insulin secretion from the pancreas. It lowers blood sugar levels and aids in growth hormone production. Leucine works in conjunction with isoleucine and valine to protect muscle and act as fuel for the body. Doses of 3 to 5 g postworkout have been suggested by some experts for accelerating muscle repair and recovery (Churchward-Venne et al, 2014; Stark et al, 2012).

Beta-Hydroxy-Beta-Methylbutyrate (HMB)

HMB is an important compound made in the body and a metabolite of the essential amino acid leucine. In human research, HMB has been found to reduce muscle damage associated with exercise and to shorten recovery time. Supplementation has been found to inhibit muscle proteolysis, enhance protein synthesis, and increase body mass in the young, elderly, untrained, trained, and clinically cachexic.

Regarding HMB supplementation and exercise recovery, several studies have found that subjects supplemented with HMB may have less stress-induced muscle protein breakdown. Recent research suggests that acute and chronic administration of HMB are associated with less exercise-induced muscle damage and soreness (Wilson et al, 2013).

Creatine

As an amino acid, creatine is produced normally in the body from arginine, glycine, and methionine. Most dietary creatine comes from meat, but half is manufactured in the liver and kidneys. For meat eaters, dietary intake of creatine is approximately 1 g daily. The body also synthesizes approximately 1 g of creatine per day, for a total production of approximately 2 g daily.

In normal, healthy persons approximately 40% of muscle creatine exists as free creatine; the remainder combines with phosphate to form CP. Approximately 2% of the body's creatine is broken down daily to creatinine before excretion by the kidneys. The normal daily excretion of creatinine is approximately 2 g for most persons. Those with lower levels of intramuscular creatine such as vegetarians may respond to creatine supplementation (McArdle et al, 2013).

Creatine monohydrate is one of the most popular supplements used by strength and power athletes. Supplementation elevates muscle creatine levels and facilitates the regeneration of CP, which helps to regenerate ATP. A variety of synthetic

creatine supplements have been developed including creatine malate, pyruvate, citrate, and many more with marketing claims of greater performance enhancement and absorption, although no advantage of one over the other has been reported.

Classical loading consists of an initial loading phase of 15 to 20 g per day for 4 to 7 days, followed by a maintenance dose of 2 to 5 g per day. However, alternative dosing methods also have been shown to effectively increase creatine stores and result in strength gains. Regimens without the loading include a dose of 0.3 g/kg body weight for 5 to 7 days, followed by maintenance dose of 0.03 g/kg body weight for 4 to 6 weeks. However, with this regimen creatine stores increase more slowly, and it may take longer to see the strength training effects (Buford et al, 2007; Hall and Trojjan, 2013).

As one of the most researched supplements, numerous studies support the use and effectiveness of creatine for short-term, maximum output exercise such as weight lifting, running a 100-m sprint, swinging a bat, or punting a football. When creatine stores in the muscles are depleted, ATP synthesis is prevented and energy can no longer be supplied at the rate required by the working muscle. Improved athletic performance has been attributed to this ATP resynthesis.

Creatine supplementation increases body mass or muscle mass during training. It may improve submaximal exercise performance for HIIT, which promotes fitness similar to endurance training. A recent 2013 study on swimmers showed creatine supplementation improved swimming performance and reduced blood lactate levels after intermittent sprint swimming bouts (Dabidi Roshan et al, 2013).

Studies are conflicting on creatinine's effect on aerobic performance. In a double-blind, placebo-controlled study 16 male amateur soccer players, consuming 20 g of creatine per day, or a placebo for 7 days, experienced no beneficial effect on physical measures obtained during a 90-minute soccer test (Williams et al, 2013). More research in this area has been suggested because indirectly creatine supplementation may affect substrate utilization changes and enhanced muscle glycogen storage, which potentially can improve longer distance and timed sports (Cooper et al, 2012).

Creatine absorption appears to be stimulated by insulin. Therefore ingesting creatine supplements in combination with carbohydrate, amino acids, or protein can increase muscle creatine concentrations. Once creatine is taken up by the muscles, it is trapped within the muscle tissue. It is estimated that muscle creatine stores decline slowly and will still be elevated 2 to 3 months after ingestion of 20 g of creatine for 5 days.

Few data exist on the long-term benefits and risks of creatine supplementation. Because of the long-term risks, the American Orthopedic Society for Sports Medicine, the ACSM, and the AAP advises children and adolescents younger than 18 years and pregnant or nursing women to never take creatine supplements. People with kidney problems also should never take creatine supplements.

Betaine

A derivative of the amino acid glycine, one of the main functions of betaine is to maintain water retention of body cells. Some studies have suggested that betaine supplementation may reduce inflammation and also may contribute the compounds necessary to synthesize creatine in muscles; improve

metabolically demanding strength-based and endurance performance; and promote adiposity reductions and lean mass gains, although the mechanisms are not completely understood and more research is recommended (Cholewa et al, 2014).

Betaine is a component of many foods, including wheat, spinach, beets, and shellfish. Betaine is also synthesized in the body. The daily intake of betaine is estimated to be 1 g to 2.5 g a day for individuals who consume the foods mentioned. Although one 2014 research review suggests that 2.5 g a day may result in performance benefits, because betaine research study doses have ranged from 2 to 5 g a day, more research is suggested to determine whether there is a dose-related response (Cholewa et al, 2014).

Quercetin

Quercetin, a natural flavonoid in many foods, including apples, cranberries, blueberries, and onions, has many beneficial biologic benefits such as antiinflammatory, anticarcinogenic, cardioprotective, and neuroprotective properties (Mason and Lavallee, 2012). Quercetin may enhance performance through a caffeine-like psychostimulant effect, or it may enhance mitochondrial biogenesis. In a recent study of 60 male students with an athletic history of at least 3 years, lean body mass, total body water, basal metabolic rate, and total energy expenditure increased significantly in the group given quercetin compared with the group without quercetin supplementation (Askari et al, 2013). Another 2009 study showed 2 weeks of quercetin supplementation in cyclists was effective in countering inflammation after 3 days of heavy exertion (Nieman et al, 2009). More studies are needed to confirm positive effects on postexercise inflammation markers, work performed in heat, and race performance.

PERFORMANCE ENHANCEMENT SUBSTANCES AND DRUGS (PES/PED): DOPING IN SPORT

The use of performance enhancement substances (PES) is not a new phenomenon in sports. As early as 776 BC the Greek Olympians were reported to use substances such as dried figs, mushrooms, and strychnine to perform better. Its use is prevalent in amateur and professional athletes, receiving even greater attention with the use by high-profile accomplished athletes such as Lance Armstrong, Alex Rodriguez, and Ryan Braun, and disqualification of some professional athletes for failed drug tests, and the seizure of companies caught with tainted supplements (Pope et al, 2013).

Since 2004, the World Anti-Doping Agency (WADA) has a list of banned drugs for athletes who compete and a strategy to detect drugs such as anabolic steroids, erythropoietin, human growth hormone (HGH), and insulin-like growth factor (IGF-1). WADA annually updates their prohibited list of supplements suspected of 1) illegally enhancing athletic performance, 2) representing an actual or potential health risk to the athlete, or 3) violating the spirit of the sport.

As the number of individuals participating in different sports increases so does the variety of doping agents. According to WADA, the rate of use has been fairly consistent, suggesting a prevalence of approximately 2% of elite athletes. Rates derived from self-reports have ranged from 1.2% to 26%. Between 10% and 24% of male athletes have reported they would use doping if it would help them achieve better results without the risk of consequences, with an additional 5% to 10%, indicating potential

doping behavior regardless of health hazards. One report noted that 25% of male and female dancers surveyed would use doping if it were to ensure successful dance performance (Zenit et al, 2010).

Reasons given for using banned substances include achievement of athletic success by improving performance, financial gain, improving recovery and prevention of nutritional deficiencies, and the idea that others use them or the “false consensus effect.”

Steroids

Androgenic-anabolic steroids (AASs) categorize all male sex steroid hormones, their synthetic derivatives, and their active metabolites used to enhance athletic performance and appearance. AAS use was reported in the 1950 Olympics and was banned in 1976. Steroids may be used as oral or intramuscular preparations.

The legal and illegal use of these drugs is increasing as a result of society’s preoccupation with increasing muscle strength, size, and libido. Originally designed for therapeutic uses to provide enhanced anabolic potency, nontherapeutic use of AAS is increasing among adolescents and females. Anecdotal evidence suggests widespread use of anabolic steroids among athletes (20% to 90%), especially at the professional and elite amateur levels. Use among high school boys is approximately 5% to 10%; rates among college athletes are slightly higher.

Anabolic effects of AAS include increased muscle mass; increased bone mineral density; increased blood cell production; decreased body fat; increased heart, liver, and kidney size; vocal cord changes; and increased libido. Anabolic steroids increase protein synthesis in skeletal muscles and reverse catabolic processes, however, increased muscle mass and strength are observed only in athletes who maintain a high-protein, high-calorie diet during steroid administration. **Androgenic effects** are the development of secondary sexual characteristics in men, changes in genital size and function, and growth of auxiliary pubic and facial hair. Some adverse effects associated with steroid use are irreversible, especially in women.

Although steroid use has some valid medical uses (e.g., the treatment of delayed puberty, or body wasting resulting from disease), it also has adverse physical and emotional consequences in adolescents, such as arrested bone growth, internal organ damage, feminization in males, and masculinization in females. It also is associated with other high-risk behaviors, such as the use of other illicit drugs, reduced involvement in school, poor academic performance, engaging in unprotected sex, aggressive and criminal behavior, and suicidal ideation and attempted suicide.

Erythropoietin

EPO is used commonly to promote the body’s production of red blood cells in patients with bone marrow suppression such as patients with leukemia, those who are receiving chemotherapy, or those with renal failure (see Chapters 35 and 36). In athletes, injections increase the serum hematocrit and oxygen-carrying capacity of the blood, and thus enhance VO_{2max} and endurance. EPO use as an ergogenic aid is difficult to detect because it is a hormone produced by the kidneys, although newer blood tests can detect its use. Typically, athletes with elevated hematocrit have been banned from endurance sports for suspected EPO misuse; however, despite its ban by the IOC, it is still commonly abused. Drastically high hematocrit combined

with exercise-induced dehydration can lead to thick or viscous blood, which can lead to coronary or cerebral vascular occlusions, heart attack, or stroke. EPO also can cause elevated blood pressure or elevated potassium levels.

Human growth hormone (HGH) has many functions in the body, and it is produced naturally throughout life. It stimulates protein synthesis, enhances carbohydrate and fat metabolism, helps to maintain sodium balance, and stimulates bone and connective tissue turnover. HGH production decreases with age after the peak growth years. The amount secreted is affected by diet, stress, exercise, nutrition, and medications. HGH is banned by the IOC; however, it continues to be used by athletes. Potential side effects include skin changes, darkening of moles, adverse effects on glucose and lipid metabolism and the growth of bones as evidenced by development of a protruding jaw and boxy forehead.

Prohormones and Steroids

Prohormones are popular among bodybuilders, many of whom believe that these prohormones are natural boosters of anabolic hormones. Androstenedione, 4-androstenediol, 19-nor-4-androstenedione, 19-nor-4-androstenediol, 7-keto dehydroepiandrosterone (DHEA), and 7-keto DHEA are naturally derived precursors to testosterone and other anabolic steroids.

Androstenedione

Androstenedione (andro) is a prehormone, an inactive precursor to female estrogen and male testosterone. It has about one seventh of the activity of testosterone and is a precursor that directly converts to testosterone by a single reaction. It is produced naturally in the body from either DHEA or 17-alpha-hydroxyprogesterone. Some researchers have found that taking andro elevates testosterone more than DHEA does; however, the induced increase lasts only several hours and remains at peak levels for just a few minutes. Acute or long-term administration of testosterone precursors does not effectively increase serum testosterone levels and fails to produce any significant changes in lean body mass, muscle strength, or performance improvement.

Adverse reactions occur in male and female athletes, including muscle tightness and cramps, increased body weight, acne, GI problems, changes in libido, amenorrhea, liver damage, and stunted growth in adolescents. Consumption of a prohormone supplement can alter a patient's hypothalamic-pituitary-gonadal axis. Andro-related hormones may elevate abnormally estrogen-related

hormones and alter elevations of serum estrogen, which is thought to increase the risk for developing prostate or pancreatic cancers. A significant decline in HDLs occur, leading to an increased cardiovascular disease risk. Therefore taking androstenedione may be irresponsible because of the potential risks associated with long-term use. Until there is scientific support for its use, andro should not be sold under the assumption that it is either an effective or a safe athletic ergogenic aid. Clearly adolescents and women of childbearing age should not use it. In 1998 andro was added to the list of banned substances by the IOC and several amateur and professional organizations, including the NFL and the NCAA.

Dehydroepiandrosterone (DHEA) is a weak androgen and product of dehydroandrosterone-3-sulfate (DHEA-S) and is used to elevate testosterone levels. It is a precursor to more potent testosterone and dihydrotestosterone. Although DHEA-S is the most abundant circulating adrenal hormone in humans, its physiologic role is poorly understood. DHEA has been labeled the “fountain of youth” hormone because its levels peak during early adulthood. The decline with aging has been associated with increased fat accumulation and risk of heart disease. Several studies have suggested a positive correlation between increased plasma levels of DHEA and improved vigor, health, and well-being in persons who range in age from 40 to 80 years. By decreasing cortisol output from the liver by 50%, DHEA could have an anabolic effect.

DHEA supplementation does not increase testosterone levels or increase strength in men, but it may increase testosterone levels in women with a virilizing effect. Because DHEA can take several different hormonal pathways, the one that it follows depends on several factors, including existing levels of other hormones. It can take several routes in the body and interact with certain enzymes along the sex-steroid pathway. Thus it can turn into less desirable byproducts of testosterone, including dihydrotestosterone, which is associated with male-pattern baldness, prostate enlargement, and acne.

The benefits of taking DHEA for sports performance have not been clearly established, and the effects of chronic DHEA ingestion are not known. Long-term safety has not been established, and there are concerns that chronic use in men may worsen prostate hyperplasia or even promote prostate cancer. DHEA is not recommended for athletic use because it can alter the testosterone-epitesterone ratio so that it exceeds the 6:1 limit set by the IOC, the U.S. Olympic Committee, the NFL, and the NCAA.

CLINICAL CASE STUDY

Guillermo is a 32-year-old former college athlete who has been competing in long-distance triathlon and marathon events for the past year. He complains of low energy as training and racing duration increases and is plagued by gut issues—gas and bloating after meals, nausea, and vomiting during races. He also suffers from sleep issues, waking up frequently during the night. He works full time at a stressful job as manager of an electrical contracting firm and trains in swimming, cycling, and running 10 to 12 hours/week.

Assessment

His height is 5ft 9 in and his weight is 174 lb. His body composition analysis as measured by the RD using the ISAK method was 6.8% (10.4 lb body fat, 164 lb [74kg] FFM). He is satisfied with his body fat percentage but would like to reduce his weight if possible to lighten up for the running portion of his events.

Urine specific gravity was assessed to determine hydration status on three visits: 1.035, 1.025, and 1.030

Cholesterol levels were 250, HDL 50, LDL 170, triglycerides 160; all other values were within normal limits.

Using the Cunningham method to calculate REE:

$$500 + (22 \times \text{FFM [Kg]}) \quad 500 + (22 \times 74) = \mathbf{2128 \text{ REE}}$$

Day off training: Activity factor 1.2, = approx. 2553 calories

1-2 hours steady state training: Activity factor 1.4 = approx. 2979 calories

3-4 hours steady state training: Using Activity factor 1.6 = approx. 3404 calories

4-6 hours training steady state: Using 1.73 Activity factor = approximately 4581 calories

Continued

CLINICAL CASE STUDY—cont'd

Current Diet

Breakfast 1 hour before workout
 12 oz coffee with 1 oz coffee creamer
 3 eggs fried with onions, 2 slices bacon, 2 slices ham
 1 spiced apple bran muffin
 Analysis: 570 calories, 30 grams fat (49%), 40 grams carbs (28%) 570 mg cholesterol
 Workout: 2000-yard swim, 2-hour bicycle ride, 4-mile run
 During swim portion of workout (less than 1 hour): nothing
 During cycle portion of workout: 2 hours
 2 electrolyte pills every 20 minutes on bike—total 12 pills
 Each pill contains: 40 mg Na—480 mg sodium
 3 16 oz bottles fluid:

- 1 × 170 cal, 32 g cho, 10 g pro
- 1 bottle high carbohydrate, hypertonic sports drink with maltodextrin—270 cal, 54 g carb, 7 g sugar and protein, 220 mg Na, 25 mg caffeine
- Water

1 gel pack every 30 minutes= 6 packs
 Double latte with caffeine 110 cal, 27g carbs, 200 mg Na
During run portion of workout (less than 1 hour): nothing
 Total workout fuel: 1100 calories, 248 g carbohydrates (124 g/hr cycling, 900 mg Na)

Immediately after workout: nothing
 Breakfast
 Coffee with half-and-half
 1 plain bagel, cream cheese, jelly
 Banana
 12 ounces milk
 Snack: none
 Lunch
 2-6 oz chicken breasts grilled with skin, 2 cups white rice, 1 cup black beans, ½ cup fried plantains
 Snack: high-protein sports bar
 Dinner
 1 onion soup with melted cheese
 12 oz grilled steak
 1 c yellow rice
 Sautéed mushrooms

Dietary Analysis

3041 calories, 216 g protein (2.77 g/Kg) (28%), 249 g carbohydrates (3.15 g/kg)(33%), 13.5% saturated fat, 1172 mg cholesterol, 5634 mg Na
 RDA: 64% potassium, 85% Ca and folate, 26% C, 30% E, 13% K, dietary fluid intake= 9 cups

Assessment**Gut/Energy Antagonists**

Whole food portion of diet appears to be:
 Low in calories: 3041 calories (4141 with sport fuel) vs. 4581 calories required
 Carbohydrates: 249 g carbohydrates (3.15 g/kg) (33%) (497 g sport fuel), vs. a minimum of 5 to 7 g/kg = 395-553 g

High in fat (38% total cal), saturated fat and cholesterol 1172 mg and sodium 5634 mg
 Low in antioxidants
 Excessive in fat pre-workout breakfast
 Excessive in sport fuel carbohydrates and sodium for 2-hour bike portion of ride
 Excessive in mealtime calories and protein
 Questionable whether athlete can tolerate FODMAPs foods, i.e., onions, beans, mushrooms, cream cheese, dairy (lactose), sport fuel sources of HFCS, and gluten

Intervention

Increase meal frequency and calories while modifying fat, sat fat, and cholesterol
 Increase plant-based tolerable sources of protein and complex carbohydrates
 Modify amounts of animal protein at mealtime to 4 to 5 oz (30 to 35 g)
 Improve leafy green vegetable intake via juicing if whole food veggies not desired or tolerated
 Improve intake of antioxidant rich fruits and fruit juices without added sugar

Recommendations

Probiotic, EAA to heal and strengthen gut; enzymes before meals
 Adjust sport fuel intake, decrease electrolyte pills, reduce and modify carbohydrate-containing liquids and source, switch to waxy maize if maltodextrin or HFCS contributing to issue
 Meditation or yoga on day off from training and/or prayer or meditation 5 to 10 minutes a day for relaxation
 Melatonin and/or theanine for sleep issues, restlessness

Further Biochemical Evaluation and Testing

Hydrogen/methane breath testing, gut dysbiosis
 Spectracell to determine extent of vitamin or mineral deficiency, assimilation, and absorption
 Upper/lower GI series if elimination diet, FODMAPs diet, and adjustments in eating/sport fuel do not resolve problems during training and racing
 Follow-up lipid profile after 9 to 12 weeks on modified fat, saturated fat, and cholesterol diet

Nutrition Care Questions

1. Calculate calorie and macronutrient needs using Cunningham Formula and guidelines provided in chapter
2. Assess what eating/lifestyle behaviors may be affecting this athlete's energy levels, i.e., sleep, stress, portion sizes at meal time
3. Calculate training/race day/recovery fuel formulas for preworkout, workout calories, carbohydrates, and sodium
4. List issues that appear to be a valid reason to initiate FODMAPs and elimination diet.
5. Provide a list and justification for supplementation based on the dietary information and performance enhancement information from this chapter.

Nutrition and Bone Health

Karen Chapman-Novakofski, PhD, RDN, LDN

KEY TERMS

25-hydroxyvitamin D₃ (calcifediol)
1,25-dihydroxy vitamin D₃ (calcitriol)
age-related primary osteoporosis
bisphosphonates
bone densitometry
bone mineral content (BMC)
bone mineral density (BMD)
bone modeling
bone remodeling
calcium homeostasis
calcitonin
cancellous bone

cholecalciferol (vitamin D₃)
cortical bone
estrogen-androgen deficient osteoporosis
estrogen receptor (ER)
estrogen replacement therapy (ERT)
hydroxyapatite
intermittent parathyroid hormone
(PTH) therapy
osteoid
osteoblast
osteocalcin
osteoclast

osteocyte
osteomalacia
osteopenia
osteoporosis
parathyroid hormone (PTH)
peak bone mass (PBM)
secondary osteoporosis
selective estrogen receptor modulator
(SERM)
trabecular bone

Adequate nutrition is essential for the development and maintenance of the skeleton. Although diseases of the bone such as osteoporosis and **osteomalacia** (a condition of impaired mineralization caused by vitamin D and calcium deficiency) have complex causes, the development of these diseases can be minimized by providing adequate nutrients throughout the life cycle. Of these diseases, osteoporosis is the most common and destructive on productivity and quality of life. As is true of many chronic diseases, signs and symptoms of osteoporosis become more evident in older age.

The number of people older than 65 years continues to increase: almost 25% of the population by 2020. As a result of the increasing numbers of older adults, osteoporosis with resulting hip fractures has become more significant in cost, morbidity, and mortality in the United States. Prevention and treatment are equally important to the quality of life.

BONE STRUCTURE AND BONE PHYSIOLOGY

Bone is a term used to mean an organ, such as the femur, and a tissue, such as trabecular bone tissue. Each bone contains bone tissues of two major types, trabecular and cortical. These tissues undergo bone modeling during growth (height gain) and bone remodeling after growth ceases.

Bone mass is a generic term that refers to **bone mineral content (BMC)**. **Bone mineral density (BMD)** describes the mineral content of bone per unit of bone (or BMC/bone area). Neither BMC nor BMD provides information on the microarchitectural (three-dimensional) structural quality of bone tissue (i.e., index of risk of fracture).

Composition of Bone

Bone consists of an organic matrix, or **osteoid**, primarily collagen fibers, in which salts of calcium and phosphate

are deposited in combination with hydroxyl ions in crystals of **hydroxyapatite**. The cable-like tensile strength of collagen and the hardness of hydroxyapatite combine to give bone its great strength. Other components of the bone matrix include **osteocalcin**, osteopontin, and several other matrix proteins.

Types of Bone Tissue

Approximately 80% of the skeleton consists of compact or cortical bone tissue. Shafts of the long bones contain primarily **cortical bone**, which consists of osteons or Haversian systems that undergo continuous but slow remodeling. Both contain an outer periosteal layer of compact circumferential lamellae and an inner endosteal layer of trabecular tissue. The remaining 20% of the skeleton is **trabecular** or **cancellous bone** tissue, which exists in the knobby ends of the long bones, the iliac crest of the pelvis, the wrists, scapulas, vertebrae, and the regions of bones that line the marrow. Trabecular bone is less dense than cortical bone as a result of an open structure of interconnecting bony spicules that resemble a sponge in appearance.

The elaborate interconnecting components (columns and struts) of trabecular bone add support to the cortical bone shell of the long bones and provide a large surface area that is exposed to circulating fluids from the marrow, and is lined by a disproportionately larger number of cells than cortical bone tissue. Therefore trabecular bone tissue is much more responsive to estrogens or the lack of estrogens than cortical bone tissue (see **Figure 24-1**). The loss of trabecular bone tissue late in life is largely responsible for the occurrence of fractures, especially those of the spine.

Bone Cells

Osteoblasts are responsible for the formation or production of bone tissue, and **osteoclasts** govern the resorption or breakdown of bone (also see **Bone Modeling** and **Bone Remodeling**

FIGURE 24-1 Schematic diagram of the structure of a long bone (hemisection of a long bone, such as the tibia). The ends of the long bones contain high percentages of trabecular (cancellous) bone tissue, whereas the shaft contains predominately cortical bone tissue. Inset A includes an enlarged section (approximately 100-fold) of the growth plate (epiphysis) and the subjacent hyperproliferative zone containing cartilage cells stacked like coins. Inset B includes a section of collagen molecules (triple helices) surrounded by mineralized deposits (dark spheroids) at a magnification of approximately 1,000,000-fold. These collagen-mineral complexes exist in trabecular and cortical bone tissues. Inset C shows the cross-section of half of the midshaft of a long bone (magnification 10-fold). This section of cortical bone tissue contains vertical Haversian systems (osteons) that run parallel with the shaft axis; many are required to extend this system from one end of the shaft to the other. At the center of each osteon is a canal that contains an artery that supplies bone tissues with nutrients and oxygen, a vein for removing wastes, and a nerve for returning afferent relays to the brain. (Copyright John J. B. Anderson and Sanford C. Garner.)

TABLE 24-1 Functions of Osteoblasts and Osteoclasts

Osteoblasts	Osteoclasts
Bone Formation	Bone Resorption
Synthesis of matrix proteins: Collagen type 1 (90%) Osteocalcin and others (10%)	Degradation of bone tissue via enzymes and acid (H ⁺) secretion
Mineralization	
Communication: Secretion of cytokines that act on osteoblasts	Communication: Secretion of enzymes that act on osteoclasts

later in this chapter). The functions of these two cell types are listed in Table 24-1.

Two other important cell types also exist in bone tissue, **osteocytes** and bone-lining cells (inactive osteoblasts), both of which are derived from osteoblasts. The origin of the osteoblasts is mesenchymal stem cells, whereas osteoclasts arise from hematopoietic stem cells (progenitors of macrophages) from the bone marrow, now known to be stimulated by hormones and growth factors as part of their differentiation to become mature, functional bone cells.

Cartilage

In the embryo, cartilage forms the first temporary skeleton, until it develops into a mature bone matrix. In the adult, cartilage is found as flexible supports in areas such as the nose and ear. Cartilage is not bone and is neither vascularized nor calcified.

Calcium Homeostasis

Bone tissue serves as a reservoir of calcium and other minerals. **Calcium homeostasis** refers to the process of maintaining a constant serum calcium concentration. The serum calcium is regulated by complex mechanisms that balance calcium intake and excretion with bodily needs. When calcium intake is not adequate, homeostasis is maintained by drawing on mineral from the bone to keep the serum calcium ion concentration at its set level (approximately 8.5-10 mg/dl). Homeostasis can be accomplished by drawing from two major skeletal sources: readily mobilizable calcium ions in the bone fluid, or through osteoclastic resorption from the bone tissue. The daily turnover of skeletal calcium ions (transfers in and out of bone) supports the dynamic activity of bone tissue in calcium homeostasis.

Serum calcium concentration is regulated by two calcium-regulating hormones: **parathyroid hormone (PTH)** and **1,25 dihydroxy vitamin D₃ (calcitriol)**. If serum calcium levels fall, PTH increases reabsorption from the kidney and bone, and calcitriol increases gut absorption and initiates osteoclastic activity for bone breakdown. Increased serum calcium or hypercalcemia, occurs primarily as a result of hyperparathyroidism. Serum calcium includes free calcium (formerly called ionized calcium) and albumin-bound calcium.

Bone Modeling

Bone modeling is the term applied to the growth of the skeleton until mature height is achieved. In long bones, growth occurs at terminal epiphyses (growth plates that undergo hyperproliferation) and circumferentially in lamellae; at each location cells undergo division and contribute to the formation of new bone tissue (see Figure 24-1). Bone modeling typically is completed in females by ages 16 to 18 and in males by ages 18 to 20.

During this growth period, formation exceeds the resorption of bone. **Peak bone mass (PBM)** is reached by 30 years of age or so (see Figure 24-2). The long bones stop growing in length by approximately age 18 in females and age 20 in males, but bone mass continues to accumulate for a few more years by a process known as consolidation (i.e., filling-in of osteons in the shafts of long bones). The age when BMD acquisition ceases varies, depending not only on diet but also on physical activity.

PBM is greater in men than in women because of men's larger frame size. BMC, but not necessarily BMD, is typically lower in women. The lean and fat components of body composition contribute to these differences in bone mass. BMD is also greater in blacks and Hispanics than in whites and Asians, related to larger muscle mass, differences in body weight, lifestyle

FIGURE 24-2 The early gain and later loss of bone in females. Peak bone mineral density (BMD) typically is achieved by age 30. Menopause occurs at approximately age 50 or within a few years. Postmenopausal women typically enter the fracture risk range after age 60. Men have a more gradual decline in BMD, which starts at 50 years. (Copyright John J. B. Anderson and Sanford C. Garner.)

factors, and dietary intake (Pothiswala et al, 2006; Reid, 2008). Heredity is a major factor contributing to BMD and may contribute as much as 50% to 80% of BMD.

PBM is related to appropriate nutrient intake, physical activity, and genetics. Because bone formation begins in the embryo, more attention is being focused on maternal nutrition and health as a predictor of the child's future PBM (Prentice et al, 2011). PBM is diminished in cases of anorexia nervosa (Misra and Klibanski, 2006), as well as in chronic and malabsorptive diseases.

Bone Remodeling

Bone is a dynamic organ both during growth and maintenance. **Bone remodeling** is a process in which bone is resorbed continuously through the action of the osteoclasts and reformed through the action of the osteoblasts. The remodeling process is initiated by the *activation* of preosteoclastic cells in the bone

marrow. Interleukin (IL)-1 and other cytokines released from bone-lining cells act as the triggers in the activation of precursor stem cells in bone marrow. The preosteoclast cells from the bone marrow migrate to the surfaces of bone while differentiating into mature osteoclasts. The osteoclasts then cover a specific area of trabecular or cortical bone tissue. Acids and proteolytic enzymes released by the osteoclasts form small cavities on bone surfaces and *resorb* bone mineral and matrix on the surface of trabecular bone or cortical bone. The resorptive process is rapid, and it is completed within a few days, whereas the refilling of these cavities by osteoblasts is slow (i.e., 3 to 6 months or even as long as a year or more in older adults).

The *rebuilding* or *formation* stage involves secretion of collagen and other matrix proteins by the osteoblasts, also derived from precursor stem cells in bone marrow. Collagen polymerizes to form mature triple-stranded fibers, and other matrix proteins are secreted. Within a few days salts of calcium and phosphate begin to precipitate on the collagen fibers, developing into crystals of hydroxyapatite. Approximately 4% of the total bone surface is involved in remodeling at any given time as new bone is renewed continually throughout the skeleton. Even in the mature skeleton, bone remains a dynamic tissue. Normal bone turnover is illustrated in Figure 24-3.

When the resorption and formation phases are in balance, the same amount of bone tissue exists at the completion of the formation phase as at the beginning of the resorption phase. The benefit to the skeleton of this remodeling is the renewal of bone without any microfractures. With aging, osteoclastic resorption becomes relatively greater than formation by osteoblasts (see Figure 24-4). This imbalance between formation and resorption is referred to as “uncoupling” of the osteoblastic and osteoclastic activity.

Because of this uncoupling of cell activity, age is an important determinant of BMD. At approximately age 40, BMD begins to diminish gradually in both sexes, but bone loss increases greatly in women after menopause because of the loss of estrogen's effects on bone. Men continue to have bone loss, but at a much lower rate than women of the same age until age 70, when the loss rates are about the same for both genders. Loss of

FIGURE 24-3 Normal bone turnover in healthy adults. (Copyright John J. B. Anderson and Sanford C. Garner.)

FIGURE 24-4 Effects of persistently elevated serum concentration of parathyroid hormone (PTH) on bone mass; this incorporates the effect of estradiol, counteracting the effect of PTH. (Copyright John J. B. Anderson and Sanford C. Garner.)

bone mass is the result of changes in the hormone-directed mechanisms that govern bone remodeling.

Cortical bone tissue and trabecular bone tissue undergo different patterns of aging. Loss of cortical bone eventually plateaus and may even cease late in life. Trabecular bone loss begins in both sexes as early as 40 years of age. Premenopausal loss of trabecular bone in women is much greater than that of cortical bone. Loss of both kinds of bone accelerates in women after menopause, although trabecular bone is lost at a much higher rate than cortical bone.

OSTEOPENIA AND OSTEOPOROSIS

This loss of bone can continue throughout aging, eventually leading to osteopenia or osteoporosis. However, not all older persons have poor bone health, and bone disease can occur in younger people, although rarely. Differences between normal and osteoporotic bone—both trabecular and cortical tissues—are shown in [Figure 24-5](#).

Prevalence

It is estimated from the National Health and Nutrition Examination Survey of 2006 to 2008 that 9% of adults over age 50 have osteoporosis. Another 49% have low bone mass, or osteopenia, at the femur neck or spine, leaving about 49% with healthy bone. These results differ by age, gender, race and ethnicity, with the oldest having higher prevalence. Women more often have poor bone health than men, and for both genders, Hispanics are at higher risk than non-Hispanic whites, whereas African Americans are at lower risk ([Looker et al, 2012](#)).

Types of Osteoporosis

Osteoporosis is considered to have a broad spectrum of variant forms. There are two types of primary osteoporosis, distinguished in general by sex, the age at which fractures occur, and the kinds of bone involved. **Secondary osteoporosis** results when an identifiable drug or disease process causes loss of bone tissue (see [Box 24-1](#)).

FIGURE 24-5 Difference between normal bone (A) and osteoporotic bone (B). (From Maher AB et al: *Orthopaedic nursing*, Philadelphia, 1994, Saunders.)

BOX 24-1 Medical Conditions that Increase the Risk of Osteoporosis

- Chronic diarrhea or intestinal malabsorption (including celiac disease)
- Chronic obstructive lung disease
- Chronic renal disease
- Diabetes
- Hemiplegia
- Hyperparathyroid disease
- Hyperthyroidism
- Subtotal gastrectomy

Estrogen-androgen deficient osteoporosis occurs in women within a few years of menopause from loss of trabecular bone tissue and cessation of ovarian production of estrogens. BMC and BMD measurements of the lumbar spine of women with postmenopausal osteoporosis may be as much as 25% to 40% lower than in age-matched nonosteoporotic control women of

the same age range. Other bone sites with a preponderance of trabecular bone such as the pelvis, ribs, and proximal femur also display low BMD. Rarely, men may develop androgen-deficient osteoporosis if they have a significant decline in androgen production. This osteoporosis is characterized by fractures of the distal radius (Colles fractures) and “crush” fractures of the lumbar vertebrae that are often painful and deforming.

Age-related primary osteoporosis occurs at approximately age 70 and beyond. Many women lose several inches in height between 50 and 80 years of age (see [Figure 24-6](#)). Although age-associated osteoporosis affects both sexes, women are affected more severely because they have a smaller skeletal mass than men.

Causes and Risk Factors

Osteoporosis is a complex heterogeneous disorder, and many risk factors contribute during a lifetime. Low BMD is common to all types of osteoporosis, but an imbalance between bone resorption and formation results from an array of factors characteristic of each form of this disease. Risk factors for osteoporosis include age, race, gender, and factors noted in [Box 24-2](#).

Alcohol and Cigarettes

Cigarette smoking and excessive alcohol consumption are risk factors for developing osteoporosis, probably because of toxic effects on osteoblasts. Moderate alcohol intake has no detrimental effect on bone, and some studies show a modest positive effect in postmenopausal women. Three or more drinks per day is associated with increased risk of falling and may pose other threats to bone health. The risk appears significant even after

BOX 24-2 Risk Factors for Developing Osteoporosis

Age, especially older than age 60
Amenorrhea in women as a result of excessive exercise
Androgen depletion with hypogonadism in men
Cigarette smoking
Estrogen depletion from menopause or early oophorectomy
Ethnicity: white or Asian
Excessive intake of alcohol, caffeine
Female gender
Family history of osteoporosis or parental history of hip fracture
Inadequate calcium or vitamin D intake
Lack of exercise
Prolonged use of certain medications (see Box 24-3)
Sarcopenia
Underweight, low body mass index, low body fatness
Genetic diseases: Marfan syndrome, porphyria, homocystinuria, Gaucher disease, cystic fibrosis, glycogen storage disease, Ehlers-Danlos, hemochromatosis

adjusting for BMD when comparing smokers versus nonsmokers ([North America Menopause Society, 2010](#)). Excessive consumption (more than three drinks a day) for an extended period may result in bone loss. The combination of smoking and alcohol, common among young women and men, places them at increased risk for osteoporosis.

Low body weight is a principal determinant of bone density and fracture risk; adipose tissue mass is a major contributor ([Reid, 2010](#)). The greater the body mass, the greater the BMD. Fat and bone are linked by pathways involving adiponectin; insulin, amylin, and preptin; and leptin and adipocytic estrogens, which ultimately serve the function of providing a skeleton appropriate to the mass of adipose tissue it is carrying ([Reid, 2010](#)).

The lower the BMI, the lower the BMD is. Young girls who are typically premenarcheal may incur fractures with minimum trauma because of low BMC and BMD related to rapid growth in height that is not accompanied with a proportionate increase in weight. Young, overweight males with low bone mass also may suffer fractures ([Goulding et al, 2005](#)). Weight loss from dieting, bariatric surgery, or sarcopenia also are associated with bone loss. Thus being overweight is protective against osteoporosis and underweight is a risk factor for fractures ([Reid, 2010](#)).

Ethnicity

As previously noted, recent data suggest that Hispanics are at higher risk than non-Hispanic whites, whereas blacks are at lower risk for low bone density ([Looker et al, 2012](#)). However, non-Hispanic whites suffer more fractures than other racial or ethnic groups. Nevertheless, the incidence of fracture has declined in all racial and ethnic groups except Hispanics ([Wright et al, 2012](#)).

Limited Weight-Bearing Exercise

Maintenance of healthy bone requires exposure to weight-bearing pressures. A good diet plus exercise from roughly ages 10 to 20 years is particularly important for skeletal growth, accrual of bone mass, and increased femoral bone dimensions ([Iuliano-Burns et al, 2005](#)). Physical activity, especially upper body activities, is thought to contribute to an increase in bone mass or density ([Chubak et al, 2006](#)). Lack of exercise and a sedentary mode of living also may contribute to bone loss,

FIGURE 24-6 Normal spine at age 40 and osteoporotic changes at ages 60 and 70. These changes can cause a loss of as much as 6 to 9 inches in height and result in the dowager’s hump (*far right*) in the upper thoracic vertebrae. (From Ignatavicius D, Workman M: *Medical-surgical nursing: critical thinking for collaborative care*, ed 5, Philadelphia, 2006, Saunders.)

although the most important influence is probably an inadequate accumulation of bone mass.

Exercise is beneficial for reducing skeletal inflammatory markers (see Chapters 3 and 7) in frail older individuals (Lambert et al, 2008). Stresses from muscle contraction and maintaining the body in an upright position against the pull of gravity stimulate osteoblast function. Bones not subjected to normal use rapidly lose mass.

Immobility in varying degrees is well recognized as a cause of bone loss. Invalids confined to bed or persons unable to move freely are commonly affected. Astronauts living in conditions of zero gravity for only a few days experience bone loss, especially in the lower extremities; appropriate exercise is a feature of their daily routines.

Loss of Menses

Loss of menses at any age is a major determinant of osteoporosis risk in women. Acceleration of bone loss coincides with menopause, either natural or surgical, at which time the ovaries stop producing estrogen. Estrogen replacement therapies have been shown to conserve BMD and reduce fracture risk within the first few years after menopause, at least in short-term studies.

Any interruption of menstruation for an extended period results in bone loss. The amenorrhea that accompanies excessive weight loss seen in patients with anorexia nervosa or in individuals who participate in high-intensity sports, dance, or other forms of exercise has the same adverse effect on bones as menopause. BMD in amenorrheic athletes has been measured at levels 25% to 40% below normal. Young women with the “female athlete triad” of disordered eating, amenorrhea, and low BMD are at increased risk for having fractures (see Chapter 23). These young women may benefit from the use of oral contraceptive agents plus calcium and vitamin D supplements.

Nutrients

Many nutrients and several nonnutrients have been implicated as causal risk factors for osteoporosis and have been discussed in previous paragraphs. Frank vitamin D deficiency has been widely reported at northern latitudes in North America and Europe. Vitamin D insufficiency also is now considered more common at latitudes closer to the equator than previously thought because of reduced exposure to sunlight. (Hypponen and Power, 2007). WHO recognizes that calcium, vitamin D, protein, phosphate, vitamin K, magnesium, and other trace elements and vitamins are related to bone health. Energy intake is related as well.

Medications

A number of medications contribute adversely to osteoporosis, either by interfering with calcium absorption or by actively promoting calcium loss from bone (see Box 24-3). For example, corticosteroids affect vitamin D metabolism and can lead to bone loss. Excessive amounts of exogenous thyroid hormone can promote loss of bone mass over time (see Chapter 8 and Appendix 23).

DIAGNOSIS AND MONITORING

Bone densitometry measures bone mass on the basis of tissue absorption of photons produced by x-ray tubes. DXA is available in most hospitals and many clinics for the measurement of the total body and regional skeletal sites, such as the lumbar

BOX 24-3 Medications that Increase the Risk of Osteoporosis

- Aluminum-containing antacids
- Corticosteroids
- Cyclosporine

- Phenobarbital
- Phenothiazine derivatives
- Phenytoin (Dilantin)
- Proton pump inhibitors (PPIs)
- Thyroid hormone
- Tetracycline

vertebrae and the proximal femur (hip). Results of DXA measurements are expressed commonly as T-scores and Z-scores. When the BMD T-score is 2.5 standard deviations (SD) below the mean, a diagnosis of **osteoporosis** is made; between 1 and 2.5 SD is considered low bone mass or **osteopenia**; and within 1 SD of the adult mean is considered normal. There are not separate standards for men yet, and so these standards for women are applied to men over the age of 50. For premenopausal women or men under the age of 50, Z-scores should be used. The diagnosis of osteoporosis should not be made in premenopausal women unless they experience a low trauma fracture or have Z-scores below 3 (National Osteoporosis Foundation (NOF), 2014). The International Society for Clinical Densitometry (ISCD) recommends separate diagnostic criteria to assess bone health in children and teens (<http://www.iscd.org/official-positions/2013-iscd-official-positions-adult/>).

Ultrasound Measurements of Bone

Ultrasound instruments measure the velocity of sound waves transmitted through bone and broadband ultrasound attenuation (BUA). Measurements at the calcaneus (heel) correlate fairly well with BMD measurements at this same skeletal site. However, ultrasound measurements are considered screening tools, whereas DEXA measurements are considered diagnostic.

Fracture Risk Assessment

The World Health Organization (WHO) developed an algorithm to predict fracture by using femoral head BMD and clinical indicators of low bone mass. This uses economic modeling to guide the most cost-effective instances to begin medications. Vertebral fractures that are confirmed by x-rays are a strong predictor of future vertebral fractures, as well as fractures at other sites (NOF, 2014).

Bone Markers

Enzymes or degradation products in serum or urine have been used for research and are beginning to be used more often to monitor drug treatment effectiveness. Serum procollagen type I N-terminal propeptide (PINP), a bone formation marker, and serum collagen type I crosslinked C-telopeptide (sCTX), a bone resorption marker, are recommended by the International Osteoporosis Foundation and the International Federation of Clinical Chemistry and Laboratory Medicine, with caution because of the need for standardization of techniques and recognition of variation sources (Vasikaran et al, 2011).

CLINICAL INSIGHT

Tools to Estimate Probability of Fracture

The World Health Organization developed a tool based on epidemiologic data to calculate the 10-year probability of fracture. The risk algorithm, known as FRAX, is a computer program that includes gender, age, body mass index, parental history of hip fracture, current tobacco smoking, long-term use of oral glucocorticoids, having rheumatoid arthritis or other secondary cause of osteoporosis, and alcohol intake of three or more servings daily. Bone mineral density data of the femoral neck also can be used in the FRAX assessment. The risk assessment does not include any diet or physical activity information, or information about the frequency of falling or likelihood of falling.

The FRAX is used by clinicians to help them decide when medications should be started. According to FRAX, a probability of more than a 20% risk of fracture indicates that some discussion should begin with the patient about whether medication should be started. However, the FRAX guidelines also should consider the patient's individual situation.

The tool has been adapted for use in many countries and is applicable for men and women between 40 and 90 years of age. However, the specificity of the tool for fracture risk is higher for women. One purpose of using the FRAX is to determine the point at which prescribing medications becomes cost effective. It is most valuable in determining risk of fracture in osteopenic individuals.

Used less in clinical practice are three other risk assessment tools: the Simple Calculated Osteoporosis Estimation (SCORE) survey, the Osteoporosis Risk Assessment Instrument (ARAI), and the Osteoporosis Index of Risk (OSIRIS). SCORE calculators are available online and include a person's race, existence of rheumatoid arthritis, estrogen therapy, number of previous fractures, age and weight. The ORAI includes age, weight and current estrogen use. The OSIRIS includes age, weight, estrogen use, and previous fractures.

NUTRITION AND BONE

Calcium, phosphate, and vitamin D are essential for normal bone structure and function. Protein, calories, and other micronutrients also help develop and maintain bone (Tucker, 2009).

Energy

Energy intake does not have a direct effect on bone; rather, inadequate energy intake leading to low body weight, or too many calories leading to overweight have effects on bone. Being underweight is considered a risk factor for osteoporosis, whereas being overweight may be protective.

Protein

Protein and calcium are important components of PBM, especially before puberty (Rizzoli, 2008). Adequate protein intake, with adequate calcium intake, is needed for optimal bone health. A meta-analysis of studies concerned with protein intake and indicators of bone health found a slight positive effect on BMD, but it did not influence the risk of fracture over the long term when total protein, animal protein, or vegetable protein intake were considered (Darling et al, 2009). Unfortunately, this analysis did not consider calcium intake.

The negative effects of either too high or too low an intake of protein is more pronounced with inadequate calcium intake, especially in seniors (Tucker, 2009). The theory that higher protein intakes produce a higher acidic load, which increases calcium urinary excretion, has not been verified (see *Clinical Insight: Acid and Alkaline Diets* in Chapter 35). Although dietary protein may increase acid load and thereby increase urinary calcium excretion, protein also may improve calcium absorption and increase growth factors, which also could improve bone health (Thorpe and Evans, 2011).

Very low protein intake may negatively affect bone turnover and development. In cases of negative nitrogen balance, such as with fracture or surgery, higher protein intake may be advised.

Minerals

Calcium

Calcium intake in the primary prevention of osteoporosis has received much attention. The Dietary Reference Intakes (DRIs) for calcium and vitamin D, are given as RDAs. The RDA for calcium from preadolescence (age 9 years) through adolescence (up to 19 years) was increased to 1300 mg/day for both genders

(IOM, 2011). The RDAs for calcium for adults, pregnant and lactating women, and children are listed on the inside front cover.

Most females older than age 8 do not meet the adequate intake level for calcium when all sources of calcium are considered; intake of males from birth until age 70 appears to be better, although many are still low. Calcium intake from all sources by males aged 70 and older is similar to females (Bailey et al, 2010).

Food sources are recommended first for supplying calcium needs because of the coingestion of other essential nutrients. In the United States the primary source of calcium is dairy foods, and this intake is higher in Caucasian than in African American women (Plawecki et al, 2009). However, calcium fortification of nondairy foods such as nondairy milks and other beverages, juices, breakfast cereals, bread, and some crackers is common.

Calcium bioavailability from foods is generally good, and the amount of calcium in the food is more important than its bioavailability. However, the order of concern relative to calcium absorption efficiency is first the individual's need for calcium, second the amount consumed because absorption efficiency is inversely related to amount consumed, and third the intake of absorption enhancers or inhibitors. For example, absorption from foods high in oxalic and phytic acid (certain vegetables and legumes) is lower than from dairy products.

The amount of calcium in foods varies with the brand, serving size, and whether it has been fortified. When reading the Nutrition Facts label to determine the amount of calcium per serving, multiply the daily value (DV) percentage by 10 to determine the milligrams of calcium per serving. For example, a 20% DV equals 200 mg of calcium (see Chapter 11). Labeling for "excellent" (more than 200 mg/serving) and "good" (100 to 200 mg/serving) sources of calcium are regulated by the Food and Drug Administration (FDA, 2013).

Reaching RDA levels for calcium from foods should be the first goal, but if insufficient amounts of calcium from foods are consumed, supplements of calcium should then be ingested to reach the age-specific RDA. Other sources of calcium include mineral water and medications, especially antacids. The amount of calcium in tap water across the U.S. and Canada is generally low, although ranges from 4 mg/L to 220 mg/L, with an average of about 50 mg/L, or the amount of calcium that could be found in a medium orange (Morr et al, 2006).

An increasing percentage of the population is taking calcium supplements. Persons who should take supplements include

those not meeting the RDA on most days, those taking corticosteroids, those with low bone mass or osteoporosis, women who are perimenopausal or postmenopausal, and those who are lactose intolerant.

Calcium carbonate is the most common form of calcium supplement. It should be taken with food because an acidic environment enhances absorption. For those with achlorhydria, which often occurs in seniors, calcium citrate may be more appropriate because it does not require an acidic environment for absorption and does not further reduce the acidity of the stomach (Straub, 2007).

The absorption of calcium supplementation is optimal when taken as individual doses of 500 mg or less. Many formulations include vitamin D, because the likelihood of needing vitamin D is high if calcium supplementation is needed. Choosing a supplement that has the United States Pharmacopeia (USP) designation increases the likelihood that the supplement quantity is consistent with the label, and that good manufacturing practices are used. Calcium supplementation increases the risk of reaching the upper limit of safety (UL). The UL for calcium for each age group is listed in Table 24-2.

Phosphate

The body's reserve of phosphorus is found in the bone as hydroxyapatite. Phosphate salts are available in practically all foods either naturally or because of processing. In healthy adults, the urinary phosphorus excretion approximately equals intake.

Soft drinks are poor in nutrient value but often high in phosphate content. However, studies have found that the soft drink primarily displaces milk as a beverage, concluding that the negative effect is from lower calcium intake rather than higher phosphate intake. Another hypothesis about the negative affect of soft drink consumption on bones has to do with the rapid rate of phosphorus absorption and greater phosphorus bioavailability from processed foods such as cola drinks (Calvo and Tucker, 2013). Those at high risk and those who have osteoporosis may want to avoid these beverages (Tucker, 2009).

Trace Minerals

Few studies are available about the effects of trace minerals on bone. Iron, zinc, copper, manganese, and boron may function in bone cells, but their specific roles in preventing bone loss are not well established. In one study, 77 adults took a combination of nutrients most or all the time during a 12-month intervention period. The nutrients included docosahexanoic acid, vitamin D, vitamin K, strontium, and magnesium along with a diet rich in calcium, and daily impact exercise. In the sample of 40 who completed the trial, about half demonstrated a >3%

change in bone mineral density at either the femoral neck, total hip, or spine (Genuis, Bouchard, 2012).

Fluoride ions enter the hydroxyapatite crystals of bone as substitutes for hydroxyl ions. Water containing 1 mg/liter has been determined to be optimal for dental health. The upper limits (UL) for fluoride vary by age, beginning with 0.7 mg/day for infants 0 through 6 months, and up to 10 mg/day for children over 8 years through adulthood (IOM, 1997) (see Chapter 25). Fluoride does not help bone in the same way that it helps tooth surfaces. Within narrow limits of safety (less than 2 ppm), fluoride ions have little effect on increasing the hardness of bone mineral.

Vitamins

Vitamin A

Vitamin A consumption consists of retinol (animal sources) and carotenoids (plant sources). Although the research is not definitive, a general guideline is that retinol intake should not be excessive, and carotenoids may have a beneficial role in bone health (Tanumihardjo, 2013). The window of safe consumption of retinol is fairly narrow, especially for older adults.

Vitamin D

In 2008, the Food and Drug Administration amended the label health claim regulations concerning calcium and osteoporosis so that they could also include vitamin D because of increasing recognition that vitamin D plays a pivotal role in calcium uptake and therefore bone homeostasis (FDA, 2008). Although the main function of vitamin D is to maintain serum calcium and phosphorus levels within a constant range, vitamin D is important in stimulating intestinal calcium transport. Vitamin D also stimulates activity of osteoclasts in bone. In both these areas the net desired effect is to increase calcium availability.

Vitamin D also may have a role in muscle tone and fall prevention. Although vitamin D supplementation for fall prevention has had positive and negative results (Theodoratou et al, 2014), older adults with vitamin D deficiency as measured by blood 25-hydroxyvitamin D₃ (calcifediol) levels had muscle weakness and poor balance (Hirani et al, 2014).

An individual's vitamin D status depends mostly on sunlight exposure, and secondarily on dietary intake of vitamin D. The synthesis of vitamin D by skin exposed to sunlight varies considerably as a result of many factors, including skin tone, sunscreen use, environmental latitude, and age (McCarty, 2008) (see Appendix 45). The skin of older individuals is less efficient at producing vitamin D after exposure to ultraviolet (UV) light because the skin is thinner and it contains fewer cells that can synthesize vitamin D. In addition, older adults living in nursing homes and similar institutions typically have little exposure to sunlight. Those who live at northern latitudes in the United States and Canada are at increased risk of osteoporosis because of limited UV light during winter months, although those at more southern latitudes also may be at risk if exposure to sunlight is limited (Hypponen and Power, 2007).

The few foods that naturally contain vitamin D are egg yolks, fatty fish such as salmon, mackerel, catfish, tuna, and sardines, cod liver oil, and some mushrooms (see Appendix 45). The vitamin D content of fish varies, as does the content in UV-exposed mushrooms. Fluid milk in the United States is fortified with vitamin D₂ at a standardized level of 400 IU vitamin D₂ per quart, whereas other foods, including juices, cereals, yogurt, and margarines, may be fortified in varying amounts. The RDAs for vitamin D across the life cycle are shown inside the

TABLE 24-2 Upper Limit for Calcium Intake

Age	Amount, mg
Birth to 6 months	1000
7 to 12 months	1500
1 to 8 years	2500
9 to 18 years	3000
19 to 50	2500
Over 50 years	2000

front cover. The upper limit is 100 µg (4000 IU) for everyone older than 8 years, and lower levels for younger children (see inside back cover). From any source, vitamin D must be hydroxylated in the kidney before becoming the physiologically active calcitriol (1,25-hydroxy vitamin D₃).

To prevent rickets, the American Academy of Pediatrics recommends that all infants who are exclusively breastfed be supplemented with 400 IU of vitamin D. Infants who are both formula and breastfed also should be supplemented until they are consistently taking 1 L (1 quart) of formula a day. They further recommend continuing the supplementation until 1 year of age, when children begin drinking vitamin D–fortified milk (Wagner and Greer, 2008).

The older adult is at increased risk for vitamin D deficiency because of the decreased synthesis of vitamin D by the skin secondary to age-related skin changes and decreased exposure to sunlight; increased body fat; decreased renal function that decreases the hydroxylation of vitamin D to its active form; and decreased levels of insulin-like growth factor 1, **calcitonin**, and estrogen, which affect hydroxylase activity. In general, seniors may benefit from daily vitamin D supplementation of 10 to 20 mcg (400 IU to 800 IU) to reach serum **25-hydroxy vitamin D (calcidiol)** levels of at least 30 ng/ml (75 nmol/L). Older adults who are frail or institutionalized may need up to 50 mcg (2000 IU)/day. Mobility, skin tone, body weight, and dietary habits may modify these recommendations (Oudshoorn et al, 2009). The most common blood test for vitamin D status is serum 25-(OH) D level, and the normal range is considered to be 30 to 75 ng/ml (Topiwala, 2013).

Vitamin K

Vitamin K is an essential micronutrient for bone health. Its role in post-translational modification of several matrix proteins, including **osteocalcin**, is well established. After bone resorption, osteocalcin is released and enters the blood. In this way, osteocalcin serves as a serum bone marker for predicting the risk of a fracture.

Most of the vitamin K intake by individuals in the United States is from green leafy vegetables, with about one third from fats and oils. Although menaquinones, a form of vitamin K, are formed in the gut by bacteria, the influence of this source on vitamin K status appears to be weak. Many older adults have inadequate intakes of vitamin K, primarily because their consumption of dark-green leafy vegetables is so low. It is important to consider the vitamin K intake in older persons who also may be taking blood-thinning medications (vitamin K antagonists) (see Chapter 8 and Appendix 23). Rather than having these patients avoid vitamin K in foods and thus jeopardize their bone status, it is better to have the vitamin K daily intake be consistent and regulate the vitamin K antagonist medication. In fact, it has been shown that therapeutic international normalized ratio (INR) ranges from blood thinning medication can be achieved with vitamin K in low-dose supplementation and when fluctuations are few (Ford and Moll, 2008).

Other Dietary Components

Several other dietary factors have been associated with bone health, but their relative quantitative importance is not clear.

Alcohol

Although previously mentioned as a risk factor, moderate consumption of wine and beer may be beneficial to bone in men and

postmenopausal women. Nonalcoholic constituents, such as silicon in beer, need further investigation. In men, high liquor intakes (more than 2 drinks per day) are associated with significantly lower BMD (Kanis et al, 2005; Tucker et al, 2009). Heavy alcohol consumption also may be accompanied by poor dietary intake, cigarette smoking, poor balance, and an increased risk of falls.

Caffeine and Soft Drinks

The relationship of moderate consumption of caffeine to osteoporosis has not been clearly established. *Excessive* caffeine intake may have a deleterious effect on BMD (Ruffing et al, 2006). Intake of colas also is associated with lower BMD. Although the primary issue may be displacement of dairy beverages, there is also a potential direct effect (Tucker, 2009). Rapid metabolizers of caffeine may be a high risk group for bone loss (Hallström et al, 2010).

Dietary Fiber

Excessive dietary fiber intake may interfere with calcium absorption, but any interference is considered extremely small in the typical low-fiber diet. Vegans who may consume as much as 50 g of fiber a day are most likely to have a significant depression in intestinal calcium absorption, but this is often offset by adequate calcium intake. Fiber includes a variety of different compounds, and so intake of “fiber” as a category can produce different effects on bone. The inulin-type fructans are a group of fiber compounds found in wheat, onion, bananas, garlic, and leeks that may enhance calcium and magnesium absorption (Roberfroid, 2007), whereas high-fiber foods that contain phytates or oxalates may lower calcium absorption. The calcium content of these foods, such as spinach or legumes, is also lower than in dairy foods (Dairy Research Institute, 2011).

Isoflavones

The isoflavones in soybeans function as estrogen agonists and antioxidants in bone cells. They inhibit bone resorption in female animal models without ovaries, but not in young adult females with normal estrogen status. Some, but not all, studies show modest skeletal benefits (Lagari, Levis, 2013).

High Acid or Alkaline Diets

Higher acid diets include those high in protein, dairy, and grains (see *Clinical Insight: Acid and Alkaline Diets* in Chapter 35). It is theorized that these higher acid diets may increase calcium excretion and have a detrimental effect on bone. The theory also supports a converse beneficial effect of an alkaline diet on bone. Several meta-analyses, experimental studies, and reviews have not supported either the negative effect of higher acid diets on bone or the positive effects of an alkaline diet on bone. Higher protein intake may, in fact, have a positive effect on bone (Cao and Nielsen, 2010; Fenton et al, 2010; Fenton et al, 2011; Frassetto et al, 2012; Hanley and Whiting, 2013).

Sodium

A high sodium intake may contribute to osteoporosis because of increased calcium excretion (Massey, 2005). Although the calciuric effect of sodium has been speculated, there seems to be no adverse effects when there is adequate calcium and vitamin D intake (Ilich et al, 2010).

Vegetarian Diets

Research is inconclusive concerning the effects of vegetarian diets on bone mass, bone density, and osteoporosis risk. Vegans

and lactovegetarians differ in their intake of protein, calcium, and other nutrients, and often have lifestyle patterns that also differ from the general population. In addition, ethnicities with a traditional practice of vegetarianism may have differences in terms of genetics that influence body frame and size (Ho-Pham et al, 2009).

PREVENTION OF OSTEOPOROSIS AND FRACTURES

The increasing longevity of the population emphasizes the need for prevention of osteoporosis (see Box 24-4). Universal guidelines apply to everyone. Consuming adequate amounts of calcium, and vitamin D, along with lifelong muscle strengthening and weight-bearing exercise, avoidance of tobacco, moderate or no intake of alcohol, and steps to avoid falls are all part of the holistic approach to a lifestyle that promotes optimal bone health (NAMS, 2010).

Exercise

To preserve bone health through adulthood, the American Academy of Sports Medicine recommends weight-bearing activity three to five times per week and resistance exercise two to three times per week with moderate to high bone-loading force for a combination of 30 to 60 minutes per week. Regular walking and swimming appear to have minor benefits in older individuals. More active participation (such as weight-bearing exercises and intensive walking) have positive effects on BM (Guadalupe-Grau et al, 2009; Gomez-Cabello et al, 2012). For older adults, posture, balance, and flexibility are also important.

Diet

The National Osteoporosis Foundation recommends universal guidelines for all adults for the prevention of osteoporosis that includes adequate calcium and vitamin D, and a balanced diet of low-fat dairy, fruits, and vegetables. Although the NOF recommends the same amount of calcium intake as the IOM, the NOF recommends a higher intake of vitamin D than does the IM for those 50 years and older (800 to 1000 IU/day). If these intake goals are not reached by food, supplements should be considered (NOF, 2013). In addition, achieving and maintaining a healthy weight and consuming a lower sodium diet is recommended for optimal bone health for women (Cox et al, 2013).

FDA-Approved Drug Treatments

Raloxifene and tamoxifen, which are **estrogen agonist/antagonist agents**; alendronate sodium, risedronate sodium, and zoledronic acid, which are **bisphosphonates**; and **estrogen replacement therapy (ERT)** are all approved for the prevention

of osteoporosis, especially for postmenopausal women (NOF, 2013). However, because of potential side effects, nonestrogen treatment for prevention is recommended, especially if menopausal symptom relief is not also a goal of the therapy (NOF, 2013). The **bisphosphonates** act as inhibitors on osteoclasts to reduce bone resorption. They have been shown to be effective in reducing the incidence of new fractures (Epstein, 2006). Side effects include gastrointestinal problems and rare cases of jaw necrosis. However, stopping the medication after 2 to 3 years is recommended. Estrogen agonists or antagonists, which used to be referred to as SERMS (**selective estrogen receptor modulators**), are able to stimulate **estrogen receptors (ER)** in bone tissue and yet have very little effect on the ERs of the breast or uterus. The most common side effect is hot flashes. Teriparatide, the only anabolic on the market, and Denosumab, a RANK (**Receptor Activator of Nuclear Factor κ B**) inhibitor are approved therapies. **Receptor Activator of Nuclear Factor κ B** is part of a signaling pathway that regulates osteoclast activation.

TREATMENT OF OSTEOPOROSIS

Medical Nutrition Therapy

Calcium (1000 mg/day) and vitamin D (800 to 1000 units/day) typically are recommended as supplements for patients being treated with one of the bone drugs, either antiresorptive or anabolic. These amounts are considered safe and sufficient for bone formation. Because of the range of nutrients involved in bone health, a healthy diet emphasizing the key nutrients seems most promising in achieving an intake for optimal bone health (Tucker, 2009). The dietitian nutritionist should evaluate the client's diet for all bone-related nutrients and tailor recommendations based on personal preferences, cultural differences, nutrient recommendations, and the need for supplements (McCabe-Sellers and Skipper, 2010).

Exercise

For those with osteoporosis, exercises that exert strong force against potentially weak bone are not recommended, such as sit-ups or twisting. Exercises should focus on posture, balance, gait, coordination, and hip and trunk stabilization (IOF, 2014). For those in need of rehabilitation, the client should be evaluated for capabilities and deficiencies, with attention to weight-bearing aerobic activities, posture, resistance training, stretching, and balance training (IOF, 2014).

FDA-Approved Drug Treatments

All the medications that are approved for prevention are also approved for treatment of osteoporosis, with the exception of estrogen replacement therapy. Another bisphosphonate, ibandronate sodium, is also approved only for treatment. In addition, **calcitonin**, the hormone, is used to inhibit osteoclastic bone resorption by blocking the stimulatory effects of PTH on these cells. Calcitonin can be administered by nasal spray. It improves BMD, especially of the lumbar spine, and it may reduce the recurrence of fractures in patients with osteoporosis. Calcitonin is approved by the FDA for postmenopausal treatment of osteoporosis, but it is recommended that the women be at least 5 years postmenopausal.

PTH therapy is approved by the FDA for the treatment of postmenopausal women and men at high risk for fracture and for those on long-term glucocorticoid therapy. Although the chronic, physiologic rise in PTH that can occur with aging or in

BOX 24-4 FDA-Approved Medications for Prevention or Treatment of Osteoporosis

Bisphosphonates
Calcitonin—treatment only
Estrogen—prevention only when menopausal symptoms are primarily being treated
Estrogen agonist/antagonist—treatment only
Tissue specific estrogen complex—treatment only
Parathyroid hormone (PTH)—treatment only
Receptor activator of nuclear factor κ ligand (RANKL) inhibitor—treatment only

hyperparathyroidism resulting from other causes increases osteoclastic activity and decreases bone density, the **intermittent PTH therapy** has the opposite effect. The drug PTH works by increasing osteoblast number and function (Kousteni and Bilezikian, 2008). PTH increases spine, hip, and total body BMD. PTH is often prescribed first, followed by bisphosphonates, so that an increase in bone mass is followed by antiresorptive therapy (Cosman, 2008).

Denosumab, which works at the receptor level to inhibit RANKL, is approved by the FDA for men and women at high risk of fracture.

Drug Treatments Not Yet Approved by the FDA

There are many medications not approved by the FDA for prevention or treatment of osteoporosis. These include calcitriol (1,25-dihydroxy vitamin D₃); PTH 1-84, which is an intact human recombinant form of PTH; sodium fluoride; and strontium ranelate.

CLINICAL CASE STUDY

Liz B. is a 73-year-old white woman who is seeing her doctor for a regular physical. She is married and retired, but volunteers for several organizations and watches her grandchildren two mornings a week. She and her husband play golf about once a week during the spring, summer, and fall. She weighs 130 pounds and always thought she was 5'6". However, when she was measured at this physical, she was 5'4". Because of her age and height loss, she has a dual-energy x-ray absorptiometry (DEXA) measurement that shows that she has low bone mineral density (BMD) values of her proximal femur and lumbar vertebrae (both values are classified as osteoporotic according to World Health Organization definitions). A chest x-ray also revealed two vertebral fractures. However, she has no pain in her back or neck.

The RDN and Liz discuss her diet, concluding that her diet is low in calcium and vitamin D, but high in sodium. Along with suggestions to decrease her sodium intake and increase her fruit and vegetable intake, she is advised to start taking supplements of calcium (1000 mg/day) and vitamin D (800 units/day). They discuss avoiding high-impact exercise affecting the spine because of the low bone mass and existing vertebral fractures, but increasing flexibility, balance, and posture exercises. Because of the DXA results, she also begins on a bisphosphonate drug in addition to the calcium and vitamin D supplements. She receives baseline tests of bone turnover, to be rechecked in 6 months and an appointment for another DXA in 1 year.

After 1 year on the medication, supplements, diet and exercise changes, Liz has another DXA. Her BMD has improved to the osteopenia level, and she is taken off the bisphosphonate medication.

Nutrition Diagnostic Statement

Inadequate calcium and vitamin D intake related to avoidance of dairy products as evidenced by diet history revealing less than 20% of estimated requirements. NOTE: This may be resolved once she starts taking supplements.

Nutrition Care Questions

1. If Liz wants to increase her calcium through fortified foods rather than take a supplement, how would you counsel her?
2. Design a set (3 days minimum) of daily menus that provide approximately 800 mg of calcium from foods alone, which, coupled with a 500-mg supplement, would provide a total of 1300 mg daily, the current adequate intake for calcium. Similarly, design these same meals to include 400 units of vitamin D, with another 400 units coming from supplements.
3. If Liz's sodium intake is high, what foods would you advise her to eat less frequently?

Diet and nutrition play key roles in tooth development, integrity of the **gingiva** (gums) and mucosa, bone strength, and the prevention and management of diseases of the oral cavity. Diet has a local effect on tooth integrity; the type, form, and frequency of foods and beverages consumed have a direct effect on the oral pH and microbial activity, which may promote dental decay. Nutrition systemically affects the development, maintenance, and repair of teeth and oral tissues.

Nutrition and diet affect the oral cavity, but the reverse is also true: that is, the status of the oral cavity may affect one's ability to consume an adequate diet and achieve nutritional balance. Indeed, there is a lifelong synergy between nutrition and the integrity of the oral cavity in health and disease related to the known roles of diet and nutrients in the growth, development, and maintenance of the oral cavity structure, bones, and tissues (Touger-Decker and Mobley, 2013).

NUTRITION FOR TOOTH DEVELOPMENT

Primary tooth development begins at 2 to 3 months' gestation. Mineralization begins at approximately 4 months' gestation and continues through the preteen years. Therefore maternal nutrition must supply the preeruptive teeth with the appropriate building materials. Inadequate maternal nutrition consequently affects tooth development.

Teeth are formed by the mineralization of a protein matrix. In **dentin**, protein is present as collagen, which depends on vitamin C for normal synthesis. Vitamin D is essential to the process by which calcium and phosphorus are deposited in crystals of **hydroxyapatite**, a naturally occurring form of calcium and phosphorus that is the mineral component of **enamel** and dentin. Fluoride added to the hydroxyapatite provides unique caries-resistant properties to teeth in prenatal and postnatal developmental periods.

Diet and nutrition are important in all phases of tooth development, eruption, and maintenance (see [Figure 25-1](#)). Posteruption diet and nutrient intake continue to affect tooth development and mineralization, enamel development and strength, and eruption patterns of the remaining teeth. The local effects of diet, particularly **fermentable carbohydrates** and eating frequency, affect the production of organic acids by oral bacteria and the rate of tooth decay as described later in this chapter.

DENTAL CARIES

Dental caries is one of the most common infectious diseases. According to a Surgeon General's report on oral health in 2000, dental caries is seven times more common than hay fever and five times more common than asthma. Unfortunately, differences are evident in caries prevalence; approximately 20% to 25% of U.S. children have 80% of the dental caries. Trends in dental caries have demonstrated that children who come from homes in which parents have a college education have fewer caries than children from homes in which parents have less than a college education (Centers for Disease Control and Prevention [CDC], 2010). These differences, or health disparities, may happen as a result of lack of access to care, cost of care not reimbursed by third-party payers (e.g., insurance, Medicaid), lack of knowledge of preventive dental care, or a combination of factors.

Pathophysiology

Dental caries is an oral infectious disease in which organic acid metabolites lead to gradual **demineralization** of tooth enamel, followed by rapid proteolytic destruction of the tooth structure. Caries can occur on any tooth surface. The cause of dental caries involves many factors. Four factors must be present simultaneously: (1) a susceptible host or tooth surface; (2) microorganisms such as *Streptococcus* or *Lactobacillus* in the dental plaque or oral

FIGURE 25-1 Anatomy of a tooth.

cavity; (3) fermentable carbohydrates in the diet, which serve as the substrate for bacteria; and (4) time (duration) in the mouth for bacteria to metabolize the fermentable carbohydrates, produce acids, and cause a drop in salivary pH to less than 5.5. Once the pH is acidic, which can occur within minutes, oral bacteria can initiate the demineralization process. Figure 25-2 shows the formation of dental caries.

Susceptible Tooth

The development of dental caries requires the presence of a tooth that is vulnerable to attack. The composition of enamel and dentin, the location of teeth, the quality and quantity of saliva, and the presence and extent of pits and fissures in the tooth crown are some of the factors that govern susceptibility. Alkaline saliva has a protective effect and acidic saliva increases susceptibility to decay.

Microorganisms

Bacteria are an essential part of the decay process. *Streptococcus mutans* is the most prevalent, followed by *Lactobacillus casein* and *Streptococcus sanguis*. All three contribute to the process because they metabolize carbohydrates in the mouth, producing acid as a byproduct, which is sufficient to cause decay. Genetic variations of the type and quantity of bacteria present in the oral cavity may put someone at an increased risk for caries and periodontal disease, but the quantity and quality of oral hygiene contributes directly to the risk of oral infectious disease.

Substrate

Fermentable carbohydrates, those carbohydrates susceptible to the actions of salivary amylase, are the ideal substrate for bacterial metabolism. The acids produced by their metabolism cause a drop in salivary pH to less than 5.5, creating the environment for decay. Bacteria are always present and begin to reduce pH when they have exposure to fermentable carbohydrates.

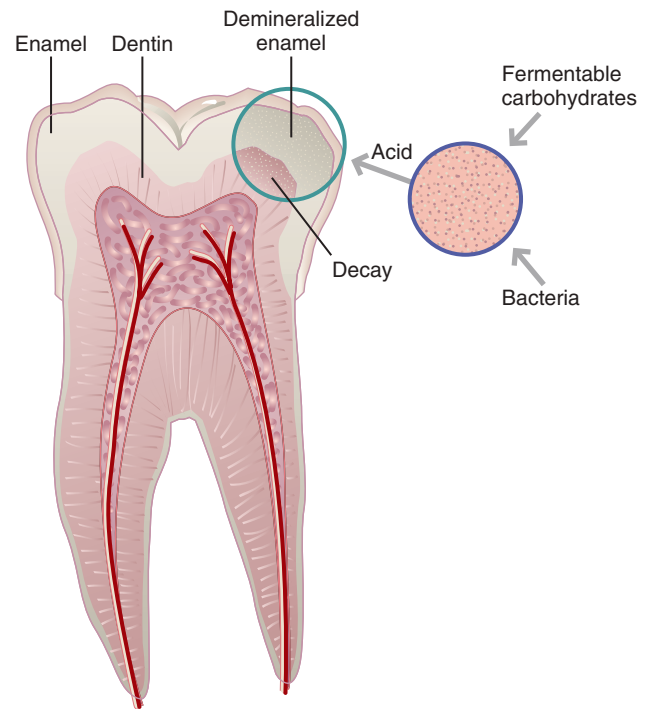

FIGURE 25-2 Formation of dental caries.

Although the Dietary Guidelines for Americans and the MyPlate Food Guidance system support a diet high in carbohydrates, it is important to be aware of the cariogenicity of foods. **Cariogenicity** refers to the caries-promoting properties of a diet or food. The cariogenicity of a food varies, depending on the form in which it occurs, its nutrient composition, when it is eaten in relation to other foods and fluids, the duration of its exposure to the tooth, and the frequency with which it is eaten (see Box 25-1). Individuals should be aware of the form of food consumed and the frequency of intake to integrate positive diet and oral hygiene habits to reduce risk of oral disease.

Fermentable carbohydrates are found in three of the five MyPlate food groups: (1) grains, (2) fruits, and (3) dairy. Although some vegetables may contain fermentable carbohydrates, little has been reported about the cariogenicity, or caries-promoting properties, of vegetables. Examples of grains and starches that are cariogenic by nature of their fermentable carbohydrate composition include crackers, chips, pretzels, hot and cold cereals, and breads.

All fruits (fresh, dried, and canned) and fruit juices may be cariogenic. Fruits with high water content, such as melons, have a lower cariogenicity than others such as bananas and dried fruits. Fruit drinks, sodas, ice teas, and other sugar-sweetened beverages; desserts; cookies; candies; and cake products may be cariogenic.

BOX 25-1 Factors Affecting Cariogenicity of Foods

- Frequency of consumption
- Food form (liquid or solid, slowly dissolving)
- Sequence of eating certain foods and beverages
- Combination of foods
- Nutrient composition of foods and beverages
- Duration of exposure of teeth

Dairy products sweetened with fructose, sucrose, or other sugars can also be cariogenic because of the added sugars; however, dairy products are rich in calcium, and their alkaline nature may have a positive influence, reducing the cariogenic potential of the food.

Like other sugars (glucose, fructose, maltose, and lactose), sucrose stimulates bacterial activity. The causal relationship between sucrose and dental caries has been established (Moynihan and Kelly, 2014). All dietary forms of sugar, including honey, molasses, brown sugar, agave, and corn syrup solids, have cariogenic potential and can be used by bacteria to produce organic acid.

Caries Promotion by Individual Foods

It is important to differentiate between cariogenic, cariostatic, and anticariogenic foods. **Cariogenic** foods are those that contain fermentable carbohydrates, which, when in contact with microorganisms in the mouth, can cause a drop in salivary pH to 5.5 or less and stimulate the caries process.

Cariostatic foods do not contribute to decay, are not metabolized by microorganisms, and do not cause a drop in salivary pH to 5.5 or less within 30 minutes. Examples of cariostatic foods are protein foods such as eggs, fish, meat, and poultry; most vegetables; fats; and sugarless gums. Sugarless gum may help to reduce decay potential because of its ability to increase saliva flow and because it uses noncarbohydrate sweeteners (Deshpande and Jadad, 2008; Splieth et al, 2009).

Anticariogenic foods are those that, when eaten before an acidogenic food, prevent plaque from recognizing the acidogenic food. Examples are aged cheddar, Monterey Jack, and Swiss because of the casein, calcium, and phosphate in the cheese. The five-carbon sugar alcohol, **xylitol**, is considered anticariogenic because bacteria cannot metabolize five-carbon sugars in the same way as six-carbon sugars such as glucose, sucrose, and fructose. It is not broken down by salivary amylase and is not subject to bacterial degradation. Salivary stimulation leads to increased buffering activity of the saliva and subsequent increased clearance of fermentable carbohydrates from tooth surfaces. Another anticariogenic mechanism of xylitol gum is that it replaces fermentable carbohydrates in the diet. *S. mutans* cannot metabolize xylitol and is inhibited by it. The antimicrobial activity against *S. mutans* and the effect of gum chewing on salivary stimulation are protective. Consumers should be advised to look for chewing gum in which xylitol is listed as the first ingredient.

Remineralization is mineral restoration of the hydroxyapatite in dental enamel. Casein phosphopeptide-amorphous calcium phosphate (CPP-ACP) is a substance that promotes remineralization of enamel surfaces (Cochrane et al, 2012). It is currently available as an ingredient trademarked as Recaldent (Cadbury Enterprises, Australia) in some brands of chewing gum (http://www.recaldent.com/c_faq.asp).

Factors Affecting Cariogenicity of Food

Cariogenicity also is influenced by the volume and quality of saliva; the sequence, consistency, and nutrient composition of the foods eaten; dental plaque buildup; and the genetic predisposition of the host to decay.

Form and Consistency

The form and consistency of a food have a significant effect on its cariogenic potential and pH-reducing or buffering capacity. Food form determines the duration of exposure or retention time of a food in the mouth, which, in turn, affects how long the decrease in pH or the acid-producing activity will last. Liquids are rapidly cleared from the mouth and have low

adherence (or retentiveness) capabilities. Solid foods such as crackers, chips, pretzels, dry cereals, and cookies can stick between the teeth (referred to as the *interproximal spaces*) and have high adherence (or retention) capability.

Consistency also affects adherence. Chewy foods such as gum drops and marshmallows, although high in sugar content, stimulate saliva production and have a lower adherence potential than solid, sticky foods such as pretzels, bagels, or bananas. High-fiber foods with few or no fermentable carbohydrates, such as popcorn and raw vegetables, are cariostatic.

Exposure

The duration of exposure may be best explained with starchy foods, which are fermentable carbohydrates subject to the action of salivary amylase. The longer starches are retained in the mouth, the greater their cariogenicity. Given sufficient time, such as when food particles become lodged between the teeth, salivary amylase makes additional substrate available as it hydrolyzes starch to simple sugars. Processing techniques, either by partial hydrolysis or by reducing particle size, make some starches rapidly fermentable by increasing their availability for enzyme action.

Sugar-containing candies rapidly increase the amount of sugar available in the oral cavity to be hydrolyzed by bacteria. Sucking on hard candies such as lollipops or sugared breath mints results in prolonged sugar exposure in the mouth. Simple carbohydrate-based snacks and dessert foods (e.g., potato chips, pretzels, cookies, cakes, and doughnuts) provide gradually increasing oral sugar concentrations for a longer duration because these foods often adhere to the tooth surfaces and are retained for longer periods than candies. In school age children, more frequent snacking on carbohydrate-containing foods was associated with greater incidence of dental caries (Chankanka et al, 2011).

Nutrient Composition

Nutrient composition contributes to the ability of a substrate to produce acid and to the duration of acid exposure. Dairy products, by virtue of their calcium- and phosphorus-buffering potential, are considered to have low cariogenic potential. Evidence suggests that cheese and milk, when consumed with cariogenic foods, help to buffer the acid pH produced by the cariogenic foods. Because of the anticariogenic properties of cheese, eating cheese with a fermentable carbohydrate, such as dessert at the end of a meal, may decrease the cariogenicity of the meal and dessert (Ravishankar et al, 2012).

Nuts, which do not contain a significant amount of fermentable carbohydrates and are high in fat and dietary fiber, are cariostatic. Protein foods such as seafood, meats, eggs, and poultry, along with other fats such as oils, margarine, butter, and seeds, are also cariostatic.

Sequence and Frequency of Eating

Eating sequence and combination of foods also affect the caries potential of the substrate. Bananas, which are cariogenic because of their fermentable carbohydrate content and adherence capability, have less potential to contribute to decay when eaten with cereal and milk than when eaten alone as a snack. Milk, as a liquid, reduces the adherence capability of the fruit. Crackers eaten with cheese are less cariogenic than when eaten alone.

The frequency with which a cariogenic food or beverage is consumed determines the number of opportunities for acid production. Every time a fermentable carbohydrate is consumed, a decline in pH is initiated within 5 to 15 minutes, causing caries-promoting activity. Small, frequent meals and snacks,

often high in fermentable carbohydrate, increase the cariogenicity of a diet more than a diet consisting of three meals and minimal snacks. Eating several cookies at once, followed by brushing the teeth or rinsing the mouth with water, is less cariogenic than eating a cookie several times throughout a day. [Table 25-1](#) lists messages that can be given to children to reduce the risk of developing dental caries.

The Decay Process

The carious process begins with the production of acids as a byproduct of bacterial metabolism taking place in the dental plaque. Decalcification of the surface enamel continues until the buffering action of the saliva is able to raise the pH above the critical level. See [Box 25-2](#) for prevention guidelines and the Practice Paper of the Academy of Nutrition and Dietetics on Oral Health and Nutrition ([Mallonnee et al, 2014](#)).

Plaque is a sticky, colorless mass of microorganisms and polysaccharides that forms around the tooth and adheres to teeth and gums. It harbors acid-forming bacteria and keeps the

TABLE 25-1 Nutrition Messages Related to Oral Health for 3- to 10-Year-Old Children and Their Caregivers

Message	Rationale
Starchy, sticky, or sugary foods should be eaten with nonsugary foods.	The pH will rise if a nonsugary item that stimulates saliva is eaten immediately before, during, or after a challenge.
Combine dairy products with a meal or snack.	Dairy products (nonfat milk, yogurt) enhance remineralization and contain calcium.
Combine chewy foods such as fresh fruits and vegetables with fermentable carbohydrates.	Chewy, fibrous foods induce saliva production and buffering capacity.
Space eating occasions at least 2 hours apart and limit snack time to 15 to 30 minutes.	Fermentable carbohydrates eaten sequentially one after another promote demineralization.
Limit bedtime snacks.	Saliva production declines during sleep.
Limit consumption of acidic foods such as sports drinks, juices, and sodas.	Acidic foods promote tooth erosion that increases risk for caries.
Combine proteins with carbohydrates in snacks.	Proteins act as buffers and are cariostatic.
Examples: tuna and crackers, apples and cheese	
Combine raw and cooked or processed foods in a snack.	Raw foods encourage mastication and saliva production, whereas cooked or processed foods may be more available for bacterial metabolism if eaten alone.
Encourage use of xylitol- or sorbitol-based chewing gum and candies immediately after a meal or snack.*	Five minutes of exposure is effective in increasing saliva production and dental plaque pH.
Recommend sugar-free chewable vitamin and mineral supplements and syrup-based medication.	Sugar-free varieties are available and should be suggested for high caries risk groups.
Encourage children with pediatric GERD to adhere to dietary guidelines.	GERD increases risk for dental erosion and thus increases risk for caries.

Modified from Mobley C: Frequent dietary intake and oral health in children 3 to 10 years of age, *Building Blocks* 25:17, 2001.

GERD, Gastroesophageal reflux disease.

*Gum is not recommended for children younger than 6 years old.

BOX 25-2 Caries Prevention Guidelines

Brush at least twice daily, preferably after meals.
 Rinse mouth after meals and snacks.
 Chew sugarless gum for 15 to 20 min after meals and snacks.
 Floss twice daily.
 Use fluoridated toothpastes.
 Pair cariogenic foods with cariostatic foods.
 Snack on cariostatic and anticariogenic foods such as cheese, nuts, popcorn, and vegetables.
 Limit between-meal eating and drinking of fermentable carbohydrates.

organic products of their metabolism in close contact with the enamel surface. As a cavity develops, the plaque blocks the tooth, to some extent, from the buffering and remineralization action of the saliva. In time the plaque combines with calcium and hardens to form **calculus**.

An acidic pH is also required for plaque formation. Soft drinks (diet and regular), sports beverages, citrus juices and “ades,” and chewable vitamin C supplements have high acid content and may contribute to erosion ([Tedesco et al, 2012](#)). Research using National Health and Nutrition Examination Survey III data reported significantly more dental caries in children (ages 2-10 years) who consumed large amounts of carbonated soft drinks or juices compared with children who had high consumption of water or milk ([Sohn et al, 2006](#)). Other beverages and foods contribute to **dental erosion**, a loss of minerals from tooth surfaces by a chemical process in the presence of acid ([Wongkhantee et al, 2006](#)).

Roles of Saliva

Salivary flow clears food from around the teeth as a means to reduce the risk of caries. The bicarbonate-carbonic acid system, calcium, and phosphorus in saliva also provide buffering action to neutralize bacterial acid metabolism. Once buffering action has restored pH above the critical point, remineralization can occur. If fluoride is present in the saliva, the minerals are deposited in the form of **fluoroapatite**, which is resistant to erosion. Salivary production decreases as a result of diseases affecting salivary gland function (e.g., Sjögren syndrome); as a side effect of fasting; as a result of radiation therapy to the head and neck involving the parotid gland; normally during sleep and aging; with the use of medications associated with reduced salivary flow; or with **xerostomia**, dry mouth caused by inadequate saliva production. An estimated 400 to 500 medications currently available by prescription or over the counter may cause dry mouth. The degree of xerostomia may vary but may be caused by medications such as those to treat depression, hypertension, anxiety, human immunodeficiency virus (HIV), and allergies.

Caries Patterns

Caries patterns describe the location and surfaces of the teeth affected. **Coronal caries** affect the crown of the tooth, the part of the tooth visible above the gum line, and may occur on any tooth surface. Although the overall incidence of decay in the United States has declined, many states report 40% to 70% of children having some decay by age 8 ([CDC, 2010](#)).

Root caries, occurring on the root surfaces of teeth secondary to gingival recession, affect a large portion of the older population. Root caries is a dental infection that is increasing in older adults, partly because this population is retaining their natural teeth longer. The gums recede in

older age, exposing the root surface. Other factors related to the increased incidence of this decay pattern are lack of fluoridated water, poor oral hygiene practices, decreased saliva, frequent eating of fermentable carbohydrates, and dementia (Chalmers and Ettinger, 2008). Management of root caries includes dental restoration and nutrition counseling. Poor oral health from caries, pain, or edentulism often adversely affects dietary intake and nutritional status in older adults (Quandt et al, 2009).

Lingual caries, or caries on the lingual side (surface next to or toward the tongue) of the anterior teeth, are seen in persons with gastrointestinal reflux, bulimia, or anorexia-bulimia (see Chapter 22). Frequent intake of fermentable carbohydrates, combined with regurgitation or induced vomiting of acidic stomach contents, results in a constant influx of acid into the oral cavity. The acid contributes to erosion of tooth surfaces that can result in tooth sensitivity and dental caries. The pattern of erosion may be indicative of erosion from reflux versus from foods or beverages (Schlueter et al, 2012).

Fluoride

Fluoride is an important element in bones and teeth (Palmer and Gilbert, 2012). Used systemically and locally, it is a safe, effective public health measure to reduce the incidence and prevalence of dental caries (American Dental Association [ADA], 2014; CDC, 2013). Water fluoridation began in 1940; by 1999 the Centers for Disease Control and Prevention listed water fluoridation as one of the top 10 greatest public health achievements of the twentieth century because of its influence on decreasing the rate of dental caries (CDC, 2013). The effect of fluoride on caries prevention continues with water fluoridation, fluoridated toothpastes, oral rinses, and dentifrices, as well as beverages made with fluoridated water. Optimal water fluoridation concentrations (0.7-1.2 ppm) can provide protection against caries development without causing tooth staining (ADA, 2014). Despite the positions from the American Dental Association (ADA) and the Academy of Nutrition and Dietetics (AND), and the data from the CDC on fluoride for oral health, there is a controversy over the use of topical fluoride on teeth and systemic fluoridation in water supplies. Arguments against widespread fluoride use include claims that it can be carcinogenic and toxic; however, consumers should be urged to read the evidence (e.g., <http://fluorideinfo.org/>).

Mechanism of Action

There are four primary mechanisms of fluoride action on teeth: (1) when incorporated into enamel and dentin along with calcium and phosphorus, it forms fluoroapatite, a compound more resistant to acid challenge than hydroxyapatite; (2) it promotes repair and remineralization of tooth surfaces with early signs of decay (incipient carious lesions); (3) it helps to reverse the decay process while promoting the development of a tooth surface that has increased resistance to decay; and (4) helps to deter the harmful effects of bacteria in the oral cavity by interfering with the formation and function of microorganisms.

Food Sources

Most foods, unless prepared with fluoridated water, contain minimal amounts of fluoride, except for brewed tea, which has approximately 1.4 ppm (Morin, 2006). Fluoride may be added unintentionally to the diet in a number of ways, including through the use of fluoridated water in the processing of foods

and beverages. Fruit juices and drinks, particularly white grape juice produced in cities with fluoridated water, may have increased fluoride content; however, because of the wide variation in fluoride content, it is difficult to estimate amounts consumed.

Supplementation

Health professionals should consider a child's fluid intake as well as food sources and the availability of fluoridated water in the community before prescribing fluoride supplements. Because bones are repositories of fluoride, bone meal, fish meal, and gelatin made from bones are potent sources of the mineral. In communities without fluoridated water, dietary fluoride supplements may be recommended for children ages 6 months to 16 years.

Fluoride can be used topically and systemically. When consumed in food and drink, it enters the systemic circulation and is deposited in bones and teeth. Systemic sources have a topical benefit as well by providing fluoride to the saliva. A small amount of fluoride enters the soft tissues; the remainder is excreted. The primary source of systemic fluoride is fluoridated water; food and beverages supply a smaller amount. Table 25-2 contains a schedule of fluoride supplementation.

Fluoride supplements are not recommended for formula-fed infants or for breast-fed infants living in fluoridated communities if these infants receive drinking water between feedings. If the infant does not drink water between feedings or drinks bottled water when on a diet of only breast milk, he or she should be supplemented according to the fluoride supplement guidelines. Fluoride supplements must be prescribed by the child's health care provider; they are not available as over-the-counter supplements (ADA, 2014).

Topical fluoride sources include toothpastes, gels, and rinses used by consumers daily, along with more concentrated forms applied by dental professionals in the form of gels, foams, and rinses. Frequent fluoride exposure via topical fluorides, fluoridated toothpastes, rinses, and fluoridated water is important in maintaining an optimal concentration of fluoride, but excess intake should be avoided.

Excess Fluoride

Fluorosis occurs when too much fluoride is provided during tooth development and can range from mild to severe and present on teeth from unnoticeable to very apparent dark spots on teeth (Bronckers, 2009). Causes of mild fluorosis from excessive fluoride intake include misuse of dietary fluoride supplements, ingestion of fluoridated toothpastes and rinses, or excessive fluoride intake secondary to fluoride in foods and beverages processed in fluoridated areas and transported to other areas. Topical fluorides, available as fluoridated toothpaste and mouthwashes, are effective

TABLE 25-2 Dietary Fluoride Supplement Schedule

Age	FLUORIDE ION LEVEL IN DRINKING WATER (ppm)*		
	<0.3 ppm	0.3-0.6 ppm	>0.6 ppm
Birth-6 mo	None	None	None
6 mo-3 yr	0.25 mg/day [†]	None	None
3-6 yr	0.50 mg/day	0.25 mg/day	None
6-16 yr	1.0 mg/day	0.50 mg/day	None

Approved by The American Dental Association, The American Academy of Pediatrics, and The American Academy of Pediatric Dentistry, 1994.

*1 ppm = 1 mg/L.

[†]2.2 mg of sodium fluoride contains 1 mg of fluoride ion.

sources of fluoride that can be used in the home, school, or dental office. Caries prevention efforts in preschool children include diet modification, water fluoridation or supplements in nonfluoridated areas, and supervised toothbrushing with fluoridated toothpaste (ADA, 2014).

Children younger than 6 years of age should not use fluoridated mouthwashes, and older children should be instructed to rinse, but not swallow, mouthwash. No more than a pea-size amount of toothpaste should be placed on a child's toothbrush to reduce the risk of accidental fluoride ingestion. Topical fluorides may be administered in the dental office.

Fluoride gels often are prescribed for adults and older adults. Such gels are effective in reducing the risk of coronal and root decay and tooth loss (Weintraub et al, 2006). Fluoride is most effective when given from birth through ages 12 to 13, the period when mineralization of unerupted permanent teeth occurs.

EARLY CHILDHOOD CARIES

Early childhood caries (ECC), often called “baby-bottle tooth decay,” describes a caries pattern in the maxillary anterior teeth of infants and young children. Characteristics include rapidly developing carious lesions in the primary anterior teeth and the presence of lesions on tooth surfaces not usually associated with a high caries risk. Because tooth decay remains a common oral disease of childhood, caries are a primary marker for a child's oral health. Good behavioral habits and child nutrition patterns must be encouraged, beginning in infancy.

Pathophysiology and Incidence

Often ECC follows prolonged bottle-feeding, especially at night, of juice, milk, formula, or other sweetened beverages. The extended contact time with the fermentable carbohydrate-containing beverages, coupled with the position of the tongue against the nipple, which causes pooling of the liquid around the maxillary incisors, particularly during sleep, contributes to the decay process. The mandibular anterior teeth usually are spared (see Figure 25-3) because of the protective position of the lip and tongue and the presence of a salivary duct in the floor of the mouth. In general, children from low-income families and minority populations experience the greatest amount of oral disease, the most extensive disease, and the most frequent use of dental services for pain relief; yet these children have the fewest overall dental visits (CDC, 2010).

Nutrition Care

Management of ECC includes diet and oral hygiene education for parents, guardians, and caregivers. Messages should be

FIGURE 25-3 Early childhood caries. (From Swartz MH: *Textbook of physical diagnosis, history, and examination*, ed 5, Philadelphia, 2006, Saunders.)

targeted to counter the health habits that contribute to this problem: poor oral hygiene, failure to brush a child's teeth at least daily, frequent use of bottles filled with sweetened beverages, and lack of fluoridated water. Dietary guidelines include removal of the bedtime bottle and modification of the frequency and content of the daytime bottles. Bottle contents should be limited to water, formula, or milk. Infants and young children should not be put to bed with a bottle. Teeth and gums should be cleaned with a gauze pad or washcloth after all bottle feedings. All efforts should be made to wean children from a bottle by 1 year of age. Educational efforts should be positive and simple, focusing on oral hygiene habits and promotion of a balanced, healthy diet. Between-meal snacks should include cariostatic foods. When foods are cariogenic, they should be followed by tooth brushing or rinsing the mouth. Parents and caregivers need to understand the causes and consequences of ECC and how they can be avoided.

CARIES PREVENTION

Caries prevention programs focus on a balanced diet, modification of the sources and quantities of fermentable carbohydrates, and the integration of oral hygiene practices into individual lifestyles. Meals and snacks should be followed with brushing, rinsing the mouth vigorously with water, or chewing sugarless gum for 15 to 20 minutes, preferably gum that contains xylitol (Splieth et al, 2009). Positive habits should be encouraged, including snacking on anticariogenic or cariostatic foods, chewing sugarless gum after eating or drinking cariogenic items, and having sweets with meals rather than as snacks. Despite the potential for a diet that is based on the dietary guidelines to be cariogenic, with proper planning and good oral hygiene a balanced diet low in cariogenic risk can be planned (see Figure 25-4 for a sample diet).

Practices to avoid include sipping sugar-sweetened and low pH beverages for extended periods. Adding lemon and other fruits to water has become a common practice but this lowers the pH and in general should be avoided. Frequent snacking and harboring candy, sugared breath mints, or hard candies in the mouth for extended periods are discouraged. Over-the-counter chewable or liquid medications and vitamin preparations, such as chewable vitamin C or liquid cough syrup, may contain sugar and contribute to caries risk. Patients with dysphagia may use thickening agents in beverages or liquid foods (soups) to reduce the risk of aspiration. Good oral hygiene should be emphasized in these situations because the thickening agent may contain fermentable carbohydrate, and the type of dysphagia may contribute to inadequate clearing of food from the oral cavity.

Fermentable carbohydrates such as candy, crackers, cookies, pastries, pretzels, snack crackers, chips, and even fruits should be eaten with meals. Notably, “fat-free” snack and dessert items and “baked” chips and snack crackers tend to have a higher simple sugar concentration than their higher fat-containing counterparts.

TOOTH LOSS AND DENTURES

Tooth loss (**edentulism**) and removable prostheses (dentures) can have a significant effect on dietary habits, masticatory function, olfaction, and nutritional adequacy. As dentition status declines, masticatory performance is compromised and may have a negative effect on food choices, resulting in decreased intake of meat, whole grains, fruits, and vegetables (Tsakos et al, 2010). This

Breakfast:	1½ cups toasted oat cereal + 1 cup low-fat milk or 2 slices wheat toast with 1 oz melted cheese 1 cup fresh berries coffee + low-fat milk BRUSH TEETH
Lunch:	2 slices of mushroom pizza small salad with 2 Tbs Italian dressing 16 oz spring water banana FOLLOW WITH 2 PIECES XYLITOL GUM
Afternoon snack:	1 cup pretzels + 1 oz cheese FOLLOW WITH 2 PIECES XYLITOL GUM
Dinner:	tossed salad with 2 Tbs grated cheese 1½ cups spaghetti + 1 cup marinara sauce + ½ cup sauteed peppers 1 cup fresh fruit salad 1 slice Italian bread with 1 pat margarine ½ cup ice cream 1 cup low-fat milk
Snack:	4 cups popcorn BRUSH TEETH BEFORE BED

FIGURE 25-4 A balanced diet plan with low cariogenic risk.

problem is more pronounced in older adults, whose appetite and intake may be compromised further by chronic disease, social isolation, and the use of multiple medications (see Chapter 8).

Dentures must be checked periodically by a dental professional for appropriate fit. Changes in body weight or changes in alveolar

bone over time possibly may alter the fit of the dentures. This is a common problem in the elderly that interferes with eating. Counseling on appropriate food choices and textures is advocated.

Nutrition Care

Full dentures replace missing teeth but are not a perfect substitute for natural dentition. Before and after denture placement, many individuals may experience difficulty biting and chewing. The foods found to cause the greatest difficulty for persons with complete dentures include fresh whole fruits and vegetables (e.g., apples and carrots), hard-crusted breads, and whole muscle meats. Therefore dietary assessment and counseling related to oral health should be provided to the denture wearer. Simple guidelines should be provided for cutting and preparing fruits and vegetables to minimize the need for biting and reduce the amount of chewing. The importance of positive eating habits must be stressed as a component of total health. Overall, guidelines that reinforce the importance of a balanced diet should be part of the routine counseling given to all patients.

OTHER ORAL DISORDERS

Oral diseases extend beyond dental caries. Deficiencies of several vitamins (riboflavin, folate, B₁₂, and C) and minerals (iron and zinc) may be detected first in the oral cavity because of the rapid tissue turnover of the oral mucosa. Periodontal disease is a local and systemic disease. Select nutrients play a role, including vitamins A, C, E; folate; beta-carotene; and the minerals calcium, phosphorus, and zinc.

Oral cancer, often a result of tobacco and alcohol use, can have a significant effect on eating ability and nutritional status. This problem is compounded by the increased caloric and nutrient needs of persons with oral carcinomas. In addition, surgery, radiation therapy, and chemotherapy are modalities used to treat oral cancer that also can affect dietary intake, appetite, and the integrity of the oral cavity. Some but not all problems affecting the oral cavity are discussed here with relevant nutrition care. Patients may try over-the-counter natural products to prevent or treat oral disease or conditions (see *Clinical Insight: Natural Products in Oral Health*).

CLINICAL INSIGHT

Natural Products in Oral Health

Natural products include herbal and dietary supplements and probiotics (National Center for Complementary and Integrative Health [NCCIH], 2015). The following lists some herbal and dietary supplements that may be used

to prevent or treat oral health issues. Other resources should be consulted to evaluate the efficacy and safety of natural products before choosing to use them in addition to or in place of conventional therapy.

Oral Use(s)	Natural Product	Use	Considerations
Mucositis	Hyaluronic acid	Topically (oral gel)	May cause allergic reaction in sensitive individuals
	German chamomile	Oral rinse	
	Glutamine	Oral rinse	
	Iodine	Oral rinse (in chemotherapy treatment)	
	Kaolin	Oral rinse (in radiation treatment)	
Mucosal lesions	Aloe	Oral rinse	Should not be ingested
	Slippery elm	Topically (lozenges)	
Periodontal disease	Coenzyme Q10	Systemically	
	Chitosan	Topically	
	Pomegranate extract and gotu kola extract	Topically	
Dental Caries	Fluoride	Topically	
	Xylitol	In chewing gum or in place of fermentable carbohydrate	

Natural Medicines Comprehensive Database (www.naturaldatabase.com).

PERIODONTAL DISEASE

Pathophysiology

Periodontal disease is an inflammation of the gingiva with infection caused by oral bacteria and subsequent destruction of the tooth attachment apparatus. Untreated disease results in a gradual loss of tooth attachment to the bone. Progression is influenced by the overall health of the host and the integrity of the immune system. The primary causal factor in the development of periodontal disease is plaque. Plaque in the **gingival sulcus**, a shallow, V-shaped space around the tooth, produces toxins that destroy tissue and permit loosening of the teeth. Important factors in the defense of the gingiva to bacterial invasion are (1) oral hygiene, (2) integrity of the immune system, and (3) optimal nutrition. The defense mechanisms of the gingival tissue, epithelial barrier, and saliva are affected by nutritional intake and status. Healthy epithelial tissue prevents the penetration of bacterial endotoxins into subgingival tissue.

Nutritional Care

Deficiencies of vitamin C, folate, and zinc increase the permeability of the gingival barrier at the gingival sulcus, increasing susceptibility to periodontal disease. Severe deterioration of the gingiva is seen in individuals with scurvy or vitamin C deficiency. Although other nutrients, including vitamins A, E, beta-carotene, and protein, have a role in maintaining gingival and immune system integrity, no scientific data support supplemental uses of any of these nutrients to treat periodontal disease. However when periodontal disease causes pain and avoidance of foods, nutrient intake may be limited and should be monitored (Staudte et al, 2012). The dietetics professional can make recommendations for modified food consistency to minimize nutrient deficits.

In societies in which malnutrition and periodontal disease are prevalent, poor oral hygiene is also usually evident. In such instances it is difficult to determine whether malnutrition is the cause of the disease or one of many contributing factors, including poor oral hygiene, heavy plaque buildup, insufficient saliva, or coexisting illness.

The roles of calcium and vitamin D relate to the link between osteoporosis and periodontal disease, in which bone loss may be the common denominator. Although causal relationships have not been determined, the association of calcium and dairy foods with periodontal disease warrants advocating a sufficient intake of dairy foods in those who tolerate them. Management strategies for the patient or client with periodontal disease follow many of the same guidelines as for caries prevention listed in [Box 25-2](#).

Severe periodontal disease may be treated surgically. Diet adequacy is particularly important before and after periodontal surgery, when adequate nutrients are needed to regenerate tissue and support immunity to prevent infection. Adequacy of calories, protein, and micronutrients should be part of the postoperative care plan.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Acute systemic diseases such as cancer and infections, as well as chronic diseases such as diabetes mellitus, autoimmune diseases, and chronic kidney disease, are characterized by oral manifestations that may alter the diet and nutritional status. Cancer therapies, including irradiation of the head and neck region, chemotherapy, and surgeries to the oral cavity, have a

significant effect on the integrity of the oral cavity and on an individual's eating ability, which may consequently affect nutrition status (see Chapter 36).

If the condition of the mouth adversely affects one's food choices, the person with chronic disease may not be able to follow the optimal diet for medical nutrition therapy. For example, poorly controlled diabetes may manifest in xerostomia or candidiasis, which may then affect the ability to consume a diet to appropriately control blood sugar, further deteriorating glucose control.

In addition, many medications alter the integrity of the oral mucosa, taste sensation, or salivary production (see Chapter 8). Phenytoin (Dilantin) may cause severe gingivitis. Many of the protease inhibitor drugs used to treat HIV and acquired immune deficiency syndrome (AIDS) are associated with altered taste and dry mouth. Reduced saliva may contribute to increased caries risk and also may alter the ability to form a bolus and swallow foods, especially dry foods that may crumble with mastication. Care should be taken to assess the effects of medication on the oral cavity and minimize these effects using alterations in diet or drug therapy.

Diabetes Mellitus

Diabetes is associated with several oral manifestations, many of which occur only in periods of poor glucose control. These include burning mouth syndrome, periodontal disease, candidiasis, dental caries, and xerostomia. The microangiopathic conditions seen in diabetes, along with altered responses to infection, contribute to risk of periodontal disease in affected persons. Tooth infection, more common in those with diabetes, leads to deterioration of diabetes control (Al-Khabbaz, 2014). In addition to blood glucose control, dietary management for people with diabetes after any oral surgery procedures or placement of dentures should include modifications in the consistency, temperature, and texture of food to increase eating comfort, reduce oral pain, and prevent infections or decay (see Chapter 30).

Fungal Infections

Oropharyngeal fungal infections may cause a burning, painful mouth and dysphagia. The ulcers that accompany viral infections such as herpes simplex and cytomegalovirus cause pain and can lead to reduced oral intake. Very hot and cold foods or beverages, spices, and sour or tart foods may cause pain and should be avoided. Consumption of temperate, moist foods without added spices should be encouraged. Small, frequent meals followed by rinsing with lukewarm water or brushing to reduce the risk of dental caries are helpful. Once the type and extent of oral manifestations are identified, a nutrition care plan can be developed. Oral high calorie–high protein supplements in liquid or pudding form may be needed to meet nutrient needs and optimize healing.

Head and Neck Cancers

Head, neck, and oral cancers can alter eating ability and nutrition status because of the surgeries and therapies used to treat these cancers. Surgery, depending on the location and extent, may alter eating or swallowing ability, as well as the capacity to produce saliva. Radiation therapy of the head and neck area and chemotherapeutic agents can affect the quantity and quality of saliva and the integrity of the oral mucosa. Thick, ropery saliva is often the result of radiation therapy to the head and neck

TABLE 25-3 Effects of Oral Infections

Location	Problem	Effect	Diet Management
Oral cavity	Candidiasis, KS, herpes, stomatitis	Pain, infection, lesions, altered ability to eat, dysgeusia	Increase kilocalorie and protein intake; administer oral supplements; provide caries risk reduction education
	Xerostomia	Increased caries risk, pain, difficulty with mastication, lack of saliva to form bolus, tendency of food to stick, dysgeusia	Moist, soft, nonspicy foods; “smooth” cool or warm foods and fluids; caries risk reduction education
Esophagus	Candidiasis, herpes, KS, cryptosporidiosis	Dysphagia, odynophagia	Try oral supplementation first; if that is unsuccessful, initiate NG feedings using silastic feeding tube or PEG
	CMV, with or without ulceration	Dysphagia, food accumulation	PEG

CMV, Cytomegalovirus; KS, Kaposi sarcoma; NG, nasogastric; PEG, percutaneous endoscopic gastrostomy.

area, causing xerostomia. Dietary management focuses on the recommendations described earlier for xerostomia, along with modifications in food consistency after surgery (see Chapters 36 and 40).

HIV Infection and AIDS

Viral and fungal infections, stomatitis, xerostomia, periodontal disease, and Kaposi sarcoma are oral manifestations of HIV that can cause limitations in nutrient intake and result in weight loss and compromised nutrition status. These infections often are compounded by a compromised immune response, preexisting malnutrition, and gastrointestinal consequences of HIV infection (see Chapter 37). Viral diseases, including herpes simplex and cytomegalovirus, result in painful ulcerations of the mucosa.

Stomatitis, or inflammation of the oral mucosa, causes severe pain and ulceration of the gingiva, oral mucosa, and palate, which makes eating painful. **Candidiasis** on the tongue, palate, or esophagus can make chewing, sucking, and swallowing painful (odynophagia), thus compromising intake. [Table 25-3](#) outlines the effects of associated oral infections.

Xerostomia

Xerostomia (dry mouth) is seen in poorly controlled diabetes mellitus, Sjögren syndrome, other autoimmune diseases, and as a consequence of radiation therapy and certain medications (see [Box 25-3](#)). Xerostomia from radiation therapy may be more permanent than that from other causes ([Kielbassa et al, 2006](#)). Radiation therapy procedures to spare the parotid gland should be implemented when possible to reduce the damage to the salivary gland. Efforts to stimulate saliva production using pilocarpine and citrus-flavored, sugar-free candies may ease eating difficulty.

Individuals without any saliva at all have the most difficulty eating; artificial salivary agents may not offer sufficient relief. Lack of saliva impedes all aspects of eating, including chewing, forming a bolus, swallowing, and sensing taste; causes pain; and

increases the risk of dental caries and infections. Dietary guidelines focus on the use of moist foods without added spices, increased fluid consumption with and between all meals and snacks, and judicious food choices.

Problems with chewy (steak), crumbly (cake, crackers, rice), dry (chips, crackers), and sticky (peanut butter) foods are common in persons with severe xerostomia. Alternatives should be suggested, or the foods should be avoided to avert dysphagia risk. Drinking water with a lemon or lime twist or citrus-flavored seltzers or sucking on frozen tart grapes, berries, or sugar-free candies may help. Because these foods or beverages may contain fermentable carbohydrate or contribute to reduced pH, good oral hygiene habits are important in reducing the risk of tooth decay and should be practiced after all meals and snacks.

CLINICAL CASE STUDY

Gina is a 74-year-old woman with a history of type 2 diabetes, hypertension, and arthritis. She states that her dentist told her she has xerostomia and periodontal disease and will need multiple tooth extractions and a full maxillary (upper) and partial mandibular (lower) denture. Because of the condition of her teeth she consumes soft foods and lots of diet soda because her mouth always feels dry. She takes glyburide for glucose control, amlodipine (Norvasc) for blood pressure control, and glucosamine and chondroitin to alleviate her arthritis. She is 5'1" and weighs 176 lb. She lives alone, but receives assistance with food shopping and cooking from her family and friends. She occasionally conducts self-monitoring fasting glucose via fingerstick and states that her usual reading is 150 mg/dl.

Nutrition Diagnostic Statements

1. Chewing difficulty secondary to poor dentition and xerostomia as evidenced by patient report and choice of soft foods.
2. Altered nutrition-related laboratory value (glucose) secondary to diabetes and possibly food choices as evidenced by inadequate blood glucose control.

Nutrition Care Questions

1. What are the cultural, educational, and environmental influences affecting dental and nutritional health?
2. What are the diet counseling recommendations for the dental conditions (anticipated extractions, dry mouth, full and partial dentures)?
3. List an appropriate intervention for each of the diagnostic statements. How would you evaluate the impact of your intervention?
4. What would you assess at your follow-up (monitoring) appointment with Gina?

BOX 25-3 Medications that May Cause Xerostomia

Antianxiety agents	Diuretics
Anticonvulsants	Narcotics
Antidepressants	Sedatives
Antihistamines	Serotonin reuptake inhibitors
Antihypertensives	Tranquilizers

Medical Nutrition Therapy

This section contains chapters that reflect the evolution of nutritional science, from the identification of nutrient requirements and the practical application of this knowledge, to the concepts that relate nutrition to the prevention of chronic and degenerative diseases and optimization of health. The role of nutrition in reducing inflammation, a contributor to the state chronic disease, supports the awareness of diet in disease prevention and management.

Medical nutrition therapy (MNT) includes the assessment, nutrition diagnosis, interventions, monitoring, and evaluation of established disease. In some cases, medical nutrition therapy is a powerful preventive measure. The list of diseases amenable to nutrition intervention continues to increase, especially because hundreds of conditions are now known to have a genetic component and a connection with the nutrient-gene expression pathway.

Sophisticated feeding and nourishment procedures place an increased responsibility on those who provide nutrition care. The nutrition-related disorders included here can be managed by changes in dietary practices based on current knowledge. The goal in all cases is to move the individual along the continuum of disease and health management toward better nutritional health and overall well-being.

Medical Nutrition Therapy for Adverse Reactions to Food: Allergies and Intolerances

*L. Kathleen Mahan, MS, RDN, CD
Kathie Madonna Swift, MS, RDN, LDN, FAND*

Consultant Reviewer: Janice M. Joneja, PhD, RD

KEY TERMS

adverse reactions to food (ARF)	Food Allergen Labeling and Consumer Protection Act (FALCPA)	latex-fruit syndrome or latex-food syndrome
allergen	food allergen-specific serum IgE testing	“leaky gut”
anaphylaxis	food allergy	lymphocyte
antibodies	food and symptom record	macrophage
antigen	food autoimmune or immune reactivity	mast cells
antigen-presenting cell (APC)	food challenge	microbiome
atopic dermatitis (eczema)	food dependent exercise-induced anaphylaxis (FDEIA)	microbiota
atopy	food immunotherapy vaccine	monocytes
basophils	food intolerance	neutrophils
B-cells	food protein-induced enterocolitis syndrome (FPIES)	natural rubber latex (NRL)
CAP-fluorescein-enzyme immunoassay (FEIA)	food protein-induced proctocolitis (FPIP)	oral allergy syndrome (OAS)
conformational epitopes	food sensitivity	oral tolerance
cow’s milk protein allergy (CMPA)	granulocyte	pollen-food syndrome (PFS)
cross-reactivity	gut-associated lymphoid tissue (GALT)	prebiotics
cytokines	haptens	probiotics
dendritic cells (DCs)	histamine	radioallergosorbent test (RAST)
double-blind, placebo-controlled food challenge (DBPCFC)	increased intestinal permeability or “leaky gut”	sensitivity-related illness (SRI)
dysbiosis	IgE-mediated food allergy	sensitization
elimination diet	immunoglobulin (Ig)	skin-prick test
eosinophils	inflammatory mediators	specific oral tolerance induction (SOTI)
eosinophilic esophagitis (EoE)		T-cells
eosinophilic gastroenteritis (EGE)		Th cells
epigenetics		Th1 cells
epitope		Th2 cells

There is growing evidence that adverse reactions to food (ARFs) are more prevalent than in the past, with a defined increase in severity and scope (Skypala, 2011). Changes in the modern diet and environmental influences interacting with genetic predisposition have been implicated in the escalation of ARFs and the parallel rise in other chronic disorders such as asthma and autoimmune diseases. Estimates suggest that 20% of the population alter their diet because of perceived ARFs (Sicherer and Sampson, 2010; Turnbull et al, 2015). Currently the prevalence of food allergy in the U.S. population, when documented objectively with serologic assessment and food challenges, is 2.5% to 3%. The prevalence is higher in children and is estimated to be about 4% to 7%, and in adults it is estimated to be 1% to 2% (Turnbull et al, 2015).

ARFs are implicated in many conditions as a result of the involvement of major organ systems, including the dermatologic, respiratory, gastrointestinal, and neurologic systems. The management of ARFs is complex because of the diverse response by which the body reacts to food constituents and the multifaceted nature of the mechanisms involved. The clinical relevance of ARFs should be carefully assessed and evaluated in the nutrition care process, because they can greatly affect a person’s quality of life.

DEFINITIONS

It is important to comprehend the language of ARFs; it can be a source of confusion and misunderstanding (see [Box 26-1](#)).

BOX 26-1 Adverse Reactions to Foods: Definitions

- **Adverse reactions to food (ARFs):** encompass food allergies and food intolerances, both of which can result in distressing symptoms and adversely affect health
- **Atopy:** a condition of genetic predisposition to produce excessive IgE antibodies in response to an allergen that results in the development of typical symptoms such as asthma, rhinoconjunctivitis, or eczema
- **Food allergy:** an adverse immune-mediated reaction to a food, usually a food protein, glycoprotein, or hapten that the person has been sensitized to, and which, when eaten, causes the release of inflammatory mediators or chemicals that act on body tissues and result in symptoms
- **Food autoimmune or immune reactivity:** the concept that when the body's normal tolerance of friendly antigenic substances (autoantigens produced by an individual's body) is disrupted because of disease, injury, shock, trauma, surgery, drugs, blood transfusion, or environmental triggers, the ingestion of foods containing antigenic substances with a composition similar to those of the body's autoantigens can result in the production of antibodies that react to the food antigens and the body's own tissues (Vojdani, 2015)
- **Food intolerance:** an adverse reaction to a food or food additive that does not involve the immune system and results from the body's inability to digest, absorb, or metabolize a food or component of the food
- **Food sensitivity:** a term often used to describe a reaction when it is unclear whether it is immunologically mediated or due to a biochemical or physiologic defect
- **Oral tolerance:** the process that allows an individual to eat food (which is "foreign") without any ill effects or reactions to it
- **Sensitivity-related illness:** the concept that an individual who is exposed to some type of toxicant or insult may then, by as yet unclear mechanisms, become sensitive to a food, inhalant, or chemical (Genuis, 2010)

Adverse reactions to food (ARF) encompass food allergies and food intolerances, both of which can result in distressing symptoms and adversely affect health. **Food allergy** is an immune system response that is triggered when a food is eaten by a person who has been sensitized to it. An **antigen** is any molecule that will elicit an immune response in the body. When it elicits a hypersensitivity reaction as in allergy, it is called an **allergen**. The key event in food allergy is the recognition of the food by components of the immune system, which then cause the release of chemicals (inflammatory mediators) that act on body tissues and result in a specific set of symptoms. The allergen is usually a food protein or a glycoprotein (protein to which a carbohydrate chain is attached) or a **hapten** (a small inorganic compound that can elicit an immune response when attached to a large carrier protein). An **epitope** is the actual section of the allergen that connects with the immune molecule. Some carbohydrates can act as allergens on their own and are referred to as carbohydrate epitopes (Soh et al, 2015). These carbohydrate epitopes are responsible for much of the cross-reactivity between allergens (Soh et al, 2015). There is also the possible contribution of genetically modified or engineered (GM or GE) molecules in food crops to act as epitopes and

allergens and result in sensitization and food allergy. This remains an area of ongoing investigation (Ladics et al, 2014) (see *Focus On: GMO or Genetically Engineered (GE) Foods*).

The adverse reactions that occur are caused by the individual's unique response to the food, not by the food itself. Furthermore, the symptoms of the allergy in one individual can differ greatly from those in another in response to the same food. Symptoms of food allergy are noted in **Box 26-2**.

The definition of allergy has been broadened to encompass any immunologic reaction to a component of food resulting in adverse symptoms and now includes reactions to foods that include the following:

- Reactions that elicit production of specific IgE
- Reactions that result from release of inflammatory mediators in response to IgE produced against nonfood materials such as inhaled pollens or latex
- Reactions that result from inflammatory mediators released from granulocytes such as eosinophils in the digestive tract
- Food protein enteropathies due to proteins in milk or soy
- Food-associated disease such as gluten-sensitive enteropathy (celiac disease), which has an immune component

BOX 26-2 Symptoms of Food Allergy

Gastrointestinal

Abdominal pain
Abdominal bloating and distention
Indigestion
Belching
Nausea
Vomiting
Constipation
Diarrhea
Gastrointestinal bleeding
Oral and pharyngeal pruritus

Skin and Mucous Membranes

Urticaria (hives)
Angioedema (swelling of deeper tissues)
Eczema (atopic dermatitis)
Contact dermatitis
Erythema (skin inflammation)
Pruritus (itching)
Redness (erythema)
Oral allergy syndrome

Respiratory

Rhinitis
Rhinorrhea (runny nose)
Asthma
Bronchospasm
Cough
Laryngeal edema (throat tightening due to swelling of tissues)
Airway tightening
Hoarseness

Eyes, Ears, Nose, and Throat

Dark circles around eyes
Spots before eyes
Serous otitis media (earache with effusion)
Conjunctivitis (itchy, watery reddened eyes)

Systemic

Anaphylaxis
Hypotension
Dysrhythmias

Nervous System

Migraine headaches
Other headaches
Listlessness
Hyperactivity
Lack of concentration
Tension-fatigue syndrome
Fibromyalgia
Irritability
Chilliness
Dizziness

Other

Frequent urination
Bed-wetting
Excessive sweating
Pallor
Muscle aches
Low-grade fever

The umbrella generic term **food sensitivity** is used when it is unclear whether the reaction is immunologically related or due to a biochemical or physiologic defect (Jones, 2013).

Food intolerance is an adverse reaction to a food or food additive that does not involve the immune system and results from the body's inability to digest, absorb, or metabolize a food or component of the food (Jones, 2013; Turnbull et al, 2015). It may be caused by a toxic, gastrointestinal, pharmacologic, genetic/metabolic, psychogenic, or an idiopathic reaction to a food or chemical substances in that food. For example, an individual can be intolerant to milk not because of an allergy to milk protein, but because of an inability to digest the carbohydrate lactose (see Figure 26-1).

An emerging hypothesis called **sensitivity-related illness** proposes that an individual who is exposed to some type of toxicant or insult, usually in the GI tract, may subsequently become sensitive to food, inhalants, or chemicals (Genius, 2010).

ETIOLOGY

ARFs illustrate the critical importance of appreciating “biochemical uniqueness” as a core clinical concept in nutrition assessment. Numerous factors, including genetics and epigenetics, intestinal barrier integrity, microbiota, and loss of biodiversity, maternal and early fetal and early life factors such as cesarean delivery and lack of breastfeeding, stress, psychologic factors, exercise, and environmental and physiologic influences such as changes in hormone levels, affect an individual's unique response to food or food component and its ultimate interpretation by the body as either “friend” or “foe.”

Genetics and Epigenetics

Food allergy has a hereditary component that is not yet clearly defined. **Atopy** is a condition of genetic predisposition to produce IgE antibodies in response to an **allergen** and to develop typical symptoms. Atopic individuals, usually identified in infancy and confirmed by positive skin-prick test, are characterized

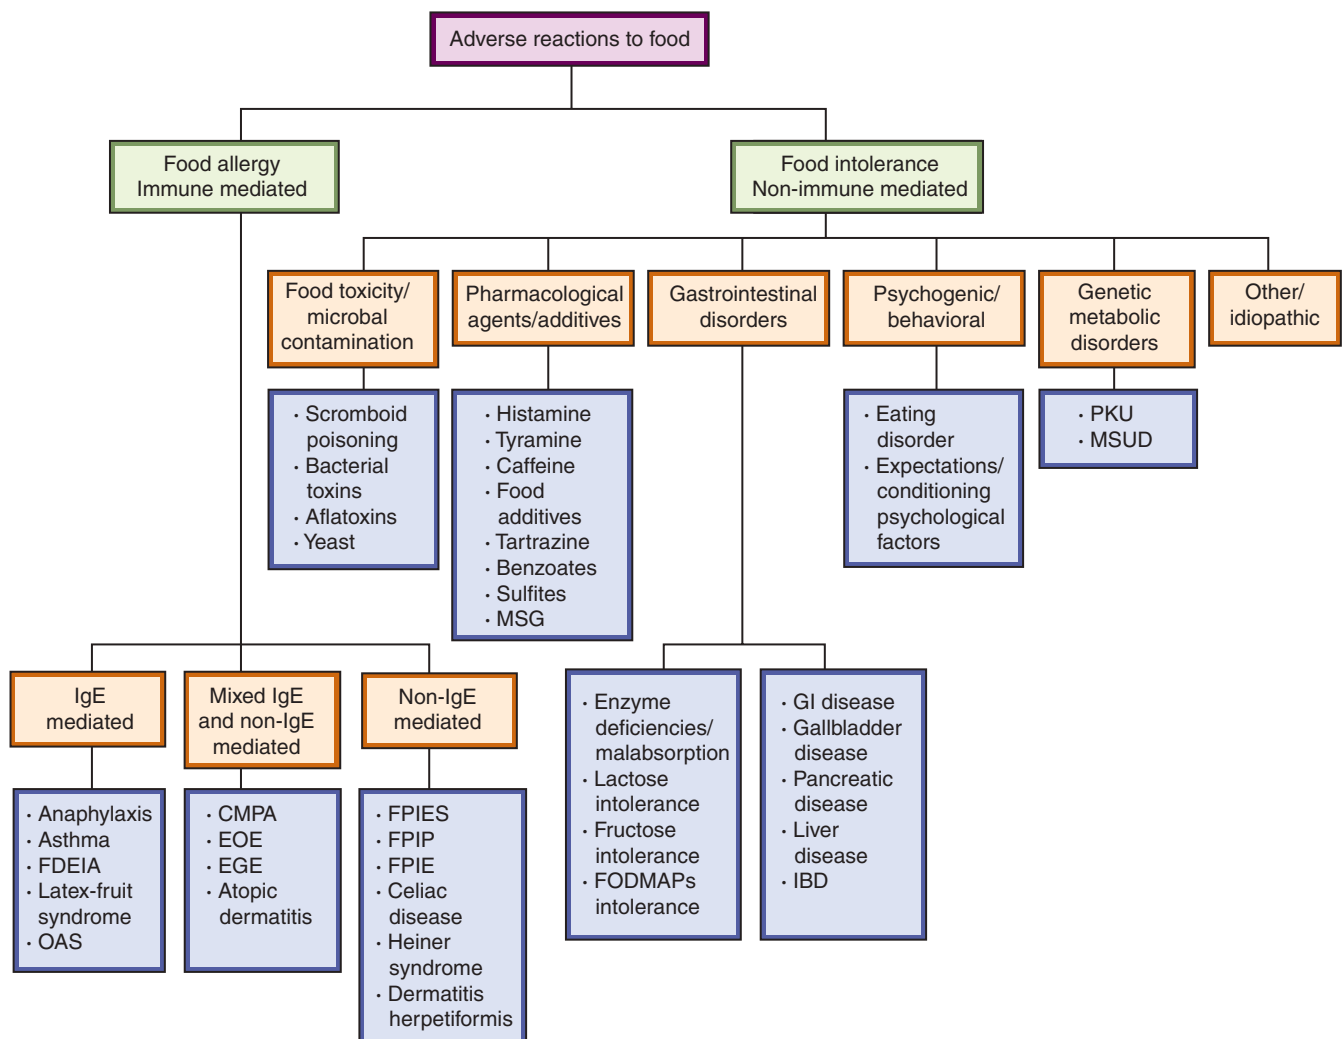

FIGURE 26-1 Adverse reactions to food. CMPA, cow's milk protein allergy; EOE, eosinophilic esophagitis; EGE, eosinophilic gastroenteritis; FDEIA, food dependent exercise-induced anaphylaxis; FODMAPs, fructose, oligo-, di-, monosaccharides, and polyols syndrome; FPIE, food protein-induced enteropathy; FPIES, food protein-induced enterocolitis syndrome; FPIP, food protein-induced proctocolitis; IBD, inflammatory bowel disease; MSUD, maple syrup urine disease; OAS, oral allergy syndrome; PKU, phenylketonuria.

by severe IgE-mediated reactions to dander, pollens, food, or other environmental factors, which present as food allergy, **atopic dermatitis (eczema)**, atopic conjunctivitis, atopic rhinitis, asthma, and symptoms in all organ systems, with the most severe being life-threatening anaphylaxis (see [Box 26-2](#)). A study of Finnish children showed that up to the age of 4 years, children with two parents reporting any type of allergic reaction were three times as likely to have a food allergy as children with allergy-free parents. Children with one allergic parent were twice as likely to have a food allergy ([Pyrhönen et al, 2011](#)).

However, genetic susceptibility alone does not completely explain the prevalence of food allergy. **Epigenetic** factors may alter the genetic expression of food allergy and atopy (see Chapter 5). Environmental exposures in early childhood such as diet, maternal or family smoking, air pollution, and microbial contact may, through epigenetic mechanisms, induce a long-lasting propensity that then influences the development of allergic symptoms ([Tezza et al, 2013](#)). Most likely it is multiple environmental changes or exposures over a lifetime at specific intervals (including pregnancy) that interact to predispose an individual to allergic sensitization and expression of allergic disease ([Haahnela et al, 2013](#)).

Antigen Exposure and Oral Tolerance

Humans are exposed to thousands of foreign molecules daily from food and the environment. Exposure to these foreign molecules in the digestive tract is usually followed by immune regulation or suppression, such that the food is recognized as “foreign but safe,” which is a prerequisite for the development of tolerance to a food or food molecule. This is known as **oral tolerance** ([Brandtzaeg, 2010](#); [Weiner et al, 2011](#)). Oral tolerance is mediated by several immune cells, including antigen-presenting cells, such as **dendritic cells (DCs)** and **macrophages**, and regulatory T-cells (T_{reg} cells), which are important suppressors of cellular and humoral immune responses ([Bauer et al, 2015](#)).

Food allergy occurs when oral tolerance fails and the food ingested acts as an allergen causing an immune-mediated reaction as discussed below. Ongoing research is focused on how oral tolerance develops and is maintained.

The amount of antigen presented to the sensitized immune cell also influences whether allergy symptoms develop. The effects of food antigens and other antigens may be additive. For example, clinical symptoms of food allergy may increase when

inhalant allergies are exacerbated by seasonal or environmental changes. Similarly, the effects of environmental factors, toxins, tobacco smoke, stress, and exercise may exacerbate the clinical symptoms of food allergy.

The Gastrointestinal Function and the Microbiome

Gastrointestinal (GI) function and the ability to prevent the inappropriate passage of molecules through the intestinal wall is key to maintenance of oral tolerance and avoidance of the allergic response. Essential to this function of the GI tract is the presence of the **microbiota**, the population of bacteria that live in the human gut—about 10 trillion of them, with most of them residing in the lower GI tract. The **microbiome** is the collection of genes belonging to hundreds of different types of bacteria that live on the skin and in the gut. **Dysbiosis** exists when there is an imbalance in the microbiota, which can impair digestion and affect overall health.

Dysbiosis contributes to **increased intestinal permeability**, also referred to as “**leaky gut**,” and the increased likelihood that inappropriate molecules will pass through and reach the lymphoid tissue, leading to allergy development. Disruptions in the microbiota and the intestinal wall barrier are the result of various factors, including cesarean delivery, lack of breastfeeding, antibiotics, chronic stress, infections, and alterations in the microbiota (see Chapters 1 and 28 for further discussion of the microbiota).

The **gut-associated lymphoid tissue (GALT)** is the largest mass of lymphoid tissue in the body. A leaky gut with altered GI permeability and possible dysbiosis allows antigen penetration and presentation to the GALT lymphocytes and sensitization ([Fritscher-Ravens et al, 2014](#); [Groschwitz and Hogan, 2009](#)). Other conditions such as GI disease, malnutrition, fetal prematurity, and immunodeficiency also may be associated with increased gut permeability and risk of development of food allergy (see [Figure 38-4](#)).

The Immune System Arsenal

Antibodies contain a globulin protein; because of their association with the immune system, they are referred to as **immunoglobulins (Ig)**. Five distinct classes of antibodies have been identified: IgA, IgD, IgE, IgG, and IgM. Each Ig has a specific function in immune-mediated reactions (see [Box 26-3](#)).

Lymphocytes are the “command and control” cells of the immune system and include two important groups: **B-cells**, arising from stem cells in the bone marrow, and **T-cells**

BOX 26-3 The Immunoglobulins

IgA

Found in two forms—serum IgA and secretory IgA (sIgA). The latter is present in mucus secretions in the mouth, respiratory and gastrointestinal tracts, vagina, and colostrum in mammalian milk. It includes a “secretory piece” in its structure that protects it from protein-destroying enzymes in the digestive tract so that it survives in an active form as a “first-line” defense against antigens entering from the external environment. Serum IgA, which does not have the secretory piece, is in the second highest amount in circulation, exceeded only by IgG.

IgD

Found in small amounts in the tissues that line the belly and chest; involved in immunoglobulin class switching; its role in allergy is probably minimal.

IgE

The classic allergy antibody of hay fever, asthma, eczema, and food-induced anaphylaxis, oral allergy syndrome, and immediate gastrointestinal hypersensitivity reactions. Immediate allergic reactions usually involve IgE and are the most clearly understood mechanisms.

IgG

The only antibody that crosses the placenta from mother to baby. Defends against pathogens and persists long after the threat is over; it may be responsible for some non-IgE-mediated hypersensitivity reactions. Four subtypes include IgG1, IgG2, IgG3, and IgG4. IgG4 has been implicated in some types of adverse reactions to food. Food protein-specific IgG antibodies tend to rise in the first few months after the introduction of a food and then decrease even though the food may continue to be consumed. It appears to be part of the process of development of tolerance to a food. A rise in antigen-specific IgG4 accompanied by a drop in IgE often indicates recovery (tolerance) from a food allergy. People with inflammatory bowel disorders such as celiac disease or ulcerative colitis often have high levels of IgG and IgM ([Stapel et al, 2008](#)), possibly indicating the passage of food molecules as “foreign invaders” into circulation.

IgM

The largest antibody; a first-line defender that can mop up many antigens at one time. It is produced by the fetus in utero and its level rises in the presence of an in utero infection.

also originate from stem cells but are later transported to the thymus gland, where they mature. **Monocytes** and macrophages are primarily phagocytes that engulf foreign material, break it apart, and display specific molecules of the material on their surfaces, making them **antigen-presenting cells (APC)**. The antigenic component displayed on the surface is an epitope and is recognized by T-cells. T-cells respond by generating a cytokine message that stimulates their differentiation.

T-cells are a diverse group of lymphocytes with several different roles in the immune response under different circumstances, and they secrete different sets of cytokines. **Th cells** are helper cells that moderate and adjust the system. **Th1 cells** regulate the activities of the B-cells to produce antibodies and direct damage to target cells, resulting in the destruction of antigens. This function is useful in defending against bacteria, viruses, and other pathogenic cells. **Th2 cells** mediate the allergic response by regulating the production by B-cells of IgE sensitized to food or other allergens. Other T cells are T-regulatory cells (T-reg cells) and T-suppressor cells that regulate the immune response so that there is tolerance of the foreign but safe molecule.

In the process of making antibodies, the B-cells convert to plasma cells and the antibodies, or IgE, is generated from the plasma cells (see Figure 26-2). These allergen-specific antibodies attach themselves to **mast cells** (in the lungs, skin, tongue, and linings of the nose and intestinal tract) or **basophils** (in circulation).

Mast cells and basophils are granulocytes. **Granulocytes** contain intracellular granules, or small vessels that are storage depots for defense chemicals or inflammatory mediators that protect the body from invading pathogens but also cause allergic symptoms. Allergen-specific IgE antibodies attach to the surface of a mast cell by coupling with specific receptors on the cell's surface. When the eliciting allergens enter on a subsequent occasion, they attach to their matching (homologous) IgE antibodies on the mast cell's surface. The allergen attaches to two adjacent IgE molecules, forming a "bridge" between them. This bridging activates the mast cell by a series of energy-requiring processes, resulting in calcium channeling into the cell. This triggers degranulation of the intracellular granules, releasing the **inflammatory mediators**, such as **histamine** (in greatest amount), prostaglandins, leukotrienes, and **cytokines**.

FIGURE 26-2 Sensitization process and IgE-mediated allergic reaction.

Each of the mediators has a specific effect on local tissues and at distant sites, resulting in the symptoms of allergy (Jones, 2013). Other granulocytes such as **neutrophils** and **eosinophils** are attracted to the reaction site by mediators such as chemokines. These arise from degranulation of mast cells and release additional inflammatory chemicals, which further enhance the allergic response, resulting in increased symptom severity. This is also evidenced in a later biphasic reaction or recurrence of symptoms after the initial response has waned.

PATHOPHYSIOLOGY

The basic pathophysiology of the allergic response can be described in three phases: the breakdown of oral tolerance, allergen sensitization, and reactivity to allergens leading to allergy symptoms (Bauer et al, 2015). Other mechanisms still under investigation are increases in gastric pH, direct action of bioactive chemicals, neuroenteric hypersensitivity, and osmotic effects with luminal distention (Swift and Lisker, 2012).

Oral tolerance, as already discussed, is the norm in most individuals. It is the breakdown or loss of oral tolerance that promotes allergen sensitization. Loss of oral tolerance is associated with a lowered T_{reg} cell response and increased levels of APCs reaching the epithelial cells of the intestinal mucosa. With loss of oral tolerance, the immune system mistakenly recognizes a food or molecule as foreign.

When a food or molecule is no longer seen as safe, the second phase, **sensitization**, takes place, in which immune cells respond at this first exposure to the allergen. This is characterized by a Th-2 response and involves dendritic and epithelial cells.

The third phase is reactivity to allergens such that whenever that same foreign material or allergen enters the body, the immune system responds with an immune-mediated reaction, usually with the release of inflammatory mediators or defensive chemicals, resulting in allergic symptoms. Because individuals can develop immunologic sensitization, as evidenced by the production of allergen-specific IgE without having clinical symptoms

upon subsequent exposure to those foods, an **IgE-mediated food allergy** requires the presence of sensitization and the development of specific signs and symptoms on exposure to the food. Sensitization alone is not sufficient to define food allergy (Boyce et al, 2011; NIH, NIAID, 2010; Vickery et al, 2011) (see Figure 26-2).

IgE-Mediated Reactions

IgE-mediated food allergic reactions are rapid in onset, occurring within minutes to a few hours of exposure. The methods of exposure include inhalation, skin contact, and ingestion. A wide range of symptoms has been attributed to this type of food allergy and frequently involve the GI, dermatologic, or respiratory systems and can range from mild hives to life-threatening multiple organ anaphylaxis.

A few foods account for the vast majority of IgE-mediated allergic reactions: milk, eggs, peanuts, tree nuts, soy, wheat, fish, shellfish, and sesame (see <http://foodallergysupport.olicentral.com/index.php/topic,319.45.html> for more information on sesame allergies). However, any food is capable of eliciting an IgE-mediated reaction after a person has been sensitized to it. Food-induced anaphylaxis, asthma, urticaria (hives), eczema, oral allergy syndrome (OAS), latex-fruit allergy, and food dependent exercise-induced anaphylaxis (FDEIA) are IgE-mediated immune reactions (see Table 26-1).

Food-Induced Anaphylaxis

Food-induced **anaphylaxis** is an acute, often severe, and sometimes fatal immune response that usually occurs within a limited period following exposure to an antigen. Multiple organ systems are affected. Symptoms can include respiratory distress, abdominal pain, nausea, vomiting, cyanosis, arrhythmia, hypotension, angioedema, urticaria, diarrhea, shock, cardiac arrest, and death. The vast majority of anaphylactic reactions to foods in adults in North America involve peanuts, tree nuts, fish, and shellfish, whereas in children peanuts and tree nuts are the most common causes of anaphylactic reactions but anaphylactic reactions to milk have been reported (Jones, 2013).

TABLE 26-1 Types of Allergic Reactions

Reaction/Classification	IgE-Mediated	Mixed IgE- and Non-IgE-Mediated
Mechanism	Th2 activation stimulates production of IgE antibodies by activated B-cell lymphocytes. The allergen binds with sensitized IgE antibodies on mast cells or basophils. Upon binding, chemical inflammatory mediators are released from the cell.	Antibodies and T-cells are associated with triggering inflammatory mediators and the development of symptoms.
Timing	First phase: Immediate hypersensitivity, minutes to 1 hour Late phase: May occur several hours after initial response, usually 4-6 hours after first phase	Delayed onset >2 hr; chronic, relapsing
Systemic	Anaphylaxis	
Skin and mucous membranes	Atopic dermatitis (eczema), angioedema, contact dermatitis, flushing, pruritus, urticarial (hives)	Atopic dermatitis, contact dermatitis, dermatitis herpetiformis
Gastrointestinal	Abdominal pain and bloating, belching, constipation, diarrhea, indigestion, nausea and vomiting	Eosinophilic esophagitis (EOE), eosinophilic gastroenteritis (EGE), food-protein-induced enteropathies (FPIES), celiac disease
Respiratory	Acute rhinitis (stuffy nose, hay fever), rhinorrhea (runny nose), allergic conjunctivitis (itchy, reddened, watery eyes) asthma, bronchospasm, laryngeal edema (throat tightening because of swelling of tissues)	Asthma, pulmonary hemosiderosis (Heiner syndrome)
Nervous system	Dizziness, headaches, hyperactivity, listlessness, irritability, migraine headaches, spots before eyes, tension-fatigue syndrome	Diverse symptoms similar to those listed for IgE mediated
Other	Bed-wetting, dark circles under eyes, excessive sweating, low-grade fever, hoarseness, myalgias, pallor	Diverse symptoms similar to those for IgE mediated

FPIES, Food protein-induced enterocolitis syndrome; Ig, immunoglobulin.

From Jones JV: *The health professional's guide to food allergies and intolerances*, Chicago, 2013, Academy of Nutrition and Dietetics, p 44.

Peanuts are the most common food allergen in fatal anaphylactic reactions (Turnbull et al, 2015).

People with known anaphylactic reactions to food allergens should carry and be prepared to use, epinephrine via an injectable adrenaline at all times. Epinephrine is the drug of choice to reverse an allergic reaction, even with asthma (Franchini et al, 2010). Delayed use of epinephrine has been associated with an increased risk of biphasic reactions, in which a recurrence of symptoms 4 to 12 hours after the initial anaphylactic reaction may be fatal.

Oral Allergy or Pollen-Food Allergy Syndrome

The **oral allergy syndrome (OAS)**, or **pollen-food syndrome (PFS)**, results from direct contact with food allergens in a person primarily sensitized to a specific pollen. Symptoms of OAS are confined almost exclusively to the oropharynx and include itchy mouth, scratchy throat, or swelling of the lips, mouth, uvula, tongue, and throat tightness. Itchy ears are sometimes reported. Rarely, other target organs are involved. However, there may be a reaction later (biphasic) because of histamine release in the gastrointestinal tract. OAS may be severe and present as hives, wheezing, vomiting, diarrhea, and low blood pressure or even anaphylaxis, but this is rare (American College of Allergy, Asthma and Immunology [ACAAI], 2015; <http://acaai.org/allergies/types/food-allergies/types-food-allergy/oral-allergy-syndrome>, accessed March 20, 2015).

Sensitization to the pollen occurs through the respiratory system (Fernandez-Rivas et al, 2006). The reaction to foods occurs as a result of the presence of an antigen within the food that has a structure similar to that of the pollen; it is a situation of **cross-reactivity** between inhaled and ingested proteins. The primary sensitization is to the pollen, not the food. Symptoms are rapid and appear within 5 to 30 minutes upon ingestion of the allergen-containing food, and most often subside within 30 minutes. In severe cases, throat tightening can occur as a result of swelling of tissues within the area; asphyxiation has been reported in rare instances.

OAS is most commonly seen in individuals with coexisting seasonal allergic rhinitis to trees, in particular alder and birch, ragweed, other weeds (e.g., mugwort), or grass pollens, following ingestion of specific fruits, vegetables, and some nuts (Geroldinger-Simic et al, 2011). The cooked fruit or vegetable is often tolerated because the reactions are caused by predominately heat-labile proteins, which are changed during cooking. However, this is not always the case, and a careful history and questioning about the food is important (Kondo and Urisu, 2009). **Box 26-4** lists the foods and pollens most commonly linked with OAS.

Because reactions are immediate after ingestion of the raw food, most individuals can identify the food culprit. However, if it is not obvious, an OAS elimination diet may be useful followed by careful challenge with a small amount of the food applied to the lip with observation for any reaction. Only those foods that cause an adverse reaction must be avoided.

Latex-Fruit or Latex-Food Syndrome

Natural rubber latex (NRL), used in latex rubber gloves, clothing, bottle nipples, children's rubber toys, elastic bands, and many other articles in the environment contain many proteins that can be highly allergenic. The allergic reaction is IgE-mediated and is often seen in health care workers (8% to 17%), other workers using latex rubber gloves such as hairdressers or house cleaners, those working in the latex industry, and in those undergoing multiple surgical procedures in which they have been exposed to latex rubber surgical gloves and appliances (68% of children with spina bifida) (American Latex Allergy Association, 2015, <http://>

latexallergyresources.org/statistics). Symptoms of NRL allergy include contact dermatitis, eczema, angioedema, rhinoconjunctivitis, asthma, and, in severe cases, anaphylaxis.

It is estimated that 50% to 70% of people with latex allergies have IgE antibodies that can cross-react with antigens from foods, mostly fruits, and cause allergic symptoms of the **latex-fruit syndrome** or **latex-food syndrome**. Symptoms of latex-food allergy vary, with many being similar to those with NRL allergy, including anaphylaxis. The reaction is to the latex protein found in the food (Joneja, 2013) (see *Focus On: Cross-Reactivity: How Does It Happen?*)

Assessment of the problematic foods in latex-food allergy is difficult, because even though it is an IgE-mediated reaction, there usually is no food-specific IgE in the serum, so IgE tests are not useful. For those with NRL documented allergy, but with no symptoms after consumption of associated foods, it is important to keep in mind that every NRL-allergic individual reacts differently to foods with latex cross-reacting allergens. The most frequently reported foods in latex-food allergic reactions are listed in **Box 26-5**. Many clinicians advise NRL allergic individuals to avoid these foods in the interest of safety. However, it cannot be assumed that the NRL allergic person will react to these foods or that there will not be other NRL allergen-containing foods that may cause a reaction. Management is based on an exclusion diet that begins with avoidance of foods known to be reactive for that individual (Joneja, 2013).

FOCUS ON

Cross-Reactivity: How Does it Happen?

Profilins are pathogenesis-related (PR) proteins found in fruits and vegetables that are produced in a plant when it is "under stress" and act as defensive chemicals. They are present in all eukaryotic cells, are similar in a wide range of plants, and can function as allergens. They may account for cross-reactivity between plant allergens. They occur in pollen, latex rubber, and other plants. They are often modified by processing or cooking, thus accounting for the observation that the raw food causes a reaction in an individual and when the cooked form does not.

Carbohydrate moieties are also now recognized as being able to function as allergens.

BOX 26-5 Foods Frequently Reported in Latex-Food Allergy

Avocado	Passion fruit
Banana	Tomato
Cassava	Turnip
Cherimoya	Zucchini
Chestnut	Bell pepper
Kiwi fruit	Celery
Mango	Potato
Papaya	Custard apple

Food-Dependent, Exercise-Induced Anaphylaxis (FDEIA)

Food-dependent, exercise-induced anaphylaxis (FDEIA) is a distinct form of allergy in which an offending food triggers an IgE-mediated anaphylactic reaction only when the individual exercises within 2 to 4 hours after eating (*DuToit, 2007*). Signs of developing anaphylaxis are urticaria, pruritus (itching), and erythema (reddening) followed by breathing difficulty and GI symptoms. The food is not problematic in the absence of exercise. Usually a specific food causes FDEIA, but exercise-induced anaphylaxis (EIA) can happen following consumption of a meal, regardless of the foods in the meal.

FDEIA appears to be more common in adolescents and young adults and in those with known food allergy or a history of anaphylaxis (*Joneja, 2013*). Shellfish, seafood, certain fruits, milk, celery, a gliadin component in wheat, and other foods have been reported as offending agents (*Morita et al, 2009*). In FDEIA, the combination of a sensitizing food and exercise precipitates symptoms, possibly related to increased GI permeability and absorption, blood-flow redistribution, and increased osmolality (*Robson-Ansley and Toit, 2010*). Additional factors such as ingestion of aspirin may contribute to the reaction. The prevalence and causative agents and effective methods of diagnosis in FDEIA continue to be explored.

Mixed IgE-Mediated and Non-IgE-Mediated Reactions

Disorders involving IgE- and non-IgE mediated reactions are referred to as *mixed* and include cow's milk protein allergy (CMPA), **eosinophilic esophagitis (EoE)**, **eosinophilic gastroenteritis (EGE)**, and atopic dermatitis. They involve well-studied IgE-mediated reactions along with less well-understood non-IgE-mediated reactions.

Cow's Milk Protein Allergy (CMPA)

Cow's milk protein allergy (CMPA) is common in childhood; it is reported in 2% to 7% of babies under 1 year of age (*Ludman et al, 2013*). The IgE-mediated reactions are usually recognized because the urticaria, angioedema, eczema, GI symptoms, and respiratory symptoms appear within 2 hours of cow's milk protein (CMP) consumption. Non-IgE-mediated reactions are more difficult to identify because of the longer time between their appearance and the CMP consumption, sometimes as long as 20 hours. Symptoms may include gastroesophageal reflux disease (GERD), eczema, persistent crying, diarrhea, and constipation (*Turnbull et al, 2015*).

Exposure to CMP is through either formula or breastmilk if the mother is consuming cow's milk in her diet. Most children with CMPA outgrow it by 5 years for the IgE-mediated

reactions and by 3 years for uncomplicated non-IgE-mediated reactions (*Turnbull et al, 2015*).

Eosinophilic Gastrointestinal Diseases (EGID)

The eosinophilic gastrointestinal diseases (EGID) are a group of GI disorders in which the accumulation of eosinophils (granulocytes capable of releasing inflammatory mediators) is diagnostic. **Eosinophilic esophagitis (EoE)** and **eosinophilic gastroenteritis (EGE)** are inflammatory disorders characterized by infiltration of the esophagus, stomach, or intestines with eosinophils. It is now thought that both conditions have an IgE and non-IgE component, although they are not clearly defined. Identification of specific offending allergens is not always possible (*Merves et al, 2014*).

Almost half of the patients who present with EGE have atopic features (*Eroglu et al, 2009; Roy-Ghanta et al, 2008*). EGE can occur at any age, and symptoms can easily be mistaken for functional GI disorders. EOE occurs most often in white men, usually starting some time between school age and midlife (*Furuta and Katzka, 2015*). Tests for food-specific IgE are invariably of no value in identification of the offending foods, calling into question the involvement of IgE reactions in their cause. Implementation of an elimination diet aimed at identifying and excluding food antagonists can be most helpful in the nutrition assessment and management of EGID. Heartburn with the ingestion of alcohol occurs in 30% of adult patients suggesting that the elimination of alcohol may also be useful (*Straumann et al, 2012*).

Non-IgE-Mediated Reactions

The contribution of non-IgE-mediated immune reactions to food intolerance continues to be investigated. These are associated with delayed or chronic reactions and typically appear before 6 months of age in formula-fed infants, but a few cases have been reported in breast-fed infants. It has been postulated that these reactions may play a role in atopic dermatitis, food protein-induced enterocolitis syndrome (FPIES), food protein-induced proctocolitis (FPIP), cow's milk-induced pulmonary hemosiderosis (Heiner syndrome), and food protein-induced enteropathies (Bone et al, 2009).

Multiple components of the immune system are likely to be involved with different underlying mechanisms. The reaction seems to involve Th cells that release TNF-alpha, which is a Th1 response. This is in contrast to the allergy Th2 response, which releases cytokines that result in the production of IgE. In the Th1 response, where there is release of TNF-alpha, there is also an abnormally low level of TGF-B, which is the cytokine involved in developing tolerance to foods. This suggests that the resulting lack of immunologic tolerance results in the immune system treating the food as if it were a foreign "threat" to the body's survival and becomes sensitized to it. Thus the next time the food is eaten, there is a release of mediators reflective of a Th1 response and the defensive reaction of vomiting and diarrhea. Not unexpectedly, tests for allergen-sensitized IgE are not useful in diagnosing these disorders.

Food Protein-Induced Enterocolitis Syndrome (FPIES)

An example of a non-IgE-mediated immune reaction to food is **food protein-induced enterocolitis syndrome (FPIES)**. Although rare, it is seen in formula-fed infants and begins to appear around 6 months of age. It is typically provoked by cow's milk or soy protein-based formula (*Mehr et al, 2009; Nowak-Wegrzyn and Muraro, 2009*). A response to sheep or goat's milk or other solid foods is less common but also can occur (*Järvinen and Chatchatee, 2009*). The reaction is dramatic

with immediate vomiting, often followed by diarrhea and abdominal pain. In chronic cases there may also be failure to thrive.

Occasionally FPIES is seen in breast-fed infants, presumably caused by milk proteins from the mother's diet crossing into her milk. Food-specific IgE antibodies have no value in this diagnosis; confirmation of FPIES is challenging because it mimics other GI inflammatory disorders.

Formula-fed infants should be switched to an extensively hydrolyzed casein formula (EHF) (see [Box 26-9](#)). If they do not tolerate this formula, they may require an elemental formula. Breast-fed infants should remain on the breast, and the mother should eliminate cow's milk and soy or other suspicious foods from her diet. FPIES usually resolves by 2 years of age.

Food Protein–Induced Proctitis or Proctocolitis (FPIP)

In [food protein–induced proctitis or proctocolitis \(FPIP\)](#), bloody and mucus-laden stools are seen in an otherwise apparently healthy baby, often at about 2 months of age. Parents are concerned when they see flecks of blood in their baby's stool, but it is usually slight and further development of anemia is rare. Common trigger foods are cow's milk protein or soy protein from infant formula, and their removal from the infant's diet usually solves the problem. In the case of the breast-fed infant, the mother should remove these foods from her diet and continue to breast-feed. For the formula-fed infant, it becomes necessary to switch to an extensively hydrolyzed formula (EHF), such as any of those listed in [Box 26-9](#). However, sometimes the infant requires an elemental formula, examples of which are also listed in [Box 26-9](#). The bleeding usually disappears within 3 days of implementing a formula change or change in the breastfeeding mother's diet. In most cases the FPIP resolves itself by the time the baby is 1 to 2 years old, and offending foods can be introduced with monitoring of the baby's stool for blood ([Jones, 2013](#)).

FOOD INTOLERANCES

Food intolerances are ARFs that result in clinical symptoms but are not caused by an immune system reaction. They are caused by nonimmunologic mechanisms including toxic, pharmacologic, gastrointestinal, genetic, metabolic, psychogenic, or idiosyncratic reactions (see [Table 26-2](#)). Food intolerances are much more common than food allergies and are usually triggered by small-molecular weight chemical substances and biologically active components of food ([Jones, 2013](#)). Symptoms caused by food intolerances are often similar to food allergy and include GI symptoms, cutaneous, respiratory, and neurologic manifestations such as headaches (see [Table 26-2](#)). Clinically, it is important to distinguish food intolerance from immune-mediated food allergy because food allergies can cause life-threatening anaphylactic reactions, whereas food intolerances do not.

Carbohydrate Intolerance

Carbohydrates—sugars, starches, and polysaccharides—are complex in structure and must be broken down by enzymes for optimal digestion, absorption, and assimilation. Adverse reactions can occur if there is a deficiency of enzymes responsible for carbohydrate digestion, especially of disaccharides, such as lactose or sucrose, or if there is malabsorption of the breakdown products.

Lactose Intolerance

Intolerance to the disaccharide lactose is the most common ARF, and most cases result from a genetically influenced reduction of

intestinal lactase. It is estimated that up to 75% of the world's population has hypolactasia ([Bulhøes et al, 2007](#); [Jarvela et al, 2009](#)). Abdominal bloating and cramping, flatulence, and diarrhea occur usually up to several hours following lactose ingestion. Because some of the GI symptoms are similar, lactose intolerance is often confused with allergy to cow's milk; however, most individuals who are allergic to cow's milk also have symptoms in other organ systems, including the respiratory tract, skin, and, in severe cases, systemic anaphylactic reactions. Deficiencies of lactase and other carbohydrate-digesting enzymes and their management are discussed further in Chapter 28.

Fructose Intolerance and the Inability to Digest Fructose Polymers (FODMAPs)

Fructose intolerance is evidenced by an inability to digest and absorb the monosaccharide fructose, either from a food containing fructose directly or the disaccharide sucrose (glucose + fructose) (see Chapter 28 for discussion of fructose intolerance and its management).

Malabsorption and malabsorption of the fructo-, oligo-, di-, and monosaccharides and polyols (FODMAPs) may also occur. Humans lack the hydrolase enzymes necessary to break down the bonds in the fructose polymer chains, so most individuals will develop symptoms if too much of these carbohydrates are consumed ([Jones, 2013](#)). Intake of large quantities of FODMAPs will lead to bloating, diarrhea, cramping, and flatulence. The symptoms appear to be more common in individuals who have an underlying functional GI disorder, such as irritable bowel syndrome (see Chapter 28 for discussion of FODMAPs and the diet management, which eliminates excess fructose, fructose polymers, and the sugar alcohols).

Pharmacologic Reactions

An adverse reaction to a food may be the result of a response to a pharmacologically active component in that food. A wide range of allergy-like symptoms can result from ingestion of biogenic amines such as histamine and tyramine.

Histamine

[Histamine](#) is a biogenic amine produced endogenously with very important functions. It is released as the first inflammatory mediator in an allergic reaction or in a physical defense reaction. When released, it causes vasodilation, erythema, increased permeability of cell membranes, digestive tract upset, pruritus (itching), urticaria, angioedema (tissue swelling), hypotension, tachycardia (heart racing), chest pain, nasal congestion (rhinitis), runny nose (rhinorrhea), conjunctivitis (watery, reddened, irritated eyes), headache, panic, fatigue, confusion, and irritability.

Everyone has a level of histamine that is tolerated, and when that level is exceeded in the body, the symptoms of excessive histamine develop. Basal levels of 0.3 to 1 ng/ml are considered normal ([Jones, 2013](#)). Some people are more sensitive to histamine than others, usually because of a genetically determined inability to catabolize or breakdown histamine fast enough to keep the levels manageable so that histamine-induced symptoms are not triggered.

Foods with a high histamine content include fermented foods, tomatoes, strawberries, sauerkraut, aged cheeses, processed meats and fish, alcoholic beverages (champagne and red wine), and leftovers. Symptoms of excessive histamine may be indistinguishable from those of food allergy because of histamine's mediator function in allergic reactions.

TABLE 26-2 Examples of Food Intolerances

Cause	Associated Food(s)	Symptoms
Gastrointestinal Disorders		
Enzyme Deficiencies and Malabsorptive Disorders		
Lactose intolerance (lactase deficiency)	Foods containing lactose and mammalian milk	Bloating, flatulence, diarrhea, abdominal pain
Glucose-6 phosphate dehydrogenase deficiency	Fava or broad beans	Hemolytic anemia
Fructose intolerance	Foods containing sucrose or fructose	Bloating, flatulence, diarrhea, abdominal pain
Diseases		
Cystic fibrosis	Symptoms may be precipitated by many foods, especially high-fat foods	Bloating, loose stools, abdominal pain, malabsorption
Gallbladder disease	Symptoms may be precipitated by high-fat foods	Abdominal pain after eating
Pancreatic disease	Symptoms may be precipitated by eating	Anorexia, nausea, dysgeusia, and other gastrointestinal symptoms
Inflammatory bowel disease		
Inborn Errors Of Metabolism		
Phenylketonuria	Foods containing phenylalanine	Elevated serum phenylalanine levels, mental retardation
Galactosemia	Foods containing lactose or galactose	Vomiting, lethargy, failure to thrive
Psychologic Or Neurologic Reactions		
	Symptoms may be precipitated by any food	Wide variety of symptoms involving any system
Reactions To Pharmacologic Agents In Foods		
Phenylethylamine	Chocolate, aged cheeses, red wine	Migraine headaches
Tyramine	Aged cheeses, brewer's yeast, Chianti wine, canned fish, chicken liver, bananas, eggplant, tomatoes, raspberries, plums	Migraine headaches, cutaneous erythema, urticaria and hypertensive crisis in patients taking monoamine oxidase inhibitors
Histamine	Aged cheeses, fermented foods (e.g., sauerkraut, yogurt, kefir), processed meats (e.g., sausage, bologna, salami), canned and smoked fish, red beans, soybeans, citrus, avocado, eggplant, olives, tomato products, chocolate, cocoa, tea, yeast, alcohol, many spices, food additives and preservatives	Dizziness, flushing, hives, erythema, runny nose, headaches, decreased blood pressure, nausea, vomiting, shortness of breath, edema
Histamine-releasing agents	Shellfish, egg whites, chocolate, avocado, strawberries, citrus, pineapple, tomatoes, spinach, nuts, peanuts, alcohol	Urticaria, eczema, pruritus
Reactions To Food Additives		
Artificial colors: tartrazine or FD&C yellow no. 5 and other azo dyes	Artificially colored yellow or yellow-orange foods, soft drinks, some medicines	Hives, rash, asthma, nausea, headaches
Benzoates: benzoic acid or sodium benzoate	Processed foods as antimicrobial preservatives; color preservatives; bleaching agents	Hives, rash, asthma, angioedema, nasal congestion, headache, contact dermatitis, diverse digestive tract symptoms
Butylated hydroxyanisole (BHA); butylated hydroxytoluene (BHT)	Processed foods as antioxidants and used in food packaging materials	Skin reactions such as hives
Monosodium glutamate (MSG)	Processed foods: added as a flavor enhancer; often used in Asian cuisine	Facial numbness, tingling and numbness in hands and feet, dizziness, balance problems, visual disturbances, headaches, asthma, flushing, diverse digestive tract symptoms
Nitrates and nitrites	Processed foods containing sodium nitrite, sodium nitrate, potassium nitrite and potassium nitrate commonly found in cured meats, canned meats, smoked fish, pate, pickled meats	Flushing, hives, migraine, other headaches, digestive tract symptoms
Salicylates	Naturally occurring in a variety of fruits, vegetables and some spices	Angioedema, asthma, hives; people sensitive to aspirin higher risk for developing intolerance
Sulfites		
Sodium sulfite, potassium sulfite, sodium metabisulfite, potassium metabisulfite, sodium bisulfite, potassium bisulfite, sulfur dioxide	Shrimp, avocado, instant potatoes, dried fruits and vegetables, and fresh fruits and vegetables treated with sulfites to prevent browning, acidic juices, wine, beer, and many processed foods	Acute asthma and anaphylaxis in people with asthma, reactions in skin and mucous membranes
Reactions To Microbial Contamination Or Toxins In Foods		
<i>Proteus</i> , <i>Klebsiella</i> , or <i>Escherichia coli</i> bacteria cause histidine to break down to a histamine	Unrefrigerated scombroid fish (tuna, bonito, mackerel); heat-stable toxin produced	Scombroid fish poisoning (itching, rash, vomiting, diarrhea); anaphylactic-type reaction

BHA, Butylated hydroxyanisole; BHT, butylated hydroxytoluene.

However, histamine intolerance does not have an IgE-based mechanism for the release of histamine. One percent of the U.S. population suffers from histamine intolerance, and 80% of those sufferers are middle aged (Maintz and Novak, 2007). In histamine intolerance there is an excessive reaction to histamine for the following reasons: (1) certain foods naturally contain large amounts of histamine, or its precursor histidine, that cause a reaction in the histamine sensitive individual, (2) some individuals are not able to deactivate or metabolize histamine in a timely manner because of a deficiency of the enzymes

diamine oxidase (DAO) or histamine-N-methyltransferase (HNMT), or (3) there is the presence of other amines that also influence the histamine reaction.

Foods such as strawberries, egg whites, shellfish, and some food additives (e.g., tartrazine) and preservatives (e.g., benzoates) stimulate histamine release from mast cells. The mechanisms for this reaction are not clear. Histamine intolerance or sensitivity may be suspected when an allergic cause has been ruled out (Maintz and Novak, 2007) (see Box 26-6 for histamine content of foods and a histamine-restricted diet).

BOX 26-6 Histamine Restricted Diet

Lists of histamine content of foods differ widely between testing laboratories. It is difficult to determine the accurate histamine content of food, especially of fruits and vegetables, because of variations in the foods, such as degree of ripeness, time and method of harvesting, storage conditions, degree of contamination, and differences in analytical techniques used by the testing lab.

1. Peeled, packaged fruits, salads, and vegetables often have a higher histamine content than fresh. Fresh, whole fruits and vegetables are protected from microbial invasion (and therefore histamine production) by their peels or skins. Products with cut surfaces (e.g., shredded or sliced packaged salads) are more susceptible to bacterial invasion and are therefore more likely to contain histamine. For example, packaged mung bean, lentil, and radish sprouts contain double the histamine content compared to homegrown sprouts. **Fresh is best!**
2. The restricted foods in this management program also include foods that release histamine by unknown mechanisms, such as egg white; some plant foods; and additives, such as azo dyes, sulfites, and benzoates whose adverse effects include an increase in histamine.
3. Therefore, these lists are not limited to foods reported as containing a high level of histamine when measured in the laboratory. Not all people will react to the additives, so judicious challenge after the initial trial will determine whether these need to be avoided in the long term.

The lists provided here have been compiled from a variety of resources and reflect the foods and additives that are most consistently associated with higher levels of histamine.

Histamine-Restricted Diet Guidelines

The following foods and additives are **avoided** during the 4-week elimination trial.

Fish, Eggs, Meat

- Fish and shellfish whether fresh, frozen, smoked, or canned, if processing is unknown. Note: If the fish is freshly caught, gutted, and cooked within 1/2 hour, it may be eaten.
- Eggs. Note: A small quantity of cooked egg in a baked product such as pancakes, muffins, cakes is usually tolerated.
- Processed, smoked, and fermented meats of all types such as luncheon meat, sausage, wiener, bologna, salami, pepperoni, smoked ham, cured bacon.
- Leftovers. Note: freeze any uneaten protein-based food. Bacteria will quickly act on protein at room and refrigerator temperatures, resulting in histamine production.

Milk and Milk Products

- All fermented milk products and those containing bacterial culture, including:
 - Cheese: any kind of fermented cheese such as cheddar, Colby, blue cheese, Brie, Camembert, feta, Romano, and so on
 - Cheese products such as processed cheese, cheese slices, cheese spreads
 - Cottage cheese
 - Ricotta cheese
 - Yogurt
 - Buttermilk
 - Kefir

Fruits

- Apricots
- Cherries
- Citrus fruits: Orange, grapefruit, lemon, lime
- Cranberries
- Currants (fresh or dried)
- Dates
- Grapes
- Loganberries
- Pineapple
- Prunes
- Raisins
- Raspberries
- Strawberries

Vegetables

- Avocado
- Eggplant
- Olives
- Pickles, relishes, and other foods containing vinegar
- Pumpkin
- Spinach
- Tomatoes, tomato sauces, ketchup

Legumes

- Red beans
- Soy and soy products

Food Additives

- Tartrazine and other artificial food colors
- Preservatives, especially benzoates and sulfites
- Medications and vitamin pills that contain artificial food colors, benzoates, or sulfites (a pharmacist will be able to recommend additive-free supplements and medications)

Seasonings

- Chili powder
- Cinnamon
- Cloves
- Curry powder
- Nutmeg
- Thyme
- Vinegar

Miscellaneous

- Fermented soy products (such as soy sauce, miso)
- Fermented foods (such as sauerkraut)
- Tea (regular or green)
- Chocolate, cocoa, and cola drinks
- Alcoholic beverages of all types
- Nonalcoholic versions of alcoholic beverages (e.g., nonalcoholic beer, ale, wine, etc.)

Tyramine

Tyramine is formed from the amino acid tyrosine and can cause adverse reactions in individuals who are taking monoamine oxidase inhibitors (MAOIs), which interfere with the breakdown of tyramine. This is an example of a potentially serious ARF caused by a drug-food interaction. Fortunately, the MAOIs are not prescribed as frequently today as in the past. Tyramine sensitivity in those not taking MAOIs is probably due to a deficiency of monoamine oxidase, but this is not well understood. Ingestion of tyramine-containing foods also may cause migraine headaches or chronic hives in tyramine-sensitive individuals, with the response being dose dependent (Jones, 2013). Tyramine is found in some fermented foods such as aged cheeses, wines, vinegars, and naturally in chicken liver, bananas, eggplant, raspberries, plums, and tomatoes (see Box 8-4 in Chapter 8 and Chapter 41).

Reactions to Food Additives

At the present time, many of the reaction mechanisms to food additives are poorly understood. Food additives such as salicylates, carmine (cochineal extracts), artificial food dyes and colorings such as FD & C yellow #5, and preservatives such as benzoic acid, sodium benzoate, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), nitrates, sulfites, and monosodium glutamate (MSG) can cause adverse reactions in certain individuals (Vojdani et al, 2015).

Sulfites

Reactions to sulfites are most common in asthmatics and result in a range of symptoms in sulfite-sensitive individuals. These can include dermatitis, urticaria, hypotension, abdominal pain, diarrhea, and life-threatening asthmatic and anaphylactic reactions (Vally and Misso, 2012). The mechanisms remain unclear.

Monosodium Glutamate (MSG)

Adverse reactions to MSG were originally reported as the “Chinese restaurant syndrome” because of its use in Chinese

cooking. Complaints of headache, nausea, flushing, abdominal pain, and asthma occurred after ingestion. MSG is widely distributed in the food supply (e.g., bouillon, meat tenderizers, canned food, frozen food, condiments) and occurs naturally in tomatoes, Parmesan cheese, mushrooms, and other foods. Results from double-blind, placebo-controlled food challenges (DBPCFC) found symptoms from MSG to not be persistent, clear, consistent, or serious (Geha et al, 2000; Williams and Woessner, 2009). However, more recent data in animals and humans have indicated that MSG consumption may be a contributing factor to increased risk of overweight independent of physical activity and total energy intake (He et al, 2011). Considering the ongoing debate about this common flavoring agent as an obesogenic agent, dietetic practitioners should be aware of MSG sensitivity (Savcheniuk et al, 2014).

Food Toxins and Microbial Contaminants

Food toxicity or food poisoning results from microbial contamination of food and causes a myriad of symptoms, including nausea, vomiting, diarrhea, abdominal pain, headache, and fever, many of which can be confused with an allergic reaction. It is estimated that in the United States 76 million people per year are affected by foodborne illness, and that 30% of all infections over the last 60 years worldwide were foodborne (Bold and Rastami, 2011). Fortunately, most episodes are self-limiting and should be distinguished from food allergy through a thorough history. If the cause of the symptoms cannot be determined to be a food toxin or microbial contamination, then a single food elimination diet followed by a challenge of that food may be necessary (see Table 26-3).

Psychogenic and Behavioral Factors

Evidence for the role of food allergy or intolerance in various disorders such as anxiety, depression, migraine headache, attention deficit hyperactivity disorder, and mood disorders is emerging. Increased intestinal permeability, dysbiosis, neurotransmitter production, and gut immune

TABLE 26-3 Protocol for Elimination and Challenge: Plan, Avoid, Challenge, and Evaluate (PACE)

Begin with the 4R Program:

- 1. Remove** offending agents (already known adverse reacting foods, toxins, infections, chronic stress)
- 2. Replace** digestive factors (enzymes or HCl)
- 3. Repopulate** with pre- and probiotics
- 4. Repair** with healing nutrients and botanicals

PLAN: Develop a tailored eating plan and timeline for the elimination diet based on review of the patient’s medical and clinical history, findings from a thorough nutrition assessment, including a diet and symptom record kept for minimum of 1 week, and other patient information such as patient readiness

AVOID: The elimination diet will be of either low, moderate, or high intensity and of duration of 2 to 4 weeks or longer if necessary, until the client’s symptoms clear.

Level 1: a low-intensity diet will exclude those foods suspected by the individual to be problematic; it usually means avoidance of a few selected foods

Level 2: a medium-intensity elimination diet excludes many foods or food groups, and substitute food selections are based on the patient’s preferences. The gluten- and casein-restricted diet or the Eight Food Elimination Diet are examples

Level 3: the highest intensity oligoantigenic diet, which excludes most foods and is based on just a few (maybe as few as 10), usually hypoallergenic foods. Medical foods or elemental formulas containing hypoallergenic, easily digested nutrients can be used to supplement the diet.

CHALLENGE: Reintroduction of the suspected and avoided foods is done one at a time. The diet should remain the same except for the introduction of the suspected food. A common method for reintroducing is to have the client eat a small amount of the food in the purest form at least 2 to 3 times per day on Day 1 with no test food on Day 2 and Day 3. The client will observe and document any food reactions during this 3 day period. The process is repeated with the next test food on Day 4, with no test food on Day 5 and Day 6. Again the patient observes and records for the period Day 4 to 6. Given that adverse food reactions (AFRs) can be delayed as much as 72 hours (3 days) it is important to not test another food sooner than 3 days. Foods being tested are rated as either safe, unsafe, or unsure. If the patient is unsure, he or she will wait a week and test the food again in the same manner as before.

EVALUATE: After the challenge phase is completed the clinician and client evaluate the responses and devise a long-term eating plan that prevents AFRs and maintains optimal health.

system response are currently being investigated as contributing factors (see Chapters 41 and 44). Even if a food-symptom relationship is not proven, but food avoidance is perceived as helpful because of personal experience, appropriate therapy can optimize nutritional status.

ASSESSMENT

Diagnosis of ARFs requires identification of the suspected food or food ingredient, proof that the food causes an adverse response, and verification of an immune or non-immune-mediated response. The first diagnostic tool is the detailed clinical history, and this is followed with appropriate testing (Skypala et al, 2015). Biochemical tests can rule out nonallergenic causes of symptoms. Tests that may be useful include a comprehensive metabolic profile with complete blood count and differential; stool tests for inflammatory markers, ova, parasites, or occult blood; breath hydrogen tests; intestinal permeability tests; genetic tests for celiac disease and gluten sensitivity profiles, or for histamine intolerance; tests for small intestinal bacterial

overgrowth (SIBO); and a sweat chloride test for cystic fibrosis (see Chapters 7, 27, 28, and 34). Tests for food reactivity remain controversial and should be used only in conjunction with a comprehensive history, physical, and nutrition assessment (see Table 26-4 for a complete description of tests).

Immunologic Testing

Skin-Prick Test

In **skin-prick tests** drops of standard food extracts are placed on the skin of the arm or back. The skin is then scratched or pricked with a lancet with each drop of extract. The areas of application are then observed for the development of the classic “wheal and flare” reaction. In theory, if the underlying mast cells have attached allergen-specific IgE, inflammatory mediators are released. The wheal and flare reaction results from the action of the mediators, especially histamine, on the surrounding tissue. These tests are the most economic immunologic tests of an Ig-E mediated reaction, providing results within 15 to 30 minutes. Comparison with the positive control (histamine) and the negative control (usually the solute used

TABLE 26-4 Tests Used in the Assessment of Adverse Reactions to Foods

Skin Tests		
Skin testing (scratch, prick, or puncture)	A drop of antigen is placed on the skin, and the skin is then scratched or punctured to allow penetration of the antigen to reach sensitized IgE; assesses IgE-mediated sensitization.	Screening test; cannot be relied on as sole diagnostic tool; a history of food-symptom relationship also important; more reliable for negative findings than positive; negative results confirm absence of IgE-mediated allergic response.
Atopy patch test	Small pads soaked with allergen are applied to unbroken skin for 48 hours and read at 72 hours.	Variable sensitivity and specificity; used to assess delayed or non-IgE reactions; no clinical value in diagnosis of food allergy.
Intradermal testing also called skin endpoint titration (SET)	In a clinical setting, a small amount of allergen is injected directly into subcutaneous layer of skin; presence of wheal indicates reaction.	More sensitive than skin-prick testing, but with a greater risk of adverse reactions; not recommended as sole diagnostic tool.
Blood Tests		
CAP-FEIA	Serum is mixed with food on a paper disk and then washed with radioactively labeled IgE. Compared with RAST, this test binds more allergen; best for assessing IgE-mediated reactions.	Reliable for six foods: milk, eggs, wheat, cow's milk, peanuts, and soy.
RAST	Being replaced with CAP-FEIA test; assesses IgE-mediated sensitization.	More sensitive assays now replace RAST; cannot be relied on as sole diagnostic tool. High sIgE values may not guarantee allergic reactivity, whereas low sIgE values may not eliminate the potential for allergic reactivity.
ELISA	Much like RAST, except that no radioactive material is used; being replaced with CAP-FEIA; assesses IgE-mediated sensitization.	Same as for RAST. Cannot be relied on as sole diagnostic tool. High sIgE values may not guarantee allergic reactivity, whereas low sIgE values may not eliminate the potential for allergic reactivity.
Specific IgG, IgM, IgA antibody assays	Techniques of precipitation hemagglutination complement fixation; requires special expertise.	Specific IgG not validated for diagnostic use; but still used clinically; reliability still questionable. Positive results may simply indicate previous exposure to the food.
Serum IgG4	Blood testing for food-specific IgG4.	Not validated for diagnostic use; tends to indicate previous exposure to the food, but still used clinically; reliability still questionable.
Basophil activation test (BAT)	Using whole blood, measures basophil response to allergenic cross-linking IgE on basophil granulocytes.	Not yet standardized for clinical diagnostic use. (Hoffman et al, 2015)
Cytotoxic testing *Antigen leukocyte cellular antibody test (ALCAT) *Mediator release test—(MRT)	Allergen is mixed with whole blood serum leukocyte suspension. Lysed leukocytes, primarily neutrophils, are measured against the food allergen. Changes in cell size and volume indicate response.	Nonstandardized; may result in false-positive or false-negative results; not widely validated for diagnostic use. (Pietschmann, 2015)

Continued

TABLE 26-4 Tests Used in the Assessment of Adverse Reactions to Foods—cont'd

Other Tests

Applied kinesiology, also called muscle strength testing	Subject's arm is extended and vial with test food is placed in the hand; test is considered a positive reaction if the muscle strength weakens and arm moves more easily after the food has been placed in hand.	Nonstandardized; may result in false-positive or false-negative results; not validated for diagnostic use.
Sublingual testing	Drops of allergen extract are placed under the tongue and symptoms are recorded.	May result in false-positive results; not validated for diagnostic use.
Provocation testing and neutralization	Subcutaneous injection of allergen extract elicits symptoms; this is then followed by injection of a weaker or stronger preparation to neutralize symptom.	May result in false-positive results; not validated for diagnostic use.

BAT, basophil activation test; CAP-FEIA, CAP-fluorescein-enzyme immunoassay; CRD, component-resolved diagnostics; DBPCFC, double-blind, placebo-controlled food challenge; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; MD, medical doctor; RAST, radioallergosorbent test; sIg, secretory immunoglobulin.

for the antigen or saline) provide parameters necessary for accurate readings (see Figure 26-3). All skin-prick tests are compared with the control wheal. Test wheals that are 3 mm greater than the negative control usually indicate a positive result. Negative skin-prick tests have good negative predictive accuracy and suggest the absence of an IgE-mediated reaction. Positive skin-prick test results, however, indicate only IgE sensitization and the possibility of a food allergy reaction. In the patient with a suspected food allergy, the skin-prick test is useful in supporting the diagnosis. For children younger than 2 years of age, the skin test is reserved to confirm immunologic mechanisms after symptoms have been confirmed by a positive test result from a food challenge or when the history of the reaction is impressive.

FIGURE 26-3 A skin-prick test showing the wheal and flare of the reaction to the allergen as compared with the reaction to the histamine control at the bottom.

In children with atopic dermatitis, skin-prick testing for food allergens is contraindicated because of the high reactivity of the skin, leading to false-positive reactions and the real danger of sensitization to the allergen through inflamed skin (see Figure 26-4).

All foods that test positive must correlate with a strong exposure history or be proven to cause allergic reactions through food challenges before they can be considered allergenic. The most common food allergens (milk, egg, peanut, soy, wheat, shellfish, fish, and tree nuts) account for most of the positive food skin-prick tests (Nowak-Węgrzyn and Sampson, 2006).

Serum Antibody Tests

Food allergen-specific serum IgE testing is used to identify foods that may be causing the allergic response. The **radioallergosorbent test (RAST)**, an IgE test, and the enzyme-linked immunosorbent assay (ELISA), most often an Ig-G test, are

FIGURE 26-4 Atopic eczema: An IgE-mediated skin reaction to a food allergen, commonly seen on the back of knees and the inside of elbows.

TABLE 26-5 Food Challenges

DBPCFC	Allergen is disguised and given orally and patient monitored for reaction; patient and physician blinded; also tested with placebo.	“Gold standard” for food allergy testing.
Single-blind food challenge	Suspect food is disguised from patient and orally given by physician in a clinical setting.	Less time-consuming than DBPCFC; may be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.
Open oral food challenge	Suspect food is orally given to patient in undisguised, natural form in gradual doses under medical supervision.	Less time-consuming than DBPCFC; should not be used in instances in which patient experiences symptoms secondary to fear or aversion to suspect food.
Food elimination diets	Suspect foods are eliminated from the diet for a set period to identify foods responsible for ARF. During gradual reintroduction symptoms are carefully observed.	May help identify foods responsible for ARF; strict, long-term elimination diets may require monitoring to ensure nutritional adequacy.

being replaced by the **CAP–fluorescein-enzyme immunoassay (FEIA)**. The **CAP-FEIA** is a blood test that provides a quantitative assessment of allergen-specific IgE antibodies; higher levels of antibodies are often, but not always, predictors of clinical symptoms. The CAP-FEIA test has been approved for only six foods: egg, milk, peanut, fish, wheat, and soy (soy is still not as predictive) (Sampson, 2004). It is fairly effective as shown by testing known food-allergic children whose food allergies had been previously proven with DBPCFCs. Test results should be followed with either food elimination and challenge, or DBPCFCs to complete the diagnostic process. It should be noted that CAP-FEIA or skin testing results for IgE sensitization may remain positive even after the child has resolved the allergy, and the food can be eaten without symptoms (Sampson, 2004).

Other Tests

A number of laboratory tests are now available that attempt to identify an individual’s specific ARFs. Some of these tests measure IgA, IgG, and IgG4 levels, whereas others measure the amount of cytokines released by lymphocytes and granulocytes upon degranulation in response to food antigen exposure. Continued scientific investigation into the evidence-based and validity of various types of food reactivity testing is warranted (Vojdani, 2015a; see Table 26-5).

MEDICAL NUTRITION THERAPY

A thorough history including prenatal history, method of birth (e.g., vaginal or C-section), early feeding practices (breastfed versus formula), current medical conditions, medications, dietary supplements, exercise patterns, lifestyle factors, and a nutrition-focused physical examination are important in assessing the patient with ARFs (see Chapters 4 and 7, and Appendices 21 and 22).

Anthropometric measurements for infants and children should be plotted on a growth chart and evaluated in relationship to earlier measurements (see Appendices 4 through 10). Because decreased weight-for-height measurements may be related to malabsorption or food allergy or intolerance, patterns of growth and their relationship to the onset of symptoms should be explored. Clinical signs of malnutrition should be assessed as part of the nutrition-focused physical exam.

Food and Symptom Record

A 7- to 14-day **food and symptom record** is extremely useful for uncovering ARFs (see Figure 26-4). This record also may be used to identify possible nutrient insufficiencies and

deficiencies. The food and symptom record should include the time the food is eaten, the quantity and type of food, all food ingredients if possible, the time symptoms appear relative to the time of food ingestion, and any supplements or medications taken before or after the onset of symptoms. Other influences such as stress, physical exercise, and elimination and sleep patterns can provide valuable information in piecing together the factors that affect ARFs. The more thorough the information obtained about the adverse reaction, the more useful the record. For example, a reaction that appears to be caused by a food actually may be caused by a pet or a chemical or other environmental factor. The 1- to 2-week food and symptom record also can serve as a baseline for future interventions (see Chapter 4).

Food-Elimination Diets

The elimination diet followed by food challenges is the most useful tool in the diagnosis and management of ARFs when used in conjunction with a thorough history and nutrition assessment. With the **elimination diet**, suspect foods are eliminated from the diet for a specified period, usually 4 to 12 weeks, followed by a reintroduction and food-challenge phase. All forms (i.e., cooked, raw, frozen) of a suspected food are removed from the diet, and a food and symptom record (see Figure 26-5) is kept during the elimination phase. This record is used to ensure that all forms of suspected foods have been eliminated from the diet and to evaluate the nutritional adequacy of the diet.

Elimination diets should be personalized and may entail excluding only one or two suspect foods at a time to see if there is improvement in symptoms, or it may mean eliminating several foods if multiple foods are suspected. This would entail a more limited diet as shown in Table 26-6, but again the diet should be individualized as much as possible.

Elemental formulas, medical foods, or hypoallergenic formulas also may be used for additional nutrition support in adults on an elimination diet. An elemental formula provides high-quality calories in an easily digestible, hypoallergenic form and helps to optimize nutritional status. Because of low palatability and high cost, this should be reserved for the most restrictive cases. Hydrolyzed infant formulas or extensively hydrolyzed infant formulas may be required for the allergic infant who is not being completely breastfed and who needs to avoid several foods.

After the designated elimination phase, foods are systematically reintroduced into the diet one at a time to determine any adverse reactions while the person is carefully monitored. If

FIGURE 26-5 Food and symptom diary.

symptoms persist with careful avoidance of suspect foods, other causes for the symptoms should be considered. If a positive result has been obtained on a skin prick test or allergen-specific IgE blood test and symptoms improve unequivocally with the elimination of the food, that food should be excluded from the diet until an oral food challenge is appropriate. The oral food challenge will further prove or disprove a food-symptom relationship. If symptoms improve with the elimination of multiple foods, then multiple food challenges will be necessary.

An oral **food challenge** is conducted in a supervised medical setting once symptoms have resolved, and when the person is not taking any medications such as antihistamines. Foods are challenged one at a time on different days while the person is carefully observed in a medical setting for the recurrence of symptoms (see **Box 26-7** for Food Challenge Protocols).

The form of the food ingested is an important consideration in the nutritional assessment of ARFs. For example, recent studies suggest that 70% to 80% of young children allergic to milk or eggs can tolerate baked (heat-denatured) forms of these proteins, but not the unbaked form. It is suggested that these children make IgE antibodies primarily to **conformational epitopes** (antigenic determinants on the surface of the food proteins that are recognized by the immune system) and represent those children who will naturally outgrow their food allergies (**Sicherer and Sampson, 2010**).

Allergic individuals and their families need guidelines and suggestions for avoiding allergenic foods and ingredients,

substituting permissible foods for restricted foods in meal planning and preparation, and selecting nutritionally adequate replacement foods. Care providers and school personnel working with the food-allergic child must be trained to read labels carefully before purchasing or serving food. The Food Allergy and Anaphylaxis Network (www.foodallergy.org), a nonprofit organization created to support the child with food allergies, has worked with board-certified allergists and dietitians to develop an excellent education program for day-care or school programs.

To help identify and avoid offending foods, allergy-specific lists that describe foods to avoid, state key words for ingredient identification, and present acceptable substitutes, are useful and necessary in counseling (see **Boxes 26-8 through 26-12**).

Food ingredients to be avoided may be hidden in the diet in unfamiliar forms. When a food-sensitive person ingests a hidden allergen, the most common reason is that the “safe” food was contaminated. This may happen as a result of using common serving utensils such as at an ice cream stand, salad bar, or deli (where the meat slicer may be used to slice meat and cheese). Manufacturing plants or restaurants may use the same equipment to produce two different products (e.g., peanut butter and almond butter); despite cleaning, traces of an allergen may remain on the equipment between uses. Alternatively, a restaurant may use the same oil to fry potatoes and fish (see **Box 26-13**).

In addition, the food may have been genetically modified, changing its allergenicity. Here again, label reading is essential (see **Focus On: GMO or Genetically Engineered (GE) Foods**).

Text Continued on page 502

TABLE 26-6 Guidelines for Elimination Diets

These guidelines emphasize foods that are naturally nutrient rich.

Guidelines should be personalized according to the patient's history and should eliminate other foods that are already known allergens or foods that aggravate symptoms.

Refer to label reading guidelines to avoid ingredients to be eliminated (see [Boxes 26-8 through 26-12](#)).

Amounts should be individually tailored to energy needs.

	Foods Allowed	Foods to Avoid
Elimination Diet: Milk-, Egg-, and Wheat-Free		
Animal proteins	Fish, shellfish, turkey, chicken, beef, pork	Eggs, egg substitutes containing egg whites and all products containing eggs (see Box 26-8)
Plant proteins	Beans, lentils, split peas, organic soybeans, and soy products	Nonorganic soy (GMO containing)
Dairy alternatives	Nondairy beverage alternatives including organic soy beverages	Milk (cow, goat, sheep) and all products containing mammalian milk ingredients (see Box 26-9)
Grains	Amaranth, barley, buckwheat, corn, millet, oats, quinoa, rice, rye	Wheat, all forms of wheat (see Box 26-10)
Vegetables	All vegetables and starchy vegetables	Vegetable dishes containing milk, egg, or wheat (e.g., tempura, breaded)
Fruits	All fruits and 100% fruit juices	Fruit pies, pastries, cookies, etc., that contain milk, egg, or wheat
Fats and oils	Coconut oil, organic canola oil, grapeseed oil, olive oil, flaxseed oil, sesame oil, safflower oil, milk-free organic (nonhydrogenated) margarines	Butter, margarine, hydrogenated oils, shortening
Peanuts, nuts, and seeds	Peanuts, nuts, and natural nut butters, seeds and natural seed butters	Any peanut, nut, or seed product containing milk, egg, wheat (e.g., chocolate candy with nuts)
Beverages	Tea, herbal tea, coffee, decaffeinated tea, and coffee	Beverages containing milk (cow, goat, sheep)
Sweeteners	Cane or beet sugar, honey, maple syrup, blackstrap molasses	Artificial sweeteners
Other	Salt, pepper, herbs, and spices	Egg-, milk-, or wheat-containing condiments; all artificial ingredients, salad dressing, mayonnaise, spreads containing milk, egg, wheat

Elimination Diet: Most Common 8 Allergens Elimination Diet: Milk, Egg, Wheat, Fish, Shellfish, Soy, Peanut and Tree Nut Free

Animal proteins	Turkey, chicken, lean cuts of beef, lamb, pork	Fish, shellfish, eggs, processed meats such as sausages, deli meats, etc.
Plant protein sources	Beans, lentils, split peas	Soybeans and soy products, peanuts, tree nuts
Dairy alternatives	Nondairy, soy-free, nut-free beverage alternatives (i.e., rice, hemp beverages)	Milk and all dairy alternative beverages containing soy, oats or tree nuts
Grains	Amaranth, barley, buckwheat, millet, oats, quinoa, rice, teff, tapioca, wild rice	Wheat, spelt, kamut, triticale, and all wheat-containing products
Vegetables	Most vegetables and starchy vegetables	Vegetable dishes containing ingredients to avoid such as breaded, creamed, etc.
Fruits	Most fruits and 100% fruit juices	Fruit pies, pastries, cookies, etc., containing ingredients to avoid
Fats and oils	Olive oil, coconut oil, flaxseed oil, grapeseed oil, organic canola oil, safflower oil, sunflower oil	Butter, margarine, soy oil, peanut oil
Peanuts, nuts, and seeds	Seeds and seed butters, such as pumpkin seed, sunflower seed, flax seed, chia seed	Peanuts and peanut-containing products, tree nuts and tree nut-containing products
Beverages	Herbal tea, 100% unsweetened fruit or vegetable juice, water, nondairy soy-free beverages	Coffee, caffeinated tea, other caffeinated beverages, alcoholic beverages, soft drinks
Sweeteners	Honey, maple syrup, blackstrap molasses, agave, raw cane sugar	Artificial sweeteners
Other	Salt, pepper, all spices	Any food product containing any ingredient to avoid and all artificial ingredients

Elimination Diet: Few Foods/Limited Ingredients—

Intended to be used in the short-term only

Animal proteins	Chicken, turkey, lamb
Grains	Brown rice
Vegetables	Sautéed or steamed leafy green vegetables including spinach, green beans, summer squash
Fruits	Banana
Oils	Extra virgin olive oil
Beverages	Water, herbal tea
Sweeteners	Maple syrup

BOX 26-7 Food Challenge Protocols

The three methods used to determine which foods when reintroduced into the diet are responsible for adverse reactions include the following:

1. Double-blind, placebo-controlled food challenge (DBPCFC): a food challenge in which neither the patient nor physician knows the identity of the test food component, which is usually disguised as a powder in a food known to be tolerated (such as applesauce) or in a gelatin capsule. The patient's reaction is compared to his or her reaction to the placebo, and the patient is monitored in a clinical setting.
2. Single-blind food challenge: a food challenge in which the patient is blinded to the challenge food's identity, but the clinician is not. The food or a powder of it is disguised in another food and reactions are observed and recorded.
3. Open food challenge: a food challenge in which the patient is knowingly given a serving of the suspect food and observed for several hours for a reaction

BOX 26-8 Eliminating Eggs: Label Reading and Strategies

People with an allergy to chicken eggs may also be allergic to other types of eggs, such as goose, duck, turkey, or quail.

Ingredients and Single-Ingredient Foods to Avoid*

- | | | |
|---------------------|----------------------------|--------------------|
| • Albumin | • Frozen eggs | • Ovoinhibitor |
| • α -livetin | • Globulin | • Ovomacroglobulin |
| • Apovitellin | • Goose eggs | • Ovomucin |
| • Avidin | • G2 and G3 globulins | • Ovomuroid |
| • Catalase | • Imitation egg product | • Ovomuxoid |
| • Conalbumin | • Lecithin | • Ovotransferrin |
| • Dried eggs | • Lipovitellin | • Ovovitellin |
| • Duck eggs | • Livetin | • Phosvitin |
| • Egg solids | • Low-density lipoproteins | • Powdered egg |
| • Egg substitutes | • Lysozyme | • Quail eggs |
| • Egg white | • Ovalbumin | • Simplese |
| • Egg yolk | • Ovoflavoprotein | • Turkey eggs |
| • Ficin inhibitor | • Ovoglobulin | • Vitellin |
| • Flavoprotein | • Ovoglycoprotein | |

Other Foods That Often Contain Eggs as an Ingredient

- | | |
|---------------------|--------------|
| • Béarnaise sauce | • Mayonnaise |
| • Eggnog | • Meringue |
| • Hollandaise sauce | • Surimi |

Note: Egg whites and shells may be used as a clarifying agent in soup stocks, consommés, wine, alcoholic beverages, and coffee drinks.

Egg Substitutes (Equivalent to 1 Egg) in Recipes

- | | |
|---|--------------------------------|
| • 1 packet plain gelatin + 1 c boiling water; use 3 Tbsp of this mixture | • ½ mashed banana |
| • ½ tsp baking powder + 1 Tbsp liquid + 1 Tbsp vinegar | • ¼ cup unsweetened applesauce |
| • 2 Tbsp fruit puree (use in baking for binding, but not leavening); apples, plums, peaches, or prunes | |
| • To achieve an emulsifying effect in baking: 2 Tbsp whole wheat flour + ½ tsp oil + ½ tsp baking powder + 2 Tbsp milk, water, or fruit juice | |
| • 1 Tbsp ground flax + 3 Tbsp water; blend and allow to sit for 10-15 minutes | |
| • 1 tsp yeast dissolved in ¼ c warm water | |
| • 1½ Tbsp water + 1½ Tbsp oil + 1 tsp baking powder | |
| • ¼ c soft tofu, beaten | |
| • 1 Tbsp chia seed + ½ cup water; blend and allow to sit for 10-15 minutes | |
| • 1 Tbsp agar agar + 1 Tbsp water | |

Always use caution and work closely with physicians or pharmacists to ensure that there are no egg ingredients in any of the following:

- Cosmetics
- Medications
- Vaccines
 - Albumin or chicken serum can be used in any vaccine
 - Influenza vaccines
 - MMR: measles, mumps, rubella vaccine
 - Rabies vaccine may contain small amounts
 - Typhus vaccine may contain small amounts
 - Yellow fever vaccine

*Eliminate these foods, as well as any foods containing any of these ingredients.

FARE Food Allergy Research & Education: *Tips for Avoiding Your Allergen* (website): www.foodallergy.org. Accessed Feb, 2014; Joneja JV: *The health professional's guide to food allergies and intolerances*, Chicago, 2013, Academy of Nutrition and Dietetics.

BOX 26-9 Eliminating Cow's Milk: Label Reading and Strategies**Ingredients and Single Ingredient Foods to Avoid***

- Acidophilus milk
- Ammonium caseinate
- Artificial butter flavor
- Butter
- Butter fat
- Butter oil
- Calcium caseinate
- Caramel
- Casein
- Casein hydrolysate
- Cheese and cheese flavor (e.g., cheddar, Colby, cream, Edam, Gouda, Monterey Jack, mozzarella, Muenster, Neufchâtel,, parmesan, provolone, ricotta, Romano, Swiss, etc)
- Chocolate milk
- Chocolate Sauce
- Condensed milk
- Cottage cheese
- Cultured buttermilk
- Curds
- Custard
- Delactosed whey
- Evaporated milk
- Ghee
- Goat milk[‡]
- Greek yogurt
- Half and half cream
- Hydrolysates (casein, milk protein, protein, whey, whey protein)
- Lactalbumin
- Lactalbumin phosphate
- Lactoferrin
- Lactoglobulin
- Lactose
- Lactulose
- Magnesium caseinate
- Milk (whole, 2%, 1½%, 1%, ½%, skim, evaporated, condensed)
- Milk powder (whole, low-fat, nonfat)
- Milk protein
- Potassium caseinate
- Rennet casein
- Semisweet chocolate
- Sheep milk[‡]
- Sodium caseinate
- Sour cream
- Sour cream solids
- Sour milk solids
- Sweet whey
- Sweetened condensed milk
- Whey
- Whey protein concentrate
- Whipping cream
- Yogurt, regular

Other Foods That Often Contain Cow's Milk as an Ingredient

- Alfredo sauce
- Bavarian cream flavoring
- Brown sugar flavoring
- Butter flavoring
- Caramel candy
- Caramel flavoring

- Carob candies
- Chocolate products
- Creamed candies such as caramel, fudge, taffy
- Cream dressings
- Cream sauces
- Cream soups
- Coconut cream flavoring
- Eggnog
- Gelato
- Hot cocoa mix
- Ice cream (low-fat, regular, fat free)
- Malted milk
- Milk chocolate
- Natural flavoring
- Nougat
- Protein powders
- Pudding
- Recaldent, used in tooth-whitening chewing gums
- Sherbet, most types
- Simplese
- Sour cream dressings
- Yogurt, frozen

Milk Substitutes (Equivalent to 1 Cup Cow's Milk) in Recipes

- 1 c almond, coconut, hazelnut, or other nut milk beverage
- 1 c light colored fruit juice (e.g., apple, orange, white grape)
- 1 c flax, hemp, sunflower, or other seed beverages
- 1 c milk-free infant formula, mixed
- 1 c herbal tea
- 1 c oat, rice, quinoa, or other grain beverage
- 1 c soy milk
- 1 c water

Buttermilk Substitute (Equivalent to 1 Cup Cow's Milk) in Recipes

- Add 1 tablespoon vinegar to 1 cup alternative milk (soy, rice, oat, almond, coconut, etc.), stir and let sit for 5 minutes before using in recipe.

Intact Milk Protein-Free Formulas

Partially hydrolyzed (cow's milk protein) infant formula[§]

- Enfamil Gentlease (Mead Johnson) whey/casein protein blend
- Gerber Good Start Gentle (Nestle) 100% whey protein
- Gerber Good Start Protect (Nestle) 100% whey protein
- Some store brands (Perrigo Nutritionals) - check with manufacturer

Extensively hydrolyzed infant formula

- Nutramigen with Enflora LGG (Mead Johnson)
- Pregestimil (Mead Johnson)
- Similac Expert Care Alimentum (Abbott)

Free Amino-Acid Base Infant Formulas[¶]

- EleCare for Infants (Abbott)
- PurAmino (Mead Johnson)
- Neocate products (Nutrica)

Soy Infant Formula**

- Enfamil ProSobee (Mead Johnson)
 - Gerber Good Start Soy (Nestle)
 - Similac Soy Isomil (Abbott)
 - Some store brands (Perrigo Nutritionals) - check with manufacturer
- Organic Soy Infant Formula**
- Earth's Best Organic Soy (Hain Celestial Group)
 - Soy Organic Infant Formula (Vermont Organics)

Individuals who must avoid all cow's milk sources frequently need a calcium supplement.

*Please also note that non-food products such as cosmetics, supplements, and medications can contain dairy ingredients and may cause an adverse reaction.

‡Goat and sheep milk proteins are similar to cow milk protein, and those with a cow milk allergy could experience similar symptoms with ingestion of these alternatives. Although occasionally this does not occur, they are not advised as cow milk substitutes when determining allergens (Ah-Leung et al, 2006). Goat's milk is not recommended as a cow's milk substitute, especially in infants, because it has a high renal solute load and is very low in folic acid compared with cow's milk.

§Partially hydrolyzed: Nonhypoallergenic; contains partially digested proteins that have a molecular weight greater than extensively hydrolyzed formula protein chains. May cause a reaction in one third to one half of individuals with a cow's milk protein allergy.

BOX 26-9 Eliminating Cow's Milk: Label Reading and Strategies—cont'd

¶Free amino acid-based infant formula: hypoallergenic; peptide-free formula that contains essential and nonessential amino acids. Usually tolerated by those allergic to extensively hydrolyzed formulas.

**Soy formula: Should not be used in infants younger than 6 months old with food allergies.

Ah-Leung S et al: Allergy to goat and sheep milk without allergy to cow's milk, *Allergy* 61(11):1358-1365, 2006; Bahna SL: Hypoallergenic formulas: optimal choices for treatment versus prevention, *Ann Allergy Asthma Immunol* 101:5, 2008; Greer FR et al: Effects of early nutritional interventions on the development of atopic disease in infants and children: the role dietary restriction, breastfeeding, timing of introduction of complementary foods, and hydrolyzed formulas, *Pediatrics* 121:183, 2008; Joneja JV: *The health professional's guide to food allergies and intolerances*, Chicago, 2013, Academy of Nutrition and Dietetics; Kneepkens CM, Meijer Y: Clinical practice: diagnosis and treatment of cow's milk allergy, *Eur J Pediatr* 168:891, 2009.

BOX 26-10 Eliminating Wheat: Label Reading and Strategies**Ingredients and Single Ingredient Foods to Avoid**

- All-purpose flour
- Bran
- Bread crumbs
- Bread flour
- Bulgar
- Cake flour
- Cereal extract
- Couscous
- Cracked wheat
- Durum flour
- Durum wheat
- Einkorn
- Emmer
- Enriched flour
- Farina
- Farro
- Flour
- Gluten
- Graham flour
- High-gluten flour
- High-protein flour
- Kamut
- Kamut flour
- Laubina
- Leche alim
- Minchin
- Pastry flour
- Puffed wheat
- Red wheat flakes
- Rolled wheat
- Seitan
- Semolina flour
- Soft wheat flour
- Spelt
- Sprouted wheat
- Triticale
- Vegetable gums
- Vital gluten
- Wheat
- Wheat bran
- Wheat flakes
- Wheat flour
- Wheat germ
- Wheat gluten
- Wheat malt
- Wheat meal
- Wheat starch
- Wheat tempeh
- White flour
- Whole wheat berries

- Whole wheat flour
- Winter wheat flour

Other Foods That Often Contain Wheat as an Ingredient

- Ale and beer
- Baking mixes and baked products
- Bread
- Breaded or floured goods including batter-fried foods
- Cake
- Cookies
- Crackers
- Cracker crumbs
- Cream sauces
- Cream soups
- Gelatinized starch
- Hydrolyzed vegetable protein
- Licorice
- Malted cereals
- Meats containing fillers including processed meats
- Meatloaf
- Modified food starch
- Modified starch
- Multi-grain breads
- Multi-grain chips
- Multi-grain crackers
- Multi-grain flours
- Pastries
- Roux
- Shredded wheat
- Starch
- Soy sauce
- Tempura
- Tortillas
- Vegetable gums (guar, xanthan)
- Vegetable starch
- Wheat bread
- Wheat bread crumbs
- Wheat pasta
- Wheat protein beverage
- Wheat protein powder
- White bread

Wheat Substitutes (Equivalent to 1 Cup Wheat Flour) in Recipes

With any substitution, always read labels carefully and look for gluten-free labels to ensure that no cross-contamination with other grains and wheat has occurred, which can be common.

- All Purpose Blends:
 - $\frac{3}{4}$ cup brown rice flour, 3 tablespoons potato starch, 1 tablespoon tapioca flour, and $\frac{1}{2}$ teaspoon xanthan gum

BOX 26-10 Eliminating Wheat: Label Reading and Strategies—cont'd

- ½ cup rice flour, ¼ cup tapioca flour, ¼ cup corn or potato starch
- High-Fiber Blend: Best for breads, pancakes, and snack bars
 - 1 cup brown rice or sorghum flour, ½ cup light teff flour, ½ cup millet flour, ⅔ cup tapioca flour, ⅓ cup corn or potato starch
- High-Protein Blend: Best for wraps and pie crusts
 - 1¼ cup bean flour, 1 cup arrowroot, corn, or potato starch, 1 cup tapioca flour, 1 cup brown rice flour
- Self-Rising Blend: Best for muffins, scones, cakes, or cupcakes
 - 1¼ cups white sorghum flour, 1¼ cups white rice flour, ½ cup tapioca flour, 2 teaspoons xanthan or guar gum, 4 teaspoons baking powder, ½ teaspoon salt
- Xanthan and guar gum can serve chemically as gluten substitutes in non-gluten flour blends, which can improve the texture of baked goods. Although usually made from corn, they can be made using wheat, dairy, or soy, so it is important to check the source.
 - Add ½ teaspoon per cup of flour for bars, cakes, cookies, muffins, and quick breads.
 - Add 1 teaspoon per cup of flour for baked items that call for yeast, such as pizza dough and yeasted bread.
- Pre-mixed wheat and gluten-free flour products are available commercially as well.

Wheat-Free Alternative Options

- Amaranth
- Barley (if no gluten intolerance)
- Buckwheat, raw groats
- Buckwheat, toasted kasha
- Chickpea/garbanzo
- Corn
- Job's tears (Hato Mugi)
- Lentil
- Millet
- Montina (Indian Rice Grass)
- Oats (if certified gluten free)
- Potato
- Quinoa
- Rice
- Rye (if no gluten intolerance)
- Sorghum
- Tapioca
- Teff
- Wild rice

*Please also note that non-food products such as cosmetics, supplements, and medications can contain wheat ingredients and may cause an adverse reaction.

BOX 26-11 Eliminating Peanuts: Label Reading and Strategies**Ingredients and Single Ingredient Foods to Avoid***

- Arachis oil
- Artificial tree nuts
- Beer nuts
- Cold pressed peanut oil
- Defatted peanuts
- Expelled or expressed peanut oil
- Extruded peanut oil
- Granulated peanuts
- Ground nuts
- Hydrolyzed plant protein
- Hydrolyzed vegetable protein
- Mandelonas
- Mixed nuts
- Monkey nuts
- Nut meat
- Nut pieces
- Nuts with artificial flavoring
- Peanuts, all varieties
- Peanut butter
- Peanut flakes
- Peanut flour
- Peanut meal
- Peanut oil
- Peanut protein hydrolysate

Other Foods That Often Contain Peanuts as an Ingredient†

- All candy (check ingredients)
- Baked goods
- Breeding
- Cashew butter
- Cheesecake crusts
- Chili
- Chili sauce
- Chocolate candy
- Dog food and treats
- Egg rolls
- Enchilada sauce
- Foods fried in peanut sauce
- Frozen desserts
- Gravy
- Hamster feed
- High protein food
- Ice cream
- Livestock feed
- Marzipan
- Mole sauce
- Nougat
- Pancakes
- Pie crusts
- Rice Krispie treats
- Salad dressing
- Sauces
- Soups
- Stews
- Sunflower seeds

*Eliminate all sources of peanuts from diet including cross-contaminated food or utensils. There is a high risk of cross-contamination when eating out, especially at Asian, Chinese, Mexican, Thai, Mediterranean, and Indian restaurants.

*Please also note that non-food products such as cosmetics, supplements, and medications can contain peanut ingredients and may cause an adverse reaction.

†*Peanut powder, peanut butter, and peanuts may be used as an ingredient or garnish for many dishes.*

Joneja JV: *The health professional's guide to food allergies and intolerances*, Chicago, 2013, Academy of Nutrition and Dietetics; Peanut Allergy: *Food Allergy and Research Education* (website): <https://www.foodallergy.org/allergens/peanut-allergy>, Accessed February 2014.

BOX 26-12 Eliminating Soy: Label Reading and Strategies

Ingredients and Single Ingredient Foods to Avoid*

- Asian cuisine
- Chee-fan
- Deep-fried mature soy seed
- Edamame
- Fermented soybean paste
- Fermented soybeans
- Hamanatto
- Immature green soy seed
- Ketjap
- Miso
- Natto
- Shoyu sauce
- Soy albumin
- Soy cheese
- Soy fiber
- Soy ice cream
- Soy lecithin‡
- Soy milk
- Soy nuts
- Soy protein (concentrate, hydrolyzed, isolate)
- Soy protein powders
- Soy protein shakes
- Soy sauce
- Soybean curd
- Soybean flour
- Soybean granules
- Soybean grits
- Soybean oil*
- Soybean sprouts
- Sufu
- Tamari
- Tao-cho
- Tao-si
- Taotjo
- Tempeh
- Textured soy protein
- Textured vegetable protein (TVP)
- Tofu
- Whey-soy drink

Other Foods That Often Contain Soy as an Ingredient

- Baked goods
- Canned broths and soups
- Canned tuna and meat
- Cereals
- Cold-pressed oils
- Cookies
- Crackers
- High-protein energy bars
- Hydrolyzed plant protein
- Hydrolyzed vegetable protein
- Low-fat peanut butter
- Natural flavoring
- Processed meats
- Sauces
- Vegetable broth
- Vegetable gum
- Vegetable starch

Soy Substitutes (Cup for Cup) in Recipes

- Light-colored fruit juice (e.g., apple, orange, white grape)
- Flax, hemp, sunflower, or other seed beverages
- Oat, rice, quinoa, or other grain beverages
- Almond, cashew, coconut, hazelnut, or other nut beverages

Soy Protein-Free Infant formulas

Standard Infant Formula

- Enfamil Premium Infant (Mead Johnson)
- Similac Advance (Abbott)
- Some store brands (Perrigo Nutritionals) - check with manufacturer

Partially Hydrolyzed (Cow's Milk Protein) Infant Formula§

- Gerber Good Start Gentle (Nestle) 100% whey protein
- Gerber Good Start Protect (Nestle) 100% whey protein
- Similac Total Comfort (Abbott) 100% whey protein
- Some store brands (Perrigo Nutritionals) - check with manufacturer

Extensively Hydrolyzed Infant Formula¶

- Nutramigen with Enflora LGG (Mead Johnson)
- Pregestimil (Mead Johnson)
- Similac Expert Care Alimentum (Abbott)

Free Amino-Acid Base Infant Formulas¶¶

- EleCare for Infants (Abbott)
- PurAmino (Mead Johnson)
- Neocate products (Nutricia)

There is a high risk of cross-contamination when eating out, especially dining at Asian restaurants.

*Please also note that non-food products such as cosmetics, supplements, and medications can contain soy ingredients and may cause an adverse reaction.

‡Several studies indicate that individuals who are soy allergic frequently tolerate soy lecithin and soy oil.

§Partially hydrolyzed: Nonhypoallergenic; contains partially digested cow's milk proteins that have a molecular weight greater than extensively hydrolyzed formula protein chains.

¶¶Free amino-acid based infant formula: Hypoallergenic; peptide-free formula that contains essential and nonessential amino acids. Usually tolerated by those allergic to extensively hydrolyzed formulas.

BOX 26-13 Reasons for Accidental Exposure to Allergens

- Common serving utensils used to serve different foods when some may contain the allergen
- Grocery store bulk bins contaminated with an allergen from another product bin
- Manufacture of two different food products using the same equipment without proper cleaning in between
- Misleading or inaccurate labels (e.g., nondairy creamers that contain sodium caseinate)
- Ingredients added for a specific purpose are listed on the label only in general terms of their purpose rather than as a specific ingredient (e.g., egg white that is simply listed as an “emulsifier”)
- Addition of an allergenic product to a second product that bears a label listing only the ingredients of the second product (e.g., mayonnaise, without noting eggs)
- Switching of ingredients by food manufacturers (e.g., a shortage of one vegetable oil prompting substitution with another)
- A child being offered a food by an individual who is uneducated about the allergy

FOCUS ON: GMO or Genetically Engineered (GE) Foods

Christine McCullum-Gómez, PhD, RD, Food and Nutrition Consultant, Houston, TX

Genetic engineering is one type of genetic modification (GM) that involves the intentional introduction of a targeted change in a plant, an animal, or microbial gene sequence to achieve a specific result. Genetically engineered (GE) foods, also known as GMO (genetically modified organism) foods have been in the U.S. food supply for approximately 20 years. Plants that are GE can be made to tolerate herbicides and be insect resistant. GE or GMO crops are widely grown and consumed in a number of countries, including the United States (Agapito-Tenfen et al, 2013; Bohn et al, 2014). Some of the most commonly grown GE or GMO crops include soybeans, corn, cotton, canola, and sugar beets. Despite the widespread use of GE crops by various countries, the need for biosafety remains a concern as lack of stringent standards, international harmonization, and transparency, as well as remaining claims of confidentiality on biosafety-relevant data places additional burdens on regulatory agencies (Agapito-Tenfen, 2013; Nielson, 2013).

To date, risk assessment of GE plants has focused on potential allergenicity and toxicity. As part of a safety evaluation for GE crops, an allergenicity assessment is performed to: (1) ensure that an existing allergen or cross-reactive protein(s) is not transferred to a new GE crop; (2) demonstrate that a novel protein is unlikely to become a food allergen *de novo*; and (3) evaluate existing endogenous allergen levels for potential increases in the new GE crop (i.e., soybeans) versus its non-GE control (Ladics, 2008; Ladics et al, 2014).

With this information in mind, the lack of evidence that GE food is unsafe cannot be interpreted as proof that it is safe. As observed by Ladics and colleagues (2014), “the assessment of the allergy risk of a novel protein mainly focuses on its potential to elicit an allergic reaction in consumers already sensitized to a cross-reacting protein. However, reliable tests are missing to definitely predict on their own the potential of novel proteins to sensitize *de novo* atopic individuals. Such potential depends not only on the intrinsic characteristics of the protein (e.g., structure, function, and physiochemical properties) but also on complex interactions between the genetic background and physiology of the consumers and environmental conditions . . .” [Hence], “[a] sensitive and specific validated animal model would help in the identification of proteins that might present an increased risk of sensitizing consumers if introduced in a GE crop. While some progress has been reported with a limited number of proteins, none of the animal models that have been reviewed . . . have been thoroughly tested and validated with a wide range of allergens and non-allergens” (Ladics et al, 2014).

There are also long-term concerns beyond those related to the presence of unknown allergens. A long-term study of weaning and old mice consuming either GE corn or non-GE corn found that the mice consuming the GE corn had increased presence of several cytokines that are specifically involved in inflammatory and allergic responses, and alterations in the number of B-cells and T-cells, indicating an abnormal response to GE corn (Finamore et al, 2008). Histopathologic changes have been found in some organs (liver, kidney, and small intestine) of male rats fed GE corn (El-Shamei et al, 2012).

A published review concluded that there is an incomplete picture regarding the toxicity and safety of GE products consumed by humans and animals (Zdziarski et al, 2014). In addition, evaluations of possible unintended effects derived from GE crops by the use of proteomics and transcriptomics have been reported (Barros et al, 2010; Coll et al, 2011). Based on these results, further investigation of the long-term effects of GE food consumption is needed. Profiling techniques, such as proteomics, which studies the

structure and functions of proteins, allow the simultaneous measurement and comparison of thousands of plant components without prior knowledge of their identity (Heinemann et al, 2011). “As global databases on outputs from ‘omics’ analysis become available, these [databases] could provide a highly desirable benchmark for safety assessments [of GE foods]” (Agapito-Tienfen et al, 2013).

To date, less attention has been given to the residues of herbicides and their degradation products that can accumulate in GE herbicide-tolerant plants, such as GE herbicide-tolerant soybeans (Bohn et al, 2014). Bohn and colleagues (2014) reported that GE herbicide-tolerant soybeans contained high residues of glyphosate and its main breakdown product aminomethylphosphonic acid (AMPA), whereas conventional and organic soybeans contained none of these same agrichemicals. In addition, the organic soybeans contained significantly more total protein and zinc and less saturated fat and total omega-6 fatty acids than conventional and GE soybeans (Bohn et al, 2014). The increased use of glyphosate on GE herbicide-tolerant soybeans in the United States (Benbrook, 2012) may explain the observed plant tissue accumulation of glyphosate in GE herbicide-tolerant soybeans (Brohn et al, 2014). Some scientists have reported that although glyphosate and its degradation product AMPA showed little to no observable toxic effects in isolation, a glyphosate-based formulation containing adjuvants (Roundup)—which is used with GE herbicide-tolerant crops—induced cytotoxicity, oxidative effects, and apoptosis on human cells (Chaufan et al, 2014).

More recently, the International Agency for Research on Cancer (IARC) has classified glyphosate, the herbicide that is most widely used on GE crops, as a “probable human carcinogen (2A)” (Landrigan and Benbrook, 2015). The mechanistic evidence (genotoxicity and oxidative stress) provided independent support of the IARC’s 2A classification (probably carcinogenic to humans) based on evidence of carcinogenicity in humans and experimental animals (Mesnage et al., 2015a). Results from DNA damage assays were considered to present solid mechanistic evidence supporting the 2A classification of glyphosate (Guyton et al., 2015; Mesnage et al., 2015a). In addition, chronic exposure to very low levels of glyphosate-based herbicides, which people are exposed to through drinking water, has been linked to liver and kidney damage in an established laboratory animal toxicity model system (Mesnage et al., 2015b). Finally, research indicates that xenobiotics (i.e., chemical compounds not produced by the body such as drugs and pesticides), are able to exert their toxic effects across several generations through epigenetic alterations (Nilsson and Skinner, 2015). Because the effects of reproductive toxicity of pesticides are not limited to a single generation, they have to be studied across several generations in multigenerational or transgenerational studies. However, no multigenerational or epigenetic study has been performed with the glyphosate-herbicide Roundup or its adjuvants (Mesnage et al., 2015a). As a result, some scientists are encouraging regulators “to ask for complete reassessment of glyphosate formulations, rather than glyphosate alone, in particular with a full life-span test on mammals at environmentally-relevant doses, with detailed blood and urine analyses, taking into account principles from endocrinology and epigenetics” (Mesagne et al., 2015a).

The first systems biology analysis conducted to assess the safety of GE organisms observed differences in two biomarkers, formaldehyde (a known toxin) and glutathione, which predict metabolic disruptions in

FOCUS ON: GMO or Genetically Engineered (GE) Foods—cont'd

Christine McCullum-Gómez, PhD, RD, Food and Nutrition Consultant, Houston, TX

one-carbon (C1) metabolism (Ayyadurai and Deonikar, 2015). In non-GE plants, formaldehyde remains at near zero levels, being naturally cleared through a process of formaldehyde detoxification. Concomitantly, glutathione, a known anti-oxidizing agent, in non-GE plants, is naturally replenished and remains at non-zero steady state levels to support systemic detoxification of formaldehyde (Kothandaram et al., 2015). However, in the case of GE herbicide-tolerant soybeans, accumulation of formaldehyde and a concomitant depletion of glutathione, suggests how a 'small' and single genetic modification can create 'large' and systemic perturbations to molecular systems equilibria. These authors note that given the potentially far-reaching effects of a single genetic modification, as this research suggests for the GE soybean, "at least a process, similar to the FDA clinical trials for single compound drugs, seems rational for GE safety assessment and approval" (Ayyadurai and Deonikar, 2015).

Adopting a computational systems biology approach (which aims to understand the complexity of the whole organism, as a system, rather than studying its parts in a reductionist manner) using biomarkers - such as

formaldehyde and glutathione - that predict metabolic disruptions, may be useful for modernizing the safety assessment of GE foods, while fostering a much-needed transparent, collaborative and scientific discourse. The substantial and material difference in the levels of biomarkers of formaldehyde and glutathione, across non-GE and GE soybeans, predicted from this systems biology analysis, however, demands *in vitro* and *in vivo* testing, including the development of objective standards on how such testing is to be performed (Ayyadurai and Deonikar, 2015). In the interim, some scientists have recommended labeling GE foods and long-term post-marketing surveillance to track any possible adverse effects (e.g., the emergence of novel food allergies and assessing the potential effects of synthetic herbicides applied to GE crops) (Landrigan and Benbrook, 2015).

Because using GE foods may complicate the elimination diet, or as already mentioned, aggravate an immune-mediated response, it may be prudent to advise those with documented food allergies to eat organic soybeans, corn, canola, cottonseed, beet sugar, and other foods for which there are GE versions in the food supply.

Another situation that may lead to the unknowing ingestion of an allergenic food occurs when one product is used to make a second product, and only the ingredients of the second product are listed on the food label. An example is the listing of mayonnaise as an ingredient in a salad dressing without specifically listing egg as an ingredient of

the mayonnaise. Labels must be read often to ensure that ingredients have not changed in the processing of the food (see [Box 26-14](#)).

When foods are removed from the diet, alternative nutrient sources must be provided. [Table 26-7](#) defines the levels of nutritional risk based on the types of food removed from the

BOX 26-14 Allergen Labeling of Foods

Since January 1, 2006, the updated US **Food Allergen Labeling and Consumer Protection Act (FALCPA)** requires the top allergens to be clearly listed by manufacturers as an ingredient or following the ingredient list on food labels. This includes ingredients in any amount and also mandates specific ingredients to be listed such as the type of nut or seafood.

Requirements of the Law

- **Top eight allergens must be clearly listed** by manufacturers as an ingredient or following the ingredient list on food labels of any food product containing allergens
- Applies to all packaged foods sold in the United States
- Does not apply to USDA-regulated products, including meat, poultry products, and some egg products
- Does not list sources of possible contamination
- Does not apply to prescription medication or alcoholic beverages
- Does not apply to foods packaged or wrapped after being ordered by the consumer

Top Allergens

- Any ingredient containing or derived from the top eight allergens—milk, eggs, fish, shellfish, tree nuts, peanuts, wheat, or soybeans
- For tree nuts, fish, and shellfish the specific type must be listed (e.g., walnut, pecan, shrimp, tuna)

Reading the Food Label

- Ingredients may be included within the food's ingredient list directly or in parentheses following the name, if an ingredient does not clearly identify the allergen
- Following the list of ingredients all food allergens may be listed in a "Contains" statement
- Manufacturers may voluntarily list potential unintended allergens that may be present due to cross contamination in a clear way that does not interfere with the required food ingredient list

Note: In 2013 the FDA issued a final rule defining "gluten-free" for food labeling. This final rule requires that items labeled "gluten-free" meet a defined standard for gluten content (see Chapter 28).

Note: It is being proposed that sesame be added to the list of top allergens required on labels.

TABLE 26-7 Risk of Nutritional Deficiency

Level of Risk	Food Characteristics/Examples
Low risk	Any food that can easily be eliminated with minimum or no nutritional risk to the patient; substitutes are easily incorporated into the diet; protein, fat, calorie and nutrient consumption is optimal. <i>Example:</i> Avoidance of a specific fruit or vegetable or tree nuts
Moderate risk	Any food that may be encountered frequently throughout the food supply, yet the elimination of which does not significantly limit food choices or vital nutrient sources; adequacy of protein, fat, calorie, and nutrient consumption need monitoring. <i>Example:</i> Avoidance of soy, fish, or eggs
High risk	Any food or usually group of foods that permeates the food supply, providing a significant source of specific nutrients that are not readily available through other foods that are a part of the normal diet; the elimination of which results in a significant lifestyle and dietary change because of the difficulty of avoiding that food and products containing that food; adequate protein, fat, calorie, and nutrient consumption unlikely; nutrient supplementation often necessary. <i>Example:</i> Avoidance of wheat, soy, egg, cow's milk, fish, or multiple foods

CLINICAL INSIGHT**Rotation Diets—Where's the Science? Are They Clinically Useful?**

Janice M Joneja, PhD, CDR

The Theory

Rotation diets, or the protocol of eating foods in the same food families no more often than every 4 to 10 days, were developed as a theoretical way to give the body a rest from each food family in an effort to prevent the development of food intolerances. In addition, it was claimed that rotation diets assisted in the identification of adverse food reactions and that by rotating the intake of the foods there could be freedom from allergic symptoms for a longer period.

The Data

- Evidence-based research studies to support these claims are lacking.
- Recent research has demonstrated that members of the same botanical food family are not necessarily related allergenically.
- There is often a closer antigenic association between unrelated foods than those within the same family. Examples that demonstrate this concept include oral allergy syndrome and latex-fruit syndrome.
- Diets based on the avoidance of entire food families is illogical.

Important Considerations

When an adverse reaction to foods is due to a non-immune-mediated reaction such as an enzyme deficiency (e.g., lactase), a diet that restricts the intake of all lactose-containing foods will ensure the tolerance level is not exceeded and thus symptoms are avoided. A "rotation type diet" that restricts the number and quantity of foods known to contain the culprit component is necessary to ensure that the dose of the reactive component is reduced.

Non-IgE-mediated food allergy may be dose related. A rotation diet that restricts the number and quantity of foods known to contain the culprit component is often beneficial (Joneja, 2013). However, when the food allergy is IgE mediated, there is no logic for a rotation diet. The problem food must be continually avoided until a food challenge shows that there is no longer a reaction. Then the food can be consumed on any schedule.

When the rotation diet is used, there is no scientific basis for a 4-, 5-, 7-, or even 30-day rotation of foods. All protocols have been used clinically. Such diets must be formulated on an individual basis to ensure that the dose of the reactive component is reduced to a minimum, whereas nutrients equivalent to those eliminated are supplied by alternative foods.

diet. For example, when eggs are omitted, other foods must provide choline, vitamin D, protein, and energy.

Healing the Gut and Restoring Immune Balance

Because approximately 70% of immune cells are located in the **gut-associated lymphatic tissue (GALT)**, efforts to restore gut health should improve immune function and modulate allergic responses. Besides eliminating problematic foods, other measures include optimizing stomach acidity and enzyme function; identifying and treating pathogens such as bacteria, yeasts, and parasites; restoring intestinal barrier function; repleting nutritional status and restoring gut microbiota balance (see Chapters 27 and 28).

EMERGING THERAPIES

Food immunotherapy vaccines is a possible future treatment meant to complement food allergen avoidance, but these vaccines are still experimental. Recent research has produced encouraging evidence that **specific oral tolerance induction (SOTI)** can be achieved by introducing the culprit food via the digestive tract in minute then increasing quantities for

an extended period (Clark et al, 2009; Joneja, 2013; Zapatero et al, 2008).

Several potential treatments are under active investigation in animal and human studies. Some of these approaches include oral, sublingual, and epicutaneous immunotherapy, immunotherapy combined with anti-IgE, and Chinese herbal medicine. Also being studied are modified protein immunotherapy, adjuvants, DNA vaccines, and helminth administration (Keet and Wood, 2014).

Nutritional Adequacy

The nutritional adequacy of the diet should be monitored on a regular basis by conducting an ongoing evaluation of the patient's nutritional status and food and symptom records. The omission of foods from the diet on the basis of proper or improper diagnosis can and has impaired the nutritional status of the allergic individual. Malnutrition and poor growth may occur in children who consume improperly planned and nutritionally inadequate elimination diets (Keller et al, 2012). Vitamin and mineral supplementation may be needed to prevent this, especially when multiple foods are omitted. Nutrition assessment must be conducted on a regular basis.

Because food is an important part of a person's culture, the social aspects of eating can make adherence to an elimination diet challenging. Continued support from health care providers is needed to minimize the effect of dietary changes on family and social life. The strategies listed in **Box 26-15** can help families and individuals cope with ARFs.

It was previously thought that most children would achieve tolerance and "outgrow" their food allergies by 3 years of age; however, it is becoming apparent that this is not the case. Only 11% of egg-allergic and 19% of milk-allergic children resolve their allergies by 4 years of age. However, almost 80% resolve these allergies by age 16 (Savage et al, 2007; Skripak et al, 2007). Peanut allergy tends to be lifelong for most children, with only about 20% of children able to resolve it (Sicherer and Sampson, 2010; NIH, NIAID, 2010). New therapies for peanut allergy are on the horizon, so this may change (DuToit et al, 2015, Fleischer et al, 2015).

PREVENTING FOOD ALLERGY

Intensive research is being focused on the pathogenesis and prevention of allergic disease, including the role of genetics, epigenetics, and environmental factors such as early dietary exposures and feeding practices. Allergy prevention guidelines have gradually shifted away from allergen avoidance to examination of the role of specific dietary and lifestyle factors in the development and prevention of allergic disease (Jennings and Prescott, 2010; Joneja, 2012). For prevention, focus is turning to lifestyle factors that promote oral tolerance (see **Box 26-16**).

Allergen Exposure

The traditional approach for dietary allergy prevention has been avoidance of food allergens in the maternal diet and early postnatal period. However, there is a lack of evidence that maternal dietary restrictions during pregnancy help prevent atopic disease in infants. Food restriction to avoid antigen exposure while breastfeeding does not appear to prevent atopic disease, with the possible exception of atopic eczema (Greer et al, 2008). However, recent research indicates that exposure to food antigens in the "safe" environment of pregnancy and in breast milk is more likely to lead to tolerance rather than sensitization to those foods in the infant. Current trials on infant feeding are

BOX 26-15 Strategies for Coping with Food Allergy

Food Substitutions

Try to substitute item-for-item at meals. For example, if the family is eating pasta for dinner, substitution of a gluten-free pasta may be better accepted for the gluten-sensitive or wheat-allergic person than a dissimilar item.

Dining Out and Eating Away from Home

Eating meals away from home can be risky for individuals with food allergies. Whether at a fancy restaurant or a fast-food establishment, inadvertent exposure to an allergen can occur, even among the most knowledgeable individuals. Here are some precautions to take:

- Bring “safe” foods along to make eating out easier. For breakfast, bring along an appropriate milk if others will be having cereal with milk.
- Alert the wait staff to the potential severity of the food allergy or allergies.
- Question the wait staff carefully about ingredients.
- Always carry medications.

Special Occasions

Call the host family in advance to determine what foods will be served. Offer to provide an acceptable dish that all can enjoy.

Grocery Shopping

Be informed about what foods are acceptable, and read labels carefully. Product ingredients change over time; continue to read the labels on foods, even if they were previously determined to be “safe” foods. Allow for the fact that shopping will take extra time.

Label Reading

Labeling legislation makes it easier for individuals with food allergies to identify certain potential allergens from the ingredient list on food labels. For example, when food manufacturers use protein hydrolysates or hydrolyzed vegetable protein, they must now specify the source of protein used (e.g., hydrolyzed soy or hydrolyzed corn). Although reactions to food colors or food dyes are rare, individuals who suspect an intolerance will find them listed separately on the food label, rather than categorized simply as “food color.”

attempting to elucidate the concept of oral tolerance and define the effect that the timing of introduction of solids and allergenic foods has on development of allergic disease.

Breastfeeding

Breast milk contains a host of immunologically active compounds, such as transforming growth factor- β , lactoferrin, lysozymes, long-chain fatty acids, antioxidants, and secretory IgA (sIgA), all of which have an effect on immune development, including oral tolerance, and help to reinforce the gut-epithelial barrier (Brandtzaeg, 2009; Jennings and Prescott, 2010). Breastfeeding without any maternal dietary restrictions is strongly encouraged, although the exact role of breastfeeding in allergy prevention is unclear. There is evidence that exclusive breastfeeding for at least 3 months protects against wheezing in early life (Greer et al, 2008). For infants at high risk of developing atopic disease (infants with a first-degree relative with allergy) exclusive breastfeeding for at least 4 months is recommended (Host et al, 2008). Continuation of breastfeeding through the time when solid foods are introduced is believed to further help prevent the development of food allergy.

Sensitivity to breast milk is rare but has been reported. Allergens such as cow’s milk, eggs, and peanuts in the mother’s diet can pass into the breast milk and cause an allergic reaction in the “exclusively” breast-fed infant, but cannot cause sensitization.

BOX 26-16 Recommendations to Promote Oral Tolerance and Prevent Allergy

- Support breastfeeding and delay introduction of solid foods until 4 to 6 months.
- Strengthen immunity by increasing connection to natural environments, pets, and farms.
- Strengthen immunity by regular physical exercise.
- Use antibiotics only when necessary; the majority of microbes are useful and help build healthy immune function.
- Consume fermented food or other probiotic preparations to strengthen immune system.
- Do not smoke: parental and family smoking around infants and children can increase risk of asthma.

From Haahtela T et al: The biodiversity hypothesis and allergic disease: world allergy organization position statement, *World Allergy Organ J* 6:3, 2013.

The infant may have been sensitized from an external source such as from small amounts of infant formula given to him or her.

Infant formulas should be given in the first 4 to 6 months only if exclusive breastfeeding is not possible for some reason. Soy-based infant formulas offer no advantage for the purpose of allergy prevention, and some infants may react adversely to these formulas. Extensively hydrolyzed formulas may be more protective than partially hydrolyzed formulas in prevention of atopic disease (Greer et al, 2008). Amino acid-based formulas may be used in managing an established food allergy but have not been adequately studied for atopy prevention (see Boxes 26-9 and 26-12).

Solid Food Introduction

Exclusive breastfeeding for 6 months is highly recommended. Complementary solid foods other than breast milk should not be introduced until 4 to 6 months of age. There is no convincing evidence that delaying introduction beyond this time prevents the development of atopic disease, and this even pertains to the introduction of foods that are considered to be highly allergenic, such as peanuts, eggs, and fish (Jennings and Prescott, 2010). In fact a recent study found that the early introduction of peanut in a powdered form as early as 4 to 11 months with a 3 times per week consumption, resulted in a significant and substantial decrease in the development of peanut allergy in high-risk infants. Peanut avoidance was associated with a greater frequency of peanut allergy by age 5 years than was peanut consumption (Du Toit et al, 2015).

Early Diet and Immunomodulatory Factors

A number of regulatory factors in early life may influence the development of asthma and other allergic diseases. The immunoregulatory network in newborns is orchestrated by a variety of events and agents, many incompletely understood. Nutrients such as vitamin A, vitamin D, omega-3 fatty acids, folate, and other micronutrients have been cited as potential influences (Brandtzaeg, 2010). The intestinal microbiota are important. For example parental sucking of their infant’s pacifier has been shown to reduce the risk of allergy development, possibly by stimulation of the immune system by microbes transferred to the infant in the parent’s saliva (Hesselmar et al, 2013).

Antioxidants

Diets high in antioxidants such as carotenoids and other phytonutrients, vitamin C, vitamin E, zinc, and selenium may prevent the

development of food allergies. There have been positive associations found between maternal antioxidant status in pregnancy and cord blood immune responses (West et al, 2010). Higher maternal intake of green and yellow vegetables, citrus fruit, and beta-carotene during pregnancy was significantly associated with a reduced risk of eczema, but not wheezing, in the infants. Maternal vitamin E consumption was inversely related to the risk of infantile wheeze, but not eczema (Miyake et al, 2010). Thus, optimizing food sources of antioxidants from fruit and vegetable intake during pregnancy may be an effective effort for allergy risk reduction.

Vitamin D

It has been proposed that the increase in the development of food allergy in children may be due to an increased prevalence of vitamin D deficiency. Suboptimal vitamin D status in a developmentally critical period increases susceptibility to colonization of the gut with abnormal intestinal microbial flora and GI infections, contributing to an abnormally porous gut and inappropriate exposure of the immune system to dietary allergens. Vitamin D helps promote immunoregulation through T-cell differentiation. Cord blood levels of 25-OH vitamin D at birth have been found to be inversely correlated with reduced eczema at 6 months (Jones et al, 2015). It is suggested that early correction of vitamin D deficiency may promote mucosal immunity, healthy microbial ecology, and allergen tolerance and may prevent food allergy development (Jones et al, 2012; Rueter et al, 2014).

Folate

Folate deficiency has been associated with several disorders characterized by enhanced activation of the cellular, Th1-type immune response. An intriguing development has been the recognition of epigenetic effects of dietary folate in the development of asthma (Jennings and Prescott, 2010). DNA methylation and inflammation appear to be the two main pathways through which folate may influence the development of childhood asthma and allergy (Brown et al, 2014). The small increase in risk that has been reported was associated only with maternal folate exposure during late pregnancy (Brown et al, 2014). Impaired folate metabolism may be related to the development of atopy, but the relationship and the significance warrants further investigation (Binkley et al, 2011, Brown et al, 2014).

Polyunsaturated Fatty Acids (PUFAs)

The role of polyunsaturated fatty acids (omega-3 and omega-6 PUFAs) in allergy development has been the subject

of investigation, because PUFAs have effects on inflammation and immune function. Some studies have suggested that maternal consumption of fish oil (a source of omega-3 fatty acids) in pregnancy protects against the development of asthma, eczema, and allergic sensitization, whereas others have not shown these results (Palmer et al, 2013). A recent systematic review indicates that it is not clear that supplementation with omega-3 and omega-6 oils will play a role in the prevention of sensitization or allergic disease (Miles and Calder, 2014). Further studies are needed to elucidate the role of fatty acids in allergy prevention and their role in the inflammatory cascade (see Chapter 3).

Pre- and Probiotics

Probiotics are defined as live microorganisms that, when administered in adequate amounts, impart health benefits to the host. **Prebiotics** are non-digestible, fermentable oligosaccharides that stimulate the growth and activity of the gastrointestinal microbiota, thus conferring benefits upon host health (International Scientific Association for Probiotics and Prebiotics [IASPP], 2015). The combination of pro- and prebiotics is sometimes referred to as a synbiotics (see Chapter 28).

The role of probiotics in allergy prevention continues to be investigated. The administration of probiotics during pregnancy and early infancy has been shown to reduce the risk of eczema (Fiocchi et al, 2015; West, 2014). The results of some studies support the use of probiotics during the first 6 months of life in infants at high risk of developing allergy, but more data are needed to recommend routine use of probiotics (Doerge et al, 2011). The effect of the individual strain, timing of administration (pre- or postnatal), dosage, and environmental factors that affect colonization have yet to be determined (Esposito et al, 2014; Haahtela et al, 2015). It has been reported that low gut microbiota richness and an elevated ratio of the Enterobacteriaceae/Bacteroidaceae microbiota in early infancy are associated with subsequent food sensitization, and this may contribute to development of allergic disease, including food allergy (Azad et al, 2015). Interestingly, the Bacteroidaceae are one of the families of bacteria known to stimulate the production and degradation of mucin, so important in the maintenance of an intact microbiota-mucin barrier. Early deficiency of Bacteroidetes has been reported in infants with atopic dermatitis and food allergy (Ling et al, 2014).

CLINICAL CASE STUDY

Clara is 17 months old. At birth she was breastfed, but 2 weeks later cow's milk-based formula was introduced, which she did not appear to tolerate. Each feeding resulted in diarrhea and vomiting. The pediatrician recommended that her mother switch to a partially hydrolyzed casein infant formula, which Clara seemed to tolerate. However, at age 4 months she developed eczema that was treated with steroid creams. Cow's milk was introduced when Clara was 12 months of age. Her skin symptoms increased remarkably. When eggs and later peanut butter were introduced, she experienced immediate wheezing; watery, swelling eyes; hives; increased itchiness; and diarrhea. Clara's parents are unaware of how to look for egg or peanut sources; thus Clara has experienced several trips to the emergency room. The last reaction was much more intense. Her family physician suspects egg and peanut allergies and has sent her to see a board-certified allergist and a registered dietitian.

Nutrition Diagnostic Statements

- Food and nutrition-related knowledge deficit by parents related to food sources of eggs and peanuts as evidenced by serious reactions in their daughter following ingestion.
- Intake of unsafe foods related to ingestion of egg- and peanut-containing foods as evidenced by serious reactions to foods.

Nutrition Care Questions

- How many food allergen suspects are there, and what are they? Why?
- What measures will her parents need to take if Clara is to lose sensitivity to any of the food allergens?
- What other circumstances may arise that may warrant special instructions to caregivers?
- How often should Clara be checked for sensitivity changes?
- What would you tell Clara's parents to look for on food labels?
- What nutrient substitutions must be considered?

Medical Nutrition Therapy for Upper Gastrointestinal Tract Disorders

Gail Cresci, PhD, RDN, LD, CNSC; Arlene Escuro, MS, RDN, CNSC

KEY TERMS

achalasia	functional dyspepsia	Nissen fundoplication
achlorhydria	gastrectomy	odynophagia
achylia gastrica	gastric pull-up	parietal cells
atrophic gastritis	gastric ulcer	parietal cell vagotomy
Barrett's esophagus (BE)	gastritis	peptic ulcer
bezoar	gastroesophageal reflux (GER)	pyloroplasty
Billroth I	gastroesophageal reflux disease (GERD)	Roux-en-Y
Billroth II	gastroparesis	Rome III criteria
dumping syndrome	heartburn	stress ulcer
duodenal ulcer	<i>Helicobacter pylori</i>	upper esophageal sphincter (UES)
dyspepsia	hematemesis	vagotomy
dysphagia	hiatal hernia	vagotomy, truncal
endoscopy	lower esophageal sphincter (LES)	vagus nerve
esophagectomy	melena	
esophagitis	mucosa-associated lymphoid tissue (MALT)	
esophagoduodenoscopy (EGD)		

Digestive disorders are among the most common problems in health care. Between 60 and 70 million people are affected by all digestive diseases, with more than 50 million ambulatory care visits made annually in the United States alone. More than 20 million diagnostic and surgical procedures involving the gastrointestinal (GI) tract are performed each year (CDC, 2014). Dietary habits and specific food types can play an important role in the onset, treatment, and prevention of many GI disorders. Nutrition therapy is integral in the prevention and treatment of malnutrition and deficiencies that can develop from a GI tract disorder. Diet and lifestyle modifications can improve a patient's quality of life by alleviating GI symptoms and decreasing the number of health care visits and costs associated with GI disease.

ASSESSMENT PARAMETERS

Components of a comprehensive nutrition assessment of patients with GI disorders include the clinical examination and evaluation of anthropometrics, biochemical markers, and the patient's nutrition history. A detailed nutrition history includes the typical dietary intake, changes in appetite, food allergies and intolerances, mastication and swallowing ability, and GI symptoms such as nausea, vomiting, diarrhea, constipation, and the use of dietary supplements (see Chapter 4). Assessment of body weight changes and evaluation of lean body mass (LBM) guide nutrition assessment, estimation of nutritional requirements, and the development of a nutrition care plan. Patients should

be evaluated for unexplained weight loss changes, particularly focusing on percent weight loss over a specified period of time (e.g., at least 5% in 1 month; at least 10% in 6 months). Patients with severe weight loss benefit from initiation of nutrition support early. In fact, "tuning up" a malnourished patient nutritionally before medical or surgical interventions is associated with improved patient outcomes.

Laboratory assessment can be useful to detect a subclinical nutrient deficiency or excess before physical signs manifest. Laboratory assessment should be guided by information obtained in the nutrition history for suspicion of deficiencies (see Chapter 7 and Appendix 22). Although an inadequate diet can result in suboptimal status of several nutrients, isolated vitamin, mineral, or trace element deficiencies also can be the result of disease state, medical interventions, or medication interactions (see Chapter 8 and Appendix 23).

THE ESOPHAGUS

The esophagus is a muscular tube that has an average length of 25 cm in adults (see Figure 27-1). It serves a single but very important function: conveying solids and liquids from the mouth to the stomach. It is lined with nonkeratinized stratified squamous epithelium, and submucosal glands secrete mucin, bicarbonate, epidermal growth factor, and prostaglandin E2, which protect the mucosa from gastric acid.

The top of the esophagus is connected to the pharynx and the bottom of the esophagus is connected to the stomach at the

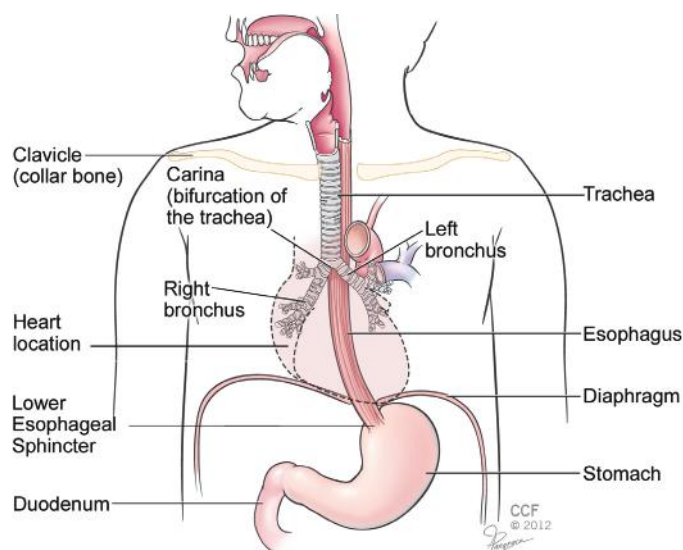

FIGURE 27-1 Normal esophagus. (Cleveland Clinic, Cleveland, Ohio.)

cardia. It is highly muscular, with muscles arranged in a way to facilitate the passage of food. As a bolus of food is moved voluntarily from the mouth to the pharynx, the **upper esophageal sphincter (UES)** relaxes, the food moves into the esophagus, and peristaltic waves move the bolus down the esophagus; the **lower esophageal sphincter (LES)** relaxes to allow the food bolus to pass into the stomach. The esophageal transit time takes an average of 5 seconds when in an upright position, and up to 30 seconds when in a supine position (la Roca-Chiapas and Cordova-Fraga, 2011).

The normal esophagus has a multitiered defense system that prevents tissue damage from exposure to gastric contents, including LES contraction, normal gastric motility, esophageal mucus, tight cellular junctions, and cellular pH regulators. Musculoskeletal disorders and motility disorders may result in dysphagia. For example, **achalasia** is characterized by a failure of esophageal neurons, resulting in a loss of ability to relax the LES and have normal peristalsis.

Gastroesophageal Reflux Disease (GERD) and Esophagitis

Etiology

Gastroesophageal reflux (GER) is considered a normal physiologic process that occurs several times a day in healthy infants, children and adults. GER generally is associated with transient relaxation of the LES independent of swallowing, which permits gastric contents to enter the esophagus. Limited information is known about the normal physiology of GER in infants, but regurgitation and spitting up, as the most visible symptom, is reported to occur daily in 50% of all infants (Lightdale et al, 2013).

Gastroesophageal reflux disease (GERD) is a more serious, chronic or long-lasting form of GER and is defined as symptoms or complications resulting from the reflux of gastric contents into the esophagus or beyond, and even into the oral cavity (including larynx) or lung.

In developed countries, the prevalence of GERD (defined by symptoms of **heartburn** [painful, burning sensation that

radiates up behind the sternum of fairly short duration] and regurgitation, or both, at least once a week) is 10% to 20%, with a slightly lower prevalence in Asia (Jung, 2011). The types of GERD can be distinguished by **esophagogastroduodenoscopy (EGD)**, which uses a fiberoptic endoscope to directly visualize the esophagus, stomach, and duodenum. GERD can be classified as the presence of symptoms without abnormalities or erosions on endoscopic examination (nonerosive disease or NERD), or GERD with symptoms and erosions present (ERD). ERD generally is associated with more severe and prolonged symptoms compared with NERD (Katz et al, 2013).

Some patients experience GERD symptoms primarily in the evening (nocturnal GERD), which has a greater impact on quality of life compared with daytime symptoms. Nocturnal GERD is associated significantly with severe **esophagitis** (inflammation of the esophagus) and intestinal metaplasia (Barrett's esophagus) and can lead to sleep disturbance. Patients with ERD are more likely to be men, and women are more likely to have NERD. There is a definite relationship between GERD and obesity. Several meta-analyses suggest an association between body mass index (BMI), waist circumference, weight gain, and the presence of symptoms and complications of GERD. GERD is frequent during pregnancy, usually manifesting as heartburn, and may begin in any trimester. Significant predictors of heartburn during pregnancy are increasing gestational age, heartburn before pregnancy, and parity (Katz et al, 2013) (see Chapter 15).

Chest pain may be a symptom of GERD, and distinguishing cardiac from noncardiac chest pain is required before considering GERD as a cause of chest pain. Although the symptoms of dysphagia can be associated with uncomplicated GERD, its presence warrants investigation for a potential complication including an underlying motility disorder, stricture, or malignancy. Patients with disruptive GERD (daily or more than weekly symptoms) have an increase in time off work and decrease in work productivity, and a decrease in physical functioning (Katz et al, 2013).

Pathophysiology

The pathophysiology of GERD is complex. **Box 27-1** describes possible mechanisms involved in GERD. Three components make up the esophagogastric junction: the lower esophageal sphincter (LES), the crural diaphragm, and the anatomic flap valve. This esophagogastric junction functions as an antireflux

BOX 27-1 Possible Mechanisms Involved in Gastroesophageal Reflux Disease (GERD)

- Decreased salivation
- Transient lower esophageal sphincter (LES) relaxation
- Reduced lower esophageal sphincter (LES) pressure
- Impaired esophageal acid clearance
- Increased esophageal sensitivity
- Acid pocket
- Increased intraabdominal pressure
- Delayed gastric emptying

Data from Beaumont H et al: The position of the acid pocket as a major risk factor for acidic reflux in healthy subjects and patients with GORD, *Gut* 59:441, 2010; Bredenoord AJ et al: Gastroesophageal reflux disease, *Lancet* 381:1933, 2013; Penagini R, Bravi I: The role of delayed gastric emptying and impaired esophageal motility, *Best Pract Res Clin Gastroenterol* 24:831, 2010.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Esophagitis

ETIOLOGY

PATHOPHYSIOLOGY

Reflux of gastric acid and/or intestinal contents through the lower esophageal sphincter (LES) and into the esophagus

MANAGEMENT

Behavioral Modification

Avoid:

- Eating within 3-4 hours of retiring
- Lying down after meals
- Tight-fitting garments
- Cigarette smoking

Medical/Surgical Management

- Proton pump inhibitors
- Histamine-2 receptor antagonists
- Antacids
- Prokinetic agents
- Fundoplication

Nutrition Management

Goal:

Decrease exposure of esophagus to gastric contents

Avoid:

- Large meals
- Dietary fat
- Alcohol

Goal:

Decrease acidity of gastric secretions

Avoid:

- Coffee
- Fermented alcoholic beverages

Goal:

Prevent pain and irritation

Avoid:

- Any food that the patient feels exacerbates his/her symptoms

barrier. The lower esophageal sphincter is a 3- to 4-cm segment of circular smooth muscle at the distal end of the esophagus. The resting tone of this muscle can vary among healthy individuals, ranging from 10 mm Hg to 35 mm Hg relative to the intragastric pressure. The most common mechanism for reflux is transient LES relaxations, which are triggered by gastric distention and serve to enable gas venting from the stomach. On average, transient LES relaxations persist for about 20 seconds, which is significantly longer than the typical swallow-induced relaxation (Bredenoord et al, 2013).

For reflux to take place, pressure in the proximal stomach must be greater than the pressure in the esophagus. Patients with chronic respiratory disorders, such as chronic obstructive pulmonary disease (COPD), are at risk for GERD because of frequent increases in intraabdominal pressure. A chronically increased pressure also is seen during pregnancy and in overweight and obese people.

Hypersensitivity to acid can occur in people with erosive esophagitis and in those with normal mucosa. A factor contributing to increased esophageal sensitivity to acid is impaired mucosal barrier function. In a systematic review, the overall rate of gastric emptying was delayed in patients with GERD (Penagini and Bravi, 2010). However, a relationship between delayed gastric emptying and increased reflux could not be seen in this study, suggesting that impaired emptying of the stomach as a whole is not an important determinant of GER.

Good peristaltic function is an important defense mechanism against GERD as prolonged acid clearance correlates with the severity of esophagitis and the presence of complication such as Barrett's esophagus. Acid pocket is an occurrence during the postprandial period when a layer of acidic gastric juice is ready to reflux resulting from absence of peristaltic contraction in the proximal stomach (Beaumont et al, 2010).

Prolonged acid exposure can result in esophagitis, esophageal erosions, ulceration, scarring, stricture, and in some cases dysphagia (see *Pathophysiology and Care Management Algorithm: Esophagitis*). Acute esophagitis may be caused by reflux, ingestion of a corrosive agent, viral or bacterial infection, intubation, radiation, or eosinophilic infiltration. Eosinophilic esophagitis (EOE) is characterized by an isolated, severe eosinophilic infiltration of the esophagus manifested by GERD-like symptoms that may be caused by an immune response (see Chapter 26).

The severity of the esophagitis resulting from the gastroesophageal reflux is influenced by the composition, frequency, and volume of the gastric reflux; the health of the mucosal barrier; length of exposure of the esophagus to the gastric reflux; and the rate of gastric emptying. Symptoms of esophagitis and GERD may impair the ability to consume an adequate diet and interfere with sleep, work, social events, and the overall quality of life (see Table 27-1).

Abnormalities in the body such as **hiatal hernia** also may contribute to gastroesophageal reflux and esophagitis. The esophagus passes through the diaphragm by way of the esophageal hiatus or ring. The attachment of the esophagus to the hiatal ring may become compromised, allowing a portion of the upper stomach to move above the diaphragm. Table 27-2 describes the four types of hiatal hernia. The most common symptom of hiatal hernia is heartburn. When acid reflux occurs with a hiatal hernia, the gastric contents remain above the hiatus longer than normal. The prolonged acid exposure

TABLE 27-1 Clinical symptoms associated with GERD

Dental corrosion	Slow, progressive tooth surface loss associated with acid regurgitation
Dysphagia	Difficulty initiating a swallow (oropharyngeal dysphagia) or sensation of food being hindered or “sticks” after swallowed (esophageal dysphagia)
Heartburn (pyrosis)	Painful, burning sensation that radiates up behind the sternum of fairly short duration
Odynophagia	Painful swallow
Regurgitation	Backflow of gastric content into the mouth not associated with nausea or retching
Noncardiac chest pain	Unexplained substernal chest pain resembling a myocardial infarction without evidence of coronary artery disease
Extraesophageal symptoms	Chronic cough, hoarseness, reflux-induced laryngitis, or asthma

Data from Bredenoord AJ et al: Gastro-esophageal reflux disease, *Lancet* 381:1933, 2013; Katz PO et al: Guidelines for the diagnosis and management of gastroesophageal reflux disease, *Am J Gastroenterol* 108:308, 2013.

TABLE 27-2 Types of Hiatal Hernia

Type 1 (sliding hiatal hernia)	Most common type; gastroesophageal junction is pushed above the diaphragm, causing a symmetric herniation of the proximal stomach.
Type 2 (true paraesophageal hernia)	Fundus slides upward and moves above the gastroesophageal junction
Type 3 (mixed paraesophageal hernia)	Combined sliding and paraesophageal herniation
Type 4 (complex paraesophageal hernia)	Less common form; intrathoracic herniation of other organs, such as the colon, and small bowel into the hernia sac

increases the risk of developing more serious esophagitis. Figure 27-2 illustrates a hiatal hernia (A), and postsurgical reduction (B). As the hiatal hernia enlarges, regurgitation may be more prominent, especially when lying down or when bending over. Epigastric pain occurs in the upper middle region of the abdomen after large, energy-dense meals. Weight reduction and decreasing meal size reduce the negative consequences of hiatal hernia.

Patients with type 3 hiatal hernia may present with severe chest pain, retching, vomiting, and **hematemesis** (vomiting of blood), because these hernias can twist and cause strangulation in the chest, which would be considered a surgical emergency (Hyun and Bak, 2011). Some patients can present with iron deficiency anemia without acute bleeding, because the diaphragm becomes so irritated that the patient may develop chronic blood loss.

Barrett's esophagus (BE) is a precancerous condition in which the normal squamous epithelium of the esophagus is replaced by an abnormal columnar-lined epithelium known as specialized intestinal metaplasia (tissue that is similar to the intestinal lining). The exact cause of BE is unknown, but GERD is a risk factor for the condition. The true prevalence of BE is unknown but is estimated to affect 1.6% to 6.8% of the general population (Gilbert et al, 2011). People with BE are at increased risk for a cancer called esophageal adenocarcinoma with

FIGURE 27-2 A, Hiatal hernia. B, Postsurgical reduction of hiatal hernia. (Cleveland Clinic, Cleveland, Ohio.)

incidence rising dramatically over the past 40 years and speculated to continue to rise during coming decades (Thrift and Whiteman, 2012). Risk factors for BE include prolonged history of GERD-related symptoms (more than 5 years), middle age, white male, obesity, smoking, and family history of BE or adenocarcinoma of the esophagus. Estrogen may be protective and account for the lower incidence of BE in females (Asanuma et al, 2016).

Medical and Surgical Management

The primary medical treatment of esophageal reflux is suppression of acid secretion. The aim in acid-suppression therapy is to raise the gastric pH above 4 during periods when reflux is most likely to occur. Proton pump inhibitors (PPIs), which decrease acid production by the gastric parietal cell, have been associated with superior healing rates and decreased relapses (Katz et al, 2013). Milder forms of reflux are managed by H₂ receptor (a type of histamine receptor on the gastric parietal cell) antagonists, and antacids, which buffer gastric acid in the esophagus or stomach to reduce heartburn. Prokinetic agents, which increase propulsive contractions of the stomach, may be used in persons with delayed gastric emptying. A trial of baclofen, a gamma-amino butyric acid (GABA) agonist, can be considered in patients with objective documentation of continued symptomatic reflux despite optimal PPI therapy (Katz et al, 2013). However, there have not been long-term data published regarding efficacy of baclofen in GERD. Refer to Table 27-3 for medications commonly used in upper GI disorders.

Of patients with severe GERD, 5% to 10% do not respond to medical therapy. The **Nissen fundoplication** was first described as a treatment for severe reflux esophagitis in 1956 and is still the most commonly performed antireflux surgery (see Figure 27-3). During this procedure, which can be done using either open or a laparoscopic technique, the fundus or top portion of the stomach is wrapped 360 degrees around the lower esophagus and sutured in place to limit reflux (see Figure 27-3). Surgical therapy is considered for individuals who have failed medical management, those who opt for surgery despite successful medical management (e.g., because of quality-of-life considerations, lifelong need for medication intake, expense of medications), those who experience complications of GERD

TABLE 27-3 Common Medications Used in the Treatment of Upper Gastrointestinal Tract Disorders

Type of Medication	Common Names	Medication Function
Antacids	Magnesium, calcium, or aluminum bound to carbonate or phosphate	Buffers gastric acid
Antigas	Simethicone	Lowers surface tension of gas bubbles
Antidumping	Acarbose	Delays carbohydrate digestion by inhibiting alpha-glycoside hydrolase, which interferes with conversion of starch to monosaccharides
Antisecretory	Octreotide (somatostatin analog) Somatostatin	Inhibits release of insulin and other gut hormones; slows rate of gastric emptying and small intestine transit time; and increases intestinal water and sodium absorption
H ₂ blocker	Cimetidine Ranitidine Famotidine Nizatidine	Blocks the action of histamine on parietal cells, decreasing the production of acid
Prokinetic	Metoclopramide Erythromycin Domperidone	Increases contractility of the stomach and shortens gastric emptying time
Proton pump inhibitor (PPI)	Omeprazole Lansoprazole Esomeprazole Pantoprazole Dexlansoprazole Rabeprazole	Inhibits acid secretion

FIGURE 27-3 Nissen fundoplication. (Cleveland Clinic, Cleveland, Ohio.)

(Barrett's esophagus, peptic stricture), and those who have extraesophageal manifestations (asthma, hoarseness, cough, chest pain, aspiration) (Stefanidis et al, 2010). Surgical approaches are reserved for children who have intractable symptom unresponsive to medical therapy or who are at risk for life-threatening complications of GERD (Lightdale et al, 2013).

BOX 27-2 Dietary Guidelines After a Nissen Fundoplication

1. Start clear liquid diet after surgery.
2. Advance oral diet to soft, moist, solid foods. This could be ordered before hospital discharge or written in hospital discharge instructions when to start solids.
3. Follow soft, moist foods diet for about 2 months. Foods must be soft to pass through the esophagus.
4. Consume small, frequent meals.
5. Swallow small bites of food and chew thoroughly to allow an easy passage through the esophagus and avoid use of straw to consume liquids. Drink slowly.
6. Avoid foods and beverages that may cause backflow of stomach contents. This consists of citrus fruits and juices, tomato, pineapple, alcohol, caffeine, chocolate, carbonated beverages, peppermint or spearmint, fatty or fried foods, spicy foods, vinegar or vinegar-containing foods.
7. Avoid dry foods that are hard to pass through the esophagus, such as bread, steak, raw vegetables, rolls, dry chicken, raw fruits, peanut butter, other dry meats, or anything with skin, seeds, or nuts.
8. Avoid any food that may cause discomfort.
9. After 2 months, start to incorporate new foods into the diet. Try one new food item or beverage at a time. By 3 to 6 months, patient should be able to tolerate most foods.
10. Consult doctor or dietitian if having difficulty eating or losing weight.

Refer to [Box 27-2](#) for dietary guidelines after Nissen fundoplication.

Lifestyle Modifications and Medical Nutrition Therapy

The first step in symptom management of GERD should consist of changes in lifestyle, including diet. The main factors that trigger reflux symptoms are caffeine, alcohol, tobacco, and stress. Initial recommendations should focus on meal size and content. Eating small rather than large meals reduces the probability that gastric contents will reflux into the esophagus.

Obesity is a contributing factor to GERD and hiatal hernia because it increases intragastric pressure, and weight reduction may reduce acid contact time in the esophagus leading to decreased reflux symptoms. The frequent advice to elevate the head of the bed by 6 to 8 inches would be rational for patients who have reflux episodes at night. Frequent bending over should be avoided. Use of loose-fitting garments in the waist area also is thought to decrease the risk of reflux.

Foods such as carminatives (such as peppermint and spearmint) and coffee have been reported to lower LES pressure, but little research has been done to establish their clinical significance in GERD when used in normal or small amounts. Fermented alcoholic beverages (such as beer and wine) stimulate the secretion of gastric acid and should be limited. Carbonated beverages enhance gastric distention, which increases transient LES relaxations. Highly acidic foods such as citrus juices and tomatoes should be avoided because they cause pain when the esophagus is already inflamed.

The role of spices in the pathologic conditions related to upper GI disorders is not clear. In patients with GI lesions, the use of foods highly seasoned with chili powder and pepper can cause discomfort. The type of chili and amount of capsaicin consumed make a difference ([Milke et al, 2006](#)). Chewing gum has been shown to increase salivary secretions, which help raise esophageal pH, but no studies have demonstrated its efficacy compared with other lifestyle measures. Limiting or avoiding

aggravating foods may improve symptoms in some individuals. Thus recommendations are to have a generally healthy diet and to avoid food items that, in the experience of the patient, trigger symptoms.

Lifestyle changes to treat GERD in infants may involve a combination of feeding changes and positioning therapy. Modifying the maternal diet if infants are breastfed, changing formulas, and reducing the feeding volume while increasing the frequency of feedings may be effective strategies to address GERD in many infants. Thickened feedings appear to decrease observed regurgitation rather than the actual number of reflux episodes. Little is known about the effect of thickening formula on the natural history of infantile reflux or the potential allergenicity of commercial thickening agents ([Lightdale et al, 2013](#)).

Use of tobacco products is contraindicated with reflux. Cigarette smoking should be stopped because it is associated with decreased LES pressure and decreased salivation, thus causing prolonged acid clearance. Smoking tobacco products also compromises GI integrity and increases the risk of esophageal and other cancers.

Identification and treatment of the mechanism underlying the GERD is the first line of therapy. [Box 27-3](#) lists lifestyle and dietary modifications that are aimed at minimizing the occurrence of reflux and optimizing esophageal acid clearance.

Head and Neck Cancer**Pathophysiology**

Cancers of the upper aerodigestive tract, collectively referred to as head and neck cancers, comprise malignancies of the oral cavity (lips and inside of the mouth, including the front portion of the tongue, and the roof and floor of the mouth), the oropharynx (back portion of the tongue and the part of the throat behind the oral cavity), the larynx, and the esophagus. The patient diagnosed with head and neck cancer faces unique challenges in maintaining adequate nutrition. The disease and the treatments, especially surgery, chemo- and radiation therapy, have significant impact on upper digestive tract function, and oral intake is often insufficient during and after therapy. Almost all patients with head and neck cancer are malnourished at the time of diagnosis. Dysphagia is a hallmark of head and neck

BOX 27-3 Nutrition Care Guidelines for Reducing Gastroesophageal Reflux and Esophagitis

1. Avoid large, high-fat meals.
2. Avoid eating 2 to 3 hours before lying down.
3. Elevate the head of bed by 6 to 8 inches for individuals who have reflux episodes at night.
4. Avoid smoking.
5. Avoid alcoholic beverages.
6. Avoid caffeine-containing foods and beverages.
7. Remain upright for a while after eating.
8. Wear loose-fitting clothing around the stomach area; tight clothing can constrict the area and increase reflux.
9. Avoid acidic and highly spiced foods when inflammation exists.
10. Consume a healthy, nutritionally complete diet with adequate fiber.
11. Lose weight if overweight.

Data from National Digestive Diseases Information Clearinghouse: *Gastroesophageal Reflux (GER) and Gastroesophageal Reflux Disease (GERD) in Adults* (website): <http://digestive.niddk.nih.gov/>, 2014. Accessed February 1, 2015.

cancer; it occurs as a result of mechanical obstruction, sensory impairment, or **odynophagia** (painful swallowing). In these patients there is a high prevalence of alcohol abuse and long-term tobacco use, which are also associated with chronic malnutrition (Schoeff et al, 2013).

Medical Nutrition Therapy

Depending on the tumor site, the surgical procedure may significantly alter the anatomy and lead to scarring that can negatively affect swallowing. The patient is likely to be restricted from oral intake while healing from the surgery. Placement of a gastrostomy tube is the most common approach to ensure safe delivery of adequate nutrition, but the optimal timing is not defined. Although the goal is eventual transition to oral feeding, some patients will require additional enteral nutrition (EN) because of structural and sensory deficits.

Aggressive prophylactic swallowing therapy is a recent development in the treatment of dysphagia in patients with head and neck cancer. This approach focuses on maintaining or regaining function rather than simply accommodating dysfunction (reliance on feeding tube) and empowers patients to progress carefully with oral intake despite imperfect swallowing (Schoeff et al, 2013).

Surgery of the Esophagus

The primary indication for an **esophagectomy** is esophageal cancer or Barrett's esophagus with high-grade dysplasia. A patient undergoing esophagectomy often presents with dysphagia, decreased appetite, side effects from chemotherapy, and weight loss. Esophagectomy requires that there be another conduit in place to transport food from the oropharynx to the rest of the GI tract for digestion and absorption. Placement of an enteral feeding tube preoperatively, or at the time of surgery provides enteral access for patients who will experience eating challenges and a slow transition back to a normal diet. The enteral route of nutrition is preferred; however, if the GI tract is not functional, parenteral nutrition (PN) must be provided (see Chapter 13).

Medical Nutrition Therapy

Nutrition assessment of an esophagectomy candidate includes evaluation of treatment plans, history of weight loss, and the ability to swallow solid foods and liquids. Generally, the only esophagectomy patients screened at low nutrition risk preoperatively are those with Barrett's esophagus with high-grade dysplasia, or those who are asymptomatic.

Preoperative Phase. Swallowing difficulty (**dysphagia**) is the commonly identified problem in patients awaiting an esophagectomy. The dietary modifications may range from regular food with adequate chewing and slow eating, to soft foods, or to pureed or blenderized foods (see Chapter 13). Patients also benefit from calorically dense oral nutrition supplements to maximize energy and protein intake. Nutrition support from a nasogastric feeding tube inserted in the preoperative patient may be necessary if the oral dietary modifications do not prevent further weight loss.

Postoperative Phase. A **gastric pull-up** procedure (see Figure 27-4) involves removal of a segment of or the entire esophageal tract and replacing it with the stomach tissue. Complications after this procedure include increased risk of aspiration, dysphagia, anastomosis leak, wound infection, and stricture at the anastomosis site. A jejunostomy feeding tube may be placed at surgery to provide postoperative nutrition until adequate oral intake is achieved. The tube feeding schedule is changed eventually from continuous to cyclical

FIGURE 27-4 Gastric pull-up. (Cleveland Clinic, Cleveland, Ohio.)

BOX 27-4 Nutrition Guidelines After Esophagectomy

1. Nutrition support is provided through a jejunostomy feeding tube after esophagectomy.
A patient cannot eat or drink anything by mouth until instructed by the doctor.
2. Once an oral diet can be started, patient is provided with specific guidelines on how to taper the tube feedings and how to advance the oral diet (from sips of clear liquids to very moist, tender foods).
3. It may take several weeks to taper the tube feedings and adjust to oral diet. When tube feeding is discontinued, the patient should continue to flush the jejunostomy tube daily. A patient will continue to adjust to oral feedings for about 3 months.
4. During the 3-month transition:
 - Eat 6 small meals per day and include sources of protein and fat at every small meal.
 - Choose very tender, moist foods that can be easily cut with the side of fork or spoon and use sauces or gravies to moisten food.
 - Gradually increase the volume and variety of foods at each meal.
 - Avoid skins, seeds, nuts, tough or dry meats, breads and rolls, peanut butter, fried and greasy foods, raw vegetables, cooked corn and peas, and raw fruits.
 - Avoid items that can cause heartburn and stomach reflux such as caffeine, citrus fruits, pineapples, tomatoes, carbonated beverages, mints, and alcohol.
 - Drink no more than 4 fluid ounces of water or other liquids with meals. Drink fluids about 30 minutes before or after the meal and sip slowly.
 - Avoid concentrated sweets and sugars.
 - Eat slowly and chew foods thoroughly.
5. After 3 months, more food should be added back into the diet. Try one new food or beverage at a time.
6. After 6 months, a patient should be eating normally. It is still advised to eat frequent small meals.

feedings at night as the patient is transitioned to an oral diet during the day.

Transition to oral intake postoperatively proceeds from clear liquids to a soft, moist foods diet. The patient is advised to eat small frequent meals with limited fluids at mealtimes. Some patients may experience dumping syndrome if food passes into the small intestine too quickly. The symptoms of dumping syndrome include abdominal pain, nausea, diarrhea, weakness, and dizziness. Box 27-4 lists dietary guidelines after esophageal

surgery to prevent dumping syndrome (see [Dumping Syndrome](#) later in this chapter for more details).

THE STOMACH

The stomach accommodates and stores meals, mixes food with gastric secretions, and controls emptying into the duodenum. Gastric volume is approximately 50 ml when empty, but can expand to approximately 4 L. Gastric **parietal cells** (acid-producing cells) produce 1.5 to 2 L of acid daily resulting in a pH between 1 and 2 (see Chapter 1 for a detailed discussion of healthy stomach function).

The mucosa of the stomach and duodenum is protected from proteolytic actions of gastric acid and pepsin by a coating of mucus secreted by glands in the epithelial walls from the lower esophagus to the upper duodenum. The mucosa also is protected from bacterial invasion by the digestive actions of pepsin and hydrochloric acid (HCl). Prostaglandins play an important role in protecting the gastroduodenal mucosa by stimulating the secretion of mucus and bicarbonate and maintaining blood flow during periods of potential injury.

Dyspepsia and Functional Dyspepsia

Pathophysiology

Dyspepsia (indigestion) refers to nonspecific, persistent upper abdominal discomfort or pain. It affects an estimated 20% to 40% of the general population and significantly reduces quality of life ([Ford and Moayyedi, 2013](#)). The underlying causes of dyspepsia may include GERD, **peptic ulcer** disease, gastritis, gallbladder disease or other identifiable pathologic conditions.

Functional dyspepsia (FD) is defined by the **Rome III criteria** as the presence of symptoms thought to originate in the gastroduodenal region in the absence of any organic, systemic, or metabolic disease likely to explain the symptoms. Symptoms of FD do not consistently predict the underlying pathologic condition. Epigastric pain or discomfort is the hallmark symptom in patients with FD. The word discomfort is important to emphasize, because many patients will not complain of pain, but rather complain of burning, pressure, or fullness in the epigastric area, or that they cannot finish a normal-sized meal (early satiety). Other symptoms include postprandial nausea, belching, and abdominal bloating ([Talley and Ford, 2015](#)).

Medical Nutrition Therapy

Current treatments for FD have generally ignored the potential role of diet. The possible effect of specific foods and macronutrients and other dietary habits to induce or exacerbate FD symptoms has been poorly studied, and often there are conflicting results ([Lacy et al, 2012](#)). Using a food and symptom diary during a clinical evaluation of a patient with FD and assessing symptoms associated with eating patterns is useful. Dietary modifications such as consuming smaller meals with a reduction in dietary fat may be promising in FD therapy. Helping the client identify problematic foods also can be helpful.

Gastritis and Peptic Ulcers

Pathophysiology

Gastritis is a nonspecific term literally meaning inflammation of the stomach. It can be used to describe symptoms relating to the stomach, an endoscopic appearance of the gastric mucosa, or a histologic change characterized by infiltration of the epithelium with inflammatory cells such as polymorphonuclear cells

FOCUS ON

Changing Face of *H. pylori* and Gastric Cancer

Traditionally, gastric cancer was considered a single disease. However, scientists now classify gastric cancer by its location in either the top inch of the stomach near the esophagus (gastric cardia) or the rest of the stomach (noncardia).

This new classification of gastric cancers was adopted in part because of the role of *Helicobacter pylori*. *H. pylori* appears to be a strong risk factor for noncardia gastric cancer; however, the role of *H. pylori* in the development of gastric cardia cancer remains controversial.

A study of patients in Finland investigated *H. pylori* infection from blood obtained at the time of enrollment, before the patients actually developed cancer ([Kamangar et al, 2006](#)). When patients who developed cancer were compared with age-matched controls who did not develop cancer, *H. pylori* infection resulted in an eightfold increase in the incidence of noncardia gastric cancer but a 60% decrease in the incidence of cardia gastric cancer. The decrease in gastric cardia cancer with *H. pylori* infection was an unexpected finding because previous studies had not shown this. One reason that older studies may have had misleading results was that researchers did not check for the presence of *H. pylori* until after the diagnosis of gastric cancer, and *H. pylori* does not flourish on precancerous or malignant cells. Population studies support the protective effect of *H. pylori* on gastric cardia cancer ([Whiteman et al, 2010](#)).

Developed countries have seen a decrease in this infection in recent years because of increased information, testing, and effective treatment. Concomitantly, there has been a decreased incidence of noncardia gastric cancer, but an increase in the incidence of gastric cardia and esophageal cancers in these countries. The revelation that treating *H. pylori* infection decreases the risk for some cancers but may increase the risk of other cancers is prompting more research.

(PMNs). Acute gastritis refers to rapid onset of inflammation and symptoms. Chronic gastritis may occur over a period of months to decades, with reoccurring symptoms. Symptoms include nausea, vomiting, malaise, anorexia, hemorrhage, and epigastric pain. Prolonged gastritis may result in atrophy and loss of stomach parietal cells, with a loss of HCL secretion (achlorhydria) and intrinsic factor, resulting in pernicious anemia (see Chapter 32).

Helicobacter pylori Gastritis

Helicobacter pylori is a gram-negative bacteria that is somewhat resistant to the acidic environment in the stomach. *H. pylori* infection is responsible for most cases of chronic inflammation of the gastric mucosa and peptic ulcer, gastric cancer, and **atrophic gastritis** (chronic inflammation with deterioration of the mucous membrane and glands), resulting in achlorhydria and loss of intrinsic factor ([Dos Santos and Carvalho, 2014](#); see [Focus On: Changing Face of *H. pylori* and Gastric Cancer](#)).

H. pylori infection prevalence generally correlates with geography and the socioeconomic status of the population and begins during childhood, but generally is not diagnosed until adulthood. *H. pylori* is believed to be spread through contaminated food and water. Its prevalence ranges from approximately 10% in developed countries to 80% to 90% in developing countries. Although gastritis is a characteristic observation, most people infected with *H. pylori* never develop ulcers. *H. pylori* infection does not resolve spontaneously, and risks of complications increase with the duration of the infection. Other risk factors contributing to pathology and disease severity include patient age at onset, specific strain and concentration of the organism, genetic factors related to the host, and the patient's lifestyle and overall health.

In the first week after *H. pylori* infection, many PMNs and a few eosinophils infiltrate the gastric mucosa. These are replaced gradually with the mononuclear cells. The presence of lymphoid follicles is called **mucosa-associated lymphoid tissue (MALT)**. MALT may become autonomous to form a low-grade, B-cell lymphoma called MALT lymphoma. *H. pylori* can cause duodenitis if it colonizes gastric tissue that may be present in the duodenum.

Treating *H. pylori* with antibiotics can cause PMNs to disappear within a week or two, but a mild gastritis can persist for several years as the reduction in mononuclear cells is slow. In countries where *H. pylori* is common, so is gastric cancer. Because *H. pylori* can cause peptic ulcer and gastric cancer, antibiotic treatment is favored when it is diagnosed.

Non-*Helicobacter pylori* Gastritis

Aspirin and non-steroidal antiinflammatory drugs (NSAIDs) are corrosive; both inhibit prostaglandin synthesis, which is essential for maintaining the mucus and bicarbonate barrier in the stomach. Thus chronic use of aspirin or other NSAIDs, steroids, alcohol, erosive substances, tobacco, or any combination of these factors may compromise mucosal integrity and increase the chance for acquiring acute or chronic gastritis. Eosinophilic gastroenteritis (EGE) also may contribute to some cases of gastritis (see Chapter 26). Poor nutrition and general poor health may contribute to the onset and severity of the symptoms and can delay the healing process.

Medical Treatment

Treatment for gastritis involves removing the inciting agent (e.g., pathogenic organism, NSAIDs). Noninvasive methods for diagnosing *H. pylori* include a blood test for *H. pylori* antibodies, a urea breath test, or a stool antigen test. **Endoscopy** is a common invasive diagnostic tool (see *Focus On: Endoscopy and Capsules*). Antibiotics and proton pump inhibitors (PPIs) are the primary medical treatments. Side effects of chronic acid suppression either from disease or chronic use of PPIs should be considered (Katz, 2010). These include reduction of gastric secretion of HCL, which can reduce absorption of nutrients (e.g., vitamin B₁₂, calcium, and nonheme iron) that require intragastric proteolysis to make them bioavailable (McColl, 2009) (see Chapter 8 and Appendix 23.) Acid suppression may increase incidence of some bone fractures (Yang, 2012), as well as increase the risk for intestinal infection because gastric acidity is a primary defense against ingested pathogens (Linsky et al, 2010).

Peptic Ulcers

Etiology

Normal gastric and duodenal mucosa is protected from the digestive actions of acid and pepsin by the secretion of mucus, the production of bicarbonate, the removal of excess acid by normal blood flow, and the rapid renewal and repair of epithelial cell injury. **Peptic ulcer** refers to an ulcer that occurs as a result of the breakdown of these normal defense and repair mechanisms. Typically more than one of the mechanisms must be malfunctioning for symptomatic peptic ulcers to develop. Peptic ulcers typically show evidence of chronic inflammation and repair processes surrounding the lesion.

The primary causes of peptic ulcers are *H. pylori* infection, gastritis, use of aspirin, other NSAIDs and corticosteroids, and severe illness (see *Stress Ulcers* later in this chapter and *Pathophysiology and Care Management Algorithm: Peptic Ulcer*). Life stress may

FOCUS ON

Endoscopy and Capsules

The mucosa of the upper gastrointestinal (GI) tract can be viewed, photographed, and biopsied by means of endoscopy, a procedure that involves passing a flexible tube into the esophagus that has a light and camera on the distal end. It can be passed through the esophagus and into the stomach or upper small bowel. This procedure is called **esophagogastro-duodenoscopy (EGD)**. Inflammation, erosions, ulcerations, changes in the blood vessels, and destruction of surface cells can be identified. These changes can then be correlated with chemical, histologic, and clinical findings to formulate a diagnosis. This may be useful when physicians suspect certain conditions, such as complicated GERD strictures, BE, esophageal varices, or gastroduodenal ulcers or celiac disease.

EGD also can be used for a number of therapeutic purposes such as cauterization at ulcer sites, dilation or deployment of stents in areas of stricture, and placement of percutaneous feeding tubes. Endoscopy may be used in long-term monitoring of patients with chronic esophagitis and gastritis because of the possibility that they will develop premalignant lesions or carcinoma (Wong et al, 2010).

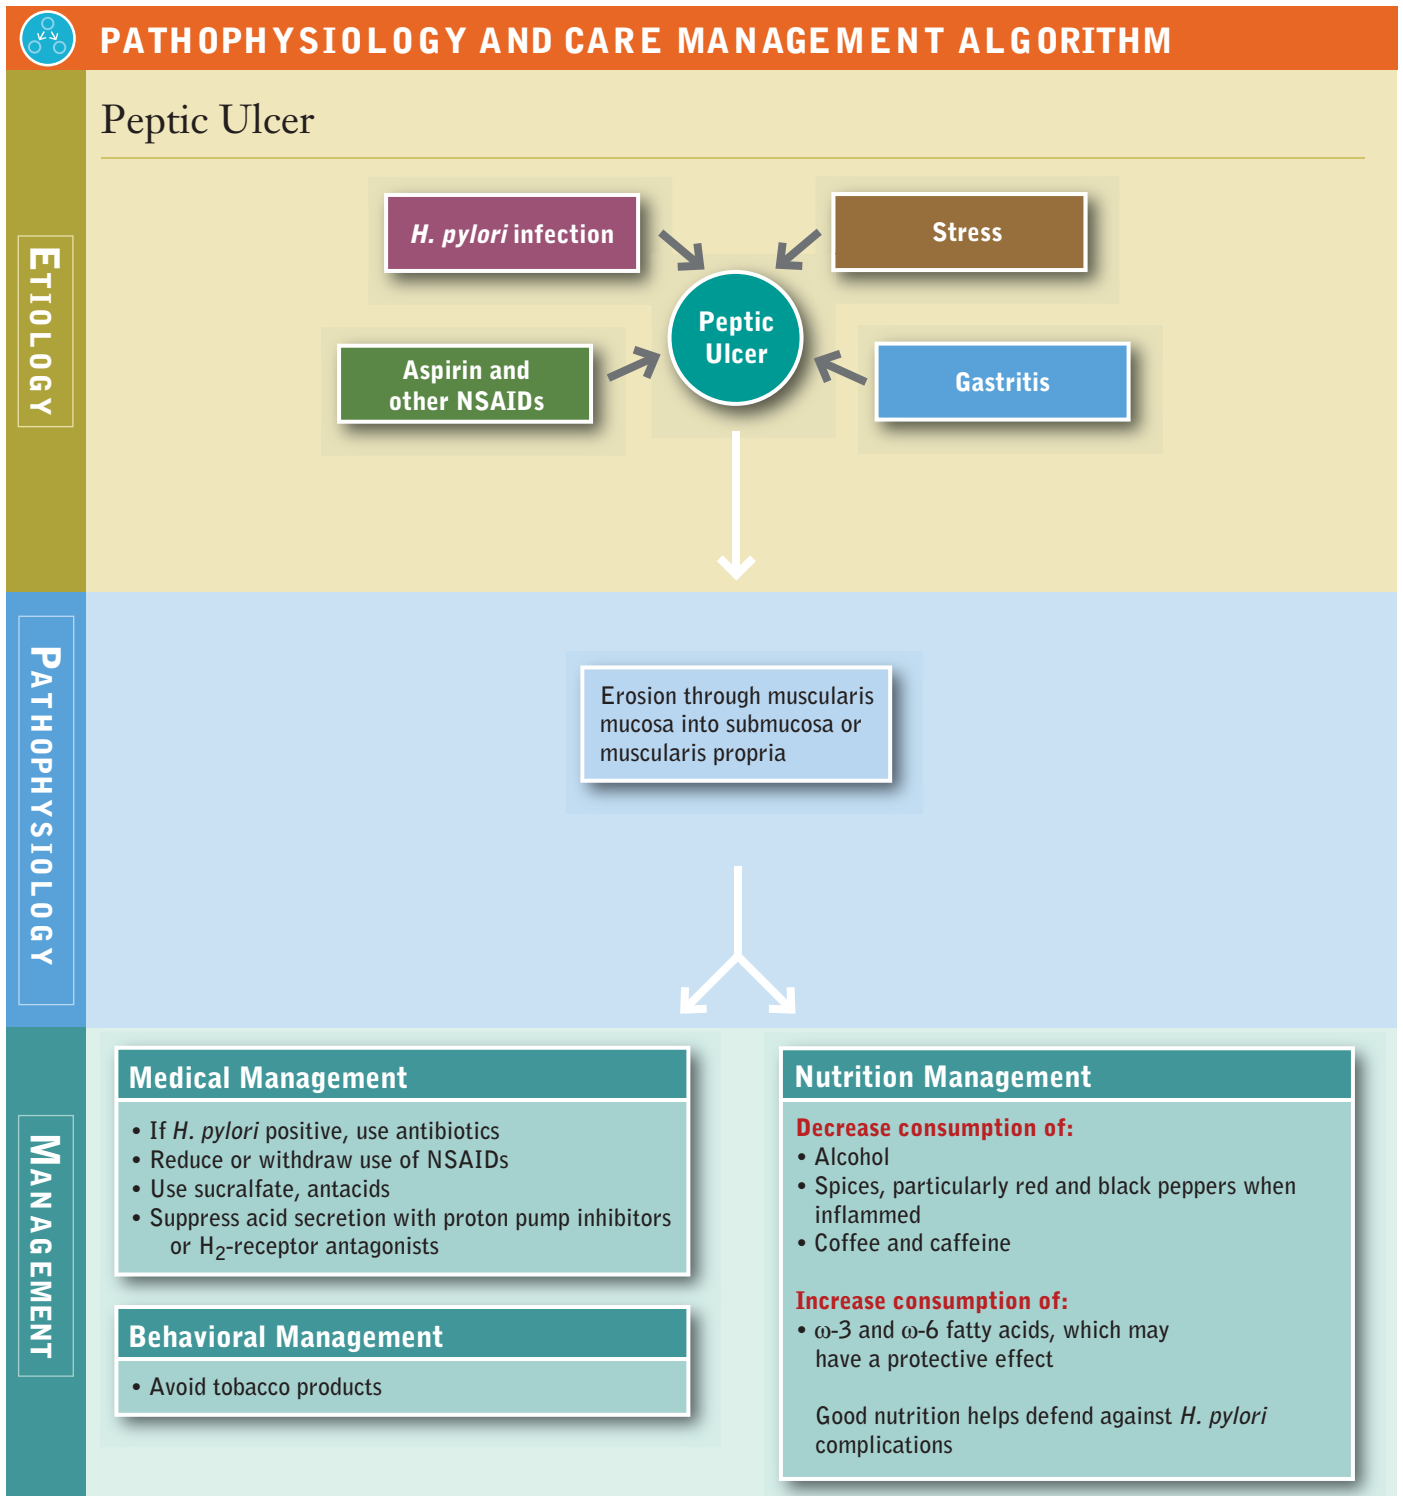

Capsules containing a miniaturized video camera, light, and radio transmitter that can be swallowed and the signal transmitted to a receiver worn on the waist of the patient, allowing wireless capsule endoscopy. Capsule endoscopy can be used to view segments of the GIT that are not accessible by standard EGD, to screen for abnormalities or bleeding, check pH, and measure the time it takes to pass through different segments of the GIT. The procedure is less invasive than normal endoscopy and provides the advantage of being able to observe, record, and measure GI function as the patient is ambulatory.

However, the images from capsule endoscopy can be blurred by rapid intestinal transit or limited in number after battery failure in cases of slow transit. In addition, reviewing the thousands of images obtained after each capsule endoscopy can be very time consuming. Prototypes of the newest generation of capsule endoscopy allow the physician to magnetically guide the capsule to a specific location by having the patient lie on a special table. Future generations of capsule endoscopy are on the drawing boards to hopefully allow therapeutic measures to be accomplished in the small bowel via capsule endoscopy.

lead to behaviors that increase peptic ulcer risk. Although excessive use of concentrated forms of ethanol can damage gastric mucosa, worsen symptoms of peptic ulcers, and interfere with ulcer healing, alcohol consumption in moderation does not cause peptic ulcers in healthy people. Use of tobacco products also is linked with peptic ulcer risk, because tobacco decreases bicarbonate secretion and mucosal blood flow, exacerbates inflammation, and is associated with additional complications of *H. pylori* infection. Other risk factors include gastrinoma and Zollinger-Ellison syndrome (see Chapter 29).

The incidence and number of surgical procedures related to peptic ulcers has decreased markedly in the past 3 decades because of recognition of symptoms and risk factors, and earlier screening for *H. pylori*. Peptic ulcers normally involve two major regions: gastric and duodenal. Uncomplicated peptic ulcers in either region may present with signs similar to those associated with dyspepsia and gastritis.

Abdominal discomfort is the most common symptom of duodenal and gastric ulcers. Felt anywhere between the navel and the breastbone, this discomfort usually is a dull or burning pain, occurs when the stomach is empty—between meals or during the night, may be briefly relieved by eating food, in the case of duodenal ulcers, or by taking antacids. In both types of peptic ulcers the symptoms last for minutes to hours and come and go for several days or weeks. Other symptoms include

bloating, burping, nausea, vomiting, poor appetite, and weight loss. Some people experience only mild symptoms or none at all.

Peptic ulcers also may have “emergency symptoms,” in which medical assistance should be sought immediately. These include sharp, sudden, persistent, and severe stomach pain, bloody or black stools (**melena**), bloody vomit (**hematemesis**),

or vomit that looks like coffee grounds. These symptoms could be signs of a serious problem, such as acute or chronic GI bleeding—when acid or the peptic ulcer breaks a blood vessel; perforation—when the peptic ulcer burrows completely through the stomach or duodenal wall potentially penetrating an adjacent organ (e.g., pancreas); or obstruction—when the peptic ulcer blocks the path of food trying to leave the stomach.

FIGURE 27-5 Diagram showing (A) normal stomach and duodenum; (B) a gastric ulcer; (C) a duodenal ulcer.

Complications of hemorrhage and perforation contribute significantly to the morbidity and mortality of peptic ulcers.

Gastric versus Duodenal Ulcers

Pathophysiology

Although gastric ulcers can occur anywhere in the stomach, most occur along the lesser curvature (see Figure 27-5). **Gastric ulcers** typically are associated with widespread gastritis, inflammatory involvement of parietal cells, and atrophy of acid- and pepsin-producing cells occurring with advancing age. In some cases gastric ulceration develops despite relatively low acid output. Antral hypomotility, gastric stasis, and increased duodenal reflux are associated commonly with gastric ulcers, and when present, may increase the severity of the gastric injury. The incidence of hemorrhage and overall mortality is higher with a gastric ulcer than a duodenal ulcer.

A **duodenal ulcer** is characterized by increased acid secretion throughout the entire day accompanied with decreased bicarbonate secretion. Most duodenal ulcers occur within the first few centimeters of the duodenal bulb, in an area immediately below

the pylorus. Gastric outlet obstruction occurs more commonly with duodenal ulcers than with gastric ulcers, and gastric metaplasia (e.g., replacement of duodenal villous cells with gastric-type mucosal cells) may occur with duodenal ulcer related to *H. pylori*.

Medical and Surgical Management of Ulcers

Regardless of the type of ulcer, the first intervention is to evaluate the patient endoscopically and resuscitate as needed. Control acute bleeding if present.

Peptic Ulcers. *H. pylori* is the primary cause of gastritis and peptic ulcers, thus its diagnosis if present, and treatment, should be the first medical intervention. At the first endoscopy, diagnostic biopsies should be taken for *H. pylori*. Treatment of *H. pylori* infection entails eradication of this organism with the appropriate antibiotic and acid suppressive regimen. Although surgical intervention is less prevalent, emergent and elective procedures and surgeries are still required for peptic ulcer complications. Interventions can range from endoscopic, open, and laparoscopic procedures to treat individual lesions, to partial gastrectomy and occasionally selective vagotomies.

In addition to traditional medical treatments, several complementary medicine interventions have been investigated. Use of foods or their extracts (e.g., phenolic fractions of ginger and ginger hydrolysed phenolic fractions of ginger, *Zingiber officinale*) that contain phenolic antioxidants have been found to be potent inhibitors of proton potassium ATPase activity and *H. pylori* growth (Siddaraju and Dharmesh, 2007). Although certain species of probiotics (e.g., *Lactobacillus acidophilus*, *Lactobacillus salivarius*, *Lactobacillus rhamnosus*, and *Bifidobacterium bifidum*) have been shown to exert direct inhibitory effects on *H. pylori* in in-vitro and in-vivo animal models, these effects have not consistently been found in humans, leaving probiotic supplementation for this purpose controversial. Systematic reviews of the literature have shown that various probiotic species (including *Lactobacillus* spp., *Bifidobacterium* spp., *Saccharomyces* spp., and *Bacillus* spp.) can help diminish eradication-related side effects, including diarrhea, nausea, dyspepsia, and dysgeusia, thus increasing tolerability and therefore compliance. It has been postulated that it is this increase in the number of patients completing the therapy as prescribed that could, in turn, lead to higher eradication rates (Medeiros and Pereira, 2013).

Stress Ulcers. **Stress ulcers** may occur as a complication of metabolic stress caused by trauma, burns, surgery, shock, renal failure, or radiation therapy. A primary concern with stress ulceration is the potential for significant GI hemorrhage. Gastric ischemia associated with GI hypoperfusion, oxidative injury, reflux of bile salts and pancreatic enzymes, microbial colonization, and mucosal barrier changes also have been implicated. Although stress ulcerations usually occur in the fundus and body of the stomach, they also may develop in the antrum, duodenum, or distal esophagus. Typically shallow and causing oozing of blood from superficial capillary beds, stress ulcer lesions also may occur deeper, eroding into the submucosa, causing massive hemorrhage or perforation.

Stress ulcers that bleed can be a significant cause of morbidity in the critically ill patient (see Chapter 38). Although current prevention and treatment include sucralfate, acid suppressives, and antibiotics as needed, high-quality evidence to guide clinical practice in effective treatments is limited. Efforts to prevent gastric ulcers in stressed patients have focused on preventing or

limiting conditions leading to hypotension and ischemia and coagulopathies. Avoiding NSAIDs and large doses of corticosteroids is also beneficial.

Providing oral or enteral feeding, when possible, increases GI vascular perfusion and stimulates secretion and motility. A meta-analysis of studies in critically ill patients that received an H₂-receptor antagonist for stress ulcer prevention found this therapy to be preventative only in patients who did not receive enteral feeding. In fact, for patients receiving enteral feeding, H₂-receptor antagonist therapy may increase the risk of pneumonia and death (Chanpura and Yende, 2012). Further research is needed to prospectively test the effect of enteral feeding on the risk of stress ulcer prophylaxis.

Medical Nutrition Therapy

In persons with atrophic gastritis, vitamin B₁₂ status should be evaluated because of lack of intrinsic factor and gastric acid results in malabsorption of this vitamin (see Chapter 32). Low acid states may influence absorption of iron, calcium, and other nutrients because gastric acid enhances bioavailability. In the case of iron deficiency anemia, other causes may be the presence of *H. pylori* and gastritis. Eradication of *H. pylori* has resulted in improved absorption of iron and increased ferritin levels (Hershko and Ronson, 2009).

For several decades dietary factors have gained or lost favor as a significant component in the cause and treatment of dyspepsia, gastritis, and peptic ulcer disease. There is little evidence that specific dietary factors cause or exacerbate gastritis or peptic ulcer disease. Protein foods temporarily buffer gastric secretions, but they also stimulate secretion of gastrin, acid, and pepsin. Milk or cream, which in the early days of peptic ulcer management was considered important in coating the stomach, is no longer considered medicinal.

The pH of a food has little therapeutic importance, except for patients with existing lesions of the mouth or the esophagus. Most foods are considerably less acidic than the normal gastric pH of 1 to 3. The pH of orange juice and grapefruit is 3.2 to 3.6, and the pH of commonly used soft drinks ranges from approximately 2.8 to 3.5. On the basis of their intrinsic acidity and the amount consumed, fruit juices and soft drinks are not likely to cause peptic ulcers or appreciably interfere with healing. Some patients express discomfort with ingestion of acidic foods, but the response is not consistent among patients, and in some, symptoms may be related to heartburn. The dietary inclusion of “acidic foods” should be individualized based on the patient’s perception of their effect.

Consumption of large amounts of alcohol may cause at least superficial mucosal damage and may worsen existing disease or interfere with treatment of the peptic ulcer. Modest consumption of alcohol does not appear to be pathogenic for peptic ulcers unless coexisting risk factors are also present. On the other hand, beers and wines significantly increase gastric secretions and should be avoided in symptomatic disease.

Coffee and caffeine stimulate acid secretion and also may decrease LES pressure; however, neither has been strongly implicated as a cause of peptic ulcers outside of the increased acid secretion and discomfort associated with their consumption.

When very large doses of certain spices are fed orally or placed intragastrically without other foods, they increase acid secretion and cause small, transient superficial erosions, inflammation of the mucosal lining, and altered GI permeability or motility. Most often incriminated are chili, cayenne, and black

peppers. Small amounts of chili pepper or its pungent ingredient, capsaicin, may increase mucosal protection by increasing production of mucus. However, large amounts may cause superficial mucosal damage, especially when consumed with alcohol. Another spice, curcumin, through its antiinflammatory activity that inhibits the NF- κ B pathway activation may be a chemopreventative candidate against *H. pylori*-related cancer (Zaidi et al, 2009) (see Chapter 12).

The synergy of food combinations may inhibit the growth of *H. pylori*. Food provides an interesting alternative to therapies that include antibiotics, PPIs and bismuth salts (Kennan et al, 2010). Studies suggest that green tea, broccoli sprouts, black currant oil, and kimchi (fermented cabbage) help with *H. pylori* eradication. Probiotics species (*Lactobacillus*, *Bifidobacterium*) also have been studied for prevention, management, and eradication of *H. pylori* (Zhu et al, 2014).

Although these dietary supplements have some interesting results, they are not consistent, and therefore this therapy has not made it into general medical nutrition intervention. More controlled studies are needed.

Omega-3 and omega-6 fatty acids are involved in inflammatory, immune, and cytoprotective physiologic conditions of the GI mucosa, but they have not yet been found to be effective for treatment. Long-term clinical trials have not been performed.

Overall, a high-quality diet without nutrient deficiencies may offer some protection and may promote healing. Persons being treated for gastritis and peptic ulcer disease should be advised to avoid foods that exacerbate their symptoms and to consume a nutritionally complete diet with adequate dietary fiber from fruits and vegetables.

Carcinoma of the Stomach

Although the incidence and mortality have fallen dramatically over the last 50 years in many regions, gastric cancer is still the second most common cause of cancer death worldwide, with varying incidence in different parts of the world and among various ethnic groups (Nagini, 2012). Despite advances in diagnosis and treatment, the 5-year survival rate of stomach cancer is only 20%.

Etiology

The cause of gastric cancer is multifactorial, but more than 80% of cases have been attributed to *H. pylori* infection. In addition, diet, lifestyle, genetic, socioeconomic, and other factors contribute to gastric carcinogenesis. A Western diet, high in processed meats, fat, starches, and simple sugars, is associated with an increased risk of gastric cancer compared with a diet high in fruits and vegetables (Bertuccio et al, 2013). Other factors that may increase the risk of gastric cancer include alcohol consumption, excess body weight, smoking, intake of highly salted or pickled foods, or inadequate amounts of micronutrients. Certain cooking practices also are associated with increased risk of gastric cancer including broiling of meats, roasting, grilling, baking, and deep frying in open furnaces, sun drying, salting, curing, and pickling, all of which increase the formation of carcinogenic N-nitroso compounds. Polycyclic aromatic hydrocarbons such as benzo[a]pyrene formed in smoked food have been incriminated in many areas of the world (Nagini, 2012).

Pathophysiology

Stomach cancer refers to any malignant neoplasm that arises from the region extending between the gastroesophageal junction

and the pylorus. Because symptoms are slow to manifest themselves and the growth of the tumor is rapid, carcinoma of the stomach frequently is overlooked until it is too late for a cure. Loss of appetite, strength, and weight frequently precede other symptoms. In some cases **achylia gastrica** (absence of HCl and pepsin) or **achlorhydria** (absence of HCl in gastric secretions) may exist for years before the onset of gastric carcinoma. Malignant gastric neoplasms can lead to malnutrition as a result of excessive blood and protein losses or, more commonly, because of obstruction and mechanical interference with food intake.

Medical and Surgical Management

Most cancers of the stomach are treated by surgical resection; thus part of the nutritional considerations includes partial or total resection of the stomach, a **gastrectomy**. Some patients may experience difficulties with nutrition after surgery.

Medical Nutrition Therapy

The dietary regimen for carcinoma of the stomach is determined by the location of the cancer, the nature of the functional disturbance, and the stage of the disease. The patient with advanced, inoperable cancer should receive a diet that is adjusted to his or her tolerances, preferences, and comfort. Anorexia is almost always present from the early stages of disease. In the later stages of the disease, the patient may tolerate only a liquid diet. If a patient is unable to tolerate oral feeding, consideration should be given to using an alternate route, such as a gastric or intestinal enteral tube feeding, or if this is not tolerated or feasible, parenteral feeding. The nutritional support for the patient should be in accordance with the patient's goals of care (see Chapter 13).

Gastric Surgeries

Because of increased recognition and treatment for *H. pylori* and acid secretion, gastric surgeries are performed less frequently. However, partial or total gastrectomy may still be necessary for patients with ulcer disease that does not respond to therapy, or for those with malignancy. Gastric surgeries performed for weight loss or bariatric surgeries are more common. These surgeries, such as Roux-en-Y gastric bypass, gastric banding, sleeve gastrectomy, vertical banding gastroplasty, and jejunioileal bypass are designed to induce weight loss through volume restriction, malabsorption, or both (see Chapter 21).

Types of Surgeries

A total gastrectomy involves removal of the entire stomach, whereas only a portion of the stomach is removed with a subtotal gastrectomy. A gastrectomy is accompanied by a reconstructive procedure. A total gastrectomy is performed for malignancies that affect the middle or upper stomach. The total stomach is removed and a Roux-en-Y reconstruction is performed to maintain GI tract continuity. With a **Roux-en-Y**, the jejunum is pulled up and anastomosed to the esophagus. The duodenum is then connected to the small bowel so that bile and pancreatic secretions can flow into the intestine. **Billroth I (gastroduodenostomy)** involves removal of the pylorus and/or antrum, and an anastomosis of the proximal end of the duodenum to the distal end of the remnant stomach. A **Billroth II (gastrojejunostomy)** involves removal of the stomach antrum and an anastomosis of the remnant stomach to the side of the jejunum, which creates a blind duodenal loop (see Figure 27-6).

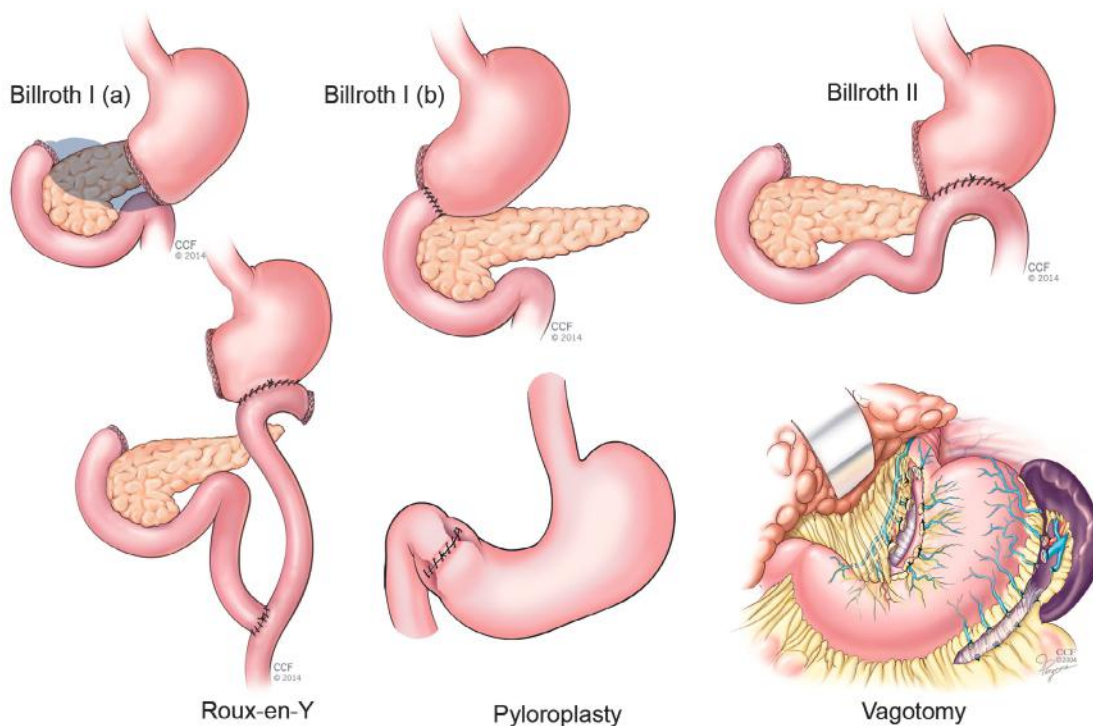

FIGURE 27-6 Gastric surgical procedures [Billroth I (A: preoperative and B: postoperative), Billroth II, Roux en Y, pyloroplasty, vagotomy].

TABLE 27-4 Gastric Surgery–Related Nutrition Complications

Surgical Procedure	Potential Complications
Vagotomy	Impairs motor function of stomach
Total gastric and truncal vagotomy	Gastric stasis and poor gastric emptying
Total gastrectomy	Early satiety, nausea, vomiting Weight loss Inadequate bile acids and pancreatic enzymes available because of anastomotic changes Malabsorption Protein-energy malnutrition Anemia Dumping syndrome Bezoar formation Vitamin B ₁₂ deficiency Metabolic bone disease
Subtotal gastrectomy with vagotomy	Early satiety Delayed gastric emptying Rapid emptying of hypertonic fluids

Cresci G et al: *Nutrition essentials of general surgery*, ed 5, Lippincott Williams & Wilkins, 2013, Table 3-13, p 72.

The **vagus nerve** is responsible for not only motility, but also stimulation of parietal cells in the proximal stomach, therefore a **vagotomy** often is performed to eliminate gastric acid secretion. **Truncal vagotomy**, complete severing of the vagus nerve on the distal esophagus, decreases acid secretion by parietal cells in the stomach and decreases their response to the hormone gastrin. A **parietal cell vagotomy** (partial or selective) divides and severs only the vagus nerve branches that affect the proximal stomach where gastric acid secretion occurs, whereas the antrum and pylorus remain innervated. Vagotomy at certain levels can alter the normal physiologic function of the stomach, small intestine, pancreas, and biliary system. Vagotomy procedures commonly are accompanied by a drainage procedure (antrectomy or **pyloroplasty**) that aids with gastric emptying.

Postoperative Medical Nutrition Therapy

Oral intake of fluids and foods is initiated as soon as GI tract function returns (typically 24 to 72 hours postoperatively). Small frequent feedings of ice or water are normally initiated, followed by liquids and easily digested solid foods, after which the patient can progress to a regular diet. Although this is the common postoperative diet intervention, there is limited evidence supporting this practice. In fact, some studies suggest beginning a regular diet of tolerated foods as the first diet to improve patient tolerance (Warren et al, 2011). If the patient is unable to tolerate an oral diet for an extended period of time (e.g., 5 to 7 days), then enteral feeding should be considered if appropriate feeding access is available, and if not, parenteral nutrition should be considered.

Understanding the surgery performed and patient's resulting anatomy is paramount to providing proper nutritional care. Nutritional complications after gastric surgeries are varied (see Table 27-4). Complications such as obstruction, dumping, abdominal discomfort, diarrhea, and weight loss may occur, depending on the nature and extent of the disease and surgical interventions (see Figure 27-6). Patients may have difficulty regaining normal preoperative weight because of inadequate

food intake related to (1) early satiety, (2) symptoms of dumping syndrome (see later in this chapter), or (3) nutrient malabsorption.

Patients with certain gastric surgeries, such as Billroth II, result in a mismatch in timing of food entry into the small intestine and the release and interaction with bile and pancreatic enzymes, contributing to impaired nutrient digestion and absorption. Patients who are lactose tolerant before gastric surgery may experience relative lactase deficiency, either because food enters the small intestine further downstream from adequate lactase presence, or because the rate of transit through the proximal small intestine is increased. Because of the complications of reflux or dumping syndrome associated with traditional gastrectomies, other procedures are used, including truncal, selective, or parietal cell vagotomy, pyloromyotomy, antrectomy, Roux-en-Y esophagojejunostomy, loop esophagojejunostomy, and pouches or reservoirs made from jejunal or ileocecal segments.

Some chronic nutritional complications that can occur after gastric surgery include anemia, osteoporosis, and select vitamin and mineral deficiencies resulting from inadequate intake and or malabsorption. Iron deficiency may be attributed to loss of acid secretion because gastric acid normally facilitates the reduction of iron compounds, allowing their absorption. Rapid transit and diminished contact of dietary iron with sites of iron absorption can also lead to iron deficiency.

Vitamin B₁₂ deficiency may cause a megaloblastic anemia (see Chapter 32). If the amount of gastric mucosa is reduced, intrinsic factor may not be produced in quantities adequate to allow for complete vitamin B₁₂ absorption, and pernicious anemia may result. Bacterial overgrowth in the proximal small bowel or the afferent loop contributes to vitamin B₁₂ depletion because bacteria compete with the host for use of the vitamin. Therefore after gastrectomy patients should receive prophylactic vitamin B₁₂ supplementation (injections) or take synthetic oral supplementation.

Dumping Syndrome

Etiology

The **dumping syndrome** is a complex GI and vasomotor response to the presence of large quantities of hypertonic foods and liquids in the proximal small intestine. Dumping syndrome usually occurs as a result of surgical procedures that allow excessive amounts of liquid or solid foods to enter the small intestine in a concentrated form. Milder forms of dumping may occur to varying degrees in persons without surgical procedures, and most of the symptoms can be reproduced in normal individuals by infusing a loading dose of glucose into the jejunum. Dumping may occur as a result of total or partial gastrectomy, manipulation of the pylorus, fundoplication, vagotomy, and some gastric bypass procedures for obesity. As a result of better medical management of peptic ulcers, use of selective vagotomies, and newer surgical procedures to avoid complications, classic dumping is encountered less frequently in clinical practice.

Pathophysiology

Symptoms can be divided into two stages of dumping of solids and liquids into the small intestine: early (within 10 to 30 minutes postprandially) and late (1-3 hrs postprandially). Characteristics and severity of symptoms vary between patients.

Early dumping is characterized by GI and vasomotor symptoms, which include abdominal pain, bloating, nausea, vomiting, diarrhea, headache, flushing, fatigue, and hypotension.

These early symptoms likely occur because of the rapid influx of hyperosmolar contents into the duodenum or small intestine. A subsequent fluid shift from the intravascular compartment to the intestinal lumen occurs resulting in small intestine distention potentially causing cramps and bloating.

Late symptoms are predominantly vasomotor and include perspiration, weakness, confusion, shakiness, hunger, and hypoglycemia (Tack et al, 2009). Late dumping is likely the result of reactive hypoglycemia. Rapid delivery, as well as hydrolysis and absorption of carbohydrates, produces an exaggerated rise in insulin level and a subsequent decline in blood glucose. The rapid changes in blood glucose and the secretion of gut peptides, glucose insulinotropic polypeptide, and glucagon-like polypeptide-1 appear to be at least partly responsible for the late symptoms (Deloose et al, 2014) (see Chapter 30).

Medical Management

Medical intervention typically involves dietary changes as the initial treatment, and they are usually effective. However, in 3% to 5% of patients, severe dumping persists despite dietary change. In these patients, medications may be used to slow gastric emptying and delay transit of food through the GI tract. Some, such as acarbose, inhibit alpha glycoside hydrolase and interfere with carbohydrate absorption, and octreotide, a somatostatin analog, inhibits insulin release (see Table 27-3 for common medications). Rarely, surgical intervention is used to treat dumping syndrome.

Medical Nutrition Therapy

Patients with dumping syndrome may experience weight loss and malnutrition caused by inadequate intake, malabsorption, or a combination of both. The prime objective of nutrition therapy is to restore nutrition status and quality of life. Because they are digested more slowly, proteins and fats are better tolerated than carbohydrates, particularly simple carbohydrates. Simple carbohydrates such as lactose, sucrose, fructose, glucose and dextrose are hydrolyzed rapidly and should be limited, but complex carbohydrates (starches) can be included in the diet.

Liquids leave the stomach and enter the jejunum rapidly; thus some patients have trouble tolerating liquids with meals. Patients with severe dumping may benefit from limiting the amount of liquids taken with meals and drinking liquids between meals without solid food. Reclining (approximately 30 degrees) after meals may also minimize severity of symptoms.

The use of fiber supplements, particularly pectin or gums (e.g., guar) can be beneficial in managing dumping syndrome because of fiber's ability to form gels with carbohydrates and fluids and delay GI transit. Patients may need to be taught about portion sizes of foods, especially of carbohydrate foods such as juices, soft drinks, desserts, and milk. The exchange list given in Appendix 27 can be used to calculate carbohydrate intake and teach about carbohydrate control.

Postgastroectomy patients often do not tolerate lactose, but small amounts (e.g., 6 g or less per meal) may be tolerated at one time. Patients typically do better with cheeses or unsweetened yogurt than with fluid milk. Nondairy milks are also useful. Vitamin D and calcium supplements may be needed when intake is inadequate. Commercial lactase-containing products are available for those with significant lactose malabsorption (see Chapter 28 for further discussion of lactose intolerance and its management).

When steatorrhea (greater than 7% of dietary fat in the stool) exists, reduced fat formulas or pancreatic enzymes may

BOX 27-5 Basic Guidelines for Dumping Syndrome

1. Eat small, frequent "meals" per day.
2. Limit fluids to 4 ounces (½ cup) at a meal, just enough to "wash" food down.
3. Drink remaining fluids at least 30 to 40 minutes before and after meals.
4. Eat slowly and chew foods thoroughly.
5. Avoid extreme temperatures of foods.
6. Use seasonings and spices as tolerated (may want to avoid pepper, hot sauce).
7. Remain reclined at least 30 minutes after eating.
8. Sugar-containing foods and liquids are limited. Examples: fruit juice, Gatorade, PowerAde, Kool Aid, sweet tea, sucrose, honey, jelly, corn syrup, cookies, pie, doughnuts.
9. Complex carbohydrates are unlimited (e.g., bread, pasta, rice, potatoes, vegetables).
10. Include a protein-containing food at each meal.
11. Limit fats (less than 30% of total calories).
Avoid fried foods, gravies, fat containing sauces, mayonnaise, fatty meats (sausage, hot dogs, ribs), chips, biscuits, pancakes.
12. Milk and dairy products may not be tolerated because of lactose. Introduce these slowly in the diet if they were tolerated preoperatively. Lactose-free milk or soy milk is suggested.

be beneficial. Box 27-5 provides general nutrition guidelines for patients with dumping syndrome after gastric surgery; however, each diet must be adjusted based on a careful dietary and social history from the patient.

GASTROPARESIS

Etiology

Gastroparesis, or delayed gastric emptying, is a complex and potentially debilitating condition. The nature of gastroparesis is complex in part because gastric motility is orchestrated by a variety of chemical and neurologic factors. Viral infection, diabetes, and surgeries are the most common causes for gastroparesis; however, more than 30% of cases are idiopathic. Numerous classes of clinical conditions are associated with gastroparesis, including acid-peptic diseases, gastritis, postgastric surgery, disorder of gastric smooth muscle, psychogenic disorders, long-term uncontrolled diabetes, and neuropathic disorders.

Pathophysiology

Clinical symptoms may include abdominal bloating, decreased appetite and anorexia, nausea and vomiting, fullness, early satiety, halitosis, and postprandial hypoglycemia. The gold-standard measure of gastric emptying rate is scintigraphy, a nuclear test of gastric emptying. This consists of the patient ingesting a radionuclide-labeled meal (such as an egg labeled ^{90m}technetium), and scintigraphic images are taken over time (generally 4 hours) to assess the rate of gastric emptying. Gastric emptying is abnormal when greater than 50% of the meal is retained after 2 hours of study or when greater than 10% of the meal is retained after 4 hours (Maurer and Parkman, 2006).

Medical Management

Numerous symptoms of gastroparesis can affect oral intake, and the management of these symptoms generally improves nutrition status. Treatment of nausea and vomiting is perhaps

the most vital, and prokinetics and antiemetics are the primary medical therapies (see [Table 27-3](#)). Metoclopramide and erythromycin are medications that may be used to promote gastric motility. Small intestinal bacterial overgrowth, appetite, ileal brake (the slowing effect of intestinal transit of undigested food, often fat, reaching the ileum), or formation of a **bezoar** (concentration of undigested material in the stomach) are other factors that may affect nutritional status. In a select patient population, implantation of gastric pacemakers may be advantageous to improve gastric emptying ([Ross et al, 2014](#)).

Bezoar formation may be related to undigested food such as cellulose, hemicellulose, lignin and fruit tannins (phytobezoars), or medications (pharmacobezoars) such as cholestyramine, sucralfate, enteric-coated aspirin, aluminum-containing antacids, and bulk-forming laxatives. Treatment of bezoars includes enzyme therapy (such as papain, bromelain, or cellulase), lavage, and sometimes endoscopic therapy to mechanically break up the bezoar. Most patients respond to some combination of medication and dietary intervention; however, unresponsive and more severe cases may benefit from placement of an enteral tube into the small intestine, such as a nasoenteric small bowel feeding tube (for less than 4-week need) or percutaneous endoscopic gastrostomy with jejunal extension (PEG/J) (for more than 4 week need). The latter allows for nutrition to bypass the stomach while providing an alternative route for venting of gastric secretions, which may relieve nausea and vomiting.

Medical Nutrition Therapy

The primary dietary factors that affect gastric emptying (in order of clinical importance) are volume, liquids versus solids, hyperglycemia, fiber, fat, and osmolality. Larger volumes of food

that create stomach distension (approximately 600 ml) have been shown to delay gastric emptying and increase satiety ([Oesch et al, 2006](#)). Generally, patients benefit from smaller, more frequent meals. Patients with gastroparesis often continue to empty liquids, as they empty, in part, by gravity and do not require antral contraction.

Shifting the diet to more pureed and liquefied foods is often useful. A number of medications (such as narcotics and anticholinergics) slow gastric emptying and should be avoided if possible. Moderate to severe hyperglycemia (serum blood glucose more than 200 mg/dl) may acutely slow gastric motility, with long-term detrimental effects on gastric nerves and motility. Laboratory data considered in initial assessment include glycosylated hemoglobin A1C (if diabetes is present), ferritin, vitamin B₁₂, and 25-OH vitamin D (see Chapter 30).

Fiber, particularly pectin, can slow gastric emptying and increase risk of bezoar formation in patients who are susceptible. It is prudent to advise patients to avoid high-fiber foods and fiber supplements. The size of the fibrous particles, not the amount of fiber, is more important in bezoar risk (e.g., potato skins versus bran). This and the resistance to chewing are factors in bezoar formation. Examination of the patient's dentition is very important because patients who have missing teeth, a poor bite, or are edentulous are at greater risk. Even people with good dentition have swallowed and passed food particles up to 5 to 6 cm in diameter (potato skins, seeds, tomato skins, peanuts).

Fat is a powerful inhibitor of stomach emptying primarily mediated by cholecystokinin ([Goetze et al, 2007](#)); however, many patients tolerate fat well in liquid form. Fat should not be restricted in patients who are struggling to meet their daily caloric needs.

CLINICAL CASE STUDY

Jane is a 42-year-old female who presents with acute onset of epigastric abdominal pain associated with nausea and bilious vomiting, poor appetite, and 20-pound (9-kg) unintentional weight loss over the past 3 months. A nutrition consult is requested for assessment of nutritional status and strategies for treating nutritional issues associated with gastroparesis.

Nutrition Assessment

- Past medical history is significant for type I DM, GERD, gastroparesis, hypertension, chronic low back pain, and recent back surgery 3 months ago. Jane was discharged on narcotics, and then was recently hospitalized for similar symptoms that were attributed to diabetic gastroparesis exacerbated by narcotics use.
- Her medications on admission include insulin, Zofran, Prilosec, Reglan, lisinopril, Ultram.
- Oral intake has gradually decreased over the last 3 months to sips of liquids (water, soup, tea), and toast or crackers for the past 2 weeks. Upon further questioning, Jane reports frequent hypoglycemia after meals, early satiety, chronic constipation, and often wakes up in the morning feeling full. She has persistent epigastric abdominal pain accompanied by vomiting.
- Anthropometrics: Ht: 162.5 cm (64 inches); Wt: 72.7 kg (160 lb); BMI : 27.5 kg/m²
- Usual body weight: 81.8 kg (180 lbs); weight change: 11% change in 3 months (significant weight loss).
- Jane's nutrition-focused physical examination (NFPE) reveals the following: No evidence of muscle loss; stomach is smaller per patient report but otherwise no visible evidence of fat loss; no upper or lower extremity edema. Tongue is beefy red and swollen for the past few weeks (glossitis resulting from possible iron, folate, and vitamin B₁₂ deficiency).

- Functional capacity: Little energy or motivation to do anything for past 3 months. Dizzy and lightheaded for past 1 week.
- Laboratory data: Hb A1C (glycosylated hemoglobin) level: 9.5% (high), blood pressure: 178/95 (high), blood glucose: 293 mg/dl (high)

Nutrition Diagnostic Statements (PES Statements)

- Suboptimal oral intake (P) related to inability to consume sufficient calories (E) as evidenced by report of nausea, vomiting, and persistent abdominal pain (S).
- Unintended weight loss (P) related to altered GI function (E) as evidenced by 11% weight loss over past 3 months (S).

Nutrition Interventions

- 1) What would you estimate to be Jane's daily energy and protein requirements?
- 2) What would you work out with Jane for timing and size of her meals?
- 3) Would you recommend a trial of oral nutrition supplements?
- 4) In educating Jane on dietary guidelines for DM and gastroparesis, what would you discuss with her?
- 5) What concerns would you have related to her use of antiemetics or prokinetic agents?
- 6) Would you recommend any nutritional supplements for Jane? Which nutrients would concern you?

Nutrition Monitoring and Evaluation

- 1) What would you monitor during your followup visits with Jane to ensure that her nutrition goals are being met?

Medical Nutrition Therapy for Lower Gastrointestinal Tract Disorders

Gail Cresci, PhD, RD, LD, CNSC and Arlene Escuro, MS, RDN, CNSC

KEY TERMS

aerophagia	FODMAPs	osmotic agents
antibiotic-associated diarrhea (AAD)	fructose malabsorption	ostomy
<i>Clostridium difficile</i> infection (CDI)	functional constipation	polyp
celiac disease (CD)	glutamine	pouchitis
colitis, collagenous	gluten	prebiotics
colitis, lymphocytic	gluten intolerance	probiotics
colitis, microscopic	gluten-sensitive enteropathy	proctocolectomy
colostomy	gluten sensitivity	refractory celiac disease
constipation	high-fiber diet	Rome III criteria
Crohn's disease	high-output stoma (HOS)	short-bowel syndrome (SBS)
dermatitis herpetiformis	hypolactasia	small intestine bacterial overgrowth (SIBO)
diarrhea	ileal J-pouch	soluble fiber
dietary fiber	ileal pouch anal anastomosis (IPAA)	S-pouch
diverticulitis	ileostomy	steatorrhea
diverticulosis	inflammatory bowel disease (IBD)	stimulant laxatives
enterocutaneous fistula (ECF)	intestinal ostomy	stool softeners
eructation	irritable bowel syndrome (IBS)	synbiotics
fecal microbiota transplant (FMT)	Koch pouch	tropical sprue
fistula	lactose intolerance	ulcerative colitis (UC)
flatulence	medium-chain triglycerides (MCTs)	W-pouch
flatus	microbiota	

Nutrition status and the digestive tract are inextricably linked. Dietary interventions for many diseases of the intestinal tract are designed primarily to alleviate symptoms and to correct nutrient deficiencies. A comprehensive nutritional assessment should be performed to determine the nature and severity of the gastrointestinal (GI) problem. Information to be obtained should include a history of weight change, medications used (including supplements), presence of GI and other symptoms that may affect oral intake or fluid loss, and potential signs and symptoms of micronutrient deficiencies.

COMMON INTESTINAL PROBLEMS

It is important to understand some of the common GI processes that occur in healthy people before discussing diseases relating to lower GI tract. Dietary ramifications of intestinal gas, flatulence, constipation, and diarrhea often are considered in the management of more serious GI disorders.

Sections of this chapter were written by Nora Decher, MS, RD, CNSD and Joseph S. Krenitsky, MS, RD for the previous edition of this text.

Intestinal Gas and Flatulence

Pathophysiology

The daily volume of human intestinal gas is about 200 ml, and it is derived from complex physiologic processes, including swallowed air (**aerophagia**) and bacterial fermentation by the intestinal tract. These gases are either expelled through belching (**eructation**) or passed rectally (**flatus**). Intestinal gases include carbon dioxide (CO₂), oxygen (O₂), nitrogen (N₂), hydrogen (H₂), and sometimes methane (CH₄). Studies have detected CH₄ production in about one third of healthy adult individuals (Sahakian et al, 2010). Intestinal CH₄ production is a complex mechanism involving metabolism of other gases, particularly H₂, and from specific bacteria in the colon. Abnormal CH₄ production has been considered in the pathogenesis of several intestinal disorders, such as colon cancer, inflammatory bowel disease (IBD), irritable bowel syndrome, and diverticulosis (Triantafyllou et al, 2014).

When patients complain about “excessive gas” or **flatulence**, they may be referring to increased volume or frequency of belching or passage of rectal gas. They also may complain of abdominal distention or cramping associated with the

accumulation of gases in the upper or lower GI tract. The amount of air swallowed increases with eating or drinking too fast, smoking, chewing gum, sucking on hard candy, using a straw, drinking carbonated drinks, and wearing loose-fitting dentures. Foods that produce gas in one person may not cause gas in someone else, depending on the mix of microorganisms in the individual's colon. Inactivity, decreased motility, aerophagia, dietary components, and certain GI disorders can alter the amount of intestinal gas and individual symptoms.

Normally, the concentration of bacteria in the small intestine is significantly lower than that found in the colon. Various conditions can lead to overgrowth of bacteria in the small intestine causing bloating, distention, nausea, diarrhea, or other symptoms. Factors such as gastric acid, intestinal peristalsis, the ileocecal valve, bile acids, the enteric immune system, and pancreatic enzyme secretion prevent the overgrowth of bacteria within the small intestine.

Medical Nutrition Therapy

When evaluating a patient, clinicians must investigate and differentiate between increased production of gas and gas that is not being passed. It is also important to consider why a patient may have new or increased symptoms or if gas is accompanied by other symptoms such as constipation, diarrhea, or weight loss. Keeping a food diary to track eating habits and symptoms may help identify specific foods that cause gas. Careful review of the diet and the amount of burping or gas passed may help relate specific foods to symptoms and determine the severity of the problem.

If milk or milk products are causing gas, a patient is evaluated for lactose intolerance and advised to avoid milk products for a short time to see if symptoms improve. Recent viral or GI infection may induce temporary or even permanent impairment in the ability to digest lactose. Lactase tablets, drops, and lactose-free milk products are available to help digest lactose and reduce gas.

A sudden change in diet, such as a drastic increase in fiber intake, also can alter gas production. Specific foods that contain raffinose (a complex sugar resistant to digestion) such as beans, cabbage, broccoli, Brussels sprouts, asparagus, and some whole grains can increase gas production. [Box 28-1](#) outlines foods that may cause increase in gas production.

BOX 28-1 Foods that may Increase Gas Production

1. Beans
2. Vegetables such as broccoli, cauliflower, cabbage, Brussels sprouts, onions, mushrooms, artichokes, and asparagus
3. Fruits such as pears, apples, and peaches
4. Whole grains such as whole wheat and bran
5. Sodas: fruit drinks especially apple juice and pear juice; and other drinks that contain high-fructose corn syrup, a sweetener made from corn
6. Milk and milk products such as cheese, ice cream, and yogurt
7. Packaged foods such as bread, cereal, and salad dressing that contain small amounts of lactose, a sugar found in milk and foods made with milk
8. Sugar-free candies and gums that contain sugar alcohols such as sorbitol, mannitol, and xylitol

From National Institute of Diabetes and Digestive and Kidney Diseases: *Digestive Diseases A-Z* (website): <http://digestive.niddk.nih.gov/>. Accessed January 4, 2014.

Changes in the intestinal flora occur over time after an increase in dietary fiber. A gradual introduction of fiber with adequate fluid consumption appears to reduce complaints of gas. Inactivity, constipation, intestinal dysmotility, or partial bowel obstruction may contribute to the inability to move normal amounts of gas produced.

Constipation

Constipation is a major problem worldwide. In the US, chronic constipation leads to 8 million visits to medical providers per year ([Wald, 2016](#)). Its exact prevalence is difficult to ascertain because only a minority of patients suffering from constipation seek health care. Reports of its prevalence have varied widely, ranging from 0.7% to 29.6% in children and from 2.5% to 79% in adults ([Mugie et al, 2011](#)). This worldwide variation in prevalence rates arises from factors such as cultural diversity, genetic, environmental and socioeconomic conditions, and different health care systems. Constipation has a significant impact on quality of life and it contributes to health care financial burden. Female gender in adults, elderly age, high body mass index, and low socioeconomic status seem to be associated with a higher prevalence of constipation ([Mugie et al, 2011](#)).

Etiology

Constipation is defined as difficulty with defecation characterized by frequency or dyschezia (painful, hard, or incomplete evacuations). Normal bowel movement frequency can range from three times per day to three times per week. Stool weight is used most frequently in medical practice and clinical descriptions as an objective measure of the amount or volume of stool. A volume of as little as 200 g daily is considered normal in healthy children and adults.

The causes of constipation are varied and may be multifactorial. Inadequate fiber intake has been cited as the primary culprit since the early 1970s. [Box 28-2](#) outlines factors and conditions known to cause constipation. Treatment of the underlying disorder always should be the primary course of action. It is important to understand the symptom patterns and classification of constipation to tailor therapy based on the underlying pathophysiology.

Pathophysiology

Constipation is classified as primary or secondary. The primary causes of chronic constipation are classified further as normal transit constipation, slow transit constipation, and anorectal dysfunction ([Andrews and Storr, 2011](#)). The most common form of chronic constipation seen by clinicians is normal transit constipation (also known as functional constipation). Stool passes through the colon at a rate of about 5 days in persons with normal transit constipation. [Box 28-3](#) outlines the Rome III diagnostic criteria for functional constipation. In **functional constipation**, patients report symptoms they believe to be consistent with constipation such as the presence of hard stools or a perceived difficulty with defecation. However, on testing, stool transit is not delayed and the stool frequency is often within the normal range. Patients may experience bloating and abdominal pain or discomfort. Symptoms of functional constipation typically respond with dietary fiber alone or with the addition of an osmotic agent.

Slow transit constipation causes infrequent bowel movements (typically less than once per week). Often patients do not feel the urge to defecate and may complain of associated

BOX 28-2 Causes of Constipation

Lifestyle and Diet	Para- or quadriplegia
Lack of fiber in diet	Spinal cord injury
Low total calorie and fluid intake	Cerebrovascular disease
Iron and calcium supplements	Brain trauma
Lack of exercise	
Immobility	Pelvic Floor Disorders
Laxative abuse	Pregnancy
Postponing urge to defecate	Dyssynergic defecation
Dysmotility Disorders	Chronic Use of Opiates
Chronic intestinal pseudoobstruction	Oncology patients
Hypothyroidism	Chronic pain patients
Colonic inertia	Narcotic bowel syndrome
Gastroparesis	
Hirschprung disease	Other Gastrointestinal Disorders
Chagas disease	Diseases of the upper gastrointestinal tract
Metabolic and endocrine abnormalities such as diabetes	Diseases of the large bowel resulting in:
Neurologic Diseases	Failure of propulsion along the colon (colonic inertia)
Amyotrophic lateral sclerosis	Anorectal malformations or outlet obstruction
Multiple sclerosis	Irritable bowel syndrome (IBS)
Muscular dystrophy	Anal fissure
Parkinson's disease	
Friedrich ataxia	
Cerebral palsy	

Data from Andrews CN, Storr M: The pathophysiology of chronic constipation, *Can J Gastroenterol* 25(Suppl B):16B, 2011; Longstreth GF et al: Functional bowel disorders, *Gastroenterology* 130:1480, 2006; Schiller LR: Nutrients and constipation: cause or cure? *Pract Gastroenterol* 32:4, 2008.

BOX 28-3 Rome III Diagnostic Criteria for Functional Constipation

Criteria fulfilled for the last 3 months, with symptom onset at least 6 months before diagnosis
1. Must include two or more of the following:
a. Straining during at least 25% of defecations
b. Lumpy or hard stools in at least 25% of defecations
c. Sensation of incomplete evacuation for at least 25% of defecations
d. Sensation of anorectal obstruction/blockade for at least 25% of defecations
e. Manual maneuvers to facilitate at least 25% of defecations (i.e., digital evacuation, support of the pelvic floor)
f. Fewer than three defecations per week
2. Loose stools are rarely present without the use of laxatives.
3. There are insufficient criteria for irritable bowel syndrome (i.e., pain is not the predominant symptom).

Data from Longstreth GF et al: Functional bowel disorders, *Gastroenterology* 130:1480, 2006.

bloating and abdominal discomfort. Slowing of intestinal contents occurs more commonly in the rectosigmoid colon and results in decreased water content in the stool and reduced propulsive action. Treatment typically uses an aggressive laxative regimen. Select patients with slow transit constipation may respond well to surgical procedures such as subtotal colectomy and ileorectal anastomosis.

Anorectal dysfunction is a result of the pelvic floor muscle laxity, impaired rectal sensation, and decreased luminal pressure

in the anal canal. Frequently, laxatives are highly ineffective in anorectal dysfunction. The use of biofeedback therapy to retrain the muscles can be used by patients with constipation caused by problems in the anorectal muscles. It uses a combination of diaphragmatic muscle training, simulated defecation, and manometric or EMG (electromyogram) guided anal sphincter and pelvic muscle relaxation, with a goal of improving recto-anal coordination and sensory awareness (Lee et al, 2014). The measurements are displayed on a video screen as line graphs and sounds indicate when the patient is using the correct muscles.

Medical Management for Adults

A thorough and meticulous history is most helpful in ruling out constipation secondary to medications or other underlying medical illness. After this is done, the first approach to treat mild and functional constipation is to ensure adequate dietary fiber and fluid intake, exercise, and heeding the urge to defecate. Patients who depend on laxatives are encouraged to use milder products, reducing the dose until withdrawal is complete.

When constipation persists despite lifestyle and dietary modifications, medications that promote regular bowel movements may be prescribed. Agents used in the treatment of constipation are categorized broadly as either stool softeners or stimulants. **Stool softeners** (i.e., docusate sodium) are anionic surfactants with an emulsifying detergent-like property that increases the water content in stool to make bowel movements easier to pass. **Osmotic agents** such as magnesium hydroxide, sorbitol, lactulose, and polyethylene glycol contain poorly absorbed or nonabsorbable sugars and work by pulling fluid into the intestinal lumen. **Stimulant laxatives** such as bisacodyl and senna increase peristaltic contraction and bowel motility and act to prevent water absorption. Chronic use of laxatives is associated with abdominal cramping and fluid imbalance.

Lubiprostone (Amitiza) was recently approved by the Food and Drug Administration for idiopathic constipation and to treat irritable bowel syndrome with constipation in adults. Lubiprostone is a chloride channel activator that increases intestinal fluid secretion and mobility; however, it does not alter sodium or potassium electrolytes (Bailes and Reeve, 2013). It increases spontaneous bowel movements and is contraindicated in patients with suspected or known mechanical GI obstruction.

Medical Management for Infants and Children

Constipation is often especially troubling in infants and young children. Approximately 3% to 5% of all pediatric visits are related to chronic constipation. Some patients have symptoms that persist for 6 months or more. Constipation may be related to inadequate intake of fiber or fluid, side effects of medication, inactivity, or disordered bowel motility. Historically, a high-fiber diet has been recommended for children with constipation. However, few studies document benefit (Kranz et al, 2012). A careful history and physical examination followed by parent and child education, behavioral intervention, and appropriate use of laxatives often lead to dramatic improvement.

Medical Nutrition Therapy

Primary nutrition therapy for constipation in otherwise healthy people is consumption of adequate amounts of fluids and dietary fiber, soluble and insoluble. Fiber increases colonic fecal fluid, microbial mass (which accounts for 60% to 70% of stool

weight), stool weight and frequency, and the rate of colonic transit. With adequate intake of fluid, fiber may soften stools and make them easier to pass. Dietary Reference Intakes (DRI) recommend consumption of 14 g dietary fiber per 1000 kcal, or 25 g for adult women and 38 g for adult men. Appropriate kinds and amounts of dietary fiber for children, the critically ill, and the very old are unknown. Usual intake of dietary fiber in the United States is only about 16.2 g/day (Grooms et al, 2013).

Dietary fiber refers to edible plant materials not digested by the enzymes in the GI tract. It consists of cellulose, hemicellulose, pectins, gums, lignins, starchy materials, and oligosaccharides that are partially resistant to digestive enzymes. Fiber can be provided in the form of whole grains, fruits, vegetables, legumes, seeds, and nuts.

A high-fiber therapeutic diet may have to exceed 25 to 38 g/day. The **high-fiber diet** in **Box 28-4** provides more than the amount of fiber recommended. It is important to assess dietary fiber intake before making recommendations for fiber supplementation. If a patient is already taking 25 to 30 g of dietary fiber daily, fiber supplementation is unlikely to be helpful. If less than this amount is being consumed, fiber should be added slowly in graduated doses to eventually reach 25 to 30 g per day. Amounts greater than 50 g/day are not necessary and may increase abdominal distention and excessive flatulence due to fermentation by the colonic flora.

Bran and fiber supplements may be helpful in persons who cannot or will not eat sufficient amounts of fiber-containing foods. Several of these commercial fiber supplements are palatable and can be added to cereals, yogurts, fruit sauces, juices, or soups. Cooking does not destroy fiber, but the structure may change. Consumption of at least eight 8-oz glasses (approximately 2 L) of fluids daily is recommended to facilitate the effectiveness of a high-fiber intake. Gastric obstruction and fecal impaction may occur when boluses of fibrous gels or bran are not consumed with sufficient fluid to disperse the fiber.

Increasing dietary fiber for laxation is unlikely to help patients who have serious dysmotility syndromes, neuromuscular disorders, chronic opioid use, pelvic floor disorders, or other serious GI disease. In some conditions, such as neuromuscular disorders, a specific laxative medication regimen is a necessary part of disease management.

Diarrhea

Diarrhea is defined by the World Health Organization as the passage of three or more loose or liquid stools per day. Diarrhea

occurs when there is accelerated transit of intestinal contents through the small intestine, decreased enzymatic digestion of foodstuffs, decreased absorption of fluids and nutrients, increased secretion of fluids into the GIT, or exudative losses.

Pathophysiology

Diarrhea may be related to inflammatory disease; infections with fungal, bacterial, or viral agents; medications; overconsumption of sugars or other osmotic substances; an allergic response to a food, or insufficient or damaged mucosal absorptive surface.

Exudative diarrheas always are associated with mucosal damage, which leads to an outpouring of mucus, fluid, blood, and plasma proteins, with a net accumulation of electrolytes and water in the gut. Prostaglandin and cytokine release may be involved. Diarrhea associated with Crohn's disease, ulcerative colitis (UC), and radiation enteritis is often exudative.

Osmotic diarrheas occur when osmotically active solutes are present in the intestinal tract and are poorly absorbed. An example is the diarrhea that accompanies dumping syndrome in someone that consumes a beverage containing simple sugars after having a Billroth II procedure (gastrojejunostomy).

Secretory diarrheas are the result of active intestinal secretion of electrolytes and water by the intestinal epithelium, resulting from bacterial exotoxins, viruses, and increased intestinal hormone secretion. Unlike osmotic diarrhea, fasting does not relieve secretory diarrhea.

Malabsorptive diarrheas result when a disease process impairs digestion or absorption to the point that nutrients, such as fat, appear in the stool in increased amounts. Excess fat in the stool is called **steatorrhea**. Diarrhea occurs because of the osmotic action of these nutrients and the action of the bacteria on the nutrients that pass into the colon. Malabsorptive diarrhea occurs when there is not enough healthy absorptive area or inadequate production or interrupted flow of bile and pancreatic enzymes, or there is rapid transit, such as in inflammatory bowel disease (IBD) or after extensive bowel resection. **Box 28-5** lists diseases and conditions associated with malabsorption and diarrhea.

Medication-induced diarrheas are frequent in hospitalized and long-term care patients. Medications that cause diarrhea do so by different mechanisms. For example, medications such as lactulose (used in the management of hepatic encephalopathy) and sodium polystyrene sulfonate with sorbitol (used to treat hyperkalemia) create increased bowel movements as part of their mechanism of action. Some antibiotics have direct effects on GI function (see Chapter 8). For example, as a motilin agonist, erythromycin increases lower GI motility; clarithromycin and clindamycin also increase GI secretions.

The human intestinal tract is home for trillions of bacteria **microbiota** (see **Figure 28-1**). In the normal GI tract, commensal gut microbiota ferment sloughed intestinal cells and undigested foodstuffs to gases and short-chain fatty acids (SCFAs). Absorption of SCFAs facilitates absorption of electrolytes and water from the colon. Broad-spectrum antibiotics decrease the number of commensal bacteria in the bowel and may result in decreased fermentation byproducts reducing the absorption of electrolytes and water, and causing diarrhea.

Some antibiotics allow proliferation of opportunistic pathogenic microorganisms normally suppressed by competitive

BOX 28-4 Guidelines for High-Fiber Diets

1. Increase consumption of whole-grain breads cereals, and other products to 6 to 11 servings daily.
2. Increase consumption of vegetables, legumes, fruits, nuts, and edible seeds to 5 to 8 servings daily.
3. Consume high-fiber cereals, granolas, and legumes to bring fiber intake to 25 g in women or 38 g in men or more daily.
4. Increase consumption of fluids to at least 2 L (or approximately 2 qt) daily.

Note: Following these guidelines may cause an increase in stool weight, fecal water, and gas. The amount that causes clinical symptoms varies among individuals, depending on age and presence of gastrointestinal (GI) disease, malnutrition, or resection of the GI tract.

BOX 28-5 Diseases and Conditions Associated with Malabsorption**Inadequate Digestion**

Pancreatic insufficiency
Gastric acid hypersecretion
Gastric resection

Altered Bile Salt Metabolism with Impaired Micelle Formation

Hepatobiliary disease
Interrupted enterohepatic circulation of bile salts
Bacterial overgrowth
Drugs that precipitate bile salts

Genetic Abnormalities of Mucosal Cell Transport

Disaccharidase deficiency
Monosaccharide malabsorption
Specific disorders of amino acid malabsorption
Abetalipoproteinemia
Vitamin B₁₂ malabsorption
Celiac disease

Inflammatory or Infiltrative Disorders

Crohn's disease
Amyloidosis
Scleroderma
Tropical sprue
Gastrointestinal allergy
Infectious enteritis
Whipple disease
Intestinal lymphoma
Radiation enteritis
Drug-induced enteritis
Endocrine and metabolic disorders
Short-bowel syndrome (SBS)

Abnormalities of Intestinal Lymphatics and Vascular System

Intestinal lymphangiectasia
Mesenteric vascular insufficiency
Chronic congestive heart failure

Data from Beyer PL: Short bowel syndrome. In Coulston AM et al, editors: *Nutrition in the prevention and treatment of disease*, ed 1, San Diego, 2001, Academic Press; Branski D et al: Chronic diarrhea and malabsorption, *Pediatr Clin North Am* 43:307, 1996; Fine KD: Diarrhea. In Feldman M et al, editors: *Gastrointestinal and liver disease*, ed 6, Philadelphia, 1998, Saunders; Mitra AD et al: Management of diarrhea in HIV-infected patients, *Int J STD AIDS* 12:630, 2001; Podolsky DK: Inflammatory bowel disease, *N Engl J Med* 347:417, 2002; Sundarum A et al: Nutritional management of short bowel syndrome in adults, *J Clin Gastroenterol* 34:207, 2002.

FIGURE 28-1 Gut microbiota.

microorganisms in the GI tract. The toxins produced by some opportunistic microorganisms can cause colitis and increased secretion of fluid and electrolytes. A rise in antibiotic use has led to an increase in **antibiotic-associated diarrhea (AAD)** and overgrowth of *Clostridium difficile* with resultant **C. difficile**

infection (CDI). *C. difficile* is the leading cause of nosocomial (hospital-acquired) diarrhea in the United States (O'Keefe, 2010). This infection may cause colitis, secretory diarrhea, severe dilation of the colon (toxic megacolon), perforation of the bowel wall, peritonitis, or even death (Pattani et al, 2013).

In 2009 a survey of 12.5% of U.S. acute care facilities found a CDI prevalence rate among inpatients of 13.1 per 1000 patients (Borody and Khoruts, 2011). Resistant strains of *C. difficile* are less susceptible to treatment with antimicrobials and cause a more severe form of the disease with increased health care costs, and higher mortality (O’Keefe, 2010).

C. difficile is a spore-forming organism, and the spores are resistant to common disinfectant agents. The spore-forming ability of *C. difficile* allows the organism to be spread inadvertently to other patients by health care providers (iatrogenic infection) if strict infection control procedures are not followed. The presence of this infection is detected by analysis of a stool sample for the presence of the toxin produced by the organisms. Clindamycin, penicillins, and cephalosporins are associated most often with the development of *C. difficile* infection. Its occurrence depends on the number of antibiotics used, the duration of exposure to antibiotics, and the patient’s overall health. Chronic suppression of stomach acid with proton pump inhibitor medications during broad-spectrum antibiotic therapy also may increase susceptibility to *C. difficile* infection (Howell et al, 2010; Linsky et al, 2010).

With human immunodeficiency virus (HIV) and other immune deficiency states, several factors contribute to the diarrhea, including the toxic effects of medications, proliferation of opportunistic organisms, and the GI manifestations of the disease itself (Kulkarni et al, 2009) (see Chapter 37). Increased risk of opportunistic infection also is associated with use of antineoplastic agents (such as chemotherapy) or with malnutrition.

Medical Management

Because diarrhea is a symptom, not a disease, the first step in medical treatment is to identify and treat the underlying

problem. The next goal is to manage fluid and electrolyte replacement. In cases of severe diarrhea, restoring fluid and electrolyte is first priority. Electrolyte losses, especially potassium and sodium, should be corrected early by using oral glucose electrolyte solutions with added potassium. Oral rehydration solutions (ORS) work because they contain concentrations of sodium and glucose that are optimal for interaction with the sodium-glucose transport (SGLT) proteins in the intestinal epithelial cells (see Chapter 1).

With intractable diarrhea, especially in an infant or young child, parenteral feeding may be required. Parenteral nutrition (PN) may even be necessary if exploratory surgery is anticipated, or if the patient is not expected to resume full oral intake within 5 to 7 days (see Chapter 13).

Supplementation with **probiotics** shows some promise to prevent AAD and CDI, but there are inadequate data to recommend probiotics as a primary treatment for *C. difficile* infections (Pattani et al, 2013) (see *New Directions: Probiotics and Prebiotics and the Gut Microbiota*).

The best treatment currently is to employ **fecal microbiota transplant (FMT)** for refractory CDI. With the concept of the human gut microbiota as an organ, FMT may be considered an organ transplant. Basically the gut microbiota of the person infected with *C. difficile* is replaced with healthy donor stool, typically from a family member with similar dietary and living habits. The reported cumulative success rate of FMT in eradicating the infection is approximately 90% (Borody and Khoruts, 2011).

Products that combine probiotic microorganisms and a prebiotic fiber source have been described as **synbiotics** for their synergistic effects. However, no randomized controlled studies have systematically investigated the effectiveness of probiotics alone compared with synbiotics for the treatment of diarrhea. Controlled studies are needed to understand which strains of

NEW DIRECTIONS

Probiotics and Prebiotics and the Gut Microbiota

Some gastrointestinal conditions such as *Clostridium difficile* infection, SIBO, antibiotic-associated diarrhea, and perhaps even inflammatory bowel disease may result or have exacerbated symptoms when there are alterations to the colonies of microorganisms that exist in the small or large intestines. Exposure to broad-spectrum antibiotics causes dramatic alterations to commensal gut microbiota, placing the patient at risk for overgrowth of potentially pathogenic microbes and opportunistic GI infections.

A **probiotic** is defined by the World Health Organization as “a live microbial feed that when consumed in adequate amounts confers a health benefit on the host.” To be a probiotic, meaning “for life,” a live microbial strain must meet very stringent criteria. These include, being of human origin, resistant to acid and bile, being able to survive the upper intestinal tract environment and reach the distal gut (ileum and colon) and attach to the intestinal epithelium, and being able to colonize the distal intestine, confer health benefit to the host, and have scientifically proven health benefits (Cresci, 2012). Because of this strict criteria, most supplements termed “probiotics” are not truly probiotics and their use may be misleading to clinicians and consumers.

Certain strains of bacteria have been identified as probiotics. These may be available in supplement form (e.g., capsules, powders) or included in fermented food products (e.g., yogurts, kefir). The exact dose, means for delivery, or the duration of viability are uncertain, probably vary for different probiotic strains, and may depend on the condition to be treated. It has been suggested that probiotics may restore the balance of intestinal microbes and improve symptoms and prevent or treat conditions in which a gut dysbiosis has occurred, such as antibiotic-associated diarrhea (Pattani et al, 2013). Certain types of probiotics may be effective in reducing the

duration of enterovirus-induced acute infectious diarrhea in pediatric and adult patients and in those with IBD.

Like probiotics, prebiotics have strict criteria for their classification. Prebiotics, undigested polysaccharides, and sloughed proteins are the food source for the commensal gut microbiota.

A **prebiotic** is defined as “a selectively fermented ingredient that allows specific changes, both in the composition and activity in the gut microbiota, that confer benefits upon host well-being and health” (Cresci, 2012). Importantly, prebiotics must be resistant to gastric acidity, to hydrolysis by mammalian enzymes, and to GI absorption; must be fermented in the GI tract by the gut microbiota; and must be selective in the stimulation of the gut microbiota growth and activity that contribute to health and well-being. Prebiotics are naturally occurring or synthetic sugars and are not available to all gut microbial species. Upon reaching the distal gut, prebiotics are fermented by the gut microbiota to yield gases (carbon dioxide, hydrogen, and methane) and short-chain fatty acids. Short-chain fatty acids (acetate, propionate, butyrate) serve many biologic roles including aiding with water and electrolyte absorption, decreasing intraluminal pH, altering cell proliferation and differentiation, and modifying intestinal immune and inflammatory processes (Cresci, 2012). Although probiotics have reported safety issues with select clinical conditions, prebiotics carry little safety concerns but like probiotics, may contribute to GI discomfort (bloating, gas) if introduced too rapidly into the diet.

Because there is promise in theory and in select studies for correcting gut dysbiosis with supplements, further studies evaluating the optimal dose, timing, duration and indications for probiotics, prebiotics and their combinations are warranted.

probiotics should be provided, as well as type and amount of prebiotic fibers.

There is a long history of safe use of many strains of “live active cultures” in foods in healthy humans. However, the body of evidence is limited on the use of large doses of concentrated probiotic supplements, especially of specific strains that exhibit greater resistance to gastric acid or have increased ability to proliferate in the GI tract. Limited safety data support the use of concentrated probiotic supplements in patients with immunocompromised states, critical illness, or when probiotics are administered directly into the small intestine, as with jejunal feeding tubes, but research in this area continues (Stavrou et al, 2015). A number of case reports exist of hospitalized patients receiving concentrated strains of probiotics that have become septic because of infection in the bloodstream with the very same strain of probiotic being administered (Whelan and Myers, 2010). In a review of cases of adverse events related to probiotic administration in hospitalized patients, 25% of those adverse events resulted in the death of the patient (Whelan and Myers, 2010). Many of these case reports indicate the culprit probiotic was a nonpathogenic yeast, and since then product label warnings against providing this supplement to critically ill patients have been instated. In a large double-blind, randomized study of a high-dose multispecies probiotic administered via jejunal feeding tube in patients with severe acute pancreatitis, there were significantly more deaths in the patients who received probiotics compared with those receiving the inactive placebo (Besselink et al, 2008). Although this study is concerning and provides warning before administering live cultures to critically ill patients, study flaws lead to questions whether the increased mortality was solely the result of probiotic supplementation.

Probiotic preparations hold promise as an adjunctive or primary treatment in several gastrointestinal conditions, but additional studies are needed before routine use of these preparations is adopted, especially for hospitalized or immunocompromised patients. There remains much to be learned about true effectiveness, differences between probiotic strains, possible benefits of coadministration with prebiotics, best doses, safety, and cost-benefit of using probiotics.

Medical Nutrition Therapy

All nutrition interventions related to diarrhea must be viewed within the context of the underlying pathologic condition responsible for the diarrhea. Replacement of necessary fluids and electrolytes is the first step, using oral rehydration solutions (ORS), soups and broths, vegetable juices, and isotonic liquids. Restrictive diets, such as the BRAT diet made up of bananas, rice, applesauce, and toast, are nutrient poor; no evidence indicates that they are necessary during acute diarrheal illness. However, some clinicians recommend a progression of starchy carbohydrates such as cereals, breads, and low-fat meats, followed by small amounts of vegetables and fruits, followed by fats. The goal with this progression is to limit large amounts of hyperosmotic carbohydrates that may be maldigested or malabsorbed, foods that stimulate secretion of fluids, and foods that speed the rate of GI transit.

Sugar alcohols, lactose, fructose, and large amounts of sucrose may worsen osmotic diarrheas. Because the activity of the disaccharidases and transport mechanisms decrease during inflammatory and infectious intestinal disease, sugars may have to be limited, especially in children. Malabsorption is only one potential cause of diarrhea, and diarrhea may occur without

TABLE 28-1 Food to Limit in a Low-Fiber (Minimal Residue) Diet

Food	Comments
Lactose (in lactose malabsorbers)	6 to 12 g is normally tolerated in healthy lactase-deficient individuals, but may not be in some individuals.
Insoluble fiber (quantities >20 g)	Modest amounts (10 to 15 g) may help maintain normal consistency of gastrointestinal (GI) contents and normal colonic mucosa in healthy states and GI disease.
Sorbitol, mannitol, and xylitol (excess, >10 g/day)	Well tolerated in moderate amounts; large amounts may cause hyperosmolar diarrhea
Fructose (excess, 20-25 g/meal)	
Sucrose (excess, >25-50 g/meal)	
Caffeine	Increases GI secretions, colonic motility
Alcoholic beverages (especially wine and beer)	Increase GI secretions

significant malabsorption of macronutrients (carbohydrate, fat, and protein). Absorption of most nutrients occurs in the small intestine; diarrhea related to colonic inflammation or disease preserves the absorption of most ingested nutrients.

Minimal fiber and low-residue diets are rarely indicated (see Table 28-1). Patients are encouraged to resume a regular diet as tolerated that contains moderate amounts of soluble fiber. The metabolism of soluble fiber and resistant starches by colonic bacteria leads to production of SCFAs, which in physiologic quantities serve as a substrate for colonocytes, facilitate the absorption of fluid and salts, and may help to regulate GI motility.

Fibrous material tends to slow gastric emptying, moderate overall GI transit, and pull water into the intestinal lumen. Providing fiber to patients with diarrhea does increase the volume of stool, and in some cases (such as small intestine bacterial overgrowth [SIBO]) initially can increase gas and bloating. Modest intake of prebiotic components and **soluble fibers** such as pectin or gum slows transit through the GI tract.

Several probiotics have been studied for preventing AAD. Currently, of those tested, *Saccharomyces boulardii* and *Lactobacillus*-based formulations appear to be most effective in reducing AAD (Pattani et al, 2013). Studies are still needed to find the optimal combination of probiotics and/or prebiotics, testing for dosing schedules, and concentrations.

Severe and chronic diarrhea is accompanied by dehydration and electrolyte depletion. If also accompanied by prolonged infectious, immunodeficiency, or inflammatory disease, malabsorption of vitamins, minerals, and protein or fat also may occur, and nutrients may have to be replaced parenterally or enterally. In some forms of infectious diarrhea, loss of iron from GI bleeding may be severe enough to cause anemia. Nutrient deficiencies themselves cause mucosal changes such as decreased villi height and reduced enzyme secretion, further contributing to malabsorption. As the diarrhea begins to resolve, the addition of more normal amounts of fiber to the diet may help to restore normal mucosal function, increase electrolyte and water absorption, and increase the firmness of the stool.

Food in the lumen is needed to restore the compromised GI tract after disease and periods of fasting. Early refeeding after

rehydration reduces stool output and shortens the duration of illness. Micronutrient replacement or supplementation also may be useful for acute diarrhea, probably because it accelerates the normal regeneration of damaged mucosal epithelial cells.

Treating Diarrhea in Infants and Children

Acute diarrhea is most dangerous in infants and small children, who are easily dehydrated by large fluid losses. In these cases replacement of fluid and electrolytes must be aggressive and immediate. Standard ORS recommended by the World Health Organization and the American Academy of Pediatrics contain a 2% concentration of glucose (20 g/L), 45 to 90 mEq/L of sodium, 20 mEq/L of potassium, and a citrate base (see Table 28-2).

Newer reduced-osmolality solutions (200 to 250 mOsm/L) have advantages over the traditional WHO-recommended ORS in treating acute diarrhea in children. The use of reduced-osmolality ORS in children with acute diarrhea resulted in decreased need for intravenous therapy, significant reduction in stool output, and decreased vomiting compared with standard WHO-recommended ORS (Atia and Buchman, 2009). Commercial solutions such as Pedialyte, Infalyte, Lytren, Equalyte, and Rehydralyte typically contain less glucose and slightly less salt and are available in pharmacies, often without prescription. Oral rehydration therapy is less invasive and less expensive than intravenous rehydration and, when used with children, allows parents to assist with their children's recovery.

A substantial proportion of children 9 to 20 months of age can maintain adequate intake when offered either a liquid or a semisolid diet continuously during bouts of acute diarrhea. Even during acute diarrhea, the intestine can absorb up to 60% of the food eaten. Some practitioners have been slow to adopt the practice of early refeeding after severe diarrhea in infants despite evidence that "resting the gut" is actually more damaging.

Gastrointestinal Strictures and Obstruction

Pathophysiology

Patients with gastroparesis, adhesions, hernias, metastatic cancers, dysmotility, or volvulus are prone to obstruction, which

can result in partial or complete blockage of movement of food or stool through the intestines. Obstructions may be partial or complete and may occur in the stomach (gastric outlet obstruction), small intestine, or large intestine. Symptoms include bloating, abdominal distention and pain, nausea, and vomiting.

Obstructions are not usually caused by foods in an otherwise healthy individual, however, when sections of the GI tract are partially obstructed or not moving appropriately, foods may contribute to obstruction. Researchers have not found that eating, diet, and nutrition play a role in causing or preventing the frequency of obstructive symptoms. It is believed that fibrous plant foods can contribute to obstruction because the fiber in the foods may not be completely chewed to pass through narrowed segments of the GI tract.

Medical Nutrition Therapy

Most clinicians would recommend patients prone to obstructions to chew food thoroughly and avoid excessive fiber intake. A patient with a partial bowel obstruction may be able to tolerate a restricted-fiber diet and liquids, depending on the location of stricture or obstruction in the GI tract. A more proximal (closer to the mouth) blockage may require a semisolid or liquid diet. However, the more distal (closer to the anus) the blockage, the less likely altering the consistency of the diet will help. Symptoms are more severe during complete obstruction. Patients may be intolerant of oral intake and of their own secretions leading to progressive dehydration, electrolyte imbalance, and systemic toxicity. Initial treatment consists of aggressive fluid resuscitation, nasogastric decompression, and administration of analgesics and antiemetics.

Patients with complete bowel obstruction may require surgical intervention. In some cases, enteral feeding beyond the point of obstruction may be feasible, but if enteral feeding is not possible for a prolonged period, parenteral nutrition may be needed. Working with the patient and physician is necessary to determine the nature, site, and duration of the obstruction so that nutrition therapy can be individualized.

DISEASES OF THE SMALL INTESTINE

Celiac Disease (Gluten-Sensitive Enteropathy)

The prevalence of **celiac disease (CD)** has been underestimated in the past and now is considered to affect at least 1 in 141 persons in the United States and varies by race and ethnicity, with a marked predominance among non-Hispanic whites (Rubio-Tapia et al, 2012). The onset and first occurrence of symptoms may appear any time from infancy to adulthood, but the peak in diagnosis occurs between the fourth and sixth decade. The disease may become apparent when an infant begins eating **gluten**-containing cereals. In some, it may not appear until adulthood, when it may be triggered or unmasked during GI surgery, stress, pregnancy, or viral infection. It may be discovered as a result of evaluation for another suspected problem. Approximately 20% of cases are diagnosed after the age of 60 years.

Etiology

The presentation in young children is likely to include the more "classic" GI symptoms of diarrhea, steatorrhea, malodorous stools, abdominal bloating, apathy, fatigue, and poor weight gain. Although GI-related symptoms often are thought to be most common, an increasing number of patients present without GI

TABLE 28-2 Oral Rehydration Solution (ORS): Composition and Recipes

Element	Composition
Glucose (g/100 ml)	20
Sodium (mEq/L)	90
Potassium (mEq/L)	20
Chloride (mEq/L)	80
Bicarbonate (mEq/L)	30
Osmolality (mOsm/L)	330
Recipes* (each makes 1 liter)	
2 cups Gatorade, 2 cups water, 3/4 tsp salt	28 g glucose, 82 mEq Na, 1.5 eEq K
or	
1 quart water, 3/4 tsp salt, 6 teaspoons sugar	24 g glucose, 76 mEq Na, 0 mEq K

Recipes from Parrish CR: The clinician's guide to short bowel syndrome, *Pract Gastroenterol* 29:67, 2005.

K, Potassium; Na, sodium.

*The solution should be made fresh every 24 hr.

BOX 28-6 Symptoms and Conditions Associated with Celiac Disease**Nutritional**

Anemia (iron or folate, rarely B₁₂)
 Osteomalacia, osteopenia, fractures (vitamin D deficiency, inadequate calcium absorption)
 Coagulopathies (vitamin K deficiency)
 Dental enamel hypoplasia
 Delayed growth, delayed puberty, underweight
 Lactase deficiency

Extraintestinal

Lassitude, malaise (sometimes despite lack of anemia)
 Arthritis, arthralgia

Dermatitis herpetiformis
 Infertility, increased risk of miscarriage
 Hepatic steatosis, hepatitis
 Neurologic symptoms (ataxia, polyneuropathy, seizures); may be partly nutrition related
 Psychiatric syndromes

Associated Disorders

Autoimmune diseases: type 1 diabetes, thyroiditis, hepatitis, collagen vascular disease
 Gastrointestinal malignancy
 IgA deficiency

IgA, Immunoglobulin A.

Kupfer SS, Jabri B: Pathophysiology of celiac disease, *Gastrointest Endosc Clin N Am* 22:639, 2012.

symptoms. Fifty percent of celiac patients have few or no obvious symptoms, and some are overweight at presentation (Phatak and Pashankar, 2015). CD frequently is misdiagnosed as irritable bowel syndrome (IBS), lactase deficiency, gallbladder disease, or other disorders not necessarily involving the GI tract, because the presentation and onset of symptoms vary so greatly.

Patients may present with one or more of a host of conditions associated with CD: anemias, generalized fatigue, weight loss or failure to thrive, osteoporosis, vitamin or mineral deficiencies, and (although rare) GI malignancy. **Dermatitis herpetiformis**, yet another manifestation of CD, presents as an itchy skin rash; its presence is diagnostic of CD. Box 28-6 lists conditions associated with CD. Persons who are diagnosed late in life, who cannot or will not comply with the diet, or who were diagnosed as children, but told they would grow out of it, are at a higher risk for experiencing long-term complications from CD (Nachman et al, 2010).

Pathophysiology

CD, or **gluten-sensitive enteropathy**, is characterized by a combination of four factors: (1) genetic susceptibility, (2) exposure to gluten, (3) an environmental “trigger,” and (4) an autoimmune response. Gluten refers to specific peptide fractions of proteins (prolamines) found in wheat (glutenin and gliadin), rye (secalin), and barley (hordein). These peptides are generally more resistant to complete digestion by GI enzymes and may reach the small intestine intact. In a normal, healthy intestine, these peptides are harmless as the intestinal barrier is intact and prevents translocation from the intestine. However, in persons with CD these peptides travel from the intestinal lumen, across the intestinal epithelium, and into the lamina propria, where they can trigger an inflammatory response that results in flattening of intestinal villi and elongation of the crypt cells (secretory cells), along with a more general systemic immune response (Sams and Hawks, 2014) (see Figure 28-2).

The term **gluten sensitivity** is used commonly to describe persons with nonspecific symptoms, without the immune response characteristic of CD or the consequential intestinal damage. **Gluten intolerance** describes individuals who have symptoms and who may or may not have CD. These two terms are used to describe symptoms such as nausea, abdominal cramps, or diarrhea after ingesting gluten. Patients who experience these symptoms generally should be advised against

FIGURE 28-2 CD (gluten-sensitive enteropathy). **A**, Peroral jejunal biopsy specimen of diseased mucosa shows severe atrophy and blunting of villi, with a chronic inflammatory infiltrate of the lamina propria. **B**, Normal mucosal biopsy. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.)

following a gluten-free (GF) diet without having a workup to exclude or confirm a diagnosis of CD because (1) there may be an underlying medical condition for which a GF diet is not the treatment; (2) after following a GF diet for months or years, it is difficult to diagnose CD; and (3) although generally a healthy way to eat, a GF diet can be expensive and restrictive.

The “triggers” of CD are not well understood, but stressors (e.g., illness, inflammation) are thought to play a role. When CD remains untreated, the immune and inflammatory response eventually results in atrophy and flattening of villi. Over

time, the process can cause enough damage to the intestinal mucosa to compromise normal secretory, digestive, and absorptive functions, leading to impaired micronutrient and macronutrient absorption (Kupfer and Jabri, 2012). Cells of the villi become deficient in the disaccharidases and peptidases needed for digestion and also in the carriers needed to transport nutrients into the bloodstream. The disease primarily affects the proximal and middle sections of the small bowel, although the more distal segments also may be involved (Sams and Hawks, 2014).

Assessment

The diagnosis of CD is made from a combination of clinical, laboratory, and histologic evaluations. Persons suspected of having CD should be evaluated for the overall pattern of symptoms and family history. Biopsy of the small intestine is the gold standard for diagnosis. An intestinal biopsy positive for CD generally shows villous atrophy, increased intraepithelial lymphocytes, and crypt cell hyperplasia. However, biopsy is not used for initial screening because of its cost and invasiveness.

Elevated blood levels of certain autoantibodies are found in people with celiac disease. To screen for celiac disease several serologic tests are evaluated. These tests identify the presence of antibodies in the blood, such as anti-tissue transglutaminase (anti-TTG), and antiendomysial antibodies, and deaminated gliadin peptide. The sensitivity and specificity of these tests are 90% to 99% (Schyum and Rumessen, 2013). There is a higher incidence of immunoglobulin A (IgA) deficiency in patients with CD; thus physicians often measure IgA levels when serologic findings are normal, but the overall clinical picture suggests CD (see *Clinical Insight: Antibody Testing for Celiac Disease and Gluten Sensitivity*). Using video capsule endoscopy to image the entire intestinal mucosa can show inflammation related to CD but is not currently used in the initial diagnosis (Bouchard et al, 2014). Because dietary change alters diagnostic results, initial evaluation should be done *before* the person has eliminated gluten-containing foods from his or her diet. Serologic tests also may be used to monitor the response of a newly diagnosed patient treated with a GF diet.

Lifelong, strict adherence to a GF diet is the only known treatment for CD (see *Box 28-7* for a list of safe, questionable, and unsafe choices on the GF diet). The GF diet greatly diminishes the

autoimmune process, and the intestinal mucosa usually reverts to normal or near normal. Within 2 to 8 weeks of starting the GF diet, most patients report that their clinical symptoms have abated. Histologic, immunologic, and functional improvements may take months to years, depending on the duration of the disease, age of the subject, and degree of dietary compliance. With strict dietary control, levels of the specific antibodies usually become undetectable within 3 to 6 months in most persons. In some individuals, recovery may be slow or incomplete.

A small percentage of patients are “nonresponders” to diet therapy. Inadvertent gluten intake is the most common offender, but another coexisting disorder may be present (such as pancreatic insufficiency, IBS, bacterial overgrowth, fructose intolerance, other GI maladies, or unknown causes). For nonresponders, intensive interviewing to identify a source of gluten contamination or treatment of another underlying disease may resolve the symptoms. Diagnosis of **refractory celiac disease** is made when patients do not respond or respond only temporarily to a GF diet, and all external causes have been ruled out, including inadvertent gluten ingestion. Patients with refractory disease may respond to steroids, azathioprine, cyclosporine, or other medications classically used to suppress inflammatory or immunologic reactions.

Several novel treatments for CD are being studied for their potential as alternative therapies. Researchers seek to treat CD by reducing gluten exposure (by digestion with added enzymes), decreasing uptake of gluten (by tightening junctions between intestinal epithelial cells), altering the immune response to gluten, or repairing intestinal injury.

Medical Nutrition Therapy

Elimination of gluten peptides from the diet is the only treatment for CD presently. The diet omits all dietary wheat, rye, and barley, which are the major sources of the prolamins fractions.

In general, patients should be assessed for nutrient deficiencies before supplementation is initiated. In all newly diagnosed patients, the clinician should consider checking levels of ferritin, red blood cell folate, and 25-OH vitamin D. If patients present with more severe symptoms, such as diarrhea, weight loss, malabsorption, or signs of nutrient deficiencies (e.g., night-blindness, neuropathy, prolonged prothrombin time), other vitamins such as fat-soluble vitamins (A, E, K) and minerals (zinc) should be checked.

CLINICAL INSIGHT

Antibody testing for Celiac Disease and Gluten Sensitivity by Ruth Leye-Wallace, PhD, RDN

There are two different types of antibodies considered in celiac disease diagnosis: those which are “anti-gluten”; and those which are “anti-self” (auto-immune). “Anti-gluten” antibodies are the anti-gliadin IgG and IgA. Ig stands for “immunoglobulin” or “antibody.” “Anti-self” antibodies are anti-endomysial IgA and anti-tissue transglutaminase IgA (tTg IgA).

Antigliadin antibodies IgG and IgA recognize a small piece of the gluten protein called gliadin. Antigliadin IgG has good sensitivity, while anti-gliadin IgA has good specificity. Their combined use provides a screening test for celiac disease. Many normal individuals without celiac disease will have an elevated anti-gliadin IgG. It is estimated that 0.2-0.4% of the general population has selective IgA deficiency, while 2 to 3% or more of celiacs are IgA deficient.

If a celiac panel is only positive for anti-gliadin IgG, this is not highly suggestive for celiac disease if the patient has a normal total IgA level. An anti-gliadin IgG level 3 to 4 times the upper limit of normal for that lab is highly suggestive of a condition where the gut is abnormally permeable (“leaky”) to gluten. This can happen with food allergies, cystic fibrosis, parasitic infections, Crohn’s disease, and other types of autoimmune GI diseases. These antibodies may also be slightly elevated in individuals with no obvious disease.

The tTg IgA test is highly sensitive and specific. It correlates well with biopsy, is inexpensive, not subjective, and can be performed on a single drop of blood. However, it can be falsely positive in a patient who has other autoimmune conditions, such as type 1 diabetes. For those with a negative tTg IgA test, IgA deficiency should be considered. <http://americaneliac.org/ceeliac-disease/diagnosis/>

BOX 28-7 The Basic Gluten-Free Diet

Foods	Safe Choices	Questionable	Avoid
Grains and flours	Amaranth, arrowroot, bean flours (such as garbanzo or fava bean), buckwheat, corn (maize) or corn-starch, flax, Job's tears, millet, potato, quinoa, ragi, rice, sorghum, soybean (soya), tapioca, teff	Carob-soy flour, buckwheat pancake mixes (often contain wheat flour), pure uncontaminated oats (note: a small percentage of people with celiac disease react to pure oats; discuss with health care provider first)	Wheat (bulghur, couscous, durum, farina, graham, kamut, semolina, spelt, triticale, wheat germ), rye, barley, oats (except pure, uncontaminated oats), low gluten flour. Caution: "wheat free" does not necessarily mean "gluten free"
Cereals—hot or dry	Cream of rice, cream of buckwheat, hominy, gluten-free dry cereals, grits	Puffed rice or corn cereals (possible contamination); pure uncontaminated oats (small percentage of people with CD react to oats)	Those with wheat, rye, oats (except pure, uncontaminated), barley, barley malt, malt flavoring, wheat germ, bran
Potatoes, rice, starch	Any plain potatoes, sweet potatoes and yams, all types of plain rice, rice noodles, 100% buckwheat soba noodles, gluten-free pasta, polenta, hominy, corn tortillas, parsnips, yucca, turnips	Check labels for commercial potato or rice products with seasoning packets	Battered or deep-fried French fries (unless no other foods have been fried in the same oil), pasta, noodles, wheat starch, stuffing, flour tortillas, croutons
Crackers, chips, popcorn	Rice wafers or other gluten-free crackers, rice cakes; plain corn chips, corn tortilla chips, potato chips, and other root (taro, beet, sweet potato, or vegetable etc.) or grain (amaranth, quinoa) chips, plain popcorn	Flavored chips	On gluten-free crackers, graham crackers, rye crisps, matzo, croutons, pretzels
Desserts	Sorbet, popsicles, Italian ice	Check labels on ice cream and pudding	Ice cream with bits of cookies, "crispies," pretzels, etc; pie crust, cookies, cakes, ice cream cones, and pastries made from gluten-containing flours
Milk and yogurt	Any plain, unflavored milk or yogurt, buttermilk, cream, half and half	Flavored milks or yogurts (check labels)	Malted milk, yogurts with added "crunchies" or toppings
Cheese	Cheese (all styles including blue cheese and gorgonzola), processed cheese (i.e., American), cottage cheese	Cheese spreads or sauces (check labels)	
Eggs	All types of plain, cooked eggs	Eggs Benedict (sauce usually made with wheat flour)	
Meat, fish, shellfish, poultry	Any fresh, plain untreated meat, fish, shellfish, or poultry; fish canned in brine, vegetable broth, or water	Commercially treated, preserved, or marinated meats, luncheon meats, fish, shellfish; self-basting or cured poultry (check labels)	Breaded or battered meats
Beans and legumes	Any plain frozen, fresh, dried, or canned (no flavorings or sauces added) beans: garbanzo beans, kidney beans, lentils, pinto beans, edamame, lima, black beans, etc	Check labels for added ingredients—sauces may have gluten	
Soy products and meat analogs or alternatives	Plain tempeh, tofu, edamame	Check labels on miso, soy sauce, seasoned tofu and tempeh and hydrolyzed vegetable protein; meat analogs (imitation meat substitutes), imitation seafood and soy protein powdered drinks	Seitan; 3-Grain Tempeh
Nuts and seeds	Any plain (salted or unsalted) nuts, seeds or nut butters, coconut	Dry-roasted nuts (check with manufacturer—may dust with flour during processing)	Nut butters with gluten-containing ingredients
Fruits and juices	Any plain fresh, canned, frozen fruits or juices, plain dried fruit	Pie fillings (often thickened with gluten-containing flour)	Dried fruit dusted with flour
Vegetables	Any plain, fresh, canned or frozen vegetables including corn, peas, lima beans, etc.		Vegetables in gluten-containing sauce or gravy
Soups	Homemade soups with known allowed ingredients	Check labels on all commercial soups	
Condiments, jams, and syrups	Ketchup, mustard, salsa, wheat-free soy sauce, mayonnaise, vinegar (except malt vinegar), jam, jelly, honey, pure maple syrup, molasses	Check labels on soy sauce, salad dressings, commercial sauces, soup base, marinades, and coating mixes for gluten-free designation	Malt vinegar
Seasonings and flavorings	Any <i>plain</i> herb or spice; salt; pepper; brown or white sugar; or artificial sweetener (i.e., Equal, Sweet-N-Low, Splenda)	Seasoning mixes, bouillon; check labels for gluten-free designation	

Continued

BOX 28-7 The Basic Gluten-Free Diet—cont'd

Foods	Safe Choices	Questionable	Avoid
Fats	Butter, margarine, all pure vegetable oils (including canola), mayonnaise, cream	Check labels on salad dressings, sandwich spreads	
Baking ingredients	Yeast, baking soda, baking powder, cream of tartar, regular chocolate baking chips		See grains and flours; Check label on grain sweetened, carob or vegan chocolate chips
Beverages	Coffee, tea, pure cocoa powder, sodas, Silk soymilk, Rice Dream beverage	Check labels on flavored instant coffee mixes (such as Swiss mocha, cappuccino); herbal teas, soy or rice drinks (may contain barley malt or rice syrup)	Malted beverages
Alcohol	Wine, all distilled liquor including vodka, tequila, gin, rum, whiskey and pure liqueurs, gluten-free beers (Redbridge, Bard's Tale beer, ciders)	Drink mixes	Beer, ale, lager
Candies	Check labels—many are gluten-free		Candy from bulk food bins Licorice

Adapted from Parrish CR et al: *University of Virginia Health System Nutrition Support Traineeship Syllabus*, Charlottesville, Va, 2010, University of Virginia Health System.
CD, Celiac disease.

The healing of the intestinal mucosa that occurs after initiation of a GF diet improves nutrient absorption, and many patients who eat well-balanced GF diets do not need nutritional supplementation. However, most specialty GF products are not fortified with iron, folate, and other B vitamins like other grain products, so the diet may not be as complete without at least partial supplementation. Anemia should be treated with iron, folate, or vitamin B₁₂, depending on the nature of the anemia. Patients with malabsorption may benefit from a bone density scan to assess for osteopenia or osteoporosis. Calcium and vitamin D supplementation are likely to be beneficial in these patients. Electrolyte and fluid replacement is essential for those dehydrated from severe diarrhea.

Those who continue to have malabsorption should take a general vitamin-mineral supplement to at least meet DRI recommendations. Lactose and fructose intolerance sometimes occur secondary to CD, and sugar alcohols are not well absorbed, even in a healthy gut. A low-lactose or low-fructose diet may be useful in controlling symptoms, at least initially. Once the GI tract returns to more normal function, lactase activity also may return, and the person can incorporate lactose and dairy products back into the diet.

In general, many fruits, vegetables, non-gluten containing grains, meats, and dairy products that are plain and unseasoned are safe to eat. Oats were once thought to be questionable for persons with CD; however, extensive studies have shown that they are safe in the GF diet as long as they are pure, uncontaminated oats (Garsed and Scott, 2007). However, a very small population of patients with CD may not tolerate even pure oats. In general, patients do not need to be advised against including GF oats in their diet unless they have demonstrated intolerance to GF oats.

Flours made from corn, potatoes, rice, soybean, tapioca, arrowroot, sorghum, garbanzo beans, nuts (such as almond flour), amaranth, quinoa, millet, teff, and buckwheat can be substituted in recipes. Patients can expect differences in textures and flavors of common foods using the substitute flours, but new recipes can be palatable once the adjustment is made. In

GF baked goods, gums such as xanthan, guar, and cellulose (from nongluten grains) can be used to provide the elasticity needed to trap leavening gases in baked goods.

A truly GF diet requires careful scrutiny of the labels of all bakery products and packaged foods. Gluten-containing grains are not only used as primary ingredients in many products but also may be added during processing or preparation of foods. For example, hydrolyzed vegetable protein can be made from wheat, soy, corn, or mixtures of these grains.

In the US there is now a gluten-free labeling law that went into effect in September, 2014. (<https://www.federalregister.gov/articles/2013/08/05/2013-18813/food-labeling-gluten-free-labeling-of-foods>). This law states that all food carrying a gluten-free claim also must contain less than 20 ppm gluten (i.e., below 20 mg gluten per kg of food), including from cross-contact. Thompson discusses the law in detail (Thompson, 2015). Recent studies on the gluten content of labeled gluten-free food in the US showed that 95 – 99% of the products tested contained less than 20 ppm gluten (Sharma et al, 2015).

The diet for the person with CD requires a major lifestyle change because of the change from traditional grains in the diet. A tremendous number of foods made with wheat (in particular breads, cereals, pastas, and baked goods) are a common part of a Western diet. However, there is increasing awareness among food companies and restaurants of the expanding demand for GF foods, and food businesses are responding. The individual and family members should be taught about label reading, safe food additives, food preparation, sources of cross-contamination (such as toasters, condiment jars, bulk bins, and buffets), and hidden sources of gluten (such as medications and communion wafers) to be compliant with the diet. Box 28-8 provides sources of hidden gluten and cross-contamination. Eating in cafeterias, restaurants, vending outlets, street markets, at friends' homes, and at social events can be challenging, especially initially.

To avoid misinterpretation of information, newly diagnosed patients should be started with an in-depth instruction from a

registered dietitian nutritionist (RDN) on the GF diet, along with reliable resources for further guidance and support. Persons with CD generally need several educational or counseling sessions and often benefit from a support group ([American Gastroenterological Association \[AGA\], 2015](#)) (see [Box 28-9](#) for CD resources).

Marked gut improvement and a return to normal histologic findings occurs in the majority of patients after an average of 2 years ([Hutchinson et al, 2010](#)). Patients who are able to follow the GF diet closely have a better overall response (see *Pathophysiology and Care Management Algorithm: Celiac Disease*).

BOX 28-8 Hidden Gluten Exposure and Cross-Contamination

Hidden Gluten Exposure

Unfortunately, gluten is not always obvious. Review the list below for some “unsuspected” products that may contain gluten.

- Over-the-counter and prescription medications

The labeling requirements of the Food Allergen and Consumer Protection Act of 2004 (FALCPA) **do not** apply to medications (see [Box 26-10](#) in Chapter 26). Check with your pharmacist or call the manufacturer to determine whether there is any gluten in your medications.

Note: Dietary supplements are covered under FALCPA regulations, so wheat must be clearly listed if it is an ingredient in a vitamin, mineral, or herbal supplement.

- Communion wafers
- Gluten-free recipes are available.

- Uncommon sources

If laboratory values stay elevated and symptoms remain and, possible sources of gluten cannot be found in the diet, it may be worth checking into other sources such as toothpaste, mouthwash, or lipstick.

Cross-Contamination

Below are some of the most common sources of gluten contamination. A few crumbs that may not even be seen can cause damage to the intestine, so it is best to avoid these situations:

- Toasters used for gluten-containing foods

Keep two toasters at home and designate one as gluten free. Alternatively, there are now bags available that are designed to hold a piece of bread in the toaster.

- Bulk bins

Prepackaged food is a safer bet.

- Condiment jars (peanut butter, jam, mayonnaise, etc.)

It is best to keep a separate gluten-free jar for commonly used items and be sure to label it clearly. At the very least, make sure everyone in the house knows not to “double-dip.”

- Buffet lines

Other customers may use one serving utensil for multiple items. Food from one area may be spilled into another food container. It may be safer to order from the menu.

- Deep-fried foods

Oil is typically used over and over to fry foods. It is highly likely that French fries (or other GF foods) are fried in the same oil as battered and breaded foods like fried chicken.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Celiac Disease (Gluten-Sensitive Enteropathy or Nontropical Sprue)

ETIOLOGY

PATHOPHYSIOLOGY

Damage To Small Bowel

- Atrophy and flattening of villi
- Reduced area for absorption
- Cellular deficiency of disaccharidases and peptidases
- Reduced nutrient transport carriers

Extraintestinal Manifestations

- Anemia
- Bone loss
- Muscle weakness
- Polyneuropathy
- Endocrine disorders (e.g., infertility)
- Follicular hyperkeratosis
- Dermatitis herpetiformis

Intestinal Manifestations

- Chronic diarrhea
- Chronic constipation
- Malabsorption of vitamins and minerals

MANAGEMENT

Medical Management

- Electrolyte and fluid replacement
- Management of other co-morbid conditions

Nutrition Management

- Delete gluten sources (wheat, rye, barley) from diet
- Vitamin and mineral supplementation
- Substitute with corn, potato, rice, soybean, tapioca, arrowroot, and other non-gluten flours
- Calcium and vitamin D administration
- Read food labels carefully for hidden gluten-containing ingredients
- Supplementation with ω -3 fatty acids
- Guidance to support groups and reliable internet resources

Tropical Sprue

Tropical sprue is an acquired diarrheal syndrome with malabsorption that occurs in many tropical areas. In addition to diarrhea and malabsorption, anorexia, abdominal distention, and nutritional deficiency as evidenced by night blindness, glossitis, stomatitis, cheilosis, pallor, and edema can occur. Anemia may result from iron, folic acid, and vitamin B₁₂ deficiencies.

Pathophysiology

Diarrhea appears to be an infectious type, although the precise cause and the sequence of pathogenic events remain unknown. The syndrome may include bacterial overgrowth, changes in GI motility, and cellular changes in the GI tract. Identified intestinal organisms may differ from one region of the tropics to the next. As in CD, the intestinal villi may be abnormal, but the surface cell alterations are much less severe. The gastric mucosa is atrophied and inflamed, with diminished secretion of hydrochloric acid and intrinsic factor (Langenberg et al, 2014).

Medical Treatment

Treatment of tropical sprue typically includes use of broad-spectrum antibiotics, folic acid, fluid, and electrolytes.

Medical Nutrition Therapy

Nutrition management includes restoration and maintenance of fluids, electrolytes, macronutrients, and micronutrients, and introduction of a diet that is appropriate for the extent of malabsorption (see **Diarrhea** earlier in this chapter). Along with other nutrients, B₁₂ and folate supplementation may be needed if deficiency is identified. Nutritional deficiency increases susceptibility to infectious agents, further aggravating the condition.

INTESTINAL BRUSH-BORDER ENZYME DEFICIENCIES

Intestinal enzyme deficiency states involve deficiencies of the brush-border disaccharidases that hydrolyze disaccharides at the mucosal cell membrane. Disaccharidase deficiencies may occur as (1) rare congenital defects such as the sucrase, isomaltase, or lactase deficiencies seen in the newborn; (2) generalized forms secondary to diseases that damage the intestinal epithelium (e.g., Crohn's disease or CD); or, most commonly, (3) a genetically acquired form (e.g., lactase deficiency) that usually appears after

childhood but can appear as early as 2 years of age. For this chapter, only lactose malabsorption is described in detail (see Chapter 43 for a discussion of inborn metabolic disorders).

Lactose Intolerance

Lactose intolerance is the syndrome of diarrhea, abdominal pain, flatulence, or bloating occurring after lactose consumption. Secondary lactose intolerance can develop as a consequence of infection of the small intestine, inflammatory disorders, HIV, or malnutrition. In children it is typically secondary to viral or bacterial infections. Lactose malabsorption commonly is associated with other GI disorders, such as IBS.

Etiology

High concentrations of the brush border enzyme, lactase, is present in the small bowel of all newborn mammals. After weaning, about 75% of the world's population dramatically decreases the synthesis of this enzyme despite continued exposure to lactose (Levitt et al, 2013). These people are termed to be lactase nonpersistent. The majority of adults of Asian, African, Latino, and Native American descent are lactase nonpersistent, whereas the majority of Caucasians are lactase persistent. Lactose malabsorption or intolerance has been reported to be low in children younger than age six but increases throughout childhood, peaking at age 10 to 16 years.

Little evidence indicates that lactose intolerance increases with increasing adult age (Suchy et al, 2010). Even in adults who retain a high level of lactase levels (75% to 85% of white adults of Western European heritage), the quantity of lactase is approximately half that of other saccharidases such as sucrase, alpha-dextrinase, or glucoamylase. The decline of lactase is commonly known as **hypolactasia** (see *Focus On: Lactose Intolerance – NOT an Uncommon Anomaly*).

Pathophysiology

When large amounts of lactose are consumed, especially by persons who have little remaining lactase enzyme or with concurrent GI problems, loose stools or diarrhea can occur. As is the case with any malabsorbed sugar, lactose may act osmotically and increase fecal water, as well as provide a substrate for rapid fermentation by intestinal bacteria, which may result in bloating, flatulence, and cramps. Malabsorption of lactose is due to a deficiency of lactase, the enzyme that digests the sugar

FOCUS ON

Lactose Intolerance: NOT an Uncommon Anomaly

When lactose intolerance was first described in 1963, it appeared to be an infrequent occurrence, arising only occasionally in the white population. Because the capacity to digest lactose was measured in people from a wide variety of ethnic and racial backgrounds, it soon became apparent that disappearance of the lactase enzyme shortly after weaning, or at least during early childhood, was actually the predominant (normal) condition in most of the world's population. With a few exceptions, the intestinal tracts of adult mammals produce little, if any, lactase after weaning (the milks of pinnipeds—seals, walruses, and sea lions—do not contain lactose).

The exception of lactose tolerance has attracted the interest of geographers and others concerned with the evolution of the world's population. A genetic mutation favoring lactose tolerance appears to have arisen approximately 10,000 years ago, when dairying was first introduced. Presumably, it would have occurred in places where milk consumption was encouraged because of some degree of dietary deprivation and in groups in which milk was not fermented before consumption (fermentation breaks down much of the lactose into monosaccharides). The mutation

would have selectively endured, because it would promote greater health, survival, and reproduction of those who carried the gene.

It is proposed that the mutation occurred in more than one location and then accompanied migrations of populations throughout the world. It continues primarily among whites from northern Europe and in ethnic groups in India, Africa, and Mongolia. The highest frequency (97%) of lactose tolerance occurs in Sweden and Denmark, suggesting an increased selective advantage in those able to tolerate lactose related to the limited exposure to ultraviolet light typical of northern latitudes. Lactose favors calcium absorption, which is limited in the absence of vitamin D produced by skin exposure to sunlight.

Dairying was unknown in North America until the arrival of Europeans. Thus Native Americans and all of the non-European immigrants are among the 90% of the world's population who tolerate milk poorly, if at all. This has practical implications with respect to group feeding programs such as school breakfasts and lunches. However, many lactose-intolerant people are able to digest milk in small to moderate amounts (Shaukat et al, 2010).

in milk. Lactose that is not hydrolyzed into galactose and glucose in the upper small intestine passes into the colon, where bacteria ferment it to SCFAs, carbon dioxide, and hydrogen gas.

Medical Treatment

Lactose malabsorption is diagnosed by (1) an abnormal hydrogen breath test or (2) an abnormal lactose tolerance test. During a hydrogen breath test, the patient is given a standard dose of lactose after fasting, and breath hydrogen is measured. If lactose is not digested in the small intestine, it passes into the colon, where it is fermented by the gut microbiota to SCFAs, CO₂, and hydrogen. Hydrogen is absorbed into the bloodstream and is exhaled through the lungs. The breath hydrogen test shows increased levels 60 to 90 minutes after lactose ingestion.

During a lactose tolerance test, a dose of lactose is given, and if the individual has sufficient lactase enzyme, blood sugar rises, reflecting the digestion of lactose to galactose and glucose. If the individual is lactose intolerant (lactase deficient), blood sugar will not rise because the lactose is not absorbed; it passes into the colon and GI symptoms may appear. The lactose tolerance test was based originally on an oral dose of lactose equivalent to the amount in 1 quart of milk (50 g). Recently doses lower than 50 g of lactose have been used to approximate more closely the usual consumption of lactose from milk products.

Demonstrated lactose malabsorption does not always indicate a person will be symptomatic. Many factors play a role, including the amount of lactose ingested, the residual lactase activity, the ingestion of food in addition to lactose, the ability of the gut microbiota to ferment lactose, and the sensitivity of the individual to the lactose fermentation products (Misselwitz et al, 2013). Consumption of small amounts should be of little consequence because the SCFAs are readily absorbed and the gases can be absorbed or passed. Larger amounts, usually greater than 12 g/day, consumed in a single food (the amount typically found in a cup or 240 ml of milk) may result in more substrate entering the colon than can be disposed of by normal processes. Because serving sizes of milk drinks are increasing and more than one source of lactose may be consumed in the same meal, the amounts of lactose consumed may be more important than in years past (Misselwitz et al, 2013).

Medical Nutrition Therapy

Management of lactose intolerance requires dietary change. The symptoms are alleviated by reduced consumption of lactose-containing foods (see Table 28-3 for common foods containing lactose). Persons who avoid dairy products may need calcium and vitamin D supplementation or must be careful to get nondairy sources of these nutrients. A completely lactose-free diet is not necessary in lactase-deficient persons. Most lactose maldigesters can consume some lactose (up to 12 g/day) without major symptoms, especially when taken with meals or in the form of cheeses or fermented dairy products (Misselwitz et al, 2013).

Many adults with intolerance to moderate amounts of milk can ultimately adapt to and tolerate 12 g or more of lactose in milk (equivalent to one cup of full-lactose milk) when introduced gradually, in increments, over several weeks. Incremental or continuous exposure to increasing quantities of fermentable sugar can lead to improved tolerance, not as a consequence of increased lactase enzyme production but perhaps by altered gut microbiota composition. This has been shown with lactulose, a nonabsorbed carbohydrate that is biochemically similar to lactose (Lomer, 2014). Individual differences in tolerance may relate to the state of

TABLE 28-3 Lactose Content of Common Foods

Product	Serving Size	Approximate Lactose Content (grams)
Milk (nonfat, 1%, 2%, whole), chocolate milk, acidophilus milk, buttermilk	1 cup	10-12
Butter, margarine	1 tsp	trace
Cheese	1 ounce	0-2
Cheddar, sharp	1 ounce	0
American, Swiss, parmesan	1 ounce	1
Bleu cheese	1 ounce	2
Cottage cheese	½ cup	2-3
Cream (heavy), whipped cream	½ cup	3-4
Cream cheese	1 ounce	1
Evaporated milk	1 cup	24
Half-and-half	½ cup	5
Ice cream	½ cup	6
Ice milk	½ cup	9
Nonfat dry milk powder (unreconstituted)	1 cup	62
Sherbet, orange	½ cup	2
Sour cream	½ cup	4
Sweetened condensed milk, undiluted	1 cup	40
Yogurt, cultured, low-fat*	1 cup	5-10

*Note: Although yogurt does contain lactose, cultured yogurt is generally well tolerated by those with lactose intolerance.

colonic adaptation. Regular consumption of milk by lactase-deficient persons may increase the threshold at which diarrhea occurs.

Lactase enzyme in tablets or liquid or in milk products treated with lactase enzyme (e.g., Lactaid) are available for lactose maldigesters who have discomfort with milk ingestion. Commercial lactase preparations may differ in their effectiveness. Fermented milk products, such as aged cheeses and yogurts, are well tolerated because their lactose content is low. Tolerance of yogurt may be the result of a microbial galactosidase in the bacterial culture that facilitates lactose digestion in the intestine. The presence of galactosidase depends on the brand and processing method. Because this microbial enzyme is sensitive to freezing, frozen yogurt may not be as well tolerated. Although the addition of probiotics may change this, evidence is lacking (Morelli, 2014).

Fructose Malabsorption

Dietary fructose exists mainly in three forms: (1) the monosaccharide, (2) sucrose, a disaccharide of fructose and glucose, and (3) in chains as fructans. Consumption of fructose in the United States, especially from fruit juices, fruit drinks, and high fructose corn syrup (HFCS) in soft drinks and confections, has increased significantly in recent years. The human small intestine has a limited ability to absorb fructose, compared with the ability to absorb glucose rapidly and completely.

Etiology

Although **fructose malabsorption** is common in healthy people, its appearance depends on the amount of fructose ingested.

Absorption of fructose is improved when it is ingested with glucose (such as in sucrose) because glucose absorption stimulates pathways for fructose absorption. Although some degree of fructose malabsorption may be normal, those with coexisting GI disorders may be more likely to experience GI symptoms after fructose ingestion. Patients with IBS and visceral hypersensitivity may be more sensitive to gas, distension, or pain from fructose malabsorption, whereas those with small bowel bacterial overgrowth (SIBO) may experience symptoms from normal amounts of fructose.

Pathophysiology

Breath hydrogen testing has revealed that up to 75% of healthy people will incompletely absorb a large quantity of fructose (50 g) taken alone (Putkonen et al, 2013).

Fructose coexists in food with other poorly absorbed carbohydrates, which have been given the umbrella term of fermentable, oligosaccharides, disaccharides, monosaccharide, and polyols (FODMAPs). The efficacy of restricting all FODMAPs (see later in this chapter) compared with fructose alone for managing GI symptoms of fructose malabsorption has not been compared, but it may be a promising intervention (Staudacher et al, 2012).

Medical Nutrition Therapy

People with fructose malabsorption and those patients with GI conditions that experience symptoms of fructose malabsorption may not have problems with foods containing balanced amounts of glucose and fructose but may need to limit or avoid foods containing large amounts of free fructose. Pear, apple, mango, and Asian pear are notable in that they have substantially more “free fructose” (more fructose than glucose). In addition, most dried fruits and fruit juices may pose a problem in larger amounts because of the amount of fructose provided per serving. Foods sweetened with HFCS (as opposed to sucrose) are also more likely to cause symptoms. Hepatic fructose metabolism is similar to ethanol, in that they both serve as substrates for *de novo* lipogenesis, thus promoting hepatic insulin resistance, dyslipidemia, and hepatic steatosis (Lustig, 2010). The degree of fructose intolerance and tolerance to the symptoms of fructose malabsorption are so variable that intake of these foods must generally be individualized with each patient (see Table 28-7 for a list of foods high in fructose content).

INFLAMMATORY BOWEL DISEASES

The two major forms of IBD are Crohn’s disease and UC. Crohn’s disease and UC are relatively rare disorders, but they result in frequent use of health care resources. The prevalence and incidence is increasing as it emerges as a global disease. It is also becoming more prevalent in the elderly (Ye et al, 2015).

Etiology

The onset of IBD occurs most often in patients 15 to 30 years of age, but for some it occurs later in adulthood. Both sexes are equally affected. IBD occurs more commonly in developed areas of the world, in urban compared with rural environments, and in northern compared with southern climates. The reasons for the increased risk are not clear but are likely related to the increased inflammatory and proliferative state and nutritional factors affecting this.

Crohn’s disease and UC share some clinical characteristics, including diarrhea, fever, weight loss, anemia, food intolerances, malnutrition, growth failure, and extraintestinal manifestations (arthritic, dermatologic, and hepatic). In both forms of IBD, the risk

of malignancy increases with the duration of the disease. Although malnutrition can occur in both forms of IBD, it is more of a lifelong concern in patients with Crohn’s disease. The features that distinguish the forms of the disease in terms of genetic characteristics, clinical presentation, and treatment are discussed in Table 28-4.

Etiology

The cause of IBD is not completely understood, but it involves the interaction of the GI immunologic system and genetic and environmental factors. The genetic susceptibility is now recognized to be diverse, with a number of possible gene mutations that affect risk and characteristics of the disease. The diversity in the genetic alterations among individuals may help explain differences in the onset, aggressiveness, complications, location, and responsiveness to different therapies as seen in the clinical setting. The major environmental factors include resident and transient microorganisms in the GI tract and dietary components.

The genes affected (e.g., C677T mutation related to methylene-tetrahydrofolate reductase) normally play a role in the reactivity of the host GI immune system to luminal antigens such as those provided by intestinal flora and the diet. In animal models inflammatory disease does not occur in the absence of gut microbiota. Normally, when an antigenic challenge or trauma occurs, the immune response is initiated; it is then turned off and continues to be held in check after the challenge resolves. In IBD however, increased antigen exposure, decreased host defense mechanisms, and/or decreased tolerance to some components of the gut microbiota occurs. Inappropriate inflammatory response and an inability to suppress it play primary roles in the disease. For example, two genes, NOD₂/CARD₁₅ and the autophagy gene ATG16L1 have been linked to one functional pathway of bacterial sensing, invasion, and elimination. Failure of these genes to come

TABLE 28-4 Ulcerative Colitis versus Crohn’s Disease

	Ulcerative Colitis	Crohn’s Disease
Presentation	Bloody diarrhea	Perianal disease, abdominal pain (65%), mass in abdomen
Gross Pathology	Rectum always involved Moves continuously, proximally from rectum	Rectum may not be involved Can occur anywhere along gastrointestinal tract Not continuous: “skip lesions”
Histopathology	Thin wall Few strictures Diffuse ulceration No granulomas Low inflammation Deeper ulcers (hence named ulcerative) Pseudopolyps Abscesses in crypts	Thick wall Strictures common Cobblestone appearance Granulomas More inflammation Shallow ulcers Fibrosis
Extraintestinal manifestations	Sclerosing cholangitis	Erythema nodosum
Complications	Pyoderma gangrenosum Toxic megacolon Cancer Strictures and fistulas are very rare	Migratory polyarthritis Gallstones Malabsorption Cancer Strictures or fistulas Perianal disease

together can lead to impaired autophagy and persistence of bacteria resulting in abnormal immune responses (Bossuyt and Vermeire, 2016).

Pathophysiology

Crohn's Disease and Ulcerative Colitis Crohn's disease may involve any part of the GIT, but approximately 50% to 60% of cases involve the distal ileum and the colon. Only the small intestine or only the colon is involved in 15% to 25% of cases. Disease activity in UC is limited to the large intestine and rectum. In Crohn's disease, segments of inflamed bowel may be separated by healthy segments, whereas in UC the disease process is continuous (see Figure 28-3). Mucosal involvement in Crohn's disease is transmural in that it affects all layers of the mucosa; in UC the

disease normally is limited to the mucosa. Crohn's disease is characterized by abscesses, fistulas, fibrosis, submucosal thickening, localized strictures, narrowed segments of bowel, and partial or complete obstruction of the intestinal lumen. Bleeding is more common in UC (see Table 28-4).

The inflammatory response (e.g., increased cytokines and acute-phase proteins, increased GI permeability, increased proteases, and increased oxygen radicals and leukotrienes) results in GI tissue damage. In IBD either the regulatory mechanisms are defective or the factors perpetuating the immune and acute-phase responses are enhanced, leading to tissue fibrosis and destruction. The clinical course of the disease may be mild and episodic or severe and unremitting (see *Pathophysiology and Care Management Algorithm: Inflammatory Bowel Disease*).

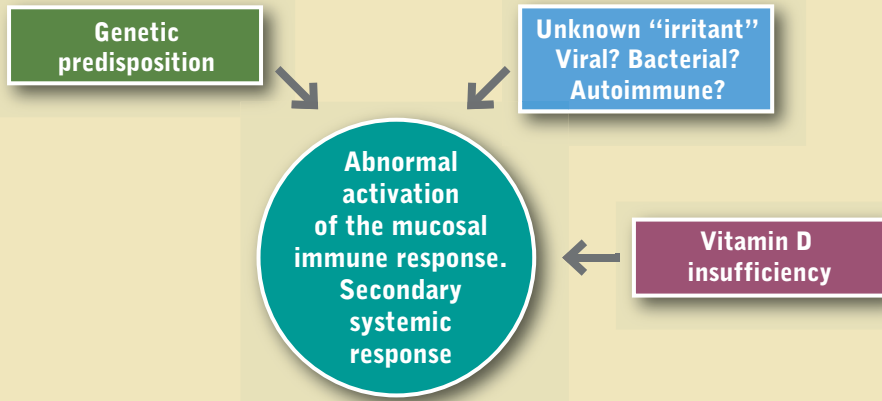

FIGURE 28-3 **A**, Normal colon. **B**, Ulcerative colitis. **C**, Crohn's disease. (A, From Fireman Z, Kopelman Y: The colon—the latest terrain for capsule endoscopy. *Dig Liver Dis* 39[10]:895-899, 2007. PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Inflammatory Bowel Disease

ETIOLOGY

PATHOPHYSIOLOGY

MANAGEMENT

- Medical Management**
- Corticosteroids
 - Anti-inflammatory agents
 - Immunosuppressants
 - Antibiotics
 - Anticytokine medications
- Surgical Management**
- Bowel resection that can result in short bowel syndrome (SBS)

- Nutrition Management**
- Oral enteral formula (tube-feed if necessary)
 - Use of foods that are well tolerated
 - Parenteral nutrition in patients with severe disease or obstruction
 - Multivitamin supplement containing folic acid, B₁₂, and B₆
 - ω-3 fatty acid supplementation
 - Consider use of prebiotics and probiotics
 - Modify fiber intake as necessary
 - Test for food intolerances

Diet is an environmental factor that may trigger relapses of IBD. Foods, microbes, individual nutrients, and incidental contaminants provide a huge number of potential antigens, especially considering the complexity and diversity of the modern diet. Malnutrition can affect the function and effectiveness of the mucosal, cellular, and immune barriers; diet also can affect the type and relative composition of the resident microflora. Several nutrients, such as dietary fats or vitamin D, can affect the intensity of the inflammatory response (Hlavaty et al, 2015; Sadeghian et al, 2015).

Food allergies and other immunologic reactions to specific foods have been considered in the pathogenesis of IBD and its symptoms; however, the incidence of documented food allergies, compared with food intolerances, is relatively small. The permeability of the intestinal wall to molecules of food and cell fragments is likely increased in inflammatory states, allowing the potential for increased interaction of antigens with host immune systems (Vermeire et al, 2011).

Food intolerances occur more often in persons with IBD than in the population at large, but the patterns are not consistent among individuals or even between exposures from one time to the next. Reasons for specific and nonspecific food intolerances are abundant and are related to the severity, location, and complications associated with the disease process. Partial GI obstructions, malabsorption, diarrhea, altered GI transit, increased secretions, food aversions, and associations are but a few of the problems experienced by persons with IBD. However, neither food allergies nor intolerances fully explain the onset or manifestations in all patients (see Chapter 26).

Medical Management

The goals of treatment in IBD are to induce and maintain remission and to improve nutrition status. Treatment of the primary GI manifestations appears to correct most of the extraintestinal features of the disease as well. The most effective medical agents include corticosteroids, antiinflammatory agents (aminosalicylates), immunosuppressive agents (cyclosporine, azathioprine, mercaptopurine), antibiotics (ciprofloxacin and metronidazole), and monoclonal tumor necrosis factor antagonists (anti-TNF), and infliximab, adalimumab, certolizumab, and natalizumab, agents that inactivate one of the primary inflammatory cytokines. Anti-TNF is normally used in severe cases of Crohn's disease and fistulas, but it has not been shown to be effective in UC.

Investigations of various treatment modalities for the acute and chronic stages of IBD are ongoing and include new forms of existing drugs as well as new agents targeted to regulate production and activity of cytokines, eicosanoids, or other mediators of the inflammatory and acute-phase response (Monteleone et al, 2014).

Surgical Management

In Crohn's disease, surgery may be necessary to repair strictures or remove portions of the bowel when medical management fails. Approximately 50% to 70% of persons with Crohn's disease undergo surgery related to the disease. Surgery does not cure Crohn's disease, and recurrence often occurs within 1 to 3 years of surgery. The chance of needing subsequent surgery in the patient's life is approximately 30% to 70%, depending on the type of surgery and the age at the first operation. Major resections of the intestine may result in varying degrees of malabsorption of fluid and nutrients. In

extreme cases patients may have extensive or multiple resections, resulting in short-bowel syndrome (SBS) and dependence on PN to maintain adequate nutrient intake and hydration (see Chapter 13).

With UC, approximately 20% of patients have a colectomy and removal of the colon, and this resolves the disease. Inflammation does not occur in the remaining GI tract. Whether a colectomy is necessary depends on the severity of the disease and indicators of increased cancer risk. After a colectomy for UC, surgeons may create an ileostomy with an external collection pouch and an internal abdominal reservoir fashioned with a segment of ileum or an ileoanal pouch, which spares the rectum, to serve as a reservoir for stool. The internal Koch pouch also may be used.

Medical Nutrition Therapy

Persons with IBD are at increased risk of nutrition problems for a host of reasons related to the disease and its treatment. Thus the primary goal is to restore and maintain the nutrition status of the individual. Foods, dietary and micronutrient supplements, and enteral and parenteral nutrition may be used to accomplish that mission. Oral diet and the other means of nutrition support may change during remissions and exacerbations of the disease.

Persons with IBD often have fears and misconceptions regarding GI symptoms and the role of food. Patients also often are confused by dietary advice from associates, various media, and health care providers. Education is a key form of nutrition intervention. There is no single dietary regimen for reducing symptoms or decreasing the flares in IBD. Diet and specific nutrients play a supportive role in maintaining nutrition status, limiting symptom exacerbations, and supporting growth in pediatric patients.

The ability of parenteral or enteral nutrition to induce remission of IBD has been debated for several years. Evaluation is confounded by the natural course of IBD with exacerbations and remissions and by the genetic diversity of the patients. Studies have concluded that (1) nutrition support may bring about some clinical remission when used as a sole source of treatment; (2) "complete bowel rest" using PN is not necessarily required; (3) enteral nutrition has the potential to feed the intestinal epithelium and alter GI flora and is the preferred route of nutrition support; (4) enteral nutrition may temper some elements of the inflammatory process, serve as a valuable source of nutrients needed for restoration of GI defects, and be steroid sparing; (5) children benefit from the use of enteral nutrition, either as sole source of nutrition or supplemental to an oral diet, to maintain growth and reduce the dependence on steroids that may affect growth and bone disease (Richmond and Rhodes, 2013). Patients and caretakers must be very committed when using enteral nutrition formulas or tube feeding because it takes 4 to 8 weeks before one sees the clinical effects.

Timely nutritional support is a vital component of therapy to restore and maintain nutritional health. Malnutrition compromises digestive and absorptive function by increasing the permeability of the GI tract to potential inflammatory agents. PN is not as nutritionally complete, has increased risk of infectious complications, and is more expensive than enteral nutrition. However, PN may be required in patients with persistent bowel obstruction, fistulas, and major GI resections that result in SBS where enteral nutrition is not possible.

Energy needs of patients with IBD are not greatly increased (unless weight gain is desired). Generally when disease activity increases basal metabolic rate, physical activity is greatly curtailed and overall energy needs are not substantially changed.

Protein requirements may be increased, depending on the severity and stage of the disease and the restoration requirements. Inflammation and treatment with corticosteroids induce a negative nitrogen balance and cause a loss of lean muscle mass. Protein losses also occur in areas of inflamed and ulcerated intestinal mucosa via defects in epithelial tight junctions (see Chapter 38). To maintain positive nitrogen balance, 1.3 to 1.5 g/kg/day of protein is recommended.

Supplemental vitamins, especially folate, B₆, and B₁₂, may be needed as well as minerals such as iron and trace elements to replace stores or for maintenance because of maldigestion, malabsorption, drug-nutrient interactions, or inadequate intake (Owczarek et al, 2016). Diarrhea can aggravate losses of zinc, potassium, and selenium. Patients who receive intermittent corticosteroids may need supplemental calcium and vitamin D. Patients with IBD are at increased risk of osteopenia and osteoporosis; 25-OH vitamin D levels and bone density should be monitored routinely and vitamin D supplemented appropriately (Hlavaty et al, 2015). Omega-3 fatty acid supplements in Crohn's disease significantly reduce disease activity. Use of omega-3 fatty acids or fish oil supplements in UC appears to result in a significant medication-sparing effect, with reductions in disease activity and increased time in remission reported (Farrukh and Mayberry, 2014). Use of foods and supplements containing prebiotics and probiotic supplements continues to be investigated for their potential to alter the gut microbiota; however, the benefit of either remains unproven (Sinegra et al, 2013).

In daily life people with IBD may have intermittent "flares" of the disease characterized by partial obstructions, nausea, abdominal pain, bloating, or diarrhea. Many patients report specific, individualized food intolerances (Hou et al, 2014). Patients sometimes are advised to eliminate the foods they suspect are responsible for the intolerance. Often, the patient becomes increasingly frustrated as the diet becomes progressively limited and symptoms still do not resolve. Malnutrition is a significant risk in patients with IBD, and an overly restricted diet only increases the likelihood of malnutrition and weight loss.

During acute and severe exacerbations of the disease, the diet is tailored to the individual. In people with rapid intestinal transit, extensive bowel resections, or extensive small bowel disease, absorption may be compromised. Here, excessive intake of lactose, fructose, or sorbitol may contribute to abdominal cramping, gas, and diarrhea; and high fat intake may result in steatorrhea. However, the incidence of lactose intolerance is no greater in patients with IBD than in the general population. Patients with IBD who tolerate lactose should not restrict lactose-containing foods because they can be a valuable source of high-quality protein, calcium, and vitamin D.

Patients with strictures or partial bowel obstruction benefit from a reduction in dietary fiber or limited food particle size. Small, frequent feedings may be tolerated better than large meals. Small amounts of isotonic, liquid oral supplements may be valuable in restoring intake without provoking symptoms. In cases in which fat malabsorption is likely, supplementation with foods made with **medium-chain triglycerides (MCTs)** may be useful in adding calories and serving as a vehicle for fat-soluble

nutrients. However, these products are expensive and may be less effective than more basic treatments.

Factors associated with the development of IBD in epidemiologic studies include increased sucrose intake, lack of fruits and vegetables, a low intake of dietary fiber, use of red meat and alcohol, and altered omega-6/omega-3 fatty acid ratios and insufficient vitamin D intake (Hlavaty, 2015). Yet dietary interventions to modify these factors during IBD flares are still under investigation (Owczarek et al, 2016).

The same foods that are responsible for GI symptoms (gas, bloating, and diarrhea) in a normal, healthy population are likely to be the triggers for the same symptoms in patients with mild stages of IBD or those in remission.

Patients receive nutritional information from a variety of sources, including support groups, Internet news groups, the audio and printed media, well-meaning friends, and food supplement salespersons. The information is sometimes inaccurate or exaggerated, or it may pertain only to one individual's situation and not to another's. The nutrition care provider can help patients sort out the role of foods in IBD management and teach them how to evaluate valid nutrition information from unproven or exaggerated claims. Patients' participation in the management of their disease may help to reduce not only the symptoms of the disease but also the associated anxiety level.

Microbiota. Probiotic foods and supplements have been investigated as potential therapeutic agents for IBD because of their ability to modify the gut microbiota and potentially modulate gut inflammatory response. Multistrain probiotic supplements (e.g., VSL#3) have been shown to be beneficial in maintaining disease remission in patients with UC who had **pouchitis**, inflammation in the ileal pouch surgically formed after colectomy. However, a different probiotic supplement at a lower dose did not significantly reduce symptoms (Holubar et al, 2010). Specific probiotic supplements also appear to be useful for induction and extension of remissions in pediatric and adult UC (Ghouri et al, 2014).

Although probiotics appear useful in UC, probiotic studies have not demonstrated significant improvement in Crohn's disease activity in adults or pediatric patients, nor do probiotic supplements appear to prolong remission in Crohn's disease (Ghouri et al, 2014).

Regular intake of prebiotic foods such as oligosaccharides, fermentable fibers, and resistant starches can beneficially affect the gut microbiota, feeding *Lactobacillus* and *Bifidobacteria* thus providing competition to and theoretically suppression of pathogenic or opportunistic microbiota. In addition, fermentation of prebiotics leads to increased production of SCFAs, theoretically creating a more acidic and less favorable environment for opportunistic bacteria.

Use of probiotics and prebiotics may prevent SIBO in predisposed individuals and may be used to treat diarrhea. Additional study is needed to identify the dose, the most effective prebiotic and probiotic foods, the form in which they can be used for therapeutic and maintenance purposes, and their relative value compared with other therapies (Ghouri et al, 2014).

Microscopic Colitis

Injury of the colon caused by UC, Crohn's disease, infections, radiation injury, and ischemic insult to the colon presents with abnormalities such as edema, redness, bleeding, or ulcerations that are visible on colonoscopy examination. Unlike the colitis of IBD, **microscopic colitis** is characterized by inflammation

that is not visible by inspection of the colon during colonoscopy and is apparent only when the colon's lining is biopsied and then examined under a microscope. Patients with microscopic colitis can have diarrhea for months or years before the diagnosis is made. The cause of microscopic colitis is unknown.

Pathophysiology

There are two types of microscopic colitis. In **lymphocytic colitis**, there is an accumulation of lymphocytes within the lining of the colon. In **collagenous colitis**, there is also a layer of collagen (like scar tissue) just below the lining. Some experts believe that lymphocytic colitis and collagenous colitis represent different stages of the same disease. Symptoms include chronic, watery diarrhea, mild abdominal cramps, and pain. More than 30% of patients report weight loss. Microscopic colitis appears more frequently in patients aged 60 to 70 years, and collagenous colitis occurs more frequently in females (Ohlsson, 2015).

Medical Nutrition Therapy

Research is underway to determine possible effective treatments for microscopic colitis, including corticosteroids and immunosuppressive agents. Medical nutrition therapy is supportive with efforts to maintain weight and nutrition status, avoid symptom exacerbation, and maintain hydration, similar to that for IBD.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a condition characterized by unexplained abdominal discomfort or pain that is associated with changes in bowel habits. Other common symptoms include gas, bloating, diarrhea and constipation, and increased GI distress associated with psychosocial distress. These symptoms may be vague and transient, making IBS a diagnosis of exclusion. It is classified as a functional disorder because tests show no diagnostic abnormalities and, therefore, diagnosis depends on symptoms. An estimated 10% to 20% of the United States population has IBS, with twice as many women as men being affected, although this may be a factor of reporting (Koff and Mullin, 2012). There are between 2.4 and 3.5 million annual physician visits for IBS in the United States alone. IBS is the most common disorder diagnosed by gastroenterologists and accounts for 20% to 40% of visits (International Foundation for Functional Gastrointestinal Disorders [IFFGD], 2013). Patients with IBS often have increased missed school and work days, decreased productivity, increased health care costs, and decreased quality of life as a result of their symptoms.

Etiology

No specific marker or test is diagnostic for IBS. When assessing a patient for IBS, the clinician must carefully review medication records because numerous over-the-counter and prescribed medications can cause abdominal symptoms such as pain and changes in bowel habits. In addition, the symptoms of IBS overlap with or are similar to, other GI diseases such as celiac disease, inflammatory bowel disease, functional dyspepsia, and functional constipation.

The **Rome III criteria** for IBS and its subtypes are used to define the diagnosis based on the presence of GI symptoms and exclusion of other disease processes (Longstreth et al, 2006). These diagnostic criteria are used in clinical research and to a lesser extent in clinical practice and are listed in **Box 28-10**. The diagnostic criteria also include a refining of subtypes of IBS based on predominant stool patterns (see **Table 28-5**).

BOX 28-10 Rome III Criteria for IBS

Criteria consists of recurrent abdominal pain or discomfort for at least 3 days per month in the last 3 months with onset at least 6 months before diagnosis and with 2 or more of the following:

1. Pain improvement with defecation
2. Change in stool frequency at onset
3. Change in stool form or appearance at onset

Data from Longstreth GF et al: Functional bowel disorders, *Gastroenterology* 130:1480, 2006.

TABLE 28-5 Subtypes of IBS Based on Stool Patterns

Type	Symptoms
IBS with constipation (IBS-C)	<3 bowel movements per week Hard or lumpy stools Straining during bowel movements
IBS with diarrhea (IBS-D)	≥3 bowel movements per day Fecal urgency Loose watery stools
Mixed IBS (IBS-M)	A mix of hard and loose stools over periods of hours to days
Unsubtyped IBS	Insufficient abnormality of stool patterns to meet criteria for IBS-C, D, or M

Data from Longstreth GF et al: Functional bowel disorders, *Gastroenterology* 130:1480, 2006.

Pathophysiology

The pathophysiology of IBS is not completely understood. A number of factors are presumed to play a role in the etiology of IBS, including nervous system alterations (abnormal GI motility and visceral hypersensitivity), gut flora alterations, genetics, and psychosocial stress. Research traditionally has focused on intestinal motility, however, studies of small bowel and colonic motility show inconsistent results and have not determined a predominant pattern of motor activity as a marker that would diagnose IBS.

Sensation in the GI tract results from stimulation of various receptors and sensory nerves in the gut wall, which transmit signals to the spinal cord and brain. Alterations in areas of the brain involved in pain modulation, autonomic nervous system dysregulation, and impaired brain-gut communication result in hyperalgesia (increased sensation to pain in the gut), visceral hypersensitivity, and altered motility (Anastasi et al, 2013). Dysregulation of serotonin concentrations in the GI tract has been correlated with the type of IBS a patient experiences; low serotonin concentrations are associated with constipation or a sluggish gut and higher serotonin concentrations are associated with diarrhea or increased peristalsis in the intestine (Kanazawa et al, 2011; Stasi et al, 2014).

Researchers believe that SIBO may contribute to IBS; however, many of these studies did not have the same results when repeated. Additional studies are needed to understand whether SIBO is directly connected to IBS or is a separate entity.

Psychologic conditions, such as depression and anxiety, often are observed in patients with IBS. Although it is unclear whether stress initiates IBS, it is accepted that stress can trigger or exacerbate symptoms in IBS. It is not unusual for patients with IBS to link their symptoms with lifetime or daily stress (Fadgyas-Stanculete et al, 2014).

Medical Management

The first step in the management of IBS and other functional GI disorders includes validating the reality of the patient's complaints and establishing an effective clinician-patient relationship. Patients with IBS should be educated that although their condition is not life threatening, it may be a lifelong struggle for them. Care should be tailored to help the patient deal with the symptoms and the factors that may trigger them. Clinician and patient should understand that no single therapy is proven to provide relief for all patients. Treatment options include medications focused mostly on symptom treatment or reduction, stress reduction and relaxation, and nutrition through diet modification. Drug therapy is aimed at management of symptoms associated with GI motility, visceral hypersensitivity, or psychologic issues. Generally, the treatment option is determined by the predominant bowel pattern and the symptoms that most disrupt the patient's quality of life (see [Table 28-6](#)).

Medical Nutrition Therapy

The goals of nutrition therapy for IBS are to ensure adequate nutrient intake, tailor the diet for the specific GI pattern of IBS, and explain the potential roles of foods in the management of symptoms. Implementation of nutrition interventions for IBS should take a stepwise approach from simple to complex. Initial steps during nutrition counseling should include (1) review of current medications for IBS and other medications; (2) review of GI symptoms (duration, severity, frequency); (3) assessment of nutritional status and food intake; (4) review of supplement intake (vitamins, minerals, fats, pre- and probiotics, herbals); and (5) review of use of mind-body therapies and the results achieved ([Caldwell and Ireton-Jones, 2012](#)).

A review of foods to avoid that may aggravate IBS symptoms should be covered during the initial nutrition consultation. Little evidence exists for restricting particular foods. Large meals and certain foods may be poorly tolerated, such as excess quantities of dietary fat, caffeine, lactose, fructose, sorbitol, and alcohol. This is especially true in patients with diarrhea-predominant IBS or mixed IBS.

Most fiber or bulking agent studies in the IBS population have shown significant shortcomings ([El-Salhy and Gundersen, 2015](#)). A combination of soluble and insoluble fiber is targeted for constipation management. However, increasing the amount of insoluble fiber in the diet, especially in patients without constipation, actually may worsen IBS symptoms. Consumption of adequate fluid is recommended, especially when powdered fiber supplements are used. Although increasing fiber intake is a usual component of initial therapy for IBS, patients may have continuing symptoms possibly related to the type of fiber consumed. Recent studies show that certain carbohydrate containing foods that include highly fermentable carbohydrates in the presence of gut bacteria actually exacerbate IBS symptoms ([Mullins et al, 2014](#)).

FODMAPs Eating Plan

There is emerging research that a diet low in FODMAPs may be an effective therapy in the management of GI symptoms in patients with IBS ([Halmos et al, 2014](#)). The term FODMAPs was coined by a group of Australian researchers who theorize that foods containing these forms of carbohydrates worsen the symptoms of some digestive disorders such as IBS and IBD.

The low **FODMAPs** diet limits foods that contain lactose, fructose, fructo-oligosaccharides (fructans), galacto-oligosaccharides (galactans), and polyols or sugar alcohols (sorbitol, xylitol, mannitol, isomaltase, and maltitol). These short-chain carbohydrates are poorly absorbed in the small intestine, are highly osmotic, and are rapidly fermented by bacteria in the large intestine, resulting in gas, pain, and diarrhea in sensitive individuals. FODMAPs have a cumulative impact on GI symptoms. A cutoff value for acceptable amounts of FODMAPs has not been well defined and is likely patient specific. Patients may tolerate small amounts, but symptoms can develop if they consume quantities that surpass their threshold. Hydrogen breath testing, if readily available, can be useful to demonstrate which foods are problematic for the individual and help to tailor the diet. Examination of the patient's current diet to determine potential triggers and diet instructions regarding malabsorption and portion control of fructose containing foods are completed before the elimination phase.

Nutrition intervention begins with elimination of all high FODMAPs foods from the diet for a trial period of 6 to 8 weeks ([Gibson, 2011](#)). The challenge phase begins with a slow, controlled reintroduction of one FODMAPs diet category at a time to observe for symptoms and identify the most challenging foods (see [Table 28-7](#)).

Nutritional deficiencies that can arise with the low FODMAPs diet include folate, thiamin, and vitamin B₆ (from limiting cereals and breads), as well as calcium and vitamin D (from avoidance of dairy). The goal is to eventually reduce or eliminate GI symptoms, by creating a diet that includes FODMAPs at the most tolerable intake level, and with use of alternative foods. It does not present a cure but a dietary approach to

TABLE 28-6 Treatment Options for IBS Symptoms

Symptom	Treatment
Abdominal pain and discomfort	Antispasmodic agents Tricyclic antidepressants Serotonin-directed agents (selective serotonin reuptake inhibitors, serotonin-3 receptor antagonists, or serotonin-4 receptor agonists)
Constipation	Fiber supplements Stool softeners Laxatives (osmotic, stimulant) Chloride channel activator (lubiprostone)
Diarrhea	Antidiarrheal agents (loperamide, diphenoxylate with atropine)
Small intestinal bacterial overgrowth (SIBO)	Antibiotics
Global symptoms and/or overall well-being	Psychotherapy (cognitive behavioral therapy, relaxation therapy, gut-directed hypnotherapy) Complementary and alternative medicine (acupuncture, meditation) Peppermint oil Probiotics Prebiotics

TABLE 28-7 Foods Containing High FODMAPs, and Low FODMAP Diet Instructions

FODMAP	High FODMAP Food
Excess free fructose	Fruits: apples, pears, mango, watermelon, boysenberries, cherries, figs, tamarillo Vegetables: asparagus, artichokes, sugar snap peas Sweeteners and condiments: honey, high fructose corn syrup, agave nectar, fructose, fruit juice concentrate
Lactose	Milk (cow, goat and sheep), ice cream, soft cheeses (e.g., ricotta, cottage cheese, cream cheese, mascarpone)
Oligosaccharides (fructans and galacto-oligosaccharides)	Fruits: nectarines, persimmon, watermelon, peaches, tamarillo Vegetables: artichokes (globe and Jerusalem), garlic, leeks, onions (yellow, red, white, onion powder), shallots, scallions (white part) Cereals: wheat, barley, and rye-based products (in large amounts) Legumes: chickpeas, lentils, beans (e.g., kidney, black, cannellini, great northern, pinto, navy, lima, butter, adzuki, soy, mung, and fava beans) Nuts: pistachios, cashews
Polyols	Fruits: apples, apricots, pear, nectarine, peaches, plums, prunes, watermelon, blackberries Vegetables: cauliflower, mushrooms, snow peas Sweeteners: sorbitol, mannitol, maltitol, xylitol, polydextrose, isomalt

Low FODMAP Diet Instructions

- Consider and look over the list of all high FODMAPs foods. If any of these foods are taken in too much, try cutting them out first.
- If symptoms do not improve, avoid all high FODMAPs foods for 6 to 8 weeks.
- Fructose containing foods with a 1:1 ratio of fructose to glucose are usually well tolerated as opposed to foods with excess fructose compared to glucose.
- Avoid foods that contain significant free fructose in excess of glucose (unless fructose malabsorption is not demonstrated).
- Foods containing excess fructose are those that contain 0.2 g or more of fructose compared with glucose per serving. Fructose and glucose content of foods can be found in the USDA database: <http://ndb.nal.usda.gov/ndb/nutrients/index>.
- Try ingesting a source of glucose with fructose-containing foods (i.e., sucrose contains equal amounts of glucose and fructose).
- Avoid foods that contain significant amounts of fructans and galacto-oligosaccharides (GOS) when first implementing the low FODMAPs diet because no one absorbs them well.
- Restrict lactose-containing foods (unless lactose malabsorption is not demonstrated).
- Avoid polyol-containing foods.
- Some FODMAPs cause more trouble in some people than others. This depends on the proportions of each FODMAPs in the diet, how well or poorly fructose or lactose is absorbed, and how sensitive one is to each FODMAPs.
- If symptoms have improved after 6 to 8 weeks, it is recommended to gradually reintroduce one FODMAPs group at a time.

FODMAPs, Fermentable oligo-, di-, monosaccharides and polyols.

improve symptoms and quality of life (Marcason, 2012) (see Table 28-7). An increasing number of resources facilitate adherence to the diet, including a mobile device app from the creators of the diet at Monash University in Australia, several cookbooks, and websites (Monash University, 2014).

Diverticular Disease

Diverticular disease is one of the most common medical conditions among industrialized societies. **Diverticulosis** is characterized by the formation of sac-like outpouchings or pockets (diverticula) within the colon that form when colonic mucosa and submucosa herniate through weakened areas in the muscle. The prevalence of diverticulosis is difficult to determine given that most individuals remain asymptomatic. This condition becomes more common as people age, particularly in people older than age 50 (Peery et al, 2012). **Diverticulitis** is a complication of diverticulosis that indicates inflammation of one or more diverticulum. It often represents a flare-up of diverticulosis, and after it subsides into a period of remission, it reverts to the state of diverticulosis. In Western populations, diverticulosis is found most often on the left side typically in the sigmoid colon; this is in contrast to right-sided colonic involvement found in the African and Asian populations (Feingold and Whelan, 2008).

Etiology

The cause of diverticulosis has not been elucidated clearly. Epidemiologic studies have implicated low-fiber diets in the

development of diverticular disease. Low-fiber diets reduce stool volume, predisposing individuals to constipation and increased intracolonic pressures, which suggests that diverticulosis occurs as a consequence of pressure-induced damage to the colon. However, a study found that a low-fiber diet was not associated with diverticulosis and that a high-fiber diet and more frequent bowel movements may be linked to an increased rather than decreased chance of diverticula (Peery et al, 2012). Other studies have focused on the role of decreased levels of the neurotransmitter serotonin in causing decreased relaxation and increased spasms of the colon muscle. Studies also have found links between diverticular disease and obesity, vitamin D insufficiency, lack of exercise, smoking, and certain medications, including nonsteroidal antiinflammatory drugs such as aspirin and steroids (McGuire et al, 2015; Peery et al, 2012).

Pathophysiology

Evolving pathophysiologic mechanisms in diverticulosis and diverticulitis suggest chronic inflammation, alterations in colonic microbiota, disturbed colonic sensorimotor function, and abnormal colon motility have likely interrelated roles in the development of diverticular disease (Strate et al, 2012). Complications of diverticular disease range from painless, mild bleeding and altered bowel habits to diverticulitis. Acute diverticulitis includes a spectrum of inflammation, abscess formation, bleeding, obstruction, fistula, and sepsis from perforation (rupture).

Medical and Surgical Treatment

Treatment typically includes antibiotics and adjustment of oral intake as tolerated. Patients with severe cases of diverticulitis with acute pain and complications likely will require a hospital stay and treatment with intravenous (IV) antibiotics and a few days of bowel rest. Surgery is reserved for patients with recurrent episodes of diverticulitis and complications when there is little or no response to medication. Surgical treatment for diverticulitis removes the diseased part of the colon, most commonly, the left or sigmoid colon.

Medical Nutrition Therapy

Historically, it has been common in clinical practice to recommend avoidance of nuts, seeds, hulls, corn, and popcorn to prevent symptoms or complications of diverticular disease. However, an 18-year study found no association between nut, corn, or popcorn consumption and diverticular bleeding (Strate et al, 2008). In fact, an inverse relationship between nut and popcorn consumption and the risk of diverticulitis was demonstrated, suggesting a protective effect.

During an acute episode of diverticulitis or diverticular bleeding, oral intake is generally reduced until symptoms subside. Complicated cases may necessitate bowel rest and require parenteral nutrition (PN) support. Once oral intake has been resumed, or in mild to moderate cases, it is prudent to begin a low-fiber diet (10 to 15 g/day) as the diet is being advanced, followed by a gradual return to a high-fiber diet.

Although no convincing evidence exists that a high-fiber diet can reverse the pathophysiology of diverticular disease, there is reasonable evidence that this type of diet can improve diverticular symptoms (Tarleton and DiBaise, 2011). A high-fiber diet in combination with adequate hydration promotes soft, bulky stools that pass more swiftly and require less straining with defecation. Recommended intakes of dietary fiber, preferably from foods, are 25 g/day for adult women and 38 g/day for men.

Fiber intake should be increased gradually because it may cause bloating or gas. If a patient cannot or will not consume the necessary amount of fiber, methylcellulose or psyllium fiber supplements have been used with good results. A high-fiber diet possibly with fiber supplementation is advocated in asymptomatic diverticulosis to reduce the likelihood of disease progression, prevent the recurrence of symptom episodes, and prevent acute diverticulitis. Adequate fluid intake should accompany the high fiber intake. The potential role of altered bacterial flora in diverticular inflammation suggests that combining probiotic therapy with other therapies may prove effective in the management of this disorder (Maconi et al, 2013).

Intestinal Polyps and Colorectal Cancer

In the United States and worldwide, colorectal cancer (CRC) is the third most common cancer in adults and is also the second most common cause of cancer death. There are approximately 142,820 new cases of CRC per year, and the incidence is more common in men than women and among those of African American descent (National Cancer Institute, 2014).

Etiology

About 85% of CRCs are considered to be sporadic, whereas approximately 15% are familial. Familial adenomatous polyposis

(FAP) accounts for less than 1% of CRCs. It is a hereditary syndrome characterized by the development of hundreds to thousands of polyps in the colon and rectum during the second decade of life. Almost all patients with FAP will develop CRC if they are not identified and treated at an early stage.

An evaluation of the association of major known risk factors for CRC with colorectal polyp risk by histology type, quantified the impact of lifestyle modifications on the prevention of polyps (Fu et al, 2012). Several lifestyle factors, including cigarette smoking, obesity, no regular use of non-steroidal antiinflammatory drugs, high intake of red meat, low intake of fiber, low intake of calcium, and low vitamin D levels were found to be independently associated with the risk of polyps. The risk of polyps increased progressively with an increasing number of these adverse lifestyle factors (Bostick, 2015; Fu et al, 2012).

Pathophysiology

Polyps are established precursors of CRCs and defined as a mass that arises from the surface of the intestinal epithelium and projects into the intestinal lumen. Factors that increase the risk of CRC include family history, chronic IBD, FAP, adenomatous polyps, and several dietary components. Patterns of dietary practices rather than specific nutrients may be more predictive of the risk of developing CRC.

Medical Management

The treatment of a colorectal polyp is removal, usually by colonoscopy. Large polyps often require surgery for complete removal, even if the presence of cancer is not confirmed before resection. In a recent prospective analysis, it showed that compared with no endoscopy, colonoscopy and sigmoidoscopy are associated with a lower incidence of distal CRC, whereas only colonoscopy is associated with a reduced incidence of proximal colon cancer, and that reduction was modest. Furthermore, compared with no screening, colonoscopy, screening colonoscopy and sigmoidoscopy are associated with lower mortality from CRC, whereas only colonoscopy is associated with lower mortality from proximal colon cancer (Nishihara et al, 2013). Patients diagnosed with CRC may require moderate to significant interventions, including, medications, radiation therapy, chemotherapy, surgery, enteral and/or PN support.

Medical Nutrition Therapy

Recommendations from national cancer organizations include sufficient exercise; weight maintenance or reduction; modest and balanced intake of lipids; adequate intake of micronutrients from fruits, vegetables, legumes, whole grains, and dairy products; and limited use of alcohol. Supplements are normally encouraged if the diet is not adequate. The diet for cancer survivors typically follows these prevention guidelines.

NUTRITIONAL CONSEQUENCES OF INTESTINAL SURGERY

Small Bowel Resections and Short-Bowel Syndrome

Short-bowel syndrome (SBS) can be defined as inadequate absorptive capacity resulting from reduced length or decreased functional bowel after resection. A loss of 70% to 75% of small

bowel usually results in SBS, defined as 100 to 120 cm of small bowel without a colon, or 50 cm of small bowel with the colon remaining. A more practical definition of SBS is the inability to maintain nutrition and hydration needs with normal fluid and food intake, regardless of bowel length.

Patients with SBS often have complex fluid, electrolyte, and nutritional management issues. Consequences of SBS include malabsorption of micronutrients and macronutrients, frequent diarrhea, steatorrhea, dehydration, electrolyte imbalances, weight loss, and growth failure in children. Other complications include gastric hypersecretion, oxalate renal stones, and cholesterol gallstones. Individuals who eventually need long-term PN have increased risk of catheter infection, sepsis, cholestasis, and liver disease, and reduced quality of life associated with chronic intravenous nutrition support (DiBaise, 2014).

Etiology

The most common reasons for major resections of the intestine in adults include Crohn's disease, radiation enteritis, mesenteric infarct, malignant disease, and volvulus (Shatnawei et al, 2010). In the pediatric population most cases of SBS result from congenital anomalies of the GI tract, atresia, volvulus, or necrotizing enterocolitis.

Pathophysiology

Duodenal Resection. Resections of the duodenum (approximately 10 in) are rare, which is fortunate because it is the preferred site for absorption of key nutrients such as iron, zinc, copper, and folate. The duodenum is a key player in the digestion and absorption of nutrients, because it is the portal of entry for pancreatic enzymes and bile salts (see Chapter 1).

Jejunal Resections. The jejunum (6 to 10 ft) is responsible for a large portion of nutrient absorption. Normally most digestion and absorption of food and nutrients occurs in the first 100 cm of small intestine, which also includes the duodenum. Jejunal enterohormones play key roles in digestion and absorption. Cholecystokinin (CCK) stimulates pancreatic secretion and gallbladder contraction, and secretin stimulates secretion of bicarbonate from the pancreas. Gastric inhibitory peptide slows gastric secretion and gastric motility, whereas vasoactive inhibitory peptide inhibits gastric and bicarbonate secretion (see Table 1-3). What remains to be digested or fermented and absorbed are small amounts of sugars, resistant starch, lipids, dietary fiber, and fluids. After jejunal resections, the ileum typically adapts to perform the functions of the jejunum. The motility of the ileum is comparatively slow, and hormones secreted in the ileum and colon help to slow gastric emptying and secretions. Because jejunal resections result in reduced surface area and faster intestinal transit, the functional reserve for absorption of micronutrients, excess amounts of sugars (especially lactose), and lipids is reduced.

Ileal Resections. Significant resections of the ileum, especially the distal ileum, produce major nutritional and medical complications. The distal ileum is the only site for absorption of bile salts and the vitamin B12-intrinsic factor complex. The ileum also absorbs a major portion of the 7 to 10 L of fluid ingested and secreted into the GI tract daily (see Chapter 1). The ileocecal valve, at the junction of the ileum and cecum, maximizes nutrient absorption by controlling the rate of passage of ileal contents into the colon and

preventing reflux of colonic bacteria, which may decrease risk for SIBO.

Although malabsorption of bile salts may appear to be benign, it creates a cascade of consequences. If the ileum cannot “recycle” bile salts secreted into the GI tract, hepatic production cannot maintain a sufficient bile salt pool or the secretions to emulsify lipids. The gastric and pancreatic lipases are capable of digesting some triglycerides to fatty acids and monoglycerides, but, without adequate micelle formation facilitated by bile salts, lipids are poorly absorbed. This can lead to malabsorption of fats and fat-soluble vitamins A, D, E, and K. In addition, malabsorption of fatty acids results in their combination with calcium, zinc, and magnesium to form fatty acid–mineral soaps, thus leading to their malabsorption as well. To compound matters, colonic absorption of oxalate is increased, leading to hyperoxaluria and increased frequency of renal oxalate stones. Relative dehydration and concentrated urine, which are common with ileal resections, further increase the risk of stone formation (see Chapter 35).

Colon Resections

The colon (approximately 5 ft long) is responsible for reabsorbing 1 to 1.5 L of electrolyte-rich (particularly sodium and chloride) fluid each day but is capable of adapting to increase this capacity to 5 to 6 L daily. Preservation of colon is key to maintaining hydration status. However, if the patient has any colon left, malabsorption of bile salts can act as a mucosal irritant, increasing colonic motility with fluid and electrolyte losses. Consumption of high-fat diets with ileal resections and retained colon also may result in the formation of hydroxy fatty acids, which also increase fluid loss. Cholesterol gallstones occur because the ratio of bile acid, phospholipid, and cholesterol in biliary secretions is altered. Dependence on PN increases the risk of biliary “sludge,” secondary to decreased stimulus for evacuation of the biliary tract (see Chapters 13 and 29).

Medical and Surgical Management of Resections

The first step in management is assessment of the remaining bowel length from patient surgical and health records or interview. Assessment should quantify dietary intake, as well as stool and urine output, over 24 hours. Medications and hydration status should be assessed. Medications may be prescribed to slow GI motility, decrease secretions, or treat bacterial overgrowth. The primary “gut slowing” medications include loperamide, and, if needed, narcotic medications. Somatostatin and somatostatin analogs; glucagon-like polypeptide 2; growth hormone; and other hormones with antisecretory, antimotility, or trophic actions have been studied for use to slow motility and secretions. Surgical procedures such as creation of reservoirs (“pouches”) to serve as a form of colon, intestinal lengthening, and intestinal transplant have been performed to help patients with major GI resections. Intestinal transplant is very complex and is reserved for gut failure, or when patients develop significant complications from PN.

Medical Nutrition Therapy

Most patients who have significant bowel resections require PN initially to restore and maintain nutrition status. The duration of PN and subsequent nutrition therapy will be based on the extent of the bowel resection, the health of the patient, and the

condition of the remaining GI tract. In general, older patients with major ileal resections, patients who have lost the ileocecal valve, and patients with residual disease in the remaining GI tract do not do as well. Enteral feeding provides a trophic stimulus to the GI tract; PN is used to restore and maintain nutrient status.

The more extreme and severe the problem, the slower the progression to a normal diet. Small, frequent mini meals (6 to 10 per day) are likely to be better tolerated than larger feedings. Tube feeding may be useful to maximize intake when a patient would not typically eat, such as during the night (see Chapter 13). Because of malnutrition and disuse of the GI tract, the digestive and absorptive functions of the remaining GI tract may be compromised, and malnutrition will delay postsurgical adaptation. The transition to more normal foods may take weeks to months, and some patients may never tolerate normal concentrations or volumes of foods and always require supplemental PN to maintain adequate fluid and nutritional status.

Maximum adaptation of the GI tract may take 1 to 2 years after surgery. Adaptation improves function, but it does not restore the intestine to normal length or capacity. Whole nutrients are the most important stimuli of the GI tract; other nutritional measures also have been studied as a means of hastening the adaptive process and decreasing malabsorption, but their evidence for use is limited. For example, **glutamine** is the preferred fuel for small intestinal enterocytes and thus may be valuable in enhancing adaptation. Nucleotides (in the form of purines, pyrimidine, ribonucleic acid) also may enhance mucosal adaptation, but unfortunately they are often lacking in parenteral and enteral nutritional products. SCFAs (e.g., butyrate, propionate, acetate), carbohydrate fermentation byproducts of commensal gut microbiota, are major fuels for the colonic epithelium (see *Clinical Insight: Intestinal Adaptation: What Enhances It?*).

Patients with jejunal resections and an intact ileum and colon will likely adapt quickly to normal diets. A normal balance of protein, fat, and carbohydrate sources is satisfactory. Six small feedings with avoidance of lactose, large amounts of concentrated sweets, and caffeine may help to reduce the risk of bloating, abdominal pain, and diarrhea. Because the typical American diet may be nutritionally lacking and the intake of some micronutrients may be marginal, patients should be advised that the quality of the diet is of utmost importance. A multivitamin and mineral supplement may be required to meet nutritional needs.

Patients with ileal resections require increased time and patience in the advancement from parenteral to enteral nutrition. Because of losses, fat-soluble vitamins, calcium, magnesium, and zinc may have to be supplemented. Dietary fat may have to be limited, especially in those with little remaining colon. Small amounts at each feeding are more likely to be tolerated and absorbed.

MCT products add to the caloric intake and serve as a vehicle for lipid-soluble nutrients. Because boluses of MCT oil (e.g., taken as a medication in tablespoon amounts) may add to the patient's diarrhea, it is best to divide the doses equally in feedings throughout the day. Fluid and electrolytes, especially sodium, should be provided in small amounts and frequently.

In patients with SBS an oral diet or enteral nutrition plus the use of gut-slowing medications should be maximized to prevent dependence on PN. Frequent meals, removal of osmotic medications and foods, use of oral hydration therapies, and other interventions should be pursued. In some cases, overfeeding in an attempt to compensate for malabsorption results in further malabsorption, not only of ingested foods and liquids but also of the significant amounts of GI fluids secreted in response to food ingestion. Patients with an extremely short bowel may depend on parenteral solutions for at least part of their nutrient and fluid supply. Small, frequent snacks provide some oral gratification for these patients, but typically they can supply only a portion of their fluid and nutrient needs (see Chapter 13 for discussion of home PN).

CLINICAL INSIGHT

Intestinal Adaptation: What Enhances It?

By Laura Matarese, PhD, RD

Short bowel syndrome (SBS) occurs after surgical resection, congenital defect, or disease of the bowel. The severity of SBS depends on the length and anatomy of the bowel resected, the health of the remaining mucosa, as well as the presence of an intact stomach, pancreas and liver (Jeejeebhoy, 2002). During the 2 years after resection, the remnant bowel undergoes an adaptation process that increases its absorptive capacity (Buchman et al, 2003). This intestinal adaptation is evidenced by hyperplasia of intestinal cells, an increase of villus height, deepening of intestinal crypts, and upregulation of transporter proteins.

Proper dietary management of SBS can augment this naturally occurring intestinal adaptation. Compared with parenteral nutrition (PN) and intravenous fluids (IV), enteral nutrition (EN) results in greater adaptation and should be instituted to the extent possible (Feldman et al, 1976; Ford et al, 1984; Johnson et al, 1975). The type of nutrition consumed has important effects. Complex luminal nutrients in the form of whole foods are potent stimuli to intestinal adaptation (Tappenden, 2006).

Hormonal therapy may facilitate intestinal adaptation in patients with SBS. Recombinant human growth hormone (rGH) and glucagon-like peptide 2 (GLP-2) have each been shown to enhance intestinal adaptation and nutrient absorption (Drucker et al, 1996; Jeppesen et al, 2001; Seguy et al, 2003). In a phase III trial conducted in PN-dependent patients with SBS,

administration of rGH (Zorbtive; EMD Serono, Rockland, MD) with modified diet and oral glutamine resulted in a significant decrease in necessary PN volume, calories, and infusion frequency compared with glutamine treatment with a modified diet (Byrne et al, 2005). In another recently published phase III trial, patients with SBS who received teduglutide (GAT-TEX; NPS Pharmaceuticals, Bedminster, NJ), a degradation-resistant analog of GLP-2, showed significant reductions in PN/IV volume and number of infusion days compared with patients who received placebo (Jeppesen et al, 2012).

Long-term PN/IV has been associated with complications such as catheter sepsis, vascular thrombosis, cholelithiasis, and metabolic bone disease. In addition, it is associated with high costs and diminished quality of life (Compher et al, 2008; Winkler, 2005). A reduction in PN days and volumes will allow the patient to sleep uninterrupted by excessive urination and have the freedom of a night without PN infusion.

The goal of SBS therapy should be to decrease PN/IV dependence to the extent possible. Even in the absence of complete weaning, reductions in the number of PN/IV days or session volumes can be beneficial to patients.

Introducing appropriate EN and hydration as soon as possible after resection facilitates intestinal adaptation and may promote eventual full weaning.

Small Intestine Bacterial Overgrowth

Small intestine bacterial overgrowth (SIBO) is a syndrome characterized by overproliferation of bacteria normally found in the large intestine within the small intestine. A number of physiologic processes normally limit the amount of bacteria in the small intestine. Gastric acid, bile, and pancreatic enzymes have bacteriostatic and bactericidal action within the small bowel. Normal propulsive action of bowel motility “sweeps” bacteria into the distal bowel. The ileocecal valve prevents retrograde migration of the large numbers of colonic bacteria into the small intestine. SIBO also has been referred to as “blind loop syndrome” because one cause of bacterial overgrowth can result from stasis of the intestinal tract as a result of obstructive disease, strictures, radiation enteritis, or surgical procedures that leave a portion of bowel without normal flow (a blind loop or Roux limb).

Etiology

Frequently, more than one of the normal homeostatic defenses must be impaired before small intestine bacteria overproliferate to the point that symptoms develop. Chronic use of medications that suppress gastric acid allow more ingested bacteria to survive and pass into the small bowel. Liver diseases or chronic pancreatitis can decrease the production or flow of bile and pancreatic enzymes that control bacterial growth, into the bowel. Gastroparesis, narcotic medications, or bowel dysmotility disorders decrease peristalsis and can impair the ability to propel bacteria to the distal bowel. Surgical resection of the distal ileum and ileocecal valve can result in retrograde proliferation of colonic bacteria.

Pathophysiology

Although symptoms vary depending on the amount and type of bacteria present in the small intestine, one of the most common symptoms of SIBO is chronic diarrhea from fat maldigestion. Bacteria within the small bowel deconjugate bile salts resulting in impaired formation of micelles and thus impaired fat digestion and steatorrhea. Carbohydrate malabsorption occurs because of injury to the brush border secondary to the toxic effects of bacterial products and consequent enzyme loss. The expanding numbers of bacteria use the available vitamin B₁₂ and other nutrients for their own growth, and the host becomes deficient. Bacteria within the small bowel produce folic acid as a byproduct of their metabolism, and vitamin B₁₂ deficiency with normal or elevated serum folic acid is common. Bloating and distention also are reported frequently in SIBO, resulting from the action of bacteria on carbohydrates with production of hydrogen and methane within the small bowel.

D-lactic acidosis is a rare neurologic complication of SIBO in SBS patients caused by malabsorption of a large carbohydrate load. A lower colonic pH, induced by a large production of lactate and short-chain fatty acids, promotes growth of acid-resistant bacteria that go on to produce D-lactate. Because of the lack of D-lactate dehydrogenase, humans cannot metabolize D-lactate and symptoms of D-lactic acidosis develop: from lethargy, altered mental status, ataxia, and slurred speech to aggression and coma (Hytte et al, 2011).

Medical Treatment

Treatment is directed toward control of the bacterial growth. Because of the difficulty of testing for SIBO in patients with SBS,

prescribing a therapeutic trial of antibiotics when suspicion is high is considered acceptable. Generally a broad-spectrum antibiotic that covers aerobic and anaerobic bacteria is used. Treatment may involve cycling of several antibiotics until improvement of symptoms is observed. Typically a 7- to 10-day course of antibiotics is successful, but some patients may require 1 to 2 months of treatment (Bohm et al, 2013). The antibiotic should be rotated to prevent bacterial resistance. The addition of probiotics to the antibiotic treatment has not been well studied and the benefits are inconclusive. If probiotics are used, then strains that produce D-lactate (e.g., *Lactobacillus acidophilus*, *Lactobacillus fermenti*) should be avoided because this may increase the risk of developing D-lactic acidosis, which can be life threatening.

Medical Nutrition Therapy

Dietary modification should target alleviation of symptoms and correction of nutrient deficiencies. Part of the problem with bacterial overgrowth in the small intestine is that carbohydrates reaching the site where microbes are harbored serve as fuel for their proliferation, with subsequent increased production of gases and organic acids. At least theoretically then, a diet that limits refined carbohydrates that are readily fermented, such as refined starches and sugars (e.g., lactose, fructose, alcohol sugars), and substitutes whole grains, and vegetables, can limit the proliferation of bacteria and increase gut motility (see Table 28-7).

An assessment of the medical problem and the patient's dietary intake is necessary as vitamin B₁₂ may be lost in fermentation, the diet may lack key dietary nutrients, or the absence or removal of greater than 60 cm of the terminal ileum has occurred, putting the patient at risk for deficiencies. A routine intramuscular vitamin B₁₂ may be required. If bile salts are being degraded, as in the case of blind loop syndrome, MCTs may be helpful if they provide a source of lipid and energy. Deficiencies of fat soluble vitamins A, D, and E are of concern if fat malabsorption is present.

Fistula

A **fistula** is an abnormal passage of an organ to another organ, skin, or wound. An **enterocutaneous fistula (ECF)** is an abnormal passage from a portion of the intestinal tract to the skin or to a wound (e.g., colcutaneous fistula between the large intestine and the skin).

Etiology

Fistulas may occur in any part of the GI tract but frequently develop in the small and large intestine. ECF can be classified several ways: by volume of output per day, cause (surgical versus spontaneous), site of origin, and number of fistula tracts. Surgery accounts for the majority of ECF development and usually manifests 7 to 10 days postoperatively. Fistulas of the intestinal tract can be serious threats to nutrition status because large amounts of fluids and electrolytes are lost and malabsorption and sepsis can occur. Box 28-11 lists conditions associated with fistula development.

Medical Treatment

Definitive assessment of fistula source, fistula route, and presence of obstructions or abscesses is essential in determining the appropriate medical intervention (Frantz et al, 2012). A fistulogram is considered the gold standard for identifying

BOX 28-11 Conditions Associated with Fistula Development

Bowel resection for cancer
 Bowel resection for inflammatory bowel disease
 Surgery for pancreatitis
 Surgery on radiated bowel
 Emergent surgery
 Surgical wound dehiscence
 Inflammatory bowel disease (Crohn's disease or ulcerative colitis)
 Radiation enteritis
 Bowel ischemia
 Diverticular disease

Data from Frantz D et al: Gastrointestinal disease. In Mueller CM et al, editors: *The A.S.PEN. Adult Nutrition Support Core Curriculum*, ed 2, Silver Spring, Md, 2012, American Society for Parenteral and Enteral Nutrition.

the location and route of the fistulous tract. Fluid and electrolyte balance must be restored, infection must be brought under control, and aggressive nutrition support may be necessary to permit spontaneous closure or to maintain optimal nutritional status before surgical closure.

Medical Nutrition Therapy

Nutrition management of patients with ECF can be very challenging. Initial management may include keeping the patient NPO (*nil per os*) as fistula output is quantified and administering nutritional support during the initial workup phase. PN, tube feeding, oral diet, or a combination is used in patients with ECF. The decision regarding which route to feed patients with ECF depends on several factors, including the origin of the fistula, the presence of obstructions or abscesses, the length of functional bowel, the likelihood of fistula closure, the ability to manage fistula output, and the patient's overall medical condition (see Chapter 13).

Intestinal Ostomies

The word ostomy, derived from the Latin word *ostium*, refers to mouth or opening. An **intestinal ostomy** is a surgically created opening between the intestinal tract and the skin, and is specifically named according to the site of origin along the intestinal tract. Approximately 100,000 people in the United States undergo operations that result in a colostomy or ileostomy each year (Sheetz et al, 2014). The high incidence of ostomy is due in part to the increasing prevalence of CRC and diverticular surgeries in the United States. Ostomies are created for many reasons; Table 28-8 lists indications for the creation of ostomies.

Colostomies and ileostomies can be categorized as either loop or end ostomies. A **loop ostomy** is formed when a loop of bowel is brought up to the skin, and an incision is made on one side. The distal end is sutured to the skin, whereas the proximal side of the loop is everted back on itself (Martin and Vogel, 2012). The result is a stoma with two openings: the proximal (functional) limb from which the effluent or stool is discharged, and the distal limb, which may connect to the anus and secrete mucus. A loop ostomy is used most often when a temporary ostomy is formed. **End ostomies** are created when the bowel is cut and the end is brought through the skin to create the stoma. End and loop ostomies are potentially reversible. The output from an ileostomy is termed effluent, whereas output from a colostomy is stool (Willcutts et al, 2005).

TABLE 28-8 Potential Indications for Creation of Intestinal Ostomy

Ileostomy	Colostomy
Crohn's disease	Colon cancer
Ulcerative colitis	Rectal cancer
FAP	Diverticulitis
Colon cancer	Rectal trauma
Rectal cancer	Radiation proctitis
Bowel perforation	Distal obstruction
Bowel ischemia	Fecal incontinence
Rectal trauma	Complex fistula
Fecal incontinence	
Fecal diversion	
Colonic dysmotility	
Toxic colitis	
Anastomotic leak	
Distal obstruction	
Enterocutaneous fistula	

FAP, Familial adenomatous polyposis.

Colostomy

A **colostomy** is a surgically created opening from the colon to the skin when a portion of the large intestine is removed or bypassed (see Figure 28-4). It can originate from any part of the colon: ascending, transverse, descending, or sigmoid. It typically starts functioning 2 to 5 days after surgery and the amount and type of output varies slightly, depending on the amount of remaining colon. Stool from a colostomy on the left side of the colon is firmer than that from a colostomy on the right side, with stool output ranging from 200 to 600 ml/day. Patients with sigmoid colostomies have elimination patterns similar to their preoperative states, usually one to two soft stools daily.

FIGURE 28-4 Colostomy. (Cleveland Clinic, Cleveland, Ohio, USA.)

FIGURE 28-5 Ileostomy. (Cleveland Clinic, Cleveland, Ohio, USA.)

Ileostomy

An **ileostomy** is a surgically created opening from the distal small bowel (most often the terminal ileum) to the skin when the entire colon, rectum, and anus are removed or bypassed (see [Figure 28-5](#)). Typically, a new ileostomy will start functioning within 24 hours after surgery, and the effluent is initially bilious in color and watery ([Willcutts and Touger-Decker, 2013](#)). Stoma output increases initially to about 1200 ml per 24 hours for the first 1 to 2 weeks. As the bowel adapts over the next 2 to 3 months, the effluent thickens (semiliquid to porridge-like consistency) and output drops to less than a liter per day.

Medical Management

Management of a new ostomy patient involves maintenance of nutritional and hydration status, meticulous skin care, and adequate containment of the fecal stream using a pouching system in the hospital and as the patient transitions to home ([McDonough, 2013](#)). It is very helpful when a patient is evaluated by an enterostomal therapist (who specializes in the care of stomas) before surgery to mark the most appropriate site for an ostomy. This minimizes potential skin and pouch system problems. A poorly constructed ostomy can cause skin excoriation and difficulty with pouch application, and may significantly affect patient quality of life (QoL). A well-functioning ostomy is associated with a superior QoL. In those patients who express concerns regarding suboptimal QoL, social restrictions, psychosexual issues, and fear of the ostomy appliance leaking, seem to be the major limiting factors ([Charua-Guindic et al, 2011](#)).

Medical Nutrition Therapy

Traditional recommendations for postoperative feeding of patients with either a colostomy or ileostomy are to hold feeding until the bowel has started to “function” or put out stool or

effluent. However, there is evidence that an oral diet or tube feeding can start early after surgery for any type of fecal diversion stoma that was created during an elective surgery. The Academy of Nutrition and Dietetics (AND) and the United Ostomy Association of America recommend a low fiber diet for approximately 6 to 8 weeks after surgery ([AND, 2014](#); [United Ostomy Associations of America, 2014](#)). This advice is based on the premise that the bowel is edematous and therefore at risk for being damaged and/or becoming obstructed after surgery. Most patients transition to a normal diet with a gradual increase in dietary fiber intake after approximately 6 weeks.

Vitamin B₁₂ and bile salts or fat malabsorption are normally not a concern with a distal ileostomy. Greater than 100 cm of ileum must be resected before steatorrhea or fat-soluble vitamin deficiency occurs, and greater than 60 cm must be resected before vitamin B₁₂ absorption is compromised ([Parrish and DiBaise, 2014](#)).

Controlling flatus and odor is a common concern for the colostomy patient rather than for a patient with an ileostomy. Many patients elect to limit foods that have the potential to increase flatus or cause increased odor of stool output. A patient must experiment with how different foods affect output. Deodorants are available, and ostomy appliances are made with odor-barrier material and can include charcoal filters that vent and deodorize gas.

Another concern for an ileostomy is the potential for intestinal blockage or obstruction at the stoma site resulting from narrowing of the intestinal lumen at the point where the ileum is brought through the abdominal wall. Patients are instructed to chew their food very well to reduce the chance of blockage. Ileostomy patients with higher volumes of watery effluent are encouraged to incorporate thickening foods to help thicken stoma output. The patient may have to experiment because thickened output may be desirable at times but can cause discomfort if output is thickened too much. Refer to [Table 28-9](#) for the effects of various foods on ostomy output.

Maintenance of adequate fluid and electrolyte status is an important nutrition-related issue in managing a patient with colostomy or ileostomy. Patients with an ileostomy must recognize the symptoms of dehydration and understand the importance of maintaining adequate fluid intake throughout the day. In addition, patients may have to increase their salt, potassium, and magnesium intake resulting from losses in ileostomy output.

Ostomy output may become acutely or chronically elevated, and this is much more common with an ileostomy. The generally accepted definition of a **high-output stoma (HOS)** is output that exceeds 2000 ml/day over 3 consecutive days, at which point water, sodium, and magnesium depletion are expected ([Baker et al, 2011](#)). There are multiple potential causes of HOS, including inflammatory bowel disease, *Clostridium difficile*, intraabdominal sepsis, partial or intermittent obstruction, medication-related causes, drinking too much fluid (especially hypertonic fluids), or surgery that results in less than 200 cm of residual small bowel and no colon ([Parrish and DiBaise, 2014](#)).

Management of HOS includes assessment and correction of depleted electrolytes and minerals; initiation of an oral rehydration solution (ORS) sipped throughout the day; avoidance of hypertonic, simple sugar containing liquids and foods; restriction of foods high in insoluble fiber; separation of solids and liquids at meals; and consumption of smaller meals, more often (up to 6 to 8 per day) ([McDonough, 2013](#); [Parrish and](#)

TABLE 28-9 Foods that may Alter Ostomy Output

Gas-Forming Foods	Odor-Producing Foods	Foods that May Control Odor
Broccoli	Asparagus	Buttermilk
Brussels sprouts	Beans	Cranberry juice
Cabbage	Broccoli	Orange juice
Cauliflower	Brussels sprouts	Yogurt
Garlic	Cabbage	Parsley
Onions	Cauliflower	Spinach
Fish	Garlic	Tomato juice
Eggs	Onions	
Carbonated beverages	Fish	
Alcoholic beverages	Eggs	
Dairy products	Some vitamins	
Legumes (dried beans)	Strong cheese	
Chewing gum		
Foods that may Thicken Stool	Foods that may Cause Obstruction	Foods that may Cause Diarrhea
Pasta	Apple peel	Alcoholic beverages
White bread	Orange	Caffeinated fluids
White rice	Pineapple	Chocolate
Potatoes	Grapes	Whole grains
Cheese	Dried fruits	Bran cereals
Pretzels	Raw cabbage	Fresh fruits
Creamy peanut butter	Raw celery	Grape juice
Applesauce	Chinese vegetables	Prune juice
Banana	Corn	Raw vegetables
Marshmallow	Mushrooms	Spicy foods
Tapioca	Coconut	Fried foods
	Popcorn	High-fat foods
	Nuts	Foods high in refined sugar or sorbitol

Data from Academy of Nutrition and Dietetics (AND): *Nutrition Care Manual, Ileostomy* (website: <http://nutritioncaremanual.org/>, 2014. Accessed March 16, 2014. McDonough MR: A dietitian's guide to colostomies and ileostomies, *Support Line* 35(3):3, 2013; United Ostomy Associations of America: *Diet and Nutrition Guide* (website: http://www.ostomy.org/ostomy_info/pubs/OstomyNutritionGuide.pdf), 2011 (Accessed 03.16.14); Willcutts K et al: Ostomies and fistulas: a collaborative approach, *Pract Gastroenterol* 29:63, 2005.

DiBaise, 2014). Malnutrition can occur in cases of persistent HOS, and many patients must increase their intake to maintain their nutritional status. Meeting the increased nutritional demand may not be possible via oral means for some patients, and nutrition support via enteral tube feeding may become necessary. Antidiarrheal and antisecretory medications are the two major classes of medications recommended to reduce output in HOS.

Restorative Proctocolectomy with Ileal Pouch Anal Anastomosis

Restorative **proctocolectomy** with **ileal pouch anal anastomosis (IPAA)** has evolved as the surgical treatment of choice for patients with medically refractory ulcerative colitis and familial adenomatous polyposis. About 30% of patients with ulcerative colitis eventually require colectomy, and the majority of these patients elect to have an IPAA. This procedure involves removal of the entire colon and rectum (proctocolectomy), while preserving the anal sphincter followed by creation of a reservoir using a portion of the distal ileum (ileal pouch). This pouch is then reconnected (pouch-anal anastomosis) to the preserved anal canal, thus maintaining continence and voluntary function. This offers a cure for the disease processes and avoids a permanent ileostomy.

Construction usually requires use of the distal-most 30 to 40 cm of ileum, with pouch configuration determined by the number of bowel limbs used. The most common pouch is the **ileal J-pouch**, which uses two limbs of bowel (see [Figure 28-6](#)).

FIGURE 28-6 J-pouch. (Cleveland Clinic, Cleveland, Ohio, USA.)

It is the preferred ileal pouch because of the efficiency of construction and optimal functional results. Alternatives to the J-pouch configuration include three- and four-limbed pouches, such as an **S-pouch** or **W-pouch**. These alternative configurations are rarely performed because of the complexity of construction. The final decision as to which type is used remains at the discretion of the surgeon.

With any pouch surgery the recovery is longer than in those who have a conventional ileostomy because of the two-stage procedure. There will be a period of adaptation of the new reservoir after the ileostomy is closed. Initially, there could be up to 15 bowel movements a day with some problems of control and the need to get up several times at night. Eventually, most patients experience 4 to 6 bowel movements daily, have good control, and are not troubled by nighttime incontinence. This improves over time as the pouch capacity gradually increases.

A **Koch pouch** is a type of applianceless ileostomy that uses an internal reservoir with a one-way valve, constructed from a loop of intestine that is attached to the abdominal wall with a skin-level stoma. Patients must insert a tube or catheter into the stoma to open the valve and allow drainage of the ileostomy contents. The technical difficulties of surgical construction and the potential for complications has led to decreased use of the Koch pouch in favor of the ileal J-pouch.

Medical Management

Acute and chronic complications can necessitate removal of the ileal pouch and eventual construction of a permanent ileostomy. **Pouchitis** is a nonspecific inflammation of the mucosal tissue forming the ileal pouch and is the most frequent long-term complication of IPAA in patients with UC. The cause of pouchitis is not entirely clear, but it may be related to bacterial overgrowth, unrecognized Crohn's disease, immunologic changes, bile salt malabsorption, or insufficient short-chain fatty acid (SCFA) production. The usual presenting symptoms include increased stool frequency, urgency, incontinence, nocturnal seepage, abdominal cramps, and pelvic discomfort. Pouchitis may be classified based on the cause, disease duration and activity, and response to medical therapy. In the majority of patients, the etiology of pouchitis is not clear and thus termed as idiopathic pouchitis (Zezos and Saibil, 2015).

Pouch endoscopy is the main modality in the diagnosis and differential diagnosis in patients with pouch dysfunction. Antibiotic therapy is the mainstay of treatment for active pouchitis. Some patients may develop dependency on antibiotics, requiring long-term maintenance therapy. The evidence for the use of probiotics in maintenance treatment of pouchitis is controversial. There may be roles for postoperative probiotic supplementation to prevent pouchitis and in maintaining remission in antibiotic-dependent pouchitis (Shen et al, 2014). Clinical expert-generated guidelines concur that probiotics (VSL #3) can be effective for preventing recurrence of pouchitis (Ciorba, 2012).

Medical Nutrition Therapy

Patients who have undergone an IPAA procedure usually require supplemental vitamin B₁₂ injections. The cause of vitamin B₁₂ deficiency may be multifactorial: (1) there is reduced absorptive capacity because of distal ileal resection (main site of vitamin B₁₂ absorption); (2) bacterial overgrowth is a well-known phenomenon in patients with an ileal pouch, and anaerobic bacteria can bind vitamin B₁₂ in its free and intrinsic forms, leading to a decreased concentration available for absorption; and (3) there may be insufficient B₁₂ intake. The anemia experienced by patients after IPAA can also be due to iron deficiency, because of impaired absorption, decreased oral intake, increased requirements, and blood loss.

Patients with a pouch often describe specific food sensitivities that may require diet alteration, even more so than do patients with permanent ileostomy (United Ostomy Associations of America, 2014). Problems commonly reported include obstructive symptoms and increased stool output, frequency, and gas. The incidence of obstruction may be avoided by limiting insoluble fibers, chewing thoroughly, and consuming small meals frequently throughout the day. Patients may try to experiment with timing of meals by eating larger meals earlier in the day and limiting the amount of food and fluid intake toward the end of the day to minimize sleep interruptions. The same dietary measures that are used to reduce excessive stool output (reduced caffeine, lactose avoidance if lactase-deficient, limitation of foods high in simple sugars, fructose and sorbitol) will likely reduce stool volume and frequency in patients with IPAA.

CLINICAL CASE STUDY

Lisa is a 35-year-old female with underlying diagnosis of fistulizing Crohn's colitis who underwent total abdominal colectomy (TAC) with end ileostomy. She had a difficult postoperative course complicated by ileus, high ostomy output, and slow introduction to oral diet. A nutrition consult was received for management of high ostomy output and malabsorption. Her ileostomy effluent was described as thin and watery.

Nutrition Assessment

- Anatomy: Patient has entire small bowel to ileostomy and no colon remaining, no ileocecal valve (ICV), no rectum, and no anus. The patient has no further potential for bowel reconnection surgery.
- Oral intake history: Decline in appetite and oral intake over past 3 months due to abdominal pain, nausea, and diarrhea. Before admission she was eating ½ of her usual meals. Unable to tolerate commercial nutrition supplements. Fluids: drinks "lots of fluids" (coffee, iced tea, water), 8 to 10 glasses per day
- Current intake: taking 50% of meals provided, tolerating snacks, and sipping up to 500 mL of oral rehydration solution (ORS) daily. She feels that her appetite is slowly improving.
- Weight history: Ht: 152.4 cm (60 inches) Wt: 43.2 kg (95 lb), dosing weight BMI: 18.6 kg/m²
- Usual body weight: 51 kg (112 lb); weight change: 15% change × 3 months (significant weight loss)
- Physical examination: sunken, dark eye sockets, slight depression at temples, scapula protrudes, thin quadriceps and calves, fat loss at the ribs, no edema
- Functional capacity: low energy level over past 3 months, unable to go to her son's soccer games, fatigued and tired all the time
- Medications: started loperamide 2 mg before meals and bedtime, chewable multivitamin, KCl sustained release tablet, IV fluids to replace stoma losses
- 24 hour urine and ostomy output: 650 ml and 2200 ml
- Pertinent labs: serum sodium (130) low, serum potassium (3.4) low, serum magnesium (2.0) low normal, CRP: not available, stool toxin analysis for *Clostridium difficile* negative
- Current diet: GI Soft Fiber-controlled diet, Low Simple Sugars Diet

Nutrition Diagnoses (Pes Statement)

- Malnutrition (P) related to chronic illness (E) as evidenced by inadequate energy intake, weight loss, subcutaneous fat loss, muscle loss, and decline in functional capacity (S)
- Suboptimal protein-energy intake (P) related to altered GI function (E) as evidenced by high output stoma and weight loss (7.8 kg loss over 3 months representing 15% weight change × 3 months) (S)

Nutrition Interventions

- Estimated energy needs: 1300 to 1700 calories/day (30 to 40 kcal/kg/day)
- Estimated protein needs: 65 to 86 g protein/day (1.5 to 2.0 g protein/kg/day)
- Nutrition goal(s): Oral intake to meet estimated needs, and stabilize ostomy output to the point where patient's hydration is maintained.
- Replace electrolyte and fluid losses. Monitor fluid balance.
- Continue GI soft fiber-controlled, low simple sugars diet. Patient to make high-salt, high-starch, low simple sugar food choices from the menu. Encourage separation of beverages at mealtimes.
- Provide salty/starchy snacks between meals. Encourage "thickening foods," such as boiled white rice, pasta, noodles, bread, potatoes, banana, oatmeal, applesauce, peanut butter, cheese, and tapioca pudding.
- Sip 1 L of oral rehydration solution (ORS) between meals.
- Avoid caffeinated and hypertonic fluids.
- Consider trial of soluble fiber supplement to slow down transit time and thicken stoma output.
- Continue escalation of antidiarrheal medications depending on volume and consistency of ileostomy effluent.
- Diet education: discuss with patient and family nutrition management of high output stoma and maintaining hydration with ileostomy.
- Monitor ostomy output and assess need for home intravenous fluids (HIVF) versus home parenteral nutrition (HPN).

Nutrition Monitoring And Evaluation

- Monitor oral intake via calorie counts with a goal of meeting 75% to 100% of estimated energy and protein needs.
- Monitor ostomy output via intake/output records (I/Os) and stabilize to less than 1500 ml per day before hospital discharge.

Medical Nutrition Therapy for Hepatobiliary and Pancreatic Disorders

*Jeanette M. Hasse, PhD, RDN, LD, CNSC, FADA,
Laura E. Matarese, PhD, RDN, LDN, CNSC, FADA, FASPEN, FAND*

KEY TERMS

alcoholic liver disease	fulminant liver disease	pancreatic islet auto-transplantation
aromatic amino acids (AAAs)	hemochromatosis	pancreatitis
ascites	hepatic encephalopathy	paracentesis
bile	hepatic failure	portal hypertension
branched-chain amino acids (BCAAs)	hepatic osteodystrophy	portal systemic encephalopathy
calculi	hepatic steatosis	postcholecystectomy syndrome
cholangitis	hepatitis	primary biliary cirrhosis (PBC)
cholecystectomy	hepatorenal syndrome	primary sclerosing cholangitis (PSC)
cholecystitis	jaundice	secondary biliary cirrhosis
choledocholithiasis	Kayser-Fleischer ring	steatorrhea
cholelithiasis	Kupffer cells	transamination
cholestasis	nonalcoholic fatty liver disease (NAFLD)	varices
cirrhosis	nonalcoholic steatohepatitis (NASH)	Wernicke encephalopathy
detoxification	oxidative deamination	Wilson's disease
fasting hypoglycemia	pancreaticoduodenectomy (Whipple procedure)	
fatty liver		

The liver is of primary importance; one cannot survive without a liver. The liver and pancreas are essential to digestion and metabolism. Although it is important, the gallbladder can be removed, and the body will adapt comfortably to its absence. Knowledge of the structure and functions of these organs is vital. When they are diseased, the necessary medical nutrition therapy (MNT) is complex.

PHYSIOLOGY AND FUNCTIONS OF THE LIVER

Structure

The liver is the largest gland in the body, weighing approximately 1500 g. The liver has two main lobes: the right and left. The right lobe is further divided into the anterior and posterior segments; the right segmental fissure, which cannot be seen externally, separates the segments. The externally visible falciform ligament divides the left lobe into the medial and lateral segments. The liver is supplied with blood from two sources: the hepatic artery, which supplies approximately one third of the blood from the aorta; and the portal vein, which supplies the other two thirds and collects blood drained from the digestive tract.

Approximately 1500 mL of blood per minute circulates through the liver and exits via the right and left hepatic veins into the inferior vena cava. The liver has a system of blood vessels and a series of bile ducts. **Bile**, which is formed in the

liver cells, exits the liver through a series of bile ducts that increase in size as they approach the common bile duct. Bile is a thick, viscous fluid secreted from the liver, stored in the gallbladder, and released into the duodenum when fatty foods enter the duodenum. It emulsifies fats in the intestine and forms compounds with fatty acids to facilitate their absorption.

Functions

The liver has the ability to regenerate itself. Only 10% to 20% of functioning liver is required to sustain life, although removal of the liver results in death, usually within 24 hours. The liver is integral to most metabolic functions of the body and performs more than 500 tasks. The main functions of the liver include (1) metabolism of carbohydrate, protein, and fat; (2) storage and activation of vitamins and minerals; (3) formation and excretion of bile; (4) conversion of ammonia to urea; (5) metabolism of steroids; (6) detoxification of substances such as drugs, alcohol, and organic compounds; and (7) function as a filter and flood chamber.

The liver plays a major role in carbohydrate metabolism. Galactose and fructose, products of carbohydrate digestion, are converted into glucose in the hepatocyte or liver cell. The liver stores glucose as glycogen (glycogenesis) and then returns it to the blood when glucose levels become low (glycogenolysis). The liver also produces “new” glucose

(gluconeogenesis) from precursors such as lactic acid, glycolytic amino acids, and intermediates of the tricarboxylic acid cycle.

Important protein metabolic pathways occur in the liver. **Transamination** (transfer of an amino group from one compound to another) and **oxidative deamination** (removal of an amino group from an amino acid or other compound) are two such pathways that convert amino acids to substrates that are used in energy and glucose production as well as in the synthesis of nonessential amino acids. Blood-clotting factors such as fibrinogen and prothrombin as well as serum proteins including albumin, alpha-globulin, beta-globulin, transferrin, ceruloplasmin, and lipoproteins are formed by the liver.

Fatty acids from the diet and adipose tissue are converted in the liver to acetyl-coenzyme A by the process of beta-oxidation to produce energy. Ketones also are produced. The liver synthesizes and hydrolyzes triglycerides, phospholipids, cholesterol, and lipoproteins as well.

The liver is involved in the storage, activation, and transport of many vitamins and minerals. It stores all the fat-soluble vitamins in addition to vitamin B₁₂ and the minerals zinc, iron, copper, and manganese. Hepatically synthesized proteins transport vitamin A, iron, zinc, and copper in the bloodstream. Carotene is converted to vitamin A, folate to 5-methyl tetrahydrofolic acid, and vitamin D to an active form (25-hydroxycholecalciferol) by the liver.

In addition to functions of nutrient metabolism and storage, the liver forms and excretes bile. Bile salts are metabolized and used for the digestion and absorption of fats and fat-soluble vitamins. Bilirubin is a metabolic end product from red blood cell destruction; it is conjugated and excreted in the bile.

Hepatocytes detoxify ammonia by converting it to urea, 75% of which is excreted by the kidneys. The remaining urea finds its way back to the gastrointestinal tract (GIT). The liver also metabolizes steroids. It inactivates and excretes aldosterone, glucocorticoids, estrogen, progesterone, and testosterone. It is responsible for the **detoxification** of substances, including drugs and alcohol as well as toxins such as pollutants, pesticides and herbicides, herbal products, and toxic mushrooms (*A. phalloides*). Finally, the liver acts as a filter and flood chamber by removing bacteria and debris from blood through the phagocytic action of **Kupffer cells** located in the sinusoids and by storing blood backed up from the vena cava as in right heart failure.

Laboratory Assessment of Liver Function

Biochemical markers are used to evaluate and monitor patients having or suspected of having liver disease. Enzyme assays measure the release of liver enzymes, and other tests measure liver function. Screening tests for hepatobiliary disease include serum levels of bilirubin, alkaline phosphatase, aspartate amino transferase, and alanine aminotransferase. **Table 29-1** elaborates common laboratory tests for liver disorders (see also Appendix 22).

TABLE 29-1 Common Laboratory Tests Used to Test Liver Function

Laboratory Test	Comment
Hepatic Excretion	
Total serum bilirubin	When increased, may indicate bilirubin overproduction or impaired hepatic uptake, conjugation, or excretion
Indirect serum bilirubin	Unconjugated bilirubin; increased with excessive bilirubin production (hemolysis), immaturity of enzyme systems, inherited defects, drug effects
Direct serum bilirubin	Conjugated bilirubin; increased with depressed bilirubin excretion, hepatobiliary disease, intrahepatic or benign postoperative jaundice and sepsis, and congenital conjugated hyperbilirubinemia
Cholestasis	
Serum alkaline phosphatase	Enzyme widely distributed in liver, bone, placenta, intestine, kidney, leukocytes; mainly bound to canalicular membranes in liver; increased levels suggest cholestasis but can be increased with bone disorders, pregnancy, normal growth, and some malignancies
γ -Glutamyl transpeptidase (GGT)	Enzyme found in high concentrations in epithelial cells lining bile ductules in the liver; also present in kidney, pancreas, heart, brain; increased with liver disease, but also after myocardial infarction, in neuromuscular disease, pancreatic disease, pulmonary disease, diabetes mellitus, and during alcohol ingestion
Hepatic Serum Enzymes	
Alanine aminotransferase (ALT, formerly SGPT, serum glutamic pyruvic transaminase)	Located in cytosol of hepatocyte; found in several other body tissues but highest in liver; increased with liver cell damage
Aspartate aminotransferase (AST, formerly SGOT, serum glutamic oxaloacetic transaminase)	Located in cytosol and mitochondria of hepatocyte; also in cardiac and skeletal muscle, heart, brain, pancreas, kidney; increased with liver cell damage
Serum lactic dehydrogenase	Located in liver, red blood cells, cardiac muscle, kidney; increased with liver disease but lacks sensitivity and specificity because it is found in most other body tissues
Serum Proteins	
Prothrombin time (PT)	Most blood coagulation factors are synthesized in the liver; vitamin K deficiency and decreased synthesis of clotting factors increase prothrombin time and risk of bleeding.
International Normalized Ratio (INR)	A standardized way to report PT levels so that levels from different laboratories can be compared

Continued

TABLE 29-1 Common Laboratory Tests Used to Test Liver Function—cont'd

Laboratory Test	Comment
Serum albumin	Main export protein synthesized in the liver and most important factor in maintaining plasma oncotic pressure; hypoalbuminemia can result from expanded plasma volume or reduced synthesis as well as increased losses as occurs with protein-losing enteropathy, nephrotic syndrome, burns, gastrointestinal bleeding, exfoliative dermatitis.
Serum globulin	Alpha ₁ and alpha ₂ -globulins are synthesized in the liver; levels increase with chronic liver disease; limited diagnostic use in hepatobiliary disease although the pattern may suggest underlying cause of liver disease (e.g., elevated immunoglobulin [IgG] suggests autoimmune hepatitis, elevated IgM suggests primary biliary cirrhosis, elevated IgA suggests alcoholic liver disease)
Markers of Specific Liver Diseases	
Serum ferritin	Major iron storage protein; increased level sensitive indicator of genetic hemochromatosis
Ceruloplasmin	Major copper-binding protein synthesized by liver; decreased in Wilson's disease
Alpha-fetoprotein	Major circulating plasma protein; increased with hepatocellular carcinoma
Alpha ₁ -antitrypsin	Main function is to inhibit serum trypsin activity; decreased levels indicate alpha ₁ -antitrypsin deficiency, which can cause liver and lung damage.
Markers for Viral Hepatitis	
Anti-HAV IgM (antibody to hepatitis A virus)	Marker for hepatitis A; indicates current or recent infection or convalescence
HBsAg (hepatitis B surface antigen)	Marker for hepatitis B; positive in most cases of acute or chronic infection
Anti-HBc (antibody to hepatitis B core antigen)	Antibody to hepatitis B core antigen; marker for hepatitis B; Recent or past hepatitis infection
Anti-HBs (antibody to hepatitis B surface antigen)	Antibody to HBsAg; marker for hepatitis B; denotes prior hepatitis B infection or hepatitis B vaccine; protective
HBeAg (hepatitis Be antigen)	Marker for hepatitis B; transiently positive during active virus replication; reflects concentration and infectivity of virus
Anti-HBe (antibody to hepatitis Be antigen)	Marker for hepatitis B; positive in all acute and chronic cases; positive in carriers; not protective
HBV-DNA (hepatitis B deoxyribonucleic acid)	Measures hepatitis B viral load
Anti-HCV (antibody to hepatitis C virus)	Marker for hepatitis C; positive 5-6 weeks after onset of hepatitis C virus; not protective; reflects infectious state and is detectable during and after treatment
HCV-RNA (hepatitis C virus ribonucleic acid)	Measures hepatitis C viral load
Anti-HDV	Marker for hepatitis D; indicates infection; not protective
Miscellaneous	
Ammonia	Liver converts ammonia to urea; may increase with hepatic failure and portal-systemic shunts

Data from Wedemeyer H, Pawlowsky JM: Acute viral hepatitis. In Goldman L et al, editors: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Elsevier Saunders. Pawlowsky JM, Mchuthinson J: Chronic viral and autoimmune hepatitis. In Goldman L et al, editors: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Elsevier Saunders. Woreta TA, Alqahtani SA: Evaluation of abnormal liver tests. *Med Clin North Am* 98:1, 2014. Martin P, Friedman LS: Assessment of liver function and diagnostic studies. In Friedman LS, Keeffe B, editors: *Handbook of liver disease*, ed 3, Philadelphia, 2012, Elsevier Saunders; 2012. Khalili H et al: Assessment of liver function in clinical practice. In Gines P et al, editors: *Clinical gastroenterology: chronic liver failure*, New York, 2011, Springer.

Physical examination as well as diagnostic procedures (e.g., endoscopy) or abdominal imaging tests (e.g., abdominal ultrasound, magnetic resonance imaging, or computed tomography scan) can be used to diagnose or evaluate patients for liver disease. A liver biopsy is considered the gold standard to assess the severity of hepatic inflammation and fibrosis.

DISEASES OF THE LIVER

Diseases of the liver can be acute or chronic, inherited or acquired. The following section provides a brief overview of viral hepatitis, nonalcoholic fatty liver disease (NAFLD), alcoholic liver disease, cholestatic liver diseases, inherited disorders, and other liver diseases.

Viral Hepatitis

Viral hepatitis is a widespread inflammation of the liver and is caused by various hepatitis viruses including A, B, C, D, and E (see Figure 29-1 and Table 29-2). Hepatitis A and E are the infectious

forms, mainly spread by fecal-oral route. Hepatitis B, C, and D are the serum forms that are spread by blood and body fluids (Wedemeyer and Pawlowsky, 2012). Minor agents such as Epstein-Barr virus, cytomegalovirus, and herpes simplex also can cause an acute hepatitis.

The clinical manifestations of acute viral hepatitis are divided into four phases. The first phase, the incubation phase, often is characterized by nonspecific symptoms such as malaise, loss of appetite, nausea, and right upper quadrant pain (Wedemeyer and Pawlowsky, 2012). This is followed by the preicteric phase, in which the nonspecific symptoms continue. In addition, about 10% to 20% of patients can have immune-mediated symptoms such as fever, arthralgia, arthritis, rash, and angioedema in the preicteric phase. The third phase is the icteric phase, in which jaundice (a yellowing of the skin, mucous membranes, and the eyes) appears and the nonspecific symptoms worsen. Finally, during the convalescent or recovery phase, jaundice and other symptoms begin to subside.

FIGURE 29-1 **A**, Normal liver. **B**, Liver with damage from chronic active hepatitis. **C**, Liver with damage from sclerosing cholangitis. **D**, Liver with damage from primary biliary cirrhosis. **E**, Liver with damage from polycystic liver disease (*background*) and normal liver (*foreground*). (Courtesy Baylor Simmons Transplant Institute, Baylor University Medical Center, Dallas, TX.)

Complete spontaneous recovery is expected in all of hepatitis A cases, in nearly 90% of acute hepatitis B cases acquired as an adult, but in only 20% to 50% of acute hepatitis C cases. Chronic hepatitis usually does not develop with hepatitis E (Wedemeyer and Pawlotsky, 2012). There are vaccines only for hepatitis A and B; however, recent advances have resulted in effective antiviral drugs to treat chronic hepatitis B and C.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a spectrum of liver disease ranging from steatosis to steatohepatitis and

cirrhosis. It involves the accumulation of fat droplets in the hepatocytes and can lead to fibrosis, cirrhosis, and even hepatocellular carcinoma. Causes of NAFLD can include drugs, inborn errors of metabolism, and acquired metabolic disorders (type 2 diabetes mellitus, lipodystrophy, jejunal ileal bypass, obesity, and malnutrition). However, NAFLD is associated most commonly with obesity, type 2 diabetes mellitus, dyslipidemia, and metabolic syndrome (Chalasani et al, 2012).

The initial stage of NAFLD is nonalcoholic fatty liver (NAFL) which is characterized by the simple accumulation of fat within the liver. **Nonalcoholic steatohepatitis (NASH)** is

TABLE 29-2 Types of Viral Hepatitis

Virus	Transmission	Comments
Hepatitis A	Fecal-oral route; is contracted through contaminated drinking water, food, and sewage	Anorexia is the most frequent symptom, and it can be severe. Other common symptoms include nausea, vomiting, right upper quadrant abdominal pain, dark urine, and jaundice (icterus). Recovery is usually complete, and long-term consequences are rare. Serious complications may occur in high-risk patients; subsequently, great attention must be given to adequate nutritional intake.
Hepatitis B and C	HBV and HCV are transmitted via blood, blood products, semen, and saliva. For example, they can be spread from contaminated needles, blood transfusions, open cuts or wounds, splashes of blood into the mouth or eyes, or sexual contact.	HBV and HCV can lead to chronic and carrier states. Chronic active hepatitis also can develop, leading to cirrhosis and liver failure.
Hepatitis D	HDV is rare in the United States and depends on the HBV for survival and propagation in humans.	HDV may be a coinfection (occurring at the same time as HBV) or a superinfection (superimposing itself on the HBV carrier state). This form of hepatitis usually becomes chronic.
Hepatitis E	HEV is transmitted via the oral-fecal route.	HEV is rare in the United States (typically only occurs when imported), but it is reported more frequently in many countries of southern, eastern, and central Asia; northern, eastern, and western Africa; and Mexico. Contaminated water appears to be the source of infection, which usually afflicts people living in crowded and unsanitary conditions. HEV is generally acute rather than chronic.
Hepatitis G/GB	HGV and a virus labeled GBV-C appear to be variants of the same virus.	Although HGV infection is present in a significant proportion of blood donors and is transmitted through blood transfusions, it does not appear to cause liver disease.

HBV, Hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HGV, hepatitis G virus.

associated with hepatocyte injury with or without fibrous tissue in the liver. NASH can develop into chronic liver disease and NASH cirrhosis. The progression to cirrhosis is variable depending on age and the presence of obesity and type 2 diabetes, which contribute to a worsening prognosis (Chalasanani, 2012).

The treatment recommendations for NAFLD from the American Association for the Study of Liver Diseases (AASLD) include weight loss, insulin-sensitizing drugs such as thiazolidinediones, and vitamin E (Chalasanani et al, 2012). Based on the AASLD Guidelines, a 3% to 5% weight loss can improve steatosis, but up to 10% weight loss may be needed to improve necroinflammation. The AASLD Guidelines state that pioglitazone (an oral antihyperglycemia medication used to treat diabetes mellitus) may be considered for NASH treatment, although long-term safety and efficacy is not known. Vitamin E (800 IU/day of alpha-tocopherol) is considered first-line treatment for NASH in patients without diabetes (Chalasanani et al, 2012; Lavine et al, 2011; Sanyal et al, 2010). Emerging data suggest drinking coffee is protective against NAFLD (Chen et al, 2013; Yesil and Yilmaz, 2013).

Alcoholic Liver Disease

Alcoholic liver disease is one of the most common liver diseases in the United States. In 2009, 48% of deaths from cirrhosis were related to alcohol (Yoon and Yi, 2012). Acetaldehyde is a toxic byproduct of alcohol metabolism that causes damage to mitochondrial membrane structure and function. Acetaldehyde is produced by multiple metabolic pathways, one of which involves alcohol dehydrogenase (see *Focus On: Metabolic Consequences of Alcohol Consumption*).

FOCUS ON

Metabolic Consequences of Alcohol Consumption

Ethanol is metabolized primarily in the liver by alcohol dehydrogenase. This results in acetaldehyde production with the transfer of hydrogen to nicotinamide adenine dinucleotide (NAD), reducing it to NADH. The acetaldehyde then loses hydrogen and is converted to acetate, most of which is released into the blood.

Many metabolic disturbances occur because of the excess of NADH, which overrides the ability of the cell to maintain a normal redox state. These include hyperlacticacidemia, acidosis, hyperuricemia, ketonemia, and hyperlipemia. The tricarboxylic acid (TCA) cycle is depressed because it requires NAD. The mitochondria, in turn, use hydrogen from ethanol rather than from the oxidation of fatty acids to produce energy via the TCA cycle, which leads to a decreased fatty acid oxidation and accumulation of triglycerides. In addition, NADH may actually promote fatty acid synthesis. Hypoglycemia also can occur in early alcoholic liver disease secondary to the suppression of the TCA cycle, coupled with decreased gluconeogenesis resulting from ethanol.

Several variables predispose some people to alcoholic liver disease. These include genetic polymorphisms of alcohol-metabolizing enzymes, gender (women more than men), simultaneous exposure to other drugs, infections with hepatotropic viruses, immunologic factors, obesity, and poor nutrition status. The pathogenesis of alcoholic liver disease progresses in three stages (see Figure 29-2): hepatic steatosis (see Figure 29-3), alcoholic hepatitis, and finally cirrhosis.

Fatty infiltration, known as **hepatic steatosis** or **fatty liver**, is caused by a culmination of these metabolic disturbances: (1) an increase in the mobilization of fatty acids from adipose tissue; (2) an increase in hepatic synthesis of

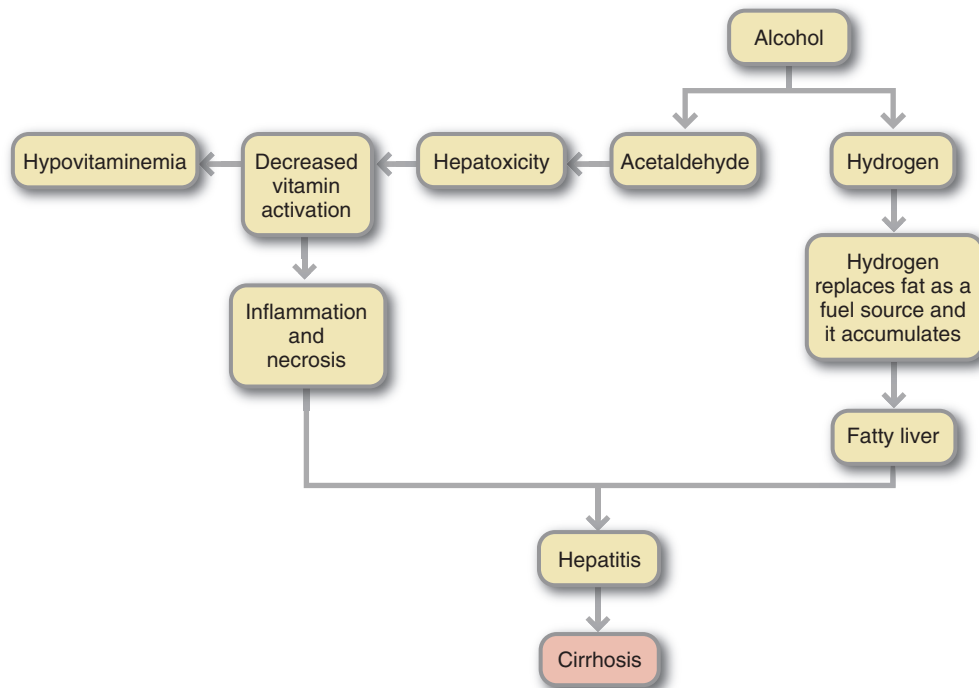

FIGURE 29-2 Complications of excessive alcohol consumption stem largely from excess hydrogen and from acetaldehyde. Hydrogen produces fatty liver and hyperlipemia, high blood lactic acid, and low blood sugar. The accumulation of fat, the effect of acetaldehyde on liver cells, and other factors as yet unknown lead to alcoholic hepatitis. The next step is cirrhosis. The consequent impairment of liver function disturbs blood chemistry, notably causing a high ammonia level that can lead to coma and death. Cirrhosis also distorts liver structure, inhibiting blood flow. High pressure in vessels supplying the liver may cause ruptured varices and accumulation of fluid in the abdominal cavity. Response to alcohol differs among individuals; in particular, not all heavy drinkers develop hepatitis and cirrhosis.

FIGURE 29-3 **A**, Microscopic appearance of a normal liver. A normal portal tract consists of the portal vein, hepatic arteriole, one to two interlobular bile ducts, and occasional peripherally located ductules. **B**, Acute fatty liver. This photomicrograph on low power exhibits fatty change involving virtually all the hepatocytes, with slight sparing of the liver cells immediately adjacent to the portal tract (*top*). (From Kanel G, Korula J, editors: *Atlas of liver pathology*, Philadelphia, 1992, Saunders.)

fatty acids; (3) a decrease in fatty acid oxidation; (4) an increase in triglyceride production; and (5) a trapping of triglycerides in the liver. Hepatic steatosis is reversible with abstinence from alcohol. Conversely, if alcohol abuse continues, cirrhosis can develop. Patients with alcoholic fatty liver disease usually are asymptomatic but can have symptoms such as fatigue, poor appetite, right upper quadrant discomfort, or hepatomegaly.

Alcoholic hepatitis generally is characterized by hepatomegaly, modest elevation of serum transaminase levels, increased serum bilirubin concentrations, normal or depressed serum albumin concentrations, or anemia. Patients also may have abdominal pain, anorexia, nausea, vomiting, weakness, diarrhea, weight loss, or fever. Some patients can develop jaundice, coagulopathy, ascites, or encephalopathy. If patients discontinue alcohol intake, hepatitis may resolve; however, the condition often progresses to the third stage.

Clinical features of alcoholic cirrhosis, the third stage, vary. Symptoms can mimic those of alcoholic hepatitis; or patients can develop complications of cirrhosis such as gastrointestinal bleeding, hepatic encephalopathy, or portal hypertension (elevated blood pressure in the portal venous system caused by the obstruction of blood flow through the liver). Patients with alcoholic cirrhosis often develop ascites, the accumulation of fluid, serum protein, and electrolytes within the peritoneal cavity caused by increased pressure from portal hypertension and decreased production of albumin (which maintains serum colloidal osmotic pressure). A liver biopsy usually reveals micronodular cirrhosis, but it can be macronodular or mixed. Prognosis depends on abstinence from alcohol and the degree of complications already developed. Ethanol ingestion creates specific and severe nutritional abnormalities (see *Clinical Insight: Malnutrition in the Alcoholic*).

CLINICAL INSIGHT

Malnutrition in the Alcoholic

Several factors contribute to the malnutrition common in individuals with chronic alcoholic liver disease:

1. Alcohol can replace food in the diet of moderate and heavy drinkers, displacing the intake of adequate calories and nutrients. In light drinkers, it is usually an additional energy source, or empty calories. Although alcohol yields 7.1 kcal/g, when it is consumed in large amounts it is not used efficiently as a fuel source. When individuals consume alcohol on a regular basis but do not fulfill criteria for alcohol abuse, they are often overweight because of the increased calories (alcohol addition). This is different from the heavy drinker who replaces energy-rich nutrients with alcohol (alcohol substitution).
2. In the alcoholic, impaired digestion and absorption are related to pancreatic insufficiency, as well as morphologic and functional alterations of the intestinal mucosa. Acute and chronic alcohol intake impairs hepatic amino acid uptake and synthesis into proteins, reduces protein synthesis and secretion from the liver, and increases catabolism in the gut.
3. Use of lipids and carbohydrates is compromised. An excess of reduction equivalents (e.g., nicotinamide adenine dinucleotide phosphate [NADH])

and impaired oxidation of triglycerides result in fat deposition in the hepatocytes and an increase in circulating triglycerides. Insulin resistance is also common.

4. Vitamin and mineral deficiencies occur in alcoholic liver disease as a result of reduced intake and alterations in absorption, storage, and ability to convert the nutrients to their active forms. Steatorrhea resulting from bile acid deficiency is also common in alcoholic liver disease and affects fat-soluble vitamin absorption. Vitamin A deficiency can lead to night blindness. Thiamin deficiency is the most common vitamin deficiency in alcoholics and is responsible for Wernicke encephalopathy (Leevy et al, 2005). Folate deficiency can occur as a result of poor intake, impaired absorption, accelerated excretion, and altered storage and metabolism. Inadequate dietary intake and interactions between pyridoxal-5-phosphate (active coenzyme of vitamin B₆) and alcohol reduce vitamin B₆ status. Deficiency of all B vitamins and vitamins C, D, E, and K is also common. Hypocalcemia, hypomagnesemia, and hypophosphatemia are not uncommon among alcoholics; furthermore, zinc deficiency and alterations in other micronutrients can accompany chronic alcohol intake.

Cholestatic Liver Diseases

Cholestatic liver diseases refer to conditions affecting the bile ducts.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic cholestatic disease caused by progressive destruction of small and intermediate-size intrahepatic bile ducts. The extrahepatic biliary tree and larger intrahepatic ducts are normal. Ninety-five percent of patients with PBC are women. The disease progresses slowly, eventually resulting in cirrhosis, portal hypertension, liver transplantation, or death (Afdhal, 2012).

PBC is an autoimmune disorder. PBC typically presents with a mild elevation of liver enzymes with physical symptoms of pruritus and fatigue. Several nutritional complications from cholestasis can occur with PBC, including osteopenia, hypercholesterolemia, and fat-soluble vitamin deficiencies.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is characterized by fibrosing inflammation of segments of extrahepatic bile

ducts, with or without involvement of intrahepatic ducts. The progressive disease can be characterized by three syndromes. The first is cholestasis with biliary cirrhosis followed by recurrent cholangitis with large bile duct strictures, and finally cholangiocarcinoma (Afdhal, 2012). Like PBC, PSC is considered an immune disorder. Of patients with PSC, 70% to 90% also have inflammatory bowel disease (especially ulcerative colitis), and men are more likely than women (2.3:1) to have PSC (Afdhal, 2012). Patients with PSC are also at increased risk of fat-soluble vitamin deficiencies resulting from steatorrhea associated with this disease. **Hepatic osteodystrophy** may occur from vitamin D and calcium malabsorption, resulting in secondary hyperparathyroidism, osteomalacia, or rickets. No treatment slows progression of the disease or improves survival. Ursodeoxycholic acid may improve laboratory values (serum bilirubin, alkaline phosphatase, and albumin), but has no effect on survival (Afdhal, 2012).

Inherited Disorders

Inherited disorders of the liver include hemochromatosis, Wilson's disease, alpha₁-antitrypsin deficiency, and cystic fibrosis.

Porphyria, glycogen storage disease, and amyloidosis are metabolic diseases with a genetic component.

Hemochromatosis

Hemochromatosis is an inherited disease of iron overload usually associated with the gene HFE (Bacon, 2012). Patients with hereditary hemochromatosis absorb excessive iron from the gut and may store 20 to 40 g of iron compared with 0.3 to 0.8 g in normal persons (see Chapter 32). Increased transferrin saturation (at least 45%) and ferritin (more than two times normal) suggest hemochromatosis. Hepatomegaly, esophageal bleeding, ascites, impaired hepatic synthetic function, abnormal skin pigmentation, glucose intolerance, cardiac involvement, hypogonadism, arthropathy, and hepatocellular carcinoma may develop. Early diagnosis includes clinical, laboratory, and pathologic testing, including elevated serum transferrin levels. Life expectancy is normal if phlebotomy is initiated before the development of cirrhosis or diabetes mellitus.

Wilson's Disease

Wilson's disease is an autosomal-recessive disorder associated with impaired biliary copper excretion. Copper accumulates in various tissues, including the liver, brain, cornea, and kidneys. **Kayser-Fleischer rings** are greenish-yellow pigmented rings encircling the cornea just within the corneal margin, formed by copper deposits. Patients can present with acute, fulminant (occurring suddenly great severity), or chronic active hepatitis and neuropsychiatric symptoms. Low serum ceruloplasmin levels, elevated copper concentration in a liver biopsy, and high urinary copper excretion confirm the diagnosis.

Copper-chelating agents (such as D-penicillamine or trientine) and zinc supplementation (to inhibit intestinal copper absorption and binding in the liver) are used to treat Wilson's disease once it is diagnosed. Ongoing copper chelation is required to prevent relapses and liver failure; transplantation corrects the metabolic defect. A low-copper diet is no longer required but may be helpful in the initial phase of treatment. High-copper foods include organ meats, shellfish, chocolate, nuts, and mushrooms. For a comprehensive list of copper content of food, refer to the US Department of Agriculture National Nutrient Database (<http://ndb.nal.usda.gov/>). If this disease is not diagnosed until onset of fulminant failure, survival is not possible without transplantation.

Alpha₁-Antitrypsin Deficiency

Alpha₁-antitrypsin deficiency is an inherited disorder that can cause liver and lung disease. Alpha₁-antitrypsin is a glycoprotein found in serum and body fluids; it inhibits serine proteinases. Cholestasis or cirrhosis is caused by this deficiency, and there is no treatment except liver transplantation.

Other Liver Diseases

Liver disease can be caused by several conditions other than those already discussed. Liver tumors can be primary or metastatic, benign or malignant. Hepatocellular carcinoma (HCC) usually develops in cirrhotic livers. Although the incidence of HCC is rising worldwide, the majority of cases occur in Asia and Africa resulting from the high prevalence of hepatitis B and C in those continents (Dhanasekaran et al, 2012). The liver

also can be affected by systemic diseases such as rheumatoid arthritis, systemic lupus erythematosus, polymyalgia, temporal arteritis, polyarteritis nodosa, systemic sclerosis, and Sjögren syndrome. When hepatic blood flow is altered, as in acute ischemic and chronic congestive hepatopathy, Budd-Chiari syndrome, and hepatic venoocclusive disease, dysfunction occurs. Individuals with hepatic or portal vein thromboses should be evaluated for a myeloproliferative disorder. Parasitic, bacterial, fungal, and granulomatous liver diseases also occur. Finally, cryptogenic cirrhosis is any cirrhosis for which the cause is unknown.

Classifying Liver Disease According to Duration

Liver disease can be classified according to the time of onset and duration of the disease. Liver disease can be fulminant, acute, and chronic.

Fulminant hepatitis is a syndrome in which severe liver dysfunction is accompanied by hepatic encephalopathy, a clinical syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness. **Fulminant liver disease** is defined by the absence of preexisting liver disease and the development of hepatic encephalopathy within 2 to 8 weeks of the onset of illness. The causes of fulminant hepatitis include viral hepatitis in approximately 75% of cases, chemical toxicity (e.g., acetaminophen, drug reactions, poisonous mushrooms, industrial poisons), and other causes (e.g., Wilson's disease, fatty liver of pregnancy, Reye syndrome, hepatic ischemia, hepatic vein obstruction, and disseminated malignancies). Extrahepatic complications of fulminant hepatitis are cerebral edema, coagulopathy and bleeding, cardiovascular abnormalities, renal failure, pulmonary complications, acid-base disturbances, electrolyte imbalances, sepsis, and **pancreatitis** (inflammation of the pancreas).

Acute liver disease is identified typically as liver dysfunction that has been present for less than 6 months. Recovery is expected in a majority of patients who develop acute liver disease.

To be diagnosed with chronic hepatitis, a patient must have at least a 6-month course of hepatitis or biochemical and clinical evidence of liver disease with confirmatory biopsy findings of unresolving hepatic inflammation. Chronic hepatitis can have autoimmune, viral, metabolic, drug, or toxin causes. The most common causes of chronic hepatitis are hepatitis B, hepatitis C, and autoimmune hepatitis. Other causes are drug-induced liver disease, metabolic diseases, and NASH. Cryptogenic cirrhosis is cirrhosis of an unknown cause.

Clinical symptoms of chronic hepatitis are usually nonspecific, occur intermittently, and are mild. Common symptoms include fatigue, sleep disorders, difficulty concentrating, and mild right upper quadrant pain. Severe advanced disease can lead to jaundice, muscle wasting, tea-colored urine, ascites, edema, hepatic encephalopathy, gastrointestinal **varices** (abnormal enlarged veins often caused by portal hypertension) with resultant gastrointestinal bleeding, splenomegaly, palmar erythema, and spider angiomas.

In some instances, chronic hepatitis leads to cirrhosis and end-stage liver disease. **Cirrhosis** has many clinical manifestations, as illustrated in Figure 29-4. Several major complications of cirrhosis and end-stage liver disease (ESLD), including malnutrition, ascites, hyponatremia, hepatic encephalopathy, glucose alterations, fat malabsorption, hepatorenal syndrome, and osteopenia, have nutrition implications.

FIGURE 29-4 Clinical manifestations of cirrhosis.

COMPLICATIONS OF ESLD: CAUSE AND NUTRITION TREATMENT

End-stage liver disease can have several physical manifestations including portal hypertension, ascites and edema, hyponatremia, and hepatic encephalopathy. It is important to understand the underlying cause of these complications as well as the medical and nutrition treatment options.

Portal Hypertension

Pathophysiology and Medical Treatment

Portal hypertension increases collateral blood flow and can result in swollen veins (**varices**) in the GIT. These varices often bleed, causing a medical emergency. Treatment includes administration of alpha-adrenergic blockers to decrease heart rate, endoscopic variceal ligation, and radiologic placement of shunts. During an acute bleeding episode, somatostatin or its analog may be administered to decrease bleeding, or a nasogastric tube equipped with an inflatable balloon is placed to alleviate bleeding from vessels.

Medical Nutrition Therapy

During acute bleeding episodes, nutrition cannot be administered enterally; parenteral nutrition (PN) is indicated if a patient will be taking nothing enterally for at least 5 to 7 days (see Chapter 13). Repeated endoscopic therapies may cause esophageal strictures or impair a patient's swallowing. Finally, placement of shunts may

increase the incidence of encephalopathy and reduce nutrient metabolism because blood is shunted past the liver cells.

Ascites

Pathophysiology and Medical Treatment

Fluid retention is common, and **ascites** (accumulation of fluid in the abdominal cavity) is a serious consequence of liver disease. Portal hypertension, hypoalbuminemia, lymphatic obstruction, and renal retention of sodium and fluid contribute to fluid retention. Increased release of catecholamines, renin, angiotensin, aldosterone, and antidiuretic hormone secondary to peripheral arterial vasodilation causes renal retention of sodium and water.

Large-volume paracentesis may be used to relieve ascites. Diuretic therapy often is used and frequently includes spironolactone and furosemide. These drugs often are used in combination for best effect. Major side effects of loop diuretics such as furosemide include hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and hypochloremic acidosis.

Conversely, spironolactone is potassium sparing. Therefore serum potassium levels must be monitored carefully and supplemented or restricted if necessary because deficiency or excess can contribute to metabolic abnormalities. Weight, abdominal girth, urinary sodium concentration, and serum levels of urea nitrogen, creatinine, albumin, uric acid, and electrolytes should be monitored during diuretic therapy.

Medical Nutrition Therapy

Dietary treatment for ascites includes sodium restriction. Sodium commonly is restricted to 2 g/day (see Chapter 33 and Appendix 30 for discussions of low-sodium diets). More severe limitations may be imposed; however, caution is warranted because of limited palatability and the risk of overrestricting sodium. Adequate protein intake is also important to replace losses from frequent paracentesis.

Hyponatremia

Pathophysiology

Hyponatremia often occurs because of decreased ability to excrete water resulting from the persistent release of antidiuretic hormone, sodium losses via paracentesis, excessive diuretic use, or overly aggressive sodium restriction.

Medical Nutrition Therapy

Fluid intake is often restricted to 1 to 1.5 L/day, depending on the severity of the edema and ascites although recent recommendations call for fluid restriction only if the sodium level is less than 125 mg/dl (Runyon, 2013). A moderate sodium intake of about 2000 mg/day should be continued because excessive sodium intake results in worsened fluid retention and the further dilution of serum sodium levels (hyponatremia).

Hepatic Encephalopathy

Pathophysiology and Medical Treatment

Hepatic encephalopathy is a syndrome characterized by impaired mentation, neuromuscular disturbances, and altered consciousness. Gastrointestinal bleeding, fluid and electrolyte abnormalities, uremia, infection, use of sedatives, hyperglycemia or hypoglycemia, alcohol withdrawal, constipation, azotemia, dehydration, portosystemic shunts, and acidosis can precipitate hepatic encephalopathy. Subclinical or minimal hepatic encephalopathy also affects patients with chronic **hepatic failure**. Hepatic or **portal systemic encephalopathy** results in neuromuscular and behavioral alterations. **Box 29-1** describes the four stages of hepatic encephalopathy.

Different theories exist regarding the mechanism by which hepatic encephalopathy occurs. However, one of the most common theories involves ammonia accumulation because it is considered to be an important causal factor in the development of encephalopathy. When the liver fails, it is unable to detoxify ammonia to urea. Ammonia levels are elevated in the brain and bloodstream, leading to impaired neural function through a complex system. The main source of ammonia is its endogenous production by the GIT from the metabolism of protein and from the degradation of bacteria and blood from gastrointestinal bleeding. Exogenous protein is also a source of ammonia. Some clinicians suggest that dietary protein causes an

increase in ammonia levels and subsequently hepatic encephalopathy, but this has not been proven in studies.

Drugs such as lactulose and rifaximin are given to treat hepatic encephalopathy. Lactulose is a nonabsorbable disaccharide. It acidifies the colonic contents, retaining ammonia as the ammonium ion. It also acts as an osmotic laxative to remove the ammonia. Rifaximin is a nonabsorbable antibiotic that helps decrease colonic ammonia production.

One nutrition-related hypothesis is the “altered neurotransmitter theory,” which involves amino acid imbalance. A plasma amino acid imbalance exists in ESLD in which the **branched-chain amino acids (BCAAs)** valine, leucine, and isoleucine are decreased. The BCAAs furnish as much as 30% of energy requirements for skeletal muscle, heart, and brain when gluconeogenesis and ketogenesis are depressed causing serum BCAA levels to fall. **Aromatic amino acids (AAAs)** tryptophan, phenylalanine, and tyrosine, plus methionine, glutamine, asparagine, and histidine are increased. Plasma AAAs and methionine are released into circulation by muscle proteolysis, but the synthesis into protein and liver clearance of AAAs is depressed. This changes the plasma molar ratio of BCAAs to AAAs and has been theorized to contribute to the development of hepatic encephalopathy. Conversely, high levels of AAAs have been theorized to limit the cerebral uptake of BCAAs because they compete for carrier-mediated transport at the blood-brain barrier.

Medical Nutrition Therapy

The outdated practice of protein restriction in patients with low-grade hepatic encephalopathy is based on the premise that protein intolerance causes hepatic encephalopathy, but it has never been proven in a study. True dietary protein intolerance is rare except in fulminant hepatic failure, or in a rare patient with chronic endogenous hepatic encephalopathy. Unnecessary protein restriction may worsen body protein losses and must be avoided. In fact, patients with encephalopathy often do not receive adequate protein. More than 95% of patients with cirrhosis can tolerate mixed-protein diets up to 1.5 g/kg of body weight.

Studies evaluating the benefit of supplements enriched with BCAAs and restricted in AAAs have varied in study design, sample size, composition of formulas, level of encephalopathy, type of liver disease, duration of therapy, and control groups. When high methodological quality studies are evaluated, no significant improvements or survival benefits are associated with giving extra BCAAs to patients.

Other theories postulate that vegetable proteins and casein may improve mental status compared with meat protein. Casein-based diets are lower in AAAs and higher in BCAAs than meat-based diets. Vegetable protein is low in methionine and ammoniagenic amino acids but BCAA rich. The high-fiber content of a vegetable-protein diet also may play a role in the excretion of nitrogenous compounds.

Finally, it has been proposed that probiotics and synbiotics (sources of gut-friendly bacteria and fermentable fibers) can be used to treat hepatic encephalopathy. Probiotics may improve hepatic encephalopathy by reducing ammonia (Pereg et al, 2011) or by preventing production or uptake of lipopolysaccharides in the gut (Gratz et al, 2010). Thus they decrease inflammation and oxidative stress in the hepatocyte (thus increasing hepatic clearance of toxins including ammonia), and minimizing uptake of other toxins.

BOX 29-1 Four Stages of Hepatic Encephalopathy

Stage	Symptoms
I	Mild confusion, agitation, irritability, sleep disturbance, decreased attention
II	Lethargy, disorientation, inappropriate behavior, drowsiness
III	Somnolent but arousable, incomprehensible speech, confused, aggressive behavior when awake
IV	Coma

Glucose Alterations

Pathophysiology

Glucose intolerance occurs in almost two thirds of patients with cirrhosis, and as many as one third of patients develop overt diabetes. Glucose intolerance in patients with liver disease occurs because of insulin resistance in peripheral tissues. Hyperinsulinism also occurs in patients with cirrhosis, possibly because insulin production is increased, hepatic clearance is decreased, portal systemic shunting occurs, there is a defect in the insulin-binding action at the receptor site, or there is a postreceptor defect.

Fasting hypoglycemia, or low blood glucose, can occur because of the decreased availability of glucose from glycogen in addition to the failing gluconeogenic capacity of the liver when the patient has ESLD. Hypoglycemia occurs more often in acute or fulminant liver failure than in chronic liver disease. Hypoglycemia also may occur after alcohol consumption in patients whose glycogen stores are depleted by starvation because of the block of hepatic gluconeogenesis by ethanol.

Medical Nutrition Therapy

Patients with diabetes should receive standard medical and nutrition therapy to achieve normoglycemia (see Chapter 30). Patients with hypoglycemia should eat frequently to prevent this condition (see *Clinical Insight: Fasting Hypoglycemia*). Evening snacks may help prevent morning hypoglycemia.

CLINICAL INSIGHT

Fasting Hypoglycemia

Two thirds of the glucose requirement in an adult is used by the central nervous system. During fasting, plasma glucose concentrations are maintained for use by the nervous system and the brain because liver glycogen is broken down, or new glucose is made from nonglucose precursors such as alanine. Fasting hypoglycemia occurs when there is reduced synthesis of new glucose or reduced liver glycogen breakdown (see Chapter 30).

Causes of fasting hypoglycemia include cirrhosis, consumption of alcohol, extensive intrahepatic cancer, deficiency of cortisol and growth hormone, or non- β -cell tumors of the pancreas (insulinomas). The method for detecting fasting hypoglycemia involves measuring plasma insulin when plasma glucose is low. The diagnostic hallmark of an insulinoma is altered insulin secretion in the presence of hypoglycemia. Fasting hypoglycemia also may be caused by spontaneously produced antibodies to insulin. All patients with liver or pancreatic disease should be monitored for fasting hypoglycemia. Nutrition therapy involves balanced meals with small, frequent snacks to avoid periods of fasting. Monitoring of blood glucose and insulin levels is required.

Fat Malabsorption

Pathophysiology

Fat absorption may be impaired in liver disease. Possible causes include decreased bile salt secretion (as in PBC, sclerosing cholangitis, and biliary strictures), administration of medications such as cholestyramine, and pancreatic enzyme insufficiency. Stools may be greasy, floating, or light- or clay-colored, signifying malabsorption, which can be verified by a 72-hour fecal fat study (see Chapter 28).

Medical Nutrition Therapy

If significant steatorrhea is present, replacement of some of the long-chain triglycerides or dietary fat with medium-chain

triglycerides (MCTs) may be useful. Because MCTs do not require bile salts and micelle formation for absorption, they are readily taken up via the portal route (see Chapter 28). Some nutrition supplements contain MCTs, which can be used in addition to liquid MCT oil (see Chapter 13).

Significant stool fat losses may warrant a trial of a low-fat diet. If diarrhea does not resolve, fat restriction should be discontinued because it decreases the palatability of the diet and severely hampers adequate calorie intake. Because of the degree of malabsorption and steatorrhea, it is important to be suspicious that the patient may have deficiencies of multiple micronutrients especially fat-soluble vitamins.

Renal Insufficiency and Hepatorenal Syndrome

Pathophysiology, Medical, and Nutrition Therapies

Hepatorenal syndrome is renal failure associated with severe liver disease without intrinsic kidney abnormalities. Hepatorenal syndrome is diagnosed when the urine sodium level is less than 10 mEq/L and oliguria persists in the absence of intravascular volume depletion. If conservative therapies, including discontinuation of nephrotoxic drugs, optimization of intravascular volume status, treatment of underlying infection, and monitoring of fluid intake and output fail, dialysis may be required. In any case, renal insufficiency and failure may necessitate alteration in fluid, sodium, potassium, and phosphorus intake (see Chapter 35).

Osteopenia

Pathophysiology

Osteopenia often exists in patients with PBC, sclerosing cholangitis, and alcoholic liver disease. Depressed osteoblastic function and osteoporosis also can occur in patients with hemochromatosis, and osteoporosis is prevalent in patients who have had long-term treatment with corticosteroids. Corticosteroids increase bone resorption; suppress osteoblastic function; and affect sex hormone secretion, intestinal absorption of dietary calcium, renal excretion of calcium and phosphorus, and the vitamin D system.

Medical Nutrition Therapy

Prevention or treatment options for osteopenia include weight maintenance, ingestion of a well-balanced diet, adequate protein to maintain muscle mass, 1500 mg of calcium per day, adequate vitamin D from the diet or supplements, avoidance of alcohol, and monitoring for steatorrhea, with diet adjustments as needed to minimize nutrient losses (see Chapter 24).

NUTRITION ISSUES RELATED TO END-STAGE LIVER DISEASE

Nutrition Assessment

Nutrition assessment must be performed to determine the extent and cause of malnutrition in patients with liver disease. However, many traditional markers of nutrition status are affected by liver disease and its sequelae, making traditional assessment difficult. [Table 29-3](#) summarizes the factors that affect interpretation of nutrition assessment parameters in patients with liver dysfunction.

Objective nutrition assessment parameters that are helpful when monitored serially include anthropometric measurements and dietary intake evaluation (see Chapters 4 and 7). Caution should be taken when assessing biochemical markers

TABLE 29-3 Factors That Affect Interpretation of Objective Nutrition Assessment Parameter in Patients with End-Stage Liver Disease

Parameter	Factors Affecting Interpretation
Body weight	Affected by edema, ascites, and diuretic use
Anthropometric measurements	Questionable sensitivity, specificity, and reliability Multiple sources of error Unknown if skinfold measurements reflect total body fat References do not account for variation in hydration status and skin compressibility
Nitrogen balance studies	Nitrogen is retained in the body in the form of ammonia Hepatorenal syndrome can affect the excretion of nitrogen
Single-frequency bioelectrical impedance	Invalid with ascites and edema

Modified from Hasse J: Nutritional aspects of adult liver transplantation. In Busuttill RW, Klintmalm GB, editors: *Transplantation of the liver*, ed 2, Philadelphia, 2005, Elsevier Saunders.

in the advanced liver disease patient because the typical nutrition criteria will be affected due to the liver disease itself. The best way to perform a nutrition assessment may be to combine these parameters with the subjective global assessment (SGA) approach, which has demonstrated an acceptable level of reliability and validity. The SGA gives a broad perspective, but it is not sensitive to changes in nutrition status. Other available parameters should also be reviewed. The SGA approach is summarized in [Box 29-2](#).

BOX 29-2 Subjective Global Assessment Parameters for Nutrition Evaluation of Liver Disease Patients

History

Weight change (consider fluctuations resulting from ascites and edema)
Appetite
Taste changes and early satiety
Dietary intake (calories, protein, sodium)
Persistent gastrointestinal problems (nausea, vomiting, diarrhea, constipation, difficulty chewing or swallowing)

Physical Findings

Muscle wasting
Fat stores
Ascites or edema

Existing Conditions

Disease state and other problems that could influence nutrition status such as hepatic encephalopathy, gastrointestinal bleeding, renal insufficiency, infection

Nutritional Rating Based on Results

Well nourished
Moderately (or suspected of being) malnourished
Severely malnourished

From Hasse J: Nutritional aspects of adult liver transplantation. In: Busuttill RW, Klintmalm GB, editors: *Transplantation of the liver*, ed 2, Philadelphia, 2005, Elsevier Saunders.

Malnutrition

Moderate to severe malnutrition is a common finding in patients with advanced liver disease (see [Figure 29-5](#)). This is extremely significant, considering that malnutrition plays a major role in the pathogenesis of liver injury and has a profound negative effect on prognosis. The prevalence of malnutrition depends on nutrition assessment parameters used, type and degree of liver disease, and socioeconomic status (see [Appendix 21](#)).

Numerous coexisting factors are involved in the development of malnutrition in liver disease (see [Pathophysiology and Care Management Algorithm: Malnutrition in Liver Disease](#)). Inadequate oral intake, a major contributor, is caused by anorexia, dysgeusia, early satiety, nausea, or vomiting associated with liver disease and the drugs used to treat it. Another cause of inadequate intake is dietary restriction.

Maldigestion and malabsorption also play a role. **Steatorrhea**, presence of fat in the stool, is common in cirrhosis, especially if there is disease involving bile duct injury and obstruction. Medications also may cause specific malabsorptive losses. In addition, altered metabolism secondary to liver dysfunction causes malnutrition in various ways. Micronutrient function is affected by altered storage in the liver, decreased transport by liver-synthesized proteins, and renal losses associated with alcoholic and advanced liver disease. Abnormal macronutrient metabolism and increased energy expenditure also can contribute to malnutrition. Finally, protein losses can occur from large-volume **paracentesis** when several liters of fluid from the abdomen (ascites) are removed through a needle.

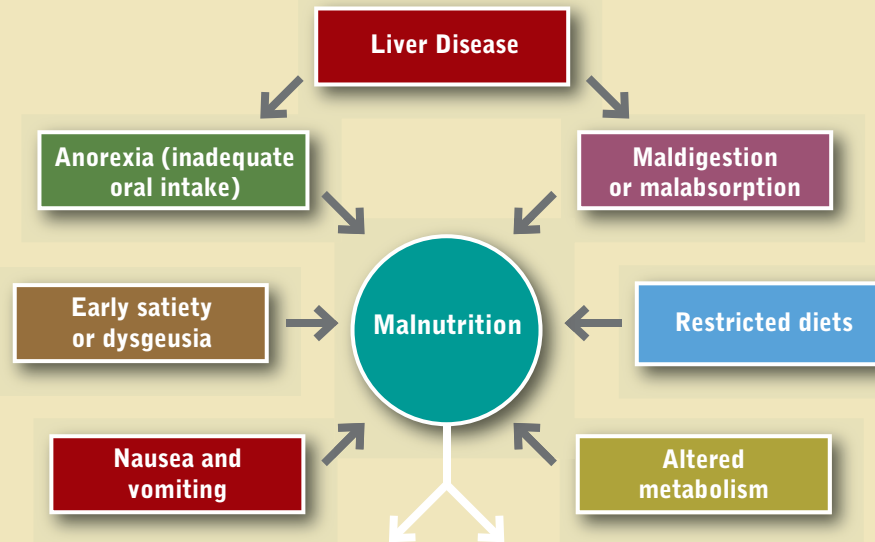

FIGURE 29-5 Severe malnutrition and ascites in a man with end-stage liver disease.

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Malnutrition in Liver Disease

ETIOLOGY

PATHOPHYSIOLOGY

Clinical Findings

- Abnormal liver function tests
- Jaundice
- Ascites and edema
- Hepatic encephalopathy
- Portal hypertension and varices
- Vitamin/mineral deficits
- Glucose intolerance or fasting hypoglycemia

Nutrition Assessment

- Serial monitoring of body weight and anthropometry
- Dietary intake
- Subjective global assessment
- Laboratory tests for nutritional deficiencies such as vitamins, magnesium, iron, and others

MANAGEMENT

Medical Management

- Diuretic therapy
- Medication for encephalopathy (e.g., lactulose, rifaximin)
- Management of portal hypertensive bleeding (e.g., pharmacologic therapy, shunts, banding)
- Monitoring of blood glucose

Nutrition Management

- Increased energy intake via small, frequent meals
- Sodium restriction for fluid retention
- Fluid restriction for hyponatremia
- Carbohydrate-controlled diets for hyperglycemia
- Vitamin and mineral supplements
- Oral liquid supplements or enteral (tube) feeding

Route of Nutrition

Although oral diet is the preferred route of nutrition for patients with ESLD, anorexia, nausea, dysgeusia, and other gastrointestinal symptoms can make adequate nutrition intake difficult to achieve. Early satiety is also a frequent complaint such that smaller, more frequent meals are better tolerated than three large meals. In addition, frequent feedings may also improve nitrogen balance and prevent hypoglycemia. Oral liquid supplements

should be encouraged, and, when necessary, enteral tube feedings used. Adjunctive nutrition support should be given to malnourished patients with liver disease if their intake is suboptimal and if they are at risk for fatal complications from the disease. Tube feeding is preferred over parenteral nutrition and history of varices are usually not a contraindication for tube feeding, provided there is no active bleeding (see *Portal Hypertension Pathophysiology and Medical Treatment*).

Treatment.

Although oral or enteral nutrition support may be necessary in malnourished patients or patients with inadequate nutrient intake, it is important to note that a recent trial and meta-analysis did not find survival benefits with oral or enteral nutrition in patients with cirrhosis (Dupont et al, 2012; Ney et al, 2013). However, study limitations and lack of statistical power preclude any firm conclusions on other benefits of oral or enteral nutrition support in these patients (Ney et al, 2013).

NUTRIENT REQUIREMENTS FOR CIRRHOSIS**Energy**

Energy requirements vary among patients with cirrhosis. Several studies have measured resting energy expenditure (REE) in patients with liver disease to determine energy requirements. Some studies found that patients with ESLD had normal metabolism and that others had hypometabolism or hypermetabolism. Ascites or shunt placement may increase energy expenditure slightly.

In general, energy requirements for patients with ESLD and without ascites are approximately 120% to 140% of the REE. Requirements increase to 150% to 175% of REE if ascites, infection, and malabsorption are present, or if nutritional repletion is necessary. This equates to approximately 25 to 35 calories per kilogram body weight, although needs could be as low as 20 calories per kilogram for obese patients and as high as 40 calories per kilogram for underweight patients (Amodio et al, 2013). Estimated dry body weight or ideal weight should be used in calculations to prevent overfeeding.

Carbohydrate

Determining carbohydrate needs is challenging in liver failure because of the primary role of the liver in carbohydrate metabolism. Liver failure reduces glucose production and peripheral glucose use. The rate of gluconeogenesis is decreased, with preference for lipids and amino acids for energy. Alterations in the hormones insulin, glucagon, cortisol, and epinephrine are responsible in part for the preference for alternative fuels. In addition, insulin resistance can be present with liver dysfunction.

Lipid

In cirrhosis, plasma-free fatty acids, glycerol, and ketone bodies are increased in the fasting state. The body prefers lipids as an energy substrate. Lipolysis is increased with active mobilization of lipid deposits, but the net capacity to store exogenous lipid is not impaired. An average of 30% of calories as fat is sufficient, but additional fat can be given as a concentrated source of calories for those who need additional calories.

Protein

Protein is by far the most controversial nutrient in liver failure, and its management is also the most complex. Cirrhosis has long been thought of as a catabolic disease with increased protein breakdown, inadequate synthesis, depleted status, and muscle wasting. However, protein kinetic studies demonstrate increased nitrogen losses only in patients with fulminant hepatic failure or decompensated disease, but not in stable cirrhosis.

Patients with cirrhosis also have increased protein utilization. Studies suggest that 0.8 g of protein/kg/day is the mean protein requirement to achieve nitrogen balance in stable cirrhosis. Therefore in uncomplicated hepatitis or cirrhosis with or without encephalopathy, protein requirements range from 1 to 1.5 g/kg of ideal weight per day (Amodio et al, 2013).

To promote nitrogen accumulation or positive balance, at least 1.2 to 1.3 g/kg daily is needed. In situations of stress such as alcoholic hepatitis or decompensated disease (sepsis, infection, gastrointestinal bleeding, or severe ascites), at least 1.5 g of protein per kg per day should be provided.

Vitamins and Minerals

Vitamin and mineral supplementation is needed in all patients with ESLD because of the intimate role of the liver in nutrient transport, storage, and metabolism, in addition to the side effects of drugs (see Table 29-4). Vitamin deficiencies can contribute to complications. For example, folate and vitamin B₁₂ deficiencies can lead to macrocytic anemia. Deficiency of pyridoxine, thiamin, or vitamin B₁₂ can result in neuropathy. Confusion, ataxia, and ocular disturbances can result from a thiamin deficiency (Wernicke encephalopathy).

TABLE 29-4 Vitamin and Mineral Deficits in Severe Hepatic Failure

Vitamin or Mineral	Predisposing Factors	Signs of Deficiency (see Appendix 21)
Vitamin A	Steatorrhea, neomycin, cholestyramine, alcoholism	Night blindness, increased infection risk
Vitamin B ₁ (thiamine)	Alcoholism, high-carbohydrate diet	Neuropathy, ascites, edema, central nervous system (CNS) dysfunction
Vitamin B ₃ (niacin)	Alcoholism	Dermatitis, dementia, diarrhea, inflammation of mucous membranes
Vitamin B ₆ (pyridoxine)	Alcoholism	Mucous membrane lesions, seborrheic dermatitis, glossitis, angular stomatitis, blepharitis, peripheral neuropathy, microcytic anemia, depression
Vitamin B ₁₂ (cyanocobalamin)	Alcoholism, cholestyramine	Megaloblastic anemia, glossitis, CNS dysfunction
Folate	Alcoholism	Megaloblastic anemia, glossitis, irritability
Vitamin D	Steatorrhea, glucocorticoids, cholestyramine	Osteomalacia, rickets (in children), possible link to cancer or autoimmune disorders
Vitamin E	Steatorrhea, cholestyramine	Peripheral neuropathy, ataxia, skeletal myopathy, retinopathy, immune system impairment
Vitamin K	Steatorrhea, antibiotics, cholestyramine	Excessive bleeding, bruising
Iron	Chronic bleeding	Stomatitis, microcytic anemia, malaise
Magnesium	Alcoholism, diuretics	Neuromuscular irritability, hypokalemia, hypocalcemia
Phosphorus	Anabolism, alcoholism	Anorexia, weakness, cardiac failure, glucose intolerance
Zinc	Diarrhea, diuretics, alcoholism	Immunodeficiency, impaired taste acuity, delayed wound healing, impaired protein synthesis

Deficiencies of fat-soluble vitamins have been found in all types of liver failure, especially in cholestatic diseases in which malabsorption and steatorrhea occur. Impaired dark adaptation can occur from vitamin A deficiency. Hepatic osteodystrophy or osteopenia can develop from vitamin D deficiency. Therefore supplementation is necessary, and may require using water-miscible forms. Intravenous or intramuscular vitamin K often is given for 3 days to rule out vitamin K deficiency as the cause of a prolonged prothrombin times. Water-soluble vitamin deficiencies associated with liver disease include thiamin (which can lead to Wernicke encephalopathy), pyridoxine (B₆), cyanocobalamin (B₁₂), folate, and niacin (B₃). Large doses (100 mg) of thiamin are given daily for a limited time if deficiency is suspected (see Appendix 22).

Mineral nutriture also is altered in liver disease. Iron stores may be depleted in patients experiencing gastrointestinal bleeding; however, iron supplementation should be avoided by persons with hemochromatosis or hemosiderosis (see Chapter 32). Manganese deposition has been noted to accumulate in brains of patients with cirrhosis leading to impaired motor function and parkinsonism (Butterworth, 2013). Elevated serum copper levels are found in cholestatic liver diseases (i.e., PBC and PSC).

In Wilson's disease, excess copper in various organs causes severe damage. Treatment typically includes administration of oral chelating agents such as D-penicillamine or trientine that release copper from organs where it can be filtered out of the blood and excreted in urine. Zinc acetate can block absorption of copper from food but typically is used with one of the chelating drugs. Dietary copper restriction can be useful during initial therapy. Copper also can be present in water where copper pipes are used. Running tap water for several seconds before using the water can reduce copper concentrations.

Zinc and magnesium levels are low in liver disease related to alcoholism, in part because of diuretic therapy. Calcium, as well as magnesium and zinc, may be malabsorbed with steatorrhea. Therefore the patient should take supplements of these minerals at least at the level of the DRI.

HERBAL SUPPLEMENTS AND LIVER DISEASE

Hepatotoxicity from herbal and dietary supplementation is one of the greatest concerns associated with herbal and dietary supplementation. There are many case reports of different herbal supplements resulting in liver failure. Some of the more commonly known hepatotoxic herbs are included in Box 29-3. However, one recent review lists more than 150 herbal products that have been reported to have caused hepatotoxicity (Teschke et al, 2013). This extensive list emphasizes the gravity of the potential for harm to the liver from herbal products and practitioners should be vigilant in asking patients about supplement usage.

Other dietary products also have been implicated in hepatotoxicity. Among the most common products are some Herbalife products, Hydroxycut, and OxyElite Pro (CDC, 2013; Fong et al, 2010; Jóhannsson et al, 2010; Schoepfer, 2007; Sharma et al, 2010). The most recent event was in 2013 when 56 individuals (43 in Hawaii) taking OxyElite Pro developed acute or fulminant liver failure. Several patients required liver transplantation and at least one patient died (CDC, 2013; Food and Drug Administration [FDA], 2013).

Despite reports of hepatotoxicity with numerous herbal supplements, some herbal supplements have been investigated

BOX 29-3 Selected Herbal Supplements Associated with Hepatotoxicity

Baikal skullcap (*Scutellaria*)
 Chaparral (*Larrea tridentate*)
 Pyrrolizidine alkaloids
 Comfrey (*Symphytum*)
Heliotropium
 Crotalaria
 Germander (*Teucrium chamaedrys*)
 Greater celandine (*Chelidonium majus*)
 Saw palmetto (*Serenoa repens*)
 Noni juice (*Morinda citrifolia*)
 Margosa oil (*Antelaea azadirachta*)
 Aloe vera
 Black cohosh (*Actea racemosa* or *Actea cimicifuga*)
 LipoKinetix (usnic acid)
Atractylis gummifera
 Impila (*Callilepis laureola*)
 Mistletoe (*Viscum album*)
 Valerian (*Valerian officinalis*)
 Senna (*Cassia angustifolia*)
 Pennyroyal (squawmint oil)
 Kava (*Piper methysticum*)
Liatrix callilepis
 Green tea extract (*Camellia sinensis*)
 Cascara sagrada
 OxyElite Pro
 Chinese herbal medicines
 Jin Bu Huan (*Lycopodium serratum*)
 Ma Huang (*Ephedra sinica*)
 Dai-saiko-to (*Sho-saiko-to*)
 Hydroxycut
 Herbalife supplements
 Ayurvedic herbal products

LipoKinetix (Syntrax Innovations, Inc, Cape Girardeau, MO), OxyElite Pro (USP Labs, LLC, Dallas, TX), Hydroxycut (Iovate Health Sciences USA, Inc, Blasdel, NY), Herbalife supplements (Herbalife International of America, Inc, Los Angeles, CA).

for benefits on liver disease. S-adenosyl-L-methionine (SAME) is a complementary medicine product sometimes suggested for use with liver disease. It is purported to act as a methyl donor for methylation reactions and participates in glutathione (an antioxidant) synthesis. A Cochrane review did not find beneficial effects for SAME in patients with alcoholic liver disease (Rambaldi and Gluud, 2006). Betaine has been evaluated for treatment of NASH. Although there is theoretical promise, there is a lack of strong evidence for benefit (Abdelmalek et al, 2009; Mukherjee, 2011).

Milk thistle appears to be the most popular and extensively studied herbal supplement for liver disease. The active component in milk thistle is silymarin with silybin (constituting 50% to 70% of silymarin) believed to have the most biologic activity. Milk thistle is proposed to reduce free radical production and lipid peroxidation associated with hepatotoxicity as well as block the binding of toxins to hepatocytes (Abenavoli, 2010). Milk thistle has been evaluated for viral hepatitis, alcoholic liver disease, and toxin-induced liver disease; its use also is being explored for treatment of NAFLD. Despite its popularity and widespread use, a clear consensus is lacking as to a beneficial effect of milk thistle on liver disease. However, data are not sufficient to suggest that it is unsafe or toxic for patients with liver disease.

LIVER RESECTION AND TRANSPLANTATION

As with any major surgery, protein and energy needs increase after liver resection. Needs also are increased for liver cell regeneration. Enteral tube feeding (EN) can be beneficial by providing portal hepatotropic factors necessary for liver cell proliferation. Optimal nutrition is most important for patients with poor nutrition status before hepatectomy (e.g., patients with hepatocellular carcinoma or cholangiocarcinoma).

Liver transplantation has become an established treatment for ESLD. Malnutrition is common in liver transplant candidates. Dietary intake often can be enhanced if patients eat small, frequent, nutrient-dense meals, and oral nutritional supplements also may be well tolerated. EN is indicated when oral intake is inadequate or contraindicated. Varices are not an absolute contraindication for placement of a feeding tube. Because PN can affect liver function adversely, EN is preferred. PN is reserved for patients without adequate gut function (see Chapter 13).

In the acute posttransplant phase, nutrient needs are increased to promote healing, deter infection, provide energy for recovery, and replenish depleted body stores. Nitrogen requirements are elevated in the acute posttransplant phase and can be met with early postoperative tube feeding. Early postoperative tube feeding has been associated with reduced infections in liver transplant recipients (Hasse et al, 1995; Ikegami et al, 2012). Administration of probiotics and fiber with tube feeding may reduce postoperative infection rate better than tube feeding or fiber alone (Raves et al, 2005).

Multiple medications used after transplant have nutritional side effects such as anorexia, gastrointestinal upset, hypercatabolism, diarrhea, hyperglycemia, hyperlipidemia, sodium

retention, hypertension, hyperkalemia, and hypercalciuria. Therefore dietary modification is based on the specific side effects of drug therapy (see Table 29-5). During the posttransplant phase, nutrient requirements are adjusted to prevent or treat problems of obesity, hyperlipidemia, hypertension, diabetes mellitus, and osteopenia. Table 29-6 summarizes nutrient needs after liver transplantation.

PHYSIOLOGY AND FUNCTIONS OF THE GALLBLADDER

The gallbladder lies on the undersurface of the right lobe of the liver (see Figure 29-6). The main function of the gallbladder is to concentrate, store, and excrete bile, which is produced by the liver. During the concentration process, water and electrolytes are resorbed by the gallbladder mucosa. Bile is composed of bile salts and excretory endogenous and exogenous compounds. Other components include fatty acids, cholesterol, phospholipids, bilirubin, protein and other compounds. Bile salts are made by liver cells from cholesterol and are essential for the digestion and absorption of fats, fat-soluble vitamins, and some minerals (see Chapter 1). Bilirubin, the main bile pigment, is derived from the release of hemoglobin from red blood cell destruction. It is transported to the liver, where it is conjugated and excreted via bile.

The primary transporter responsible for bile salt secretion is the bile salt export pump (BSEP). Overall, bile salts play a key role in a wide range of physiologic and pathophysiologic processes (Lam et al, 2010). Excreted into the small intestine via bile, bile salts are later resorbed into the portal system (enterohepatic circulation). This is the primary excretory pathway for the minerals copper and manganese.

TABLE 29-5 Drugs Commonly Used After Liver Transplantation

Immunosuppressant Drug	Possible Nutritional Side Effects	Proposed Nutrition Therapy
Azathioprine	Macrocytic anemia Mouth sores Nausea, vomiting, diarrhea, anorexia, sore throat, stomach pain, decreased taste acuity	Give folate supplements. Adjust food and meals as needed; monitor intake.
Antithymocyte globulin (ATG), lymphocyte immune globulin	Nausea, vomiting	Adjust food and meals as needed; monitor intake.
Cyclosporine	Sodium retention Hyperkalemia Hyperlipidemia Hyperglycemia Decreased serum magnesium level Hypertension	Decrease sodium intake. Decrease potassium intake. Limit fat and simple carbohydrate intake. Decrease simple carbohydrate intake. Increase magnesium intake; give supplements. Limit sodium intake.
Glucocorticoids	Nausea, vomiting Sodium retention Hyperglycemia Hyperlipidemia False hunger Protein wasting with high doses Decreased absorption of calcium and phosphorus	Adjust food and meals as needed; monitor intake. Decrease sodium intake. Decrease simple carbohydrate intake. Limit fat and simple carbohydrate intake. Avoid overeating. Increase protein intake. Increase calcium and phosphorus intake; give supplements as needed.
Mycophenolate mofetil, mycophenolic acid	Nausea, vomiting, diarrhea	Adjust food and meals as needed; monitor intake.
Sirolimus	Possible GI symptoms Hyperlipidemia	Adjust food and meals as needed; monitor intake. Limit fat and simple carbohydrate intake.
Tacrolimus	Hyperglycemia Hyperkalemia Nausea, vomiting	Decrease simple carbohydrate intake. Decrease potassium intake. Adjust food and meals as needed; monitor intake.

GI, Gastrointestinal.

TABLE 29-6 General Nutrient Requirements for Liver Transplant Patients

	Pretransplantation	Immediate Posttransplantation (First 2 Posttransplant Months)	Long-Term Posttransplantation
Protein	Dependent on nutrition status and medical condition but usually 1-1.5 g/kg	Dependent on nutrition status, medical condition, and dialysis requirement but usually 1.2-1.75 g/kg	Maintenance – about 1 g/kg
Calories	Dependent on nutrition status and losses; usually 20%-50% above basal	Dependent on nutrition status and metabolic stress but usually 20%-30% above basal	Dependent on activity and weight goals; usually 20% above basal for sedentary activity if at goal weight
Fat	As needed	Approximately 30% of calories	Moderate fat (30% of calories)
Carbohydrate	Reduced carbohydrate if diabetes or obesity present	Reduced carbohydrate if diabetes present	Reduced simple carbohydrate, especially if diabetes or obesity present
Sodium	2 g/day	2 g/day (as indicated)	2 g/day (as indicated)
Fluid	Restrict to 1000-1500 mL/day (if hyponatremic)	As needed	As needed
Calcium	800-1200 mg/day	800-1200 mg/day	1200-1500 mg/day
Vitamins	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels; additional water- and fat-soluble vitamins as indicated	Multivitamin/mineral supplementation to DRI levels

DRI, Dietary reference intake.

*Use estimated dry or ideal weight.

Bile contains immunoglobulins that support the integrity of the intestinal mucosa. Fibroblast growth factor receptor (FGFR4) controls bile acid metabolism and protects the liver from fibrosis; FGFR1 and FGFR2 assist in regeneration of the liver (Böhm et al, 2010). Molecular crosstalk between bile acid-activated nuclear receptors and proinflammatory nuclear mediators provides new understanding of inflammation-induced cholestasis (Kosters and Karpén, 2010; Lam et al, 2010).

Bile is removed by the liver via bile canaliculi that drain into intrahepatic bile ducts. The ducts lead to the left and right hepatic ducts, which leave the liver and join to become the common hepatic duct. The bile is directed to the gallbladder via the cystic duct for concentration and storage. The cystic duct joins

the common hepatic duct to form the common bile duct. The bile duct then joins the pancreatic duct, which carries digestive enzymes.

During the course of digestion, food reaches the duodenum, causing the release of intestinal hormones such as cholecystikinin (CCK) and secretin. This stimulates the gallbladder and pancreas and causes the sphincter of Oddi to relax, allowing pancreatic juice and bile to flow into the duodenum at the ampulla of Vater to assist in fat digestion. For this reason diseases of the gallbladder, liver, and pancreas often are interrelated.

DISEASES OF THE GALLBLADDER

Disorders of the biliary tract affect millions of people each year, causing significant suffering and even death by precipitating pancreatitis and sepsis. A diverse spectrum of disease affects the biliary system, often presenting with similar clinical signs and symptoms. Treatment may involve diet, medication, or surgery.

Cholestasis

Pathophysiology and Medical Management

Cholestasis is a condition in which little or no bile is secreted or the flow of bile into the digestive tract is obstructed. This can occur in patients without oral or enteral feeding for a prolonged period, such as those requiring PN, and can predispose to acalculous **cholecystitis**. BSEP deficiency results in several different genetic forms of cholestasis and acquired forms of cholestasis such as drug-induced cholestasis and intrahepatic cholestasis of pregnancy (Lam et al, 2010). Prevention of cholestasis requires stimulation of biliary motility and secretions by at least minimum enteral feedings. If this is not possible, drug therapy is used.

Cholelithiasis

Pathophysiology

The formation of gallstones (**calculi**) is **cholelithiasis**. Virtually all gallstones form within the gallbladder. Gallstone disease affects millions of Americans each year and causes significant morbidity. In most cases gallstones are asymptomatic. Gallstones that pass from the gallbladder into the common bile duct

FIGURE 29-6 Schematic drawing showing relationship of organs of the upper abdomen. **A**, Liver (retracted upward); **B**, gallbladder; **C**, esophageal opening of stomach; **D**, stomach (shown in dotted outline); **E**, common bile duct; **F**, duodenum; **G**, pancreas and pancreatic duct; **H**, spleen; **I**, kidneys. (Courtesy Cleveland Clinic, Cleveland, Ohio, 2002.)

may remain there indefinitely without causing symptoms, or they may pass into the duodenum with or without symptoms.

Cholelithiasis develops when stones slip into the bile ducts, producing obstruction, pain, and cramps. If passage of bile into the duodenum is interrupted, **cholecystitis** can develop. In the absence of bile in the intestine, lipid absorption is impaired, and without bile pigments, stools become light in color (acholic). If uncorrected, bile backup can result in jaundice and liver damage (**secondary biliary cirrhosis**). Obstruction of the distal common bile duct can lead to pancreatitis if the pancreatic duct is blocked.

Most gallstones are unpigmented cholesterol stones composed primarily of cholesterol, bilirubin, and calcium salts. Bacteria also play a role in gallstone formation. Low-grade chronic infections produce changes in the gallbladder mucosa, which affect its absorptive capabilities. Excess water or bile acid may be absorbed as a result. Cholesterol may then precipitate out and cause gallstones (Völzke et al, 2005).

High dietary fat intake over a prolonged period may predispose a person to gallstone formation because of the constant stimulus to produce more cholesterol for bile synthesis required in fat digestion. Rapid weight loss (as with jejunoileal and gastric bypass and fasting or severe calorie restriction) is associated with a high incidence of biliary sludge and gallstone formation. Indeed, cholelithiasis and fatty liver disease share risk factors, including central obesity, insulin resistance, and diabetes (Koller et al, 2012; Weikert et al, 2010).

Risk factors for cholesterol stone formation include female gender, pregnancy, older age, family history, obesity and truncal body fat distribution, diabetes mellitus, inflammatory bowel disease, and drugs (lipid-lowering medications, oral contraceptives, and estrogens). Certain ethnic groups are at greater risk of stone formation, including Pima Indians, Scandinavians, and Mexican Americans. In addition, approximately 30% of individuals with cirrhosis have gallstones (Acalovschi, 2014).

Pigmented stones typically consist of bilirubin polymers or calcium salts. They are associated with chronic hemolysis. Risk factors associated with these stones are age, sickle cell anemia and thalassemia, biliary tract infection, cirrhosis, alcoholism, and long-term PN.

Medical and Surgical Management

Cholecystectomy is surgical removal of the gallbladder, especially if the stones are numerous, large, or calcified. The cholecystectomy may be performed as a traditional open laparotomy or as a less invasive laparoscopic procedure.

Chemical dissolution with the administration of bile salts, chenodeoxycholic acid, and ursodeoxycholic acid (litholytic therapy) or dissolution by extracorporeal shockwave lithotripsy may also be used less often than surgical techniques. Patients with gallstones that have migrated into the bile ducts may be candidates for endoscopic retrograde cholangiopancreatography techniques.

Medical Nutrition Therapy

Gallstones are more prevalent in low-fiber, high-fat, westernized diets. Consumption of large amounts of animal protein and animal fat, especially saturated fat, and a lack of dietary fiber, promote gallstone development.

There also may be some benefit in replacing simple sugars and refined starches with high-fiber carbohydrates. Individuals consuming refined carbohydrates have a 60% greater risk for

developing gallstones, compared with those who consumed the most fiber, in particular insoluble fiber (Mendez-Sanchez et al, 2007). Thus plant-based diets may reduce the risk of cholelithiasis. Vegetarian diets are high in fiber and low in fat, consisting primarily of unsaturated fat. Vitamin C, which is generally high in vegetarian diets, affects the rate-limiting step in the catabolism of cholesterol to bile acids and inversely is related to the risk of gallstones in women.

Weight cycling (repeatedly losing and regaining weight), fasting, and very-low-calorie diets increase the likelihood of cholelithiasis. Along with weight reduction, some evidence indicates that physical activity reduces the risk of cholecystitis. In cholecystitis, MNT includes a high-fiber, low-fat, plant-based diet to prevent gallbladder contractions. Data are conflicting as to whether intravenous lipids stimulate gallbladder contraction.

After surgical removal of the gallbladder, oral feedings can be advanced to a regular diet as tolerated. In the absence of the gallbladder, bile is secreted directly by the liver into the intestine. The biliary tract dilates, forming a “simulated pouch” over time to allow bile to be held in a manner similar to the original gallbladder.

Cholecystitis Pathophysiology

Inflammation of the gallbladder is known as **cholecystitis**, and it may be chronic or acute. It usually is caused by gallstones obstructing the bile ducts (calculous cholecystitis), leading to the backup of bile. Bilirubin, the main bile pigment, gives bile its greenish color. When biliary tract obstruction prevents bile from reaching the intestine, it backs up and returns to the circulation. Bilirubin has an affinity for elastic tissues (such as the eye and the skin); therefore when it overflows into the general circulation, it causes the yellow skin pigmentation and eye discoloration typical of **jaundice**.

Acute cholecystitis without stones (acalculous cholecystitis) may occur in critically ill patients or when the gallbladder and its bile are stagnant. Impaired gallbladder emptying in chronic acalculous cholecystitis appears to be due to diminished spontaneous contractile activity and decreased contractile responsiveness to cholecystokinin (CCK). The walls of the gallbladder become inflamed and distended, and infection can occur. During such episodes, the patient experiences upper-quadrant abdominal pain accompanied by nausea, vomiting, and flatulence.

Chronic cholecystitis is longstanding inflammation of the gallbladder. It is caused by repeated, mild attacks of acute cholecystitis. This leads to thickening of the walls of the gallbladder. The gallbladder begins to shrink and eventually loses the ability to perform its function: concentrating and storing bile. Eating foods that are high in fat may aggravate the symptoms of cholecystitis, because bile is needed to digest such foods. Chronic cholecystitis occurs more often in women than in men, and the incidence increases after the age of 40. Risk factors include the presence of gallstones and a history of acute cholecystitis.

Surgical Management

Acute cholecystitis requires surgical intervention unless medically contraindicated. Without surgery, the condition may either subside or progress to gangrene.

Medical Nutrition Therapy

Acute Cholecystitis In an acute attack, oral feedings are discontinued. PN may be indicated if the patient is malnourished and it

is anticipated that he or she will not be taking anything orally for a prolonged period. When feedings are resumed, a low-fat diet is recommended to decrease gallbladder stimulation. A hydrolyzed low-fat formula or an oral low-fat diet consisting of 30 to 45 g of fat per day can be given. Table 29-7 shows a fat-restricted diet.

After cholecystectomy, patients may experience symptoms of gastritis secondary to duodenogastric reflux of bile acids.

The reflux also may be responsible for symptoms in this **postcholecystectomy syndrome**. At present, there are no well-established pharmacologic approaches in the management of postcholecystectomy gastritis. The symptoms are not caused, but exacerbated, by the cholecystectomy. The addition of soluble fiber to the diet may act as a sequestering agent and bind the bile in the stomach between meals to avoid gastritis.

TABLE 29-7 Fat-Restricted Diet*

Food Allowed	Food Excluded
<p>Beverages Skim milk or buttermilk made with skim milk; coffee, tea, Postum, fruit juice, soft drinks, cocoa made with cocoa powder and skim milk</p>	Whole milk, buttermilk made with whole milk, chocolate milk, cream in excess of amounts allowed under fats
<p>Bread and Cereal Products Plain, nonfat cereals; spaghetti, noodles, rice, macaroni; plain whole grain or enriched breads, air-popped popcorn, bagels, English muffins</p>	Biscuits, breads, egg or cheese bread, sweet rolls made with fat; pancakes, doughnuts, waffles, fritters, popcorn prepared with fat; muffins, natural cereals and breads to which extra fat is added
<p>Cheese Fat-free or low-fat cottage cheese, $\frac{1}{4}$ c to be used as substitute for 1 oz of cheese, or low-fat cheeses containing less than 5% butterfat</p>	Whole-milk cheeses
<p>Desserts Sherbet made with skim milk; nonfat frozen yogurt; nonfat frozen non-dairy desserts; fruit ice; sorbet; gelatin; rice, bread, cornstarch, tapioca, or pudding made with skim milk; fruit whips with gelatin, sugar, and egg white; fruit; angel food cake; graham crackers; vanilla wafers; meringues</p>	Cake, pie, pastry, ice cream, or any dessert containing shortening, chocolate, or fats of any kind, unless especially prepared using part of fat allowance
<p>Eggs Three per week prepared only with fat from fat allowance; egg whites as desired; low-fat egg substitutes</p>	More than one/day unless substituted for part of the meat allowed
<p>Fats Choose up to the limit allowed among the following (1 serving in the amount listed equals 1 fat choice): 1 tsp butter or margarine 1 Tbsp reduced-fat margarine 1 tsp shortening or oil 1 tsp mayonnaise 2 tsp Italian or French dressing 1 Tbsp reduced-fat salad dressing 1 strip crisp bacon $\frac{1}{8}$ avocado (4-inch diameter) 2 Tbsp light cream 1 Tbsp heavy cream 6 small nuts 5 small olives</p>	Any in excess of amount prescribed on diet; all others
<p>Fruits As desired</p>	Avocado in excess of amount allowed on fat list
<p>Lean Meat, Fish, Poultry, and Meat Substitutes Choose up to the limit allowed among the following: poultry without skin, fish, veal (all cuts), liver, lean beef, pork, and lamb, all with visible fat removed—1 oz cooked weight equals 1 equivalent; $\frac{1}{4}$ c water packed tuna or salmon equals 1 equivalent; tofu or tempeh—3 oz equals 1 equivalent</p>	Fried or fatty meats, sausage, scrapple, frankfurters, poultry skins, stewing hens, spareribs, salt pork, beef unless lean, duck, goose, ham hocks, pig's feet, luncheon meats (unless reduced fat), gravies unless fat-free, tuna and salmon packed in oil, peanut butter
<p>Milk Skim, buttermilk, or yogurt made from skim milk</p>	Whole, 2%, 1%, chocolate, buttermilk made with whole milk
<p>Seasonings As desired</p>	None

TABLE 29-7 Fat-Restricted Diet—cont'd

Food Allowed	Food Excluded	
<p>Soups Bouillon, clear broth, fat-free vegetable soup, cream soup made with skim milk, packaged dehydrated soups</p> <p>Sweets Jelly, jam, marmalade, honey, syrup, molasses, sugar, hard sugar candies, fondant, gumdrops, jelly beans, marshmallows, cocoa powder, fat-free chocolate sauce, red and black licorice</p> <p>Vegetables All plainly prepared vegetables</p>	<p>All others</p> <p>Any candy made with chocolate, nuts, butter, cream, or fat of any kind</p> <p>Potato chips; buttered, au gratin, creamed, or fried potatoes and other vegetables unless made with allowed fat; casseroles or frozen vegetables in butter sauce</p>	
Daily Food Allowances for 40-g-Fat Diet		
Food	Amount	Approximate Fat Content (g)
Skim milk	2 c or more	0
Lean meat, fish, poultry	6 oz or 6 equivalents	18
Whole egg or egg yolks	3 per week	2
Vegetables	3 servings or more, at least 1 or more dark green or deep yellow	0
Fruits	3 or more servings, at least 1 citrus	0
Breads, cereals	As desired, fat-free	0
Fat exchanges*	4-5 exchanges daily	20-25
Desserts and sweets	As desired from permitted list	0
	Total Fat	38-43

* Fat content can be reduced further by reducing the fat exchanges. 1 Fat exchange = 5 g of fat.

Chronic Cholecystitis. Patients with chronic conditions may require a long-term, low-fat diet that contains 25% to 30% of total kilocalories as fat (see Table 29-7). Stricter limitation is undesirable because fat in the intestine is important for some stimulation and drainage of the biliary tract. The degree of food intolerance varies widely among persons with gallbladder disorders; many complain of foods that cause flatulence and bloating. For this reason it is best to determine with the patient which foods should be eliminated (see Chapter 28 for a discussion of potential gas-forming foods). Administration of water-soluble forms of fat-soluble vitamins may be of benefit in patients with chronic gallbladder conditions or in those in whom fat malabsorption is suspected.

Cholangitis

Pathophysiology and Medical Management

Inflammation of the bile ducts is known as **cholangitis**. Patients with acute cholangitis need resuscitation with fluids and broad-spectrum antibiotics. If the patient does not improve with conservative treatment, placement of a percutaneous biliary stent or cholecystectomy may be needed.

Sclerosing cholangitis can result in sepsis and liver failure. Most patients have multiple intrahepatic strictures, which makes surgical intervention difficult, if not impossible. Patients are generally on broad-spectrum antibiotics. Percutaneous ductal dilation may provide short-term bile duct patency in some patients. When sepsis is recurrent, patients may require chronic antibiotic therapy (see **Primary Sclerosing Cholangitis**).

COMPLEMENTARY AND INTEGRATIVE MEDICINE

Patients often seek complementary and integrative approaches to disease of the gallbladder, including various nutritional

supplements, herbal medications, and gallbladder flushes. Vitamin C deficiency has been linked to gallstone formation in animals models (Jenkins, 1978). The data in humans are limited but vitamin C supplementation has been associated with a decreased risk of gallstones in postmenopausal women who consume alcohol (Simon et al, 1998). Vitamin E has been shown to limit gallstone formation in hamsters provided with a high-fat diet (Christensen et al, 1953).

Choleretic herbs such as milk thistle, dandelion root, artichoke, turmeric, greater celandine, and Oregon grape stimulate bile flow and reduce the amount of cholesterol in bile. However, no trials in humans show benefit. Some integrative practitioners may prescribe gallbladder flushes that typically include olive oil, herbs, and fruit juice. The belief is that the monosaturated fat in olive oil may stimulate gallbladder contraction and improve bile flow. However, this has not been validated clinically and actually may trigger attacks of gallbladder pain.

PHYSIOLOGY AND FUNCTIONS OF THE EXOCRINE PANCREAS

The pancreas is an elongated, flattened gland that lies in the upper abdomen behind the stomach. The head of the pancreas is in the right upper quadrant below the liver within the curvature of the duodenum, and the tapering tail slants upward to the hilum of the spleen (see Figure 29-6). This glandular organ has an endocrine and exocrine function. Pancreatic cells manufacture glucagon, insulin, and somatostatin for absorption into the bloodstream (endocrine function) for regulation of glucose homeostasis (see Chapter 30). Other cells secrete enzymes and other substances directly into the intestinal lumen, where they aid in digesting proteins, fats, and carbohydrates (exocrine function).

In most people the pancreatic duct, which carries the exocrine pancreatic secretions, merges with the common bile duct into a unified opening through which bile and pancreatic juices drain into the duodenum at the ampulla of Vater. Many factors regulate exocrine secretion from the pancreas. Neural and hormonal responses play a role, with the presence and composition of ingested foods being a large contributor. The two primary hormonal stimuli for pancreatic secretion are secretin and CCK (see Chapter 1).

Factors that influence pancreatic secretions during a meal can be divided into three phases: (1) the cephalic phase, mediated through the vagus nerve and initiated by the sight, smell, taste, and anticipation of food that leads to the secretion of bicarbonate and pancreatic enzymes; (2) gastric distention with food initiates the gastric phase of pancreatic secretion, which stimulates enzyme secretion; and (3) the intestinal phase, mediated by the release of CCK, with the most potent effect.

DISEASES OF THE EXOCRINE PANCREAS

Pancreatitis

Pathophysiology and Medical Management

Pancreatitis is an inflammation of the pancreas and is characterized by edema, cellular exudate, and fat necrosis. The disease can range from mild and self-limiting to severe, with autodigestion, necrosis, and hemorrhage of pancreatic tissue. [Ranson and colleagues \(1974\)](#) identified 11 signs that could be measured during the first 48 hours of admission and that have prognostic significance (see [Box 29-4](#)). By using these observations, one can determine the likely outcome of hospitalization. Surgical intervention may be necessary. Pancreatitis is classified as either acute or chronic, the latter with pancreatic destruction so extensive that exocrine and endocrine function are severely diminished, and maldigestion and diabetes may result.

The symptoms of pancreatitis can range from continuous or intermittent pain of varying intensity to severe upper abdominal pain, which may radiate to the back. Symptoms may worsen with the ingestion of food. Clinical presentation also may include nausea, vomiting, abdominal distention, and steatorrhea. Severe cases are complicated by hypotension, oliguria, and dyspnea. There is extensive destruction of pancreatic tissue with

subsequent fibrosis, enzyme production is diminished, and serum amylase and lipase may appear normal. However, absence of enzymes to aid in the digestion of food leads to steatorrhea and malabsorption. [Table 29-8](#) describes several tests used to determine the extent of pancreatic destruction.

Medical Nutrition Therapy

Alcohol use, smoking, body weight, diet, genetic factors, and medications affect the risk of developing pancreatitis. Thus diet modification has an important role after diagnosis. Dietary recommendations differ, depending on whether the condition is acute or chronic. Obesity appears to be a risk factor for the development of pancreatitis and for increased severity ([Martinez J et al, 2004](#)).

Depressed serum calcium levels are common. Hypoalbuminemia occurs, with subsequent third spacing of fluid. The calcium, which is bound to albumin, is thus affected and may appear artificially low. Another occurrence is “soap” formation in the gut by calcium and fatty acids, created by the fat necrosis that results in less calcium absorption. Checking an ionized calcium level is a method of determining available calcium.

Acute Pancreatitis. Pain associated with acute pancreatitis (AP) is partially related to the secretory mechanisms of pancreatic enzymes and bile. Therefore nutrition therapy is adjusted to provide minimum stimulation of these systems (see [Pathophysiology and Care Management Algorithm: Pancreatitis](#)). The basis for nutrition therapy is to put the pancreas “at rest.” In less severe attacks, a clear liquid diet with negligible fat may be given once abdominal pain is decreasing and inflammatory markers are improving, generally within a few days ([International Association of Pancreatology \[IAP\], American Pancreatic Association \[APA\], 2013](#)). Several recent randomized controlled trials demonstrated that starting these patients on a low-fat diet is as safe as a clear liquid diet, with varying effect on length of hospital stay ([Jacobson BC et al, 2007; Moraes et al, 2010; Rajkumar et al, 2013; Sathiaraj et al, 2008; Teich N et al, 2010](#)). The patient should be monitored for any symptoms of pain, nausea, or vomiting. The diet should be progressed as tolerated to easily digested foods with a low fat content with more fat added as tolerated. Foods may be better tolerated if they are divided into six small meals (see [Table 29-7](#)).

BOX 29-4 Ranson’s Criteria to Classify the Severity of Pancreatitis

At Admission or Diagnosis

Age >55 yr
White blood cell count >16,000 m³
Blood glucose level >200 mg/100 mL
Lactic dehydrogenase >350 units/L
Aspartate transaminase >250 units/L

During the Initial 48 Hours

Hematocrit decrease of >10%
Blood urea nitrogen increase of >5 mg/dL
Arterial Po₂ <60 mm Hg
Base deficit >4 mEq/L
Fluid sequestration >6000 mL
Serum calcium level <8 mg/mL

Modified from [Ranson JH et al](#): Prognostic signs and the role of operative management in acute pancreatitis, *Surg Gynecol Obstet* 139:69, 1974.

TABLE 29-8 Some Tests of Pancreatic Function

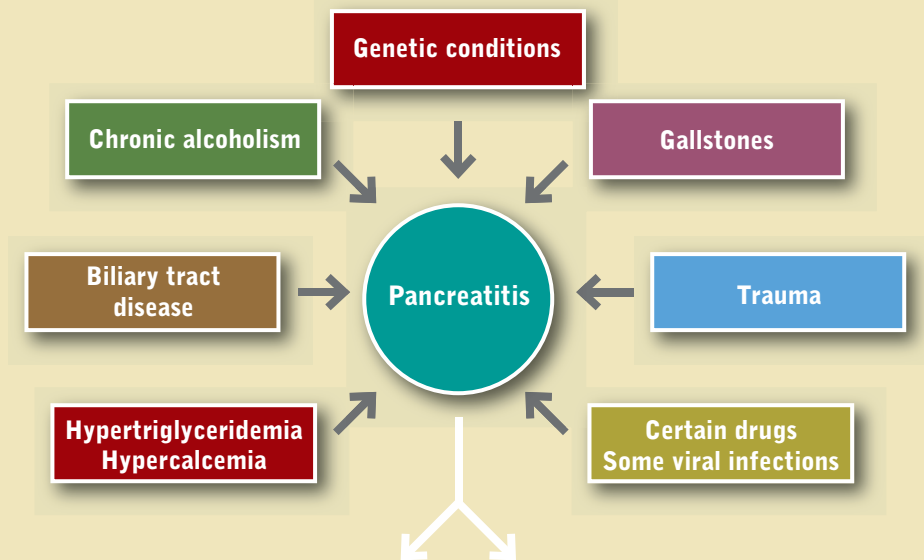

Test	Significance
Secretin stimulation test	Measures pancreatic secretion, particularly bicarbonate, in response to secretin stimulation
Glucose tolerance test	Assesses endocrine function of the pancreas by measuring insulin response to a glucose load
72-hr stool fat test	Assesses exocrine function of the pancreas by measuring fat absorption that reflects pancreatic lipase secretion
Fecal elastase	Enzyme most commonly used to determine pancreatic function; indirect test. Levels >200 mcg/g are considered normal; concentration <15 mcg/g of feces consistent with pancreatic exocrine insufficiency

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Pancreatitis

ETIOLOGY

PATHOPHYSIOLOGY

Diagnosis

I: Apply Ranson’s criteria
 II: Tests of pancreatic function
 Secretin stimulation test
 Glucose tolerance test
 72-hour stool fat test
 Fecal elastase

Clinical Findings

Symptoms:

- Abdominal pain and distention
- Nausea
- Vomiting
- Steatorrhea

In severe form:

- Hypotension
- Oliguria
- Dyspnea

MANAGEMENT

Medical Management

Acute:

- Withhold oral feeding
- Give IV fluids
- Administer H₂-receptor antagonists, somatostatin

Chronic:

- Manage intestinal pH with:
 - Antacids
 - H₂-receptor antagonists
 - Proton pump inhibitors
- Administer insulin for glucose intolerance

Nutrition Management

Acute:

- Withhold oral and enteral feeding
- Support with IV fluids
- If oral nutrition cannot be initiated in 5 to 7 days, start tube feeding
- Once oral nutrition is started, provide
 - Easily digestible foods
 - Low-fat diet
 - 6 small meals
 - Adequate protein intake
 - Increased calories

Chronic:

- Provide oral diet as in acute phase
- TF can be used when oral diet is inadequate or as a treatment to reduce pain
- Supplement pancreatic enzymes
- Supplement fat-soluble vitamins and vitamin B₁₂

Severe acute pancreatitis (SAP) results in a hypermetabolic, catabolic state with immediate metabolic alterations in the pancreas and also in remote organs. Metabolic demands are similar to those of sepsis. Amino acids are released from muscle and used for gluconeogenesis. These patients often exhibit signs of stress-induced malnutrition such as decreased serum levels of albumin, transferrin, and lymphocytes reflecting the inflammatory response (see Chapter 3). SAP is associated with significant morbidity and mortality. These patients often develop complications such as fluid collections, pseudocysts, pancreatic necrosis, and infection or multisystem organ failure.

The optimal route and timing of nutrition in SAP has been the subject of much controversy. PN and EN are equally effective in terms of days to normalization of serum amylase and serum albumin levels, days to resumption of oral feeding, days to clear nosocomial infections, and the clinical outcome in patients with mild to moderate pancreatitis (Petrov et al, 2009; Wu et al, 2014). The favorable effect of either EN or PN on patient outcome may be enhanced by supplementation with modulators of inflammation and systemic immunity (McClave et al, 2006) (see Chapter 3). However, failure to use the gastrointestinal tract (GIT) in patients with SAP may exacerbate the stress response and disease severity, leading to more complications and prolonged hospitalization; thus EN is preferred for nutrition therapy (Al-Omran et al, 2010; McClave, 2013; Mirtallo et al, 2012). Some data support the use of early EN in acute pancreatitis. In a meta-analysis of observational data from individuals with acute pancreatitis, starting EN within 24 hours after hospital admission, compared with after 24 hours, was associated with a reduction in complications (Bakker et al, 2014).

Nasogastric EN has been shown to be efficacious in SAP (Nally et al, 2014). However, to minimize pancreatic stimulation it is best to place jejunal feeding tubes endoscopically as far down the intestine as possible, generally more than 40 cm past the ligament of Treitz (O'Keefe et al, 2001).

EN results in a substantial cost savings with fewer septic complications and overall reduction of morbidity and mortality (Petrov et al, 2008; Sun et al, 2013). The location of the feeding and the composition of the formula is thought to determine the degree of pancreatic stimulation. Infusion into the jejunum eliminates the cephalic and gastric phases of exocrine pancreatic stimulation. The use of jejunal feedings may be better tolerated and allow for an increase in the amount of nutrition that is delivered in the face of AP. However, not any controlled trial has clearly demonstrated a significant improvement of feeding tolerance, mortality, or length of ICU stay with the use of jejunal feeding compared with gastric feedings (Zhang et al, 2013). Because the placement of a nasogastric feeding tube is easier than a jejunal tube, it is reasonable to consider gastric feedings for AP and reserve jejunal feedings for those who are intolerant to gastric feeding (Petrov, 2014). For those patients with severe AP complicated by organ failure, pancreatic necrosis, or fluid collections, nasojejunal feeding is the preferred method of delivery (Seminario et al, 2014) to minimize pancreatic stimulation (see Chapter 13 for jejunal feeding details).

Although various formulations have been used in pancreatitis, no studies have determined the relative merits of standard, partially digested, elemental, or "immune-enhanced" formulations. Polymeric formulas infused at various sections of the gut stimulate the pancreas more than elemental and hydrolyzed formulas. Peptide-based formula can be used safely and standard formulas can be tried if the patient is tolerant (Mirtallo et al, 2012). Close observation for patient tolerance is important. Tolerance may be enhanced with the use of supple-

mental pancreatic enzymes during enteral feeding (Berry, 2014). These can be provided by mouth, mixed with water and delivered via the feeding tube, or added directly to the enteral formula. When the patient is allowed to eat, supplemental pancreatic enzymes may also be required to treat steatorrhea. In severe, prolonged cases, PN may be necessary.

Patients with mild to moderate stress can tolerate dextrose-based solutions, whereas patients with more severe stress require a mixed fuel system of dextrose and lipid to avoid complications of glucose intolerance. Lipid emulsion should not be included in a PN regimen if hypertriglyceridemia is the cause of the pancreatitis (Patel et al, 2014). A serum triglyceride level should be obtained before lipid-containing PN is initiated. Lipids may be given to patients with triglyceride values less than 400 mg/dL. Because of the possibility of pancreatic endocrine abnormalities and a relative insulin resistance, close glucose monitoring also is warranted. H₂-receptor antagonists may be prescribed to decrease hydrochloric acid production, which reduce stimulation of the pancreas. The hormone somatostatin is considered the best inhibitor of pancreatic secretion and may be used in conjunction with PN.

Chronic Pancreatitis. In contrast to AP, chronic pancreatitis (CP) evolves insidiously over many years. CP is characterized by recurrent attacks of epigastric pain of long duration that may radiate into the back. The pain can be precipitated by meals. Associated nausea, vomiting, or diarrhea make it difficult to maintain adequate nutrition status (Verhaegh et al, 2013).

Patients with CP are at increased risk of developing protein-calorie malnutrition because of pancreatic insufficiency and inadequate oral intake. Patients with CP admitted to a tertiary care center usually have malnutrition, increased energy requirements, weight loss, deficits of lean muscle and adipose tissue, visceral protein depletion, impaired immune function, and vitamin deficiencies (Duggan et al, 2014) (see Appendix 21).

The objective of therapy for patients is to prevent further damage to the pancreas, decrease the number of attacks of acute inflammation, alleviate pain, decrease steatorrhea, and correct malnutrition. Dietary intake should be as liberal as possible, but modifications may be necessary to minimize symptoms.

The first goal of MNT is to provide optimal nutrition support, and the second is to decrease pain by minimizing stimulation of the exocrine pancreas. Because CCK stimulates secretion from the exocrine pancreas, one approach is to decrease CCK levels. If postprandial pain is a limiting factor, alternative enteral therapies that minimally stimulate the pancreas are warranted. Nutrition counseling, antioxidants, and pancreatic enzymes may play a role in effective management of CP as well (Afghani et al, 2014).

When pancreatic function is diminished by approximately 90%, enzyme production and secretion are insufficient; maldigestion and malabsorption of protein and fat thus become a problem. Large meals with high-fat foods and alcohol should be avoided.

The patient may present with weight loss despite adequate energy intake and will complain of bulky, greasy stools. This is definitely the case with idiopathic CP associated with a cystic fibrosis gene mutation; therapies directed toward cystic fibrosis may benefit these patients (see Chapter 34). Of these therapies, pancreatic enzyme replacement is mandatory at this time. Pancreatic enzyme replacements are given orally with meals; the dosage should be at least 30,000 units of lipase with each meal. To promote weight gain, the level of fat in the diet should be the maximum a patient can tolerate without increased steatorrhea or pain.

Additional therapies that may be tried to maintain nutrition status and minimize symptoms in patients with maximum enzyme supplementation include a lower-fat diet (40 to 60 g/day) (see Table 29-7) or substitution of some dietary fat with MCT oil to improve fat absorption and weight gain (see Chapter 13). The diet should be low fat, primarily from vegetable-based oils such as olive oil. Trans fatty acids, found in commercially baked goods and other processed foods should be eliminated. Meals should be small and frequent.

Malabsorption of the fat-soluble vitamins may occur in patients with significant steatorrhea. Also, deficiency of pancreatic protease, necessary to cleave vitamin B₁₂ from its carrier protein, potentially could lead to vitamin B₁₂ deficiency. With appropriate supplemental enzyme therapy, vitamin absorption should be improved; however, the patient should still be monitored periodically for vitamin deficiencies. Water-miscible forms of the fat-soluble vitamins or parenteral administration of vitamin B₁₂ may be necessary. Some evidence indicates that increasing intake of antioxidants (found in fruits and vegetables) may help protect against pancreatitis or alleviate symptoms of the condition (Ahmed et al, 2014).

Because pancreatic bicarbonate secretion is frequently defective, medical management also may include maintenance of an optimal intestinal pH to facilitate enzyme activation. Antacids, H₂-receptor antagonists, or proton pump inhibitors that reduce gastric acid secretion may be used to achieve this effect.

In chronic pancreatitis with extensive pancreatic destruction, the insulin-secreting capacity of the pancreas decreases, and glucose intolerance develops. Treatment with insulin and nutrition therapy is then required (see Chapter 30). Management is delicate and should focus on control of symptoms rather than normoglycemia.

Effort should be made to cater to the patient's tolerances and preferences for nutritional management; however, alcohol is prohibited because of the possibility of exacerbating the pancreatic disease. There is evidence that the progressive destruction of the pancreas will be slowed in the alcoholic patient who abstains from alcohol (Nordback et al, 2008).

COMPLEMENTARY AND INTEGRATIVE MEDICINE

The role of complementary and integrative medicine in the treatment of pancreatic disorders remains unclear (Saxena et al, 2014). Certainly, non-FDA-approved proteolytic enzymes can be purchased without a prescription. No data support their use, especially in those individuals with pancreatic disease. Several supplements such as oral calcium, saw palmetto, and other herbs have been suggested for treatment in pancreatitis. However, many of these supplements cause pancreatitis (Kim et al, 2013; Lesser and Hillesheim, 2007; Pronisceva et al, 2014; Wargo et al, 2010). Melatonin may have a protective effect and may alter the disease progression (Belyaev et al, 2011; Jaworek et al, 2012; Jin et al, 2013).

PANCREATIC SURGERY

A surgical procedure often used for pancreatic carcinoma is a **pancreaticoduodenectomy (Whipple procedure)**, in which distal segment (antrum) of the stomach, the first and second portions of the duodenum, the head of the pancreas, the common bile duct, and the gallbladder are removed. The basic concept behind the pancreaticoduodenectomy is that the head of the pancreas and the duodenum share the same arterial blood supply (the gastroduodenal artery). These arteries run through the head of the pancreas, so both organs must be removed if the single

blood supply is severed. If only the head of the pancreas were removed, it would compromise blood flow to the duodenum, resulting in tissue necrosis. A cholecystectomy, vagotomy, or a partial gastrectomy also may be performed during the surgery. The pancreatic duct is reanastomosed to the jejunum. Partial or complete pancreatic insufficiency can result, depending on the extent of the pancreatic resection. Most patients who have undergone pancreatic resection are at risk for vitamin and mineral deficiencies and will benefit from vitamin and mineral supplementation. Nutrition care is similar to that for CP.

Pancreatic and Islet Cell Transplantation

There have been significant improvements in the outcomes of patients undergoing pancreatic transplants or pancreatic transplants combined with a kidney transplant. In patients with brittle diabetes who suffer from bouts of hyper- and hypoglycemia, transplantation can restore normal glucose homeostasis and prevent, halt, or reverse the progression of secondary complications (Dunn, 2014; Gruessner et al, 2013).

Pancreatic islet allo-transplantation is a procedure in which islets from the pancreas of a deceased organ donor are purified, processed, and transferred into a recipient. It is performed in certain patients with type 1 diabetes mellitus whose blood glucose levels are extremely labile and difficult to control. **Pancreatic islet autotransplantation** is performed after total pancreatectomy in patients with severe and chronic, or long-lasting, pancreatitis that cannot be managed by other treatments. After pancreatectomy, islets are extracted and purified from the pancreas. The islets then are infused through a catheter into the liver. The goal is to give the body enough healthy islets to make insulin. A person who receives a pancreatic islet cell transplant should follow a meal plan designed for a person with diabetes (see Chapter 30). Immunosuppressive medications are required for allo- but not auto-transplantation; these medications can contribute to weight gain, hypertension, dyslipidemia, and labile blood glucose levels (Chhabra et al, 2014).

CLINICAL CASE STUDY 1

A 62-year-old man is admitted to the hospital from the doctor's office with altered mental status. Past medical history reveals cirrhosis resulting from hepatitis C, esophageal varices, hepatic encephalopathy, and ascites. The patient reports missing his doses of lactulose the two previous days. Muscle wasting is noted in the form of squared shoulders, prominent clavicle, temporal wasting, and thin extremities. He has 3+ edema in his lower extremities and a protuberant abdomen from ascites. His abnormal laboratory values on admission included elevated liver function enzymes and total bilirubin, sodium 127 mEq/L, glucose 68 mg/dL. Nutritional data include height, 177.8 cm; weight, 71.8 kg; ideal body weight, 75 kg; recent body weight range due to fluid fluctuations, 63.6 kg to 90.9 kg.

Nutrition Diagnostic Statements

1. Involuntary weight loss related to cirrhosis as evidenced by loss of dry body weight and physical signs of malnutrition.
2. Altered laboratory values related to cirrhosis as evidenced by hyponatremia and hypoglycemia.

Interventions

Initiate 2 g sodium diet with small, frequent meals.
Initiate commercial beverage twice daily.

Monitoring and Evaluation

Monitor food and beverage intake.
Assess food and nutrition knowledge.
Assess adherence to prescribed diet.

CLINICAL CASE STUDY 2

A 42-year-old female presents with a history of chronic pancreatitis resulting from pancreatic divisum (a congenital abnormality in which there are two pancreatic ducts instead of one). The patient has had multiple hospitalizations for acute pancreatitis. Despite placement of pancreatic stents, she has developed chronic pancreatitis (confirmed by abnormal endoscopic ultrasound and low fecal elastase) and depends on chronic pain medications. She presents for evaluation of total pancreatectomy with islet-autotransplantation. The patient is thin with apparent muscle wasting and reports that she is very fatigued and no longer able to work because of chronic pain. She describes chronic abdominal pain that worsens with eating so that she is only drinking clear soft drinks throughout the day and eating only one small meal per day. She often is constipated, but this can alternate with diarrhea with greasy, foul-smelling loose stools. Her nutritional data include height, 160 cm; weight, 40.5 kg; ideal body weight, 52.3 kg; usual body weight, 54.5 kg (1 year ago). Her 25-hydroxy-vitamin D level is <10 ng/mL.

Nutrition Diagnostic Statements

1. Involuntary weight loss due to pain with eating as evidenced by 31-lb weight loss.
2. Altered nutrition-related laboratory values due to malabsorption as evidenced by vitamin D level <10 ng/mL.

Interventions

Insert feeding tube (for supplemental nocturnal nutrition)
 Nutrition-related medication management (start pancreatic enzymes with meals)
 Initiate vitamin D supplement.

Monitoring and Evaluation

Monitor total energy intake.
 Monitor enteral intake – formula/solution (for tolerance and adequacy).
 Monitor vitamin A, D, E levels.

Medical Nutrition Therapy for Diabetes Mellitus and Hypoglycemia of Nondiabetic Origin

Marion J. Franz, MS, RDN, LD, CDE, Alison B. Evert, MS, RDN, CDE

KEY TERMS

acanthosis nigricans	honeymoon phase	macrovascular diseases
amylin	hyperglycemia	metabolic syndrome
autonomic symptoms	hyperglycemic hyperosmolar state (HHS)	microvascular diseases
carbohydrate counting	hypoglycemia (or insulin reaction)	neuroglycopenic symptoms
continuous glucose monitoring (CGM)	hypoglycemia of nondiabetic origin	polydipsia
correction factor (CF)	immune-mediated diabetes mellitus	polyphagia
counterregulatory (stress) hormones	impaired fasting glucose (IFG)	polyuria
dawn phenomenon	impaired glucose tolerance (IGT)	postprandial (after a meal) blood glucose
diabetic ketoacidosis (DKA)	incretins	postprandial (reactive) hypoglycemia
fasting hypoglycemia	insulin	prediabetes
gastroparesis	insulin deficiency	preprandial (fasting/premeal) blood glucose
gestational diabetes mellitus (GDM)	insulin resistance	self-monitoring of blood glucose (SMBG)
glucagon	insulin secretagogues	Somogyi effect
glucose-lowering medications	latent autoimmune diabetes of aging (LADA)	type 1 diabetes (T1DM)
glucotoxicity	lipotoxicity	type 2 diabetes (T2DM)
glycemic index (GI)	macroemia	Whipple's triad
glycemic load (GL)		
glycosylated hemoglobin (A1C)		

Diabetes mellitus is a group of diseases characterized by high blood glucose concentrations resulting from defects in insulin secretion, insulin action, or both. **Insulin** is a hormone produced by the beta-cells of the pancreas that is necessary for the use or storage of body fuels (carbohydrate, protein, and fat). Persons with diabetes do not produce adequate insulin; with **insulin deficiency, hyperglycemia** (elevated blood glucose) occurs.

Diabetes mellitus contributes to a considerable increase in morbidity and mortality rates, which can be reduced by early diagnosis and treatment. Direct medical expenditures such as inpatient care, outpatient services, and nursing home care are astronomical and indirect costs such as disability, work loss, and premature mortality are equally high. Average medical expenditures among people with diabetes are double that of people who do not have diabetes. Thus providing medical nutrition therapy (MNT) for prevention and treatment of diabetes has tremendous potential to reduce these costs. Fortunately, people with diabetes can take steps to control the disease and lower the risk of complications or premature death.

INCIDENCE AND PREVALENCE

In 2014 total prevalence of diabetes in the United States in all ages was 29.1 million people (15.5 million adult men and

13.4 adult women), or 9.3% of the population. Of these, 21.0 million are diagnosed, and 8.1 million undiagnosed. In 2012 1.7 million new cases of diabetes were diagnosed in people age 20 years or older (CDC, 2014). Diabetes prevalence also increases with age, affecting 11.2 million people age 65 years and older, or 25.9% of all people in this age group.

Much of the increase in prevalence is because the prevalence of type 2 diabetes is increasing dramatically in younger age groups in the last decade, especially in minority populations. Among youth with newly diagnosed diabetes, approximately 20% have type 2 diabetes. The prevalence of type 2 diabetes is highest in ethnic groups in the United States. Data indicate in people aged 20 years or older, 15.9% of American Indians and Alaska Natives, 13.2% of non-Hispanic blacks, 12.8% of Hispanics, and 9.0% of Asian Americans had diagnosed diabetes. Among Hispanics, rates were 14.8% for Puerto Ricans, 13.9% for Mexican Americans, and 9.3% for Cubans (CDC, 2014). Of great concern, are the 86 million people (37% of adults 20 years or older and 51% of adults 60 years or older) with **prediabetes**, which includes **impaired glucose tolerance (IGT)** and **impaired fasting glucose (IFG)** (ADA, 2014b). All are a high risk for conversion to type 2 diabetes and cardiovascular disease (CVD) if lifestyle prevention strategies are not implemented.

CATEGORIES OF GLUCOSE INTOLERANCE

Assigning a type of diabetes to an individual often depends on the circumstances present at the time of diagnosis, and many individuals do not easily fit into a single category. Thus it is less important to label the particular type of diabetes than it is to understand the pathogenesis of the hyperglycemia and to treat it effectively (ADA, 2014a). What is essential is the need to intervene early with lifestyle interventions, beginning with prediabetes and continuing through the disease process.

Prediabetes

Individuals with a stage of impaired glucose homeostasis that includes IFG and IGT are referred to as having prediabetes, indicating their relatively high risk for the development of diabetes and CVD. People at risk may have IFG (fasting plasma glucose 100-125 mg/dL), IGT (2-hour postchallenge glucose of 140 to 199 mg/dl), both, or a hemoglobin A1c (A1C) of 5.7% to 6.4% and should be counseled about strategies, such as reduced energy intake, weight loss, and physical activity, to lower their risks.

Type 1 Diabetes

At diagnosis, people with **type 1 diabetes (T1DM)** often experience excessive thirst, frequent urination, and significant weight loss. The primary defect is pancreatic beta-cell destruction, usually leading to absolute insulin deficiency and resulting in hyperglycemia, **polyuria** (excessive urination), **polydipsia** (excessive thirst), **polyphagia** (excessive hunger), weight loss, dehydration, electrolyte disturbance, and ketoacidosis. The rate of beta-cell destruction is variable, proceeding rapidly in infants and children and slowly in others (mainly adults.) The capacity of a healthy pancreas to secrete insulin is far in excess of what is needed normally. Therefore the clinical onset of diabetes may be preceded by an extensive asymptomatic period of months to years, during which beta-cells are undergoing gradual destruction.

T1DM accounts for 5% to 10% of all diagnosed cases of diabetes. Persons with T1DM are dependent on exogenous insulin to prevent ketoacidosis and death. T1DM can develop at any age. Although more cases are diagnosed in people before the age of 30 years, it also occurs in older individuals. Most individuals are lean but some are diagnosed without any or with more subtle symptoms and may be overweight, reflecting the trend of increasing obesity among children and adults.

T1DM has two forms: immune-mediated and idiopathic. **Immune-mediated diabetes mellitus** results from an autoimmune destruction of the beta-cells of the pancreas, the only cells in the body that make the hormone insulin. Idiopathic T1DM refers to forms of the disease that have no known etiology. Although only a minority of individuals with T1DM fall into this category, of those who do, most are of African or Asian ancestry (ADA, 2014b). At this time there are no known means to prevent T1DM.

Autoimmune thyroid disease and celiac disease are two immune-mediated diseases that occur with increased frequency in persons with type 1 diabetes. Autoimmune thyroid disease occurs in 17% to 30% of persons with type 1 diabetes, and celiac disease occurs in 1% to 16% of individuals compared with 0.3% to 1% in the general population (ADA, 2014b). Children with type 1 diabetes should be screened for celiac disease soon after diagnosis. If celiac disease is biopsy-confirmed, children

should be placed on a gluten-free diet by a RDN experienced in managing diabetes and celiac disease (Chiang et al, 2014).

Pathophysiology

Markers of the immune destruction of the beta-cells include islet cells autoantibodies, autoantibodies to insulin, autoantibodies to glutamic acid decarboxylase (GAD65) (a protein on the surface of the beta-cells), and autoantibodies to the tyrosine phosphatases IA-2 and IA-2beta. One and usually more of these autoantibodies are present in 85% to 90% of individuals when fasting hyperglycemia is detected initially. The disease also has strong genetic factors, which involve the association between T1DM and histocompatibility locus antigen (HLA) with linkage to the DQA and DQB genes, and is influenced by the DRB genes. These HLA-DR/DQ alleles can be either predisposing or protective (ADA, 2014a).

The rate of clinical beta-cell destruction is quite variable, being rapid in some individuals (mainly infants and children) and slow in others (mainly adults). Hyperglycemia and symptoms develop only after greater than 90% of the secretory capacity of the beta-cell mass has been destroyed.

Frequently, after diagnosis and the correction of hyperglycemia, metabolic acidosis, and ketoacidosis, endogenous insulin secretion recovers. During this **honeymoon phase** exogenous insulin requirements decrease dramatically for up to 1 year or longer, and good metabolic control may be easily achieved. However, the need for increasing exogenous insulin replacement is inevitable and always should be anticipated. Intensive insulin therapy along with attention to MNT and self-monitoring of glucose from early diagnosis has been shown to prolong insulin secretion. Within 5 to 10 years after clinical onset, beta-cell loss is complete, and circulating islet cell antibodies can no longer be detected.

Amylin, a glucoregulatory hormone also is produced in the pancreatic beta-cell and cosecreted with insulin. Amylin complements the effects of insulin by regulating postprandial glucose levels and suppressing glucagon secretion. T1DM is also an amylin-deficient state. Individuals with T1DM are also prone to other autoimmune disorders such as Graves' disease, Hashimoto's thyroiditis, Addison's disease, vitiligo, celiac disease, autoimmune hepatitis, myasthenia gravis, and pernicious anemia.

Latent autoimmune diabetes of aging (LADA) may account for as many as 10% of cases of insulin-requiring diabetes in older individuals and represents a slowly progressive form of autoimmune diabetes that frequently is confused with T2DM. Adults with LADA have HLA genetic susceptibility as well as autoantibodies. Their diabetes may be controlled initially with nutrition therapy but within a relatively short period of time glucose-lowering medication and progression to insulin treatment are required (Naik et al, 2009).

Type 2 Diabetes

Type 2 diabetes (T2DM) accounts for 90% to 95% of all diagnosed cases of diabetes and is a progressive disease that, in many cases, is present long before it is diagnosed. Hyperglycemia develops gradually and is often not severe enough in the early stages for the person to notice any of the classic symptoms of diabetes. Although undiagnosed, these individuals are at increased risk of developing macrovascular and microvascular complications.

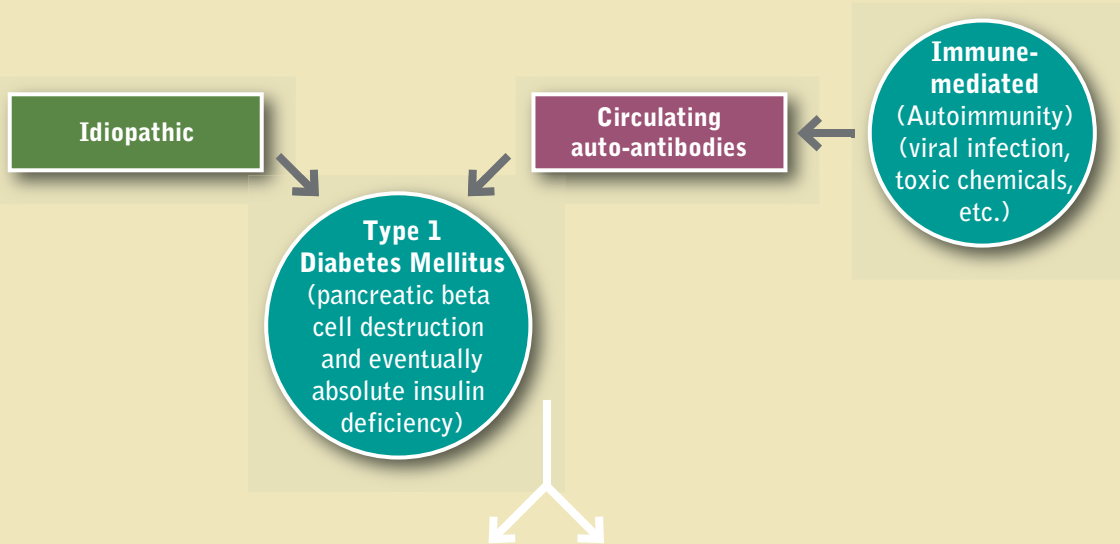

Most persons with T2DM are obese, and obesity itself causes some degree of **insulin resistance**. Persons who are not obese

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Type 1 Diabetes Mellitus

ETIOLOGY

PATHOPHYSIOLOGY

Symptoms

- Hyperglycemia
- Excessive thirst
- Frequent urination
- Significant weight loss
- Electrolyte disturbances

Complications

Ketoacidosis

Macrovascular diseases

- Coronary heart disease
- Peripheral vascular disease
- Cerebrovascular disease

Microvascular diseases

- Retinopathy
- Nephropathy

Neuropathy

MANAGEMENT

Medical Management

Medical nutrition therapy

Medications

- Insulin by injection or insulin infusion pumps

Monitoring

- Self-monitoring of blood glucose
- A1C testing
- Lipids
- Blood pressure
- Ketones
- Weight and growth in children

Self-management education

Medical Nutrition Therapy (MNT)

- Integrate insulin regimen into preferred eating and physical activity schedule; consistency in timing and amount of carbohydrate eaten if on fixed insulin doses
- Adjust premeal insulin dose based on insulin-to-carbohydrate ratios
- Energy intake to prevent weight gain in adults
- Adequate energy and nutrient intake to promote growth and development in children
- Cardioprotective nutrition interventions

by traditional weight criteria may have an increased percentage of body fat distributed predominately in the abdominal region. However, many obese persons never develop T2DM. Therefore obesity combined with a genetic predisposition may be necessary for T2DM to occur. Other risk factors include genetic and environmental factors, including a family history of diabetes, older age, physical inactivity, a prior history of gestational diabetes, prediabetes, hypertension or dyslipidemia, and race or ethnicity.

Pathophysiology

T2DM is characterized by a combination of insulin resistance and beta-cell failure. Endogenous insulin levels may be normal, depressed, or elevated, but they are inadequate to overcome concomitant insulin resistance (decreased tissue sensitivity or responsiveness to insulin.) As a result, hyperglycemia ensues. The inflammatory response to excess weight, insulin resistance, and beta-cell failure occurs approximately 5 to 10 years before the elevation of glucose above normal. When T2DM is diagnosed, it is estimated that people already have lost approximately 50% of their beta-cell function. There is disagreement among researchers whether this is loss of beta-cell mass or function. Persons in the upper tertile of IGT before the diagnosis of T2DM are reported to have lost more than 80% of their beta-cell function.

Insulin resistance is demonstrated first in target tissues, mainly muscle, liver, and adipose cells. Initially there is a compensatory increase in insulin secretion (hyperinsulinemia), which maintains glucose concentrations in the normal or prediabetic range. In many persons the pancreas is unable to continue to produce adequate insulin, hyperglycemia occurs, and the diagnosis of diabetes is made. Therefore insulin levels are always deficient relative to elevated glucose levels before hyperglycemia develops.

Hyperglycemia is first exhibited as an elevation of **postprandial (after a meal) blood glucose** caused by insulin resistance at the cellular level and is followed by an elevation in fasting glucose concentrations. As insulin secretion decreases, hepatic glucose production increases, causing the increase in **preprandial (fasting) blood glucose** levels. The insulin response is also inadequate in suppressing alpha-cell glucagon secretion, resulting in glucagon hypersecretion and increased hepatic glucose production. Compounding the problem is **glucotoxicity**, the deleterious effect of hyperglycemia on insulin sensitivity and insulin secretion; hence the importance of achieving near-euglycemia in persons with T2DM.

Insulin resistance also is demonstrated at the adipocyte level, leading to lipolysis and an elevation in circulating free fatty acids. In particular, excess intraabdominal obesity, characterized by an excess accumulation of visceral fat around and inside abdominal organs, results in an increased flux of free fatty acids to the liver, leading to an increase in insulin resistance. Increased fatty acids also cause a further decrease in insulin sensitivity at the cellular level, impair pancreatic insulin secretion, and augment hepatic glucose production (**lipotoxicity**). The above defects contribute to the development and progression of T2DM and are also primary targets for pharmacologic therapy.

Persons with T2DM may or may not experience the classic symptoms of uncontrolled diabetes (polydipsia, polyuria, polyphagia, weight loss) and they are not prone to develop ketoacidosis except during times of severe stress. The progressive loss of beta-cell secretory function means that persons with T2DM

require more medication(s) over time to maintain the same level of glycemic control; eventually exogenous insulin will be required. Insulin is also required sooner for control during periods of stress-induced hyperglycemia, such as during illness or surgery.

If at diagnosis it is not clear whether T1DM or T2DM is present, C-peptide may be measured. When the pancreas produces insulin, it begins as a large molecule—proinsulin. This molecule splits into two equal-sized pieces: insulin and C-peptide. A person with T1DM has a low level of C-peptide, whereas as a person with T2DM can have a normal or high level of C-peptide. As T2DM progresses, C-peptide also may be measured to see if endogenous insulin is still being produced by the pancreas. If it is not, exogenous insulin is needed.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) occurs in about 7% of all pregnancies (ranging from 1% to 14% depending on the population studied), resulting in more than 200,000 cases annually (ADA, 2014a). After delivery, about 90% of all women with GDM become normoglycemic but are at increased risk of developing GDM earlier in subsequent pregnancies. Immediately after pregnancy, 5% to 10% of women with GDM are diagnosed with T2DM. Women who have had GDM have a 35% to 60% chance of developing diabetes in the next 5 to 10 years (CDC, 2014). Lifestyle modifications aimed at reducing or preventing weight gain and increasing physical activity after pregnancy may reduce the risk of subsequent diabetes.

Previously GDM was defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, the number of pregnant women with undiagnosed diabetes has increased and therefore it has now been recommended that women with risk factors for diabetes should be screened for undiagnosed T2DM at the first prenatal visit, using standard diagnostic criteria. Women found to have diabetes in the first trimester should receive a diagnosis of overt, not gestational, diabetes (ADA, 2014b).

All women not previously known to have diabetes should be screened for GDM at 24 to 28 weeks of gestation. GDM is diagnosed most often during the second or third trimester of pregnancy because of the increase in insulin-antagonist hormone levels and insulin resistance that normally occurs at this time. GDM screening can be accomplished with either of two strategies:

1. “One-step” 3-hr 75-g OGTT. A fasting glucose >92 mg/dl (5.1 mmol/L), a 1-hour >180 mg/dL (10 mmol/L), or a 2-hr >153 mg/dl (8.4 mmol/L) is diagnostic of GDM
2. “Two-step” approach with a 1-hr 50-g (nonfasting) screen followed by a 3-hr 100-g OGTT for those with plasma glucose ≥ 140 mg/dl (10.0 mmol/L). The diagnosis of GDM is made when the plasma glucose level measured 2 hr after the test is ≥ 140 mg/dl (7.8 mmol/L).

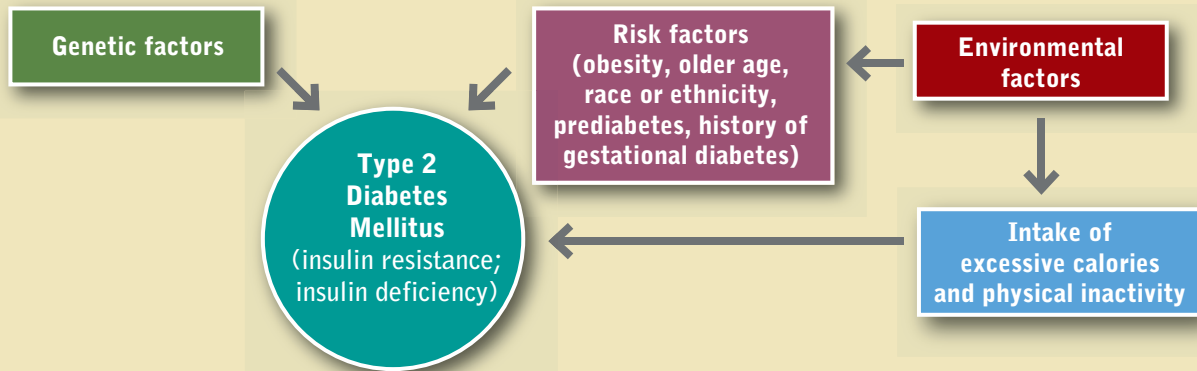

During pregnancy, treatment to normalize maternal blood glucose levels reduces the risk of adverse maternal, fetal, and neonatal outcomes. Extra glucose from the mother crosses the fetal placenta and the fetus’ pancreas responds by releasing extra insulin to cope with the excess glucose. The excess glucose is converted to fat, which results in **macrosomia**. The fetus may become too large for a normal birth resulting in the need for cesarean delivery. Neonatal hypoglycemia at birth is another common problem. The above normal levels of maternal glucose have caused the fetus to produce extra insulin. However, after

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Type 2 Diabetes Mellitus

ETIOLOGY

PATHOPHYSIOLOGY

Symptoms (variable)

- Hyperglycemia
- Fatigue
- Excessive thirst
- Frequent urination

Clinical Findings

- Abnormal patterns of insulin secretion and action
- Decreased cellular uptake of glucose and increased postprandial glucose
- Increased release of glucose by liver (gluconeogenesis) resulting in fasting hyperglycemia
- Central obesity
- Hypertension
- Dyslipidemia

MANAGEMENT

Medical Management

Medical nutrition therapy

Physical activity

Medications

- Glucose-lowering medications
- Insulin

Monitoring

- Self-monitoring of blood glucose
- A1C testing
- Lipids
- Blood pressure
- Weight

Self-management education

Medical Nutrition Therapy (MNT)

- Lifestyle strategies (food/eating and physical activity) that improve glycemia, dyslipidemia, and blood pressure
- Nutrition education (carbohydrate counting and fat modification) and counseling
- Energy restriction
- Blood glucose monitoring to determine adjustments in food or medications
- Cardioprotective nutrition interventions

birth the extra glucose is no longer available to the fetus, but until his or her pancreas can adjust, the neonate may require extra glucose through intravenous feedings for a day or two to keep blood glucose levels normal.

GDM does not cause congenital anomalies. Such malformations occur in women with diabetes before pregnancy who have uncontrolled blood glucose levels during the first 6 to 8 weeks of pregnancy when fetal organs are being formed. Because GDM does not appear until later in pregnancy, the fetal organs were formed before hyperglycemia became a problem.

When optimal blood glucose levels are not being maintained with MNT or the rate of fetal growth is excessive, pharmacologic therapy is needed (AND, 2008b). Research supports the use of insulin, insulin analogs, metformin, and glyburide during pregnancy. Women with GDM should be screened for diabetes 6 to 12 weeks postpartum and should have lifelong screening for the development of diabetes or prediabetes at least every 3 years (ADA, 2014b).

Other Types of Diabetes

This category includes diabetes associated with specific genetic syndromes (such as maturity-onset diabetes of youth), genetic defects in insulin action, diseases of the exocrine pancreas (such as cystic fibrosis), endocrinopathies, (such as acromegly or Cushing's syndrome), drug or chemical induced (such as in the treatment of HIV/AIDS or after organ transplantation), infections, and other illnesses. Such types of diabetes may account for 1% to 5% of all diagnosed cases of diabetes (ADA, 2014a).

SCREENING AND DIAGNOSTIC CRITERIA

Screening for Diabetes

Screening for diabetes should be considered in all adults who are overweight (body mass index [BMI] ≥ 25 kg/m²) and who have one or more additional risk factors for T2DM listed below. In those without these risk factors, testing should begin at age 45 years. If tests are normal, testing should be done at 3-year intervals; A1C, FPG, or 2-h OGTT, can be used to test for either prediabetes or diabetes (ADA, 2014b). Additional risk factors for diabetes are the following:

- Physical inactivity
- First-degree relative with diabetes
- Members of a high-risk population (African Americans, Latino, Native American, Asian American, and Pacific Islander)
- Women who have delivered a baby weighing more than 9 lb or have been diagnosed with GDM
- Hypertensive (blood pressure $\geq 140/90$ mm Hg or taking medication for hypertension)
- High-density lipoprotein (HDL) cholesterol level < 35 mg/dl (0.9 mmol/L) and/or a triglyceride level > 250 mg/dl (2.82 mmol/L)
- Women with polycystic ovary syndrome (PCOS)
- A1C $\geq 5.7\%$, IGT, or IFG on previous testing
- Other clinical condition associated with insulin resistance (e.g., severe obesity, **acanthosis nigricans** [gray-brown skin pigmentations])
- History of CVD

Consistent with screening recommendations for adults, children and youth at increased risk for T2DM should be tested. The age of initiation of screening is age 10 years or at onset of puberty, and the frequency is every 3 years (ADA, 2014b). Youth

who are overweight (BMI > 85 th percentile for age and sex, weight for height above the 85th percentile, or weight more than 120% of ideal for height) and have any two of the following risk factors should be screened:

- Family history of T2DM in first- or second-degree relative
- Race/ethnicity (Native American, African American, Latino, Asian American, Pacific Islander)
- Signs of insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS, or small-for-gestational-age birth weight)
- Maternal history of diabetes or GDM during the child's gestation

Diagnostic Criteria

Four diagnostic methods may be used to diagnose diabetes and each, in the absence of unequivocal hyperglycemia, must be confirmed, on a subsequent day, by repeat testing. It is preferable that the same test be repeated for confirmation (ADA, 2014b). Diagnostic criteria for diabetes and prediabetes are summarized in Table 30-1.

Plasma glucose criteria, either the fasting plasma glucose (FPG) or the 2-hr plasma glucose after a 75-g OGTT, was the method usually used to diagnosis diabetes. However, the A1C assay now is highly standardized and is a reliable measure of chronic glucose levels. The A1C test reflects longer-term glucose concentrations and is assessed from the results of **glycosylated hemoglobin** (simplified as A1C) tests. When hemoglobin and other proteins are exposed to glucose, the glucose becomes attached to the protein in a slow, nonenzymatic, and concentration-dependent fashion. Measurements of A1C therefore reflect a weighted average of plasma glucose concentration over the preceding weeks. In nondiabetic persons A1C values are 4% to 6%; these values correspond to mean blood glucose levels of

TABLE 30-1 Criteria for the Diagnosis of Diabetes Mellitus and Increased Risk for Diabetes (Prediabetes)

Diagnosis	Criteria
Diabetes	A1C $\geq 6.5\%$ * OR FPG ≥ 126 mg/dl (≥ 7.0 mmol/L) * OR 2-h PG ≥ 200 mg/dl (≥ 11.1 mmol/L) during an OGTT * OR In patients with classic symptoms of hyperglycemia or hyperglycemic crisis, a random PG ≥ 200 mg/dL (≥ 11.1 mmol/L)
Prediabetes	FPG 100-125 mg/dL (5.6-6.9 mmol/L) [Impaired fasting glucose] OR 2-hPG in the 75-g OGTT 140-199 mg/dl (7.8-11.0 mmol/L) (Impaired glucose tolerance) OR A1C 5.7-6.4%
Normal	FPG < 100 mg/dL (< 5.6 mmol/L) 2-hPG < 140 mg/dL (< 7.8 mmol/L) A1C 4 to 5.6%

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 37(S1):S5, 2014.

*In the absence of unequivocal hyperglycemia, criteria 1 to 3 should be confirmed by repeat testing.

FPG, fasting plasma glucose; 2-hPG, 2-hour plasma glucose level (measured 2 hours after an oral glucose tolerance test [OGTT] with administration of 75 g of glucose).

about 70 to 126 mg/dL (3.9 to 7.0 mmol/L). A1C values vary less than FPG, and testing is more convenient because patients are not required to be fasting or to undergo an OGTT. However, A1C levels may vary with person's race/ethnicity as glycation rates may differ by race (ADA, 2014b). It is also unclear if the same A1C cutoff point should be used to diagnose children or adolescents with diabetes, because studies used to recommend A1C to diagnose diabetes have all been performed in adult populations. For conditions with abnormal red cell turnover, such as hemolysis (blood loss), pregnancy, or iron deficiency, the diagnosis of diabetes must use glucose criteria exclusively (ADA, 2014b). The A1C test should be performed using a method certified by the National Glycohemoglobin Standardization Program.

MANAGEMENT OF PREDIABETES

In no other disease does lifestyle—healthy and appropriate food choices and physical activity—play a more important role in prevention and treatment than in diabetes. Studies comparing lifestyle modifications to medication have provided support for the benefit of weight loss (reduced energy intake) and physical activity as the first choice to prevent or delay diabetes. Clinical trials comparing lifestyle interventions to a control group have reported risk reduction for T2DM from lifestyle interventions ranging from 29% to 67% (Youssef, 2012). Two frequently cited studies are the Finnish Diabetes Prevention Study and the Diabetes Prevention Program (DPP), in which lifestyle interventions focused on a weight loss of 5% to 10%, physical activity of at least 150 min/week of moderate activity, and ongoing counseling and support. Both reported a 58% reduction in the incidence of T2DM in the intervention group compared with the control group and persistent reduction in the rate of conversion to T2DM within 3 to 14 years postintervention follow-up (DPP Research Group, 2009; Li et al, 2008; Lindström et al, 2006).

Medical Management

Use of the pharmacologic agents metformin, alpha-glucosidase inhibitors, orlistat, and thiazolidinediones has been shown to decrease incidence of diabetes by various degrees (Youssef, 2012). At this time, metformin is the only drug that should be considered for use in diabetes prevention. It is the most effective in those with a BMI of at least 35 kg/m² and who are under age 30. For other drugs, issues of cost, side effects, and lack of persistence of effect are of concern.

Medical management must include lifestyle changes. Physical activity is important to prevent weight gain and maintain weight loss. For cardiovascular fitness and to reduce risk of T2DM, recommendations include moderate-intensity aerobic physical activity a minimum of 30 minutes 5 days per week (150 min/week) (i.e., walking 3 to 4 miles/hr) or vigorous-intensity aerobic physical activity a minimum of 20 minutes 3 days per week (90 min/week). Muscle-strengthening activities involving all major muscle groups two or more days per week are also recommended (US Department of Health and Human Services [USDHHS], 2008). Physical activity independent of weight loss improves insulin sensitivity.

Medical Nutrition Therapy for Prediabetes

Goals of MNT for prediabetes emphasize the importance of food choices that facilitate moderate weight loss. Structured

programs that emphasize lifestyle changes that include moderate weight loss (7% of body weight) with strategies including reduced calories and reduced intake of fat are effective. More recently, moderate to high adherence to a Mediterranean-style eating pattern characterized by high levels of monounsaturated fatty acids such as olive oil, high intake of plant-based foods (vegetables, legumes, fruits, and nuts), moderate amounts of fish and wine, and a low intake of red and processed meat and whole-fat dairy products versus low adherence has been associated with a lower incidence of diabetes (Youssef, 2012).

In addition, whole grains and dietary fiber are associated with reduced risk of diabetes. Increased intake of whole grain-containing foods improves insulin sensitivity independent of body weight, and increased intake of dietary fiber has been associated with improved insulin sensitivity and improved ability to secrete insulin adequately to overcome insulin resistance. Moderate consumption of alcohol (1 to 3 drinks per day [15 to 45 g alcohol]) is linked with decreased risk of T2DM, coronary heart disease, and stroke. But the data do not support recommending alcohol consumption to persons at risk for diabetes who do not already drink alcoholic beverages.

High consumption of sugar-sweetened beverages, which includes soft drinks, fruit drinks, and energy and vitamin water-type drinks containing sucrose, high-fructose corn syrup, and/or fruit juice concentrates is associated with the development of T2DM (Malik et al, 2010). Studies also have reported that an eating pattern high in saturated fatty acids and trans fatty acids is associated with increased markers of insulin resistance and risk for type 2 diabetes, whereas unsaturated fatty acid intake is associated inversely with risk of diabetes (Youssef, 2012). Therefore individuals at increased risk for T2DM should be encouraged to limit their intake of sugar-sweetened beverages and decrease saturated fat intake.

Adhering to a combination of healthy lifestyle habits (a healthy eating pattern, participating in regular physical activity, maintaining a normal body weight, moderate alcohol intake, and being a nonsmoker) was shown to reduce the risk of developing T2DM by as much as 84% for women and 72% for men (Reis et al, 2011).

Bariatric Surgery and Prediabetes

Observational studies have demonstrated that bariatric surgery reduces the incidence of T2DM, but there are no randomized controlled trials (RCTs) on the role of bariatric surgery in the prevention of diabetes (Reis et al, 2011). Possible mechanisms for this weight-independent impact of bariatric surgery on glucose include enterohormonal changes and neurohormonal events resulting from the anatomic changes of the surgery (Lautz et al, 2011).

MANAGEMENT OF DIABETES

Two classic clinical trials have demonstrated beyond a doubt the clear link between glycemic control and the development of complications in persons with T1DM and T2DM, as well as the importance of nutrition therapy in achieving control. The Diabetes Control and Complications Trial (DCCT) studied approximately 1400 persons with T1DM treated with either intensive (multiple injections of insulin or use of insulin infusion pumps guided by blood glucose monitoring results) or conventional (one or two insulin injections per day) regimens. Epidemiology of Diabetes Interventions (EDIC) is an observational

study following the DCCT cohort. A 30-year follow-up of the DCCT/EDIC cohort convincingly demonstrated that an intervention that aimed to achieve glycemia as close to the nondiabetic range as safely possible reduced all of the microvascular and cardiovascular complications of diabetes and should be implemented as early as possible after diagnosis (Nathan, 2014). Another study, the **United Kingdom Prospective Diabetes Study (UKPDS)**, demonstrated conclusively that glucose and blood pressure control decreased the risk of long-term complications in T2DM (Holman et al, 2008). A reduction in energy intake was at least as important, if not more important, than the actual weight lost.

Medical Management

The management of all types of diabetes includes MNT, physical activity, monitoring, medications, and self-management education and support. An important goal of medical treatment is to provide the individual with diabetes with the necessary tools to achieve the best possible control of glucose, lipids, and blood pressure to prevent, delay, or manage the microvascular and macrovascular complications while minimizing hypoglycemia and excess weight gain. Insulin, the primary hormone in glucose control is also anticatabolic and anabolic and facilitates cellular transport (see Table 30-2). In general, the **counterregulatory (stress) hormones** (glucagon, growth hormone, cortisol, epinephrine, and norepinephrine) have the opposite effect of insulin.

The ADA’s glycemic treatment goals for persons with diabetes are listed in Table 30-3. Achieving goals requires open communication between the health care provider and the persons with diabetes and appropriate self-management education. Patients can assess day-to-day glycemic control by **self-monitoring of**

blood glucose (SMBG) and measurement of urine or blood ketones. Longer-term glycemic control is assessed by A1C testing. Lipid levels and blood pressure also must be monitored (see Table 30-4). In most adults, lipids should be measured at least annually and blood pressure at every routine visit (ADA, 2014b). Optimal control of diabetes also requires the restoration of normal carbohydrate, protein, and fat metabolism.

It is important that people with diabetes receive medical care from a team that may include physicians, dietitians, nurses, pharmacists, and mental health professionals with expertise in diabetes. Individuals with diabetes also must assume an active role in their care. For T1DM a flexible, individualized management program using the principles of intensive insulin therapy is essential. T2DM is a progressive disease. The “diet” doesn’t fail; the pancreas fails to secrete enough insulin to maintain adequate glucose control. As the disease progresses, MNT alone is not enough to keep A1C level at 7% or less. Therapy must intensify over time. Medications, and eventually insulin, have to be combined with nutrition therapy. Through the collaborative development of individualized nutrition interventions and ongoing support of behavior changes, health care professionals can facilitate the achievement of the person with diabetes health goals.

Medical Nutrition Therapy for Diabetes

MNT is integral to total diabetes care and management. To integrate MNT effectively into the overall management of diabetes requires a registered dietitian nutritionist (RDN) who is knowledgeable and skilled in implementing current nutrition therapy recommendations into the medical management of diabetes. MNT requires an individualized approach and effective nutrition self-management education, counseling, and

TABLE 30-2 Action of Insulin on Carbohydrate, Protein, and Fat Metabolism

Effect	Carbohydrates	Protein	Fat
Anticatabolic (prevents breakdown)	Decreases breakdown and release of glucose from glycogen in the liver	Inhibits protein degradation, diminishes gluconeogenesis	Inhibits lipolysis, prevents excessive production of ketones and ketoacidosis
Anabolic (promotes storage)	Facilitates conversion of glucose to glycogen for storage in liver and muscle	Stimulates protein synthesis	Facilitates conversion of pyruvate to free fatty acids, stimulating lipogenesis
Transport	Activates the transport system of glucose into muscle and adipose cells	Lowers blood amino acids in parallel with blood glucose levels	Activates lipoprotein lipase, facilitating transport of triglycerides into adipose tissue

TABLE 30-3 Recommendations for Glycemic Control for Adults with Diabetes

Glycemic Control	Criteria
A1C	<7.0%*
Preprandial capillary plasma glucose	80-130 mg/dL* (4.4-7.2 mmol/L)
Peak postprandial capillary plasma glucose†	<180 mg/dL* (<10.0 mmol/L)

Modified from American Diabetes Association: Standards of medical care in diabetes—2014, *Diabetes Care* 37(S1):S14, 2014.

*Goals should be individualized, such as for the elderly, individuals with a history of cardiovascular disease, or hypoglycemia unawareness

†Postprandial glucose measurements should be made 1 to 2 hr after the beginning of the meal, generally peak levels in patients with diabetes.

TABLE 30-4 Recommendations for Lipid and Blood Pressure for Most Adults with Diabetes

Lipids/Blood Pressure	Criteria
LDL cholesterol	<100 mg/dl (<2.6 mmol/l)*
HDL cholesterol	
Men	>40 mg/dl (>1.1 mmol/l)
Women	>50 mg/d (>1.4 mmol/l)
Triglycerides	<150 mg/dl (<1.7 mmol/l)
Blood pressure	<140/90 mm Hg

Modified from American Diabetes Association: Standards of medical care in diabetes—2014, *Diabetes Care* 37(S1):S14, 2014.

*In individuals with overt CVD, a lower LDL cholesterol goal of <70 mg/dl (1.8 mmol/l), using a high dose of a statin, is an option.

support. Monitoring glucose, A1C and lipid levels, blood pressure, weight, and quality-of-life issues is essential in evaluating the success of nutrition-related recommendations. If desired outcomes from MNT are not met, changes in overall diabetes care and management should be recommended (Evert et al, 2013). Effective nutrition therapy interventions may be implemented in individualized sessions or in a comprehensive diabetes education program.

The Academy of Nutrition and Dietetics (AND) published evidence-based nutrition practice guidelines (EBNPG) for T1DM and T2DM in adults in their Evidence Analysis Library and in print (AND, 2008a; Franz et al, 2010). The ADA nutrition recommendations are published in a position statement and are summarized in their annual standards of care (Evert et al, 2013; ADA, 2014b).

Goals and Desired Outcomes

The goals for MNT for diabetes emphasize the role of lifestyle in improving glucose control, lipid and lipoprotein profiles, and blood pressure. Goals of MNT are summarized in Box 30-1. Medicare reimburses qualified RDN providers for providing evidence-based MNT for diabetes management to eligible participants. Improving health through food choices and physical activity is the basis of all nutrition recommendations for the treatment of diabetes.

Besides being skilled and knowledgeable in assessing and implementing MNT, RDNs also must be aware of expected outcomes from MNT, when to assess outcomes, and what feedback, including recommendations, should be given to referral sources. Furthermore, the effect of MNT on A1C will be known by 6 weeks to 3 months, at which time the RDN must assess whether the goals of therapy have been met by changes in lifestyle or whether changes or additional medications are needed (Evert et al, 2013; AND, 2008a).

Multiple research studies support MNT as an effective therapy in reaching diabetes treatment goals. MNT implemented by RDNs reduced A1C levels by an average of 1% to 2% depending on the type and duration of diabetes and the A1C level at implementation (Pastors and Franz, 2012). These outcomes are similar or greater to those from glucose-lowering medications. MNT also is reported to improve lipid profiles, decrease blood

pressure, promote weight loss, decreased need for medications, and decrease risk of onset and progression to diabetes-related comorbidities. A variety of nutrition therapy interventions such as reduced energy/fat intake, **carbohydrate counting**, simplified meal plans, healthy food or exchange choices, use of insulin-to-carbohydrate ratios, physical activity, and/or behavioral strategies can be implemented. A unified focus of MNT for T2DM is a reduced energy intake and for T1DM carbohydrate counting is used to adjust bolus (premeal) insulin doses (insulin-to-carbohydrate ratios).

Energy Balance and Weight Management

Facilitating the achieving and maintaining of body weight goals is another important focus of MNT for diabetes. Provision of adequate calories for normal growth and development for children and adolescents with T1DM is a key component of MNT. Therefore it is important to monitor growth by measuring height and weight every 3 months and recording it on growth charts (Chiang et al, 2014). Although caloric requirements based on age, sex, and activity level are available, assessing usual caloric and nutrient intake is recommended. Usual caloric intake then can be adjusted to accommodate growth or to prevent excessive weight gain. For youth with T2DM, nutrition therapy goals include ceasing of excessive weight gain with normal linear growth. For adults with T1DM, attention to weight goals is also important.

Overweight and obesity are, however, common health problems in persons at risk for and with T2DM. Weight loss frequently is recommended as the solution to improve glycemic control (Evert et al, 2013). Weight loss interventions implemented in persons with prediabetes and newly diagnosed with T2DM have been shown to be effective in improving glycemic control, but the benefit of weight loss interventions in T2DM of longer duration is controversial (Franz, 2013). The AND EBNPG reported that approximately half of the weight loss intervention studies in persons with T2DM improved A1C at 1 year and one-half did not (AND, 2008a). In the weight loss studies lasting 1 year or longer reviewed by the ADA only 2 study groups achieved weight losses of 5% or greater: a Mediterranean-style eating pattern (−6.2 kg) in persons with newly diagnosed diabetes and the intensive lifestyle intervention in the Look AHEAD (Action for Health in Diabetes) (−8.4 kg) (Esposito et al, 2009; Look AHEAD Research Group, 2010). The other weight loss interventions resulted in weight losses of less than 5% (4.8 kg or less) at 1 year (Evert et al, 2013). The weight losses greater than 5% resulted in consistent improvements in A1C, lipids, and blood pressure; however, weight losses less than 5% did not result in consistent 1 year improvements in A1C, lipids, or blood pressure (AND, 2008a; Franz, 2013). Furthermore, it appears to be more difficult for persons with diabetes to lose weight. In a systematic review of 80 studies with 26,455 participants primarily without diabetes, the average weight loss was 7.5 kg (8% of baseline weight) (Franz et al, 2007). Therefore the RDN should collaborate with individuals who have diabetes to integrate nutrient-dense eating patterns that focus on a reduced energy intake (which may or may not lead to weight loss) and regular physical activity. Support for lifestyle changes is also essential.

Bariatric Surgery

Bariatric surgery can be an effective weight loss treatment for severely obese patients with T2DM and can result in marked

BOX 30-1 Goals of Medical Nutrition Therapy that Apply to Adults with Diabetes

1. To promote and support healthful eating patterns, emphasizing a variety of nutrient-dense foods in appropriate portion sizes, to improve overall diet and specifically to:
 - Attain individualized glucose, blood pressure, and lipids goals
 - Achieve and maintain body weight goals
 - Delay or prevent complications of diabetes
2. To address individual nutrition needs based on personal and cultural preferences, health literacy and numeracy, access to healthful food choices, willingness and ability to make behavioral changes.
3. To maintain the pleasure of eating by providing positive messages about food choices while limiting food choices only when indicated by scientific evidence.
4. To provide the individual with diabetes with practical tools for day-to-day meal planning rather than focusing on individual macronutrients, micronutrients, or single foods.

Adapted from Evert AB et al: Nutrition therapy recommendations for the management of adults with diabetes, *Diabetes Care* 36:3821, 2013.

improvements in glycemia (Schauer et al, 2014). The ADA states it may be considered for adults with BMI of at least 35 kg/m² and T2DM, especially if the diabetes or associated comorbidities are difficult to control with lifestyle and pharmacologic therapy (ADA, 2014b). In 4434 adults with T2DM, gastric bypass surgery resulted in 68.2% initial complete diabetes remission within 5 years after surgery (Arterburn et al, 2013). However, 35.1% had redeveloped diabetes within the next 5 years and the median duration of remission was 8.3 years. Predictors of relapse were poor preoperative glycemic control, insulin use, and longer diabetes duration.

Macronutrient Percentages and Eating Patterns

Although numerous studies have attempted to identify the optimal percentages of macronutrients for the Eating Plan of persons with diabetes, review of the evidence shows clearly that there is not an ideal percentage of calories from carbohydrate, protein, and fat for all persons with diabetes (Evert et al, 2013). Total energy intake rather than the source of the energy is the priority. However, even total energy intake is determined by changes that the individual with diabetes is willing and able to make.

The ADA also reviewed research on eating patterns (Mediterranean-style, vegetarian and vegan, low-fat, low-carbohydrate, and DASH) implemented for diabetes management and concluded that a variety of eating patterns are acceptable (Evert et al, 2013). The RDN must take into consideration personal preferences and metabolic goals when recommending one eating pattern over another.

Because macronutrients require insulin for metabolism and influence healthy eating, they still, however, must be reviewed. Although numerous factors influence glycemic response to foods, monitoring total grams of carbohydrates, whether by use of carbohydrate counting or experienced based estimation remains a key strategy in achieving glycemic control (Evert et al, 2013). Evidence exists that the quantity and type of carbohydrate eaten influence blood glucose levels; however, the total amount of carbohydrate eaten is the primary predictor of glycemic response. Day-to-day consistency in the amount of carbohydrate eaten at meals and snacks is reported to improve glycemic control, especially in persons on either MNT alone, glucose-lowering medications, or fixed insulin regimens. Whereas in persons with T1DM or T2DM who adjust their mealtime insulin doses or who are on insulin pump therapy, insulin doses should be adjusted to match carbohydrate intake (Evert et al, 2013).

Carbohydrate counting is an Eating Plan method based on the principle that all types of carbohydrate (except fiber) are digested with the majority being absorbed into the bloodstream as molecules of glucose and that the total amount of carbohydrate consumed has a greater effect on blood glucose elevations than the specific type. Carbohydrate foods include starches, such as breads, cereals, pasta, rice, beans and lentils, starchy vegetables, crackers, and snack chips; fruits and fruit juices; milk, milk substitutes and yogurt; and sweets and desserts. One carbohydrate choice or serving is a portion of food containing 15 grams of carbohydrate. A RDN and the person with diabetes collaboratively create an eating plan that lists the number of carbohydrate choices to be selected for meals and, if desired, for snacks. Individuals are encouraged to keep protein and fat food sources as consistent as possible because they do not greatly affect blood glucose levels even though they require insulin for

metabolism. Energy needs determine daily total servings of macronutrients.

There are two main Eating Plans using carbohydrate counting; using insulin-to-carbohydrate ratios to adjust premeal insulin doses for variable carbohydrate intake (physiologic insulin regimens), or following a consistent carbohydrate Eating Plan when using fixed insulin regimens. Testing premeal and postmeal glucose levels is important for making adjustments in either food intake or medication to achieve glucose goals.

Carbohydrate Intake

Sugars, starch, and fiber are the preferred carbohydrate terms. As noted earlier, blood glucose levels after eating are determined primarily by the rate of appearance of glucose from carbohydrate digestion and absorption into the bloodstream, and the ability of insulin to clear glucose from the circulation. Low-carbohydrate diets may seem to be a logical approach to lowering postprandial glucose. However, foods that contain carbohydrates (whole grains, legumes, fruits, vegetables, and low-fat milk) are excellent sources of vitamins, minerals, dietary fiber, and energy and are encouraged over other sources of carbohydrates, or sources with added fats, sugars, or sodium to improve overall nutrient intake (Evert et al, 2013).

The long-held belief that sucrose must be restricted based on the assumption that sugars are more rapidly digested and absorbed than starches is not justified. The total amount of carbohydrate eaten at a meal, regardless if the source is starch or sucrose, is the primary determinant of postprandial glucose levels. The glycemic effect of carbohydrate foods cannot be predicted based on their structure (i.e., starch versus sugar) owing to the efficiency of the human digestive tract in reducing starch polymers to glucose. Starches are rapidly metabolized into 100% glucose during digestion, in contrast to sucrose, which is metabolized into only approximately 50% glucose and approximately 50% fructose. Fructose has a lower glycemic response, which has been attributed to its slow rate of absorption and its storage in the liver as glycogen. Sucrose-containing foods can be substituted for isocaloric amounts of other carbohydrate foods. However, as for the general population, care should be taken to avoid excess energy intake and to avoid displacing nutrient-dense food choices. The ADA advises that people with or at risk for diabetes avoid sugar-sweetened beverages (soft drinks, fruit drinks, energy and vitamin-type water drinks containing sucrose, high-fructose corn syrup, and/or fruit juice concentrates) to reduce the risk of worsening the cardiometabolic risk profile and to prevent weight gain.

Glycemic Index and Glycemic Load

The **glycemic index (GI)** of food was developed to compare the physiologic effects of carbohydrates on glucose. The GI measures the relative area under the postprandial glucose curve of 50 g of digestible carbohydrates compared with 50 g of a standard food, either glucose or white bread. When bread is the reference food, the GI value for the food is multiplied by 0.7 to obtain the GI value that is comparable to glucose being used as the reference food (GI of glucose = 100; GI of white bread = 70.) The GI does not measure how rapidly blood glucose levels increase. The peak glucose response for individual foods and meals, either high or low GI, occurs at approximately the same time (Brand-Miller et al, 2009).

The estimated **glycemic load (GL)** of foods, meals, and dietary patterns is calculated by multiplying the GI by the amount of available carbohydrate (divided by 100) in each food and

then totaling the values for all foods in a meal or dietary pattern. For example, two slices of white bread with a GI of 75 and 30 g of carbohydrate has a GL of 22.5 ($75 \times 30/100 = 22.5$) (see Appendix 37 for GI and GL of foods).

In studies comparing low- and high-GI diets, total carbohydrate first is kept consistent. The ADA systematic review of macronutrients concluded that, in general, there is little difference between low-GI and high-GI or other diets in terms of glycemic control and cardiovascular risk (Wheeler et al, 2012). The review notes that a slight improvement in glycemia may result from a lower-GI diet; however, confounding by higher fiber is not accounted for in some of the studies. A major problem with the GI is the variability of response to a specific carbohydrate food. For example, the mean glycemic response and standard deviation of 50 grams of carbohydrate from white bread tested in 23 subjects was 78 ± 73 with an individual coefficient of variation (CV) of 94%. Although the average GI of bread from three tests was 71%, the range of GI values was broad, ranging from 44 to 132 and the CV was 34% (Vega-López et al, 2007).

Studies are complicated further by differing definitions of “high GI” or “low GI” diets or quartiles. GIs in the low GI diets range from 38% to 77% and in the high GI diets from 63% to 98%. More recently, two trials, each 1 year in duration, reported no significant differences in A1C levels from a low GI versus high GI diet or a more usual diet (Ma et al, 2008; Wolever et al, 2008). Furthermore, most people appear to consume a moderate GI diet. It is unknown if reducing the usual GI by a few percentage points will result in improved glycemic control.

Fiber and Whole Grains

Evidence is lacking to recommend a higher fiber intake for people with diabetes than for the population as a whole. Thus recommendations for fiber intake for people with diabetes are similar to the recommendations for the general public. Although diets containing 44 to 50 g of fiber daily improve glycemia, more usual fiber intakes (up to 24 g daily) have not shown beneficial effects. It is unknown if free-living individuals can daily consume the amount of fiber needed to improve glycemia. However, consuming foods containing 25 g fiber per day for adult women and 38 g per day for adult men is encouraged (Evert et al, 2013). As with the general population, individuals with diabetes should consume at least half of all grains as whole grains.

Grams of fiber (and sugar alcohols) are included on food labels and are calculated as having about half the energy (2 kcal/g) of most other carbohydrates (4 kcal/g.) However, for most people, it is not necessary to subtract the amount of dietary fiber (or sugar alcohols) when carbohydrate counting (Evert et al, 2013). Adjustments in carbohydrate intake values is practical only if the amount per serving is more than 5 g. In that case, counting half of the carbohydrate grams from fiber (and sugar alcohols) would be useful in calculating food choices for food labels or recipes.

Non-nutritive and Hypocaloric Sweeteners

Reduced calorie sweeteners approved by the Food and Drug Administration (FDA) include sugar alcohols (erythritol, sorbitol, mannitol, xylitol, isomalt, lactitol, and hydrogenated starch hydrolysates) and tagatose. They produce a lower glycemic response and contain, on average, 2 calories per gram. There is no evidence that the amounts of sugar alcohols likely to be consumed will

reduce glycemia or energy intake. Although their use appears to be safe, some people report gastric discomfort after eating foods sweetened with these products, and consuming large quantities may cause diarrhea, especially in children.

Saccharin, aspartame, neotame, acesulfame potassium, and sucralose are non-nutritive sweeteners currently approved for use by the FDA. All such products must undergo rigorous testing by the manufacturer and scrutiny from the FDA for effectiveness and safety before they are approved and marketed to the public. For all food additives, including non-nutritive sweeteners, the FDA determines an *acceptable daily intake* (ADI), defined as the amount of a food additive that can be consumed safely on a daily basis over a person's lifetime without risk. The ADI generally includes a 100-fold safety factor and greatly exceeds average consumption levels. For example, aspartame actual daily intake in persons with diabetes is 2 to 4 mg/kg of body weight daily, well below the ADI of 50 mg/kg daily. The stevia-derived sweetener, Rebaudioside A, and monk fruit are generally recognized as safe (GRAS) and are currently being marketed. However, as new so-called “natural” and other sweeteners (such as agave nectar) appear in the market, people with diabetes should be aware that many do contain energy and carbohydrate as do foods sweetened with them.

All FDA-approved non-nutritive sweeteners, when consumed within the established daily intake levels, can be used by persons with diabetes, including pregnant women. Furthermore, nonnutritive sweeteners could facilitate reductions in added sugars intake; thereby resulting in decreased total energy and promoting beneficial effects on related metabolic parameters (Gardner et al, 2012).

Protein Intake

The amount of protein usually consumed by persons with diabetes (15% to 20% of energy intake) has minimal acute effects on glycemic response, lipids, and hormones, and no long-term effect on insulin requirements. For people with diabetes, evidence is inconclusive to recommend an ideal amount of protein intake for optimizing glycemic control or improving CVD risk factors; therefore goals should be individualized (Evert et al, 2013).

Although nonessential amino acids undergo gluconeogenesis, in well-controlled diabetes, the glucose produced does not appear in the general circulation; the glucose produced is likely stored in the liver as glycogen. When glycolysis occurs, it is unknown if the original source of glucose was carbohydrate or protein. Although protein is just as potent a stimulant of acute insulin release as carbohydrate, it has no long-term effect on insulin needs. Adding protein to the treatment of hypoglycemia does not prevent subsequent hypoglycemia and the addition of protein only adds unnecessary and usually unwanted calories. Furthermore, protein does not slow the absorption of carbohydrates and should not be added to snacks (or meals) to prevent hypoglycemia.

Fat Intake

Evidence is also inconclusive for an ideal amount of total fat for people with diabetes and therefore goals should be individualized (Evert et al, 2013). The type of fat consumed is more important than total fat in terms of metabolic goals and influencing CVD risk. Individuals should be encouraged, however, to moderate their fat intakes to be consistent with their goals to lose or maintain weight.

Monounsaturated fatty acid (MUFA)-rich foods as a component of the Mediterranean-style eating pattern are associated with improved glycemic control and improved CVD risk factors in persons with type 2 diabetes. Controversy exists on the best ratio of omega-6 to omega-3 fatty acids; however, polyunsaturated fatty acids (PUFAs) and MUFAs are recommended as substitutes for saturated fatty acids (SFAs) or trans fatty acids. The amount of SFAs, cholesterol, and trans fat recommended for people with diabetes is the same as for the general population.

There is evidence from the general population that foods containing omega-3 fatty acids have beneficial effects on lipoproteins and prevention of heart disease. Therefore the recommendations for the general public to eat fish (particularly fatty fish) at least two times (two servings) per week is also appropriate for people with diabetes. However, evidence from RCT does not support recommending omega-3 supplements for people with diabetes for the prevention or treatment of CVD despite evidence from observational and preclinical studies (Evert et al, 2013).

Alcohol

Moderate amounts of alcohol ingested with food have minimum, if any, acute effect on glucose and insulin levels. If individuals choose to drink alcohol, daily intake should be limited to one drink or less for adult women and two drinks or less for adult men (1 drink = 12 oz beer, 5 oz of wine, or 1.5 oz of distilled spirits.) Each drink contains =15 g alcohol. The type of alcoholic beverage consumed does not make a difference. The same precautions that apply to alcohol consumption for the general population apply to persons with diabetes. Abstinence from alcohol should be advised for people with a history of alcohol abuse or dependence; for women during pregnancy; and for people with medical problems such as liver disease, pancreatitis, advanced neuropathy, or severe hypertriglyceridemia.

Alcohol consumption may place people with diabetes who take insulin or insulin secretagogues at increased risk for delayed hypoglycemia. Consuming alcohol with food can minimize the risk of nocturnal hypoglycemia. Education and awareness of delayed hypoglycemia after consuming alcoholic beverages is important. Alcoholic beverages should be considered an addition to the regular food and meal plan for all persons with diabetes. No food should be omitted, given the possibility of alcohol-induced hypoglycemia and because alcohol does not require insulin to be metabolized. Excessive amounts of alcohol (three or more drinks per day) on a consistent basis, contribute to hyperglycemia which improves as soon as alcohol use is discontinued.

In persons with diabetes, light-to-moderate amounts of alcohol (1to -2 drinks per day; 15- to 30 g of alcohol) are associated with a decreased risk of coronary heart disease, likely because of improved insulin sensitivity associated with alcohol consumption. Ingestion of light-to-moderate amounts of alcohol does not raise blood pressure or triglycerides; whereas excessive, chronic ingestion of alcohol does raise blood pressure and may be a risk factor for stroke.

Micronutrients and Herbal Supplements

No clear evidence has been established for benefits from vitamin or mineral supplements in persons with diabetes (compared with the general population) who do not have underlying deficiencies (Evert et al, 2013). Because diabetes may be a state of

increased oxidative stress, there has been interest in prescribing antioxidant vitamins in people with diabetes. Clinical trial data not only indicate the lack of benefit from antioxidants on glycemic control and progression of complications but also provide evidence of the potential harm. Therefore routine supplementation is not advised. At this time there is also insufficient evidence to support the routine use of micronutrients such as chromium, magnesium, and vitamin D as well as use of cinnamon or other herbs/supplements for the treatment of diabetes.

In addition, herbal products are not standardized and vary in their content of active ingredients and have the potential to interact with and potentiate the effect of other medications. Therefore it is important that people with diabetes report the use of supplements and herbal products to their health care provider/RDN. Without well-designed clinical trials to prove efficacy, the benefit of pharmacologic doses of supplements is unknown, and findings from small clinical and animal studies frequently are extrapolated to clinical practice.

Physical Activity/Exercise

Physical activity involves bodily movement produced by the contraction of skeletal muscles that requires energy expenditure in excess of resting energy expenditure. Exercise is a subset of physical activity: planned, structured, and repetitive bodily movement performed to improve or maintain one or more components of physical fitness. Aerobic exercise consists of rhythmic, repeated, and continuous movements of the same large muscle groups for at least 10 minutes at a time. Examples include walking, bicycling, jogging, swimming, and many sports. Resistance exercise consists of activities that use muscular strength to move a weight or work against a resistive load. Examples include weight lifting and exercises using resistance-providing machines.

Physical activity should be an integral part of the treatment plan for persons with diabetes. Exercise helps all persons with diabetes improve insulin sensitivity, reduce cardiovascular risk factors, control weight, and improve well-being. Given appropriate guidelines, the majority of people with diabetes can exercise safely. The activity plan will vary, depending on interest, age, general health, and level of physical fitness.

Despite the increase in glucose uptake by muscles during exercise, glucose levels change little in individuals without diabetes. Muscular work causes insulin levels to decline, while counterregulatory hormones (primarily glucagon) rise. As a result, the increased glucose use by the exercising muscles is matched with increased glucose production by the liver. This balance between insulin and counterregulatory hormones is the major determinant of hepatic glucose production, underscoring the need for insulin adjustments in addition to adequate carbohydrate intake during exercise for people with diabetes.

In persons with T1DM, the glycemic response to exercise varies, depending on overall diabetes control, plasma glucose and insulin levels at the start of exercise; timing, intensity, and duration of the exercise; previous food intake; and previous conditioning. An important variable is the level of plasma insulin during and after exercise. Hypoglycemia can occur because of insulin-enhanced muscle glucose uptake by the exercising muscle.

In persons with T2DM, blood glucose control can improve with physical activity, largely because of decreased insulin resistance and increased insulin sensitivity, which results in increased peripheral use of glucose not only during but also after

the activity. This exercise-induced enhanced insulin sensitivity occurs independent of any effect on body weight. Structured exercise interventions of at least 8 weeks' duration are reported to lower A1C. Exercise also decreases the effects of counterregulatory hormones; this, in turn, reduces the hepatic glucose output, contributing to improved glucose control.

Potential Problems with Exercise

Hypoglycemia is a potential problem associated with exercise in persons taking insulin or insulin secretagogues. Hypoglycemia can occur during, immediately after, or many hours after exercise. Hypoglycemia has been reported to be more common after exercise—especially exercise of long duration—strenuous activity or play, or sporadic exercise, than it is during exercise. This is because of increased insulin sensitivity after exercise and the need to replete liver and muscle glycogen, which can take up to 24 to 30 hours (see Chapter 23).

Blood glucose levels before exercise reflect only the value at that time, and it is unknown if this is a stable blood glucose level or a blood glucose level that is dropping. If blood glucose levels are dropping before exercise, adding exercise can contribute to hypoglycemia during exercise. Furthermore, hypoglycemia on the day before exercise may increase the risk of hypoglycemia on the day of exercise as well.

Hyperglycemia also can result from exercise of high intensity, likely because the effects of counterregulatory hormones. When a person exercises at what for him or her is a high level of exercise intensity, there is a greater-than-normal increase in counterregulatory hormones. As a result, hepatic glucose release exceeds the rise in glucose use. The elevated glucose levels also may extend into the postexercise state. Hyperglycemia and worsening ketosis also can result in persons with T1DM who are deprived of insulin for 12 to 48 hours and are ketotic. Vigorous activity should be avoided in the presence of ketosis (ADA, 2014b). It is not, however, necessary to postpone exercise based simply on hyperglycemia, provided the individual feels well and urine and/or blood ketones are negative. High-intensity exercise is more likely to be the cause of hyperglycemia than insulin deficiency.

Exercise Guidelines

The variability of glucose responses to exercise contributes to the difficulty in giving precise guidelines for exercising safely. Frequent blood glucose monitoring before, during, and after exercise helps individuals identify their response to physical activities. To meet their individual needs, individuals must modify general guidelines to reduce insulin doses before (or after) or ingest carbohydrates after (or before) exercise. Similar to the general population without diabetes, it is also important for individuals with diabetes to stay hydrated when performing physical activities.

Carbohydrate for Insulin or Insulin Secretagogue Users. During moderate-intensity exercise, glucose uptake is increased by 8 to 13 g/hr; this is the basis for the recommendation to add 15 g carbohydrate for every 30 to 60 minutes of activity (depending on the intensity) over and above normal routines. Moderate exercise for less than 30 minutes usually does not require any additional carbohydrate or insulin adjustment, unless the individual is hypoglycemic before the start of exercise. Added carbohydrates should be ingested if pre-exercise glucose levels are less than 100 mg/dl (5.6 mmol/L). Supplementary carbohydrate is generally not needed in individuals

with T2DM who are not treated with insulin or insulin secretagogues; it simply adds unnecessary calories (ADA, 2014b).

In all persons, blood glucose levels decline gradually during exercise, and ingesting a carbohydrate feeding during prolonged exercise can improve performance by maintaining the availability and oxidation of blood glucose. For the exerciser with diabetes whose blood glucose levels may drop sooner and lower than the exerciser without diabetes, ingesting carbohydrate after 40 to 60 minutes of exercise is important and also may assist in preventing hypoglycemia. Drinks containing 6% or less of carbohydrates empty from the stomach as quickly as water and have the advantage of providing both needed fluids and carbohydrates. Consuming carbohydrates immediately after exercise optimizes repletion of muscle and liver glycogen stores. For the exerciser with diabetes, this takes on added importance because of increased risk for late-onset hypoglycemia.

Insulin Guidelines. It is often necessary to adjust the insulin dosage to prevent hypoglycemia. This occurs most often with moderate to strenuous activity lasting more than 45 to 60 minutes. For most persons a modest decrease (of about 1 to 2 units) in the rapid- (or short-) acting insulin during the period of exercise is a good starting point. For prolonged vigorous exercise, a larger decrease in the total daily insulin dosage may be necessary. After exercise, insulin dosing also may have to be decreased.

Precautions for Persons with Type 2 Diabetes. Persons with T2DM may have a lower VO_{2max} and therefore need a more gradual training program. Rest periods may be needed, but this does not impair the training effect from physical activity. Autonomic neuropathy or medications, such as for blood pressure, may not allow for increased heart rate, and individuals must learn to use perceived exertion as a means of determining exercise intensity. Blood pressure also may increase more in persons with diabetes than in those who do not have diabetes, and exercise should not be undertaken if systolic blood pressure is greater than 180 to 200 mm Hg (ADA, 2014b).

Exercise Recommendations

Adults with diabetes should be advised to perform at least 150 min/week of moderate-intensity aerobic physical activity (50% to 70% of maximum heart rate), or at least 90 min/week of vigorous aerobic exercise (more than 70% of maximum heart rate), spread over at least 3 days/week with no more than 2 consecutive days without physical activity. In the absence of contraindications, adults with T2DM should be encouraged to perform resistance exercise at least twice per week with each session consisting of at least one set of five or more different resistance exercises involving large muscle groups. There is an additive benefit of combined aerobic and resistance training in adults with T2DM. Children with diabetes or prediabetes should be encouraged to engage in at least 60 min/day of physical activity (ADA, 2014b).

Routine screening pre-exercise is not recommended. Providers should use clinical judgment in this area. High-risk patients should be encouraged to start with short periods of low-intensity exercise and increase the intensity and duration slowly (ADA, 2014b).

Medications

A consensus statement on the approach to management of hyperglycemia in T2DM has been published by the ADA and the European Association for the Study of Diabetes (Inzucchi et al, 2015). Interventions at the time of diagnosis include healthy

eating, weight control, physical activity, and diabetes education. Metformin is the preferred initial pharmacologic agent for type 2 diabetes, either in addition to lifestyle counseling and support for weight loss and physical activity, or when lifestyle efforts alone have not achieved or maintained glycemic goals. If A1C target goals are not reached after approximately 3 months, a second oral agent, a glucagon-like peptide 1 (GLP-1) receptor agent, or basal insulin is added. If A1C goals are not reached after another approximately 3 months, a three-drug intervention is implemented. If this combination therapy that includes a long-acting insulin does not achieve A1C goals, a more complex insulin therapy involving multiple daily doses, usually in combination with one or more noninsulin agents, is implemented. A patient-centered approach is stressed, including patient preferences, cost and potential side effects (ADA, 2014b). The overall objective is to achieve and maintain glycemic control and to change interventions, including the use of insulin, when therapeutic goals are not being met.

All persons with T1DM and many persons with T2DM who no longer produce adequate endogenous insulin need replacement of insulin. Circumstances that require the use of insulin in T2DM include the failure to achieve adequate control with administration of glucose-lowering medications; periods of acute injury, infection, extreme heat exposure, surgery, or pregnancy.

Glucose-Lowering Medications for Type 2 Diabetes

Understanding that T2DM is a progressive disease is important for the understanding of treatment choices. Assisting individuals with diabetes to understand the disease process also helps them to understand and accept changes in medications that occur over time. Diabetes is first diagnosed when there is insufficient insulin available to maintain euglycemia, and as insulin deficiency progresses, medications and eventually insulin will be required to achieve glycemic goals. This is not a “diet failure” or a “medication failure” but rather a failure of the insulin secreting capacity of the beta-cells.

Glucose-lowering medications target different aspects of the pathogenesis of T2DM—insulin resistance at the cellular level, incretin system defects, endogenous insulin deficiency, elevated levels of glucagon, and excessive hepatic glucose release. Because the mechanisms of action differ, the medications can be used alone or in combination. Table 30-5 lists the generic and brand names of glucose-lowering medications and their principal sites of action for persons with T2DM.

Biguanides. Metformin is the most widely used first-line type 2 medication. It suppresses hepatic glucose production, is not associated with hypoglycemia, may cause small weight losses when therapy begins, and is relatively inexpensive. The most common side effects are gastrointestinal, which often

TABLE 30-5 Glucose-Lowering Medications for Type 2 Diabetes

Class	Brand Name	Site and Mechanism of Action	Adverse Effects/Nutrition Considerations
Biguanide	Metformin (Glucophage) Metformin Extended Release (Glucophage XR)	Liver Decrease hepatic glucose production and may help reduce insulin resistance	Nausea, vomiting, diarrhea, and gas May be able to reduce side effects by slowly increasing dose and taking with a meal
Sulfonylureas (second-generation)	Glipizide (Glucotrol) Glipizide (Glucotrol XL) Glyburide (Glynase Prestabs) Glimpiride (Amaryl)	Pancreas Stimulate insulin secretion from the beta-cells	Hypoglycemia
Meglitinides (Glinides)	Repaglinide (Prandin) Nateglinide (Starlix)	Pancreas Stimulate insulin secretion from beta-cells	Hypoglycemia
Thiazolidinediones	Pioglitazone (Actos) Rosiglitazone (Avandia)	Muscle Improve peripheral insulin sensitivity	Weight gain, fluid retention
Glucagon-like peptide-1 (GLP-1) Receptor Agonists	Exenatide (Byetta) Exenatide Extended Release (Bydureon) Liraglutide (Victoza) Albiglutide (Tanzeum) Dulaglutide (Trulicity)	Pancreas, liver, and gastrointestinal tract Enhances glucose-dependent insulin secretion Suppresses postprandial glucagon secretion Slows gastric emptying Increases satiety	Nausea, vomiting, and hypoglycemia if taken with a sulfonylurea or insulin Exenatide can be injected up to 60 minutes before meal. If nausea and/or vomiting occur, try moving injection closer to meal: 10-20 minutes or immediately before eating
Dipeptidyl peptidase-4 (DPP-4) inhibitors	Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Tradjenta) Alogliptin (Nesina)	Pancreas and liver Enhance the effects of GLP-1 and GIP by preventing degradation	No major side effects Possible cold symptoms
Alpha glucosidase inhibitors	Acarbose (Precose) Miglitol (Glyset)	Small intestine Delay carbohydrate absorption	Diarrhea, gas, and nausea (can lessen effects by slowly increasing dose) If mild to moderate hypoglycemia occurs in combination with another antidiabetic drug such as a sulfonylurea or insulin, the hypoglycemia should be treated with oral glucose (dextrose) instead of sucrose (table sugar) because the drug blocks the digestion of sucrose to glucose.

Continued

TABLE 30-5 Glucose-Lowering Medications for Type 2 Diabetes—cont'd

Class	Brand Name	Site and Mechanism of Action	Adverse Effects/Nutrition Considerations
Amylin agonists	Pramlintide (Symlin)	Liver, gastrointestinal tract, brain Decreases glucagon production, which decreases mealtime hepatic glucose release and prevents postprandial hyperglycemia	Bladder infections
Sodium-glucose transport protein inhibitors (SGLT)	Canagliflozin (Invokana) Dapagliflozin (Farxiga) Empagliflozin (Jardiance)	Kidney Reduces the reabsorption of glucose in the kidneys via sodium glucose cotransporter-2 (SGLT2) inhibition	Constipation, diarrhea, nausea, urinary frequency and genitourinary infections
Insulins	See Table 30-6	Supplements endogenous insulin	Hypoglycemia

Adapted from Inzucchi SE et al: Management of hyperglycemia in type 2 diabetes: a patient-centered approach, *Diabetes Care* 35:1364, 2012.

disappear with time. To minimize these effects, the medication should be taken with food consumption and the smallest dose (500 mg) given twice a day for a week and gradually increased to maximum doses. A rare side effect is severe lactic acidosis, which can be fatal. The acidosis usually occurs in patients who use alcohol excessively, have renal dysfunction, or have liver impairments.

Sulfonylureas. The sulfonylureas are **insulin secretagogues** and promote insulin secretion by the beta-cells of the pancreas. First- and second-generation sulfonylurea drugs differ from one another in their potency, pharmacokinetics, and metabolism. Disadvantages of their use include weight gain and the potential to cause hypoglycemia. They have the advantage of being inexpensive.

Thiazolidinediones (TZDs). Thiazolidinediones (TZDs) or glitazones (pioglitazone [Actos] and rosiglitazone [Avandia]) decrease insulin resistance in peripheral tissues and thus enhance the ability of muscle and fat cells to take up glucose. TZDs also have a favorable effect on lipids and do not independently cause hypoglycemia. Adverse effects include weight gain, fluid retention leading to edema and/or heart failure, and increased risk of bone fractures.

Glucagon-like Peptide-1 (GLP-1) Receptor Agonist. Incretins are hormones made by the gastrointestinal tract and includes GLP-1. GLP-1 is released during nutrient absorption, which increases glucose-dependent insulin secretion, slows gastric emptying, decreases glucagon production, and enhances satiety. Exenatide (Byetta) and liraglutide (Victoza) are synthetic drugs that have many of the same glucose lowering effects as the body's naturally occurring incretin, GLP-1. A primary benefit is weight loss (liraglutide has also been approved as a weight-loss drug). Typically exenatide is injected twice a day, at breakfast and at the evening meal and liraglutide is injected once a day, at any time, independent of meals. There are two once-weekly injection GLP-1s: exenatide extended (Bydureon) and dulaglutide (Trulicity).

Dipeptidyl Peptidase 4 Inhibitors (DPP-4). GLP-1 and glucose-dependent insulinotropic peptide (GIP), the main intestinal stimulants of insulin are rapidly degraded by DPP-4. As a result, incretins have very short half-lives of 2 to 3 minutes. DPP-4 inhibitors prolong their half-lives. Oral DPP-4 inhibitors are sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina). They have a modest effect

on A1C; however, advantages include being weight neutral and relatively well tolerated. Furthermore, they do not cause hypoglycemia when used as monotherapy.

Alpha Glucosidase Inhibitors. Acarbose (Precose) and miglitol (Glyset) are alpha-glucosidase inhibitors that work in the small intestine to inhibit enzymes that digest carbohydrates, thereby delaying carbohydrate absorption and lowering postprandial glycemia. They do not cause hypoglycemia or weight gain when used alone, but they can frequently cause flatulence, diarrhea, cramping, or abdominal pain. Symptoms may be alleviated by initiating therapy at a low dose and gradually increasing the dose to therapeutic levels.

Glinides. The meglitinides repaglinide (Prandin) and nateglinide (Starlix) differ from the sulfonylureas in that they have short metabolic half-lives, which result in brief episodic stimulation of insulin secretion. They are given before meals decreasing postprandial glucose excursions and less risk of hypoglycemia. Nateglinide only works in the presence of glucose and is a somewhat less potent secretagogue. Risk of weight gain is similar to sulfonylureas.

Sodium-Glucose Transporter 2 (SGLT-2) Inhibitors. Canagliflozin (Invokana), dapagliflozin (Farxiga) and empagliflozin (Jardiance) are drugs in a new class that target blood glucose lowering action in the kidneys. SGLT-2 inhibitors block a transporter protein that returns glucose to the bloodstream after it is filtered through the kidneys. Blocking this protein causes more glucose to be flushed out in the urine. Used independently it does not cause hypoglycemia or weight gain.

Amylin Agonists (Pramlintide). Pramlintide (Symlin) is a synthetic analog of the hormone amylin, a hormone normally cosecreted with insulin by the beta-cell in response to food that is deficient in people with T1DM and T2DM. It is injected before meals slowing gastric emptying and inhibiting glucagon production, resulting in a decrease in postprandial glucose excursions, which is related to a decrease in glucagon production from the pancreatic alpha cells. It must be injected separately from insulin.

Insulin. Insulin strategies for persons with T2DM may begin with basal insulin at bedtime to suppress nocturnal hepatic glucose production and to normalize fasting glucose levels. Glucose-lowering medications usually are continued during the day. The next step is to add one mealtime rapid-acting insulin with the basal insulin or use of premixed insulin twice daily. If

A1C goals are not achieved, mealtime rapid-acting insulin is used before each meal. Insulin secretagogues usually are stopped but other glucose lowering agents may be continued.

Insulin

Insulin has three characteristics: onset, peak, and duration (see Table 30-6). U-100 is the concentration of insulin used in the United States. This means it has 100 units of insulin per milliliter of fluid (100 units/ml). U-100 syringes deliver U-100 insulin; however, insulin pens are now being used more frequently as an alternative to the traditional syringe-needle units. Humulin R U-500 (500 units/ml) is useful in the treatment of insulin-resistant patients who require daily doses more than 200 units.

Rapid-Acting Insulins. Included are insulin lispro (Humalog), insulin aspart (Novolog), and insulin glulisine (Apidra) and are used as bolus (premeal or prandial) insulins. They are insulin analogs that differ from human insulin in amino acid sequence but bind to insulin receptors and thus function in a manner similar to human insulin. To determine the accuracy of the dose, blood glucose checking is done before meals and 2 hours after the start of the meals.

Regular Insulin. A short-acting insulin with a slower onset of action and later activity peak. For best results the slow onset of regular insulin requires it to be taken 30 to 60 minutes before meals.

Intermediate-Acting Insulin. NPH is the only available intermediate-acting insulin and is cloudy in appearance.

Long-Acting Insulins. Insulin glargine (Lantus) and insulin detemir (Levemir) are long-acting insulins. Insulin glargine is an insulin analog that, because of its slow dissolution at the injection site, results in a relatively constant and peakless delivery over 24 hours. Because of its acidic pH, it cannot be mixed with any other insulin in the same syringe before injection and

usually is given at bedtime. However, glargine can be given before any meal, but, whichever time is chosen, it must be given consistently at that time. Insulin detemir is absorbed from the subcutaneous tissue relatively quickly but then binds to albumin in the bloodstream, resulting in a prolonged action time of approximately 17 hours. Therefore it may have to be given twice a day. Basal insulin analogs decrease the chances of hypoglycemia, especially nocturnal hypoglycemia.

Premixed Insulins. Included are 70% NPH/30% regular, 75% lispro protamine (NPL [addition of neutral protamine to lispro to create an intermediate-acting insulin])/25% lispro, 50% lispro protamine and 50% lispro, and 70% protamine (addition of neutral protamine to aspart to create an immediate-acting insulin)/30% aspart. Persons using premixed insulins must eat at specific times and be consistent in carbohydrate intake to prevent hypoglycemia.

Insulin Regimens. All persons with T1DM and those with T2DM who no longer produce adequate endogenous insulin need replacement of insulin that mimics normal insulin action. After individuals without diabetes eat, their plasma glucose and insulin concentrations increase rapidly, peak in 30 to 60 minutes, and return to basal concentrations within 2 to 3 hours. To mimic this, rapid-acting (or short-acting) insulin is given before meals, and this is referred to as bolus or mealtime insulin.

Mealtime insulin doses are adjusted based on the amount of carbohydrate in the meal. An insulin-to-carbohydrate ratio can be established for an individual that will guide decisions on the amount of mealtime insulin to inject. Basal or background insulin dose is that amount of insulin required in the postabsorptive state to restrain endogenous glucose output primarily from the liver. Basal insulin also limits lipolysis and excess flux of free fatty acids to the liver. Long-acting insulins are used for basal insulin (see Figure 30-1).

TABLE 30-6 Action Times of Human Insulin Preparations

Type of Insulin	Onset of Action	Peak Action	Usual Effective Duration	Monitor Effect In
Rapid-Acting				
Insulin lispro (Humalog)	<0.25-0.5 hr	0.5-2.5 hr	3-6.5 hr	1-2 hr
Insulin aspart (NovoLog)	<0.25 hr	0.5-1.0 hr	3-5 hr	1-2 hr
Insulin glulisine (Apidra)	<0.25 hr	1-1.5 hr	3-5 hr	1-2 hr
Short-Acting				
Regular (Humulin R and Novolin R)	0.5-1 hr	2-3 hr	3-6 hr	4 hr (next meal)
Intermediate-Acting				
NPH	2-4 hr	4-10 hr	10-16 hr	8-12 hr
Long-Acting				
Insulin glargine (Lantus)	2-4 hr	Peakless	20-24 hr	10-12 hr
Insulin detemir (Levemir)	0.8-2 hr (dose dependent)	Peakless	12-24 hr (dose dependent)	10-12 hr
Mixtures				
70/30 (70% NPH, 30% regular)	0.5-1 hr	Dual	10-16 hr	
Humalog Mix 75/25 (75% neutral protamine lispro [NPL], 25% lispro)	<0.25 hr	Dual	10-16 hr	
Humalog Mix 50/50 (50% protamine lispro, 50% lispro)	<0.25 hr	Dual	10-16 hr	
NovoLog Mix 70/30 (70% neutral protamine aspart [NPA], 30% aspart)	<0.25 hr	Dual	15-18 hr	

Adapted from Kaufman FR editor: *Medical management of type 1 diabetes*, ed 6, Alexandria, Va, 2012, American Diabetes Association.

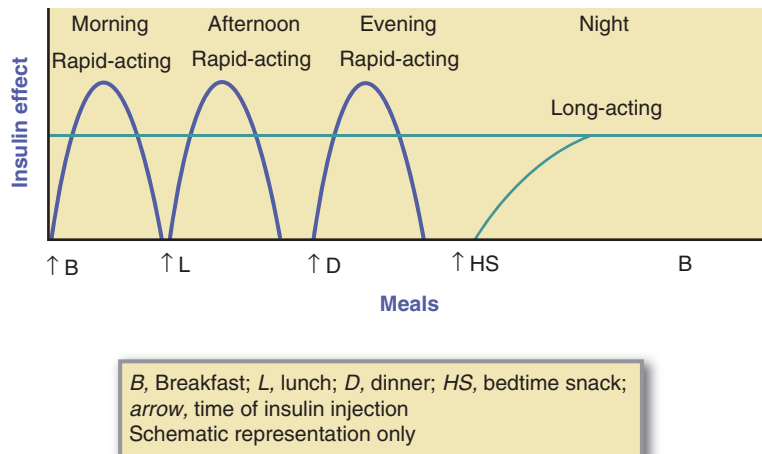

FIGURE 30-1 Time actions of flexible insulin regimens.(Modified from Kaufman FR, editor: *Medical management of type 1 diabetes*, ed 6, Alexandria, Va, 2012, American Diabetes Association.)

These physiologic insulin regimens allow increased flexibility in the type and timing of meals. For normal-weight persons with T1DM, the required insulin dosage is about 0.5 to 1 unit/kg of body weight per day. About 50% of the total daily insulin dose is used to provide for basal or background insulin needs. The remainder (rapid-acting insulin) is divided among the meals either proportionately to the carbohydrate content or by giving about 1 to 1.5 units of insulin per 10 to 15 g of carbohydrates consumed. As a result of the presence in the morning of higher levels of counterregulatory hormones many individuals may require larger doses of mealtime insulin for carbohydrates consumed at breakfast than meals later in the day. Persons with T2DM may require insulin doses in the range of 0.5 to 1.2 units/kg of body weight daily. Large doses, even more than 1.5 units/kg of body weight daily, may be required at least initially to overcome prevailing insulin resistance. The type and timing of insulin regimens should be individualized, based on eating and exercise habits and blood glucose concentrations.

Insulin Regimens: Continuous Sustained Insulin Infusion (CSII) or Insulin Pump Therapy. The insulin (usually a rapid-acting insulin) is pumped continuously by a mechanical device in micro amounts through a subcutaneous catheter. The pump delivers insulin in two ways: in a steady, measured, and continuous dose (basal insulin) and as a surge (bolus) dose before meals. Pump therapy requires a committed and motivated person who is willing to do a minimum of four blood glucose tests per day, understand increased risk of **diabetic ketoacidosis**, and learn the technical features of pump use such as the bolus calculator and “insulin-on-board” features. The individual also should be educated on MNT, including carbohydrate counting/estimation. Prandial boluses are dependent on carbohydrate intake as well as circadian variation in insulin sensitivity, current blood glucose levels, and planned physical activity. Regularly scheduled outpatient follow-up with diabetes care providers knowledgeable in the use of CSII is recommended to optimize glycemic control long term.

Self-Management Education

Diabetes management is a team effort. Persons with diabetes must be at the center of the team because they have the responsibility for day-to-day management. RDNs, nurses, physicians,

and other health care providers contribute their expertise to developing therapeutic regimens that help the person with diabetes achieve the best metabolic control possible. The goal is to provide patients with the knowledge, skills, and motivation to incorporate self-management into their daily lifestyles. The Academy of Nutrition and Dietetics (AND) Evidence-Based Nutrition Practice Guidelines (EBNPG) recommends that individuals with diabetes be referred for MNT early after the diagnosis of diabetes. MNT is to be provided by a RDN in an initial series of three to four encounters each lasting 45 to 90 minutes. This series should be completed within 3 to 6 months, and the RDN should determine whether additional encounters are needed after the initial series based on the nutrition assessment of learning needs and progress toward desired outcomes. At least one follow-up encounter is recommended annually to reinforce lifestyle changes and to evaluate and monitor outcomes that affect the need for changes in MNT or medication(s). The RDN should again determine whether additional MNT encounters are needed. Although glycemic control is the primary focus for diabetes management, cardioprotective nutrition interventions for the prevention and treatment of CVD also should be implemented in the initial series of encounters (AND, 2008a; Franz et al, 2010).

Dietitians can demonstrate their specialized diabetes knowledge by obtaining certification beyond the RDN credential. Two diabetes care certifications available to RDs are the Certified Diabetes Educator (CDE), a specialty certification, and Board Certified-Advanced Diabetes Management (BC-ADM), an advanced practice certification.

Monitoring

The health care team, including the individual with diabetes, should work together to implement blood glucose monitoring and establish individual target blood glucose goals (see Table 30-3). Several methods are available to assess the effectiveness of the diabetes management plan on glycemic control: SMBG or **continuous glucose monitoring (CGM)** of interstitial glucose and A1C. SMBG is used on a day-to-day basis to manage diabetes effectively and safely; however, measurement of A1C levels provides the best available index of overall diabetes control.

Self-Monitoring of Blood Glucose (SMBG)

The ADA recommendations state that persons on multiple-dose insulin (MDI) or insulin pump therapy should do SMBG before meals and snacks, occasionally postprandially at bedtime, before exercise, when they suspect low blood glucose, after treating low blood glucose until they are normoglycemic, and before critical tasks such as driving. For persons using less frequent insulin injections or noninsulin therapies, SMBG results may be helpful to guide treatment decisions (ADA, 2014b).

The AND EBNPG for diabetes reviewed the evidence on glucose monitoring and recommended that for persons with T1DM or T2DM on insulin therapy, at least three to four glucose tests per days are needed to determine the accuracy of the insulin dose(s) and to guide adjustments in insulin dose(s), food intake, and physical activity. Once established some insulin regimens require less frequent SMBG. For persons on MNT alone or MNT in combination with glucose-lowering medications, frequency and timing are dependent on diabetes management goals and therapies.

Self-management education and training is necessary to use SMBG devices and data correctly (ADA, 2014b). Individuals must be taught how to adjust their management program based on the results of SMBG. The first step in using such records is to learn how to identify patterns in blood glucose levels taken at the same time each day that are outside the target range—generally high readings for three or more days in a row or low readings 2 days in a row. The next step is to determine whether a lifestyle factor (meal times, carbohydrate intake, quantity and time of physical activity) or medication dose adjustment is needed.

If changes in medication doses such as insulin are needed, adjustments are made in the insulin (or medications) acting at the time of the problem glucose readings. After pattern management is mastered, algorithms for insulin dose changes to compensate for an elevated or low glucose value can be used. A commonly used formula determines the insulin sensitivity, or **correction factor (CF)**, which defines how many milligrams per deciliter a unit of rapid- (or short-acting) insulin will lower blood glucose levels over a 2- to 4-hr period (Kaufman, 2012). The CF is determined by using the “1700 rule,” in which 1700 is divided by the total daily dose (TDD) of insulin the individual typically takes. For example, if the TDD is 50 units of insulin, the $CF = 1700/50 = 35$. In this case 1 unit of rapid-acting insulin should lower the individual’s blood glucose level by 35 mg/dl (2 mmol/L).

In using blood glucose monitoring records, remember that factors other than food affect blood glucose concentrations. An increase in blood glucose can be the result of insufficient insulin or insulin secretagogue; too much food; or increases in glucagon and other counterregulatory hormones as a result of stress, illness, or infection. Factors that contribute to hypoglycemia include too much insulin or insulin secretagogue, not enough food, unusual amounts of exercise, and skipped or delayed meals. Urine glucose testing, used in the past, has so many limitations that it should not be used.

Continuous Glucose Monitoring (CGM)

CGM systems include a tiny glucose-sensing device called a sensor that is inserted under the skin in the subcutaneous fat tissue for several days at a time. The sensor measures glucose in interstitial fluid and transmits readings every 5 minutes to a monitor that is worn or carried externally. CGM devices also provide information not just on current glucose level, but also

on the trend and rate of change in glucose levels (i.e., whether the glucose level is rising or falling and how quickly). Other features include alerts for glucose highs and lows and the ability to download data and track trends over time. The ADA recommends that CGM in conjunction with intensive insulin regimens can be a useful tool to lower A1C in selected adults (age of more than 25 years) with T1DM. Evidence is less strong for A1C lowering in children, teens, and younger adults; however, CGM may be also helpful in these groups (ADA, 2014b).

A1C Monitoring

A1C tests should be done at least twice a year in persons who are meeting treatment goals and have stable glycemic control. They should be done quarterly in persons whose therapy has changed or who are not meeting glycemic goals. In persons without diabetes A1C values are 4% to 6%. These values correspond to mean plasma glucose levels of approximately 70 to 126 mg/dl (3.9 to 7.0 mmol/L). Correlation between A1C levels and average glucose levels recently have been verified. An A1C of 6% reflects an average glucose level of 126 mg/dL (7.0 mmol/L). Lowering A1C to below or around 7% is a reasonable goal for many nonpregnant adults with diabetes. An A1C less than 7% has been shown to reduce cardiovascular complications of diabetes and is associated with long-term reduction of macrovascular disease (ADA, 2014b). Less stringent goals, such as less than 8% may be appropriate for individuals with advanced macrovascular and microvascular complications, history of severe hypoglycemia, or other extensive comorbid conditions.

Ketone, Lipid, and Blood Pressure Monitoring

Urine or blood testing can be used to detect ketones. Testing for ketonuria or ketonemia should be performed regularly during periods of illness and when blood glucose levels consistently exceed 240 mg/dl (13.3 mmol/L). The presence of persistent, moderate, or large amounts of ketones, along with elevated blood glucose levels, requires insulin adjustments. Persons with T2DM rarely have ketosis; however, ketone testing should be done when the person is seriously ill.

For most adults, lipids should be measured at least annually; however, in adults with low-risk lipid values, assessments may be repeated every 2 years. Blood pressure should be measured at every routine diabetes visit (ADA, 2014b).

IMPLEMENTING THE NUTRITION CARE PROCESS

The nutrition care process (NCP) articulates the consistent and specific steps used to deliver MNT (AND, 2012). For some individuals with diabetes MNT will be implemented in individual sessions and for others in group sessions. Providing nutrition interventions in groups is becoming increasingly important; however, group interventions must also allow for individualization of MNT and evaluation of outcomes. The following sections review implementation of individual MNT.

Nutrition Assessment

The nutrition assessment involves obtaining information before and during the encounter needed to identify nutrition-related problems. Assessment data can be obtained from the referral source or the patient’s medical records and from the patient/client. Patient/client data can be collected from forms the patient completes before the first encounter or directly from the patient. By collecting as much data as possible before the

first session, completion of the assessment and implementation of interventions can begin more efficiently. Nutrition assessment is an ongoing process that involves not only initial data collection but also reassessment and analysis of patient data and needs. [Box 30-2](#) provides a summary of assessment categories ([Franz et al, 2012](#)).

The AND EBNPG for diabetes highlights three specific assessment recommendations. First, the RDN should assess food intake (focusing on carbohydrates) medication, metabolic control (glycemia, lipids, and blood pressure), anthropometric measurements, and physical activity as the basis for the implementation of the nutrition prescription, goals, and interventions (see Chapters 4 and 7). Second, the RDN should assess glycemic control and focus MNT to achieve and maintain blood glucose levels in the target range. However, the need for cardioprotective nutrition interventions also should be assessed. Third, the RDN should assess the relative importance of weight management for persons with diabetes who are overweight or obese. Although modest weight loss has been shown to improve insulin resistance in overweight and obese insulin-resistant individuals, research on sustained weight loss interventions lasting 1 year or longer report inconsistent effects on A1C ([AND, 2008a](#)).

Nutrition Diagnosis

The nutrition diagnosis identifies and describes a specific nutrition problem that can be resolved or improved through treatment/intervention by an RDN. Patients may have more than one nutrition diagnoses, in which case the RDN will need to prioritize them in the nutrition intervention step. The nutrition diagnostic language includes three domains: (1) intake problems related to the quantity of intake versus requirements, (2) clinical findings/problems related to medical (or physical) condition, and (3) behavioral-environmental findings/problems related to knowledge, attitudes/beliefs,

physical environment, and access to food. A nutrition diagnosis is written in the PES format that states the *problem* (P), the *etiology* (E), and *signs and symptoms* (S). Examples of diabetes-related nutrition diagnoses are listed in [Box 30-3](#) ([Franz et al, 2012](#)).

Nutrition Interventions

Nutrition interventions include two distinct steps: planning the nutrition goals and implementing the actual interventions. Planning involves prioritizing the nutrition diagnoses, conferring with the persons with diabetes and others, reviewing current nutrition practice guidelines for diabetes, setting goals, determining the nutrition prescription, and choosing specific intervention strategies.

Implementation is the action phase. In the food and nutrient delivery phase, an individualized eating plan is developed and specific nutrient recommendations are included. Nutrition

BOX 30-2 Nutrition Assessment

Nutrition Assessment Categories

- Biochemical data, medical tests, and procedures, which include laboratory data such as for A1C, glucose, lipids, kidney function, and blood pressure measurements
- Anthropometric measurements, which include height, weight, body mass index (BMI), waist circumference, growth rate, and rate of weight change
- Client history, which includes:
 - General patient information, such as age, gender, race/ethnicity, language, literacy, and education
 - Medical/health history and medical treatment, including goals of medical therapy and prescribed medications related to medical condition for which MNT is being implemented
 - Readiness to change nutrition-related behaviors
 - Weight management goals
 - Physical activity history and goals
 - Social history, such as social and medical support, cultural and religious beliefs, and socioeconomic status
 - Other medical or surgical treatments, therapy, and alternative medicine
- Food/nutrition history
 - Food intake, nutrition and health knowledge and beliefs
 - Food availability
 - Supplement use

Modified from [Franz MJ et al: ADA pocket guide to lipid disorders, hypertension, diabetes, and weight management](#), Chicago, 2012, Academy of Nutrition and Dietetics.

BOX 30-3 Examples of PES Statements Related to Diabetes Mellitus

Nutrition Diagnosis: Inconsistent carbohydrate intake

- Inconsistent carbohydrate intake (P) related to incorrect application of carbohydrate counting (E) as evidenced by food records revealing 2 additional carbohydrate servings for many meals and wide fluctuations in blood glucose levels, most days of the week (S).

Nutrition Diagnosis: Inconsistent carbohydrate intake

- Inconsistent carbohydrate intake (P) related to inconsistent timing of meals (E) as evidenced by wide fluctuations in blood glucose levels (S).

Nutrition Diagnosis: Excessive carbohydrate intake

- Excessive carbohydrate intake (P) compared with insulin dosing related to inaccurate carbohydrate counting (E) as evidenced by the number of carbohydrate servings per meal noted in food record and postmeal glucose levels consistently >200 mg/dl (S).

Nutrition Diagnosis: Inappropriate intake of food fats

- Excessive saturated fat intake (P) related to lack of knowledge of saturated fat content of foods (E) as evidenced by self-report of high saturated fat intake (S).

Nutrition Diagnosis: Altered laboratory values

- Altered blood glucose values (P) related to insufficient insulin (E) as evidenced by hyperglycemia despite very good eating habits (S).

Nutrition Diagnosis: Overweight/obesity

- Overweight (P) related to excessive energy intake with limited physical activity (E) as evidenced by a BMI of 30 and food history indicating consumption of 2800 kcal per day vs 2200 calories (estimated needs) and sedentary lifestyle (S).

Nutrition Diagnosis: Food- and nutrition-related knowledge deficit

- Food- and nutrition-related knowledge deficit (P) related to lack of exposure to information (E) as evidenced by new diagnosis of diabetes (or prediabetes, lipid disorder, hypertension) (S)

Nutrition Diagnosis: Not ready for lifestyle change

- Not ready for lifestyle change (P) related to denial of need to change in precontemplation (E) as evidenced by reluctance to begin participation in physical activity program (S)

Modified from [Franz MJ et al: ADA pocket guide to lipid disorders, hypertension, diabetes, and weight management](#), Chicago, 2012, Academy of Nutrition and Dietetics.

education involves the transfer of knowledge to the specific deficits identified in the nutrition diagnosis statements. Nutrition counseling involves behavior and attitude change through the use of strategies that promote behavior changes and/or motivation and intention to change (see Chapter 14). Nutrition care also must be coordinated with other health care providers that can assist in the implementation of the nutrition prescription and nutrition therapy. If home care is needed, follow-up should take place.

Nutrition Therapy Interventions for All People with Diabetes

The first priority is to promote and support a healthful eating pattern, emphasizing a variety of nutrient dense foods in appropriate portion sizes. However, monitoring carbohydrate intake also can be important nutrition therapy strategy for persons with all types of diabetes. It is important that individuals with diabetes know what foods contain carbohydrates—starchy vegetables, grains, fruit, milk and milk products, vegetables, and sweets; portion sizes; and how many servings they should select for meals (and if they desire, snacks). When choosing carbohydrate foods, nutrient-dense, high-fiber foods are recommended whenever possible instead of processed foods with added sodium, fat, and sugars. Sugar-sweetened beverages also should be avoided.

Nutrition Therapy Interventions for Specific Populations

Persons with T1DM and Insulin-Requiring T2DM. The first priority is to integrate an insulin regimen into the usual eating habits and physical activity schedule. With the many insulin options now available (rapid- and long-acting insulins), an insulin regimen can be planned that will conform to an individual's preferred meal routines and food choices. It is no longer necessary to create unnatural or artificial divisions of meals and snacks.

Physiologic insulin regimens that mimic natural insulin secretion involve multiple injections (three or more insulin injections per day) or use of insulin pump therapy. These types of insulin regimens allow increased flexibility in choosing when and what to eat. Mealtime insulin doses are adjusted to match carbohydrate intake (insulin-to-carbohydrate ratios). Therefore, it is important that individuals learn how to count carbohydrates or use another meal planning approach to quantify carbohydrate intake. The insulin action times of the currently available rapid-acting insulin analogs are: onset 5 to 15 minutes, a peak between 30 to 90 minutes, and a duration of approximately 4 to 6 hours. "Lag time" is defined as the amount of time that elapses between the injection of rapid-acting insulin and the meal; it is critical in control of postprandial hyperglycemia and in later risk of hypoglycemia. Given the pharmacodynamics of insulin analogs, a sufficient lag time of approximately 10 to 15 minutes before start of meal helps to decrease postprandial hyperglycemia.

For persons who receive fixed insulin regimens such as with the use of premixed insulins or those who do not adjust their mealtime insulin doses, day-to-day consistency in the timing and amount of carbohydrates eaten is recommended. Insulin doses also must be taken at consistent times every day. The amount of carbohydrate is individualized to the person's nutritional needs. The amount of mealtime insulin (rapid- or short-acting) that the person takes only changes for the blood glucose level. Some people with T1DM or insulin-requiring T2DM still use this method for a variety of reasons, such as age, cost, fewer required injections, lack of access to insulin analogs, personal preference, or prescribing habits of the health care provider.

With so much attention focused on the carbohydrate component of the diabetes Eating Plan, consideration also must be paid to total energy intake. Weight gain may adversely affect glycemia, lipids, blood pressure, and general health; thus prevention of weight gain in adults is desirable. Furthermore, it is assumed that protein and fat content is kept fairly consistent. However, there may be occasions when fat and protein intake is significantly increased and small amounts of additional bolus insulin may be needed for their metabolism (Wolpert et al, 2013).

Persons with Type 2 Diabetes on MNT Alone or with Glucose-Lowering Medications. The first priority is to adopt lifestyle interventions that improve the metabolic abnormalities of glycemia, dyslipidemia, and hypertension. Lifestyle interventions independent of weight loss that can improve glycemia include reduced energy intake and increased energy expenditure through physical activity. Because many persons also have dyslipidemia and hypertension, a cardioprotective eating pattern also is recommended. These interventions should be implemented as soon as the diagnosis of diabetes is made.

MNT interventions for established T2DM differ from interventions for prevention. Because of the progressive nature of T2DM, MNT interventions progress from prevention of obesity, to the prevention or delay of T2DM, to strategies for improved metabolic control. Modest weight loss is beneficial in persons with insulin resistance; however, as the disease progresses to insulin deficiency, medications usually have to be combined with MNT. Emphasis should be on blood glucose control, improved food choices, increased physical activity, and moderate energy restriction rather than weight loss alone as it is unclear whether weight loss alone may or may not improve glycemic control (AND, 2008a).

The first step in food and meal planning is teaching which foods are sources of carbohydrate, appropriate portion sizes, and how many servings to select at meals (and snacks, if desired). Important components of successful MNT for T2DM include: teaching that unsaturated fats should be substituted for foods high in saturated and trans fats, encouraging physical activity, and using blood glucose monitoring to adjust food and eating patterns; medications are also important components of successful MNT for T2DM. Frequent follow-up with an RDN can provide the problem-solving techniques, encouragement, and support that lifestyle changes require.

Physical activity improves insulin sensitivity, acutely lowers blood glucose in persons with diabetes, and also may improve cardiovascular status. By itself it has only a modest effect on weight; however, it is essential for long-term weight maintenance.

Youth with Type 1 Diabetes. Involvement of a multidisciplinary team, including a physician, RDN, nurse, and behavioral specialist, all trained in pediatric diabetes, is the best means of achieving optimal diabetes management in youth. However, the most important team members are the child or adolescent and his or her family/caregiver.

A major nutrition goal for children and adolescents with T1DM is maintenance of normal growth and development. Possible causes of poor weight gain and linear growth include poor glycemic control, inadequate insulin, and overrestriction of calories. The last may be a consequence of the common erroneous belief that restricting food, rather than adjusting insulin, is the way to control blood glucose. Additional reasons for poor weight gain unrelated to diabetes management may include other autoimmune conditions such as thyroid abnormalities

(Hashimoto's thyroiditis) and malabsorption syndromes (celiac disease) or disordered eating behaviors or insulin omission. Excessive weight gain can be caused by excessive caloric intake, overtreatment of hypoglycemia, or overinsulinization. Other causes include low physical activity levels and hypothyroidism, accompanied by poor linear growth (Chiang et al, 2014).

The nutrition prescription is based on the nutrition assessment. Newly diagnosed children often present with weight loss and hunger; as a result, the initial meal plan must be based on adequate calories to restore and maintain appropriate body weight. In about 4 to 6 weeks the initial caloric level may need to be modified to meet more usual caloric requirements. Nutrient requirements for children and adolescents with diabetes appear to be similar to those of children and adolescents without diabetes. The DRIs can be used to determine energy requirements (IOM, 2002). However, it may be preferable to use a food and nutrition history of typical daily intake, providing that growth and development are normal, to determine an individual child's or adolescent's energy needs.

Consultation with an RDN to develop and discuss the eating plan is encouraged (Chiang et al, 2014). Because energy requirements change with age, physical activity, and growth rate, an evaluation of height, weight, BMI, and the eating plan must be updated at least every year. Height and weight should be recorded on a Centers for Disease Control and Prevention (CDC) pediatric growth charts every 3 months. Good metabolic control is essential for normal growth and development (for growth charts see Appendices 4 through 11). Linear growth can be affected by an insulin prescription that is not adjusted as the child grows. Chronic undertreatment with insulin along with longstanding poor diabetes control often leads to poor growth and weight loss. However, withholding food or having the child eat consistently without an appetite for food in an effort to control blood glucose should be discouraged. Calories should be adequate for growth and restricted if the child becomes overweight.

Individualized Eating Plans, insulin regimens using basal (background) and bolus (mealtime) insulins, and insulin algorithms or insulin pumps can provide flexibility for children with T1DM as well as their families. This approach accommodates irregular meal times and schedules and varying appetites and activity levels. Blood glucose records are essential to assist in making appropriate changes in insulin regimens. Daily eating patterns in young children generally include three meals and two or three snacks, depending on the length of time between meals and the child's physical activity level. Children often prefer smaller meals and snacks. Snacks can prevent hypoglycemia between meals and provide adequate calories. Older children and teens may prefer only three meals. Blood glucose monitoring data are then used to integrate an insulin regimen into the meal, snack, and exercise schedules.

After the appropriate nutrition prescription has been determined, the meal planning approach can be selected. A number of meal planning approaches can be used. Carbohydrate counting for food planning provides youth and their families with guidelines that facilitate glycemic control while still allowing the choice of many common foods that children and adolescents enjoy. However, whatever approach to food planning is used, the youth and family must find it understandable and applicable to their lifestyle.

Youth with Type 2 Diabetes. Childhood obesity has been accompanied by an increase in the prevalence of T2DM among children and adolescents. IGT has been shown to be highly prevalent in obese youth, irrespective of ethnic group, and is associated with insulin resistance. Once T2DM develops, beta-cell

failure is also a factor. Thus T2DM in youth follows a progressive pattern similar to T2DM in adults. However, because of the increase in overweight and obesity in children and adolescents, it can be difficult to determine immediately whether a youth has T1DM or T2DM. Testing for islet antibodies is performed, but it may take weeks to get the results of the test. Therefore guidelines for the management of type 2 diabetes in youth recommend starting the youth on insulin if it is unclear whether the youth has T1DM or T2DM (Springer et al, 2013). When the youth has been diagnosed with T2DM, metformin and lifestyle changes, including nutrition therapy and physical activity, are recommended (Copeland et al, 2013).

Successful lifestyle treatment of T2DM in children and adolescents involves cessation of excessive weight gain, promotion of normal growth and development, and the achievement of blood glucose and A1C goals. Nutrition guidelines also should address comorbidities such as hypertension and dyslipidemia. Offer behavior modification strategies to decrease intake of high-caloric, high-fat, and high-carbohydrate foods (extra-large desserts) and sugar-sweetened beverages while encouraging healthy eating habits and regular physical activity for the entire family. Youth with T2DM should be encouraged to exercise at least 60 minutes a day and to limit their nonacademic "screen time" (video games, television) to less than 2 hours a day (Springer et al, 2013). The guidelines also emphasize the importance of a team effort using not only the physician but also the skills of an RDN, diabetes educator, and a psychologist or social worker to deal with the emotional and/or behavioral problems that may accompany T2DM.

Women with Preexisting Diabetes and Pregnancy.

Normalization of blood glucose levels during pregnancy is very important for women who have preexisting diabetes or who develop GDM. Table 30-7 lists glucose goals for pregnancy. The MNT goals are to assist in achieving and maintaining optimal blood glucose control and to provide adequate maternal and fetal nutrition throughout pregnancy, energy intake for appropriate maternal weight gain, and necessary vitamins and minerals (Reader, 2012). Nutrition recommendations during pregnancy and lactation appear to be similar for women with and without diabetes; therefore the DRIs can be used to determine energy and nutrient requirements during pregnancy and for lactation (IOM, 2002) (see Chapter 15).

TABLE 30-7 Plasma Glucose Goals during Pregnancy

Gestational diabetes	Preprandial: ≤ 95 mg/dl (5.3 mmol/L) and EITHER 1-h postmeal: ≤ 140 mg/dl (7.8 mmol/L) OR 2-h postmeal: ≤ 120 mg/dl (6.7 mmol/L)
Preexisting type 1 or type 2 diabetes*	Premeal, bedtime, and overnight glucose: 60-99 mg/dl (3.3-5.5 mmol/L) Peak postprandial glucose: 100-129 mg/dl (5.5-7.2 mmol/L) A1C: $< 6.0\%$
Normal	Preprandial: ~ 75 mg/dL (4.1 mmol/L) 1-h postmeal: 105 mg/dL (5.8 mmol/L) Peak postprandial glucose: 110 mg/dL (6.1 mmol/L)

*If goals can be achieved without excessive hypoglycemia
Modified from Reader, D: Nutrition therapy for pregnancy, lactation, and diabetes. In Franz MJ, Evert AB editors: *American Diabetes Association Guide to nutrition therapy for diabetes*, ed 2, Alexandria, Va, American Diabetes Association, 2012, p 188.

Preconception counseling and the ability to achieve near-normal blood glucose levels before pregnancy have been shown to be effective in reducing the incidence of anomalies in infants born to women with preexisting diabetes to nearly that of the general population. As a result of hormonal changes during the first trimester, blood glucose levels are often erratic. Although caloric needs do not differ from those preceding pregnancy, the Eating Plan may have to be adjusted to accommodate the metabolic changes. Women should be educated about the increased risk of hypoglycemia during pregnancy and cautioned against overtreatment.

The need for insulin increases during the second and third trimesters of pregnancy. At 38 to 40 weeks' postconception, insulin needs and levels peak at two to three times prepregnancy levels. Pregnancy-associated hormones that are antagonistic to the action of insulin lead to elevated blood glucose levels. For women with preexisting diabetes, this increased insulin need must be met with increased exogenous insulin.

Eating Plan adjustments are necessary to provide the additional calories required to support fetal growth, and weight should be monitored. During pregnancy the distribution of energy and carbohydrate intake should be based on the woman's food and eating habits and blood glucose responses. Insulin regimens can be matched to food intake, but maintaining consistency of times and amounts of food eaten are essential to avoid hypoglycemia caused by the continuous fetal draw of glucose from the mother. Smaller meals and more frequent snacks often are needed. A late-evening snack is often necessary to decrease the likelihood of overnight hypoglycemia and fasting ketosis. Records of food intake and blood glucose values are essential for determining whether glycemic goals are being met and for preventing and correcting ketosis.

Regular follow-up visits during pregnancy are needed to monitor caloric and nutrient intake, blood glucose control, and whether there is starvation ketosis. Urine or blood ketones during pregnancy may signal starvation ketosis that can be caused by inadequate energy or carbohydrate intake, omission of meals or snacks, or prolonged intervals between meals (e.g., more than 10 hours between the bedtime snack and breakfast). Ketonemia during pregnancy has been associated with reduced IQ scores in children, and women should be instructed to test for ketones periodically before breakfast.

Women with Gestational Diabetes Mellitus. MNT for GDM involves primarily a carbohydrate-controlled meal plan that promotes optimal nutrition for maternal and fetal health with adequate energy for appropriate gestational weight gain, achievement and maintenance of normoglycemia, and absence of ketosis. Specific nutrition and food recommendations are determined and modified based on individual assessment and blood glucose records. Monitoring blood glucose, fasting ketones, appetite, and weight gain can aid in developing an appropriate, individualized meal plan and in adjusting the meal plan throughout pregnancy.

Nutrition practice guidelines for gestational diabetes have been developed and field-tested (AND, 2008b). All women with GDM should receive MNT at diagnosis of GDM. Monitoring records guide nutrition therapy and are used to determine whether additional therapy is needed. Insulin, metformin, or glyburide therapy is added if glucose goals exceed target range (see Table 30-7) on two or more occasions in a 1- to 2-week period without some obvious explanation. Lack of weight gain and ketone testing can be useful in determining whether women are undereating to keep glucose levels within target range in an effort to avoid insulin therapy.

Carbohydrates should be distributed throughout the day into three small-to-moderate size meals and two to four snacks. All pregnant women require a minimum of 175 g of carbohydrates daily (Reader, 2012). An evening snack usually is needed to prevent accelerated ketosis overnight. Carbohydrates are not as well tolerated at breakfast as they are at other meals because of increased levels of cortisol and growth hormones. To compensate for this, the initial Eating Plan may have approximately 30 g of carbohydrate at breakfast. To satisfy hunger, protein foods can be added because they do not affect blood glucose levels.

Although caloric restriction must be viewed with caution, a modest energy restriction to slow weight gain is recommended for overweight or obese women with GDM. A slight calorie restriction results in a slowing of maternal weight gain in obese women with GDM without causing maternal or fetal compromise and/or ketonuria (Reader, 2012). Energy intake below approximately 1700 to 1800 kcal/day is not advised. Weight gain during pregnancy for women with GDM should be similar to that of women without diabetes.

Exercise assists in overcoming peripheral resistance to insulin and in controlling fasting and postprandial hyperglycemia and may be used as an adjunct to nutrition therapy to improve maternal glycemia. The ideal form of exercise is unknown, but a brisk walk after meals is often recommended.

Women with GDM (and women with preexisting diabetes) should be encouraged to breastfeed because breastfeeding is associated with a reduced incidence of future T2DM (Stuebe et al, 2005) (see Chapter 15). For women with GDM who are overweight/obese or with above-recommended weight gain during pregnancy, weight loss is advised after delivery. Weight loss reduces the risks of recurrent GDM or future development of T2DM (Reader, 2012). It has been shown that diabetes can be prevented or its onset delayed with lifestyle interventions of weight reduction and physical activity as was shown in the Diabetes Prevention Program and other prevention trials (Youssef, 2012).

Older Adults. The prevalence of diabetes and IGT increases dramatically as people age. Many factors predispose older adults to diabetes: age-related decreases in insulin production and increases in insulin resistance, adiposity, decreased physical activity, multiple prescription medications, genetics, and coexisting illnesses. A major factor appears to be insulin resistance. Controversy persists as to whether the insulin resistance is a primary change or whether it is attributable to reduced physical activity, decreased lean body mass (sarcopenia), and increased adipose tissue, which are common in older adults. Furthermore, medications used to treat coexisting diseases may complicate diabetes therapy in older persons.

Despite the increase in glucose intolerance with age, aging should not be a reason for suboptimal control of blood glucose. Even if it is incorrectly assumed that preventing long-term diabetic complications is not relevant to the care of older adults, persistent hyperglycemia has deleterious effects on the body's defense mechanisms against infection. It also increases the pain threshold by exacerbating neuropathic pain, and it has a detrimental effect on the outcome of cerebrovascular accidents.

Nutrition recommendations for older adults with diabetes should include meeting the DRI for age for nutrients, evaluating fluid intake, avoiding significant weight loss, and being sensitive to individual preferences and longstanding food habits while advocating good nutrition (Stanley, 2012) (see Chapter 20). Physical activity can reduce the decline in aerobic capacity significantly that occurs with age, improve risk factors for atherosclerosis, slow the decline in age-related lean body mass,

decrease central adiposity, and improve insulin sensitivity; thus it should be encouraged.

Malnutrition, not obesity, is the more prevalent nutrition-related problem in older adults. It often remains subclinical or unrecognized because the result of malnutrition—excessive loss of lean body mass—resembles the signs and symptoms of the aging process. Malnutrition and diabetes adversely affect wound healing and defense against infection, and malnutrition is associated with depression and cognitive deficits. The most reliable indicator of poor nutrition status in older adults is a change in body weight; involuntary weight gain or loss of more than 10 pounds or 10% of body weight in less than 6 months indicates a need to evaluate the reason.

It is essential that older adults, especially those in long-term care settings, receive an eating plan that meets their nutritional needs, enables them to attain or maintain a reasonable body weight, helps control blood glucose, and is palatable. Dietary restriction is not warranted for older residents in long-term health facilities. Residents should be served the regular, unrestricted menu with consistency in the amount and timing of carbohydrates (Swift, 2012).

Hyperglycemia and dehydration can lead to a serious complication of diabetes in older adults: **hyperglycemic hyperosmolar state (HHS)**. Patients with HHS have a very high blood glucose level (ranging from 400-2800 mg/dl, [22.2 to 155.6 mmol/L] with an average of 1000 mg/dl [55.6 mmol/L]) without ketones. Patients are markedly dehydrated, and mental alterations range from mild confusion to hallucinations or coma. Patients who have HHS have sufficient insulin to prevent

lipolysis and ketosis. Treatment consists of hydration and small doses of insulin to control hyperglycemia.

The Nutrition Prescription

To develop, educate, and counsel individuals regarding the nutrition prescription, it is essential to learn about their lifestyle and eating habits. Food and eating histories can be done several ways, with the objective being to determine a schedule and pattern of eating that will be the least disruptive to the lifestyle of the individual with diabetes and, at the same time, will facilitate improved metabolic control. With this objective in mind, asking the individual either to record or report what, how much, and when he or she typically eats during a 24-hour period may be the most useful. Another approach is to ask the individual to keep and bring a 3-day or 1-week food intake record (see Chapter 4 and Fig. 4-6). The request to complete a food record can be made when an appointment with the RDN is scheduled. It is also important to learn about daily routine and schedule. The following information is needed: (1) time of waking; (2) usual meal and eating times; (3) work schedule or school hours; (4) type, amount, and timing of exercise; (5) usual sleep habits; (6) type, dosage and timing of diabetes medication; and (7) SMBG data.

Using the assessment data and food and nutrition history information, a preliminary Eating Plan can then be designed, and, if the individual desires, sample menus provided. Developing an Eating Plan does not begin with a set calorie or macronutrient prescription; instead, it is determined by modifying the individual's usual food intake as necessary. The worksheet in Figure 30-2 can be used to record the usual foods eaten and

Food Group	Meal/Snack/Time						Total servings/day	CHO (g)	Protein (g)	Fat (g)	Calories
	Breakfast	Snack	Lunch	Snack	Dinner	Snack					
Starches							15	3	1	80	
Fruit							15			60	
Milk							12	8	1	100	
Vegetables							5	2		25	
Meats/ Substitutes								7	5(3)	75(55)	
Fats									5	45	
CHO Choices							Total grams				
							Calories/gram	X4=	X4=	X9=	Total calories
							Percent calories				

Calculations are based on medium-fat meats and skim/very low-fat milk. If diet consists predominantly of low-fat meats, use the factor 3 g instead of 5 g fat; if predominantly high-fat meats, use 8 g fat. If low-fat (2%) milk is used, use 5 g fat; if whole milk is used, use 8 g fat.

FIGURE 30-2 Worksheet for assessment and design of a meal or food plan. CHO, Carbohydrate.

to modify the usual food and nutrient intake as necessary. The macronutrient and caloric values for the food lists are listed on the form and in [Table 30-8](#); see Appendix 27 for portion sizes of the foods on the food lists. These tools are useful in evaluating nutrition assessments.

Using the form in [Figure 30-2](#), the RDN begins by totaling the number of servings from each food list and multiplying this number by the grams of carbohydrate, protein, and fat contributed by each. Next the grams of carbohydrate, protein, and fat are totaled from each column; the grams of carbohydrates and protein are then multiplied by 4 (4 kcal/g of carbohydrates and protein), and the grams of fat are multiplied by 9 (9 kcal/g of fat.) Total calories and percentage of calories from each macronutrient can then be determined. Numbers derived from these calculations are then rounded off. [Figure 30-3](#) provides an example of a preliminary Eating Plan. In this example the nutrition prescription would be the following: 1900 to 2000 calories, 230 g of carbohydrates (50%), 90 g of protein (20%), 65 g of fat (30%.) The number of carbohydrate choices for each meal and snack is the total of the starch, fruit, and milk servings. Vegetables, unless starchy or eaten in very large amounts (three or more servings per meal), generally are considered “free foods.” The carbohydrate choices are circled under each meal and snack column.

The next step is to evaluate the preliminary Eating Plan. First and foremost, does the individual think it is feasible to implement the Eating Plan into his or her lifestyle? Second, is it appropriate for diabetes management? Third, does it encourage healthful eating? Fourth, if the individual is taking diabetes medicine is the Eating Plan coordinated with the medication plan to reduce risk of hypoglycemia and/or minimize postprandial hyperglycemia?

To discuss feasibility, the Eating Plan is reviewed with the individual in terms of general food intake. Timing of meals and snacks and approximate portion sizes and types of foods are discussed. Calorie levels are only approximate, and adjustments in calories can be made during follow-up visits. A meal-planning approach can be selected later that will assist the patient in making his or her own food choices. At this point it must be determined whether this Eating Plan is reasonable.

To determine the appropriateness of the Eating Plan for diabetes management, distribution of the meals or snacks must be assessed along with the types of medications prescribed and treatment goals. For patients with T2DM receiving MNT alone or MNT with glucose-lowering medications, often the Eating Plan begins with three or four carbohydrate servings per meal for adult women and four or five for adult men and, if desired, one or two for a snack. Eating snacks when not hungry simply provides unnecessary calories. There is also no research to support the need to add protein to a snack for an individual with diabetes. Results of blood glucose monitoring before the meal and 2 hours after the meal, plus feedback from the person with diabetes, are used to assess if these recommendations are feasible and realistic and to determine whether target glucose goals are being achieved.

For people who require insulin, the timing of eating is important as insulin must be synchronized with food consumption (see [Medications](#) earlier in the chapter.) If the Eating Plan is determined first, an insulin regimen can be selected that will fit with it. The best way to ensure that the eating plan encourages healthful eating is to encourage individuals to eat a variety of foods from all the food groups. The Dietary Guidelines for Americans, with its suggested number of servings from each food group, can be used to compare the individual’s Eating Plan

TABLE 30-8 Macronutrient and Caloric Values for Food Lists*
The following chart shows the macronutrients and calories from each list.

Food List	Carbohydrate (grams)	Protein (grams)	Fat (grams)	Calories
Carbohydrates				
Starch: breads, cereals and grains, starchy vegetables, crackers, snacks, and beans, peas, and lentils	15	3	1	80
Fruits	15	—	—	60
Milk and milk substitutes	12	8	0-3	100
Fat-free, low-fat, 1%	12	8	5	120
Reduced-fat, 2%	12	8	8	160
Whole				
Sweets, desserts, and other carbohydrates	15	Varies	Varies	Varies
Nonstarchy vegetables	5	2	—	25
Proteins				
Lean	—	7	2	45
Medium-fat	—	7	5	75
High-fat	—	7	8	100
Plant-based protein	—	7	Varies	Varies
Fats	—	—	5	45
Alcohol (1 alcohol equivalent)	Varies	—	—	100

with the nutrition recommendations for all Americans (see Chapter 11).

Nutrition Education and Counseling

Implementation of MNT begins with the RDN selecting from a variety of interventions (reduced energy and fat intake, carbohydrate counting, simplified meal plans, healthy food choices, individualized meal planning strategies, insulin-to-carbohydrate ratios, physical activity and behavioral strategies) (Pastors and Franz, 2012). All of the above interventions have been shown to lead to improved metabolic outcomes. Furthermore, nutrition education and counseling must be sensitive to the personal needs, willingness to change, and ability to make changes, of the individual with diabetes (see Figure 30-3). Assessing the individual’s health literacy and numeracy also may be beneficial. No single eating plan approach has been shown to be more effective than any other, and the eating plan approach selected should allow individuals with diabetes to select appropriate foods for meals and snacks.

A popular approach to eating planning is carbohydrate counting. It can be used as a basic meal-planning approach or for more intensive management. Carbohydrate-counting educational tools are based on the concept that, after eating it is the carbohydrate in foods that is the major predictor of postprandial blood glucose levels. One carbohydrate serving contributes

15 g of carbohydrates. Basic carbohydrate counting emphasizes the following topics: basic facts about carbohydrates, primary food sources of carbohydrate, average portion sizes and the importance of consistency and accurate portions, amount of carbohydrates that should be eaten, and label reading. Advanced

FIGURE 30-4 A woman with Type 1 DM is learning about carbohydrate counseling from her RDN counselor.

carbohydrate counting emphasizes the importance of record keeping, calculating insulin-to-carbohydrate ratios, and pattern management.

An important goal of nutrition counseling is to facilitate changes in existing food and nutrition-related behaviors and the adoption of new ones. The combined use of behavior change theories may potentially have a greater impact than any individual theory or technique used alone (Franz et al, 2012). The following “five As” can guide the education/counseling sessions: step 1: ask; step 2: assess; step 3: advise; step 4: agree; and step 5: arrange. The “ask” step emphasizes the importance of questions as the RDN aims to develop a relationship with the client. Motivational interviewing techniques are used initially and throughout all of the encounters. In the “assess” step, the RDN evaluated the client’s readiness to change. Different intervention strategies may be needed for individuals at different stages of the change process (see Chapter 14). The “advise” step uses a client-centered framework that adapts nutrition interventions to meet the client’s needs, wants, priorities, preferences and expectations. In the “agree” step the RDN facilitates the client’s process of setting his or her own short-term goals related to nutrition, physical activity, or glucose monitoring (if appropriate) and helps outline the client’s potential methods for accomplishing lifestyle changes. In the “arrange” step, plans for follow-up are identified to evaluate responses to nutrition interventions. The individual also is given information on how to call or email with questions and concerns. In making plans for the next encounter, the patient is asked to keep a 3-day or weekly food record with blood glucose–monitoring data.

Nutrition Monitoring and Evaluation

Food intake, medication, metabolic control (glycemia, lipids, and blood pressure), anthropometric measurements, and physical activity should be monitored and evaluated (AND, 2008a; Franz et al, 2010). Medical and clinical outcomes should be monitored after the second or third visit to determine whether the individual is making progress toward established goals. If no progress is evident, the individual and RDN must reassess and perhaps revise nutrition interventions. Blood glucose monitoring results can be used to determine whether adjustments in foods and meals will be sufficient to achieve blood glucose goals or if medication additions or adjustments have to be combined with MNT. Nutrition care must be coordinated with an interdisciplinary team.

Documentation in the individual’s medical record serves as a communication tool for members of the health care team. The medical record also serves as a legal document of what was done and not done and supports reimbursement of nutrition services billed to insurance carriers. There are many different formats available for medical record documentation. The appropriate format depends on where the RDN practices and whether electronic health records are used. Regardless of the specific format, the RDN can document using the ADIME content; Box 30-4 lists key elements.

Follow-Up Encounters

Successful nutrition therapy involves a process of assessment, problem solving, adjustment, and readjustment. Food records can be compared with the eating plan, which will help to determine whether the initial eating plan needs changing, and can be integrated with the blood glucose–monitoring

BOX 30-4 Nutrition Care Documentation

Nutrition assessment

- Date and time of assessment
- Pertinent data collected and comparisons with standards (e.g., food and nutrition history, biochemical data, anthropometric measurements, client history, medical therapy, and supplement use)
- Patient’s readiness to learn, food and nutrition-related knowledge, and potential for change
- Physical activity history and goals
- Reason for discontinuation of nutrition therapy, if appropriate

Nutrition diagnoses

- Date and time
- Concise written statement of nutrition diagnosis (or nutrition diagnoses) written in the PES format (problem, etiology, signs and symptoms). If there is no existing or predicted nutrition problem that requires a nutrition intervention, state “no nutrition diagnosis at this time.”

Nutrition interventions

- Date and time
- Specific treatment goals and expected outcomes
- Recommended nutrition prescription and nutrition interventions (individualized for the patient)
- Any adjustments to plan and justifications
- Patient’s receptivity regarding recommendations
- Changes in patient’s level of understanding and food-related behaviors
- Referrals made and resources used
- Any other information relevant to providing care and monitoring progress over time
- Plans for follow-up and frequency of care

Nutrition monitoring and evaluation

- Date and time
- Specific nutrition outcomes indicators and results relevant to the nutrition diagnosis (or diagnoses) and intervention plans and goals, compared with previous status or reference goals
- Progress toward nutrition intervention goals
- Factors facilitating or hindering progress
- Other positive or negative outcomes
- Future plans for nutrition care, monitoring, and follow-up or discharge

Adapted from Writing Group of the Nutrition Care Process/Standardized Language Committee: Nutrition Care Process Part II: Using the International Dietetics and Nutrition Terminology to Document the Nutrition Care Process, *J Am Diet Assoc* 108:1287, 2008.

records to determine changes that can lead to improved glycemic control.

Nutrition follow-up visits should provide encouragement and ensure realistic expectations for the individual with diabetes. A change in eating habits is not easy for most people, and they become discouraged without appropriate recognition of their efforts. Individuals should be encouraged to speak freely about problems they are having with their eating plan. Furthermore, there may be major life changes that require changes in the eating plan. Job and schedule changes, travel, illness, and other factors all have an impact on the meal plan.

ACUTE COMPLICATIONS

Hypoglycemia and diabetic ketoacidosis are the two most common acute complications related to diabetes.

Hypoglycemia

A low blood glucose, or **hypoglycemia (or insulin reaction)**, is a common side effect of insulin therapy, although individuals taking insulin secretagogues also can be affected. **Autonomic symptoms** arise from the action of the autonomic nervous system and are often the first signs of mild hypoglycemia. Adrenergic symptoms include shakiness, sweating, palpitations, anxiety, and hunger. **Neuroglycopenic symptoms**, related to an insufficient supply of glucose to the brain, also can occur at similar glucose levels as autonomic symptoms but with different manifestations. The earliest signs of neuroglycopenia include a slowing down in performance and difficulty concentrating and reading. As blood glucose levels drop further, the following symptoms occur: frank mental confusion and disorientation, slurred or rambling speech, irrational or unusual behaviors, extreme fatigue and lethargy, seizures, and unconsciousness. Symptoms differ for different people but tend to be consistent from episode to episode for any one person. Several common causes of hypoglycemia are listed in **Box 30-5**.

In T1DM and T2DM it has been demonstrated that counter-regulatory responses to hypoglycemia steadily decline with frequent and repetitive episodes. It can become a vicious cycle as hypoglycemic episodes impair defenses against a subsequent hypoglycemic episode and thus can result in recurrent hypoglycemia. Hypoglycemia causes increased morbidity in most people with T1DM and many with long-duration T2DM and is sometimes fatal.

In general, a blood glucose of 70 mg/dl (3.9 mmol/L) or lower should be treated immediately. Treatment of hypoglycemia requires ingestion of glucose or carbohydrate-containing food. Although any carbohydrate will raise glucose levels, glucose is the preferred treatment. The form of carbohydrates (i.e., liquid or solid) used to treat does not make a difference. Commercially available glucose tablets have the advantage of being premeasured to help prevent overtreatment. Ingestion of 15 to 20 g of glucose is an effective but temporary treatment. Initial response to treatment should be seen in about 10 to 20 minutes; however, blood glucose should be evaluated again in about 60 minutes as additional carbohydrate may be necessary (see **Box 30-6**).

BOX 30-5 Common Causes of Hypoglycemia

Medication errors

- Inadvertent or deliberate errors in medication (generally insulin) dosages
- Excessive insulin or oral secretagogue dosages
- Reversal of morning or evening insulin doses
- Improper timing of insulin in relation to food intake

Nutrition therapy or exercise

- Omitted or inadequate food intake
- Timing errors; delayed meals or snacks
- Unplanned or increased physical activities or exercise
- Prolonged duration or increased intensity of exercise

Alcohol and drugs

- Alcohol intake without food
- Impaired mentation associated with alcohol, marijuana, or other illicit drugs

Adapted from Kaufman F: *Medical management of type 1 diabetes*, ed 6, Alexandria, Va, 2012, American Diabetes Association.

BOX 30-6 Treatment of Hypoglycemia

- Immediate treatment with carbohydrates is essential. If the blood glucose level falls below 70 mg/dL (3.9 mmol/L), treat with 15 g of carbohydrates, which is equivalent to:
 - 15 g carbohydrate from glucose tablets (4) or glucose gel
 - 4-6 ounces of fruit juice or regular soft drinks
 - 6 ounces (1/2 can) of regular soda pop (not sugar free)
 - 8 ounces (1 cup) of sports drink (not sugar free)
 - 1 tablespoon of sugar, syrup or honey
- Retest in approximately 10-15 minutes. If the blood glucose level remains <70 mg/dl (<3.9 mmol/l), treat with an additional 15 g of carbohydrates.
- Repeat testing and treatment until the blood glucose level returns to within normal range.
- If it is more than 1 hour to the next meal, test again 60 minutes after treatment as additional carbohydrate may be needed.

Adapted from Kaufman F: *Medical management of Type 1 diabetes*, ed 6, Alexandria, Va, 2012, American Diabetes Association.

Severely low blood glucose can cause loss of consciousness or seizures. If individuals are unable to swallow, administration of subcutaneous or intramuscular glucagon may be needed. Parents, roommates, and spouses should be taught how to mix, draw up, and administer glucagon so that they are properly prepared for emergency situations. Kits that include a syringe prefilled with diluting fluid are available. After the injection, turn the patient on their side to prevent choking in case of vomiting. Nausea and vomiting are common side effects of glucagon. The patient should be given food or beverage containing carbohydrate as soon as they regain consciousness and can swallow.

Self-monitoring of blood glucose is essential for prevention and treatment of hypoglycemia. Changes in insulin injections, eating, exercise schedules, and travel routines warrant increased frequency of monitoring. Some patients experience hypoglycemia unawareness, which means that they do not experience the usual symptoms of hypoglycemia. Patients must be reminded of the need to treat hypoglycemia, even in the absence of symptoms. Short-term relaxation of glycemic targets generally assists in the correction of hypoglycemia unawareness (ADA, 2014b).

Hyperglycemia and Diabetic Ketoacidosis

Hyperglycemia can lead to **diabetic ketoacidosis (DKA)**, a life-threatening but reversible complication characterized by severe disturbances in carbohydrate, protein, and fat metabolism. DKA is always the result of inadequate insulin for glucose use. As a result, the body depends on fat for energy, and ketones are formed. Acidosis results from increased production and decreased use of acetoacetic acid and 3-beta-hydroxybutyric acid from fatty acids. Ketones spill into the urine; hence the reliance on testing for ketones.

DKA is characterized by elevated blood glucose levels (>250 mg/dl but generally <600 mg/dl) and the presence of ketones in the blood and urine. Symptoms include polyuria, polydipsia, hyperventilation, dehydration, the fruity odor of ketones, and fatigue. SMBG, testing for ketones, and medical intervention can help prevent DKA. If left untreated, DKA can lead to coma and death. Treatment includes supplemental insulin, fluid and electrolyte replacement, and medical monitoring. Acute illnesses such as flu, colds, vomiting, and diarrhea, if not managed appropriately, can lead to the development of DKA. Patients need to know the steps to take during acute illness to prevent

BOX 30-7 Sick-Day Guidelines for Persons with Diabetes

1. During acute illnesses, usual doses of insulin and other glucose-lowering medications are required. The need for insulin continues, or may even increase, during periods of illness. Fever, dehydration, infection, or the stress of illness can trigger the release of counterregulatory or “stress” hormones, causing blood glucose levels to become elevated.
2. Blood glucose levels and urine or blood testing for ketones should be monitored at least four times daily (before each meal and at bedtime). Blood glucose readings exceeding 250 mg/dl and the presence of ketones are danger signals indicating that additional insulin is needed.
3. Ample amounts of liquid need to be consumed every hour. If vomiting, diarrhea, or fever is present, small sips—1 or 2 tablespoons every 15 to 30 min—can usually be consumed. If vomiting continues and the individual is unable to take fluids for longer than 4 hr, the health care team should be notified.
4. If regular foods are not tolerated, liquid or soft carbohydrate-containing foods (such as regular soft drinks, soup, juices, and ice cream) should be eaten. Eating about 10 to 15 g of carbohydrate every 1 to 2 hr (or 50 g of carbohydrate every 3 to 4 hr) is usually sufficient.
5. The health care team should be called if illness continues for more than 1 day.

Adapted from Kaufman F: *Medical management of type 1 diabetes*, ed 6, Alexandria, Va, 2012, American Diabetes Association.

DKA (see Box 30-7). During acute illness, oral ingestion of about 150 to 200 g of carbohydrates per day (45-50 g every 3-4 hr) should be sufficient, along with medication adjustments, to keep glucose in the goal range and to prevent starvation ketosis.

Fasting hyperglycemia is a common finding in persons with diabetes. The amount of insulin required to normalize blood glucose levels during the night is less in the predawn period (from 1:00-3:00 AM) than at dawn (4:00-8:00 AM). The increased need for insulin at dawn causes a rise in fasting blood glucose levels referred to as the **dawn phenomenon**. It results if insulin levels decline between predawn and dawn or if overnight hepatic glucose output becomes excessive as is common in T2DM. To identify the dawn phenomenon, blood glucose levels are monitored at bedtime and at 2:00 to 3:00 AM. With the dawn phenomenon, predawn blood glucose levels will be in the low range of normal but not in the hypoglycemic range. For patients with T2DM, metformin often is used because it decreases hepatic glucose output. For persons with T1DM, administering insulin that does not peak at 1:00 to 3:00 AM such as a long-acting insulin should be considered.

Hypoglycemia followed by “rebound” hyperglycemia is called the **Somogyi effect**. This phenomenon originates during hypoglycemia with the secretion of counterregulatory hormones (glucagon, epinephrine, growth hormone, and cortisol) and usually is caused by excessive exogenous insulin doses. Hepatic glucose production is stimulated, thus raising blood glucose levels. If rebound hyperglycemia goes unrecognized and insulin doses are increased, a cycle of overinsulinization may result. Decreasing evening insulin doses or, as for the dawn phenomenon, taking a long-acting insulin should be considered.

LONG-TERM COMPLICATIONS

Long-term complications of diabetes include macrovascular diseases, microvascular diseases, and neuropathy. **Macrovascular diseases** involve diseases of large blood vessels; **microvascular**

diseases associated with diabetes involve the small blood vessels and include nephropathy and retinopathy. In contrast, diabetic neuropathy is a condition characterized by damage to the nerves. MNT is important in managing several long-term complications of diabetes. Nutrition therapy is also a major component in reducing risk factors for chronic complications, especially those related to macrovascular disease.

Macrovascular Diseases

Insulin resistance, which may precede the development of T2DM and macrovascular disease by many years, induces numerous metabolic changes known as the **metabolic syndrome** (see Chapter 21). It is characterized by intraabdominal obesity or the android distribution of adipose tissue (waist circumference greater than 102 cm [40 in] in men and greater than 88 cm [35 in] in women) and is associated with dyslipidemia, hypertension, glucose intolerance, and increased prevalence of macrovascular complications. Other risk factors include genetics, smoking, sedentary lifestyle, high-fat diet, renal failure, and microalbuminuria.

Macrovascular diseases, including atherosclerotic cardiovascular disease (ASCVD), peripheral vascular disease (PVD), and cerebrovascular disease are more common, tend to occur at an earlier age, and are more extensive and severe in people with diabetes. Persons with diabetes have the CVD risk equivalent as persons with preexisting CVD and no diabetes (Buse et al, 2007). Furthermore, in women with diabetes the increased risk of mortality from heart disease is greater than in men, in contrast to the nondiabetic population, in which heart disease mortality is greater in men than in women.

Dyslipidemia

Patients with diabetes have an increased prevalence of lipid abnormalities that contribute to higher rates of CVD. In T2DM the prevalence of an elevated cholesterol level is about 28% to 34%. About 5% to 14% of patients with T2DM have high triglyceride levels; also, lower HDL cholesterol levels are common. Persons with T2DM typically have smaller, denser LDL particles, which increase atherogenicity even if the total LDL cholesterol level is not significantly elevated. Lifestyle intervention, including MNT, weight loss through reduced energy intake and increased physical activity, and smoking cessation always should be implemented. Evidence is inconclusive for ideal amount of total fat intake; fat quality may as important as quantity (Evert et al, 2013). Diet should be focused on reduction of saturated fat, trans fat and cholesterol and increased intake of omega-3 fat (in food, not as supplements), viscous fiber, and plant stanols/sterols (Diabetes Care 2015). In people with T2DM, a Mediterranean-style, MUFA-rich eating pattern may benefit glycemic control and CVD risk factors. Other CVD nutrition recommendations for people with diabetes are the same as for the general public. The most current AHA/ACC recommendations are for use of the DASH diet eating pattern (see Chapter 33). Statin therapy is added to nutrition therapy, regardless of lipid levels, for persons with diabetes (ADA, 2014b).

Hypertension

Hypertension is a common comorbidity of diabetes, with about 67% of adults with diabetes having blood pressure of 140/90 mm Hg or higher or using prescription medications for hypertension (CDC, 2014). Treatment of hypertension in persons with diabetes should be vigorous to reduce the risk of macrovascular and microvascular disease. Blood pressure should be measured at

every routine visit with a goal for blood pressure control of less than 140/80 mm Hg. MNT interventions for persons with hypertension include weight loss, if overweight; DASH-style eating pattern (Appendix 26); reducing sodium intake and increasing potassium intake; moderation of alcohol intake; and increased physical activity (see Chapter 33). The recommendation for the general population to reduce sodium to less than 2300 mg/day is also appropriate for people with diabetes and hypertension (Evert et al, 2013). For individuals with both diabetes and hypertension, further reduction in sodium intake should be individualized. Consideration must be given to issues such as the availability, palatability, and additional cost of low sodium food products. Pharmacologic therapy for hypertension includes either an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB); however, multiple drug therapy is generally required (ADA, 2014b).

Microvascular Diseases

Diabetic Kidney Disease

In the United States and Europe diabetic kidney disease (DKD) or diabetic nephropathy occurs in 20% to 40% of patients with diabetes and is the single leading cause of end-stage renal disease (ESRD). Because of the much greater prevalence of T2DM, such patients constitute over half of the patients with diabetes currently starting on dialysis (see Chapter 36).

An annual screening to quantitate urine albumin excretion rate should be performed in patients who have had T1DM for more than 5 years, and in all patients with T2DM starting at diagnosis (ADA, 2014b). The serum creatinine is used to estimate glomerular filtration rate (GFR) and stage the level of chronic kidney disease (CKD), if present.

To reduce the risk and slow the progression of DKD, glucose and blood pressure control should be optimized. Although low protein diets have been shown to lower albuminuria, they do not alter the course of GFR decline or improve glycemic or CVD risk measures, and therefore are not recommended (Evert et al, 2013).

Retinopathy

Diabetic retinopathy is estimated to be the most frequent cause of new cases of blindness among adults 20 to 74 years of age. Glaucoma, cataracts, and other disorders of the eye also occur earlier and more frequently with diabetes (ADA, 2014b). Laser photocoagulation surgery can reduce the risk of further vision loss but usually does not restore lost vision—thus the importance for a screening program to detect diabetic retinopathy.

Neuropathy

Chronic high levels of blood glucose also are associated with nerve damage, and 60% to 70% of people with diabetes have mild to severe forms of nervous system damage (CDC, 2014). Intensive treatment of hyperglycemia reduces the risk and slows progression of diabetic neuropathy but does not reverse neuronal loss. Peripheral neuropathy usually affects the nerves that control sensation in the feet and hands. Autonomic neuropathy affects nerve function controlling various organ systems. Cardiovascular effects include postural hypotension and decreased responsiveness to cardiac nerve impulses, leading to painless or silent ischemic heart disease. Sexual function may be affected, with impotence the most common manifestation.

Damage to nerves innervating the gastrointestinal tract can cause a variety of problems. Neuropathy can be manifested in the esophagus as nausea and esophagitis, in the stomach as

unpredictable emptying, in the small bowel as loss of nutrients, and in the large bowel as diarrhea or constipation.

Gastroparesis is characterized by delayed gastric emptying in the absence of mechanical obstruction of the stomach (Cammilleri, 2007). Symptoms are reported by 5% to 12% of persons with diabetes. It results in delayed or irregular contractions of the stomach, leading to various gastrointestinal symptoms such as feelings of fullness, bloating, nausea, vomiting, diarrhea, or constipation. Gastroparesis should be suspected in individuals with erratic glucose control.

The first step in management of patients with neuropathy should be to aim for stable and optimal glycemic control. MNT involves minimizing abdominal stress. Small, frequent meals may be better tolerated than three full meals a day; and these meals should be low in fiber and fat. If solid foods are not well tolerated, liquid meals may have to be recommended. For patients using insulin, as much as possible, the timing of insulin administration should be adjusted to match the usually delayed nutrient absorption. Insulin injections may even be required after eating. Frequent blood glucose monitoring is important to determine appropriate insulin therapy.

A prokinetic agent such as erythromycin, is used most commonly to treat gastroparesis. Antiemetic agents may be helpful for the relief of symptoms. In very severe cases, generally with unintentional weight loss, a feeding tube is placed in the small intestine to avoid the stomach. Gastric electric stimulation with electrodes surgically implanted in the stomach may be used when medications fail to control nausea and vomiting.

HYPOGLYCEMIA OF NONDIABETIC ORIGIN

Hypoglycemia of nondiabetic origin has been defined as a clinical syndrome with diverse causes in which low levels of plasma glucose eventually lead to neuroglycopenia. Hypoglycemia means low (hypo-) blood glucose (glycemia). Normally the body is remarkably adept at maintaining fairly steady blood glucose levels—usually between 60 and 100 mg/dl (3.3–5.6 mmol/L), despite the intermittent ingestion of food. Maintaining normal levels of glucose is important because body cells, especially the brain and central nervous system, must have a steady and consistent supply of glucose to function properly. Under physiologic conditions the brain depends almost exclusively on glucose for its energy needs. Even with hunger, either because it has been many hours since food was eaten or because the last meal was small, blood glucose levels remain fairly consistent.

Pathophysiology

In a small number of people, blood glucose levels drop too low. Symptoms are often felt when blood glucose is below 65 mg/dl (3.6 mmol/L). If the brain and nervous system are deprived of the glucose they need to function, symptoms such as sweating, shaking, weakness, hunger, headaches, and irritability can develop. Symptoms of hypoglycemia have been recognized at plasma glucose levels of about 60 mg/dl, and impaired brain function has occurred at levels of about 50 mg/dl.

Hypoglycemia can be difficult to diagnose because these typical symptoms can be caused by many different health problems. For example, adrenaline (epinephrine) released as a result of anxiety and stress can trigger the symptoms similar to those of hypoglycemia. The only way to determine whether hypoglycemia is causing these symptoms is to measure blood glucose levels while an individual is experiencing the symptoms. Hypoglycemia

can best be defined by the presence of three features known as **Whipple's triad**: (1) a low plasma or blood glucose level; (2) symptoms of hypoglycemia at the same time; and (3) amelioration of the symptoms by correction of the hypoglycemia.

A fairly steady blood glucose level is maintained by the interaction of several mechanisms. After eating, carbohydrates are broken down into glucose and enters the bloodstream. As blood glucose levels rise, the pancreas responds by releasing the hormone insulin, which allows glucose to leave the bloodstream and enter various body cells, where it fuels the body's activities. Glucose is also taken up by the liver and stored as glycogen for later use.

When glucose concentrations from the last meal decline, the body goes from a "fed" to a "fasting" state. Insulin levels decrease, which keeps the blood glucose levels from falling too low. Stored glucose is released from the liver back into the bloodstream with the help of **glucagon** from the pancreas. Normally the body's ability to balance glucose, insulin, and glucagon (and other counterregulatory hormones) keeps glucose levels within the normal range. Glucagon provides the primary defense against hypoglycemia; without it full recovery does not occur. Epinephrine is not necessary for counterregulation when glucagon is present. However, in the absence of glucagon, epinephrine has an important role.

Types of Hypoglycemia

Two types of hypoglycemia can occur in people who do not have diabetes. If blood glucose levels fall below normal limits within 2 to 5 hours after eating, this is **postprandial (reactive) hypoglycemia**. It can be caused by an exaggerated or late insulin response caused by either insulin resistance or elevated GLP-1; alimentary hyperinsulinism; renal glycosuria; defects in glucagon response; high insulin sensitivity; rare syndromes such as hereditary fructose intolerance, galactosemia, leucine sensitivity; or a rare beta-cell pancreatic tumor (insulinoma), causing blood glucose levels to drop too low. Alimentary hyperinsulinism is common after gastric surgery, associated with rapid delivery of food to the small intestine, rapid absorption of glucose, and exaggerated insulin response. These patients respond best to multiple, frequent feedings.

The ingestion of alcohol after a prolonged fast or the ingestion of large amounts of alcohol and carbohydrates on an empty stomach ("gin-and-tonic" syndrome) also may cause hypoglycemia within 3 to 4 hours in some healthy persons.

Idiopathic reactive hypoglycemia is characterized by normal insulin secretion but increased insulin sensitivity and, to some extent, reduced response of glucagon to acute hypoglycemia symptoms. The increase in insulin sensitivity associated with a deficiency of glucagon secretion leads to hypoglycemia late postprandially. Idiopathic reactive hypoglycemia has been inappropriately overdiagnosed by physicians and patients, to the point that some physicians doubt its existence. Although rare, it does exist but can be documented only in persons with hypoglycemia that occurs spontaneously and who meet the criteria of Whipple's triad.

Fasting hypoglycemia, or postabsorptive hypoglycemia, often is related to an underlying disease. This food-deprived hypoglycemia may occur in response to having gone without food for 8 hours or longer and can be caused by conditions that upset the body's ability to balance blood glucose. These include eating disorders and other serious underlying medical conditions, including hormone deficiency states (e.g., hypopituitarism, adrenal insufficiency, catecholamine or glucagon deficiency), acquired liver disease, renal disease, certain drugs (e.g., alcohol,

propranolol, salicylate), insulinoma (of which most are benign, but 6%-10% can be malignant), and other nonpancreatic tumors. Taking high doses of aspirin also may lead to fasting hypoglycemia. Factitious hypoglycemia, or self-administration of insulin or sulfonylurea in persons who do not have diabetes, is a cause as well. Symptoms related to fasting hypoglycemia tend to be particularly severe and can include a loss of mental acuity, seizures, and unconsciousness. If the underlying problem can be resolved, hypoglycemia is no longer a problem.

Diagnostic Criteria

One of the criteria used to confirm the presence of hypoglycemia is a blood glucose level of less than 50 mg/dl (2.8 mmol/L). Previously the OGT test was the standard test for this condition; however, this test is no longer used. Recording finger stick blood glucose measurements during spontaneous, symptomatic episodes at home is used to establish the diagnosis. An alternative method is to perform a glucose test in a medical office setting, in which case the patient is given a typical meal that has been documented in the past to lead to symptomatic episodes; Whipple's triad can be confirmed if symptoms occur. If blood glucose levels are low during the symptomatic period and if the symptoms disappear on eating, hypoglycemia is probably responsible. It is essential to make a correct diagnosis in patients with fasting hypoglycemia because the implications are serious.

Management of Hypoglycemia

The management of hypoglycemic disorders involves two distinct components: (1) relief of neuroglycopenic symptoms by restoring blood glucose concentrations to the normal range and (2) correction of the underlying cause. The immediate treatment is to eat foods or beverages containing carbohydrates. As the glucose from the breakdown of carbohydrates is absorbed into the bloodstream, it increases the level of glucose in the blood and relieves the symptoms. If an underlying problem is causing hypoglycemia, appropriate treatment of this disease or disorder is essential.

Almost no research has been done to determine what type of food-related treatment is best for the prevention of hypoglycemia. Traditional advice has been to avoid foods containing sugars and to eat protein- and fat-containing foods. Recent research on the GI and sugars has raised questions about the appropriateness of restricting only sugars because these foods have been reported to have a lower GI than many of the starches that were encouraged in the past. Restriction of sugars may contribute to a decreased intake in total carbohydrates, which may be more important than the source of the carbohydrates.

The goal of treatment is to adopt eating habits that will keep blood glucose levels as stable as possible ([International Diabetes Center, 2013](#)). To stay symptom free, it is important for individuals to eat five to six small meals or snacks per day. Doing this provides manageable amounts of glucose to the body. Recommended guidelines are listed in [Box 30-8](#).

Patients with hypoglycemia also may benefit from learning carbohydrate counting and, to prevent hypoglycemia, eating three to four carbohydrate servings (15 g of carbohydrate per serving) at meals and one to two for snacks (see Appendix 27). Foods containing protein that are also low in saturated fat can be eaten at meals or with snacks. These foods would be expected to have minimum effect on blood glucose levels and can add extra food for satiety and calories. However, because protein and carbohydrate stimulate insulin release, a moderate intake may be advisable.

BOX 30-8 Guidelines for Preventing Hypoglycemic Symptoms in People Who Do Not Have Diabetes

1. Eat small meals, with snacks interspersed between meals and at bedtime. This means eating five to six small meals rather than two to three large meals to steady the release of glucose into the bloodstream.
2. Spread the intake of carbohydrate foods throughout the day. Most individuals can eat two to four servings of carbohydrate foods at each meal and one to two servings at each snack. If carbohydrates are removed from the diet completely, the body loses its ability to handle carbohydrates properly, so this is not recommended. Carbohydrate foods include starches, fruits and fruit juices, milk and yogurt, and foods containing sugar.
3. Avoid or limit foods high in sugar and carbohydrate, especially on an empty stomach. Examples of these foods are regular soft drinks, syrups, candy, fruit juices, regular fruited yogurts, pies, and cakes.
4. Avoid beverages and foods containing caffeine. Caffeine can cause the same symptoms as hypoglycemia and make the individual feel worse.
5. Limit or avoid alcoholic beverages. Drinking alcohol on an empty stomach and without food can lower blood glucose levels by interfering with the liver's ability to release stored glucose (gluconeogenesis). If an individual chooses to drink alcohol, it should be done in moderation (one or two drinks no more than twice a week), and food always should be eaten along with the alcoholic beverage.

Modified from International Diabetes Center: *Reactive and fasting hypoglycemia*, Minneapolis, 2013, International Diabetes Center.

CLINICAL CASE STUDY

Maria P is a 65 year old, non-smoker Hispanic female who is coming to see you for management of her Type 2 diabetes. Her blood glucose levels are uncontrolled as evidenced by an A1C >10, and she complains of increasing numbness in her feet and occasionally in her fingers, and frequent urination during the day and overnight. From interviewing her and reviewing her health record, you learn the following about her:

Education: Did not complete high school, attended through middle school.
Occupation: Not employed outside the home, babysits infant grandchild on a daily basis

Household Members: Lives with her husband and with one of her four adult children.

Ethnic Background: Latin American, born in Mexico, emigrated to US in 1980
Religious Affiliation: Catholic

Language: Native Spanish, speaks English – has difficulty reading English

Patient History: Weighed more than 9 lb at birth.

Maria was diagnosed with T2DM, 10 or 15 years ago and her diabetes management history is as follows:

Type of Treatment: Nutrition therapy plus oral diabetes medication and long-acting insulin at bedtime (HS)

Medications: Meds: glargine 80 units at HS, metformin XR 1000 mg BID, enalapril 10 mg daily, simvastatin 40 mg daily, levothyroxine 75 mcg daily

Family history: Mother had type 2 diabetes, 12 year old grandson recently diagnosed with prediabetes

Medical History: type 2 diabetes, hypertension, hyperlipidemia, hypothyroidism, episodic migraines (last occurrence 2012)

Physical exam shows the following: Weight: 201 lbs.

Height: 5'2" inches,

Temp: 98.6 F

BP: 143/88 mm Hg

Heart rate; 80 bpm

Labs: A1C 9.8%, TSH 8, FT4 0.3; Total cholesterol 144 mg/dL, LDL 116 mg/dL, HDL 54 mg/dL; Triglycerides 545 mg/dL, BUN 14

Self-monitoring of blood glucose record shows:

Aggregate mean: 218 mg/dL, Standard deviation: 48 (n = 68) over last 30 days

Frequency – 2 x/day

Fasting (6 AM): 173 mg/dL, Standard deviation: 35 (n = 21)

Prebreakfast (9 AM): 248 mg/dL, Standard deviation: 30 (n = 6)

Prelunch: (1 PM): 193 mg/dL, Standard deviation: 47 (n = 17)

Predinner (6 PM): 195 mg/dL, Standard deviation: 33 (n = 11)

Bedtime (n = 9): 260 mg/dL, Standard deviation 34 (n = 13)

Range: 69 mg/dL to 304 mg/dL

Nutrition History:

General: Good appetite, with wide consumption of foods and beverages native to the region in Mexico where she was born. She plans and prepares meals for the household.

Performed a 24-hour diet recall.

Breakfast: coffee with milk and sugar (several spoons) + sweet bread 3 to 4 pieces

Lunch: chicken and vegetable soup + corn tortillas (4-6), home-prepared fruit juice (1-2 x 16 ounce glass)

Dinner: Largest meal – chicken/beef, rice (~2 cups) and beans (1½ - 2 cups), + corn tortillas (4-6), home-prepared fruit juice (1-2 x 16 ounce glass)

Afternoon snack: 1 can “natural” cola + 3 to 4 sugar-free cookies

HS snack: cereal + milk

Food allergies/intolerances/aversions: None

Previous nutrition therapy: Several years ago when diagnosed

Vitamin/supplement intake: Vitamin D3 – 2000 IU per day, One A Day vitamin supplement

Tx Plan:

1. Referral to RDN, CDE for instruction on carbohydrate counting for use with a basal-bolus insulin plan.

2. Physician prescribed:

a. rapid-acting insulin analog lispro.

Premeal dose

breakfast 10 units,

lunch 15 units,

dinner 20 units

Correction insulin (insulin sensitivity factor) 1 unit to drop blood glucose level 50 mg/dL when premeal blood glucose > 150 mg/dL

b. Increased self-monitoring of blood glucose premeal (breakfast, lunch and dinner) and 2 hour postprandial blood glucose after dinner.

Nutrition Care Questions

1) Why did Maria's physician prescribe mealtime insulin? Would another medication have been more effective at this stage of her disease?

2) What is a potential problem of the current mealtime insulin plan using “set” or “fixed” doses of premeal insulin?

3) Will the long-acting insulin need to be adjusted? If so, why?

4) What is the proposed mechanism of action of metformin? Why did her physician leave Maria on this medication after the insulin was initiated?

5) Identify at least two reasons why regular physical activity such as walking would be beneficial for Maria?

6) What is causing the numbness and tingling in Maria's feet and occasionally in her fingers?

Nutrition Assessment

7) Determine Maria's nutrition requirements

a) Identify two methods for determination of Maria's energy requirements.

b) Calculate body mass index, percent usual body weight (UBW), percent ideal body weight?

8) Intake Domain:

a) Dietary factors associated with increase of overweight/obesity and hyperglycemia are large portions of food, no regular physical activity, and increased consumption of sugar-sweetened beverages. Identify foods in Maria's diet history that fit these criteria.

b) Increased vegetable and fruit intake is associated with a reduced risk of overweight. Using Maria's usual intake, is her vegetable and fruit intake adequate?

CLINICAL CASE STUDY—cont'd

- c) Using the carbohydrate counting Eating Plan approach with 3 to 4 carbohydrate choices per meal (Breakfast/Lunch and Dinner) and 1 carbohydrate choice at HS, plan a 1 day menu for Maria.
- 9) Clinical Domain:
 - a) Why does Maria's physician order pre- and 2 hour postmeal blood glucose monitoring?
 - b) What are the pre/postmeal glucose targets?
- 10) Behavioral-Environmental Domain:
 - a) What behaviors might be contributing to Maria's overweight and obesity?
 - b) Identify one specific physical activity recommendation for Maria that she could do during the day when she is caring for her grandchild.

Nutrition Diagnostic Statements

Select two of Maria's nutrition problems and complete PES statements for each one.

PES Statements:

- 1) Food and nutrition-related knowledge deficit related to lack of previous diabetes nutrition education as evidenced by patient's nutrition history.

- 2) Limited adherence to nutrition-related recommendations related to poor understanding as evidenced by elevated hemoglobin A1C and food records that indicate that patient is consuming excessive amounts of carbohydrate and calories.
- 3) Altered blood glucose levels related to inability to match insulin to carbohydrate intake as evidenced by patient's nutrition history and glucose monitoring download data report.

Nutrition Intervention

- 4) For each of the two PES statements, write a goal, based on signs and symptoms.
- 5) For the two goals, write 2 to 3 nutrition interventions, based on the etiology that would be appropriate for Maria.

NOTE: In a real face-to-face appointment between an RDN/CDE and Maria, they would collaboratively develop Maria's goals together.

Nutrition Evaluation and Monitoring

- a) When should the next nutrition counseling session be scheduled for Maria?
- b) What would you assess at the follow-up visit based on the nutrition goals and interventions developed at the initial appointment?

Medical Nutrition Therapy for Thyroid, Adrenal, and Other Endocrine Disorders

Sheila Dean, DSc, RDN, LD, CCN, CDE

KEY TERMS

5-deiodinase	Graves' disease	thyroid-binding globulin (TBG)
Addison's disease	Hashimoto's thyroiditis	thyroglobulin antibodies (TGB Ab)
adrenal fatigue	hyperthyroidism	thyroid peroxidase (TPO)
autoimmune thyroid disorders (AITDs)	hypothalamus	thyroid peroxidase antibodies (TPO Ab)
calcitonin	hypothalamic-pituitary-thyroid (HPT) axis	thyroid-stimulating hormone (TSH)
cortisol	hypothyroidism	thyrotropin-releasing hormone (TRH)
cretinism	pituitary gland	thyrotoxicosis
euthyroid sick syndrome	polycystic ovary syndrome (PCOS)	thyroxine (T ₄)
free T ₄	reverse T ₃ (rT ₃)	triiodothyronine (T ₃)
goitrin	Schmidt syndrome	tyrosine

Diabetes mellitus appears to be the most common endocrine-related chronic disease (CDC, 2014; NIH, Medline-Plus, 2014). However, according to a comprehensive review of the prevalence and incidence of endocrine and metabolic disorders in the United States (2009), about 5% of the U.S. population age 12 and older has hypothyroidism, and more than half remain undiagnosed. Furthermore, individuals with diabetes tend to have a higher prevalence of thyroid disorders.

Thyroid-related diseases often are poorly diagnosed, and much about their treatment requires greater clarification and study. For example, radiation exposure of the thyroid at a young age is a risk factor for the development of thyroid cancer, lasting for a lifetime after exposure (Sinnott et al, 2010). Efforts to reduce exposure from medical x-ray examinations can protect the thyroid gland.

Genetic factors promote the endocrine autoimmune diseases. Recent genome-wide association studies (GWAS) have enabled identification of relevant immune response pathways; the same allele that predisposes to a certain autoimmune disease can be protective in another (Wiebolt et al, 2010). Thus endocrine GWAS are needed, especially for Graves' disease, Hashimoto's thyroiditis, and Addison's disease. Each of these disorders has stages beginning with genetic susceptibility, environmental triggers, and active autoimmunity, followed by metabolic derangements with overt symptoms of disease (Michels and Eisenbarth, 2010). Research is needed to clarify how nutrients interact with genetics, especially in these **autoimmune thyroid disorders (AITDs)**.

THYROID PHYSIOLOGY

The thyroid gland is a small, butterfly-shaped gland found just below the Adam's apple. Although it weighs less than an ounce, it produces hormones that influence essentially every organ, tissue, and cell in the body, thus having an enormous effect on health. The thyroid gland responds to stimulation by **thyroid-stimulating hormone (TSH)**, a hormone secreted by the pituitary gland. When stimulated, the thyroid gland produces two main hormones: **thyroxine (T₄)**, a thyroid hormone named for its four molecules of iodine, and **triiodothyronine (T₃)**, a thyroid hormone named for its three molecules of iodine. T₃ is the most predominant and active form of thyroid hormone that the body can use. The thyroid gland regulates many processes in the body, including fat and carbohydrate metabolism, body temperature, and heart rate. The thyroid also produces **calcitonin**, a hormone that helps regulate the amount of blood calcium. Last, **reverse T₃ (rT₃)**, an isomer of T₃, is derived from T₄ through the action of deiodinase. The body cannot use rT₃.

The synthesis of these hormones requires **tyrosine**, a key amino acid involved in the production of thyroid hormone, and the trace mineral iodine. Within the cells of the thyroid gland, iodide is oxidized to iodine by hydrogen peroxide, a reaction termed the *organification* of iodide. Two additional molecules of iodine bind to the tyrosyl ring in a reaction that involves **thyroid peroxidase (TPO)**, an enzyme in the thyroid responsible for thyroid hormone production. Completed thyroid hormones are released into the circulation; however, metabolic effects of thyroid hormones result when the hormones ultimately occupy specific thyroid receptors. It is estimated that a

cell needs five to seven times more T_4 to bind to the nuclear receptors to have a physiologic effect compared with T_3 .

The biosynthetic processes resulting in generation of thyroid hormones within the thyroid gland are controlled by feedback mechanisms within the **hypothalamic-pituitary-thyroid axis (HPT axis)**. The HPT axis is part of the endocrine system responsible for the regulation of metabolism. As its name suggests, it depends on the **hypothalamus** (a tiny, cone-shaped structure located in the lower center of the brain that communicates between the nervous and endocrine systems), the **pituitary gland** (the master gland of the endocrine system located at the base of the brain), and the thyroid gland (see Figure 31-1).

The hypothalamus produces and secretes **thyrotropin-releasing hormone (TRH)**, which travels to the pituitary gland, stimulating it to release TSH, which signals the thyroid gland to upregulate its synthetic machinery. Although T_4 , T_3 , and rT_3 are generated within the thyroid gland, T_4 is quantitatively the major secretory product. All T_4 found in circulation is generated in the thyroid unless exogenously administered. Production of T_3 and rT_3 within the thyroid is relegated to very small quantities and is not considered significant compared with their peripheral production (see Figure 31-2).

When T_4 is released from the thyroid, it is primarily in a bound form with **thyroid-binding globulin (TBG)**, a protein that transports thyroid hormones through the bloodstream, with lesser amounts bound to T_4 -binding prealbumin. It is estimated that only 0.03% to 0.05% of T_4 within the circulatory system is in a free or unbound form; this unbound T_4 is called **free T_4** . In peripheral tissues, approximately 70% of T_4 produced is either deiodinated and converted to T_3 or rT_3 , or eliminated. As mentioned, T_3 is considered to be the most metabolically active thyroid hormone. Although some T_3 is

FIGURE 31-1 The hypothalamus-pituitary-thyroid axis.

produced in the thyroid, approximately 80% to 85% is generated outside the thyroid gland, primarily by conversion of T_4 in the liver and kidneys. The pituitary and nervous system are also capable of converting T_4 to T_3 so are not reliant on T_3 produced in the liver or kidney. Within the liver and kidney, the enzyme responsible for production of T_3 is a selenium-dependent

FIGURE 31-2 Constructing thyroid hormones. (1) Accumulation of the raw materials tyrosine and iodide (I-), (2) fabrication or synthesis of the hormone, and (3) secretion of hormone into the blood either bound or as free T_4 .

FIGURE 31-3 Thyroid metabolism.

enzyme called **5-deiodinase**, an enzyme that removes one molecule of iodine from T_4 to form either T_3 or rT_3 (see Figure 31-3).

ASSESSMENT IN THYROID DISORDERS

Assessment begins with an evaluation of thyroid status based on laboratory data such as a full thyroid panel. In the absence of a full thyroid panel, a serum thyrotropin (also known as TSH) is the single best screening test for primary thyroid dysfunction, (when it does not include thyroid associated autoimmune conditions), for the vast majority of outpatient clinical situations (Garber et al, 2012). Assessments also may include a diet history to evaluate micronutrients pertaining to thyroid health along with an evaluation of calorie and carbohydrate intake. In addition, an assessment of dietary intake of goitrogenic foods may be warranted.

Laboratory Norms: Functional versus Pathologic Ranges

A typical (statistical) reference range for TSH in many laboratories is approximately 0.2 to 5.5 mIU/L. Individuals with TSH values greater than 2 mIU/L have an increased risk of developing overt hypothyroidism during the next 20 years. Subclinical autoimmune thyroid disease is so common in the population that laboratory reference ranges derived from testing apparently healthy subjects easily could be misconstrued for those with disease. Importantly, several studies have detected an increase in TPO antibody positivity with TSH

concentrations outside the narrow range of 0.2 to 1.9 mIU/L (Downs et al, 2008; Fjaellagaard et al, 2014). This fact provides evidence that TSH in the upper reference range often is associated with abnormal pathologic findings (Hak et al, 2000; Khandelwal and Tandon, 2012; Saravanan et al, 2002), mitochondrial dysfunction and morphologic skeletal muscle alterations including myalgia, muscle cramps, and weakness (Dunn et al, 2009). Additional evidence that thyroid function within the laboratory reference ranges can be associated with adverse outcomes is shown in Table 31-1. Conversely,

TABLE 31-1 Variation In Thyroid Function Within Reference Range and Adverse Outcomes

TSH >2 mIU/L*	Increased 20-year risk of hypothyroidism
TSH >2 mIU/L*	Increased frequency of thyroid autoantibodies
TSH >4 mIU/L*	Increased risk of heart disease
TSH 2-4 mIU/L*	Cholesterol values respond to thyroxine replacement
Free T_4 <10.4 pmol/L [†]	Impaired psychomotor development of infant if occurs in first trimester of pregnancy

T_3 , Triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone.

*Typical reference ranges: TSH 0.2-5.5 mIU/L

[†]Typical reference ranges: free T_4 9.8-25 pmol/L

BOX 31-1 5-Deiodinase Inhibitors

Selenium deficiency
 Inadequate protein, excess carbohydrates
 High insulin
 Chronic illness
 Stress (cortisol)
 Cd, Hg, Pb, and other heavy metal toxins
 Compromised liver or kidney function

decreased TSH levels combined with normal to high T_4 or T_3 levels may be suggestive of hyperthyroidism (see Thyroid Function Tests in Appendix 22).

Changes in 5-deiodination occur in a number of situations, such as stress, poor nutrition, illness, selenium deficiency, and drug therapy. Toxic metals such as cadmium, mercury, and lead have been associated with impaired hepatic 5-deiodination in animal models. Free radicals are also involved in inhibition of 5-deiodinase activity. In the course of chronic liver disease such as hepatic cirrhosis, alterations in hepatic deiodination resulting in increased rT_3 and a simultaneous decrease in T_3 levels also have been observed (see Box 31-1 and Chapter 29).

HYPOTHYROIDISM

Of the detected cases of underactive thyroid (**hypothyroidism**), more than half are due to an autoimmune disorder called **Hashimoto's thyroiditis**, in which the immune system attacks and destroys thyroid gland tissue. A common clinical presentation of patients with functional changes of the endocrine system is altered thyroid function. Indeed *subclinical* hypothyroidism represents the first signs of thyroid hormone dysfunction for many individuals. Typical symptoms include low energy, cold hands and feet, fatigue, hypercholesterolemia, muscle pain, depression, and cognitive deficits (see Box 31-2). Evaluation of thyroid hormone metabolism is needed before thyroid hormone replacement therapy.

BOX 31-2 Common Symptoms of Hypothyroidism and Hyperthyroidism

Hypothyroidism	Hyperthyroidism
Fatigue	Heat intolerance, sweating
Forgetfulness	Weight loss
Depression	Alterations in appetite
Heavy menses	Frequent bowel movements
Dry, coarse hair	Changes in vision
Mood swings	Fatigue and muscle weakness
Weight gain	Menstrual disturbance
Hoarse voice	Impaired fertility
Dry, coarse skin	Mental disturbances
Constipation	Sleep disturbances
	Tremors
	Thyroid enlargement

From Shomon M: *Thyroid Disease Symptoms—Hypothyroidism and Hyperthyroidism* (website): http://thyroid.about.com/cs/basics_starthere/a/symptoms.htm, 2008. Accessed December 8, 2014.

Women are five to eight times more likely than men to suffer from hypothyroidism. In addition, individuals who have celiac disease may be at risk (see *Clinical Insight: Was It Gluten That Caused Her Hypothyroidism?*)

CLINICAL INSIGHT**Was It Gluten That Caused Her Hypothyroidism?**

A case report described a 23-year-old woman with a diagnosis of hypothyroidism caused by Hashimoto's thyroiditis and autoimmune Addison's disease who was found in evaluation to have elevated antiendomysial antibody levels. During a 3-month period on a gluten-free diet, the patient demonstrated remarkable clinical improvement in her GI related symptoms and, more importantly, in her thyroid function. She required progressively less thyroid and adrenal replacement therapy. After 6 months her endomysial antibody level became negative, her antithyroidal antibody titer decreased significantly, and thyroid medication was discontinued. This case report points out the important effect of a hypoallergenic diet on thyroid function in relation to the potential reduction of antithyroidal antibodies.

A number of studies show the importance of gluten in the induction of endocrine autoantibodies and organ system dysfunction in adolescent celiac patients (Cassio et al, 2010; Meloni et al., 2009). Furthermore, the genetic risk for celiac disease is largely related to human leukocyte antigen genotypes, which in turn is largely accountable for its link to autoimmune thyroid disease (Barker and Liu, 2008). It has been reported that gluten-dependent diabetes and thyroidal-related antibodies were found in patients with celiac disease, but were abolished after a gluten-free diet was followed (Duntas, 2009). Similarly, there is a high prevalence of thyroid disorders in untreated adult patients with celiac disease; gluten withdrawal through dietary avoidance may reverse this abnormality. This is another important dietary variable that can modify thyroid hormone activity.

Pathophysiology

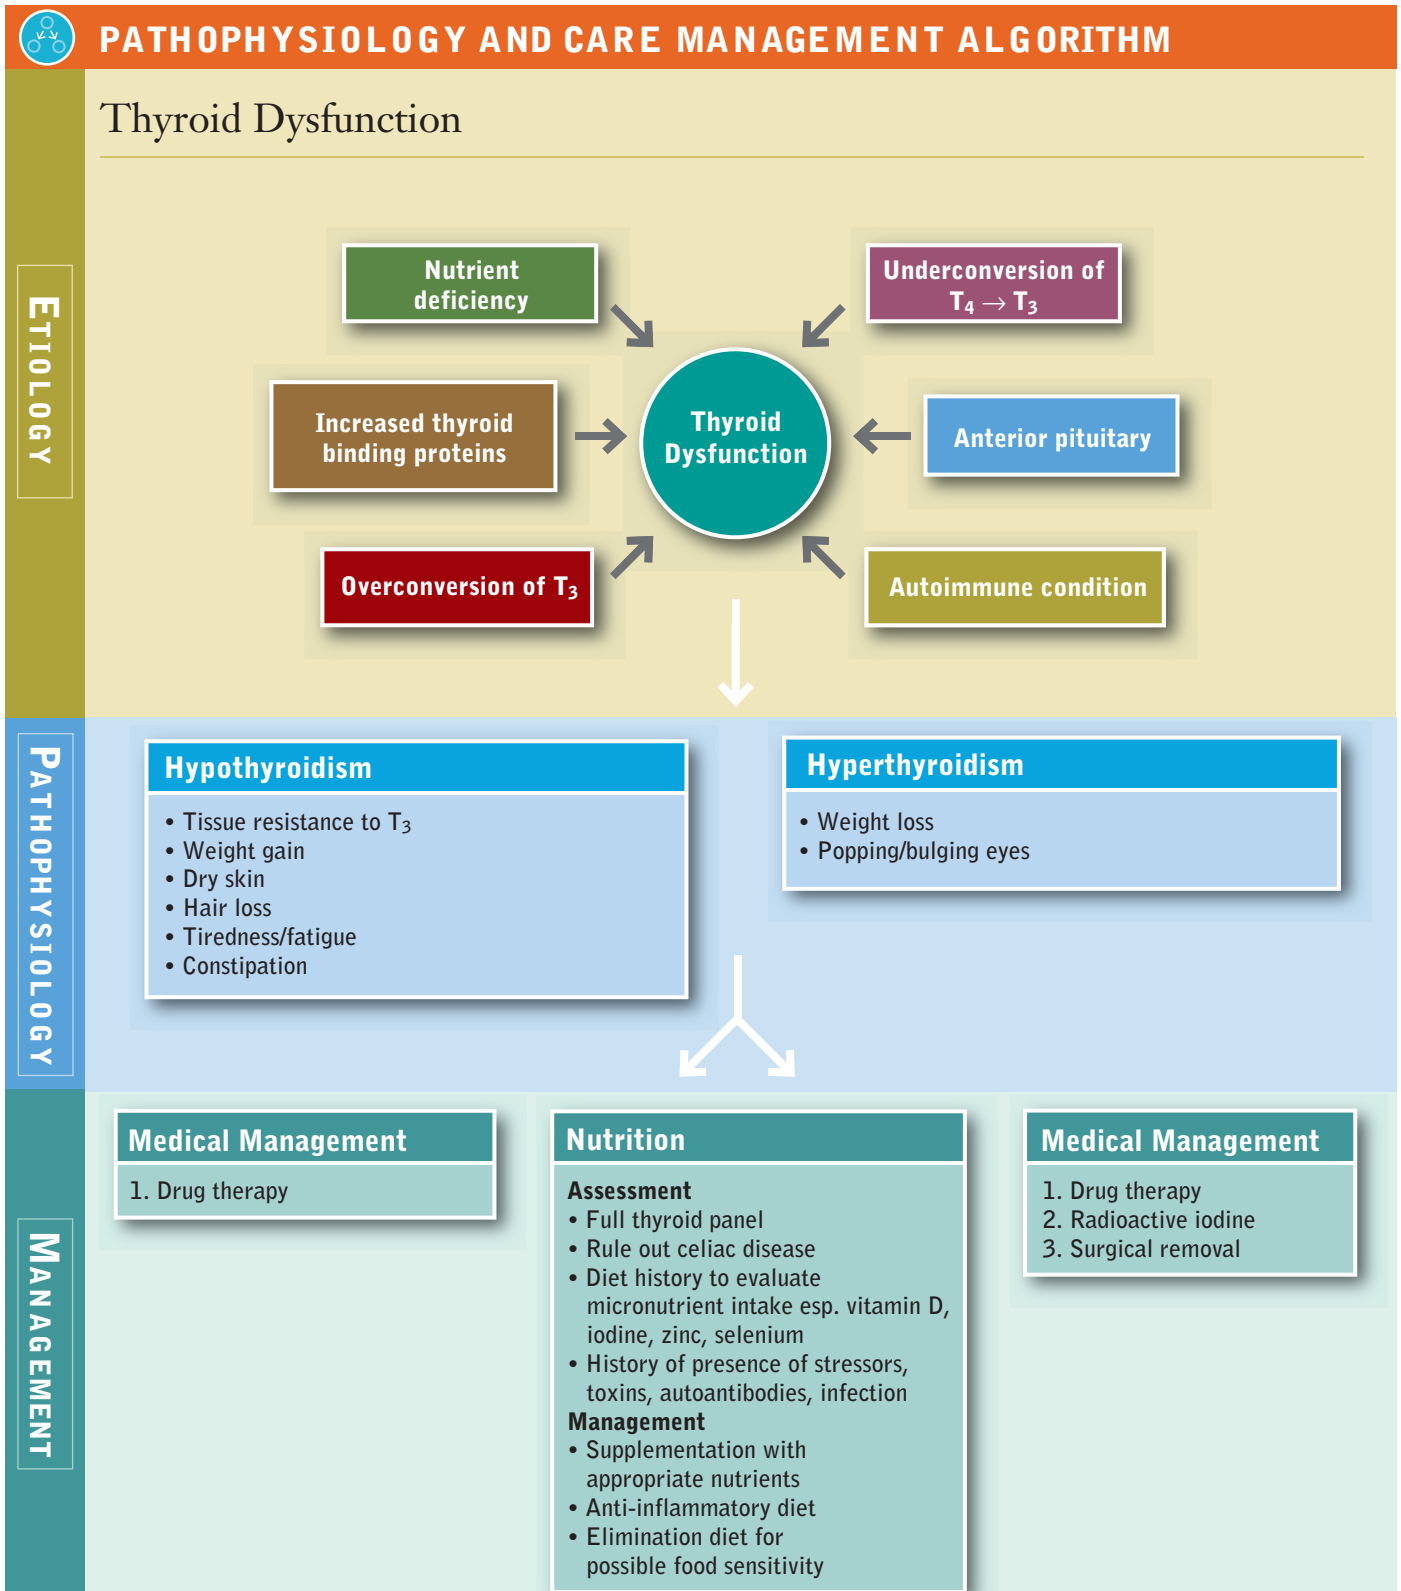

Hashimoto's thyroiditis is an autoimmune disorder in which the immune system attacks and destroys the thyroid gland. It is the most common form of hypothyroidism. The enlarged, chronically inflamed thyroid gland becomes nonfunctional, with reactive parts of the gland deteriorating after several years. Thyroid autoantibodies indicate the body's immune system is attacking itself and whether an autoimmune thyroid condition is present, be it hypothyroidism or hyperthyroidism. Epstein-Barr virus (EBV) has been implicated as a critical etiopathogenic factor in autoimmune thyroid disease. Janegova et al demonstrated a high prevalence of EBV infection in cases of Hashimoto's thyroiditis (80.7%) as well as in samples of Graves' disease (62.5%).

Specific antibody tests identify Hashimoto's thyroiditis. **Thyroid peroxidase antibodies (TPO Ab)** are immune cells that indicate the immune system is attacking TPO in the thyroid gland. The TPO Ab test is the most important, because TPO is the enzyme responsible for the production of thyroid hormones, and the most frequent target of attack in Hashimoto's. **Thyroglobulin antibodies (TGB Ab)** are immune cells that indicate the immune system is attacking thyroglobulin in the thyroid gland. Sometimes this test is necessary as well because it is the second most common target for Hashimoto's disease.

Schmidt syndrome refers to hypothyroidism with other endocrine disorders, including **Addison's disease** (adrenal insufficiency), hypoparathyroidism, and diabetes mellitus, all of which may be autoimmune in nature. **Euthyroid sick syndrome** is hypothyroidism, associated with a severe systemic illness that causes decreased peripheral conversion of T_4 to T_3 , an increased conversion of T_3 to the inactive rT_3 , and decreased binding of thyroid hormones. Conditions commonly associated

with this syndrome include protein-calorie malnutrition, surgical trauma, myocardial infarction, chronic renal failure, diabetic ketoacidosis, anorexia nervosa, cirrhosis, thermal injury,

and sepsis. Once the underlying cause is treated, the condition usually is resolved (see *Pathophysiology and Care Management Algorithm: Thyroid Dysfunction*).

Triggers

Adrenal Stress and Oxidative Stress. Low thyroid function is almost always secondary to some other condition, often **adrenal fatigue** (Kaltsas et al, 2010) (see **Adrenal Disorders** later in this chapter).

Aging. Maintaining thyroid hormone function throughout the aging process appears to be an important hallmark of healthy aging. The incidence of hypothyroidism (underactive thyroid) increases with age. By age 60, 9% to 17% of men and women have an underactive thyroid. The absence of circulating thyroid autoantibodies in healthy centenarians is noted. Because unhealthy aging is associated with a progressively increasing prevalence of organ-specific and non-organ-specific autoantibodies, the absence of these antibodies may represent a significantly reduced risk for cardiovascular disease and other chronic age-related disorders.

Menopause. The relationship between thyroid hormone and the gonadal axis is well established; however, there are few studies on the relationship between thyroid function and menopause specifically. In addition, they do not necessarily clarify whether menopause has an effect on thyroid regardless of aging, despite the fact that hypothyroid symptoms and menopause symptoms (such as hot flashes, insomnia, irritability, and palpitations) are commonly confused. According to a report from the evaluation of the Study of Women's Health Across the Nation (SWAN), thyroid function does not appear to be directly involved in the pathogenesis of menopausal complications; however, menopause may modify the clinical expression of autoimmune thyroid disorders such as Hashimoto's thyroiditis (Del Ghianda et al, 2013).

Pregnancy. Thyroid dysfunction has been related to obstetric complications such as premature delivery, gestational hypertension, preeclampsia, and placental abruption. Nearly 1 out of 50 women in the United States is diagnosed with hypothyroidism during pregnancy. Out of every 100 miscarriages, 6 are associated with thyroid hormone deficiency during pregnancy; up to 18% of women are diagnosed with postpartum thyroiditis; and approximately 25% of women develop permanent hypothyroidism (De Vivo et al, 2010; Yassa et al, 2010).

The World Health Organization (WHO) recently increased the recommended iodine intake during pregnancy from 200 to 250 mcg/day and suggested that a median urinary iodine (UI) concentration of 150 to 249 mcg/L indicates adequate iodine intake in pregnant women. In areas of severe iodine deficiency, maternal and fetal hypothyroxinemia can cause cretinism (condition of stunted physical and mental growth) and adversely affect cognitive development in children (see Chapter 15). To prevent fetal damage, iodine should be given before or early in pregnancy. In countries or regions where less than 90% of households are using iodized salt and the median UI concentration in school-age children is less than 100 mcg/L, the WHO recommends iodine supplementation in pregnancy and infancy (Zimmermann, 2009).

Environmental Factors. The major environmental triggers of autoimmune thyroid disease include excessive iodine, medications, infection, smoking, and stress (Tomer and Huber, 2009).

Medical Management

When the thyroid is underactive (hypothyroidism) because of autoimmune disease (Hashimoto's disease), radioactive iodine treatment, congenital defects, or surgical removal (thyroidectomy), the conventional pharmacologic approach for treatment is prescription thyroid hormone replacement medication. Table 31-2 provides an overview of key forms of thyroid hormone replacement. With the further elucidation of the effects of genetics, new agents are likely to become available as adjunct therapy.

Medical Nutrition Therapy

Several nutrients are involved in thyroid health, particularly iodine and selenium. Because of the critical role of iodine in the synthesis of thyroid hormone, this trace mineral has received the most attention historically with respect to thyroid disorders. Other deficiencies of micronutrients such as iron, selenium, vitamin A, and possibly zinc may interact with iodine nutrition and thyroid function (Hess, 2010; Köhrle, 2013).

Fasting or Restrictive Diets. Calorie and carbohydrate restriction may reduce substantially thyroid hormone activity.

TABLE 31-2 Pharmacologic Treatments for Hypothyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Synthroid, Levoxyl	Levothyroxine— (synthetic T ₄)	Most commonly prescribed synthetic form of thyroid hormone replacement drug (thyroxine) that provides a steady dose of T ₄ for the body to convert to T ₃ . Available in a wide range of doses. Inactive ingredients include lactose and cornstarch.
Tirosint	Levothyroxine	A synthetic form of replacement hormone that includes only three inactive ingredients - gelatin, glycerin and water. Is produced in a dedicated facility to eliminate the risk of cross-exposure.
Cytomel	Liothyronine— (synthetic T ₃)	Synthetic form of T ₃ , which can also be compounded. Sometimes prescribed in addition to T ₄ . Only effective for approximately 10 hours and must be taken twice daily.
Armour Thyroid	Desiccated natural thyroid	Prepared from dried or powdered porcine (pig) or mixed beef and pork thyroid gland for therapeutic use. Available by prescription and frequently used as an alternative to synthetic thyroid drugs. All brands contain a mixture of approximately 80% T ₄ and 20% T ₃ . Difficult to standardize. Compounded T ₃ medication is available as a time-released formula. Compounded medications are frequently not insurance covered but are less expensive than standard medications.
WP Thyroid, Nature-Thyroid	Desiccated natural thyroid	Provides the full range of thyroid hormones, including T ₄ , T ₃ , T ₂ and T ₁ which may be beneficial for those who have difficulty with T ₄ -T ₃ conversion. Available in 8-13 different strengths, ranging from low to high concentrations.
Thyrolar	Liotrix—(synthetic T ₄ -T ₃ combination)	Synthetic combination of T ₄ and T ₃ . Sometimes used in lieu of Armour Thyroid because of problem with standardization.

From Shomon M: *What is the best thyroid drug?* (website): <http://thyroid.about.com/cs/thyroiddrugs/a/bestdrug.htm>, 2014. Accessed December 8, 2014.
T₃, Triiodothyronine; T₄, thyroxine.

This varies widely between individuals. Genetics, obesity, gender, and the macronutrient content of the hypocaloric diet influence the response. Nutritional status and energy expenditure influence thyroid function centrally at the level of TSH secretion, deiodination, and possibly elsewhere. Because an increase of rT_3 is found at the expense of T_3 during caloric restriction, it is possible that the hepatic pathways play a substantial role in metabolic control during energy balance. However, when caloric restriction is longer than 3 weeks, T_4 and rT_3 levels return to normal values (DeVries et al, 2015).

Fasting also exerts a powerful influence on the metabolism of thyroid hormones to save energy and limit catabolism. Mild elevations in endogenous cortisol levels may be partly responsible. Fasting decreases serum T_3 and T_4 concentrations, whereas intrahepatic thyroid hormone concentrations remain unchanged. However, ketones generated from calorie deprivation do not appear to suppress T_3 generation and hepatic 5-deiodinase activity. It appears that fasting-induced changes in liver thyroid hormone metabolism are not regulated via the hepatic autonomic input in a major way and more likely reflect a direct effect of humoral factors on the hepatocyte. Overall during fasting, there is a down regulation of the hypothalamus-pituitary-thyroid axis, which is assumed to represent an energy-saving mechanism, instrumental in times of food shortage (DeVries et al, 2015).

Goitrogens. Cyanogenic plant foods (cauliflower, broccoli, cabbage, Brussels sprouts, mustard seed, turnip, radish, bamboo shoot, and cassava) exert antithyroid activity through inhibition of TPO. The hydrolysis of some glucosinolates found in cruciferous vegetables (e.g., progoitrin) may yield **goitrin**, a compound known to interfere with thyroid hormone synthesis. The hydrolysis of indole glucosinolates results in the release of thiocyanate ions, which can compete with iodine for uptake by the thyroid gland. Increased exposure to thiocyanate ions from cruciferous vegetable consumption, however, does not increase the risk of hypothyroidism unless accompanied by iodine deficiency.

Soybean, an important source of protein in many developing countries, also has goitrogenic properties when iodine intake is limited. The isoflavones, genistein and daidzein, inhibit the activity of TPO and can lower thyroid hormone synthesis. Furthermore, soybean interrupts the enterohepatic cycle of thyroid hormone metabolism. However, high intakes of soy isoflavones do not appear to increase the risk of hypothyroidism when iodine consumption is adequate.

Since the addition of iodine to soy-based formulas in the 1960s, there have been no further reports of hypothyroidism developing in soy formula-fed infants. Soybeans are by far the most concentrated source of isoflavones in the human diet. Small amounts are found in a number of legumes, grains, and vegetables. Average dietary isoflavone intakes in Asian countries, in particular in Japan and China, range from 11 to 47 mg/day because of intake of the traditional foods made from soybeans, including tofu, tempeh, miso, and matte, whereas intakes are considerably lower in Western countries (2 mg/day). Soy products (meat substitutes, soy milk, soy cheese, and soy yogurt), however, are gaining popularity in Western countries. Although research has not determined the exact effect of soy on the metabolic fate of thyroid hormones, excessive soy consumption is best approached cautiously in those with suspected impairment of thyroid metabolic pathways.

Iodine. As a trace element, iodine is present in the human body in amounts of 10 to 15 mg, and 70% to 80% of it is located in the thyroid gland. Ninety percent of it is organically bound to thyroglobulin (Tg). Iodide is actively absorbed in the thyroid gland to help produce the biochemically active thyroid hormones T_4 and

T_3 (see Figure 31-2). The thyroid gland must capture an estimated minimum of 60 mcg of iodide (the ionic form of iodine) daily to ensure an adequate supply for the production of thyroid hormone (Groppe et al, 2012). Inadequate intake of iodine impairs thyroid function and results in a spectrum of disorders. Randomized controlled intervention trials in iodine deficient populations have shown that providing iron along with iodine results in greater improvements in thyroid function and volume than providing iodine alone (Hess, 2010). It is also vital to thyroid function, as it is a major cofactor and stimulator for the enzyme TPO.

In autoimmune Hashimoto's, supplementing with iodine may exacerbate the condition. Because iodine stimulates production of TPO, this in turn increases the levels of TPO antibodies (TPO Abs) dramatically, indicating an autoimmune flare-up. Some people develop symptoms of an overactive thyroid, whereas others have no symptoms despite tests showing an elevated level of TPO Abs. Therefore one must be cautious regarding the use of iodine. Furthermore, although iodine deficiency is the most common cause of hypothyroidism for most of the world's population (Melse-Boonstra and Jaiswal, 2010), in the United States and other westernized countries, Hashimoto's accounts for the majority of cases (Ebert, 2010).

Although the risk of iodine deficiency for populations living in iodine-deficient areas without adequate iodine fortification programs is well recognized, concerns have been raised that certain subpopulations may not consume adequate iodine in countries considered iodine-sufficient. Vegetarian and non-vegetarian diets that exclude iodized salt, fish, and seaweed have been found to contain very little iodine. Furthermore, UI excretion studies suggest that iodine intakes are declining in Switzerland, New Zealand, and the United States, possibly because of increased adherence to dietary recommendations to restrict salt intake for reducing the incidence of hypertension.

Severe iodine deficiency during pregnancy has been shown to increase the risk of stillbirths, spontaneous abortions, and congenital abnormalities. The most severe is **cretinism**, which is a state of mental retardation mostly in combination with dwarfism, deaf-mutism, and spasticity (Chen and Hetzel, 2010). These conditions are largely irreversible. The consequences of severe iodine deficiency during pregnancy on pregnancy outcome and early infant development have been described extensively (Zimmermann, 2009); other details can be found in Chapter 15.

Iron. Historically, it has been thought that low thyroid function may cause anemia. Recent studies suggest that low thyroid function may be secondary to low iron status or anemia. The reason for this is because TPO is a glycosylated heme enzyme that is iron-dependent. The insertion of heme iron into TPO is necessary for the enzyme to translocate to the apical cell surface of thyrocytes (or thyroid epithelial cells), thus assisting TPO to catalyze the two initial steps of thyroid hormone synthesis. A full assessment of iron status could likely help to identify the cause of many cases of thyroid malfunction (Dobbs and Titchenal, 2009).

Selenium. Selenium, as selenocysteine, is a cofactor for 5-deiodinase. If selenium is deficient, the deiodinase activity is impaired, resulting in a decreased ability to deiodinate T_4 to T_3 . In animals, deficiencies of selenium are associated with impaired 5-deiodinase activity in the liver and kidney, as well as reduced T_3 levels. Evidence suggests a strong linear association between lower T_3/T_4 ratios and reduced selenium status, even among individuals considered to be euthyroid based on standard laboratory parameters. This association is particularly strong in older adults, possibly as the result of impaired peripheral conversion. An inverse relationship between T_3 and

breast cancer is associated with decreased selenium status, even when plasma T_4 and TSH concentrations may be similar. This combination of factors strongly suggests that low T_3 may be due to faulty conversion of T_4 to T_3 expected in selenium deficiency.

Selenium participates in the antioxidant network. It assists in detoxification as part of glutathione peroxidase, an enzyme whose main biologic role is to protect the organism from oxidative damage. Several studies reported on the benefit of selenium treatment in Hashimoto's thyroiditis and Graves' disease.

Evidence also suggests that high intakes of selenium may exert a detrimental influence on thyroid hormone metabolism. Although individuals exposed to high dietary levels of selenium typically have normal levels of T_4 , T_3 , and TSH, a significant inverse correlation has been found between T_3 and selenium. Some researchers have hypothesized the activity of 5-deiodinase may become depressed after a high dietary intake of selenium, suggesting a safe level of dietary selenium at or below 500 mcg daily (Köhrle and Gärtner, 2009).

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown cause that affects an estimated 3% to 12% of women of reproductive age in Western societies (Moran et al, 2010; Velez and Motta, 2014). The condition is characterized by reproductive issues such as amenorrhea or other menstrual irregularities, anovulation, enlarged ovaries with multiple cysts, and infertility. More generalized symptoms include acne, hirsutism (excessive or abnormal distribution of hair growth), male-pattern baldness, obesity, and sleep apnea (see Table 31-3).

Pathophysiology

Biochemical and endocrine abnormalities in women with PCOS include a hyperandrogenic state in which there is a higher concentration of free androgens (dehydroepiandrosterone, testosterone, and androstenedione) and decreased hepatic production of sex hormone binding globulin (Sirmans and Pate, 2013). In addition to the elevated levels of androgens, hyperinsulinemia (which results from insulin resistance), impaired glucose tolerance, and hyperlipidemia are seen. Hyperandrogenism is responsible for many of the symptoms of PCOS, such as reproductive

and menstrual abnormalities, hirsutism, and acne. Elevated androgen levels, in turn, appear to be due in part to hyperinsulinemia, which triggers the increase in androgen production. Thus interventions that improve insulin resistance and hyperinsulinemia may reverse some of the manifestations of PCOS.

The insulin resistance seen in 50% to 70% of women with PCOS is unique in that it occurs independent of body weight to some extent and is not always corrected by weight loss. It appears to result from insulin receptor phosphorylation abnormalities in an insulin-mediated signaling pathway (Sirmans and Pate, 2013). Conventional treatment of PCOS includes diet and exercise to promote weight loss. In women who are obese, weight loss may improve insulin resistance, decrease androgen levels and hirsutism, and restore ovulation in some cases. Low-glycemic index diets historically have been recommended without evidence of their clinical effectiveness. However, the capacity of dietary carbohydrates to increase postprandial blood sugar response may be an important consideration for optimizing metabolic and clinical outcomes in PCOS. Furthermore, independent of weight loss, a low-glycemic index diet appears to result in greater improvements in health, including improved insulin sensitivity, improved menstrual regularity, better emotion scores (on a questionnaire designed to detect changes in quality of life), and decreased markers of inflammation compared with a conventional low-fat diet when matched closely for macronutrient and fiber content (Marsh et al, 2010).

Medical Management

Hypothyroidism occurs in some cases of PCOS. Laboratory tests for thyroid function are frequently normal in patients with clinical evidence of hypothyroidism, and treatment with thyroid hormone results in clinical improvement in many patients. Therefore an empirical trial of thyroid hormone should be considered for patients with PCOS who have clinical evidence of hypothyroidism.

Thyroid antibody status should be taken into account when considering empirical treatment with thyroid hormone in women with PCOS. Metformin frequently is prescribed to improve insulin resistance, and treatment with this drug may lead to resumption of ovulation. Other therapies include the drugs clomiphene citrate (to induce ovulation) and spironolactone (an antiandrogen), as well as oral contraceptives (to treat menstrual irregularities and hirsutism).

Medical Nutrition Therapy

Nutritional interventions that may be beneficial for women with PCOS include dietary modifications designed to enhance insulin sensitivity. This includes restricting refined carbohydrates and total calories; consuming high-fiber foods; and eating small, frequent meals. Some patients with insulin resistance fare better on a diet high in complex carbohydrates (approximately 60% of total calories), whereas others respond better to a low-carbohydrate diet ($\leq 40\%$ of total calories). In addition, supplementation with vitamin D_3 (up to 10,000 IU/day), (Nazarian et al, 2011) and chromium picolinate (200 to 1000 mcg/day) has been reported to improve glucose tolerance, insulin secretion, and insulin sensitivity in human subjects (Lydic et al, 2006) and laboratory animals (Abdourahman and Edwards, 2008). Short-term treatment with N-acetylcysteine (600 mg twice a day) may be useful as an adjunct to clomiphene citrate in women with clomiphene citrate-resistant infertility (Rizk et al, 2005). In addition, treatment with thyroid hormone may be beneficial for women who have laboratory or clinical evidence of hypothyroidism (see Table 31-3).

TABLE 31-3 Nutrition Treatment For Polycystic Ovary Syndrome

Obesity	Institute weight management program of diet and exercise.
Insulin resistance	Restrict refined carbohydrates (low glycemic index diet) and total calories. Increase high-fiber foods. Recommend small, frequent meals. Monitor carefully to ascertain benefit from high- versus low-carbohydrate diet. Consider supplementation with chromium picolinate.
Low serum 25 hydroxy vitamin D	Administer vitamin D_3 (cholecalciferol).
Clomiphene-citrate resistant infertility	Use short-term NAC as adjunct.
Laboratory or clinical evidence of hypothyroidism	Institute thyroid hormone replacement. Use foods or supplements with selenium and iodine.

NAC, N-acetylcysteine.

FIGURE 31-4 **A**, Exophthalmos. (From SPL/Photo Researchers, Inc.) **B**, Thyroid enlargement. (From Buck C: 2011 ICD-9-CM, for Hospitals, vols 1-3, St Louis, 2011, WB Saunders.)

HYPERTHYROIDISM

Graves' disease is an autoimmune disease in which the thyroid is diffusely enlarged (goiter) and overactive, producing an excessive amount of thyroid hormones. It is the most common cause of **hyperthyroidism** (overactive thyroid) in the United States. Physical symptoms frequently include red, dry, swollen, puffy, and bulging eyes (exophthalmos), heat intolerance, difficulty sleeping, and anxiety (see [Box 31-2](#)). However, the most common sign of Graves' disease is goiter or thyroid enlargement (see [Figure 31-4](#)). The excessive thyroid hormones may cause a serious metabolic imbalance, **thyrotoxicosis**. The prevalence of maternal thyrotoxicosis is approximately 1 case per 1500 persons, with maternal Graves' disease being the most common cause (80% to 85%) ([American Thyroid Association, 2012](#)).

Pathophysiology

Commonly, patients have a family history involving a wide spectrum of autoimmune thyroid diseases, such as Graves' disease, Hashimoto's thyroiditis, or postpartum thyroiditis. In Graves' disease, the TRH receptor itself is the primary autoantigen and is responsible for the manifestation of hyperthyroidism. The thyroid gland is under continuous stimulation by circulating autoantibodies against the TRH receptor, and pituitary TSH secretion is suppressed because of the increased

production of thyroid hormones. These thyroid-stimulating antibodies cause release of thyroid hormone and thyroglobulin (Tg) and they also stimulate iodine uptake, protein synthesis, and thyroid gland growth.

The Tg and TPO Abs appear to have little role in Graves' disease. However, as mentioned earlier, they are markers of Hashimoto's autoimmune disease against the thyroid. A TSH antibody—typically referred to as thyroid-stimulating immunoglobulin—test is used to identify hyperthyroidism, or Graves' disease.

Triggers

Graves' disease is an autoimmune disorder, influenced by a combination of environmental and genetic factors. Genetic factors contribute to approximately 20% to 30% of overall susceptibility. Other factors include infection, excessive iodide intake, stress, female gender, steroids, and toxins. Smoking has been implicated in the worsening of Graves' ophthalmopathy. Graves' disease also has been associated with infectious agents such as *Yersinia enterocolitica* and *Borrelia burgdorferi*.

Genetics. Several autoimmune thyroid disease susceptibility genes have been identified and appear to be specific to either Graves' disease or Hashimoto's thyroiditis, whereas others confer susceptibility to both conditions. The genetic predisposition to thyroid autoimmunity may interact with environmental factors or events to precipitate the onset of Graves' disease. HLA-DRB1 and HLA-DQB1 appear to be associated with Graves' disease susceptibility.

Stress. Stress can be a factor for thyroid autoimmunity. Acute stress-induced immunosuppression may be followed by immune system hyperactivity, which could precipitate autoimmune thyroid disease. This may occur during the postpartum period, in which Graves' disease may occur 3 to 9 months after delivery. Estrogen may influence the immune system, particularly the beta-cells. Trauma to the thyroid also has been reported to be associated with Graves' disease. This may include surgery of the thyroid gland, percutaneous injection of ethanol, and infarction of a thyroid adenoma.

Medical Management

For patients with sustained forms of hyperthyroidism, such as Graves' disease or toxic nodular goiter, antithyroid medications can be used. The goal with this form of drug therapy is to prevent the thyroid from producing hormones (see [Table 31-4](#)).

The effects of immunotherapy are also being evaluated ([Salvi, 2014](#)) (see [Pathophysiology and Care Management Algorithm: Thyroid Dysfunction](#)).

TABLE 31-4 Treatments for Hyperthyroidism

Medication Brand Name	Medication Generic Name	Use and Comments
Tapazole	Methimazole (MMI)	Both drugs interfere with the thyroid gland's production of hormones. Both have side effects, which include rash, itching, joint pain, and fever.
Northyx	Propylthiuracil (PTU)	Liver inflammation or reduction in white blood cells may occur. Underlying hyperthyroidism can return when patient is no longer taking the medication.
Radioactive iodine		This is the most widely recommended permanent treatment of hyperthyroidism. Thyroid cells absorb radioactive iodine, which damages or kills them. If too many of the thyroid cells are damaged, remaining thyroid does not produce enough hormone, resulting in hypothyroidism, and supplemental thyroid hormone may be necessary.
Surgical Treatment		
<ul style="list-style-type: none"> • Partial or complete removal of the thyroid • Not as common as pharmacologic modes of treatment 		

MANAGING IMBALANCES OF THE HYPOTHALAMUS-PITUITARY-THYROID AXIS

The thyroid has a relationship to hypothalamic, pituitary, immune, adrenal, and cardiovascular functions that affect clinical, cellular, and molecular outcomes. A checklist of considerations is found in [Box 31-3](#) and is discussed here.

Provide adequate precursors for the formation of T₄. Iodide is a limiting nutrient in many individuals for the production of T₄. Adequate levels of organic iodide, which can come from sea vegetables, iodized salt, and seafood, are important in T₄ production. Adequate dietary protein intake is important in establishing proper protein calorie nutrition. Supplementation with tyrosine does not appear to have a beneficial effect on elevating thyroid hormones.

Reduce antithyroidal antibodies. A variety of food antigens could induce antibodies that crossreact with the thyroid gland. A food elimination diet using gluten-free grains and possible elimination of casein, the predominant milk protein, may be considered for hypothyroidism of unexplained origin. It also has been suggested that environmental toxins may play a role in inducing autoimmune thyroiditis and thyroid dysfunction. Implementing nutritional support and providing adequate levels of vitamin D to support the immune system may be beneficial.

Improve the conversion of T₄ to T₃. Nutritional agents that help support proper deiodination by the type 1 5-deiodinase enzyme include selenium (as L-selenomethionine) and zinc (as zinc glycinate or zinc citrate). Human studies repeatedly have demonstrated consequent reduced concentrations of thyroid hormones when a zinc deficiency is present ([Blazewicz et al, 2010](#)). In children with Down syndrome, zinc sulfate may reduce thyroidal antibodies, improve thyroid function, and reduce the incidence of subclinical hypothyroidism.

Enhance T₃ influence on mitochondrial bioenergetics. A number of important nutritional relationships improve thyroid hormones' effects on the mitochondria. Selenium supplementation in animals can improve the production of T₃ and lower autoantibodies to thyroid hormones, while improving energy production. Supplementation with selenomethionine results in improved deiodination of T₄, which may improve adenosine triphosphate formation by supporting improved mitochondrial activity. Food sources of selenium include the Brazil nut, snapper, cod, halibut, yellow fin tuna, salmon, sardines, shrimp, mushrooms, and barley.

BOX 31-3 Factors Promoting Thyroid Health in Adults

Consider

- Protein: 0.8 g/kg/day
- Iodine (once autoimmune disease has been ruled out): 150 mcg/day
- Selenium (as L-selenomethionine): 75 to 200 mcg/day
- Zinc (as zinc citrate): 10 mg/day
- Vitamin D (as D₃ or cholecalciferol): 1000 IU/day
- Vitamin E (as D-alpha tocopherol succinate): 100 IU/day
- Vitamin C (as ascorbic acid): 100 to 500 mg/day
- Guggulsterones (from guggul extract): 100 mg/day
- Ashwaganda: 100 mg/day

Reduce or eliminate

- Gluten (found in wheat, rye, oats, and barley)
- Processed soy
- Excessive uncooked goitrogenic foods
- Stress

Monitor use of botanical products. Based on animal studies, it appears that certain botanical preparations influence thyroid activity. The most significant products include *Commiphora mukul* (guggulsterones, from guggul extract) and *Withania somnifera* (ashwagandha). *C. mukul* demonstrates strong thyroid stimulatory action. Its administration (1 mg/100 g body weight) increases iodine uptake by the thyroid, increases TPO activity, and decreases lipid peroxidation, suggesting that increased peripheral generation of T₃ might be mediated by this plant's antioxidant effects. *W. somnifera* (ashwagandha) root extract (1.4 g/kg) may increase T₃ and T₄ concentrations without changing 5-deiodinase activity.

Avoid disruption of thyroid hormone metabolism from flavonoids. Flavonoids, natural and synthetic, have the potential to disrupt thyroid hormone metabolism. Synthetic flavonoid derivatives can decrease serum T₄ concentrations and inhibit the conversion of T₄ to T₃ and the metabolic clearance of rT₃ by the selenium-dependent 5-deiodinase. Naturally occurring flavonoids appear to have a similar inhibitory effect. Of the naturally occurring flavonoids, luteolin (most often found in leaves, but also seen in celery, thyme, dandelion, green pepper, thyme, pepper, chamomile tea, carrots, olive oil, peppermint, rosemary, and oregano) is the most active inhibitor of 5-deiodinase activity. Because isolated or concentrated flavonoids are increasingly used as therapeutic interventions, more research on the potential influence of these substances on thyroid hormone metabolism is desirable ([Goncalves et al, 2013](#)).

Use caution with supplements. Lipoic acid reduces the conversion of T₄ to T₃. Because it is usually not a therapeutic advantage to decrease peripheral activation of T₃ subsequent to T₄ therapy, use of lipoic acid supplements in hypothyroid patients receiving exogenous hormone therapy should be approached with caution.

Maintain vitamin sufficiency. One nutrient that is critically important for establishing immune balance and preventing the production of autoantibodies is vitamin D. Vitamin D is considered a prohormone with antiproliferative, differentiating, and immunosuppressive activities. Vitamin D is an effective immune modulator and may suppress the development of autoimmune diseases, such as arthritis and multiple sclerosis ([Baeke et al, 2010](#)). Conversely, a vitamin D deficiency is associated with numerous autoimmune conditions, including Hashimoto's. More than 90% of people with autoimmune thyroid disease have a genetic defect affecting their ability to metabolize vitamin D ([Feng et al, 2013](#); [Kivity et al, 2011](#)). Vitamin D also appears to work with other nutritional factors to help regulate immune sensitivity and may protect against development of autoantibodies. After exposure to heavy metals, decreases in a variety of hepatic antioxidant lipid peroxidation (the oxidative degradation of lipids) systems have been observed. Ascorbic acid has been shown to be effective in preventing cadmium-induced decreases in T₃ and hepatic 5-deiodination.

ADRENAL DISORDERS

Cushing's Syndrome

In Cushing's syndrome, too much cortisol remains in the bloodstream over a long period. The exogenous form occurs when individuals take steroids or other similar medications and ceases when the medication is stopped. Endogenous Cushing's syndrome is rare and occurs as the result of a tumor on the adrenal or pituitary gland. Weight gain, easy bruising, depres-

sion, muscle loss, and weakness are common symptoms. A weight management protocol may be needed.

Addison's Disease

Primary adrenal insufficiency, also known as Addison's disease, is rare. In this condition, insufficient steroid hormones are produced in spite of adequate levels of the hormone ACTH. Regulation of blood glucose levels and stress management are affected. Loss of appetite, fatigue, low blood pressure, nausea and vomiting, and darkening of skin on the face and neck may occur. Patients with Addison's disease should not restrict their salt intake unless they have concurrent hypertension. Those patients who live in warm climates and therefore have increased losses through perspiration may need to increase salt intake.

Adrenal Fatigue

Adrenal fatigue has been identified as a collection of signs and symptoms caused by the decreased ability of the adrenal glands to respond adequately to stress. A variety of terms are found in the scientific literature that address adrenal fatigue, including subclinical adrenal insufficiency, adrenal stress, adrenal exhaustion, adrenal burnout, and adrenal imbalance (Allen, 2013). The adrenals are the two triangular-shaped glands located at the top of each kidney and are responsible primarily for governing the body's adaptations to stress of any kind. However, adrenal fatigue can occur whether the source of stress, physical, emotional or psychologic, is chronic and continues to persist causing a cumulative effect, or is a very intense single event stressor. In other words, the adrenal glands are unable to keep pace with the demands of perpetual fight-or-flight arousal, resulting in subclinical adrenal dysfunction. The most common symptoms of adrenal fatigue include, but are not limited to, excessive fatigue and exhaustion, hair loss, hormone imbalance, poor digestion, low immune function, slow recovery from illness, inability to concentrate, and inability to cope with stressors.

Chronic adrenal stress causes the following:

- Affects communication between the brain and hormone-secreting glands. The hypothalamus and pituitary gland direct hormone production, including that of the thyroid. When the hypothalamus and pituitary weaken because of chronic adrenal stress, they are not able to communicate well with the thyroid gland
- Increases thyroid-binding protein activity, so that thyroid hormones cannot get into cells to do their job
- Hampers the conversion of T_4 to active forms of T_3 that the body can use
- Interferes with the detoxification pathways through which unnecessary thyroid hormones exit the body, leading to thyroid hormone resistance
- Causes cells to lose sensitivity to thyroid hormones
- Weakens the immune barriers of the digestive tract, lungs, and brain; promotes poor immune regulation

These factors increase the risk for triggering Hashimoto's or exacerbating it. These are some of the ways adrenal stress directly affect thyroid function.

Chronic adrenal stress affects other systems of the body, which in turn, decrease thyroid function. For example, the adrenal hormone **cortisol** plays a large role in thyroid health. Cortisol is a life-sustaining hormone essential to the maintenance of homeostasis. It often is called the "stress hormone" because it

influences, regulates, or modulates many of the changes that occur in the body in response to stress, including but not limited to the following:

- Antiinflammatory actions
- Blood glucose levels
- Blood pressure
- Central nervous system activation
- Fat, protein, and carbohydrate metabolism to maintain blood glucose
- Heart and blood vessel tone and contraction
- Immune responses

Cortisol levels follow a circadian rhythm and normally fluctuate throughout the day and night, peaking at about 8:00 AM and reaching a low at about 4:00 PM (Allen, 2013). It is very important that bodily functions and cortisol levels return to normal after a stressful event. Adrenal fatigue appears to occur when the amount of stress or combined stresses overextend the capacity of the body to compensate for and recover from that stress. When this happens repeatedly, it exhausts the adrenal and thyroid glands, as well as the hypothalamus and the pituitary gland. Over time, this exhaustion leads to functional hypothyroidism. In addition, constant cortisol production weakens the gastrointestinal (GI) tract, making one more susceptible to inflammation, dysbiosis (poor gut health), and infection. Thus a vicious cycle weakens the thyroid.

With proper care, most people who experience adrenal fatigue can expect to regain their normal quality of life. Some of the conventional approaches in the treatment of adrenal fatigue may include the following (Allolio, 2007):

- B-complex vitamins
- Exercise in moderation
- DHEA (dehydroepiandrosterone)
- Proper diet
- Relaxation
- Sleep
- Stress relief and management

CLINICAL CASE STUDY

Frank is a 72-year-old man from Jamaica who moved to the United States 2 years ago. He has been diagnosed with hypothyroidism this past year. He comes to your clinic with his medicine and traditional folk remedies, including Synthroid, garlic, and chamomile. His diet history indicates daily use of chicken, rice, celery, dandelion, green pepper, mango, and papaya. He states that he has been very tired lately, has little energy, and has constipation. His hormone levels on his last medical report were thyroxine (T_4): 1.7, triiodothyronine (T_3): 75, and thyroid-stimulating hormone (TSH): 15, indicative that his hypothyroidism is still not well controlled.

Nutrition Diagnostic Statement

Food-drug interaction related to mixing Synthroid with foods and herbs that aggravate thyroid function as evidenced by fatigue, constipation, high TSH, and low serum T_3 and T_4 .

Nutrition Care Questions

1. What other information do you need for a more thorough assessment?
2. What advice would you offer Frank about his diet?
3. What foods and herbs conflict with Synthroid?
4. Because traditional folk remedies are commonly used, how do you plan to discuss these issues with Frank?

Medical Nutrition Therapy for Anemia

Tracy Stopler, MS, RDN
Susan Weiner, MS, RDN, CDE

KEY TERMS

anemia	iron deficiency anemia	restless legs syndrome (RLS)
aplastic anemia	koilonychia	serum
ceruloplasmin	macrocytic anemia	sickle cell anemia (SCA)
ferritin	meat-fish-poultry (MFP) factor	sideroblastic (pyridoxine-responsive) anemia
ferroprotein	megaloblastic anemia	soluble serum transferrin receptors (STFRs)
hematocrit	microcytic anemia	sports anemia
heme iron	nonheme iron	thalassemia
hemochromatosis	nutritional anemias	total iron-binding capacity (TIBC)
hemoglobin	pagophagia	transferrin
hemolytic anemia	pernicious anemia	transferrin receptor
hepcidin	plasma	transferrin saturation
holotranscobalamin II (holo TCII)	polycythemia	
hypochromic	protoporphyrin	
intrinsic factor (IF)	reticulocytosis	

It is important for nutrition professionals to understand the myriad of terms related to blood disorders. **Hemoglobin** is a conjugated protein containing four heme groups and globin; it is the oxygen-carrying pigment of the erythrocytes. The **hematocrit** is the volume percentage of erythrocytes in the blood. **Plasma** is the liquid portion of whole blood containing coagulation factors; **serum** is the liquid portion of whole blood without coagulation factors.

Anemia is a deficiency in the size or number of red blood cells (RBCs) or the amount of hemoglobin they contain. This deficiency limits the exchange of oxygen and carbon dioxide between the blood and the tissue cells. Anemia classification is based on cell size—macrocytic (large), normocytic (normal), and microcytic (small)—and on hemoglobin content—hypochromic (pale color from deficiency of hemoglobin) and normochromic (normal color) (see Table 32-1).

Macrocytic anemia presents with larger-than-normal RBCs, plus increased mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC). **Microcytic anemia** is characterized by smaller-than-normal erythrocytes and less circulating hemoglobin, as in iron deficiency anemia and thalassemia.

Most anemias are caused by a lack of nutrients required for normal erythrocyte synthesis, principally iron, vitamin B₁₂, and

folic acid. These anemias that result from an inadequate intake of iron, protein, certain vitamins, copper, and other heavy metals are called **nutritional anemias**. Other anemias result from conditions such as hemorrhage, genetic abnormalities, chronic disease states, or drug toxicity, and have varying degrees of nutritional consequence.

IRON-RELATED BLOOD DISORDERS

Iron status can range from overload to deficiency and anemia. Routine measurement of iron status is necessary because approximately 6% of Americans have a negative iron balance, approximately 10% have a gene for positive balance, and approximately 1% have iron overload. As shown in Figure 32-1, stages of iron status range from iron overload to iron deficiency anemia and are summarized as follows:

- Stage I and Stage II negative iron balance (i.e., iron depletion). In these stages iron stores are low and there is no dysfunction. In Stage I negative iron balance, reduced iron absorption produces moderately depleted iron stores. Stage II negative iron balance is characterized by severely depleted iron stores.
- Stage III and IV negative iron balance (i.e., iron deficiency). Iron deficiency is characterized by inadequate body iron, possibly causing dysfunction and disease. In Stage III negative iron balance, dysfunction is not accompanied by anemia; anemia develops in Stage IV negative iron balance.
- Stage I and II positive iron balance. Stage I positive balance usually lasts for several years with no dysfunction. Supplements of iron and/or vitamin C promote

*Thank you to Melissa Fraser RD, CDN, and Mollie Kurshan RD, CDN, for their help and research for this chapter.

In memory of Victor Herbert, MD, JD, for his inspiration in the writing of the chapter.

TABLE 32-1 Morphologic Classification of Anemia

Morphologic Type of Anemia	Underlying Abnormality	Clinical Syndromes	Treatment
Macrocytic (MCV > 94; MCHC > 31)			
Megaloblastic	Vitamin B ₁₂ deficiency	Pernicious anemia	Vitamin B ₁₂
	Folic acid deficiency	Nutritional megaloblastic anemias, sprue, and other malabsorption syndromes	Folic acid
	Inherited disorders of DNA synthesis	Orotic aciduria	Treatment based on the nature of the disorder
	Drug-induced disorders of DNA synthesis	Sickle cell anemia	Discontinue offending drug and administer folic acid
Nonmegaloblastic	Accelerated erythropoiesis	Side effects of chemotherapeutic agents, anticonvulsants, oral contraceptives,	
		Hemolytic anemia	Treatment of underlying disease
Hypochromic Microcytic (MCV < 80; MCHC < 31)			
	Iron deficiency	Chronic loss of blood,	Ferrous sulfate and correction of underlying cause
	Disorders of globin synthesis	Thalassemia	Nonspecific
		Hemoglobin E Hemoglobin C	Mild – does not require treatment; Severe – frequent blood transfusions to provide healthy RBCs with normal hgb
Disorders of porphyrin and heme synthesis	Pyridoxine-responsive anemia	Pyridoxine	
	Other disorders of iron metabolism	Copper deficiency	Copper
Normochromic Normocytic (MCV 82-92; MCHC > 30)

progression to dysfunction or disease, whereas iron removal prevents progression to disease. Iron overload disease develops in persons with stage II positive balance after years of iron overload have caused progressive damage to tissues and organs.

Iron status has a variety of indicators. Serum **ferritin** is an iron apoferritin complex, one of the chief storage forms of iron. Serum ferritin levels are in equilibrium with body iron stores. Very early (stage I) positive iron balance may best be recognized by measuring **total iron-binding capacity (TIBC)**, the capacity of transferrin to take on or become saturated with iron. Conversely, measurement of serum or plasma ferritin levels may best reveal early (stage I or II) negative iron balance, although serum TIBC may be as good an indicator (see Chapter 7). **Transferrin saturation** is the measure of the amount of iron bound to transferrin and is a gauge of iron supply to the tissues; the percent saturation = serum iron/TIBC × 100.

Iron Deficiency Anemia

Pathophysiology

Iron deficiency anemia is characterized by the production of (microcytic) erythrocytes and a diminished level of circulating hemoglobin. This microcytic anemia is the last stage of iron deficiency, and it represents the end point of a long period of iron deprivation. There are many causes of iron deficiency anemia as discussed in **Box 32-1**.

With few exceptions, iron deficiency anemia in adult men is the result of blood loss. Large losses of menstrual blood can cause iron deficiency in women, many of whom are unaware that their menses are unusually heavy.

Because anemia is the last manifestation of chronic, long-term iron deficiency, the symptoms reflect a malfunction of a variety of body systems. Inadequate muscle function is reflected in decreased work performance and exercise tolerance. Neurologic

*Randall Lauffer of Harvard and Joe McCord of University of Colorado–Denver hold that any storage iron is excessive because of its potential to promote excessive free radical generation. (Herbert V et al: Most free radical injury is iron related, *Stem Cells* 12:289, 1994.)
[†]Inflammation reduces transferrin (and the plasma iron on it), because transferrin is a reverse acute-phase reactant.
[‡]Inflammation produces elevated ferritin, because ferritin protein is an acute-phase reactant.
[§]Ferritin-iron is unaffected by inflammation, so it is reliable when ferritin, transferrin, and plasma iron are not.
 Dallman (pediatrician) definition of negative balance: less absorbed than excreted.
 Herbert (internist) definition of negative balance: less absorbed than needed.

BOX 32-1 Causes of Iron Deficiency Anemia

1. Inadequate dietary intake secondary to a poor diet without supplementation
2. Inadequate absorption resulting from diarrhea, achlorhydria, intestinal disease such as celiac disease, atrophic gastritis, partial or total gastrectomy, or drug interference
3. Inadequate utilization secondary to chronic gastrointestinal disturbances
4. Increased iron requirement for growth of blood volume, which occurs during infancy, adolescence, pregnancy, and lactation and which is not being matched with intake
5. Increased excretion because of excessive menstrual blood (in females); hemorrhage from injury; or chronic blood loss from a bleeding ulcer, bleeding hemorrhoids, esophageal varices, regional enteritis, celiac disease, Crohn's disease, ulcerative colitis, parasitic or malignant disease
6. "Increased destruction" of iron from iron stores into the plasma and defective iron use caused by a chronic inflammation or other chronic disorder

involvement is manifested by behavioral changes such as fatigue, anorexia, and pica, especially **pagophagia** (ice eating). Abnormal cognitive development in children suggests iron deficiency before it has developed into overt anemia.

Growth abnormalities, epithelial disorders, and a reduction in gastric acidity are also common. A possible sign of early iron deficiency is reduced immunocompetence, particularly defects in cell-mediated immunity and the phagocytic activity of neutrophils, which may lead to frequent infections. **Restless legs syndrome (RLS)** with leg pain or discomfort may result from a lack of iron in the brain; this alters dopamine production and movement. Besides iron deficiency, kidney failure, Parkinson's disease, diabetes, rheumatoid arthritis, and pregnancy can aggravate RLS (Allen et al, 2013; National Institutes of Health [NIH], National Heart Blood and Lung Institute [NHBLI], 2010).

As iron deficiency anemia becomes more severe, defects arise in the structure and function of the epithelial tissues, especially of the tongue, nails, mouth, and stomach. The skin may appear

pale, and the inside of the lower eyelid may be light pink instead of red. Mouth changes include atrophy of the lingual papillae, burning, redness, and in severe cases a completely smooth, waxy, and glistening appearance of the tongue (glossitis). Angular stomatitis also may occur, as may a form of dysphagia. Gastritis occurs frequently and may result in achlorhydria. Fingernails can become thin and flat, and eventually **koilonychia** (spoon-shaped nails) may be noted (see Figure 32-2).

Progressive, untreated anemia results in cardiovascular and respiratory changes that can eventually lead to cardiac failure. Some behavioral symptoms respond to iron therapy before the anemia is cured, suggesting they may be the result of tissue depletion of iron-containing enzymes rather than from a decreased level of hemoglobin (see *Pathophysiology and Care Management Algorithm: Iron Deficiency Anemia*).

FIGURE 32-2 Fingernails with cuplike depressions (koilonychia) are a sign of iron deficiency in adults. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders.)

Assessment

A definitive diagnosis of iron deficiency anemia requires more than one method of iron evaluation; serum ferritin, iron and transferrin are the most useful. The evaluation also should include an assessment of cell morphology. By itself, hemoglobin concentration is unsuitable as a diagnostic tool in cases of suspected iron deficiency anemia for three reasons: (1) it is affected only late in the disease, (2) it cannot distinguish iron deficiency from other anemias, and (3) hemoglobin values in normal individuals vary widely.

After absorption, iron is transported by plasma **transferrin**—a beta-1 globulin (protein) that binds iron derived from the gastrointestinal tract, iron storage sites, or hemoglobin breakdown—to the bone marrow (hemoglobin synthesis), endothelial cells (storage), or placenta (fetal needs). Transferrin molecules are generated on the surface of RBCs in response to the need for iron. With iron deficiency, so many **transferrin receptors** are on the cell surface looking for iron that some of them break off and float in the serum. Their presence is an early measurement of developing iron deficiency; a higher quantity of **soluble serum transferrin receptors (STFRs)** means greater deficiency of iron. Progressive stages of iron deficiency can be evaluated by measurements, as shown in [Table 32-2](#).

Protoporphyrin is the iron-containing portion of the respiratory pigments that combines with protein to form hemoglobin or myoglobin. The zinc protoporphyrin (ZnPP)/heme ratio is measured to assess iron deficiency. However, both this ZnPP/heme ratio and hemoglobin levels are affected by chronic infection and other factors that can produce a condition that mimics iron deficiency anemia when, in fact, iron is adequate.

With higher altitudes, where there is a lower availability of oxygen, hematocrit and hemoglobin levels increase to adapt. This must be considered in any anemia assessment strategies ([Zubieta-Calleja et al, 2007](#)). High altitude is 4900 to 11,500 feet; very high altitude is 11,500 to 18,000 feet; extreme altitude is above 18,000 feet.

Medical Management

Treatment of iron deficiency anemia should focus primarily on the underlying cause, although this is often difficult to determine. The goal is repletion of iron stores.

Oral Supplementation. The chief treatment for iron deficiency anemia involves oral administration of inorganic iron in the ferrous form. Although the body uses ferric and ferrous iron, the reduced ferrous is easier on the gut and better absorbed. At a dose of 30 mg, absorption of ferrous iron is three times greater than if the same amount were given in the ferric form.

Iron is best absorbed when the stomach is empty; however, under these conditions it tends to cause gastric irritation. Gastrointestinal side effects can include nausea, epigastric discomfort and distention, heartburn, diarrhea, or constipation. If these side effects occur, the patient is told to take the iron with meals instead of on an empty stomach; however, this sharply reduces the absorbability of the iron. Gastric irritation is a direct result of the high quantity of free ferrous iron in the stomach. Chelated forms of iron (combined with amino acids) are more bioavailable than nonchelated iron. Chelated iron is less affected by phytate, oxalate, phosphate, and calcium (all iron absorption inhibitors). Chelated iron causes less gastrointestinal disturbances than elemental iron because it is needed in lower doses when it is absorbed into mucosal cells ([Ashmead, 2001](#)).

Health professionals usually prescribe oral iron three times daily for 3 months to treat iron deficiency. Depending on the severity of the anemia and the patient's tolerance, the daily dose of elemental iron recommended is 50-100 mg three times daily for adults and 4-6 mg/kg of body weight divided into three doses per day for children. Vitamin C greatly increases iron absorption and gastric irritation somewhat through its capacity to maintain iron in the reduced state ([Aditi and Graham, 2012](#)).

Absorption of 10 to 20 mg of iron per day permits RBC production to increase to approximately three times the normal rate and, in the absence of blood loss, hemoglobin

TABLE 32-2 Biochemical Evaluation of Iron Deficiency

Measure	Reference Range	Deficiency
Serum or plasma ferritin	Newborn 25–200 ng/mL; 25–200 mcg/dL Neonate—5 mos 50–200 ng/mL; 50–200 mcg/dL 6 mos–15 yr 7–142 ng/mL; 7–142 mcg/dL F 15 yr + 10–150 ng/mL; 10–150 mcg/dL M 15 yr + 12–300 ng/mL; 12–300 mcg/dL	The most sensitive indicator of iron deficiency. Low levels of ferritin are also seen in severe protein depletion. Females — < 10 mcg/dL Males — < 12 mcg/dL
Serum or plasma iron	F 40–150 mcg/dL; 7.2–26.9 mmol/L M 50–160 mcg/dL; 8.9–28.7 mmol/L	A good measure of quantity of iron bound to transferrin Females — < 40 mcg/dL Males — < 50 mcg
Total Iron Binding Capacity (TIBC) (Quantity of serum total circulating transferrin)	250–460 mcg/dL; 45–82 mmol/L	TIBC primarily reflects liver function and is an indirect measurement of transferrin. < 250 mcg/dL
Percent saturation of circulating transferrin	F 15–50% M 20–50%	Measures the iron supply to the tissues. It is calculated by dividing serum iron by the TIBC. Levels less than 16% are considered inadequate for erythropoiesis.
Soluble serum transferrin receptor (STFR)	F: 1.9–4.4 mg/L M: 2.2–5 mg/L	STFR reflects the rate of RBC production in bone marrow. Ordered to differentiate between anemia caused by iron deficiency and anemia caused by chronic and inflammatory diseases. It is more sensitive than serum ferritin because it is elevated with iron deficiency, is WNL in chronic disease or inflammation, and is low with iron overload.

concentration to rise at a rate of 0.2 g/dl daily. Increased **reticulocytosis** (an increase in the number of young RBCs) is seen within 2 to 3 days after iron administration, but affected persons may report subjective improvements in mood and appetite sooner. The hemoglobin level will begin to increase by day 4. Iron therapy should be continued for 4 to 5 months, even after restoration of normal hemoglobin levels, to allow for repletion of body iron reserves.

Parenteral Iron-Dextran. If iron supplementation fails to correct the anemia, (1) the patient may not be taking the medication as prescribed due to gastric distress; (2) bleeding may be continuing at a rate faster than the erythroid marrow can replace blood cells; or (3) the supplemental iron is not being absorbed, possibly as a result of malabsorption secondary to steatorrhea, celiac disease, or hemodialysis. In these circumstances parenteral administration of iron in the form of iron dextran may be necessary. Although replenishment of iron stores by this route is faster, it is more expensive than, and not as safe as, oral administration.

Medical Nutrition Therapy

In addition to iron supplementation and its dosage adjustment depending on patient tolerance, attention should be given to the amount of absorbable dietary iron consumed. A good source of iron contains a substantial amount of iron in relation to its calorie content and contributes at least 10% of the recommended dietary allowance (RDA) for iron. Liver; kidney; beef; dried fruits; dried peas and beans; nuts; dark green leafy vegetables; and fortified whole-grain breads, muffins, cereals, and nutrition bars are among the foods that rank highest in iron content (see Appendix 49). It is estimated that 1.8 mg of iron must be absorbed daily to meet the needs of 80% to 90% of adult women and adolescent boys and girls.

Bioavailability of Dietary Iron. Because typical Western diets generally contain 6 mg/1000 kcal of iron, the bioavailability of iron in the diet is more important in correcting or preventing iron deficiency than the total amount of dietary iron consumed. The rate of absorption depends on the iron status of the individual, as reflected in the level of iron stores. The lower the iron stores, the greater the rate of iron absorption. Individuals with iron deficiency anemia absorb approximately 20% to 30% of dietary iron compared with the 5% to 10% absorbed by those without iron deficiency.

Form of Iron. **Heme iron** (approximately 15% of which is absorbable) is the organic form in meat, fish, and poultry, and is known as the **meat-fish-poultry (MFP) factor**. It is much better absorbed than nonheme iron. **Nonheme iron** can also be found in MFP, as well as in eggs, grains, vegetables, and fruits, but it is not part of the heme molecule. The absorption rate of nonheme iron varies between 3% and 8%, depending on the presence of dietary enhancing factors, specifically vitamin C and meat, fish, and poultry. Vitamin C not only is a powerful reducing agent, but also binds iron to form a readily absorbed complex. The mechanism by which the MFP factor potentiates the absorption of nonheme iron in other foodstuffs is unknown.

Inhibitors. Iron absorption can be inhibited to varying degrees by factors that chelate iron, including carbonates, oxalates, phosphates, and phytates (unleavened bread, unrefined cereals, and soybeans). Factors in vegetable fiber may inhibit nonheme iron absorption. If taken with meals, tea and coffee can reduce iron absorption by 50% through the formation of insoluble iron compounds with tannin. Iron in egg yolk is poorly absorbed because of the presence of phosvitin.

IRON OVERLOAD

Excess iron is stored as ferritin and hemosiderin in the macrophages of the liver, spleen, and bone marrow. The body has a limited capacity to excrete iron. Approximately 1 mg of iron is excreted daily through the gastrointestinal tract, urinary tract, and skin. To maintain a normal iron balance, the daily obligatory loss must be replaced by the absorption of heme and non-heme food iron. Persons with iron overload excrete increased amounts of iron, especially in the feces, to compensate partially for the increased absorption and higher stores.

Excessive iron intake usually stems from accidental incorporation of iron into the diet from environmental sources. In developing countries the iron overload can result from eating foods cooked in cast iron cooking vessels or contaminated by iron-containing soils. In developed countries it likely results from excessive intake of iron-supplemented foods or multivitamin and mineral supplementation containing iron.

Uncommon disorders associated with iron overload or toxicity include thalassemias, sideroblastic anemia, chronic hemolytic anemia, ineffective erythropoiesis, transfusional iron overload (secondary to multiple blood transfusions), porphyria cutanea tarda, aplastic anemia, and alcoholic cirrhosis. **Aplastic anemia** is a normochromic-normocytic anemia accompanied by a deficiency of all the formed elements in the blood; it can be caused by exposure to toxic chemicals, ionizing radiation, and medications, although the cause is often unknown.

Brain iron increases with age, is higher in men, and is abnormally elevated in neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease (Bartzokis et al, 2010). Several gene variants affect iron metabolism and may contribute to early onset of these conditions.

Hemochromatosis

Hemochromatosis is the most common form of iron overload that causes progressive hepatic, pancreatic, cardiac, and other organ damage. People with this condition absorb three times more iron from their food than those without hemochromatosis. This disease, associated with the HFE gene, often is underdiagnosed. Persons who have two affected genes (homozygotes) will die of iron overload unless they donate blood frequently. Otherwise, the excessive iron absorption continues unabated.

Asians and Pacific Islanders have the highest levels of iron in their blood of all racial and ethnic groups, but they have the lowest prevalence of the gene mutation found with the typical form of hemochromatosis. The Hemochromatosis and Iron Overload Screening Study notes that non-Hispanic whites have the highest prevalence of the C282Y mutation of the hereditary iron (HFE) gene and thus hemochromatosis, followed by Native Americans, Hispanics, African Americans, Pacific Islanders, and Asians (Moretti et al, 2013).

In women, monthly menses slow the associated organ damage until after menopause (Moretti et al, 2013). Men are particularly susceptible to hemochromatosis because they have no physiologic mechanisms for losing iron such as menstruation, pregnancy, or lactation.

Pathophysiology

Hepcidin is a peptide synthesized in the liver that functions as the principal regulator of systemic iron homeostasis. It regulates iron transport from iron-exporting tissues into plasma. Hepcidin deficiency underlies most known forms of hereditary

hemochromatosis. Hepcidin inhibits the cellular efflux of iron by binding to and inducing the degradation of **ferroprotein**, the sole iron exporter in iron-transporting cells. Hepcidin controls plasma iron concentration and tissue distribution of iron by inhibiting intestinal iron absorption, iron recycling by macrophages, and iron mobilization from hepatic stores (Ganz, 2011).

Hepcidin synthesis is increased by iron loading and decreased by anemia and hypoxia. Its synthesis is also greatly increased during inflammation, trapping iron in macrophages, decreasing plasma iron concentrations, and causing iron-restricted erythropoiesis that is characteristic of anemia of chronic disease. There is evidence that the mutation of the HFE gene leading to hemochromatosis is also associated with increased levels of gastrin in the stomach, leading to increased levels of gastric acid and thus increased absorption of iron (Ganz, 2011). In hemochromatosis iron absorption is enhanced, resulting in a gradual, progressive accumulation of iron. Most affected persons do not know they have it. In its early stages iron overload may result in symptoms similar to iron deficiency such as fatigue and weakness; later it can cause chronic abdominal pain, aching joints, impotence, and menstrual irregularities.

A progressive, positive iron balance may result in a variety of serious problems, including hepatomegaly, skin pigmentation, arthritis, heart disease, hypogonadism, diabetes mellitus, and cancer. Individuals with abnormally high iron levels are more likely to develop cancer of the colon. Iron is a prooxidant that can be used for tumor cell growth and proliferation. There also seems to be increased risk for age-related macular degeneration and Alzheimer's disease because of the oxidant effect of iron overload (Fleming and Ponka, 2012; Leskovjan et al, 2011).

Assessment

If an iron overload is suspected, the following screening tests should be performed: serum ferritin level (storage iron), serum iron concentration, TIBC, and percent of transferrin saturation ($[\text{serum iron}/\text{TIBC}] \times 100$). Iron overload may be present if the percent of transferrin saturation is greater than 50 in women and 60 in men, and if the serum iron level is greater than 180 mg/dl. Deoxyribonucleic acid (DNA) testing, using blood or cheek cell samples, is also available for early detection of hemochromatosis. Liver biopsy is the gold standard for the diagnosis of iron overload.

Medical Management

The patient with iron overload may simultaneously be anemic as a result of damage to the bone marrow, an inflammatory disorder, cancer, internal bleeding, or chronic infection. Iron supplements should not be taken until the cause is known.

For patients with significant iron overload, weekly phlebotomy for 2 to 3 years may be required to eliminate all excess iron. Treatment for iron overload also may involve iron depletion with intravenous desferrioxamine-B, a chelating agent that is excreted by the kidneys, or with calcium disodium ethylenediaminetetraacetic acid (EDTA). Morbidity is reduced if excess body iron is removed by phlebotomy therapy before hepatic cirrhosis develops. Patients diagnosed as having hemochromatosis should inform all blood relatives so that they can be evaluated.

Medical Nutrition Therapy

Individuals with iron overload should ingest less heme iron from meat, fish, and poultry compared with nonheme iron

from plant foods. Persons with iron overload also should avoid alcohol and vitamin C supplements because both enhance iron absorption. In addition, vitamin C supplements may cause release of harmful free radical-generating excess iron from body stores.

Affected persons should avoid foods that are fortified with iron (i.e., breakfast cereals, "energy" or sports bars, and meal-replacement drinks or shakes). They should also avoid iron supplements or multiple vitamin and mineral supplements that contain iron. The recommended dietary allowance (RDA) for iron should not be exceeded, and perhaps the intake of iron should be less than that in some persons. The dietary reference intakes (DRIs) for iron are RDAs and are summarized on the inside front cover. The RDA for women in their childbearing years is 18 mg; for pregnant women, 27 mg; and the RDA for adult men, and women 51 years of age and older is 8 mg.

MEGALOBLASTIC ANEMIAS

Megaloblastic anemia reflects a disturbed synthesis of DNA, which results in morphologic and functional changes in erythrocytes, leukocytes, platelets, and their precursors in the blood and bone marrow. This anemia is characterized by the presence of large, immature, abnormal, RBC progenitors in the bone marrow; 95% of cases are attributable to folic acid or vitamin B₁₂ deficiency. Two disorders of cobalamin metabolism arise from mutations of the methionine synthase and methionine synthase reductase genes; these disorders feature megaloblastic anemia and neurologic manifestations (see Chapter 5).

Both vitamins are essential to the synthesis of nucleoproteins. Hematologic changes are the same for both; however, the folic acid deficiency is the first to appear. Normal body folate stores are depleted within 2 to 4 months in individuals consuming folate-deficient diets. By contrast, vitamin B₁₂ stores are depleted only after several years of a vitamin B₁₂-deficient diet. In persons with vitamin B₁₂ deficiency, folic acid supplementation can mask B₁₂ deficiency (see Figure 32-3).

In correcting the anemia, the vitamin B₁₂ deficiency may remain undetected, leading to the irreversible neuropsychiatric damage that is corrected **only** with B₁₂ supplementation (see Chapter 41).

Folic Acid Deficiency Anemia

Etiology

Folic acid deficiency anemia is associated with tropical sprue, can affect pregnant women, and occurs in infants born to mothers with folic acid deficiency. Folic acid deficiency in early pregnancy also can result in an infant born with a neural tube defect (see Chapter 15). Prolonged inadequate diets, inadequate absorption, inadequate use of folic acid caused by genetic aberrations resulting in reduced methylation of folic acid, and increased requirements resulting from pregnancy or growth are believed to be the most frequent causes. Other causes are gluten-induced enteropathy (childhood and adult celiac disease), idiopathic steatorrhea, nontropical sprue, and use of certain drugs (anticonvulsants, barbiturates, cycloserine, sulfasalazine, cholestyramine, and metformin), amino acid excess (glycine and methionine), and alcohol.

Because alcohol interferes with the folate enterohepatic cycle, most alcoholics have a negative folate balance or a folate deficiency. Alcoholics constitute the only group that generally has all six causes of folic acid deficiency simultaneously: inadequate

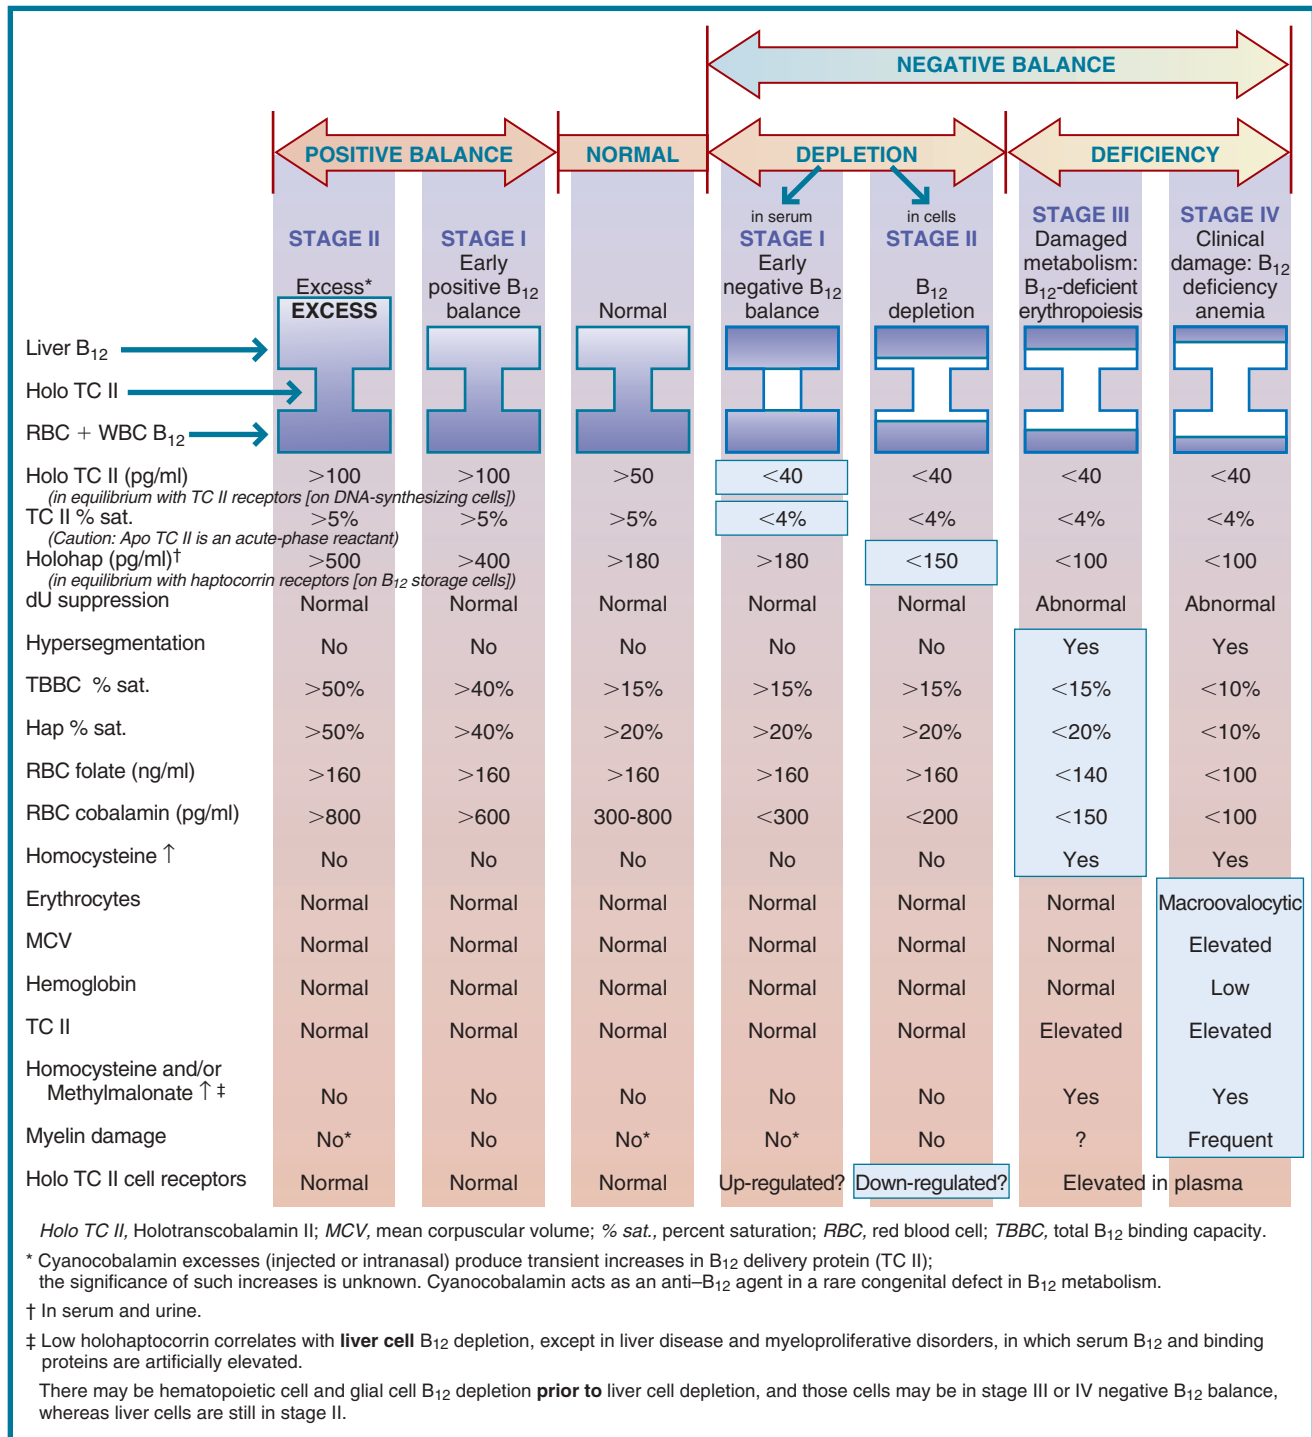

FIGURE 32-3 Sequential stages of vitamin B₁₂ status. (From Herbert V: Staging vitamin B₁₂. In Ziegler EE, Filer LJ, editors: *Present knowledge in nutrition*, ed 7, Washington, DC, 1996, International Life Sciences Institute Press.)

ingestion, absorption, and use, increased excretion, requirement, and destruction of folic acid (see Chapter 29). **Box 32-2** describes the causes of folate deficiency.

Folate absorption takes place in the small intestine. Enzyme conjugases (e.g., pteroylpolyglutamate hydrolase, the folate conjugase), found in the brush border of the small intestine, hydrolyze the polyglutamates to monoglutamates and

reduce them to dihydrofolate and tetrahydrofolic acid (THFA) in the small intestinal epithelial cells (enterocytes). From the enterocytes these forms are transported to the circulation, where they are bound to protein and transported as methyl THFA into the cells of the body.

In the absence of vitamin B₁₂, 5-methyl THFA, the major circulating and storage form of folic acid, is metabolically inactive.

BOX 32-2 Causes of Folate Deficiency**Inadequate Ingestion**

Poor diet (lack of or overcooked fruits and vegetables), vitamin B₁₂ or vitamin C deficiency, chronic alcoholism

Inadequate Absorption

Gluten-induced enteropathy or celiac disease, tropical sprue, drug interactions, congenital defects

Inadequate Utilization

Antagonists, anticonvulsants, enzyme deficiency, vitamin B₁₂ and vitamin C deficiency, chronic alcoholism, excess glycine and methionine

Increased Requirement

Extra tissue demand, infancy, increased hematopoiesis, increased metabolic activity, Lesch-Nyhan syndrome, drugs

Increased Excretion

Vitamin B₁₂ deficiency, liver disease, kidney dialysis, chronic exfoliative dermatitis

Increased Destruction

Dietary oxidants

Modified from Herbert V, Das KC: Folic acid and vitamin B₁₂. In Shils ME et al, editors: *Modern nutrition in health and disease*, ed 8, vol 1, Philadelphia, 1994, Lea & Febiger.

To be activated the 5-methyl group is removed, and THFA is cycled back into the folate pool, where it functions as the main 1-carbon-unit acceptor in mammalian biochemical reactions. THFA may then be converted to the coenzyme form of folate required to convert deoxyuridylylate to thymidylylate, which is necessary for DNA synthesis.

MTHFR Allele. A genetic defect found in 10% of whites is the methylenetetrahydrofolate reductase (MTHFR) deficiency (see Chapter 5). The allele is problematic in pregnancy and may contribute to miscarriages, anencephaly, or neural defects (see Chapter 15). Because MTHFR irreversibly reduces 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, its deficiency may result in developmental delay, motor and gait dysfunction, seizures, neurologic impairment, extremely high levels of homocysteine, clotting disorders, and other conditions.

Methylfolate Trap. Vitamin B₁₂ deficiency can result in a folic acid deficiency by causing folate entrapment in the metabolically useless form of 5-methyl THFA (see Figure 32-4). The lack of vitamin B₁₂ to remove the 5-methyl unit means that metabolically inactive methyl THFA is trapped. It cannot release its 1-carbon methyl group to become THFA, the basic 1-carbon carrier that picks up 1-carbon units from one molecule and delivers them to another. Hence a functional folic acid deficiency results.

Pathophysiology

Folate deficiency develops in four stages: two that involve depletion, followed by two marked by deficiency (see Figure 32-5):

Stage 1: Characterized by early negative folate balance (serum depletion to less than 3 ng/ml)

Stage 2: Characterized by negative folate balance (cell depletion), with a decrease in erythrocyte folate levels to less than 160 ng/ml

Stage 3: Characterized by damaged folate metabolism, with folate-deficient erythropoiesis. This stage is characterized by

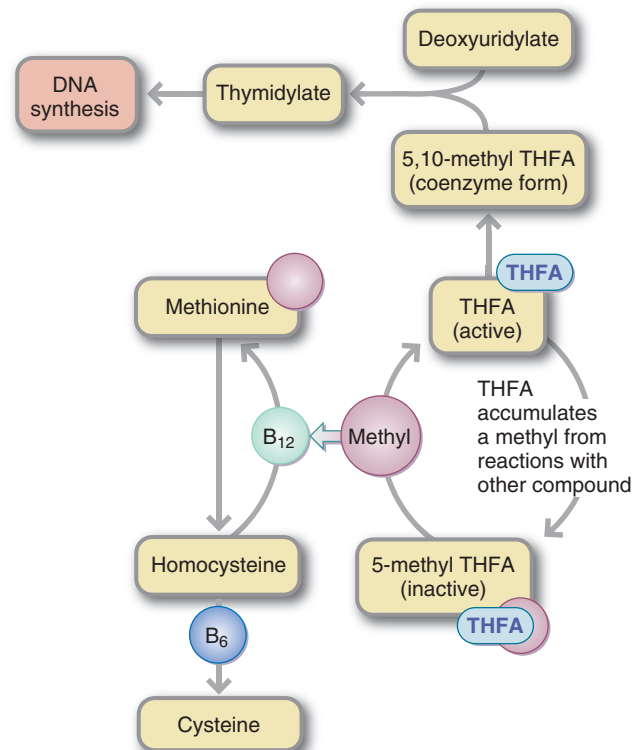

FIGURE 32-4 Methylfolate trap. A deficiency of vitamin B₁₂ can result in a deficiency of folic acid because folate is trapped in the form of 5-methyltetrahydrofolate (5-methyl THFA), which cannot be converted to THFA and methyl groups donated by the vitamin B₁₂-dependent pathway. DNA, Deoxyribonucleic acid.

slowed DNA synthesis, manifested by an abnormal diagnostic deoxyuridine (dU) suppression test correctable in vitro by folates, granulocyte nuclear hypersegmentation, and macrocytotic red cells.

Stage 4: Characterized by clinical folate-deficiency anemia, with an elevated MCV and anemia.

Because of their interrelated roles in the synthesis of thymidylate in DNA formation, a deficiency of either vitamin B₁₂ or folic acid results in a megaloblastic anemia. The immature nuclei do not mature properly in the deficient state; and large (macrocytic), immature (megaloblastic) RBCs are the result. The common clinical signs of folic acid deficiency include fatigue, dyspnea, sore tongue, diarrhea, irritability, forgetfulness, anorexia, glossitis, and weight loss.

Normal body folate stores are depleted within 2 to 4 months on a folate-deficient diet, resulting in a macrocytic, megaloblastic anemia with a decreased number of erythrocytes, leukocytes, and platelets. Folate-deficiency anemia is manifested by very low serum folate (<3 ng/ml) and RBC folate levels of less than 140 to 160 ng/ml. Whereas a low serum folate level merely diagnoses a negative balance at the time the blood is drawn, a red cell folate (RCF) level measures actual body folate stores, and thus is the superior measurement for determining folate nutriture. To differentiate folate deficiency from vitamin B₁₂ deficiency, levels of serum folate, RCF, serum vitamin B₁₂, and vitamin B₁₂ bound to transcobalamin II (TCII) can be measured simultaneously using a radioassay kit. Also diagnostic for folate deficiency is an elevated level of formiminoglutamic acid in the urine, as well as

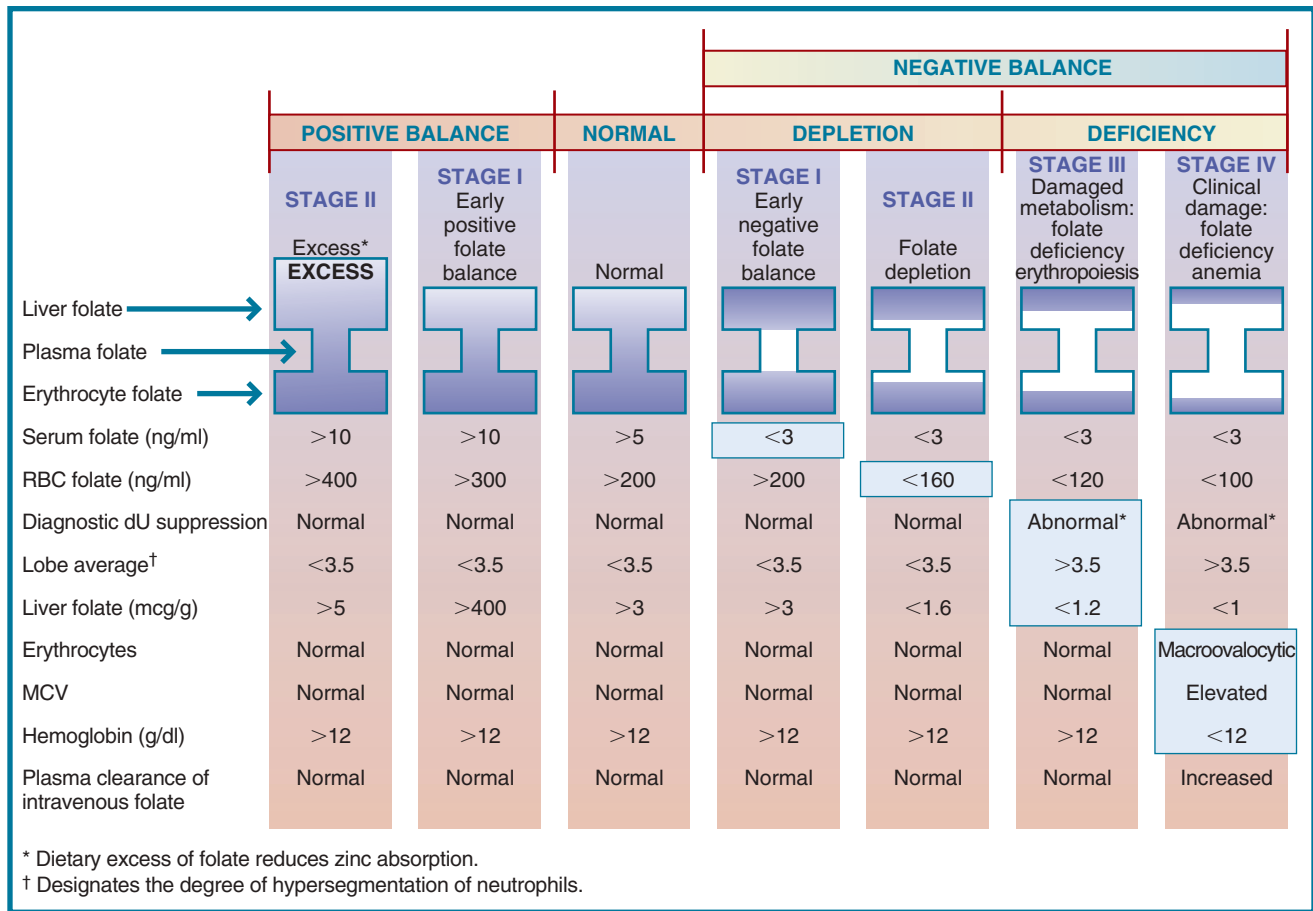

FIGURE 32-5 Sequential stages of folate status. *dU*, Deoxyuridine; *MCV*, mean corpuscular volume; *RBC*, red blood cell. (From Herbert V: Folic acid. In Shils ME et al, editors: *Modern nutrition in health and disease*, ed 9, Philadelphia 1998, Lea & Febiger.)

the dU suppression test in bone marrow cells or peripheral blood lymphocytes (see Chapter 7 and Appendix 22).

Medical Management

Before treatment is initiated, it is important to diagnose the cause of the megaloblastosis correctly. Administration of folate corrects megaloblastosis from either folate or vitamin B₁₂ deficiency, but it can mask the neurologic damage of vitamin B₁₂ deficiency, allowing the nerve damage to progress to the point of irreversibility.

A dosage of 1 mg of folate taken orally every day for 2 to 3 weeks replenishes folate stores. Maintaining repleted stores requires an absolute minimum oral intake of 50 to 100 mcg of folic acid daily. When folate deficiency is complicated by alcoholism, genetic aberrations, or other conditions that suppress hematopoiesis, increase folate requirements, or reduce folate absorption, therapy should remain at 500 to 1000 mcg daily. Symptomatic improvement, as evidenced by increased alertness, cooperation, and appetite, may be apparent within 24 to 48 hours, long before hematologic values revert to normal, a gradual process that takes approximately a month.

Medical Nutrition Therapy

After the anemia is corrected, the patient should be instructed to eat at least one fresh, uncooked fruit, or dark green vegetable or to drink a glass of vegetable or fruit and vegetable juice daily (see

Appendix 40 for a list of folate-containing foods). Fresh, uncooked fruits and vegetables are good sources of folate because folate can easily be destroyed by heat. In 1998 the Food and Drug Administration required that grains be fortified with folic acid. The DRIs for folate are RDAs and are summarized on the inside front cover of this text. The RDA for adults is 400 mcg daily. The Dietary Guidelines for Americans recommend that women of childbearing age who may become pregnant and those in their first trimester of pregnancy consume adequate synthetic folic acid (600 mcg/day) from fortified foods and supplements in addition to consuming a variety of foods containing folate.

Vitamin B₁₂ Deficiency and Pernicious Anemias

Intrinsic factor (IF) is a glycoprotein in the gastric juice that is necessary for the absorption of dietary vitamin B₁₂. Secreted by parietal cells of the gastric mucosa, IF is necessary for the absorption of exogenous vitamin B₁₂. Ingested vitamin B₁₂ is freed from protein by gastric acid and gastric and intestinal enzymes. The free vitamin B₁₂ attaches to salivary R-binder, which has a higher affinity for the vitamin than does IF. An acid pH (2.3) is needed, such as that found in the healthy stomach.

Etiology

The release of pancreatic trypsin into the proximal small intestine destroys R-binder and releases vitamin B₁₂ from its complex with R-protein. With an alkaline pH (6.8) in the intestine, IF

binds the vitamin B₁₂. The vitamin B₁₂-IF complex is then carried to the ileum. In the ileum, with the presence of ionic calcium (Ca²⁺) and a pH (>6), the complex attaches to the surface vitamin B₁₂-IF receptors on the ileal cell brush border. Here, the vitamin B₁₂ is released and attaches to **holotranscobalamin II (holo TCII)**. Holo TCII is vitamin B₁₂ attached to the beta-globulin, the major circulating vitamin B₁₂ delivery protein. Like IF, holo TCII plays an active role in binding and transporting vitamin B₁₂. The TCII-vitamin B₁₂ complex then enters the portal venous blood.

Other binding proteins in the blood include haptocorrin, also known as transcobalamin I (TCI) and transcobalamin III (TCIII). These are alpha-globulins, larger macromolecular-weight glycoproteins that make up the R-binder component of the blood. Unlike IF, the R-proteins are capable of binding not only vitamin B₁₂ but also many of its biologically inactive analogs. Although approximately 75% of the vitamin B₁₂ in human serum is bound to haptocorrin and roughly 25% is bound to TCII, only TCII is important in delivering vitamin B₁₂ to all the cells that need it. After transport through the bloodstream, TCII is recognized by receptors on cell surfaces. Patients with haptocorrin abnormalities have no symptoms of vitamin B₁₂ deficiency. Those lacking TCII rapidly develop megaloblastic anemia. Vitamin B₁₂ is excreted in urine.

Pathophysiology

Pernicious anemia is a megaloblastic, macrocytic anemia caused by a deficiency of vitamin B₁₂, most commonly from a lack of IF. Rarely, vitamin B₁₂ deficiency anemia occurs in strict vegetarians whose diet contains no vitamin B₁₂ except for traces found in plants contaminated by microorganisms capable of synthesizing vitamin B₁₂. Other causes include antibody to IF in saliva or gastric juice; small intestinal disorders affecting the ileum such as celiac disease, idiopathic steatorrhea, tropical sprue, cancers involving the small intestine; drugs (paraaminosalicylic acid, colchicine, neomycin, metformin, antiretrovirals); and long-term ingestion of alcohol or calcium-chelating agents (see [Box 32-3](#)).

Aging is associated with B₁₂ deficiency for various reasons as discussed in Chapter 20. Approximately 1% to 2% of the U.S. population over the age of 51 years has clinical B₁₂ deficiency, and it is thought that 10% to 20% have subclinical deficiency ([Carmel, 2011](#)).

BOX 32-3 Causes of Vitamin B₁₂ Deficiency

Inadequate ingestion	Poor diet resulting from a vegan diet and lack of supplementation, chronic alcoholism, poverty
Inadequate absorption	Gastric disorders, small intestinal disorders, competition for absorption sites, pancreatic disease, HIV, or AIDS
Inadequate use	Vitamin B ₁₂ antagonists, congenital or acquired enzyme deficiency, abnormal binding proteins
Increased requirement	Hyperthyroidism, increased hematopoiesis
Increased excretion	Inadequate vitamin B ₁₂ binding protein, liver disease, renal disease
Increased destruction	Pharmacologic doses of ascorbic acid when it functions as a prooxidant

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

Stages of Deficiency

As a result of normal enterohepatic circulation (i.e., excretion of vitamin B₁₂ and analogs in bile and resorption of vitamin B₁₂ in the ileum), it generally takes decades for strict vegetarians who are not receiving vitamin B₁₂ supplementation to develop a vitamin B₁₂ deficiency. Serum B₁₂, homocysteine, and methylmalonic acid levels are not as effective as predictors of B₁₂-responsive neurologic disorders; patients with unexplained leukoencephalopathy should be treated proactively because even long-standing deficits may be reversible ([Graber et al, 2010](#)).

Stage 1: Early negative vitamin B₁₂ balance begins when vitamin B₁₂ intake is low or absorption is poor, depleting the primary delivery protein, TCII. A low TCII (<40 pg/ml) may be the earliest detectable sign of a vitamin B₁₂ deficiency ([Serefhanoglu et al, 2008](#)). This is a vitamin B₁₂ predeficiency stage.

Stage 2: Vitamin B₁₂ depletion shows a low B₁₂ on TCII and a gradual lowering of B₁₂ in haptocorrin (holohap <50 pg/ml), the storage protein.

Stage 3: Damaged metabolism and vitamin B₁₂-deficient erythropoiesis includes an abnormal dU suppression, hypersegmentation, a decreased TIBC and holohap percent saturation, a low RCF level (<140 ng/ml), and subtle neuropsychiatric damage (impaired short-term and recent memory).

Stage 4: Clinical damage occurs, including vitamin B₁₂ deficiency anemia; includes all preceding parameters, including macroovalocytic erythrocytes, elevated MCV, elevated TCII levels, increased homocysteine, methylmalonic acid levels, and myelin damage. Leukoencephalopathy and autonomic dysfunction occur with very low serum B₁₂ levels (<200 pg/ml); psychiatric changes, neuropathy, and dementia also may occur ([Graber et al, 2010](#)) (see [Figure 32-3](#)).

Clinical Findings

Pernicious anemia affects not only the blood but also the gastrointestinal tract and the peripheral and central nervous systems. This distinguishes it from folic acid deficiency anemia. The overt symptoms, which are caused by inadequate myelination of the nerves, include paresthesia (especially numbness and tingling in the hands and feet), diminution of the senses of vibration and position, poor muscular coordination, poor memory, and hallucinations. If the deficiency is prolonged, the nervous system damage may be irreversible, even with initiation of vitamin B₁₂ treatment.

Helicobacter pylori causes peptic ulcer disease and chronic gastritis (see Chapter 27). Both conditions are associated with hypochlorhydria, reduced production of IF by epithelial cells in the stomach, vitamin B₁₂ malabsorption, and pernicious anemia. There is also a correlation between autoimmune gastritis and pernicious anemia. More than 90% of patients with pernicious anemia have parietal cell antibodies (PCAs), and 50% to 70% have elevated IF antibodies. Serum vitamin B₁₂ levels of the *H. pylori*-infected patients are significantly lower than that of uninfected patients ([Sato et al, 2013](#)).

A study on *H. pylori* infection and autoimmune type atrophic gastritis examined serum markers for gastric atrophy (pepsinogen I, pepsinogen I/II, and gastrin) and autoimmunity. Positive serum autoimmune markers (IF antibodies and PCA) suggest that *H. pylori* contributes to autoimmune gastritis and pernicious anemia ([Aditi and Graham, 2012](#)).

Vitamin B₁₂ deficiency is an important modifiable risk factor for osteoporosis in men and women. Adults with vitamin B₁₂

levels below 148 pg/ml have a lower average bone mineral density and greater risk for osteoporosis (Tucker et al, 2005).

Reduced vitamin B₁₂ status and elevated homocysteine concentrations are common. These alterations are problematic among vegans (Sato et al, 2013). B₁₂-folate-homocysteine interactions aggravate heart disease and may lead to adverse pregnancy outcomes (Moreiras et al, 2009) (see Chapters 15 and 33).

Assessment

Vitamin B₁₂ stores are depleted after several years without vitamin B₁₂ intake. A low holo-TCII value (<40 pg/ml) is a sign of early B₁₂ deficiency. Radioassays measure more than one component within the same biologic medium. The Becton-Dickinson SimulTRAC Radioassay Kit measures the levels of serum vitamin B₁₂ and serum folate simultaneously in a single test tube.

Other laboratory tests that may be helpful in diagnosing a vitamin B₁₂ deficiency and determining its cause include measurements of unsaturated B₁₂ binding capacity, IF antibody (IFAB), the Schilling test, and tests to determine serum homocysteine and serum methionine levels (see Chapter 7 and Appendix 22). The IFAB and Schilling urinary excretion tests can determine whether the deficiency is caused by a lack of IF. The IFAB assay is performed on a patient's serum, whereas the Schilling test requires that the patient first swallow radioactive B₁₂ alone and then a second time with IF (<http://www.nlm.nih.gov/medlineplus/ency/article/003572.htm>).

Patients with pernicious anemia excrete very little vitamin B₁₂ during the first step because little or no vitamin B₁₂ is absorbed. However, during the second step the urinary excretion becomes almost normal because more vitamin B₁₂ is absorbed with the addition of the IF. Vitamin B₁₂ deficiency secondary to malabsorption syndrome and not IF deficiency is manifested by a decrease in urinary excretion of B₁₂ that remains unchanged with IF administration. The Schilling test is ordered less often today because it uses a radioactive B₁₂ molecule which is not as available, and because the treatment, a large injection of B₁₂, is the same whether or not the malabsorption is due to inadequate IF.

Medical Management

Treatment usually consists of an intramuscular or subcutaneous injection of 100 mcg or more of vitamin B₁₂ once per week. After an initial response is elicited, the frequency of administration is reduced until remission can be maintained indefinitely with monthly injections of 100 mcg. Very large oral doses of vitamin B₁₂ (1000 mcg daily) are also effective, even in the absence of IF, because approximately 1% of vitamin B₁₂ is absorbed by diffusion. Initial doses should be increased when vitamin B₁₂ deficiency is complicated by debilitating illness such as infection, hepatic disease, uremia, coma, severe disorientation, or marked neurologic damage. A response to treatment is evidenced by improved appetite, alertness, and cooperation, followed by improved hematologic results, as manifested by marked reticulocytosis within hours of an injection.

Medical Nutrition Therapy

A high-protein diet (1.5 g/kg of body weight) is desirable for liver function and for blood regeneration. Because green leafy vegetables contain iron and folic acid, the diet should contain increased amounts of these foods. Meats (especially beef and pork), eggs, milk, and milk products are particularly rich in vitamin B₁₂ (see Appendix 40).

For those individuals prescribed metformin for treatment of diabetes, 10% to 30% have reduced vitamin B₁₂ absorption. Metformin negatively affects the calcium-dependent membrane and the B₁₂-IF complex by decreasing the absorbability by the ileal cell surface receptors. Increased intake of calcium reverses the vitamin B₁₂ malabsorption.

The Dietary Guidelines for Americans recommend that people older than age 50 consume vitamin B₁₂ in its crystalline form (i.e., in fortified cereals or supplements) to overcome the effects of atrophic gastritis. The DRIs for B₁₂ are RDAs and are summarized on the inside front cover. The RDA for adult men and women is 2.4 mcg daily.

OTHER NUTRITIONAL ANEMIAS

Anemia of Protein-Energy Malnutrition

Protein is essential for the proper production of hemoglobin and RBCs. Because of the reduction in cell mass and thus oxygen requirements in protein-energy malnutrition (PEM), fewer RBCs are required to oxygenate the tissue. Because blood volume remains the same, this reduced number of RBCs with a low hemoglobin level (**hypochromic**, normocytic anemia), which can mimic an iron deficiency anemia, is actually a physiologic (nonharmful) rather than harmful anemia. In acute PEM, the loss of active tissue mass may be greater than the reduction in the number of RBCs, leading to **polycythemia** (an increase in RBCs where they make up a larger proportion of the blood volume). The body responds to this RBC production, which is not a reflection of protein and amino acid deficiency but of an oversupply of RBCs. Iron released from normal RBC destruction is not reused in RBC production, but is stored so that iron stores are often adequate. Iron deficiency anemia can reappear with rehabilitation when RBC mass expands rapidly.

The anemia of PEM may be complicated by deficiencies of iron and other nutrients and by associated infections, parasitic infestation, and malabsorption. A diet lacking in protein is usually deficient in iron, folic acid, and, less frequently, vitamin B₁₂. The nutrition counselor plays an important role in assessing recent and typical dietary intake of these nutrients.

Copper Deficiency Anemia

Copper and other heavy metals are essential for the proper formation of hemoglobin. **Ceruloplasmin**, a copper-containing protein, is required for normal mobilization of iron from its storage sites to the plasma. In a copper-deficient state, iron cannot be released; this leads to low serum iron and hemoglobin levels, even in the presence of normal iron stores. Other consequences of copper deficiency suggest that copper proteins are needed for use of iron by the developing erythrocyte and for optimal functions of the erythrocyte membrane. The amounts of copper needed for normal hemoglobin synthesis are so minute that they are usually amply supplied by an adequate diet; however, copper deficiency may occur in infants who are fed cow's milk or a copper-deficient infant formula. It also may be seen in children or adults who have a malabsorption syndrome or who are receiving long-term total parenteral nutrition that does not supply copper.

Sideroblastic (B₆-Responsive) Anemia

Sideroblastic (pyridoxine-responsive) anemia is characterized by a derangement in the final pathway of heme synthesis,

leading to a buildup of immature RBCs. It has four primary characteristics: (1) microcytic and hypochromic RBCs; (2) high serum and tissue iron levels (causing increased transferrin saturation); (3) the presence of an inherited defect in the formation of δ -aminolevulinic acid synthetase, an enzyme involved in heme synthesis (pyridoxal-5-phosphate is necessary in this reaction); and (4) a buildup of iron-containing immature RBCs (sideroblasts, for which the anemia is named). The iron that cannot be used for heme synthesis is stored in the mitochondria of immature RBCs. These iron-laden mitochondria do not function normally, and the development and production of RBCs become ineffective. The symptoms are those of anemia and iron overload. Even though the anemia responds to the administration of pharmacologic doses of pyridoxine and thus is referred to as *pyridoxine-responsive anemia*, the neurologic and cutaneous manifestations of vitamin B₆ deficiency are not observed. This distinguishes it from anemia caused by a dietary vitamin B₆ deficiency.

Treatment consists of a therapeutic trial dose of 50 to 200 mg daily of pyridoxine or pyridoxal phosphate (PLP or pyridoxal-5-phosphate) which is 25 to 100 times the RDA. If the anemia responds to one or the other, pyridoxine therapy is continued for life. However, if the anemia is only partially corrected; a normal hematocrit value is never regained. Patients respond to this treatment to varying degrees, and some may only achieve near-normal hemoglobin levels.

Acquired sideroblastic anemias such as those attributable to drug therapy (isoniazid, chloramphenicol), copper deficiency, hypothermia, and alcoholism are not responsive to B₆ administration.

Vitamin E–Responsive Hemolytic Anemia

Hemolytic anemia occurs when defects in RBC membranes lead to oxidative damage and eventually to cell lysis.

This anemia is caused by shortened survival of mature RBCs. Vitamin E, an antioxidant, is involved in protecting the membrane against oxidative damage, and one of the few signs noted in vitamin E deficiency is early hemolysis of RBCs. Vitamin E–responsive hemolytic anemia in neonates is discussed in Chapter 42.

NONNUTRITIONAL ANEMIAS

Anemia of Pregnancy

A physiologic anemia is the anemia of pregnancy, which is related to increased blood volume and usually resolves with the end of the pregnancy. However, demands for iron during pregnancy also are increased so that inadequate iron intake may also play a role in whether it develops (see Chapter 15 for further discussion).

Anemia of Chronic Disease

Anemia of chronic disease occurs from inflammation, infection, or malignancy because there is decreased RBC production, possibly as a result of disordered iron metabolism. Ferritin levels are normal or increased, but serum iron levels and TIBC are low (see Chapter 7). It is important that this form of anemia, which is mild and normocytic, not be mistaken for iron deficiency anemia; iron supplements should not be given. Recombinant erythropoietin therapy usually corrects this anemia.

Sickle Cell Anemia

Pathophysiology

Sickle cell anemia (SCA), a chronic hemolytic anemia also known as *hemoglobin S disease*, affects about 1 of 500 African Americans in the United States as a result of homozygous inheritance of hemoglobin S. It also affects Hispanic Americans, but at a much lower rate. This results in defective hemoglobin synthesis, which produces sickle-shaped RBCs that get caught in capillaries and do not carry oxygen well (see Figure 32-6). The sickle-shaped RBCs die in 10 to 20 days. The bone marrow cannot make new cells fast enough to replace them; they are dying much faster than normal RBCs. The disease usually is diagnosed toward the end of the first year of life and is thought to affect 70,000 to 100,000 in the United States, although 2 million Americans have the sickle cell trait (NIH, NHLBI, 2012).

In addition to the usual symptoms of anemia, SCA is characterized by episodes of pain resulting from the occlusion of small blood vessels by the abnormally shaped erythrocytes. The occlusions frequently occur in the abdomen, causing acute, severe abdominal pain. The hemolytic anemia and vasoocclusive disease result in impaired liver function, jaundice, gallstones, and deteriorating renal function. The constant hemolysis of erythrocytes increases iron stores in the liver; however, iron deficiency anemia and SCA can coexist. Iron overload is less common and is usually a problem only in those who have received multiple blood transfusions.

Typically serum homocysteine levels are elevated, which may be due to low concentrations of vitamin B₆. Children with SCA were found to have these lower vitamin B₆ levels despite B₆ intakes comparable to those of unaffected children.

Medical Management

A new set of guidelines for managing sickle cell disease recommends using monthly blood transfusions and the drug

FIGURE 32-6 Sickled red blood cells. (From National Institutes of Health (NIH), National Heart, Lung and Blood Institute (NHLBI): What is sickle cell anemia? (website): <http://www.nhlbi.nih.gov/health/health-topics/topics/sca/>, 2012. Accessed January 8, 2015.)

hydroxyurea (Yawn et al, 2014). Consistent blood transfusions stop the body from producing sickle cells and attempts to normalize red blood cell count. Hydroxyurea increases the production of healthy fetal hemoglobin, reducing hospitalizations. Because hydroxyurea also lowers the number of white blood cells, patients must be monitored regularly with blood tests.

Other treatment for SCA focuses on relieving pain during a crisis, keeping the body oxygenated (using oxygen therapy if needed), and possibly administering an exchange transfusion. It is important that SCA not be mistaken for iron deficiency anemia, which can be treated with iron supplements, because iron stores in the patient with SCA secondary to transfusions are frequently excessive.

Zinc can increase the oxygen affinity of normal and sickle-shaped erythrocytes. Thus zinc supplements may be beneficial in managing sickle cell disease, especially because decreased plasma zinc is common in children with the SS genotype sickle cell disease and is associated with decreased linear and skeletal growth, muscle mass, and sexual maturation. Zinc supplementation (as little as 10 mg daily) also may prevent the deficit in growth that appears in these children (Zemel et al, 2007). Because zinc competes with copper for binding sites on proteins, the use of high doses of zinc may precipitate copper deficiency.

Medical Nutrition Therapy

Children with SCA and their families should receive instruction about how they can develop a well-balanced food plan providing enough calories and protein for growth and development. Their dietary intake may be low because of the abdominal pain characteristic of the disease. They also have increased metabolic rates, leading to a need for a higher caloric intake. This hypermetabolism probably is due to a constant inflammation and oxidative stress (Yawn et al, 2014). Therefore their diets must be high enough in calories to meet these needs and must provide foods high in folate and the trace minerals zinc and copper (see Appendix 53 for sources of zinc).

In addition, these children may be low in vitamins A, C, D, and E, folate, calcium, and fiber. The diet should be high in folate (400 to 600 mcg daily) because the increased production of erythrocytes needed to replace the cells being continuously destroyed also increases folic acid requirements (see Appendices 40 through 43).

When assessing the nutrition status of patients with SCA, clinicians must pay attention to the questions related to the use of vitamin and mineral supplements, the consumption of alcohol (which increases iron absorption), and sources of protein (animal sources being high in zinc and iron) in the diet. A multivitamin and mineral supplement containing 50% to 150% of the RDA for folate, zinc, and copper (not iron) is recommended.

Dietary fluid and sodium intake influence the risk for vaso-occlusive events in SCA; increasing fluid intake and limiting high-sodium foods should be discussed (Fowler et al, 2010) (see Chapter 33 and Appendix 30). Intake of 2 to 3 quarts of water daily is recommended. Finally, it is important to remember that patients with sickle cell disease may require higher than RDA amounts of protein.

If it is necessary for the diet to be low in absorbable iron, the diet should emphasize vegetable proteins. Iron-rich foods, such as liver, iron-fortified formula, iron-fortified cereals, and

iron-fortified energy bars and iron-fortified sport drinks should be excluded. Substances such as alcohol and vitamin C supplements, both of which enhance iron absorption, should be avoided. However, iron deficiency may be present in some patients with SCA owing to repeated phlebotomies, excessive transfusions, or hematuria secondary to renal papillary necrosis. This should be assessed and the diet adjusted appropriately.

Hypochromic Microcytic Transient Anemia (Sports Anemia)

Increased RBC destruction, along with decreased hemoglobin, serum iron, and ferritin concentrations, may occur at the initiation and early stages of a vigorous training program. Once called *march hemoglobinuria* (an unusual appearance of hemoglobin in the urine), this anemia was believed to arise in soldiers as a result of mechanical trauma incurred by erythrocytes (RBCs) during long marches. The RBCs in the capillaries are compressed every time the foot lands until they burst, releasing hemoglobin. It was thought that a similar situation existed in runners, especially long-distance runners; however, it is now thought that **sports anemia** is a physiologic anemia (i.e., a transient problem of blood volume and dilution) (see Chapter 23 for further discussion).

Athletes who have hemoglobin concentrations below those needed for optimal oxygen delivery may benefit from consuming nutrient and iron-rich foods; ensuring that their diets contain adequate protein; and avoiding tea, coffee, antacids, H₂-blockers, and tetracycline, all of which inhibit iron absorption. No athlete should take iron supplements unless true iron deficiency is diagnosed based on a complete blood cell count with differential, serum ferritin level, serum iron level, TIBC, and percent saturation of iron-binding capacity. Athletes who are female, vegetarian, involved in endurance sports, or entering a growth spurt are at risk for iron deficiency anemia and therefore should undergo periodic monitoring (see Chapter 23).

Thalassemias

Thalassemias (alpha and beta) are severe inherited anemias characterized by microcytic, hypochromic, and short-lived RBCs resulting from defective hemoglobin synthesis, which affects primarily persons in the Mediterranean region. The ineffective erythropoiesis leads to an increase in plasma volume, progressive splenomegaly, and bone marrow expansion with the result of facial deformities, osteomalacia, and bone changes. Ultimately there is increased iron absorption and progressive iron deposition in tissues, resulting in oxidative damage. The accumulation of iron causes dysfunction of the heart, liver, and endocrine glands. Because these patients require transfusions to stay alive, they also must have regular chelation therapy to prevent the damaging buildup of iron that can occur. Impaired growth in children accompanying thalassemia major can be partially corrected by increasing caloric intake.

Medical Nutrition Therapy

The diet should be high in protein, B vitamins, especially folic acid, and zinc. Multivitamin and mineral supplements that contain amounts of iron and vitamin C above the RDA should be avoided. Increased calcium intake may be required in some patients because of bone formation issues (NIH, National Library of Medicine [NLM], 2014; NIH, 2012). Patients should stay well hydrated.

CLINICAL CASE STUDY

Marisa, a 27-year-old female, reports increased symptoms of restless leg syndrome, fatigue, and painful abdominal bloating and heavy menses for the past year. A physical examination reveals inflammation and tenderness around her knee and ankle joints.

MEDICATIONS: None

HT: 5'5"

WT: 215 lb

LABORATORY VALUES:

	Client	Normal Range	
WBC	8.3	3.8 – 10.5	K/uL
RBC	4.86	3.8 – 5.20	M/uL
HGB	10.8 L	12.0 – 16.0	g/dL
HCT	32.7 L	34.5 – 45.0	%
MCV	74.1 L	80.0 – 100.0	fl
MCH	24.3 L	27.0 – 34.0	pg
MCHC	30.4 L	32.0 – 36.0	gm/dL
IRON	28 L	40 – 160	ug/dL
UIBC	429 H	110 – 370	ug/dL
TIBC	508 H	220 – 430	ug/dL
% Saturation, Iron	12 L	14-50	%
Transferrin	435 H	200 – 400	mg/dL
Ferritin	12 L	15-150	ng/mL
C-Reactive Protein	0.96 H	0.00 – 0.40	mg/dL
Vitamin D	14.6 L	30.0 – 100.0	ng/mL

Nutrition Diagnostic Statements

Increased nutrient needs (iron) related to heavy menses and suboptimal intake of dietary iron as evidenced by multiple low iron status labs including HCT, HGB and ferritin.

Altered nutrition related laboratory value related to predicted pro-inflammatory diet pattern as evidenced by low intake of omega-3 fatty acids and bioactive compounds, elevated c-reactive protein (CRP) and painful joints.

Nutrition Care Questions:

- 1) How should Marisa be further evaluated?
- 2) What vitamin/mineral supplements, if any, should be part of her treatment plan?
- 3) What factors play a role in her nutritional plan?
- 4) Evaluate her laboratory test results. Do you recommend further blood tests?
- 5) With her input devise an nutrition action plan that she can follow.
- 6) What lab tests or questions would you include in your followup with her?

Medical Nutrition Therapy for Cardiovascular Disease

Janice L. Raymond, MS, RDN, CD, CSG
Sarah C. Couch, PhD, RDN

KEY TERMS

3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA)	dyslipidemia	low-density lipoprotein (LDL)
angina	dyspnea	Mediterranean Diet (MeD)
angiography	edema	metabolic syndrome
apolipoproteins	endothelial cell	myocardial infarction (MI)
atherosclerotic cardiovascular disease (ASCVD)	essential hypertension	nitric oxide (NO)
atheroma	familial combined hyperlipidemia (FCHL)	orthopnea
bile acid sequestrant	familial dysbetalipoproteinemia	plaque
blood pressure	familial hypercholesterolemia	prehypertension
B-natriuretic peptide	fatty streak	renin-angiotensin system (RAS)
cardiac cachexia	foam cells	secondary hypertension
cardiac catheterization	heart failure (HF)	statins
cardiovascular disease (CVD)	high-density lipoprotein (HDL)	stroke
C-reactive protein (CRP)	homocysteine	syncope
chylomicron	hypertension	systolic blood pressure (SBP)
coronary artery bypass graft (CABG)	hypertriglyceridemia	thrombus
diastolic blood pressure (DBP)	intermediate-density lipoprotein (IDL)	trans fatty acids
Dietary Approaches to Stop Hypertension (DASH)	ischemia	trimethylamine-N-oxide (TMAO)
	left ventricular hypertrophy (LVH)	very-low-density lipoprotein (VLDL)
	lipoprotein	xanthoma

Cardiovascular disease (CVD) is a group of interrelated diseases that include atherosclerosis, hypertension, ischemic heart disease, peripheral vascular disease, and heart failure (HF). These diseases are interrelated and often coexist. An estimated 81,100,000 adult Americans (one in three) have one or more types of CVD (see [Box 33-1](#)).

CVD remains the number one killer of men and women in the United States; one of every 2.9 deaths is attributed to CVD. In 2010 it is estimated that 1.26 million Americans had a new or recurrent coronary attack. Every 25 seconds an American suffers a coronary event and about every minute someone will die of one ([American Heart Association \[AHA\], 2015](#)). The lifetime risk for CVD in American men is two in three and for women is one in two ([AHA, 2015](#)). Worldwide, 18 million deaths per year are attributed to CVD ([Yusuf, 2014](#)).

Of all causes of death, CVD, cancer, and stroke are the leaders ([AHA, 2015](#)). **Atherosclerotic cardiovascular disease (ASCVD)** involves the narrowing of small blood vessels that oxygenate the heart muscle by the build-up of **plaque** (the lesion in the blood vessels). The plaque, known as atherosclerosis, can rupture, causing a blood clot to form that blocks the artery or travels somewhere else in the body, causing blockage at that

site. The result can be a **myocardial infarction (MI)**, which is also called a heart attack or **stroke**. Heart disease and stroke cause the most deaths in both sexes of all ethnic groups, increasing with age. Until the age of 65 years, black men have the highest rates of ASCVD deaths; thereafter, white men have the highest rates. Black women have higher rates than white women at all ages. Among Caucasians older than age 18, 12.1% have CVD. In the same age group, 10.2% of African Americans have heart disease, and in Hispanics the incidence is 8.1%. The incidence in adult Native Americans is 12.1%, in Native Hawaiians or other Pacific Islanders it is 19.7%, and in Asians it is 5.2% ([AHA 2015](#)). This chapter discusses the incidence, pathophysiologic findings, prevention, and treatment of each of the CVDs.

ATHEROSCLEROSIS AND CORONARY HEART DISEASE

Anatomy and Physiology

Blood vessels are composed of three layers. The outer layer is mainly connective tissue that gives structure to the vessels. The middle layer is smooth muscle that contracts and dilates to control blood flow and blood pressure. The inner lining is a thin layer

BOX 33-1 Types and Incidence of Cardiovascular Disease in the United States

Hypertension: 74,500,000
 Coronary heart disease: 17,600,000
 Myocardial infarction: 8,500,000
 Angina pectoris: 10,200,000
 Heart failure: 5,800,000
 Stroke: 6,400,000

Because of comorbidities, it is not possible to add these numbers together to reach a total (AHA, 2010).

of **endothelial cells** (the endothelium) that in a healthy state is smooth and responsive. The endothelium functions as a protective barrier between tissues and circulating blood. It facilitates bidirectional passage of macromolecules and blood gases to and from tissues and blood. **Endothelial cells** sense changes in blood flow and respond with the release of bioactive substances that maintain vascular homeostasis. One such substance is **nitric oxide (NO)**. NO is a soluble gas continually synthesized from the amino acid L-arginine in endothelial cells. NO has a wide range

of biologic properties that maintain vascular homeostasis. It appears to be involved in protection from injurious substances and plays a key role in vasodilation (Tousoulis et al, 2012). Decreased NO is a factor in the endothelial cell dysfunction that disrupts vascular balance and can result in vasoconstriction, platelet activation, leukocyte adherence, and vascular inflammation.

Pathophysiology

ASCVD involves the accumulation of plaque within the walls of the arteries. It starts with injury to the endothelial cells with an associated inflammatory response involving phagocytes and monocytes. Once in the tissue, monocytes evolve into macrophages that ingest oxidized cholesterol and become **foam cells** and then **fatty streaks** in these vessels. Intracellular microcalcification occurs, forming deposits within the vascular smooth muscle cells of the surrounding muscular layer (see Figure 33-1).

A protective fibrin layer (**atheroma**) forms between the fatty deposits and the artery lining. Atheromas produce enzymes that cause the artery to enlarge over time, thus compensating for the narrowing caused by the plaque. This “remodeling” of the shape and size of the blood vessel may result in an aneurysm.

FIGURE 33-1 The structure of mature, stable, and unstable plaque. (From Rudd JHF et al: Imaging of atherosclerosis—can we predict plaque rupture? *Trends Cardiovasc Med* 15:17, 2005.)

Atheromas can rupture or break off, forming a **thrombus** (blood clot), where they attract blood platelets and activate the clotting system in the body. This response can result in a blockage and restricted blood flow.

Only high-risk or vulnerable plaque forms thrombi. Vulnerable plaque are lesions with a thin fibrous cap, few smooth muscle cells, many macrophages (inflammatory cells), and a large lipid core (see [Figure 33-2](#)). Arterial changes begin in infancy and progress asymptotically throughout adulthood (see [Figure 33-3](#)).

The clinical outcome of impaired arterial function arising from atherosclerosis depends on the location of the impairment. In the coronary arteries atherosclerosis can cause **angina** (chest pain), MI, and sudden death; in the cerebral arteries it causes strokes and transient ischemic attacks; and in the peripheral circulation it causes intermittent claudication, limb **ischemia** (inadequate blood supply), and gangrene (see [Figure 33-4](#)). Thus atherosclerosis is the underlying cause of many forms of CVD.

Dyslipidemia refers to a blood lipid profile that increases the risk of developing atherosclerosis. Three important biochemical measurements in ASCVD include lipoproteins, total cholesterol, and triglycerides. Cholesterol is delivered into cell walls by **low-density lipoprotein (LDL)**, especially smaller particles. To attract and stimulate the macrophages, the cholesterol must be released from the LDL particles and oxidized, a key step in the ongoing inflammatory process. Additionally, macrophages must move excess cholesterol quickly into **high-density lipoprotein (HDL)** particles to avoid becoming foam cells and dying. The typical dyslipidemic condition is one in which LDL levels are elevated (hyperlipidemia) and HDL levels are low.

Lipoproteins

Lipids are not water soluble, so they are carried in the blood bound to protein. These complex particles, called **lipoproteins**, vary in composition, size, and density. Lipoproteins measured in clinical practice—chylomicrons, **very-low-density lipoprotein (VLDL)**, **low-density lipoproteins (LDL)**, and **high-density lipoproteins (HDL)**—consist of varying amounts of triglyceride, cholesterol, phospholipid, and protein. Each class of lipoprotein actually represents a continuum of particles. The ratio of protein to fat determines the density; thus particles with higher levels of protein are the most dense (e.g., HDLs have more protein than LDLs). The physiologic role of lipoprotein includes transporting lipid to cells for energy, storage, or use as substrate for synthesis of other compounds such as prostaglandins, thromboxanes, and leukotrienes.

The largest particles, **chylomicrons**, transport dietary fat and cholesterol from the small intestine to the liver and periphery. Once in the bloodstream, the triglycerides within the chylomicrons are hydrolyzed by lipoprotein lipase (LPL), located on the endothelial cell surface in muscle and adipose tissue. **Apolipoproteins** carry lipids in the blood and also control the metabolism of the lipoprotein molecule. Apo C-II, one of the apolipoproteins, is a cofactor for LPL. When approximately 90% of the triglyceride is hydrolyzed, the particle is released back into the blood as a remnant. The liver metabolizes these chylomicron remnants, but some deliver cholesterol to the arterial wall and thus are considered atherogenic. Consumption of high-fat meals produces more chylomicrons and remnants.

FIGURE 33-2 Natural progression of atherosclerosis. (From Harkreader H: *Fundamentals of nursing: caring and clinical judgment*, Philadelphia, 2007, Saunders.)

FIGURE 33-3 Plaque that can be surgically removed from the coronary artery. (Photographs courtesy Ronald D. Gregory and John Riley, MD.)

FIGURE 33-4 Major clinical manifestations of atherothrombotic disease. (From Viles-Gonzalez JF et al: Atherothrombosis: a widespread disease with unpredictable and life-threatening consequences, *Eur Heart J* 25:1197, 2004.)

Plasma studies are done when fasting; chylomicrons are normally absent.

VLDL particles are synthesized in the liver to transport endogenous triglyceride and cholesterol. Triglyceride accounts for 60% of the VLDL particle. The large, buoyant VLDL particle is believed to be nonatherogenic. Vegetarian and low-fat diets increase the formation of large VLDL particles. Smaller VLDL particles (i.e., remnants) are formed from triglyceride hydrolysis by LPL. Normally these remnants, called **intermediate-density lipoproteins (IDLs)**, are atherogenic and are taken up by receptors on the liver or converted to LDLs. Some of the smaller LDL particles stay in the blood, are oxidized, and are then taken into the arterial wall. Clinically, a total triglyceride level is a measurement of the triglycerides carried on the VLDL and the IDL remnants.

LDL is the primary cholesterol carrier in blood, formed by the breakdown of VLDL. High LDL cholesterol is associated specifically with atherosclerosis (Stone et al, 2013). A recent change in recommendations from AHA/ACC was to drop the actual serum LDL ASCVD prevention target. LDL levels are used for dosing medication but are otherwise only considered part of a bigger picture of risk and should not be assessed in isolation. After LDL formation, 60% is taken up by LDL receptors on the liver, adrenals, and other tissues. The remainder

is metabolized via nonreceptor pathways. The number and activity of these LDL receptors are major determinants of the LDL level in the blood. Apolipoprotein B is the structural protein for all of the atherogenic lipoproteins (VLDL, IDL, LDL) and modulates the transport of lipids from the gut and liver to the tissues. The two forms, apo B and apoB-100 are synthesized in the liver. ApoB-100 constitutes 95% of the apolipoproteins in LDL. ApoB-48 is synthesized in the intestines and is the structural component of chylomicrons.

HDL particles contain more protein than any of the other lipoproteins, which accounts for their metabolic role as a reservoir of the apolipoproteins that direct lipid metabolism. Apo A-I, the main apolipoprotein in HDL, is an anti-inflammatory, antioxidant protein that also helps to remove cholesterol from the arterial wall to the liver for excretion or repackaging. This process prevents the build-up and oxidation of cholesterol in the arteries. Evaluation of apo A-I or the ratio of apo B to apo A-I has been proposed to assess risk and determine treatment (Navab et al, 2011). The lower the ratio, the lower the ASCVD risk. Both apo C and apo E on HDL are transferred to chylomicrons. Apo E helps receptors metabolize chylomicron remnants and also inhibits appetite. Therefore high HDL levels are associated with low levels of chylomicrons; VLDL remnants; and small, dense LDLs. Epidemiologic studies have shown an inverse correlation between HDL levels and risk of cardiovascular events. Subsequently, high HDL implies lower atherosclerotic risk, except in patients with specific genetic causes of hypercholesterolemia who can have a triglyceride-enriched HDL₃ fraction that is proatherogenic (Ottstad et al, 2006).

Total Cholesterol

A total cholesterol measurement captures cholesterol contained in all lipoprotein fractions: 60% to 70% is carried on LDL, 20% to 30% on HDL, and 10% to 15% on VLDL.

Triglycerides

The triglyceride-rich lipoproteins include chylomicrons, VLDLs, and any remnants or intermediary products formed in metabolism. Of these triglyceride-rich lipoproteins, chylomicrons and VLDL remnants are known to be atherogenic because they activate platelets, the coagulation cascade, and clot formation. All contain the apo B lipoprotein. Fasting triglyceride levels are classified as normal (<150 mg/dl), borderline high (150 to 199 mg/dl), high (200 to 499 mg/dl), and very high (>500 mg/dl) (Stone et al, 2013).

Patients with familial dyslipidemias have high triglyceride levels (**hypertriglyceridemia**). Triglycerides in the very high range place the patient at risk for pancreatitis. Triglyceride measurements are now considered along with glucose intolerance, hypertension, low HDL cholesterol, and high LDL cholesterol as part of the **metabolic syndrome**.

GENETIC HYPERLIPIDEMIAS

The study and identification of the genes responsible for the familial forms of hyperlipidemia have provided insight into the roles of enzymes, apolipoproteins, and receptors on cells involved in lipid metabolism. Several forms of hyperlipidemia have strong genetic components and are described here.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) (type IIa hyperlipidemia) is a monogenetic disorder that is seen around the world, with an estimated 14 to 34 million people being affected (Nordestgaard et al, 2013). In FH elevated cholesterol is already present at birth and results in early atherosclerotic disease. The optimal age range for screening is between 2 and 10 years. Currently, it is considered unreasonable to start a restricted diet before age 2, and there are no safety data on the use of statins before age 8 to 10 (Nordestgaard et al, 2013). Men with FH seem to develop CVD before women. Hypertension, smoking, diabetes, and high **triglycerides and low** HDL cholesterol are all well-established additional risk factors in FH.

Defects in the LDL receptor gene cause FH; 800 mutations have been identified. Treatment with statin drugs improves arterial function and structure (Masoura et al, 2011). Ultrasound of the Achilles tendon for **xanthomas** (cholesterol deposits from LDL) correctly identifies the majority of FH patients.

Polygenic Familial Hypercholesterolemia

Polygenic FH is the result of multiple gene defects. The apo E-4 allele is common in this form. The diagnosis is based on two or more family members having LDL cholesterol levels above the 90th percentile without any tendon xanthomas. Usually these patients have lower LDL cholesterol levels than patients with the nonpolygenic form, but they remain at high risk for premature disease. The treatment is lifestyle change in conjunction with cholesterol-lowering drugs.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is a disorder in which two or more family members have serum LDL cholesterol or triglyceride levels above the 90th percentile. Several lipoprotein patterns may be seen in patients with FCHL. These patients can have (1) elevated LDL levels with normal triglyceride levels (type IIa), (2) elevated LDL levels with elevated triglyceride levels (type IIb), or (3) elevated VLDL levels (type IV). Often these patients have the small, dense LDL associated with ASCVD. Consequently all forms of FCHL cause premature disease; approximately 15% of patients who have an MI before the age of 60 have FCHL. The defect in FCHL is hepatic overproduction of apo B-100 (VLDL) or a defect in the gene that produces hepatic lipase, the liver enzyme involved in triglyceride removal from the bloodstream. Patients with FCHL usually have other risk factors such as obesity, hypertension, diabetes, or metabolic syndrome. If lifestyle measures are ineffective,

treatment includes medication. Patients with elevated triglyceride levels also need to avoid alcohol.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia (type III hyperlipoproteinemia) is relatively uncommon. Catabolism of VLDL and chylomicron remnants is delayed because apo E-2 replaces apo E-3 and apo E-4. For dysbetalipoproteinemia to be seen, other risk factors such as older age, hypothyroidism, obesity, diabetes, or other dyslipidemias such as FCHL must be present. Total cholesterol levels range from 300 to 600 mg/dl, and triglyceride levels range from 400 to 800 mg/dl. This condition creates increased risk of premature ASCVD and peripheral vascular disease. Diagnosis is based on determining the isoforms of apo E. Treatment involves weight reduction, control of hyperglycemia and diabetes, and dietary restriction of saturated fat and cholesterol. If the dietary regimen is not effective, drug therapy is recommended.

Medical Diagnosis

Noninvasive tests such as electrocardiograms, treadmill stress tests, thallium scans, and echocardiography are used initially to establish a cardiovascular diagnosis. A more definitive, invasive test is **angiography (cardiac catheterization)**, in which a dye is injected into the arteries, and radiographic images of the heart are obtained. Most narrowing and blockages from atherosclerosis are readily apparent on angiograms; however, neither smaller lesions nor lesions that have undergone remodeling are visible.

Magnetic resonance imaging (MRI) scans show the smaller lesions and can be used to follow atherosclerosis progression or regression after treatments. To predict MI or stroke, measuring the intimal thickness of the carotid artery may be used. Intracoronary thermography helps to determine the presence of vulnerable plaque.

Finally, the calcium in atherosclerotic lesions can be assessed. Electron beam computed tomography (ECT) measures calcium in the coronary arteries; persons with a positive scan are far more likely to have a future coronary event than those with a negative scan.

Approximately two thirds of cases of acute coronary syndromes (unstable angina and acute MI) happen in arteries that are minimally or mildly obstructed. This illustrates the role of thrombosis in clinical events. In the ischemia of an infarction, the myocardium or other tissue is deprived of oxygen and nourishment. Whether the heart is able to continue beating depends on the extent of the musculature involved, the presence of collateral circulation, and the oxygen requirement.

Prevention and Management of Risk Factors

The identification of risk factors for ASCVD and stroke has been a landmark achievement. The primary prevention of these disorders involves the assessment and management of the risk factors in the asymptomatic person. Persons with multiple risk factors are the target population, especially those with modifiable factors (see **Box 33-2**).

Risk factor reduction has been shown to reduce CVD in persons of all ages. Many coronary events could be prevented with adoption of a healthy lifestyle (eating a heart-healthy diet, exercising regularly, managing weight, and not using tobacco) and adherence to lipid and hypertension drug therapy (Stone et al, 2013). The Framingham Study, conducted over several decades, has provided a plethora of useful information to researchers (see **Focus On: Framingham Heart Study**).

BOX 33-2 Cardiovascular Disease Risk Factors**Major Risk Factors**

Hypertension
 Age (older than 45 years for men, 55 years for women)
 Diabetes mellitus
 Estimated glomerular filtration rate <60 ml/min
 Microalbuminuria
 Family history of premature cardiovascular disease (men <55 years of age, or women <65 years of age)

Modifiable Cardiovascular Risk Factors

Lipoprotein profile
 Low-density lipoprotein cholesterol, elevated
 Total triglycerides, elevated
 Elevated TMAO (Trimethylamine N-oxide)
 High-density lipoprotein (HDL) cholesterol, low
 Inflammatory markers

Fibrinogen
 C-reactive protein

Lifestyle Risk Factors

Tobacco use, particularly cigarettes
 Physical inactivity
 Poor diet
 Stress
 Insufficient sleep
 Excessive alcohol consumption

Related Conditions

Hypertension
 Obesity (body mass index >30)
 Metabolic syndrome (including reduced HDL, elevated triglycerides, abdominal obesity)

Modified from National Institutes of Health, National Heart, Lung, and Blood Institute National High Blood Pressure Education Program: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, NIH Publication No. 04-5230, August 2004.

FOCUS ON**Framingham Heart Study**

Since 1948 various leading investigators (Dr. Joseph Mountain, Dr. Thomas Dawber, Dr. William Kannel, and Dr. William Castelli) have been studying the population (28,000) of Framingham, Massachusetts, to determine the prevalence and incidence of cardiovascular disease and factors related to its development. This is the largest epidemiologic study of cardiovascular disease in the world. Initial study participants ($n = 5209$) were healthy adults between 30 and 62 years of age. The study continues today, looking at the children and grandchildren of the original cohort. Through this cohort study, the concept of risk factors and thus prevention was born. Modifiable risk factors not only predict disease in healthy adults but also contribute to the disease process in those who have atherosclerotic disease. The seven major risk factors identified by the Framingham study are age, sex, blood pressure, total and high-density lipoprotein cholesterol, smoking, glucose intolerance, and left-ventricular hypertrophy (Opie et al, 2006).

Milestones of the Framingham Study

1960 Cigarette smoking found to increase the risk of heart disease.
 1961 Cholesterol level, blood pressure, and electrocardiogram abnormalities found to increase the risk of heart disease.
 1967 Physical activity found to reduce the risk of heart disease, and obesity found to increase the risk of heart disease.
 1970 High blood pressure found to increase the risk of stroke.

1976 Menopause found to increase the risk of heart disease.
 1978 Psychosocial factors found to affect heart disease.
 1988 High levels of high-density lipoprotein cholesterol found to reduce risk of death.
 1994 Enlarged left ventricle (one of two lower chambers of the heart) found to increase the risk of stroke.
 1996 Progression from hypertension to heart failure described.
 2006 Genetic Research Study begins to identify genes underlying cardiovascular diseases in 9000 participants from three generations.
 2008 Discovery and publication of four risk factors that raise probability of developing precursor of heart failure; new 30-year risk estimates developed for serious cardiac events.
 2009 Researchers find parental dementia may be linked to poor memory in middle-aged adults.
 2011 Blood lipids and the incidence of atrial fibrillation: The multiethnic study of atherosclerosis and the Framingham Heart Study.

In 1971 the offspring study was begun to measure the influence of heredity and environment on the offspring of the original cohort. The younger group appears to be more health conscious because they have lower rates of smoking, lower blood pressures, and lower cholesterol levels than their parents at the same age. The Generation III Cohort Study of the grandchildren is presently underway.

Data from Framingham Heart Study: *A Timeline of Milestones from The Framingham Heart Study* (website): <http://www.framingham.com/heart/timeline.htm>, 2015. Accessed May 2, 2015.

In the medical model, primary prevention of ASCVD and stroke involves altering similar risk factors toward a healthy patient profile. For ischemic stroke, atherosclerosis is the underlying disease. Therefore optimal lipid levels, as determined by the National Cholesterol Education Program (NCEP) for hypercholesterolemia, are also the target levels to prevent stroke.

Although the National Heart, Lung and Blood Institute created the NCEP, the American Heart Association (AHA) has endorsed it. AHA suggests that primary prevention of CVD should begin in children older than age 2 (Gidding et al, 2009). Dietary recommendations for children are a bit more liberal than those for adults. Activity is emphasized in maintaining ideal body weight. Early screening for dyslipidemia is

recommended for children with a family history of hypercholesterolemia or ASCVD.

For adults, a total cholesterol level of 170 mg/dl or less is now considered optimal, including an HDL of at least 50 mg/dl. The new 2013 guidelines no longer rely strictly on cholesterol levels for advising patients or dosing medications. Instead the patient's overall health is evaluated for treatment decisions. The guidelines advise assessing factors such as age, gender, race, whether a patient smokes, blood pressure and whether it is being treated, whether a person has diabetes, as well as blood cholesterol levels in determining their risk. They also suggest that health care providers should consider other factors, including family history. Only after that very personalized assessment is a decision made on what treatment would work best. The Risk Calculator

developed by the ACC/AHA expert panel is available at <http://tools.acc.org/ASCVD-Risk-Estimator/>

Inflammatory Markers

Fifty percent of heart attacks occur in individuals with normal serum cholesterol, which has led to research on other risk markers. Increasing knowledge about the role of inflammation in ASCVD gives credence to the use of inflammatory markers to indicate the presence of atherosclerosis in asymptomatic individuals or the extent of atherosclerosis in patients with symptoms. Several markers have been suggested (see [Box 33-3](#)), and research continues to look at the effects of diet on these biomarkers. Plasma levels of omega-3 fatty acids are inversely associated with the inflammatory markers CRP, IL-6, fibrinogen, and homocysteine ([Kalogeropoulos et al, 2010](#)). An inflammatory marker specific to vascular inflammation has recently become available. The PLAC™ test measures Lp-PLA2 ([Jellinger et al, 2012](#)). Lp-PLA2 levels indicate ASCVD risk independent from other markers and provides information on the relationship between inflammation and atherosclerosis (see [Chapters 3 and 7](#)).

Fibrinogen. Most MIs are the result of an intracoronary thrombosis. Prospective studies have shown that plasma fibrinogen is an independent predictor of ASCVD risk. Factors associated with an elevated fibrinogen are smoking, diabetes, hypertension, obesity, sedentary lifestyle, elevated triglycerides, and genetic factors. More clinical trials are needed to determine whether fibrinogen is involved in atherogenesis or is just a marker of vascular damage. Blood thrombogenicity increases with high LDL cholesterol and in diabetes.

C-Reactive Protein. C-reactive protein is synthesized in the liver as the acute-phase response to inflammation. In a normal individual without infection or inflammation, CRP levels are very low, less than 0.6 mg/dl. Because atherogenesis is an inflammatory process, CRP has been shown to be elevated (>3 mg/dl) in people with angina, MI, stroke, and peripheral vascular disease; the elevated levels are independent of other risk factors (see [Chapter 7](#)). Despite a lack of specificity for the cause of the inflammation, data from more than 30 epidemiologic studies have shown significant association between elevated blood levels of CRP and the prevalence of atherosclerosis ([Morrow, 2014](#)).

CRP levels are categorized for risk as low (<1 mg/L), average (2 to 3 mg/L), and high (>3 mg/L) after the average of two

measurements are taken at least 2 weeks apart. CRP levels have been shown to be inversely correlated with a vegetable-based diet ([Bloomer et al, 2010](#); [Lee et al, 2014](#)).

Homocysteine. Homocysteine, an amino acid metabolite of methionine, is a risk factor for CVD. It was first observed that children who were deficient in cystathionine B synthase, the essential enzyme for the breakdown of homocysteine, had premature atherosclerosis in some blood vessels. Elevated total homocysteine (tHcy) independently increases the odds of stroke, especially in younger individuals ([Towfighi et al, 2010](#)). Although evidence suggests that homocysteine may promote atherosclerosis, no causal link has been established. Homocysteine levels are influenced strongly by genetic factors and diet. Giving supplemental vitamins B₆ and B₁₂, which lower homocysteine levels, is being investigated actively as a treatment for CVD but as of now is not widely recommended.

Trimethylamine-N-oxide. Trimethylamine-N-oxide (TMAO) is a gut biota-dependent metabolite that contributes to heart disease ([Tang et al, 2013](#)). It is produced by the liver after intestinal bacteria have digested animal protein. TMAO has been shown to predict cardiac risk in individuals not identified by traditional risk factors and blood tests.

Lifestyle Guidelines

Lifestyle modification remains the backbone of CVD prevention and treatment. Adhering to a heart-healthy diet, regular exercising, avoidance of tobacco products, and maintenance of a healthy weight are known lifestyle factors that, along with genetics, determine CVD risk. Three critical questions (CQs) were addressed in the 2013 ACC/AHA Lifestyle modification guidelines. CQ1 presents evidence on dietary patterns and macronutrients and their effect on blood pressure and lipids, CQ2 presents evidence on the effect of dietary sodium and potassium intake on blood pressure and CVD outcomes, and CQ3 presents the evidence on the effect of physical activity on lipids and blood pressure. The recommendations are summarized in [Box 33-4](#).

Diet

The importance of diet and nutrition in modifying the risk of CVD has been known for some time. However, in general, individual dietary components have been the predominant focus. Because foods are consumed typically in combinations rather than individually and because of the possibility of synergist relationships between nutrients, there has been increasing attention to dietary patterns and their relationship to health outcomes such as CVD.

The Mediterranean Diet

There is no uniform definition of the **Mediterranean Diet (MeD)** in the published studies. Common features of the diet are greater number of servings of fruits and vegetables (mostly fresh) with an emphasis on root vegetables and greens, whole grains, fatty fish (rich in omega-3 fatty acids), lower amounts of red meat and with an emphasis on lean meats, lower fat dairy products, abundant nuts and legumes, and use of olive oil, canola oil, nut oil, or margarine blended with rapeseed oil or flaxseed oil. The MeD dietary patterns that have been studied were moderate in total fat (32% to 35%), relatively low in saturated fat (9% to 10%), high in polyunsaturated fatty acids (especially omega-3), and high in fiber (27 to 37 g per day).

BOX 33-3 Inflammatory Markers for Cardiovascular Risk

Genetic markers: angiotensin II receptor type-1 polymorphism	Interleukin-6
Oxidized low-density lipoprotein cholesterol	Tumor necrosis factor-alpha
Adhesion molecules	Acute-phase reactants
Selectins	Fibrinogen
Free fatty acids	C-reactive protein
Cytokines	Serum amyloid A
Interleukin-1	White blood cell count
	Erythrocyte sedimentation rate
	TMAO

Derived from Fung MM et al: Early inflammatory and metabolic changes in association with AGTR1 polymorphisms in prehypertensive subjects, *Am J Hypertens* 24:225, 2011; Pearson TA et al: Markers of inflammation and cardiovascular disease: application to clinical and public health practice: a statement for healthcare professionals from the Centers for Disease Control and Prevention and the American Heart Association, *Circulation* 107:499, 2003.

BOX 33-4 Summary of ACC/AHA Recommendations for Lifestyle Management

DIET

LDL-C

Advise adults who would benefit from LDL-C lowering to

1. Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages and red meats.
 - a. Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus).
 - b. Achieve this pattern by following plans such as the DASH dietary pattern, the USDA Food Pattern, or the AHA Diet.
2. Aim for a dietary pattern that achieves 5% to 6% of calories from saturated fat.
3. Reduce percent of calories from saturated fat.
4. Reduce percent of calories from trans fat.

Blood Pressure (BP)

Advise adults who would benefit from BP lowering to

1. Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meats.
 - a. Adapt this dietary pattern to appropriate calorie requirements, personal and cultural food preferences, and nutrition therapy for other medical conditions (including diabetes mellitus).
 - b. Achieve this pattern by following plans such as the DASH dietary pattern, the USDA Food Pattern, or the AHA Diet.
2. Lower sodium intake.
 - a. Consume no more than 2400 mg of sodium/day.
 - b. Further reduction of sodium intake to 1500 mg/day is desirable because it is associated with even greater reduction in BP.
 - c. Reduce intake by at least 1000 mg/day because that will lower BP, even if the desired daily sodium.
4. Combine the DASH dietary pattern with lower sodium intake.

PHYSICAL ACTIVITY

Lipids

In general, advise adults to engage in aerobic physical activity to reduce LDL-C and non-HDL-C: 3 to 4 sessions a week, lasting on average 40 minutes per session, and involving moderate-to-vigorous intensity physical activity.

Blood Pressure

In general, advise adults to engage in aerobic physical activity to lower BP: 3 to 4 sessions a week, lasting on average 40 minutes per session, and involving moderate to-vigorous intensity physical activity.

The Dietary Approaches to Stop Hypertension (DASH) Diet

The DASH dietary pattern is high in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts and low in animal protein and sugar. Two DASH variations were studied in the OmniHeart (Optimal Macronutrient Intake Trial for Heart Health) trial, one that replaced 10% of total daily energy from carbohydrate with protein; the other that replaced the same amount of carbohydrate with unsaturated fat. The former had showed better results than the latter in lowering CVD risk (Swain et al, 2008). See Appendix 26.

Vegan Diet

A vegan diet is a strict vegetarian diet that includes no dietary sources from animal origins (see Appendix 39). There is ongoing

research to suggest only this type of very restricted diet can actually reverse ASCVD (Esselstyn and Goulubic, 2014).

Physical Inactivity

Physical inactivity and a low level of fitness are independent risk factors for ASCVD. Physical activity is associated with ASCVD, independent of the common cardiometabolic risk factors of obesity, serum lipids, serum glucose and hypertension, in men and women (McGuire et al, 2009). With the high prevalence of obesity, physical activity is a high priority. Physical activity lessens ASCVD risk by retarding atherogenesis, increasing vascularity of the myocardium, increasing fibrinolysis, increasing HDL cholesterol, improving glucose tolerance and insulin sensitivity, aiding in weight management, and reducing blood pressure.

The 2013 ACC/AHA recommendations for exercise are based on studies on the role of exercise in preventing and treating CVD alone, not in combination with other interventions. Their recommendation based on the evidence is for three to four sessions of aerobic exercise per week for an average of 40 minutes duration.

Stress

Stress activates a neurohormonal response in the body that results in increased heart rate, blood pressure, and cardiac excitability. The stress hormone angiotensin II is released after stimulation of the sympathetic nervous system (SNS); exogenous infusion of angiotensin II accelerates the formation of plaque. The INTERHEART study found that the effect of stress on CVD risk is comparable to that of hypertension. Stress management was not part of the 2013 ACC/AHA lifestyle modification guidelines.

Diabetes

Diabetes is a disease that is an independent risk factor. The prevalence of diabetes mirrors that of obesity in the United States. Type 2 diabetes has continued to increase in incidence (see Chapter 30). Any form of diabetes increases the risk for ASCVD, with occurrence at younger ages. Most people with diabetes die of CVD. Similarly, 75% of people with diabetes have more than two risk factors for ASCVD (McCollum et al, 2006). Some of the increased risk seen in patients with diabetes is attributable to the concurrent presence of other risk factors, such as dyslipidemia, hypertension, and obesity. Thus diabetes is now considered an ASCVD risk factor (see Chapter 30).

Metabolic Syndrome

Since the early findings of the Framingham study, it has been known that a clustering of risk factors markedly increases the risk of CVD (see Chapter 21 for an in-depth discussion of metabolic syndrome).

Obesity

Obesity has now reached epidemic levels in children and adults in many developed countries. Body mass index (BMI) and CVD are positively related; as BMI goes up, the risk of CVD also increases. The prevalence of overweight and obesity is the highest that it has ever been in the United States; 65% of adults are overweight, and 31% are obese (Blumenthal et al, 2010). Obesity rates vary by race and ethnicity in women. Non-Hispanic black women have the highest prevalence, followed by Mexican American women, American Indians, Alaskan natives, and non-Hispanic whites. In men the rates of obesity vary from 25% to 28% of the population.

An obese-years metric was developed using more than 5000 participants of the Framingham Heart Study that captures the cumulative damage of obesity over years. The obese-years metric is calculated by multiplying the number of BMI units above 29 kg/m² by the number of years lived at that BMI. Higher obese-years were associated with higher CVD risk in the study. The metric was found to provide a slightly more accurate measure of CVD risk than obesity alone (Abdullah et al, 2014).

Carrying excess adipose tissue greatly affects the heart through the many risk factors that are often present: hypertension, glucose intolerance, inflammatory markers (IL-6, TNF- α , CRP), obstructive sleep apnea, prothrombotic state, endothelial dysfunction, and dyslipidemia (small dense LDL, increased apo B, low HDL, high triglyceride levels). Many inflammatory proteins are now known to come from the adipocyte (see Chapters 3 and 21). These concurrent risk factors may help to explain the high morbidity and mortality rates observed in people who are obese.

Weight distribution (abdominal versus gynoid) is also predictive of CVD risk, glucose tolerance, and serum lipid levels. Central or abdominal length of adiposity also has been strongly related to markers of inflammation, especially CRP. Therefore a waist circumference of less than 35 inches for women and 40 inches for men is recommended (see Chapter 21).

Small weight losses (10 to 20 lb) can improve LDL cholesterol, HDL cholesterol, triglycerides, high blood pressure, glucose tolerance, and CRP levels, even if an ideal BMI is not achieved. Weight loss also has been correlated with lower CRP levels. However, to restore vascular function, the amount of weight that must be lost, the time of weight maintenance, or the amount of improvement in endothelial function that lessens cardiovascular events is still unknown.

Nonmodifiable Risk Factors

Age and Sex

With increasing age, higher mortality rates from CVD are seen in both genders. However, gender is a factor for the assessment of risk. The incidence of premature disease in men 35 to 44 years of age is three times as high as the incidence in women of the same age. Therefore being older than 45 years of age is considered a risk factor for men. For women the increased risk comes after the age of 55 years, which is after menopause for most women. Overall the increased risk for CVD parallels age.

Family History and Genetics

A family history of premature disease is a strong risk factor, even when other risk factors are considered. A family history is considered to be positive when MI or sudden death occurs before the age of 55 years in a male first-degree relative or the age of 65 in a female first-degree relative (parents, siblings, or children). The presence of a positive family history, although not modifiable, influences the intensity of risk factor management.

Menopausal Status

Endogenous estrogen confers protection against ASCVD in premenopausal women, probably by preventing vascular injury. Loss of estrogen after natural or surgical menopause is associated with increased ASCVD risk. Rates of ASCVD in premenopausal women are low except in women with multiple risk factors. During the menopausal period total cholesterol, LDL cholesterol, and triglyceride levels increase; HDL cholesterol level decreases, especially in women who gain weight.

Medical Nutrition Therapy

Medical nutrition therapy (MNT), which includes discussion of physical activity, is the primary intervention for patients with elevated LDL cholesterol (see Box 33-4). Physicians are encouraged to refer patients to registered dietitian nutritionists (RDNs) to help patients meet goals for therapy based on LDL cholesterol levels.

With diet, exercise, and weight reduction, patients can decrease LDL cholesterol and reduce body inflammation. The complexity of changes, number of changes, and motivation of the patient will dictate how many patient visits it will take for the adherent client to be successful. An initial visit of 45 to 90 minutes followed by two to six visits of 30 to 60 minutes each with the RDN is recommended (American Dietetic Association [ADA] Evidence Library, 2006). Consequently these interventions are tried before drug therapy and also continue during pharmacologic treatment to enhance effectiveness of the medication (see *Pathophysiology and Care Management Algorithm: Atherosclerosis*).

Lifestyle Recommendations

The ACC/AHA recommends diet and lifestyle changes to reduce ASCVD risk in all people older than the age of 2 (Eckel et al, 2013). The ACC/AHA recommendations are for a diet high in vegetables, fruits, whole grains, low-fat poultry, fish, nontropical vegetable oils, nuts, and low-fat dairy and low in sweets, sugar-sweetened beverages, and red meat. The DASH diet pattern or USDA food pattern (MyPlate) is recommended to achieve this diet. The Mediterranean Diet was not specifically recommended because in the evidence evaluated the diet was not specific or consistent enough to draw conclusions. In general, the Mediterranean diet pattern (see Figure 33-5) fits the recommendations. A study recently presented at the American College of Cardiology supports the Mediterranean diet pattern for CVD risk reduction (American College of Cardiology, 2015). The study included more than 2500 Greek adults over more than 10 years. Nearly 20% of men and 12% of women in the study developed or died from heart disease. People who closely followed the Mediterranean diet were 47% less likely to develop heart disease than those who did not follow the diet. The Mediterranean Diet Score Tool was used (see Figure 33-5) to validate the dietary pattern. A Mediterranean diet may also reduce recurrent CVD by 50% to 70% and has been shown to affect lipoprotein levels positively in high-risk populations (Carter et al, 2010).

Saturated Fatty Acids. Currently in the United States the average intake of saturated fat is 11% of calories. The recommendation for decreasing LDL cholesterol is 5% to 6%. The guidelines have no specific recommendation for trans fatty acid intake but recommend it be decreased with the saturated fat. Saturated fat is generally found in animal proteins. It is recommended that intake of animal protein, especially red meat and high fat dairy be decreased.

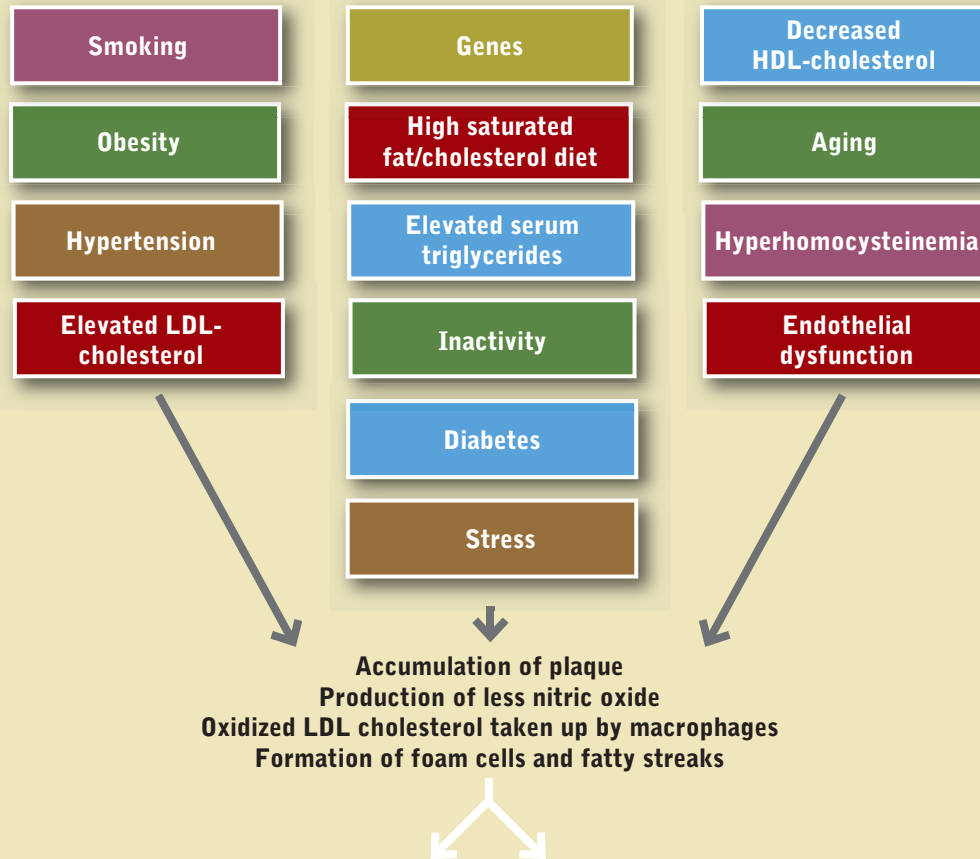

Trans Fatty Acids. Trans fatty acids (stereoisomers of the naturally occurring cis-linoleic acid) are produced in the hydrogenation process used in the food industry to increase shelf life of foods and to make margarines, made from oil, firmer. Most trans fatty acids intake comes from these partially hydrogenated oils (PHOs). In 2013 the FDA made a decision to remove PHOs from the “generally recognized as safe” list. This was based on the mounting evidence that trans fats contributed to ASCVD and was associated with increased LDL cholesterol

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Atherosclerosis

ETIOLOGY

PATHOPHYSIOLOGY

Clinical Findings

- Elevated LDL cholesterol
- Elevated serum triglycerides
- Elevated C-reactive protein
- Low HDL-cholesterol

Nutrition Assessment

- BMI evaluation
- Waist circumference; waist to hip ratio (WHR)
- Dietary assessment for:
 - SFA, *trans*-fatty acids, ω -3 fatty acids, fiber, sodium, alcohol, sugar and phytonutrients

MANAGEMENT

Medical Management

- Lifestyle change
- HMG CoA reductase inhibitors (statins)
- Triglyceride-lowering medication
- Blood pressure—lowering medication
- Medication for glucose management
- Percutaneous coronary intervention (PCI)
 - Balloon
 - Stent
- Coronary artery bypass graft (CABG)
- Antiplatelet Therapy

Nutrition Management

- DASH dietary pattern
- Mediterranean diet pattern
- Weight reduction if needed
- Increase dietary fiber to 25–30 g/day or more
- Add ω -3 fats from food sources
- Add fruits and vegetables
- CoQ₁₀ for those on statin drugs

MEDITERRANEAN DIET SCORE TOOL

A Mediterranean dietary pattern ('Med diet') is typically one based on whole or minimally processed foods. It's **rich in protective foods** (fruits, vegetables, legumes, wholegrains, fish and olive oil) and **low in adverse dietary factors** (fast food, sugar-sweetened beverages, refined grain products and processed or energy-dense foods) with moderate red meat and alcohol intake.

Evidence shows **overall dietary pattern** (reflected in TOTAL SCORE) as well as **individual components** reflect risk; a higher score is associated with lower risk of CVD and all-cause mortality (BMJ 2008;337:a1344). During rehabilitation patient scores should ideally rise in response to dietary advice and support.

This tool can be used by health professionals with appropriate nutritional knowledge and competencies, such as Registered Dietitians (NICE, 2007, 2013). It can be used as both an *audit tool* and *as part of a dietary assessment* at baseline, end of programme and 1 year follow-up, along with assessment and advice for weight management, salt intake and eating behaviours. For information on complete requirements for dietary assessments and advice, please refer to the latest NICE/Joint British Societies guidelines (BACPR, 2012. The BACPR Standards and Core Components for Cardiovascular Disease Prevention and Rehabilitation, 2nd Ed.).

	Question	Yes	No	Nutritional issue to discuss in response
1.	Is olive oil the main culinary fat used?			Choosing Healthier Fats Olive oil is high in monounsaturated fat. Using unsaturated fats instead of saturated fats in cooking and preparing food is advisable.
2.	Are ≥ 4 tablespoons of olive oil used each day?			Healthy fats are better than very low fat Med diet is more beneficial than a very low fat diet in prevention of CVD. So replacing saturated with unsaturated fat is better than replacing it with carbohydrates or protein.
3.	Are ≥ 2 servings (of 200g each) of vegetables eaten each day?			Eat plenty of fruits and vegetables Eating a wide variety of fruit and vegetables every day helps ensure adequate intake of many vitamins, minerals, phytochemicals and fibre. Studies have shown that eating plenty of these foods is protective for CVD and cancer.
4.	Are ≥ 3 servings of fruit (of 80g each) eaten each day?			
5.	Is < 1 serving (100-150g) of red meat/hamburgers/ other meat products eaten each day?			Choose lean meats and consider cooking methods Red and processed meats are high in saturated fat, can be high in salt and are best replaced with white meat or fish or vegetarian sources of protein. Grill or roast without fat, casserole or stir fry.
6.	Is < 1 serving (12g) of butter, margarine or cream eaten each day?			Keep saturated fat low These foods are high in saturated fat which can increase your blood cholesterol level. Choose plant-based or reduced-fat alternatives.
7.	Is < 1 serving (330ml) of sweet or sugar sweetened carbonated beverages consumed each day?			Excessive consumption of sugar-sweetened beverages can worsen many risk factors for CVD: keep consumption to < 1/day.
8.	Are ≥ 3 glasses (of 125ml) of wine consumed each week?			Moderate alcohol intake with meals While this does have some protective effect but there is no evidence that non-drinkers should take up drinking alcohol.
9.	Are ≥ 3 servings (of 150g) of legumes consumed each week?			Include soluble fibre These foods are high in soluble fibre and other useful nutrients. Regular consumption is advisable for raised cholesterol.
10.	Are ≥ 3 servings of fish (100-150g) or seafood (200g) eaten each week?			Eat more oily and white fish Oily fish is an excellent source of essential omega-3 fats. White fish is very low in saturated fat.
11.	Is < 3 servings of commercial sweets/pastries eaten each week?			Eat less processed food These foods are usually high in saturated fat, salt or sugar and often contain trans fats. Replacing these with healthy snacks such as fruit or unsalted nuts is beneficial.
12.	Is ≥ 1 serving (of 30g) of nuts consumed each week?			Snack on modest servings of unsalted nuts Nuts are rich in unsaturated fat, phytosterols, fibre, vitamin E and iron, e.g. walnuts, almonds, hazelnuts
13.	Is chicken, turkey or rabbit routinely eaten instead of veal, pork, hamburger or sausage?			'White meat' choices are lower in saturated fat. Remove the skin and consider your cooking method.
14.	Are pasta, vegetable or rice dishes flavoured with garlic, tomato, leek or onion eaten ≥ twice a week?			Using a tomato and garlic or onion or leek-based sauce regularly is a key feature of the Med diet.
TOTAL SCORE (total no. of 'yes' answers)				

levels. Trans fat intake is inversely associated with HDL levels (Yanai et al, 2015).

Monounsaturated Fatty Acids. Oleic acid (C18:1) is the most prevalent MUFA in the American diet. Substituting oleic acid for carbohydrate has almost no appreciable effect on blood lipids. However, replacing SFAs with MUFAs (as would happen when substituting olive oil for butter) lowers serum cholesterol levels, LDL cholesterol levels, and triglyceride levels. Oleic acid as part of the Mediterranean diet (see Figure 33-6) has been shown to have antiinflammatory effects.

Polyunsaturated Fatty Acids. The essential fatty acid linoleic acid (LA) is the predominant PUFA consumed in the American diet; its effect depends on the total fatty acid profile of the diet. When added to study diets, large amounts of LA decrease HDL serum cholesterol levels. High intakes of omega-6 PUFAs may exert adverse effects on the function of vascular endothelium or stimulate production of proinflammatory cytokines (Harris et al, 2009). Replacing PUFAs for carbohydrate in the diet results in a decline in serum LDL cholesterol. When SFAs are replaced with PUFAs in a low-fat diet, LDL and HDL cholesterol levels are lowered. Overall, eliminating SFAs is twice as effective in lowering serum cholesterol levels as increasing PUFAs.

Omega-3 Fatty Acids. The main omega-3 fatty acids (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) are high in fish oils, fish oil capsules, and ocean fish. Some studies have shown that eating fish is associated with a decreased ASCVD risk. The recommendation for the general population is to increase fish consumption specifically of fish high in omega-3 fatty acids (salmon, tuna, mackerel, sardines). Patients who have hypertriglyceridemia need 2 to 4 g of EPA and DHA per day for effective lowering. Omega-3 fatty acids lower triglyceride levels by inhibiting VLDL and apo B-100 synthesis, thereby decreasing postprandial lipemia. Fish oil consumption has been associated with high levels of HDL cholesterol (Yanai et al, 2015). See Appendix 34.

An omega-3 fatty acid from vegetables, alpha-linolenic acid (ALA), has antiinflammatory effects (see Chapter 3). CRP levels are reduced when patients consume 8 g of ALA daily (Basu et al, 2006). Omega-3 fatty acids are thought to be cardioprotective because they interfere with blood clotting and alter prostaglandin synthesis. Omega-3 fat stimulates production of nitric oxide, a substance that stimulates relaxation of the blood vessel wall (vasodilation). Unfortunately, high intakes prolong bleeding time, a common condition among Arctic Native populations

FIGURE 33-6 The Traditional Healthy Mediterranean Diet Pyramid. (Courtesy Oldways Preservation and Exchange Trust, www.oldwayspt.org.) (<http://www.cardiacrehabilitation.org.uk/docs/Mediterranean-Diet-Score.pdf>)

with high omega-3 fat dietary intakes and low incidence of ASCVD.

Dietary Cholesterol. Previous recommendations have been to decrease dietary cholesterol to decrease LDL cholesterol and reduce ASCVD risk. The ACC/AHA 2013 guidelines no longer make this recommendation, and they specifically state that dietary cholesterol does not raise LDLs. The 2015 US Dietary Guidelines also eliminate the recommendation to restrict cholesterol (see Chapter 11). However it is important to remember that most high cholesterol foods are also high in saturated fats that do raise LDL cholesterol.

Fiber. High intake levels of dietary fiber are associated with significantly lower prevalence of ASCVD and stroke (Anderson et al, 2009). The USDA MyPlate, the DASH diet, and the Mediterranean diet pattern emphasize fruits, vegetables, legumes, and whole grains, so they are innately high in fiber. This combination of foods provides a combination of soluble and insoluble fiber. Proposed mechanisms for the hypocholesterolemic effect of soluble fiber include the following: (1) the fiber binds bile acids, which lowers serum cholesterol and (2) bacteria in the colon ferment the fiber to produce acetate, propionate, and butyrate, which inhibit cholesterol synthesis. The role of fiber, if any, on inflammatory pathways is not well established. Minerals, vitamins, and antioxidants that are components of a high-fiber diet further enrich the diet.

Insoluble fibers such as cellulose and lignin have no effect on serum cholesterol levels. For the purpose of heart disease prevention, most of the recommended 25 to 30 g of fiber a day should be soluble fiber.

Antioxidants. Two dietary components that affect the oxidation potential of LDL cholesterol are the level of LA in the particle and the availability of antioxidants. Vitamins C, E, and beta-carotene at physiologic levels have antioxidant roles in the body. Vitamin E is the most concentrated antioxidant carried on LDLs, the amount being 20 to 300 times greater than any other antioxidant. A major function of vitamin E is to prevent oxidation of PUFAs in the cell membrane. The AHA does not recommend vitamin E supplementation for CVD prevention. A dietary pattern that includes increased amounts of whole grains has increased amounts of vitamin E. Foods with concentrated amounts of antioxidants are found in phytochemicals known as catechins and have been found to improve vascular reactivity. Red grapes, red wine, tea (especially green tea), berries, and broad beans (fava beans) are part of the Mediterranean diet pattern. See Figs. 33-5 and 33-6 and Appendix 31, The Anti-inflammatory Diet.

Stanols and Sterols. Since the early 1950s, plant stanols and sterols isolated from soybean oils or pine tree oil have been known to lower blood cholesterol by inhibiting absorption of dietary cholesterol. Stanols and sterols should be part of dietary recommendations for lowering LDL cholesterol in adults (Yanai et al, 2015). Because these esters also can affect the absorption of and cause lower beta-carotene, alpha-tocopherol, and lycopene levels, further safety studies are needed for use in normocholesterolemic individuals, children, and pregnant women.

Weight Loss. More than 78 million adults in the United States were obese in 2009 to 2010, and obesity raises the risk of hypertension, dyslipidemia, type 2 diabetes, ASCVD, and stroke. Obesity is associated with increased risk in all-cause and cardiovascular disease mortality (Stone et al, 2014) (see Treatment Algorithm—The Chronic Disease Management Model for Primary Care of Patients with Overweight and Obesity). Recommendations of the panel are summarized in Box 33-5.

BOX 33-5 Recommendations from the AHA/ACC/TOS Obesity Guideline

1. Patient/provider encounter for obesity prevention and management: a patient encounter is defined as an interaction with a primary care provider who assesses weight status to determine need for further assessment and treatment.
2. Measure weight and height and calculate BMI.
3. BMI 25 <30 (overweight) or BMI 30 <35 (class I obese) or BMI 35 <40 class II obese or BMI > 40 (class III obese): these BMI cutpoints define overweight and obese individuals who are at increased risk of CVD. Within these categories, additional personal risk assessment is needed.
4. Assess and treat CVD risk factors and obesity-related comorbidities: A waist circumference measurement is recommended for individuals with BMI 25 to 35 to provide additional information on risk. It is not necessary to measure waist circumference in patients with BMI >35 because the waist circumference will likely be elevated and it will add no additional information. Increased cardiometabolic risk is defined as >88 cm or >35 in for women and >102 cm or >40 in for men.
5. Assess weight and lifestyle histories: Ask questions about history of weight gain and loss over time, details of previous weight loss attempts, dietary habits, physical activity, family history of obesity and other medical conditions and medications that may affect weight.
6. Assess need to lose weight: Weight loss treatment is indicated for (1) obese (2) overweight with one or more indicators of increased CVD risk.
7. Advise to avoid weight gain and address other risk factors.

Jensen, et al, 2013 AHA/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults. *Circulation*, 129:S102, 2014.

Medical Management

Pharmacologic Management

Determination of drug therapy depends on risk category and attainment of the LDL cholesterol goal. The 2013 ACC/AHA Guidelines for Treatment of Blood Cholesterol have updated recommendations for prescribing statin drugs to be more focused on overall patient risk than on specific serum cholesterol targets. See Appendix 22 for a discussion of the guidelines for treatment with statin drugs. The primary treatment for those at risk of ASCVD are the HMG-CoA reductase inhibitors, of which there are many (see Chapter 8). The classes of drugs include the following: (1) **bile acid sequestrants** such as cholestyramine (adsorbs bile acids); (2) nicotinic acid; (3) **statins**, or **3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA)** reductase inhibitors, which inhibit the rate-limiting enzyme in cholesterol synthesis; (4) fibric acid derivatives; and (5) probucol.

Medical Intervention

Medical interventions such as percutaneous coronary intervention (PCI) are now performed in patients with asymptomatic ischemia or angina. PCI, previously known as *percutaneous transluminal coronary angioplasty*, is a procedure that uses a catheter with a balloon that, once inflated, breaks up plaque deposits in an occluded artery. Coronary stenting involves a wire mesh tube inserted to hold an artery open; it can release medication that prevents clotting (Thom et al, 2006).

PCI is often possible because of earlier detection of blockages. The most common problem with PCI is restenosis of the artery. A recent study examined more than 2200 patients, half of whom received intervention of medication and lifestyle changes such as quitting smoking, exercise, and nutrition, and

half of whom received lifestyle changes as well as angioplasty. After 5 years it was observed that the number who had heart attacks, were hospitalized, or died because of their heart problems was virtually identical in both groups. Angioplasty did not appear to provide an additional benefit versus lifestyle changes combined with medication (Boden et al, 2007).

Because PCI is performed with the patient under local anesthesia in a cardiac catheterization laboratory, recovery is quicker than with **coronary artery bypass graft (CABG)** surgery. In CABG surgery, an artery from the chest is used to redirect blood flow around a diseased vessel. Candidates for CABG usually have more than two occluded arteries. CABG surgeries have decreased since 1995 because more PCI procedures are being done. These surgeries improve survival time, relieve symptoms, and markedly improve the quality of life for patients with ASCVD. However, CABG does not cure atherosclerosis; the new grafts are also susceptible to atherogenesis. Consequently, restenosis is common within 10 years of surgery.

HYPERTENSION

Hypertension is persistently high arterial blood pressure, the force exerted per unit area on the walls of arteries. The **systolic blood pressure (SBP)**, the upper reading in a blood pressure measurement, is the force exerted on the walls of blood vessels as the heart contracts and pushes blood out of its chambers. The lower reading, known as **diastolic blood pressure (DBP)**, measures the force as the heart relaxes between contractions. Blood pressure is measured in millimeters (mm) of mercury (Hg). Adult blood pressure is considered normal at 120/80 mm Hg.

The evidence-based guideline from the Joint National Committee (JNC) Eight Report (James et al., 2014) on the management of high blood pressure in adults indicates that adults aged 60 years or older should be treated with medication if their blood pressure exceeds 150/90, which sets a higher bar for treatment than the former guideline of 140/90 (see Table 33-1). The expert panel also recommends that individuals with diabetes and chronic kidney disease younger than 60 years be treated at the same point as everyone else that age, when their blood pressure exceeds 140/90. Until now, people with those chronic conditions have been prescribed medication when their blood pressure exceeded 130/80. The recommendations are based on clinical evidence showing that stricter guidelines for these patients provided no additional benefit. Importantly, the guidelines emphasize that people with high blood pressure should follow a healthy diet and lifestyle along with medication management. Diet and lifestyle modifications are important part of primary prevention of hypertension.

TABLE 33-1 Classification of Blood Pressure for Adults Ages 18 Years or Older

	Systolic BP (mm Hg)*	and or	Diastolic BP (mm Hg)*
Normal, <60yrs	140		90
≥60yrs	150		<90

James PA, et al : 2014 evidence-based guideline for the management of high blood pressure in adults: Report from the panel members appointed to the Eighth Joint National Committee (JNC 8), JAMA 311 : 507 , 2014.

*Definitions of hypertension and pre-hypertension not addressed, goals of treatment now specific to presence of diabetes and kidney disease

Hypertension is a common public health problem in developed countries. In the United States one in three adults has high blood pressure (AHA, 2013). Untreated hypertension leads to many degenerative diseases, including heart failure (HF), end-stage renal disease, and peripheral vascular disease. It is often called a “silent killer” because people with hypertension can be asymptomatic for years and then have a fatal stroke or heart attack. Although no cure is available, hypertension is easily detected and usually controllable. Some of the decline in CVD mortality during the last two decades has been attributed to the increased detection and control of hypertension. The emphasis on lifestyle modifications has given diet a prominent role in the primary prevention and management of hypertension.

Of those persons with high blood pressure, 90% to 95% have **essential hypertension** (hypertension of unknown cause) or primary hypertension. The cause involves a complex interaction between poor lifestyle choices and gene expression. Lifestyle factors that have been implicated include poor diet (i.e., high sodium, low fruit and vegetable intake), smoking, physical inactivity, stress, and obesity. Vascular inflammation has also been implicated (Hall et al, 2012). Many genes play a role in hypertension; most relate to the renal or neuroendocrine control of blood pressure. Evaluations of more than 2.5 million genotyped polymorphisms have identified more than 40 genetic loci associated with monogenic blood pressure syndromes (Padmanabhan et al, 2012). Hypertension that arises as the result of another disease, usually endocrine, is referred to as **secondary hypertension**. Depending on the extent of the underlying disease, secondary hypertension can be cured.

Prevalence and Incidence

Approximately 78 million American adults age 20 and older have hypertension or are taking antihypertensive medication (AHA, 2013). Projections show that by 2030, prevalence of hypertension will increase by 7.2% from 2013 estimates. Non-Hispanic black adults have a higher age-adjusted prevalence of hypertension (42.6% of men; 47% of women) than non-Hispanic whites (33.4% of men; 30.7% of women) and Mexican Americans (30.1% of men; 28.8% of women) (AHA, 2013). The prevalence of high blood pressure in blacks is one of the highest rates seen anywhere in the world. Because blacks develop hypertension earlier in life and maintain higher blood pressure levels, their risk of fatal stroke, heart disease, or end-stage kidney disease is higher than whites (AHA, 2013).

A person of any age can have hypertension. Approximately 16% of boys and 9% of girls have elevated blood pressure (Ostchega et al, 2009). With aging, the prevalence of high blood pressure increases (see Figure 33-7). Before the age of 45 more men than women have high blood pressure, and after age 65 the rates of high blood pressure among women in each racial group surpass those of the men in their group (Go et al, 2014). Because the prevalence of hypertension rises with increasing age, more than half the older adult population (more than 65 years of age) in any racial group has hypertension. Although lifestyle interventions targeted to older persons may reduce the prevalence of hypertension, early intervention programs provide the greatest long-term potential for reducing overall blood pressure-related complications (Lloyd-Jones, 2012).

The relationship between blood pressure and risk of CVD events is continuous and independent of other risk factors. The higher the blood pressure, the greater is the chance of target organ damage, including left ventricular hypertrophy (LVH),

¹Statistically significant difference between ages 18-39 and 40-59 years.
²Statistically significant difference between ages 40-59 and 60 years and over.

FIGURE 33-7 Age-specific and age-adjusted prevalence of hypertension in adults: United States, 2005-2006. (Ostchega Y et al: *Hypertension awareness, treatment, and control—continued disparities in adults: United States, 2005-2006*. NCHS data brief no. 3, Hyattsville, Md, 2008, National Center for Health Statistics.)

HF, stroke, chronic kidney disease, and retinopathy (ADA, 2013). As many as 28% of adults with hypertension have treatment-resistant hypertension, which means that their blood pressure remains high despite the use of three or more antihypertensive drugs from different classes (Egan et al, 2010). Treatment-resistant hypertension puts an individual at greater risk of target organ damage. Older age and obesity are two of the strongest risk factors associated with the condition. Identification and reversal of lifestyle factors contributing to treatment resistance, along with diagnosis and appropriate treatment of secondary causes and use of effective multidrug regimens are essential treatment strategies.

Adults with diabetes have CVD death rates two to four times higher than adults without diabetes (AHA, 2013). Consequently, national health organizations, including the American Diabetes Association (ADA, 2013), have set the target blood pressure goal for antihypertensive therapy for individuals with diabetes lower than that recommended for the general population, which is 140/90 mm Hg. A recent update of the JNC 8 Report (James et al, 2014) recommends similar treatment goals for all hypertensive populations, including those with diabetes, citing insufficient evidence from randomized clinical trials (RCTs) of CVD benefits for lowered blood pressure targets. RCTs provide the highest quality of scientific evidence regarding the efficacy of treatment approaches to lower blood pressure.

Although hypertensive patients are often asymptomatic, hypertension is not a benign disease. Cardiac, cerebrovascular, and renal systems are affected by chronically elevated blood pressure. High blood pressure was the primary or a contributory cause in 348,000 of the 2.4 million U.S. deaths in 2009 (AHA, 2013). Between 1999 and 2009 the age-adjusted death rate from hypertension increased by 17.1%; overall deaths from hypertension increased by 43.6%. Death rates from hypertension are approximately three times higher in blacks than in whites (AHA, 2013). Hypertension is a major contributing factor to atherosclerosis, stroke, renal failure, and MI. Factors associated with a poor prognosis in hypertension are shown in Box 33-6.

BOX 33-6 Risk Factors and Adverse Prognosis in Hypertension

Risk Factors

Black race
 Youth
 Male gender
 Persistent diastolic pressure >115 mm Hg
 Smoking
 Diabetes mellitus
 Hypercholesterolemia
 Obesity
 Excessive alcohol intake
 Evidence of end organ damage

Electrocardiographic signs of ischemia or left ventricular strain
 Myocardial infarction
 Heart failure

Eyes

Pathophysiology

Blood pressure is a function of cardiac output multiplied by peripheral resistance (the resistance in the blood vessels to the flow of blood). Thus the diameter of the blood vessel markedly affects blood flow. When the diameter is decreased (as in atherosclerosis) resistance and blood pressure increase. Conversely, when the diameter is increased (as with vasodilator drug therapy), resistance decreases and blood pressure is lowered.

Many systems maintain homeostatic control of blood pressure. The major regulators are the sympathetic nervous system (SNS) for short-term control and the kidney for long-term control. In response to a fall in blood pressure, the SNS secretes norepinephrine, a vasoconstrictor, which acts on small arteries and arterioles to increase peripheral resistance and raise blood pressure. Conditions that result in overstimulation of the SNS (i.e., certain adrenal disorders or sleep apnea) result in increased blood pressure. The kidney regulates blood pressure by controlling the extracellular fluid volume and secreting renin,

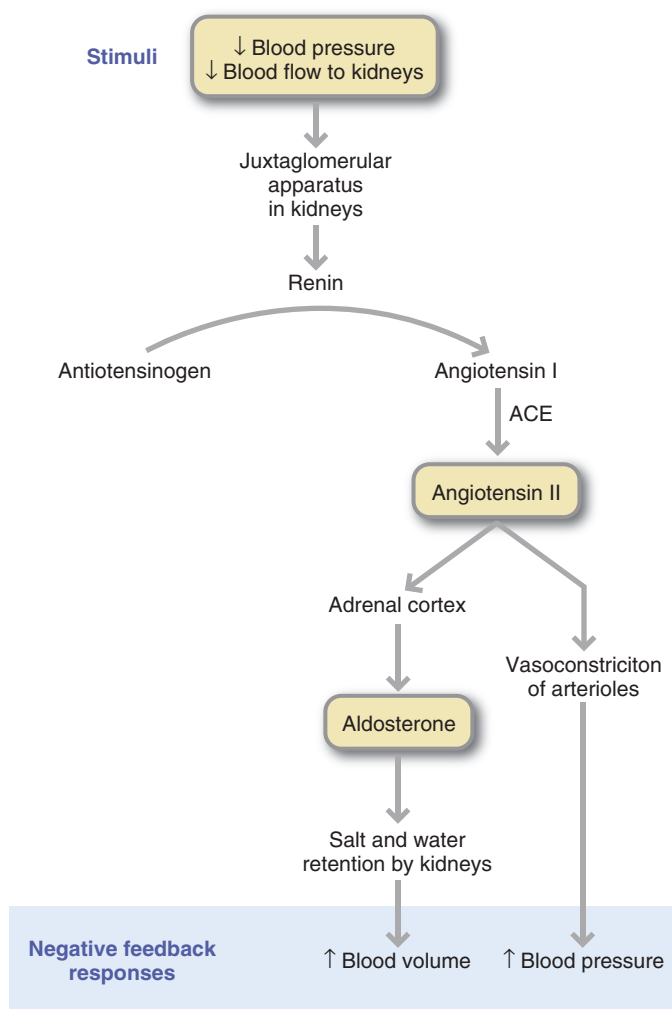

FIGURE 33-8 Renin-angiotensin cascade. ACE, Angiotensin-converting enzyme. (Reprinted with permission from Fox SI: Human physiology, ed 6, New York, 1999, McGraw-Hill.)

which activates the **renin-angiotensin system (RAS)** (see [Figure 33-8](#)). Abnormal blood pressure is usually multifactorial. In most cases of hypertension, peripheral resistance increases. This resistance forces the left ventricle of the heart to increase its effort in pumping blood through the system. With time, left ventricular hypertrophy (LVH) and eventually HF can develop.

Common genetic variants of the RAS gene, including angiotensin-converting enzyme (ACE) and angiotensinogen, have shown relationships with hypertension ([Norton et al, 2010](#)). An increased production of these proteins may increase production of angiotensin II, the primary mediator of the RAS, thus increasing blood pressure. Angiotensin II may also trigger low-grade inflammation within the blood vessel wall, a condition that predisposes to hypertension ([Savoia et al, 2011](#)).

Hypertension often occurs with other risk factors for CVD, including visceral (intraabdominal) obesity, insulin resistance, high triglycerides, and low HDL cholesterol levels. The coexistence of three or more of these risk factors leads to metabolic syndrome. It is unclear whether one or more of these risk factors precede the others or whether they occur simultaneously. Accumulation of visceral fat synthesizes increased amounts of angiotensinogen, which activates the RAS and

increases blood pressure ([Zhou et al, 2012](#)). Also, angiotensin II, the primary mediator of the RAS, promotes the development of large dysfunctional adipocytes, which produce increased amounts of leptin and reduced quantities of adiponectin. Higher levels of leptin and lower amounts of circulating adiponectin activate the SNS, a key component of the hypertensive response ([DeMarco et al, 2014](#)).

Primary Prevention

Positive changes in hypertension awareness, treatment, and control have occurred during the last several years. Based on analysis of National Health and Nutrition Examination Survey (NHANES) data from 2007 to 2010, 81.5% of people with hypertension are aware that they have it ([Go et al, 2014](#)), up from 72% in 1999 to 2004. Although current hypertension treatment and control rates have increased from 48.4% to 53.3%, respectively, during this same time period, additional efforts are needed to meet the *Healthy People 2020* objective of 61.2%. In 2010, women, younger adults (aged 18 to 39 years), and Hispanic individuals had lower rates of blood pressure control compared with men, younger individuals, and non-Hispanic whites. Improving hypertension treatment through targeted intervention programs should have a positive effect on CVD outcomes. Blood pressure treatment guidelines highlight the importance of evaluating patients for the presence of multiple CVD risk factors and individualizing lifestyle modification and drug therapies accordingly.

Changing lifestyle factors have documented efficacy in the primary prevention and control of hypertension. These factors were systematically reviewed and categorized by the Academy of Nutrition and Dietetics (AND) in 2009 and more recently by the ACC and AHA in 2013 ([Eckel et al, 2013](#)). These guidelines made a strong recommendation (i.e., high benefit/risk ratio with supporting evidence) for reducing intake of dietary sodium. A strong recommendation also was made for fruits and vegetables and dietary patterns emphasizing these foods, as well as weight management to lower blood pressure. Increasing physical activity was recommended, although the ACC/AHA felt that data showing that physical activity lowers blood pressure were limited in diverse populations. The ACC/AHA did not make a recommendation for potassium, citing insufficient evidence from RCTs to determine whether increasing dietary potassium intake without use of nutritional supplements lowers blood pressure. The AND provided a “fair” recommendation for this nutrient with consideration given to studies that included dietary and supplemental intake of potassium. A summary of recommendations and ratings from the ACC/AHA and the AND can be found in [Table 33-2](#).

Fats

Although the total quantity of dietary fat, SFA, and omega-6 PUFAs do not seem to affect blood pressure ([Cicero et al, 2009](#)), evidence from short-term feeding trials documented that MUFA, when used as a replacement for SFAs, PUFA, or carbohydrate, lowered blood pressure in some individuals with hypertension ([Appel et al, 2005](#)). In a large population study spanning different continents and diverse dietary patterns, higher intake of dietary MUFA (~13 g/day), especially oleic acid from plant oils, was associated with significantly lower DBP ([Miura et al, 2013](#)). In a recent meta-analysis, including 9 RCTs, examining the effect of MUFA on blood pressure, SBP (net change: -2.26 mm Hg), and DBP (net change: -1.15 mm Hg)

TABLE 33-2 Recommendations on Blood Pressure in Hypertensive Adults from Evidence Analysis Library (2009) and American College of Cardiology/American Heart Association (2013)

Food or Nutrient	EAL Recommendation	Rating	ACC/AHA Recommendation	Rating
Sodium	Sodium intake should be limited to no more than 2300 mg/day; if adherent to this recommendation and BP target not achieved, a further reduction in dietary sodium to 1600 mg/day should be encouraged in combination with a DASH dietary pattern.	Strong	Lower sodium intake Consume no more than 2400 mg of sodium/day; further reduction of sodium to 1500 mg/day is desirable because it is associated with even greater reduction in BP; reduce intake by at least 1000 mg/day because that will lower BP, even if the desired daily sodium intake is not achieved.	Strong Moderate
Dietary patterns emphasizing fruits and vegetables	Individuals should adopt the DASH dietary pattern, which is rich in fruits, vegetables, low-fat dairy, and nuts; low in sodium, total fat, and saturated fat; and adequate in calories for weight management.	Consensus	Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, non-tropical vegetable oils and nuts; and limits intake of sweets, sugar-sweetened beverages, and red meat; adapt the pattern to appropriate calorie requirements; achieve this pattern by following plans such as DASH, USDA food pattern or the AHA Diet; combine the DASH dietary pattern with lower sodium intake.	Strong
Fruits and vegetables	Fruits and vegetables should be recommended at a level of five to ten servings per day for significant BP reduction.	Strong		Not evaluated
Weight management	Optimal body weight should be achieved and maintained (BMI 18.5-24.9) to reduce BP.	Consensus	Counsel overweight and obese adults with high BP that lifestyle changes that produce even modest, sustained weight loss of 3% to 5% produce clinically meaningful benefits (e.g., reduce TG, blood sugar, HbA1C); >5% will reduce BP and reduce the need for medications to control BP.*	Strong
Physical activity	Individuals should be encouraged to engage in aerobic physical activity for at least 30 minutes per day on most days of the week, because it reduces SBP.	Consensus	Advise adults to engage in aerobic physical activity to lower BP: 3-4 sessions a week, lasting on average 40 minutes per session, and involving moderate-to-vigorous intensity physical activity.	Moderate
Alcohol	For individuals who can safely consume alcohol, consumption should be limited to no more than two drinks (24 oz beer, 10 oz wine, or 3 oz of 80-proof liquor) per day in most men and to no more than one drink per day in women.	Consensus		Not evaluated
Potassium	Studies support a modest relationship between increasing intake of potassium and a lower sodium-potassium ratio with lowered blood pressure.	Fair	Insufficient evidence	Low
Calcium	The effect of increasing calcium intake with lowered blood pressure is unclear; although some research indicates minimal benefit.	Fair		Not evaluated
Magnesium	The effect of increasing magnesium intake with lowered blood pressure is unknown; although some research indicates minimal benefit.	Fair		Not evaluated
Omega-3 fatty acids	Studies investigating increased consumption of omega-3 fatty acids have not demonstrated a beneficial effect on BP.	Fair		Not evaluated

BMI, Body mass index; BP, blood pressure; DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure.

Recommendations listed are for those rated by the Academy of Nutrition and Dietetics and the American Academy of Cardiology (ACC) / American Heart Association (AHA) as strong, fair/moderate, and consensus; for those with weak ratings consult the American Dietetic Association Evidence Analysis Library for Hypertension (2009) <http://www.adaevidencelibrary.com/topic.cfm?cat=3259> or the ACC/AHA data supplement at <http://circ.ahajournals.org/lookup/suppl/doi:10.1161/01.cir.0000437740.48606.d1-DC1>

*Weight management guidelines are from Jensen MD et al: 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, and the Obesity Society, *J Am Coll Cardiol* 63:2985, 2014.

TABLE 33-3 Manifestations of Target Organ Disease from Hypertension

Organ System	Manifestations
Cardiac	Clinical, electrocardiographic, or radiologic evidence of arterial wall thickening left ventricular hypertrophy; left ventricular malfunction or cardiac failure
Cerebrovascular	Transient ischemic attack or stroke
Peripheral	Absence of one or more pulses in extremities (except for dorsalis pedis) Ankle-Brachial Index < 0.9
Renal	Serum creatinine elevated: Men 1.3-1.5 mg/dL, Women 1.2-1.4 mg/dL Calculated GFR <60 mL/min/1.73 m ² Elevated albumin excretion
Retinopathy	Hemorrhages or exudates, with or without papilledema

Adapted from: Schmieder R: End organ damage in hypertension, *Dtsch Arztebl* 107:866 2010.

reductions were significantly greater among participants assigned to high MUFA diets compared with those on control diets (Schwingshackl et al, 2011). Taken together, these findings suggest that diets high in MUFA may be a useful component of blood pressure–lowering diets.

Supplementation with n-3 PUFAs (EPA + DHA) in doses higher than 2 g/day also can give modest reductions in SBP and DBP, especially in untreated hypertensive persons (Miller et al, 2014).

Protein

Evidence from observational studies and RCTs suggests replacement of protein for fat or carbohydrate in an isocaloric diet results in lowered blood pressure (Bazzano et al, 2013). Protein supplementation in doses of 60 g/day reduced SBP by 4.9 mm Hg and DBP by 2.7 mm Hg as compared with 60 g/day of carbohydrate in overweight individuals with prehypertension and untreated stage 1 hypertension (Teunissen-Beekman and van Baak, 2013). Although soy protein may contribute to the lowering of blood pressure, the effect of increased soy food intake on blood pressure remains controversial (AND, 2009).

Dietary Patterns Emphasizing Fruits and Vegetables

Several dietary patterns have been shown to lower blood pressure. Plant-based dietary patterns have been associated with lower SBP in observational studies and clinical trials. Average SBP reductions of 5 to 6 mm Hg have been reported. Specifically, the **Dietary Approaches to Stop Hypertension (DASH)** controlled feeding study showed that a dietary pattern emphasizing fruits, vegetables, low-fat dairy products, whole grains, lean meats, and nuts significantly decreased SBP in hypertensive and normotensive adults. The DASH diet (Appendix 26) was found to be more effective than just adding fruits and vegetables to a low-fat dietary pattern and was equally effective in men and women of diverse racial and ethnic backgrounds (Appel et al, 2006). This dietary pattern serves as the core for the ACC/AHA dietary recommendations for lowering blood pressure (Eckel et al, 2013). Although the DASH diet is safe and currently advocated for preventing and treating hypertension, the diet is high in potassium, phosphorus, and protein, depending on how it is planned. For this reason the DASH diet is not advisable for individuals with end-stage renal disease (Appel et al, 2006).

Several versions of the DASH diet have been examined in regard to blood pressure–lowering potential. The OmniHeart trial compared the original DASH diet to a high-protein version of the DASH diet (25% of energy from protein, approximately half from plant sources), and a DASH diet high in unsaturated fat (31% of calories from unsaturated fat, mostly monounsaturated). Although each diet lowered SBP, substituting some of the carbohydrate (approximately 10% of total calories) in the DASH diet with either protein or monounsaturated fat achieved the best reduction in blood pressure and blood cholesterol (Appel et al, 2005; Miller et al, 2006). This could be achieved by substituting nuts for some of the fruit, bread, or cereal servings.

Because many hypertensive patients are overweight, hypocaloric versions of the DASH diet also have been tested for efficacy in promoting weight loss and blood pressure reduction. A hypocaloric DASH diet versus a low-calorie, low-fat diet produces a greater reduction in SBP and DBP. More recently, the ENCORE study showed that the addition of exercise and weight loss to the DASH diet resulted in greater blood pressure reductions, greater improvements in vascular function, and reduced left ventricular mass compared with the DASH diet alone (Hinderliter et al, 2014).

The MeD dietary pattern has many similarities to the DASH diet but is generally higher in fat, primarily MUFA from olive oil, nuts, and seeds. A traditional MeD diet also contains fatty fish rich in omega-3 fatty acids. A recent systematic review of the MeD diet and CVD risk factors, found that although limited, evidence from RCTs was suggestive of a blood-pressure lowering effect of this style dietary pattern in adults with hypertension (Rees et al, 2013). According to the ACC/AHA (Eckel et al, 2013), more studies on diverse populations are warranted before recommendations can be made related to the MeD diet for use in blood pressure management.

Weight Reduction

There is a strong association between BMI and hypertension among men and women in all race or ethnic groups and in most age groups. It is estimated that at least 75% of the incidence of hypertension is related directly to obesity (AHA, 2013). Weight gain during adult life is responsible for much of the rise in blood pressure seen with aging.

Some of the physiologic changes proposed to explain the relationship between excess body fat and blood pressure are overactivation of the SNS and RAS and vascular inflammation (Mathieu et al, 2009). Visceral fat in particular promotes vascular inflammation by inducing cytokine release, proinflammatory transcription factors, and adhesion molecules (Savoia et al, 2011). Low-grade inflammation occurs in the vasculature of individuals with elevated blood pressure; whether it precedes the onset of hypertension is unclear. Weight loss, exercise, and a MeD-style diet are beneficial. Also see Appendix 31.

Virtually all clinical trials on weight reduction and blood pressure support the efficacy of weight loss on lowering blood pressure. Reductions in blood pressure can occur without attainment of desirable body weight in most participants. Larger blood pressure reductions are achieved in participants who lost more weight and were also taking antihypertensive medications. This latter finding suggests a possible synergistic effect between weight loss and drug therapy. Although weight reduction and maintenance of a healthy body weight is a major effort, interventions to prevent weight gain are needed before midlife. In addition, BMI is recommended as a screening tool in adolescence for future health risk.

Sodium

Evidence from a variety of studies supports lowering blood pressure and CVD risk by reducing dietary sodium. For example, in the Trials of Hypertension Prevention more than 2400 individuals with moderately elevated blood pressure were assigned randomly to either cut their sodium by 750 to 1000 mg per day or to follow general guidelines for healthy eating for 18 months to 4 years. In 10 to 15 years after the studies ended, individuals who cut their sodium experienced a 25% to 30% lower risk of heart attacks, strokes, or other cardiovascular events compared with the group that did not (Cook et al, 2007). A recent meta-analysis of 37 RCTs confirmed these positive effects of sodium reduction on blood pressure and cardiovascular outcomes for normotensive and hypertensive individuals (Aburto et al, 2013).

The DASH sodium trials tested the effects of three different levels of sodium intake (1500 mg, 2400 mg, and 3300 mg/day) combined with either a typical U.S. diet or the DASH diet in persons with prehypertension or stage 1 hypertension (Appel et al, 2006). The lowest blood pressures were achieved by those eating the 1500-mg sodium level in the DASH diet. In the DASH diet and the typical American diet groups, the lower the sodium, the lower the blood pressure. Such data provide the basis for the 2013 ACC/AHA (Eckel et al, 2013) sodium guideline for adults with elevated blood pressure to consume no more than 2400mg/day. For those with normal blood pressure, the Dietary Guidelines for Americans recommend an intake of less than 2300 mg of sodium, the equivalent of 6 g of salt, each day (USDA, 2015). This goal is supported by the AND Practice Guidelines (AND, 2009) and other organizations.

Some experts, including the AHA, have suggested that all individuals should aim for the lower level of 1500 mg of sodium per day, the amount considered optimal for at-risk individuals but thought to be beneficial for all. In a recent report, *Sodium Intake in Populations: Assessment of Evidence*, the Institute of Medicine (IOM, 2013) systematically reviewed the effects of sodium on clinical events, rather than blood pressure as the end point. The IOM concluded that there was insufficient evidence of benefit in the general U.S. population and some evidence suggesting risk of adverse outcomes in specific populations (specifically those with mid-to-late stage heart failure receiving aggressive medical therapy) associated with sodium intake less than 2300 mg per day. Further research is needed, the IOM concluded, on associations between lower levels of sodium (between 1500 and 2300 mg/day range) and health outcomes. Nevertheless, the 2013 guidelines from the ACC/AHA advocate for sodium reduction to 1500 mg/day in at-risk adults based on evidence of improved blood pressure reduction (Eckel et al, 2013).

There is agreement that some persons with hypertension show a greater decrease in their blood pressures in response to reduced sodium intake than others. The term salt-sensitive hypertension has been used to identify these individuals. Salt-resistant hypertension refers to individuals with hypertension whose blood pressures do not change significantly with lowered salt intakes. Salt sensitivity varies, with individuals having greater or lesser degrees of blood pressure reduction. In general, individuals who are more sensitive to the effects of salt and sodium tend to be individuals who are black, obese, and middle-aged or older, especially if they have diabetes, chronic kidney disease, or hypertension. Currently, there are no clinical tests methods for identifying the salt-sensitive individual from the salt-resistant individual.

Calcium and Vitamin D

Higher dairy versus supplemental calcium is associated with lower risk of hypertension (van Mierlo et al, 2008). In particular, low-fat dairy intake reduced the risk of hypertension by 13%, whereas supplemental calcium intake and high fat dairy sources had no effect. At least 2.5 servings of low-fat dairy per day are necessary for blood pressure improvement (Rice et al, 2013). Mechanistically, dairy intake, a major source of dietary calcium, potentiates an increase in intracellular calcium concentration. This in turn increases 1, 25-vitamin D₃ and parathyroid hormone levels, causing calcium influx into vascular smooth muscle cells and greater vascular resistance (Kris-Etherton et al, 2009). Alternatively, peptides derived from milk proteins, especially fermented milk products, may function as ACEs, thereby lowering blood pressure (Qin et al, 2009). The DASH trial found that 8-week consumption of a diet high in fruits, vegetables, and fiber; three servings of low-fat dairy products/day; and lower total and saturated fat could lower SBP by 5.5 mm Hg and DBP by 3 mm Hg further than the control diet. The fruit and vegetable diet without dairy foods resulted in blood pressure reductions approximately half that of the DASH diet. The AND Practice Guidelines recommend a diet rich in fruits, vegetables, and low-fat dairy products (versus calcium supplements) for the prevention and management of elevated blood pressure (AND, 2009). An intake of dietary calcium to meet the DRI is recommended.

Cross-sectional studies suggests lower 25-hydroxy vitamin D (25(OH)D) levels are associated with higher blood pressure levels (Fraser et al, 2010) and higher rates of incident hypertension (Kunutsor et al, 2013). Mechanistically, vitamin D has been shown to improve endothelial function, reduce RAS activity, and lower PTH levels. However, recent evidence suggests that supplementation with vitamin D is not effective as a blood pressure lowering agent and therefore is not recommended as an antihypertension agent (Beveridge, 2015).

Magnesium

Magnesium is a potent inhibitor of vascular smooth-muscle contraction and may play a role in blood pressure regulation as a vasodilator. High dietary magnesium often is correlated with lower blood pressure (Sontia and Touyz, 2007). Trials of magnesium supplementation have shown decreases in SBP of 3 to 4 mm Hg and DBP of 2 to 3 mm Hg with greater dose-dependent effects at supplementation of at least 370 mg/day (Kupetsky-Rincon and Utto, 2012). The DASH dietary pattern emphasizes foods rich in magnesium, including green leafy vegetables, nuts, and whole-grain breads and cereals. Overall food sources of magnesium rather than supplemental doses of the nutrient are encouraged to prevent or control hypertension (AND, 2009).

Potassium

Supplemental doses of potassium in the range of 1900 to 4700 mg/day lower blood pressure approximately 2 to 6 mm Hg DBP and 2 to 4 mm Hg SBP (Dickinson et al, 2006). The effects of potassium are greater in those with higher initial blood pressure, in blacks compared with whites, and in those with higher intakes of sodium. Higher potassium intake also is associated with a lower risk of stroke (Aburto et al, 2013). Although the mechanism by which potassium lowers blood pressure is uncertain, several potential explanations have been offered, including decreased vascular smooth muscle contraction by altering membrane potential or restoring endothelium-dependent vasodilation (Bazzano et al, 2013). Failure of the kidney to adapt

to a diet lower in potassium has been linked to sodium-sensitive hypertension.

The large number of fruits and vegetables recommended in the DASH diet makes it easy to meet the dietary potassium recommendations—approximately 4.7 g/day (AND, 2009). In individuals with medical conditions that could impair potassium excretion (e.g., chronic renal failure, diabetes, and congestive HF), a lower potassium intake (less than 4.7 g/day) is appropriate to prevent hyperkalemia. See Appendix 51.

Physical Activity

Less active persons are 30% to 50% more likely to develop hypertension than their active counterparts. Despite the benefits of activity and exercise in reducing disease, many Americans remain inactive. Hispanics (33% men, 40% women), African Americans (27% men, 34% women), and Caucasians (18% men, 22% women) all have a high prevalence of sedentary lifestyles (AHA, 2013). Exercise is beneficial to blood pressure. Increasing the amount of moderate-intensity physical activity to a minimum of 40 minutes on 3 to 4 days per week is an important adjunct to other blood pressure-lowering strategies (Eckel et al, 2013).

Alcohol Consumption

Excessive alcohol consumption is responsible for 5% to 7% of the hypertension in the population (Appel and American Society of Hypertension Writing Group, 2009). A three drink per day amount (a total of 3 oz of alcohol) is the threshold for raising blood pressure and is associated with a 3-mm Hg rise in SBP. For preventing high blood pressure, alcohol intake should be limited to no more than two drinks per day (24 oz of beer, 10 oz of wine, or 2 oz of 80-proof whiskey) in men, and no more than one drink a day is recommended for lighter-weight men and for women.

Medical Management

The goal of hypertension management is to reduce morbidity and mortality from stroke, hypertension-associated heart disease, and renal disease. The three objectives for evaluating patients with hypertension are to (1) identify the possible causes, (2) assess the presence or absence of target organ disease and clinical CVD, and (3) identify other CVD risk factors that help guide treatment. The presence of risk factors and target organ damage determines treatment priority.

Lifestyle modifications are definitive therapy for some and adjunctive therapy for all persons with hypertension. Several months of compliant lifestyle modifications should be tried before drug therapy is initiated. An algorithm for treatment of hypertension is shown in Figure 33-9. Even if lifestyle modifications cannot completely correct blood pressure, these approaches help increase the efficacy of pharmacologic agents and improve other CVD risk factors. Management of hypertension requires a lifelong commitment.

Pharmacologic therapy is necessary for many individuals with hypertension, especially if blood pressure remains elevated after 6 to 12 months of lifestyle changes. The blood pressure target for initiating pharmacologic treatment is 140/90 mm Hg in adults with diabetes, kidney disease, and in the general population of 60 years of age or less to reduce risk of stroke, heart failure, and ASCVD. For individuals more than 60 years of age, the blood pressure target is 150/90 mm Hg because additional health benefits in lowering blood pressure further have not been demonstrated (James et al, 2014). Most patients with

hypertension more severe than stage 1 hypertension require drug treatment; however, lifestyle modifications remain a part of therapy in conjunction with medications. Recommended pharmacologic treatment includes thiazide-type diuretics, calcium channel blockers (CCB), angiotensin-converting enzyme inhibitors (ACEI), or angiotensin receptor blockers (ARB). Thiazide-type diuretics and CCBs are recommended in black populations, including those with diabetes, because they have been shown to be more effective in improving CVD outcomes compare to other classes of medications (James et al, 2014). All these drugs can affect nutrition status (see Chapter 8).

Diuretics lower blood pressure in some patients by promoting volume depletion and sodium loss. At high doses other water-soluble nutrients are also lost and may have to be supplemented. Thiazide diuretics increase urinary potassium excretion, especially in the presence of a high salt intake, thus leading to potassium loss and possible hypokalemia. Except in the case of a potassium-sparing diuretic such as spironolactone or triamterene, additional potassium usually is required. Grapefruits and grapefruit juice can affect the action of many of the calcium channel blockers and should not be consumed while taking the medication.

A number of medications either raise blood pressure or interfere with the effectiveness of antihypertensive drugs. These include oral contraceptives, steroids, nonsteroidal anti-inflammatory drugs, nasal decongestants and other cold remedies, appetite suppressants, cyclosporine, tricyclic antidepressants, and monoamine-oxidase inhibitors (see Chapter 8 and Appendix 23).

In addition to standard, conventional medical care, more than 1/3 of Americans also use complementary approaches and this includes treatment of hypertension. Table 33-4 lists some that are most common.

Medical Nutrition Therapy

The appropriate course of nutrition therapy for managing hypertension should be guided by data from a detailed nutrition assessment. Weight history; leisure-time physical activity; and assessment of intake of sodium, alcohol, fat type (e.g., MUFA versus SFA), and other dietary patterns (e.g., intake of fruits, vegetables, and low-fat dairy products) are essential components of the medical and diet history. Nutrition assessment should include evaluation of the individual in the following specific domains to determine nutrition problems and diagnoses: food and nutrient intake; knowledge, beliefs, and attitudes; behavior; physical activity and function; and appropriate biochemical data. Following are the components of the current recommendations for managing elevated blood pressure.

Energy Intake

For each kilogram of weight lost, reductions in SBP and DBP of approximately 1 mm Hg are expected. Hypertensive patients who weigh more than 115% of ideal body weight should be placed on an individualized weight-reduction program that focuses on hypocaloric dietary intake and exercise (see Chapter 21). A modest caloric reduction is associated with a significant lowering of SBP and DBP, and LDL cholesterol levels. Hypocaloric diets that include a low-sodium DASH dietary pattern have produced more significant blood pressure reductions than low-calorie diets emphasizing only low-fat foods. Another benefit of weight loss on blood pressure is the synergistic effect with drug therapy. Weight loss should be an adjunct to drug therapy because it may decrease the dose or number of drugs necessary to control blood pressure.

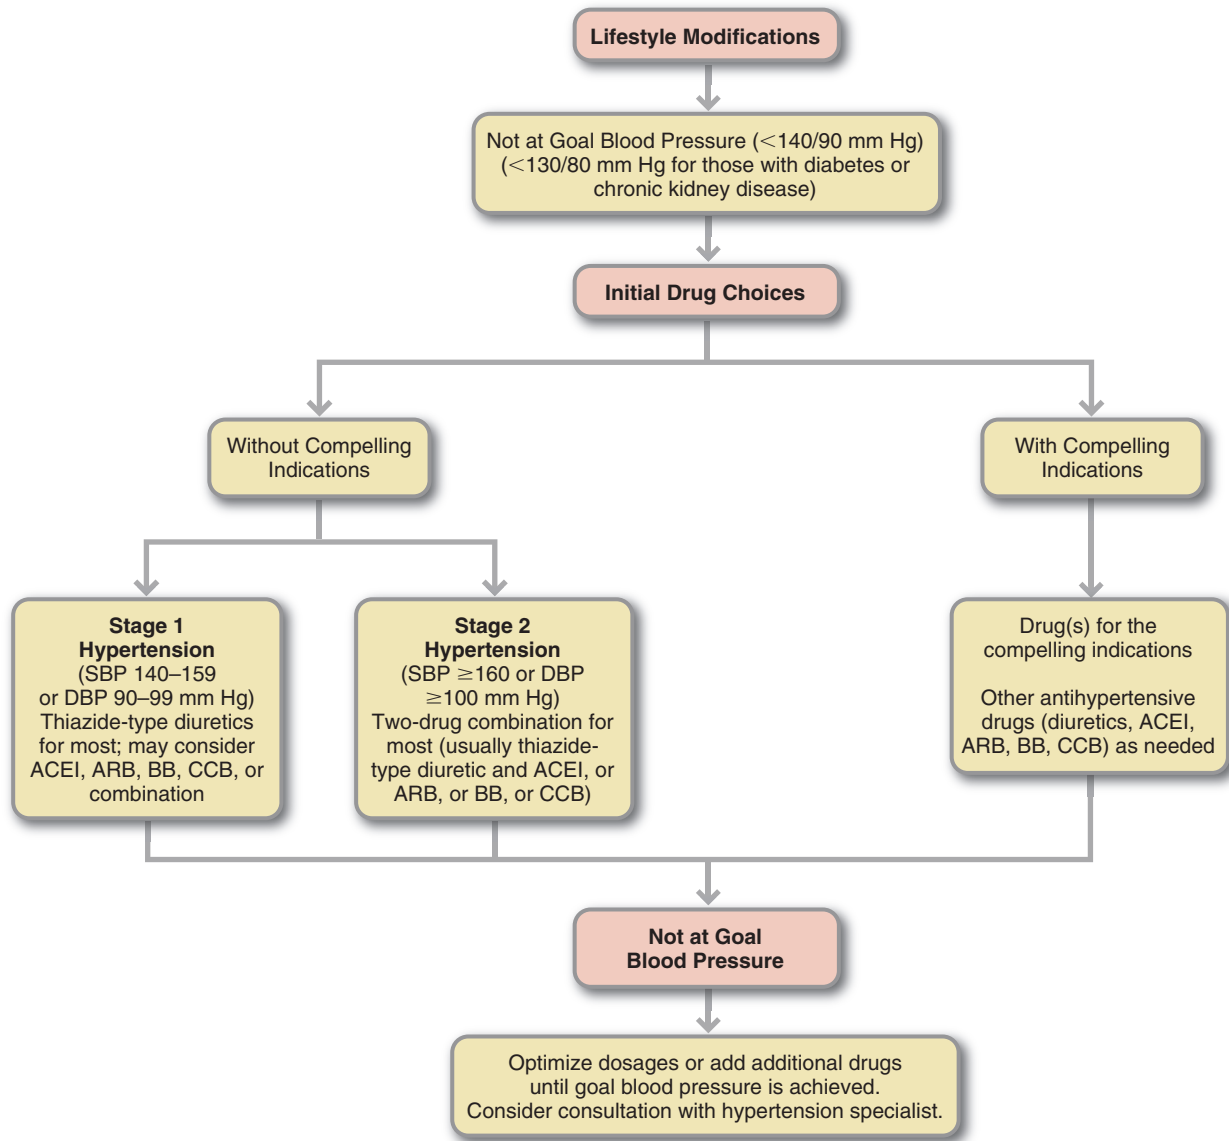

FIGURE 33-9 Algorithm for treatment of hypertension. *ACEI*, Angiotensin-converting enzyme inhibitor; *ARB*, angiotensin-receptor blocker; *BB*, beta-blocker; *CCB*, calcium channel blocker; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure. (From National Institutes of Health, National Heart, Lung and Blood Institute National High Blood Pressure Education Program: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, NIH Publication No. 04-5230, August 2004.)

DASH Diet

The DASH diet is used for preventing and controlling high blood pressure (see Appendix 26). Successful adoption of this diet requires many behavioral changes: eating twice the average number of daily servings of fruits, vegetables, and dairy products; limiting by one third the usual intake of beef, pork, and ham; eating half the typical amounts of fats, oils, and salad dressings; and eating one quarter the number of snacks and sweets. Lactose-intolerant persons may need to incorporate lactase enzyme or use other strategies to replace milk. Assessing patients' readiness to change and engaging patients in problem solving, decision making, and goal setting are behavioral strategies that may improve adherence (Appel et al, 2006).

The high number of fruits and vegetables consumed on the DASH diet is a marked change from typical patterns of Americans. To achieve the 8 to 10 servings, two to three fruits and vegetables should be consumed at each meal. Importantly, because the DASH diet is high in fiber, gradual increases in fruit, vegetables, and whole-grain foods should be made over time. Eight to 10 cups of fluids daily should be encouraged. Slow changes can reduce potential short-term gastrointestinal disturbances associated with a high-fiber diet, such as bloating and diarrhea. The DASH pattern is advocated in the 2013 ACC/AHA nutrition guidelines on lifestyle management to reduce CVD risk (Eckel et al, 2013). Servings for different calorie levels are shown in Appendix 26.

TABLE 33-4 Complementary and Alternative Approaches to Lowering Blood Pressure

Common Name	Scientific Name	Effect on BP and Mechanism of Action	Side Effects and Risks
Coenzyme Q ₁₀	Ubiquinone	Decreases SBP and DBP via a direct effect on the vascular endothelium and smooth muscle	May cause gastrointestinal discomfort, nausea, flatulence, and headaches
Vitamin C and vitamin E taken in combination as supplement	Ascorbic acid α-tocopherol	Decreases SBP and DBP, decreases arterial stiffness, and improves endothelial function by improving antioxidant status	Vitamin E supplementation alone may increase BP
Vitamin D	1,25-dihydroxy vitamin D ₃	Decreases SBP via suppression of renin expression and vascular smooth muscle cell proliferation	Hypercalcemia may occur depending on level of supplementation
Fish oil	Omega-3 polyunsaturated fatty acid	At very high doses in hypertensive individuals, SBP and DBP reductions may occur by increasing the endothelium-dependent vasodilatory response; it may also increase the bioavailability of NO in the vascular wall	May cause gastrointestinal discomfort, belching, bad breath, and altered taste
Garlic	<i>Allium sativum</i>	Reduces SBP and DBP in individuals with hypertension via vasodilation resulting from activation of potassium channels; may also be due to activation of NOS	May cause bad breath and body odor
Resveratrol	Trans-3,4',5-trihydroxystilbene	Reduces systolic BP in animals via enhanced NOS expression in the aorta	Unknown
Mistletoe	<i>Viscum album</i>	Reduces systolic BP in animals via a sympathetic mechanism	Unknown
Hawthorn berry	<i>Crataegus oxycantha</i> , <i>Crataegus monogyna</i>	Exerts a mild, gradual BP lowering effect. The mechanism is unclear	Unknown
Mulberry	<i>Morus alba</i>	Reduces SBP and DBP in animals; the mechanism is unclear	Unknown
Roselle	<i>Hibiscus sabdariffa</i>	Lowers SBP in pre- and mildly hypertensive adults via calcium channel activation	None
Dogbane plant	<i>Rauwolfia serpentine</i>	Reduces SBP by depleting catecholamines and serotonin from central and peripheral synapses	None
Quercetin	3,3',4',5,7-pentahydroxyflavone	Reduced SBP via a direct vasodilator effect; also may cause an increase in the bioavailability and biologic activity of NO	May cause joint discomfort with long-term use and gastrointestinal upset unless taken with meals. May increase estradiol and reduce the effectiveness of other forms of estrogen

Salt Restriction

The Dietary Guidelines for Americans recommend that young adults consume less than 2300 mg of sodium per day. To lower blood pressure, people with hypertension, African Americans, and middle-aged and elderly people—almost half the population—should heed this advice (Eckel, 2013). Although further blood pressure improvements may be achieved by reducing sodium to 1500 mg/day (Appel et al, 2006), patients with heart failure should be cautioned against use of this dietary approach because adverse health effects of very low sodium diets in these patients have been reported (IOM, 2013). Adherence to diets containing less than 2 g/day of sodium is very difficult to achieve.

In addition to advice to select minimally processed foods, dietary counseling should include instruction on reading food labels for sodium content, avoidance of discretionary salt in cooking or meal preparation (1 tsp salt = 2400 mg sodium), and use of alternative flavorings to satisfy individual taste. The DASH eating plan is rich in fruits and vegetables, which are naturally lower in sodium than many other foods.

Because most dietary salt comes from processed foods and eating out, changes in food preparation and processing can help patients reach the sodium goal. Sensory studies show that commercial processing could develop and revise recipes using lower sodium concentrations and reduce added sodium without affecting consumer acceptance. The food industry is embarking on efforts to reduce sodium in the American diet (see *Focus On: Sodium and the Food Industry*).

FOCUS ON

Sodium and the Food Industry

Most foods sold in supermarkets and restaurants are high in salt. The dramatic differences in sodium from brand to brand suggest that many companies could easily achieve significant reductions without sacrificing taste. According to the Center for Science in the Public Interest (Liebman, 2014), processed foods and restaurant foods contribute approximately 80% of the sodium in Americans' diets; 10% comes from salt added during cooking at home or at the table; the remaining 10% is naturally occurring. Americans now consume approximately 4000 mg of sodium per day—about twice the recommended amount. To help address this problem, the National Academy of Science and Institute of Medicine (2010) issued a report calling for urgent government action to reduce salt in packaged and restaurant foods. The report recommends five strategies to reduce sodium levels in America's food supply. The primary strategy is to set a mandatory national sodium level standard for foods. The interim strategy is voluntary reduction of sodium content in foods by food manufacturers. Supporting strategies are for government agencies, public health and consumer organizations, and the food industry to administer activities to support the reduction of sodium in the food supply and consumers' intake of sodium. An interim investigation of sodium changes made to a representative sample of foods in 2013 suggests an absence of any statistically significant changes in sodium content of the food supply over 6 years (Jacobson et al, 2013). The authors suggest that voluntary action by the food industry has not produced the results that were expected and that stronger action on the part of the FDA is required to reduce the sodium content of packaged and restaurant foods.

Potassium-Calcium-Magnesium

Consuming a diet rich in potassium may lower blood pressure and blunt the effects of salt on blood pressure in some individuals (Appel et al, 2006). The recommended intake of potassium for adults is 4.7 g/day (IOM, 2004). Potassium-rich fruits and vegetables include leafy green vegetables, fruits, and root vegetables. Examples of such foods include oranges, beet greens, white beans, spinach, bananas, and sweet potatoes. Although meat, milk, and cereal products contain potassium, the potassium from these sources is not as well absorbed as that from fruits and vegetables (USDA, 2010).

Increased intakes of calcium and magnesium may have blood pressure benefits, although there are not enough data to support a specific recommendation for increasing levels of intake (AND, 2009). Rather, recommendations suggest meeting the AI intake for calcium and the recommended dietary allowance for magnesium from food sources rather than supplements. The DASH diet plan encourages foods that would be good sources of both nutrients, including low-fat dairy products, dark green leafy vegetables, beans, and nuts.

Lipids

Current recommendations for lipid composition of the diet are recommended to help control weight and decrease the risk of CVD. Omega-3 fatty acids are not highlighted in blood pressure treatment guidelines (AND, 2009), although intakes of fish oils exceeding 2 g/day may have blood pressure benefits.

Alcohol

The diet history should contain information about alcohol consumption. Alcohol intake should be limited to no more than two drinks daily in men, which is equivalent to 2 oz of 80-proof whiskey, 10 oz of wine, or 24 oz of beer. Women or lighter-weight men should consume half this amount.

Exercise

Moderate to-vigorous aerobic activity such as brisk walking done at least three to four times per week, lasting on average 40 minutes per session, is recommended as an adjunct therapy in hypertension management (Eckel et al, 2013). Because exercise is associated strongly with success in weight-reduction and weight-maintenance programs, any increase in activity level should be encouraged for those trying to lose weight. For substantial health benefits, the dietary guidelines recommends at least 2 hours and 30 minutes a week of moderate-intensity physical activity as well as muscle-strengthening activities that include all major muscle groups on 2 or more days for all Americans (USDA, 2010).

Treatment of Hypertension in Children and Adolescents

The prevalence of primary hypertension among children in the United States is increasing in concert with rising obesity rates and increased intakes of high-calorie, high-salt foods (Flynn, 2013). Hypertension tracks into adulthood and has been linked with carotid intimal-medial thickness, LVH, and fibrotic plaque formation. Secondary hypertension is more common in preadolescent children, mostly from renal disease; primary hypertension caused by obesity or a family history of hypertension is more common in adolescents (Miller and Joye Woodward, 2014). In addition, intrauterine

growth retardation leads to hypertension in childhood (Longo et al, 2013).

High blood pressure in youth is based on a normative distribution of blood pressure in healthy children. Hypertension is defined as an SBP or DBP of greater than the 95th percentile for age, sex, and height. The designation for prehypertension in children is SBP or DBP of greater than the 90th percentile. Therapeutic lifestyle changes are recommended as an initial treatment strategy for children and adolescents with prehypertension or hypertension. These lifestyle modifications include regular physical activity, avoiding excess weight gain, limiting sodium, and consuming a DASH-type diet.

Weight reduction is considered the primary therapy for obesity-related hypertension in children and adolescents. Unfortunately, sustained weight loss is difficult to achieve in this age group. The Framingham Children's Study showed that children with higher intakes of fruits, vegetables (a combination of four or more servings per day), and dairy products (two or more servings per day) had lower SBP compared with those with lower intakes of these foods. Couch and colleagues (2008) showed that adolescents with prehypertension and hypertension could achieve a significant reduction in SBP in response to a behaviorally oriented nutrition intervention emphasizing the DASH diet. Because adherence to dietary interventions may be particularly challenging among children and teenagers, innovative nutrition intervention approaches that address the unique needs and circumstances of this age group are important considerations in intervention design (see Chapters 17 and 18).

Treatment of Blood Pressure in Older Adults

More than half of the older population has hypertension; this is not a normal consequence of aging. The lifestyle modifications discussed previously are the first step in treatment of older adults, as with younger populations. The Trial of Nonpharmacologic Interventions in the Elderly study found that losing weight (8 to 10 lb) and reducing sodium intake (to 1.8 g/day) can lessen or eliminate the need for drugs in obese, hypertensive older adults. Although losing weight and decreasing sodium in older adults are very effective in lowering blood pressure, knowing how to facilitate these changes and promote adherence remains a challenge for health professionals.

Blood pressure should be controlled regardless of age, initial blood pressure level, or duration of hypertension. Severe sodium restrictions are not adopted because these could lead to volume depletion in older patients with renal damage. Drug treatment in the older adult is supported by very strong data. Additionally, the benefits of treating hypertensive persons age 60 years and older to reach a blood pressure goal of less than 150/90 mm Hg are well supported in the literature (James et al, 2014).

HEART FAILURE

Normally the heart pumps adequate blood to perfuse tissues and meet metabolic needs (see Figure 33-10). In **heart failure (HF)**, formerly called congestive heart failure, the heart cannot provide adequate blood flow to the rest of the body, causing symptoms of fatigue, shortness of breath (**dyspnea**), and fluid retention. Diseases of the heart (valves, muscle, blood

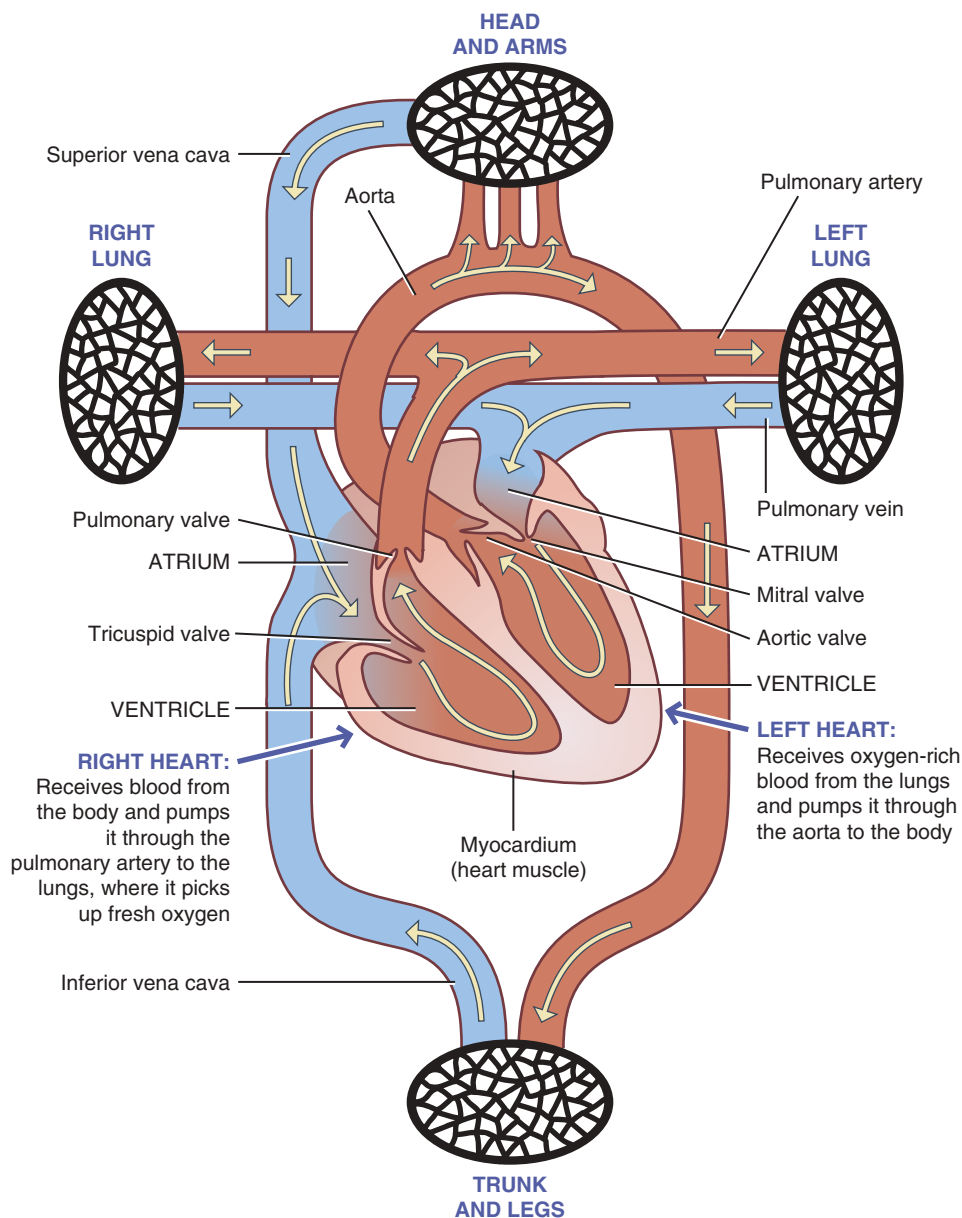

FIGURE 33-10 Structure of the heart pump.

vessels) and vasculature can lead to HF (see *Pathophysiology and Care Management Algorithm: Heart Failure*). HF can be right-sided or left-sided or can affect both sides of the heart. It is further categorized as systolic failure when the heart cannot pump, or eject, blood efficiently out of the heart or diastolic failure, meaning the heart cannot fill with blood as it should.

The lifetime risk of developing HF is 20% for Americans age 40 or older. Approximately 5.1 million in the United States have HF. The incidence increases with age, rising from approximately 20 per 1000 individuals 65 to 69 years to greater than 80 per 1000 in those individuals 85 and older (Stone et al, 2014). Black men have been shown to be at the highest risk of HF; white women have the lowest. HF in non-Hispanic black males and females has a prevalence of 4.5% and 3.8% respectively, versus 2.7% and 1.8% in

non-Hispanic white males and females, respectively (Stone et al, 2014).

Pathophysiology

The progression of HF is similar to that of atherosclerosis because there is an asymptomatic phase when damage is silently occurring (stages A and B) (see Figure 33-11). HF is initiated by damage or stress to the heart muscle either of acute MI or insidious (hemodynamic pressure or volume overloading) onset (see Table 33-5 for classifications of HF).

The progressive insult alters the function and shape of the left ventricle such that it hypertrophies in an effort to sustain blood flow, a process known as cardiac remodeling. Symptoms do not usually arise until months or years after cardiac remodeling begins. Many compensatory mechanisms from the SNS, RAS, and cytokine system are activated to restore

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Heart Failure

ETIOLOGY

PATHOPHYSIOLOGY

Clinical Findings

- Shortness of breath
- Fatigue
- Fluid retention
- Peripheral vasoconstriction
- Elevated B-natriuretic peptide
- Mental confusion
- Memory loss
- Anxiety
- Insomnia
- Syncope and headache
- Dry cough

Nutrition Assessment

- Anorexia
- Nausea, abdominal pain and feeling of fullness
- Constipation
- Malabsorption
- Malnutrition
- Cardiac cachexia
- Hypomagnesemia
- Hyponatremia

MANAGEMENT

Medical Management

- ACE inhibitors
- Angiotensin receptor blockers
- Aldosterone blockers
- β -blockers
- Digoxin
- Vasodilators
- Implantable defibrillator
- Heart transplant

Nutrition Management

- Diet low in saturated fat, *trans* fat
- Restricted sodium diet— <3 gm/day
- Increased use of whole grains, fruits, vegetables
- Limit fluid to 2 L per day
- Lose to or maintain appropriate weight
- Magnesium supplementation
- Thiamin supplementation
- Increase physical activity as tolerated
- Avoid tobacco
- Avoid alcohol

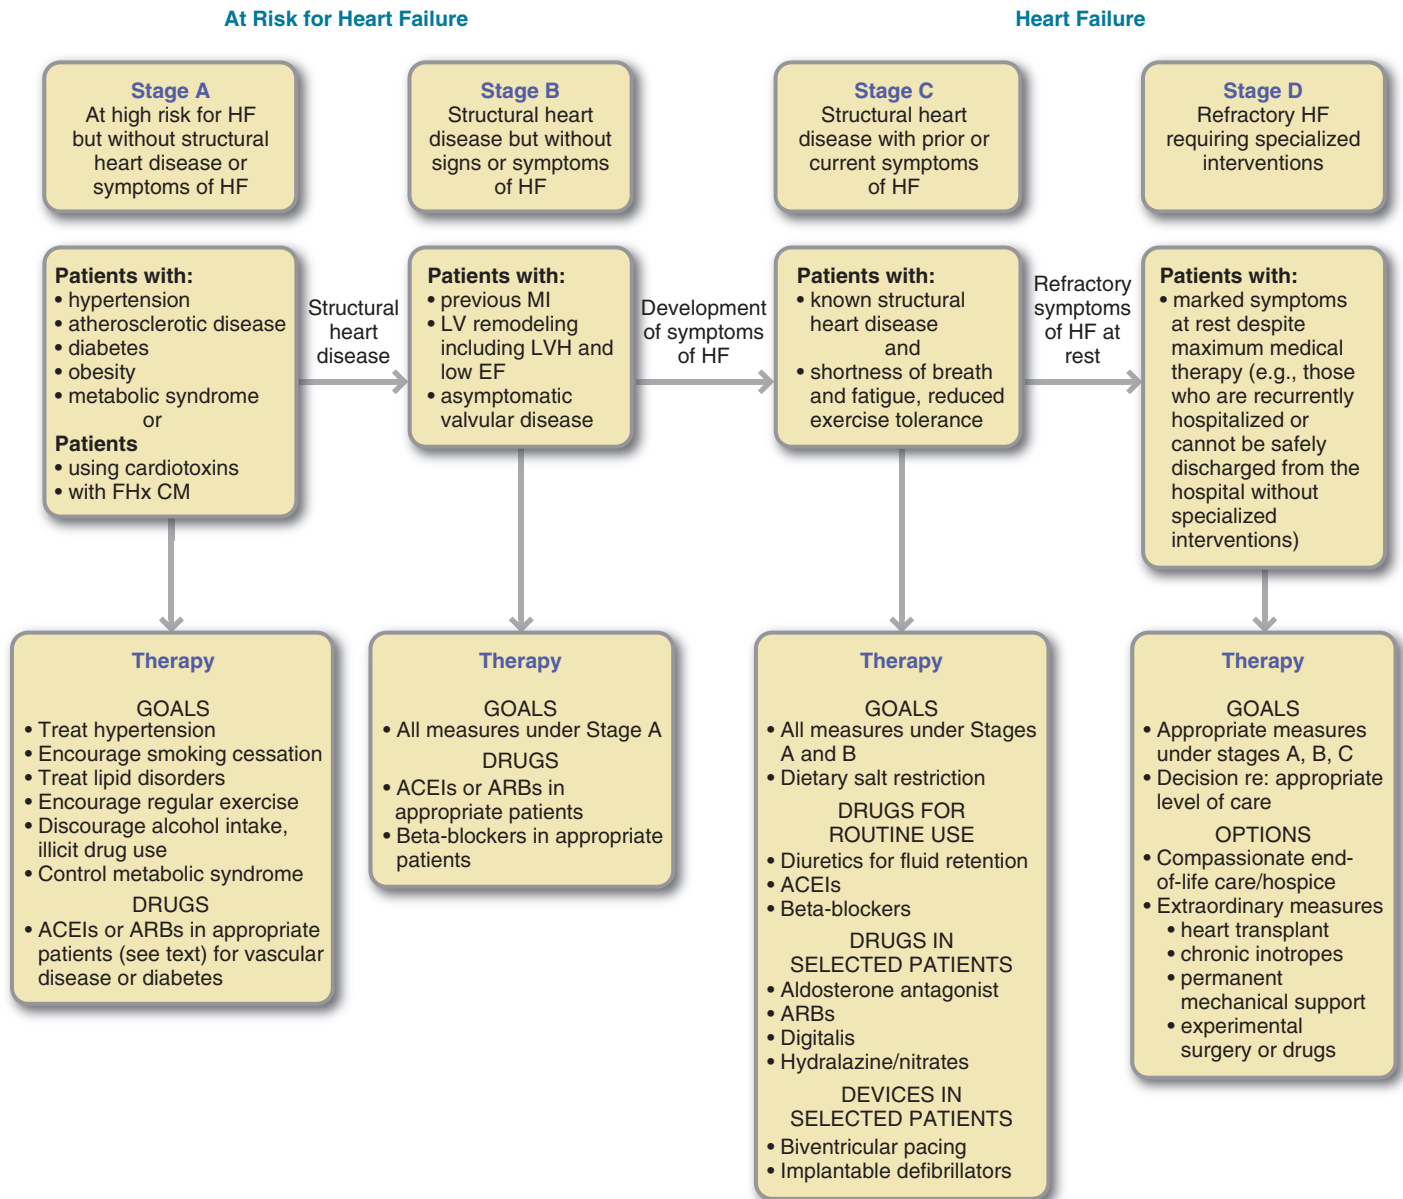

FIGURE 33-11 Stages of heart failure and recommended therapy by stage. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CM, cardiomyopathy; EF, ejection fraction; FHx, family history; HF, heart failure; IV, intravenous; MI, myocardial infarction; LV, left ventricular; LVH, left ventricular hypertrophy. (From Hunt SA et al: ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force, *J Am Coll Cardiol* 46:e1, 2005.)

TABLE 33-5 Classifications of Heart Failure

Class I	No undue symptoms associated with ordinary activity and no limitation of physical activity
Class II	Slight limitation of physical activity; patient comfortable at rest
Class III	Marked limitation of physical activity; patient comfortable at rest
Class IV	Inability to carry out physical activity without discomfort; symptoms of cardiac insufficiency or chest pain at rest

Modified from Hunt SA et al: ACC, AHA, 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines, *J Am Coll Cardiol* 46:e1, 2005.

homeostatic function. Proinflammatory cytokines, such as TNF-alpha, IL-1, and IL-6, are increased in blood and the myocardium and have been found to regulate cardiac remodeling.

Another substance, **B-natriuretic peptide (BNP)**, is secreted by the ventricles in response to pressure and is predictive of the severity of HF and mortality at any level of BMI. BNP is often highly elevated in patients with HF (greater than 100 pg/ml is abnormal, and some patients have levels more than 3000 pg/ml). For every 100 pg/mL rise in BNP concentration, there is a corresponding 35% increase in the relative risk of death (Desai, 2013).

Eventually overuse of compensatory systems leads to further ventricle damage, remodeling, and worsening of symptoms (stage C). HF patients have elevated levels of norepinephrine, angiotensin II, aldosterone, endothelin, and vasopressin; all of these are neurohormonal factors that increase the hemodynamic stress on the ventricle by causing sodium retention and peripheral vasoconstriction. These neurohormones and the proinflammatory cytokines contribute to disease progression; hence, current studies focus on inhibition of these undesirable pathways and promotion of desirable ones.

For the final stages of HF, there is a subjective scale used to classify symptoms based on the degree of limitation in daily activities (see Table 33-6). The severity of symptoms in this classification system is weakly related to the severity of left ventricular dysfunction; therefore treatment encompasses improving functional capacity and lessening progression of the underlying disease.

In HF the heart can compensate for poor cardiac output by (1) increasing the force of contraction, (2) increasing in size, (3) pumping more often, and (4) stimulating the kidneys to conserve sodium and water. For a time this compensation maintains near-normal circulation, but eventually the heart can no longer maintain a normal output (decompensation). Advanced symptoms can develop in weeks or months, and sudden death can occur at any time.

Three symptoms—fatigue, shortness of breath, and fluid retention—are the hallmarks of HF. Shortness of breath on exertion, or effort intolerance, is the earliest symptom. This shortness of breath gets worse and occurs at rest (orthopnea) or at night (paroxysmal nocturnal dyspnea). Fluid retention can manifest as pulmonary congestion or peripheral edema. Evidence of hypoperfusion includes cool forearms and legs, sleepiness, declining serum sodium level caused by fluid overload, and worsening renal function.

Decreased cranial blood supply can lead to mental confusion, memory loss, anxiety, insomnia, syncope (loss of oxygen to the brain causing brief loss of consciousness), and headache. The latter symptoms are more common in older patients and often are the only symptoms; this can lead to a delay in

diagnosis. Often the first symptom in older adults is a dry cough with generalized weakness and anorexia.

Cardiac cachexia is the end result of HF in 10% to 15% of patients. It is defined as involuntary weight loss of at least 6% of nonedematous body weight during a 6-month period (Springer et al, 2006). Unlike normal starvation, which is characterized by adipose tissue loss, this cachexia is characterized by a significant loss of lean body mass. This decrease in lean body mass further exacerbates HF because of the loss of cardiac muscle and the development of a heart that is soft and flabby. In addition, there are structural, circulatory, metabolic, inflammatory, and neuroendocrine changes in the skeletal muscle of patients with HF (Delano and Moldawer, 2006). Differences between younger and older patients are listed in Box 33-7 and Table 33-7.

Cardiac cachexia is a serious complication of HF with a poor prognosis and mortality rate of 50% in 18 months (Carlson and Dahlin, 2014). Symptoms that reflect inadequate blood supply to the abdominal organs include anorexia, nausea, a feeling of fullness, constipation, abdominal pain, malabsorption, hepatomegaly, and liver tenderness. All of these contribute to the high prevalence of malnutrition observed in hospitalized patients with HF. Lack of blood flow to the gut leads to loss of bowel integrity; bacteria and other endotoxins may enter the bloodstream and cause cytokine activation. Proinflammatory cytokines such as TNF-alpha and adiponectin are highest in patients with cardiac cachexia. An increased level of TNF-alpha is associated with a lower BMI, smaller skinfold

TABLE 33-6 Skeletal Muscle Changes in Heart Failure

Function loss	Weakness Fatigability
Structural	Loss of muscle mass Atrophy, fibrosis, no ≠ apoptosis Fiber type switch type I-type IIb Loss of mitochondria

measurements, and decreased plasma total protein levels, indicative of a catabolic state.

Adiponectin levels are high in HF and are a marker for wasting and a predictor of mortality. As with TNF-alpha, adiponectin levels also are correlated inversely with BMI. Pharmacological treatments for muscle wasting are being explored.

Risk Factors

The Framingham Study (see *Focus On: Framingham Heart Study*) showed the risk factors for HF were hypertension, diabetes, ASCVD, and **left ventricular hypertrophy (LVH)** (enlargement of the left ventricle of the heart). Antecedent hypertension is present in about three fourths of HF patients. Individuals who have diabetes mellitus and ischemic heart disease more frequently develop HF compared with patients without diabetes (Rosano et al, 2006). Diabetes is an especially strong risk factor for HF in women. The prevalence of hypertension and diabetes increases with age, making the elderly particularly vulnerable to HF. Another large cohort study of older adults (70 to 79 years) showed that waist circumference and percentage of body fat were the strongest predictors of who would develop HF (Nicklas et al, 2006). Numerous changes in cardiovascular structure and function also place the elderly at high risk for developing HF (see Box 33-7).

Prevention

Because long-term survival rates for persons with HF are low, prevention is critical. HF is categorized into four stages ranging from persons with risk factors (stage A—primary prevention) to persons with advanced HF (stage D—severe disease). For stages A and B the aggressive treatment of underlying risk factors and diseases such as dyslipidemia, hypertension, and diabetes is critical to prevent structural damage to the myocardium and the appearance of HF symptoms. Such prevention has been very effective. Even patients who experience an MI can reduce the risk of HF with antihypertensive therapy. Patients are often asymptomatic during these two stages.

For stages C and D, secondary prevention strategies to prevent further cardiac dysfunction are warranted. These strategies include the use of ACE inhibitors (first line of therapy), angiotensin receptor blockers, aldosterone blockers, beta-blockers, and digoxin. Early detection, correction of asymptomatic left ventricular dysfunction, and aggressive management of risk factors are needed to lower the incidence and mortality of HF.

Medical Management

Therapy recommendations correspond to the stage of HF. For patients at high risk of developing HF (stage A), treatment of the underlying conditions (hypertension, dyslipidemia, thyroid disorders, arrhythmias), avoidance of high-risk behaviors (tobacco, excessive alcohol, illicit drug use), and lifestyle changes (weight reduction, exercise, reduction of sodium intake, heart-healthy diet) are recommended. All these recommendations are carried through the other stages. In addition, an implantable defibrillator, which shocks the heart when it stops, can be placed in patients at risk of sudden death. Pharmacologic treatment of HF is the hallmark of therapy with progressive stages.

The last stage also includes surgically implanted ventricular-assist devices, heart transplantation, and continual intravenous therapy.

The short-term goals for the treatment of HF are to relieve symptoms, improve the quality of life, and reduce depression if it is present. The long-term goal of treatment is to prolong life by lessening, stopping, or reversing left ventricular dysfunction. Medical management is tailored to clinical and hemodynamic profiles with evidence of hypoperfusion and congestion. In some cases, surgical procedures are needed to alleviate the HF caused by valvular disease; medical management is limited in these instances.

Standard fluid restrictions are to limit total fluid intake to 2 L (2000 ml) daily. When patients are severely decompensated, a more restrictive fluid intake (1000 to 1500 ml daily) may be warranted for adequate diuresis. A sodium-restricted diet should be maintained despite low-sodium blood levels because in this case the sodium has shifted from the blood to the tissues. Serum sodium appears low in a patient who is fluid overloaded because of dilution; diuresis improves the levels by decreasing the amount of water in the vascular space.

An ACE inhibitor is the first line of pharmacologic treatment for HF. As the stages progress, a beta-blocker or angiotensin receptor blocker may be added. In Stages C and D selected patients also may take a diuretic, aldosterone antagonists, digitalis, and vasodilators (e.g., hydralazine). Basically these medications reduce excess fluid, dilate blood vessels, and increase the strength of the heart's contraction. Several of these medications have neurohormonal benefits along with their primary mechanism of action. For example, ACE inhibitors (e.g., captopril, enalapril) not only inhibit the RAS but also improve symptoms, quality of life, exercise tolerance, and survival. Similarly, spironolactone has diuretic and aldosterone-blocking functions that result in reduced morbidity and mortality in patients. Most of these medications can affect nutrition status (see Chapter 8).

Medical Nutrition Therapy

The RDN provides MNT, which includes assessment, a nutrition diagnosis, and interventions (education, counseling). As part of a multidisciplinary team (physician, pharmacist, psychologist, nurse, and social worker), the RDN positively affects patient outcomes. Reduced readmission to the hospital, fewer days in the hospital, improved compliance with restricted sodium and fluid intakes, and improved quality of life scores are the goals in HF patients.

Nutrition screening for HF in older adults can help prevent disease progression and improve disease management, overall health, and quality-of-life outcomes. The first step in screening is determination of body weight. Altered fluid balance complicates assessment of body weight in the patient with HF. Weights should be taken before eating and after voiding at the same time each day. A dry weight (weight without edema) should be determined on the scale at home. Patients should record daily weights and advise their care providers if weight gain exceeds more than 1 lb a day for patients with severe HF, more than 2 lb a day for patients with moderate HF, and more than 3 to 5 lb with mild HF. Restricting sodium and fluids along with diuretic therapy may restore fluid balance and prevent full-blown HF.

TABLE 33-8 Dietary Sodium Intake in Heart Failure

Guideline	Year	Sodium/Fluid Restriction Recommendations	Level of Evidence
National Heart Foundation of Australia/ Cardiac Society of Australia and New Zealand	2006 ⁷	<3 g/d for NYHA class II without peripheral edema/<2 g/d for NYHA class III and IV	C
Heart Failure Society, India	2007 ⁵	<2 L/d for all patients and <1.5 L/d during fluid retention episodes <2 g/d <2 L/d	Not stated
European Society of Cardiology	2008 ⁵	Moderate restriction 1.5-2 L/d in patients with severe symptoms and especially with hyponatremia	C
Canadian Cardiovascular Society	2008 ⁶	<2 g/d 2 L/d	Not stated
American College of Cardiology/ American Heart Association	2009 ²	Moderate restriction (≤ 2 g/d, if volume overload, followed by fluid intake restriction to 2 L/d if fluid retention persists)	C
Royal College of Physicians	2010 ³	<i>Salt reduction</i> <i>Fluid restriction</i>	Limited; further re- search required
Heart Failure Society of America	2010 ⁸	2-3 g/d; <2 g/d may be considered in moderate to severe heart failure <2 L/d, if fluid retention persists and if severe hyponatremia (serum Na <130 mEq/L) is present	C
Scottish Intercollegiate Guidelines Network	2010 ⁹	<2.4 g/d tailored fluid restriction	1+
American Dietetic Association	2011 ¹⁰	<2 g/d 1.4-1.9 L/d depending on clinical symptoms	Fair

Level of Evidence: C, Limited populations evaluated. Only consensus opinion of experts, case studies, or standard of care; Fair, Benefits exceed the harms but quality of evidence is not as strong; 1+, well-conducted meta-analysis, systemic reviews, or randomized controlled trials with low risk of bias.

Dietary assessments in HF patients reveal that more than half have malnutrition, usually related to the cardiac cachexia mentioned earlier. Negative energy balance and negative nitrogen balances can be noted. In overweight patients, caloric reduction must be monitored carefully to avoid excessive and rapid body protein catabolism. Nutrition education to promote behavior change is a critical component of MNT. The benefits of MNT should be communicated to patients.

The total diet must be addressed in patients with HF because underlying risk factors are often present; dietary changes to modify these risk factors are an important component of MNT. For dyslipidemia or atherosclerosis, a heart-healthy diet low in SFAs, trans fatty acids, and cholesterol and high in fiber, whole grains, fruits, and vegetables is recommended. For persons with hypertension, the DASH diet is recommended. Both of these dietary patterns emphasize lower-sodium foods and higher intake of potassium. Total energy expenditure is higher in HF patients because of the catabolic state, adequate protein and energy should be provided.

Salt Restriction

Excessive sodium intake is associated with fluid retention and edema. A 2-g sodium restriction is regularly prescribed for patients with HF. The AND (2012) evidence analysis library recommends a 2-g sodium restriction but notes that the evidence for this recommendation is only “fair.” The Heart Failure Society of America recommends 2 to 3 g of sodium daily unless severe symptoms are present, then the recommendation is for 2 g (Gupta et al, 2012). The updated AHA recommendation is for “moderate” sodium restriction. Table 33-8 summarizes the recommendations from multiple organizations. The inconsistencies in the different organizations are due to the weak database of studies. Many have small sample sizes and many were not randomized trials. Three of the larger studies that were randomized had consistent results but showed that sodium

restriction was associated with worse outcome (Gupta et al, 2012). It is hypothesized that this effect may be related to neurohormones including aldosterone, norepinephrine, and angiotensin II, all of which increased with dietary restriction. These hormones act to conserve fluid, thus trying to restore blood flow. Aldosterone promotes sodium reabsorption, and vasopressin promotes water conservation in the distal tubules of the nephron. This complex balance is further complicated by the medications used for HF.

Patient compliance with sodium restriction of 2 g/day has been shown to be poor. This can lead to generally inadequate nutritional intake that may be a contributing factor to poor outcomes associated with sodium restriction. A one-size-fits-all sodium restriction is not possible. The HF stage, amount of edema present, overall nutritional status, and medications must be taken into consideration. There is consensus that high sodium intake (above 3 g/day) is contraindicated for HF.

The degree of restriction depends on the individual (see *Focus On: Sodium and Salt Measurement Equivalents*).

FOCUS ON

Sodium and Salt Measurement Equivalents

Sodium chloride is approximately 40% (39.3%) sodium and 60% chloride. To convert a specified weight of sodium chloride to its sodium equivalent, multiply the weight by 0.393. Sodium also is measured in milliequivalents (mEq). To convert milligrams of sodium to mEq, divide by the atomic weight of 23. To convert sodium to sodium chloride (salt), multiply by 2.54. Millimoles (mmol) and milliequivalents (mEq) of sodium are the same. For example:

1 tsp of salt = approximately 6 g NaCl = 6096 mg NaCl
 $6096 \text{ mg NaCl} \times 0.393 = 2396 \text{ mg Na}$ (approximately 2400 mg)
 $2396 \text{ mg Na} / 23 = 104 \text{ mEq Na}$
 1 g Na = $1000 \text{ mg} / 23 = 43 \text{ mEq}$ or mmol
 1 tsp of salt = 2400 mg or 104 mEq Na

Adherence to sodium restrictions can be problematic for many individuals, and individualized instruction is recommended. Ethnic differences in sodium consumption must be considered. Some cultures have traditional diets that are very high in sodium such as Kosher and Asian diets. In some cases regional cooking, like in some areas in the southern United States, depends heavily on salt.

Positive outcomes (i.e., decreased urinary sodium excretion, less fatigue, less frequent edema) have been observed in HF patients receiving MNT. The type of sodium restriction prescribed should be the least restrictive diet that will achieve the desired results. The first step is to minimize or eliminate the use of table salt and high-sodium foods (see Box 33-8) (see Appendix 30 for further explanation of the sodium-restricted diet).

Poor adherence to low-sodium diets occurs in part as a result of lack of knowledge about sodium and lower-sodium food choices by the patient, and perception that the diet interferes with the social aspects of eating. Lack of cooking skills or adequate cooking facilities is another obstacle because it leads patients to eat premade foods that tend to be high in salt. Memory loss, severe fatigue, and economic issues are all challenges to following a low-sodium diet. In addition, food labels, although informative, may be hard for many patients or their caregivers to comprehend (see Box 33-9).

Alcohol

In excess, alcohol contributes to fluid intake and raises blood pressure. Many cardiologists recommend avoiding alcohol. Chronic alcohol ingestion may lead to cardiomyopathy and HF (Li and Ren, 2006). Although heavy drinking should be discouraged, there is no evidence to support total abstinence from alcohol (AND, 2012). Quantity, drinking patterns, and genetic factors influence the relationship between alcohol consumption and HF (Djousse and Gaziano, 2008). If alcohol is consumed, intake should not exceed one drink per day for women and two drinks per day for men. A drink is equivalent to 1 oz of alcohol (1 oz of distilled liquor), 5 oz of wine, or 12 oz of beer.

BOX 33-8 Top Ten Categories of High-Sodium Foods

1. Smoked, processed, or cured meats and fish (e.g., ham, bacon, corned beef, cold cuts, hot dogs, sausage, salt pork, chipped beef, pickled herring, anchovies, tuna, and sardines)
2. Tomato juices and tomato sauce, unless labeled otherwise
3. Meat extracts, bouillon cubes, meat sauces, MSG,* and taco seasoning
4. Salted snacks (potato chips, tortilla chips, corn chips, pretzels, salted nuts, popcorn, and crackers)
5. Prepared salad dressings, condiments, relishes, ketchup, Worcestershire sauce, barbecue sauce, cocktail sauce, teriyaki sauce, soy sauce, commercial salad dressings, salsa, pickles, olives, and sauerkraut
6. Packaged mixes for sauces, gravies, casseroles, and noodle, rice, or potato dishes; macaroni and cheese; stuffing mix
7. Cheeses (processed and cheese spreads)
8. Frozen entrees and pot pies
9. Canned soup
10. Foods eaten away from home

*MSG, Monosodium glutamate.

Note: Reading labels is most important; some brands are lower in sodium than others.

BOX 33-9 Food Labeling Guide for Sodium

Sodium-free	Less than 5 mg per standard serving; cannot contain any sodium chloride
Very low sodium	35 mg or less per standard serving
Low sodium	140 mg or less per standard serving
Reduced sodium	At least 25% less sodium per standard serving than in the regular food
Light in sodium	50% less sodium per standard serving than in the regular food
Unsalted, without added salt, or no salt added	No salt added during processing; the product it resembles is normally processed with salt
Lightly salted	50% less added sodium than is normally added; product must state "not a low-sodium food" if that criterion is not met

Caffeine

Until now caffeine has been considered detrimental to patients with HF because it contributes to irregular heartbeats. However, a study in the Netherlands suggests that moderate intake of either tea or coffee reduces ASCVD risk; tea actually reduces ASCVD deaths (de Konig Gans et al, 2010). Researchers in the United States followed 130,054 men and women and found that those who reported drinking four or more cups of coffee each day had an 18% lower risk of hospitalization for heart rhythm disturbances. Those who reported drinking one to three cups each day had a 7% reduction in risk (Klatsky, 2010). The antioxidant effects of coffee and tea may be beneficial.

Calcium

Patients with HF are at increased risk of developing osteoporosis because of low activity levels, impaired renal function, and prescription drugs that alter calcium metabolism (Zittermann et al, 2006). Cachectic HF patients have lower bone mineral density and lower calcium levels than HF patients without cachexia (Anker et al, 2006). Caution must be used with calcium supplements because they may aggravate cardiac arrhythmias.

L-Arginine

In patients with HF, decreased exercise capacity may be in part due to reduced peripheral blood flow related to impairment of endothelium-dependent vasodilation. L-Arginine is converted to nitric oxide, an endothelium-derived relaxing factor. At least four studies have showed some benefit with supplementation. The studies were small, and more research is needed to establish clear recommendations.

Coenzyme Q₁₀

Some studies on the use of coenzyme Q₁₀ (CoQ₁₀) supplementation in HF patients showed positive outcome. Outcomes included significantly improved exercise tolerance, decreased symptoms, and improved quality of life. CoQ₁₀ levels are generally low in HF patients; it is postulated that repletion can prevent oxidative stress and further myocardial damage. A systematic review of 7 studies and over 900 patients on the use of CoQ₁₀ in HF patients concluded that the studies were too small and too diverse in study design to draw any useful conclusions (Madmani et al, 2014). Patients on statins (HMG-CoA reductase inhibitors) may have a different reason to consider supplementation. HMG-CoA reductase inhibitors are a

class of cholesterol-lowering drugs that are known to interfere with synthesis of CoQ₁₀ (see Chapter 8).

D-Ribose

D-ribose is a component of ATP for cellular metabolism and energy production. Myocardial ischemia lowers cellular energy levels, integrity, and function. The failing heart is energy starved. D-ribose is being tested to correct this deficient cellular energy as a naturally occurring carbohydrate (Shechterle et al, 2010).

Energy

The energy needs of patients with HF depend on their current dry weight, activity restrictions, and the severity of the HF. Overweight patients with limited activity should be encouraged to maintain an appropriate weight that will not stress the myocardium. However, the nutrition status of the obese patient must be assessed to ensure that the patient is not malnourished. In patients with HF, energy needs are unclear. At least two studies found that standard energy equations used to determine calorie needs underestimated the needs of HF patients. Another study found lower calorie needs when compared with healthy controls (AND, 2012). This area requires more research. Standard nutritional assessment should be employed with careful monitoring.

Fats

Fish consumption and fish oils rich in omega-3 fatty acids can lower elevated triglyceride levels and may prevent atrial fibrillation in HF patients (Roth and Harris, 2010). Intake of at least 1 g daily of omega-3 fatty acids from either oily fish or fish-oil supplements was used in the study. However, further studies are needed. Some evidence suggests that high saturated fat feeding in mild to moderate HF preserves contractile function and prevents the switch from fatty acid to glucose metabolism, thus serving a cardioprotective role (Chess et al, 2009; Christopher et al, 2010).

Meal Strategies

Patients with HF often tolerate small, frequent meals better than larger, infrequent meals because the latter are more tiring to consume, can contribute to abdominal distention, and markedly increase oxygen consumption. All these factors tax the already stressed heart. Caloric supplements can help to increase energy intake; however, this intervention may not reverse this form of malnutrition (Anker et al, 2006).

Folate, Vitamin B₆, and Vitamin B₁₂

High dietary intakes of folate and vitamin B₆ have been associated with reduced risk of mortality from HF and stroke in some populations (Cui et al, 2010). However, deficiencies of vitamin B₁₂ and folate have been studied and found to be relatively rare in HF patients (van der Wall et al 2015).

Magnesium

Magnesium deficiency is common in patients with HF as a result of poor dietary intake and the use of diuretics, including furosemide. As with potassium, the diuretics used to treat HF increase magnesium excretion. Magnesium deficiency aggravates changes in electrolyte concentration by causing a positive sodium and negative potassium balance. Because deficient magnesium status is associated with poorer prognosis, blood magnesium levels should be measured in HF patients and treated accordingly. Magnesium supplementation (800 mg/day) produces small improvements in arterial compliance (Fuentes

et al, 2006). Poor dietary intake of magnesium has been associated with elevated CRP, a product of inflammation. Hypermagnesemia may be found in some cases of renal failure, HF, and high doses of furosemide.

Thiamin

Patients with HF are at risk for thiamin deficiency because of poor food intake; use of loop diuretics, which increases excretion; and advanced age. Thiamin is a required coenzyme in the energy-producing reactions that fuel myocardial contraction. Therefore, thiamin deficiency can cause decreased energy and weaker heart contractions. Studies have shown thiamin deficiency to be associated with HF, in great part due to the effect of commonly used medications. Loop diuretics (e.g. furosemide) can deplete body thiamin and cause metabolic acidosis. Supplementation with thiamin has been shown to improve cardiac function, urine output, weight loss and signs and symptoms of HF (DiNicolantonio et al, 2013). Thiamin deficiency is diagnosed using erythrocyte thiamin pyrophosphate. Thiamin status should be assessed in HF patients on loop diuretics and appropriate supplementation recommended if necessary. Thiamin supplementation (e.g., 100 mg/day) can improve left ventricular ejection fraction (fraction of blood pumped out of the ventricles with each heartbeat) and symptoms.

Vitamin D

Patients with a polymorphism of the vitamin D receptor gene have higher rates of bone loss than HF patients without this genotype. Vitamin D may improve inflammation in HF patients (Vieth and Kimball, 2006). In a double-blind, randomized, placebo-controlled trial, supplementation with vitamin D (50 mcg or 2000 international units of vitamin D₃ per day) for 9 months increased the anti-inflammatory cytokine IL-10 and decreased the proinflammatory factors in HF patients (Schleithoff et al, 2006). As a steroid hormone, vitamin D regulates gene expression and inversely regulates renin secretion (Meems et al, 2011). However, it remains unclear if vitamin D supplementation truly is needed in HF patients.

CARDIAC TRANSPLANTATION

Cardiomyopathies represent a heterogeneous group of diseases that often lead to progressive HF; types include dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (Wexler et al, 2009). Cardiac transplantation is the only cure for refractory, end-stage HF. Because the number of donor hearts is limited, careful selection of recipients with consideration of the likelihood for adherence to life-long therapeutic regimen and their quality of life is imperative. Nutrition support before and after transplantation is crucial to decrease morbidity and mortality. Thus the nutrition care of the heart transplant patient can be divided into three phases: pretransplant, immediate posttransplant, and long-term posttransplant.

Pretransplant Medical Nutrition Therapy

A comprehensive nutrition assessment of the pretransplant patient should include a history, physical and anthropometric assessment, and biochemical testing. Recommended lifestyle changes before transplantation include restricting alcohol consumption, losing weight, exercising, quitting smoking, and

eating a low-sodium diet (Wexler et al, 2009). Extremes in body weight (less than 80% or more than 140% of ideal body weight) increase the patient's risk for infection, diabetes, morbidity, and higher mortality. Pretransplant comorbidities such as hyperlipidemia and hypertension also reduce survival rates. If oral intake is inadequate, an enteral feeding should be tailored to the nutritional and comorbid conditions of the patient.

Immediate Posttransplant Nutrition Support

Nutrition guidelines are consistent for all types of organ transplants and not specific just to heart transplants (see Table 33-9). The nutritional goals in the acute posttransplant patient are to (1) provide adequate protein and calories to treat catabolism and promote healing, (2) monitor and correct electrolyte abnormalities, and (3) achieve optimal blood glucose control (Hasse, 2015). In the immediate posttransplant period nutrient needs are increased, as is the case after any major surgery. Protein needs are increased because of steroid-induced catabolism, surgical stress, anabolism, and wound healing.

Patients progress from clear liquids to a soft diet given in small, frequent feedings. Enteral feeding may be appropriate in the short term, especially if complications arise. Nutrient intake is often maintained by using liquid supplements and foods of high caloric density, especially in patients with poor

appetite. Weight gain to an ideal weight is the nutritional goal for patients who were cachectic before transplant. The increase in cardiac function helps to halt the presurgical cachectic state. Hyperglycemia can be exacerbated by the stress of the surgery and the immunosuppressive drug regimen. Dietary adjustments can be made to aid in glucose control (see Table 33-9).

Long-Term Posttransplant Nutrition Support

Comorbid conditions that often occur after transplantation include hypertension, excessive weight gain, hyperlipidemia, osteoporosis, and infection. Hypertension is managed by diet, exercise, and medications. Minimizing excessive weight gain is important because patients who become obese after transplantation are at higher risk for rejection and lower rates of survival.

Increases in total LDL cholesterol and triglycerides are a consequence of immunosuppressive drug therapy and increase the risk of HF after transplantation. Along with a heart-healthy diet, patients also need a lipid-lowering drug regimen to normalize blood lipids. Statins are recommended in the early and long-term postoperative periods. Because of their LDL-lowering effect, statins or sterols may be helpful to reduce statin dosages (Goldberg et al, 2006).

Before transplantation, patients are likely to have osteopenia because of their lack of activity and cardiac cachexia. After transplantation, patients are susceptible to steroid-induced osteoporosis. Patients require optimal calcium and vitamin D intake to slow bone loss; weight-bearing exercise and antiresorptive drug therapy are often necessary. Infection must be avoided because of the necessity of lifelong use of immunosuppressive drugs. Food safety should be discussed.

TABLE 33-9 Posttransplant Nutrient Recommendations

Nutrient	Short-Term Recommendations	Long-Term Recommendations
Calories	120%-140% of BEE (30-35 kcal/kg) or measure REE	Maintenance: 120%-130% BEE (20-30 kcal/kg) depending on activity level
Protein	1.3-2 g/kg/day	1 g/kg/day
Carbohydrate	~50% of calories Restrict simple sugars if glucose level elevated	~50% of calories Restrict simple sugars and encourage high-fiber complex carbohydrate choices
Fat	30% of calories (or higher with severe hyperglycemia)	≤30% of total calories <10% of calories as saturated fat
Calcium	1200 mg/day	1200-1500 mg/day (consider the need for estrogen or vitamin D supplements)
Sodium	2 g/day	2 g/day
Magnesium and phosphorus	Encourage intake of foods high in these nutrients Supplement as needed	Encourage intake of foods high in these nutrients Supplement as needed
Potassium	Supplement or restrict based on serum potassium levels	Supplement or restrict based on serum potassium levels
Other vitamins and minerals	Multivitamin/mineral-supplement to RDI levels May need additional supplements to replete suspected or confirmed deficiencies	Multivitamin/mineral-supplement to RDI levels May need additional supplements to replete suspected or confirmed deficiencies
Other	Avoid complementary or alternative products without proven safety and effectiveness in transplant patients	Avoid complementary or alternative products without proven safety and effectiveness in transplant patients

CLINICAL CASE STUDY

Tom is a 55-year-old single man with hypertension (blood pressure 145/92), high low-density lipoprotein cholesterol (241), and low high-density lipoprotein cholesterol (38) and a CRP of 4mg/L. He has a strong family history of heart disease. He reports that he often eats in his car, so he frequents fast-food restaurants. He works long hours and, other than gardening on the weekends, he does not exercise. He is 5'10" and 220 lb. His breakfast is usually a cheese-egg biscuit, bacon, and coffee without milk or cream. Lunch is often a bean and cheese burrito and ice cream. His favorite dinner is fried chicken, mashed potatoes with gravy, collards sautéed with bacon fat, and pie.

Using the following list, what are Tom's nutritional diagnoses? Which should be the top priority?

Nutrition Diagnostic Term

- Excessive energy intake
- Excessive intake of fats
- Excessive alcohol intake
- Inadequate fiber intake
- Inadequate calcium intake
- Inadequate magnesium intake
- Inadequate potassium intake
- Excessive sodium intake
- Overweight or obesity
- Food- and nutrition-related knowledge deficit
- Undesirable food choices
- Physical inactivity

Nutrition Care Questions

Which interventions would be most beneficial for Tom?
What signs and symptoms would you want to monitor and evaluate?

tuberculosis (TB)

During fetal life, from birth to maturity, and throughout adulthood, the pulmonary system is intertwined with nutrition. Optimal nutrition permits the proper growth and development of the respiratory organs, supporting structures of the skeleton and muscles, and related nervous, circulatory, and immunologic systems. A well-functioning pulmonary system enables the body to obtain the oxygen needed to meet its cellular demands for energy from macronutrients and to remove metabolic byproducts. Overall, a person's nutritional well-being and proper metabolism of nutrients are essential for the formation, development, growth, maturity, and protection of healthy lungs and associated processes throughout life.

THE PULMONARY SYSTEM

The respiratory structures include the nose, pharynx, larynx, trachea, bronchi, bronchioles, alveolar ducts, and alveoli. Supporting structures include the skeleton and the muscles (e.g., the intercostal, abdominal, and diaphragm muscles). Within a month after conception, pulmonary structures are recognizable. The pulmonary system grows and matures during gestation and childhood, and no new alveoli are produced after

approximately age 20 years. As aging occurs, there is a loss of lung capillaries and the lungs lose elasticity.

The primary function of the respiratory system is gas exchange, and the anatomy and physiology is geared to fulfill this function (see [Figure 34-1](#)). The lungs enable the body to obtain the oxygen needed to meet its cellular metabolic demands and to remove the carbon dioxide (CO₂) produced. Healthy nerves, blood, and lymph are needed to supply oxygen and nutrients to all tissues. The lungs also filter, warm, and humidify inspired air.

The respiratory center is the name for structures involved in the generation of rhythmic respiratory movements and reflexes, and is located in the medulla and pons (see [Figure 41-1](#)). The electrical impulses generated by the respiratory center are carried by the phrenic nerves to the diaphragm and other respiratory muscles. Contraction of diaphragm and other muscles increases the intrathoracic volume, which creates negative intrathoracic pressure and allows air to be sucked in. The air traverses through upper and lower airways (see [Figure 34-1, A](#)) and reaches alveoli (see [Figure 34-1, B](#)). The alveoli are surrounded by capillaries where gas exchange takes place (see [Figure 34-1, C](#)). The large pulmonary blood vessels and the conducting airways are located in a well-defined connective tissue compartment—the pleural cavity.

The lungs are an important part of the body's immune defense system, because inspired air is laden with particles and microorganisms. Mucus keeps the airways moist and traps the particles and microorganisms from inspired air. The airways

Portions of this chapter were written by Donna H. Mueller, PhD, RD, FADA, LDN, for the previous edition.

FIGURE 34-1 Functional anatomy and physiology of the respiratory system. **A**, Various parts of respiratory system. **B**, Gas exchange unit. **C**, Alveolar-capillary interface. *National Heart, Lung, and Blood Institute; National Institutes of Health; U.S. Department of Health and Human Services.*

have 12 types of epithelial cells, and most cells that line the trachea, bronchi, and bronchioles have **cilia**. The **cilia** are “hair-like” structures that move the superficial liquid lining layer from deep within the lungs, toward the pharynx to enter the gastrointestinal tract, thereby playing an important role as a lung defense mechanism by clearing bacteria and other foreign bodies. Each time a person swallows, the particle- and microorganism-containing mucus passes into the digestive tract. When bacteria inhaled by the patient are not cleared effectively, the patient is prone to develop recurrent chest infections that may eventually lead to bronchiectasis.

The epithelial surface of the alveoli contains macrophages. By the process of phagocytosis, these alveolar macrophages engulf inhaled inert materials and microorganisms and digest them. The alveolar cells also secrete **surfactant**, a compound synthesized from proteins and phospholipids that maintains the stability of pulmonary tissue by reducing the surface tension of fluids that coat the lung.

The lungs have several metabolic functions. For example, they help regulate the body’s acid-base balance (see Chapter 6). The body’s pH is maintained partially by the proper balance of CO_2 and O_2 . The lungs also synthesize arachidonic acid that ultimately may be converted to prostaglandins or leukotrienes. These appear to play a role in bronchoconstriction seen in asthma. The lungs convert angiotensin I to angiotensin II by the angiotensin-converting enzyme (ACE) found mainly in the numerous capillary beds of the lungs. Angiotensin II increases blood pressure. Because of the ultrastructure and the fact that they receive the total cardiac output, lungs are well suited to function as a chemical filter. They protect the systemic

circulation from exposure to high levels of circulating vasoactive substances. Although serotonin, 5-hydroxytryptamine (5 HT), and norepinephrine are totally or partially eliminated or inactivated in the pulmonary circulation, epinephrine and histamines pass through the lungs unchanged.

Effect of Malnutrition on the Pulmonary System

The relationship between malnutrition and respiratory disease has long been recognized. Malnutrition adversely affects lung structure, elasticity, and function; respiratory muscle mass, strength, and endurance; lung immune defense mechanisms; and control of breathing. For example, protein and iron deficiencies result in low hemoglobin levels that diminish the oxygen-carrying capacity of the blood. Low levels of calcium, magnesium, phosphorus, and potassium compromise respiratory muscle function at the cellular level. Hypoalbuminemia, as measured by serum albumen, contributes to the development of pulmonary edema by decreasing colloid osmotic pressure, allowing body fluids to move into the interstitial space. Decreased levels of surfactant contribute to the collapse of alveoli, thereby increasing the work of breathing. The supporting connective tissue of the lungs is composed of collagen, which requires ascorbic acid for its synthesis. Normal airway mucus is a substance consisting of water, glycoproteins, and electrolytes, and thus requires adequate nutritional intake.

Effect of Pulmonary Disease on Nutritional Status

Pulmonary disease substantially increases energy requirements. This factor explains the rationale for including body composition and weight parameters in nutrition assessment. Weight loss

from inadequate energy intake is significantly correlated with a poor prognosis in persons with pulmonary diseases. Malnutrition leading to impaired immunity places any patient at high risk for developing respiratory infections. Malnourished patients with pulmonary disease who are hospitalized are likely to have lengthy stays and are susceptible to increased morbidity and mortality.

The complications of pulmonary diseases or their treatments can make adequate food intake and digestion difficult. Absorption and metabolism of most nutrients are affected. As pulmonary disease progresses, several conditions may interfere with food intake and overall nutrition status. For example, abnormal production of sputum, vomiting, **tachypnea** (rapid breathing), hemoptysis, thoracic pain, nasal polyps, anemia, depression, and altered taste secondary to medications are often present. Weight loss, low body mass index (BMI), and other adverse effects are listed in [Box 34-1](#).

Medical Management

Pulmonary system disorders may be categorized as primary, such as tuberculosis (TB), bronchial asthma, and cancer of the lung; or secondary when associated with cardiovascular disease, obesity, human immunodeficiency virus (HIV) infection, sickle cell disease, or scoliosis. Conditions also may be acute or chronic. Examples of acute conditions include aspiration pneumonia, airway obstruction from foods such as peanuts, and allergic anaphylaxis from consumption of shellfish. Examples of chronic conditions include cystic fibrosis (CF) and chronic obstructive pulmonary disease (COPD).

The assessment of pulmonary status generally starts with physical examination using percussion and auscultation. These bedside techniques provide important information on the patient's breathing. Numerous diagnostic and monitoring tests such as imaging procedures, arterial blood gas determinations, sputum cultures, and biopsies also can be employed. Signs and symptoms of pulmonary disease include cough, **dyspnea** (shortness of breath), fatigue, early satiety, anorexia, and weight loss.

Pulmonary function tests are used to diagnose or monitor the status of lung disease; they are designed to measure the ability of the respiratory system to exchange oxygen and CO₂. **Pulse**

FIGURE 34-2 Pulse oximeter.

oximetry is one such test. A small device called a pulse oximeter, which uses light waves to measure the oxygen saturation of arterial blood, is placed on the end of the finger (see [Figure 34-2](#)). Normal for a young, healthy person is 95% to 99%. **Spirometry** is another common pulmonary function test. This involves breathing into a spirometer that gives information on lung volume and the rate at which air can be inhaled and exhaled.

CHRONIC PULMONARY DISEASE

Cystic Fibrosis

Cystic fibrosis (CF) is a life-threatening autosomal recessive inherited disorder that is most commonly seen in the Caucasian population with a CF incidence of 1 out of 3500 babies born in the United States ([Culhane et al, 2013](#)). It is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) protein, a complex chloride channel and regulatory protein found in all exocrine tissues. This defect causes impaired transport of chloride, sodium and bicarbonate, which results in the production of thick, viscous secretions in the lungs, pancreas, liver, intestines and reproductive tract, and leads to increased salt content in the sweat gland secretions. Most of the clinical manifestations are related to the thick, viscid secretions (see [Figure 34-3](#)). Lung disease and malnutrition are predominant burdens of the disease.

In the past, most patients were diagnosed with CF because of symptoms related to various organ systems. During the past decade, newborn screening programs have been expanded and a large number of CF cases are diagnosed before development of symptoms. In 2001 less than 10% of CF cases were diagnosed during the newborn screening programs; by 2011, almost 60% were diagnosed during screening ([Katkin, 2014](#)). When a patient has clinical disease in one or more organs and has elevated sweat chloride (more than 60 mmol/L), it is called a “typical” or “classic” presentation. About 2% of patients present with the typical clinical picture, but have a normal or intermediate sweat chloride level; this is called nonclassic presentation ([Katkin, 2014](#)).

Pathophysiology

Pulmonary and Sinus Disease

CF patients present with chronic persistent cough, dyspnea, and wheezing. As the disease progresses, patients develop **bronchiectasis**, a chronic condition of dilatation of the bronchi that develops as a result of recurrent lung infections. Examination of

BOX 34-1 Adverse Effects of Lung Disease on Nutrition Status

Increased Energy Expenditure

- Increased work of breathing
- Chronic infection
- Medical treatments (e.g., bronchodilators, chest physical therapy)

Reduced Intake

- Fluid restriction
- Shortness of breath
- Decreased oxygen saturation while eating
- Anorexia resulting from chronic disease
- Gastrointestinal distress and vomiting

Additional Limitations

- Difficulty preparing food because of fatigue
- Lack of financial resources
- Impaired feeding skills (for infants and children)
- Altered metabolism
- Food-drug interaction

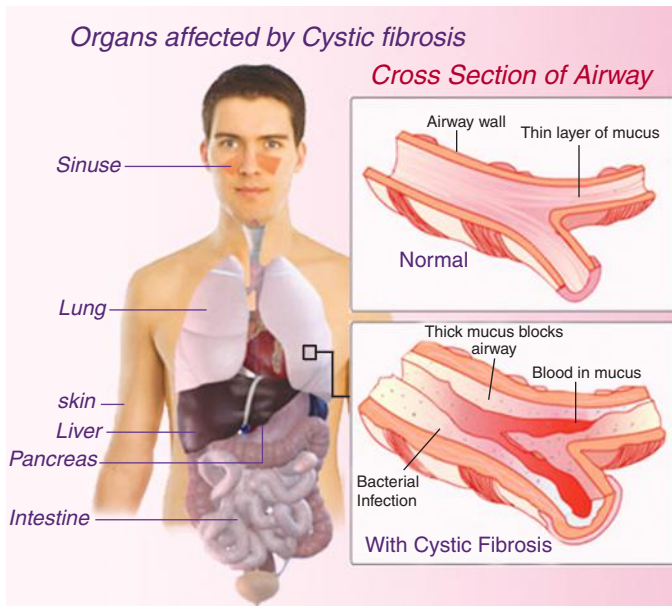

FIGURE 34-3 Illustration showing multi system involvement in CF and tenacious secretions.

a patient with bronchiectasis may show presence of **clubbing**. Digital clubbing is characterized by increased digital tip mass and increased longitudinal and transverse nail plate curvature (see [Figure 34-4](#)), and lung auscultation reveals crackles in the lungs. Chest radiograph may show hyperinflation, and a CT scan may show the classical picture of cystic bronchiectasis (see [Figure 34-5](#)). Pulmonary function testing shows airways obstruction. The spirogram shows reduced forced vital capacity (FVC), known as “restrictive pattern.” The reduced forced expiratory volume (FEV_1) and the reduced FEV_1/FVC ratio are suggestive of airways obstruction.

Early in life, the airways are colonized by bacteria. Although *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa* are common colonizers, recent research has shown that the lung may be colonized by multiple pathogens rather than one dominant organism. Many children with CF develop chronic rhinosinusitis with nasal polyps. Some questions remain unanswered as to the origin of

FIGURE 34-4 Illustration of clubbing in a patient of “yellow nail syndrome.”

FIGURE 34-5 CT scan of a patient showing cystic changes of bronchiectasis in right upper lobe.

polyps in CF patients. Chronic colonization of *Pseudomonas aeruginosa* and CF genotypes are argued to play major roles (Vital et al, 2013).

Pancreatic Disease

Several different types of pancreatic disease occur in CF patients.

Pancreatic Insufficiency. **Pancreatic insufficiency (PI)**, in which the pancreas fails to make adequate enzymes to digest food in the small intestine, is the most common gastrointestinal complication of CF, affecting approximately 90% of patients at some time in their lives (Rogers, 2013).

Up to 90% of patients exhibit fat malabsorption by 1 year of age. The production of pancreatic enzymes is decreased, which leads to the malabsorption of fats and steatorrhea. **Steatorrhea**, is characterized by foul smelling, bulky, oily stools and failure to thrive or poor weight gain. Such patients may also present with clinical features of deficiency of the fat-soluble vitamins A, D, E, and K. The CF population frequently presents with suboptimal vitamin D status. CF patients also suffer from vitamin K deficiencies and need routine supplementation.

Pancreatitis. The abnormal pancreatic secretions cause progressive pancreatic damage, so these patients can present with acute or recurrent pancreatitis.

CF-Related Diabetes. Patients with exocrine pancreatic insufficiency also may develop impaired function of the endocrine pancreas, leading to the development of **cystic fibrosis related diabetes (CFRD)**. Twenty five percent of CF patients develop CFRD, which is associated with poor growth, clinical and nutritional deterioration, and early death. The American Diabetes Association (ADA) and the Cystic Fibrosis Foundation (CFF) recommend yearly CFRD screenings, starting at age 10 (see Chapter 30 for discussion of diabetes management).

Bone Disease

Bone disease is common in CF patients and is characterized by increased fracture rates, low bone density, and **kyphosis**, which is increased curvature of the upper back, causing a hunchback.

Multiple risk factors contribute to developing bone disease—chronic corticosteroid use, failure to thrive, malabsorption of calcium, vitamin D, vitamin K and magnesium, inadequate overall intake, and reduced weight-bearing activities.

Other Conditions

Meconium ileus, rectal prolapse, biliary disease, infertility, musculoskeletal disorders, and recurrent venous thrombosis are other conditions that occur in patients with CF. CF patients are susceptible to SIBO (small intestine bacterial overgrowth) secondary to decreased motility. This disorder interferes with fat absorption and appetite (Baker et al, 2013) (see Chapter 28).

Medical Management

Cystic fibrosis is a multisystem disease and its management requires a multidisciplinary approach. Involvement of respiratory and gastrointestinal systems is responsible for significant mortality and morbidity. Sinus infection, glucose control, nutritional status, and psychosocial issues must be assessed and managed at regular intervals (see Figure 34-6).

Ivacaftor (VX-770) is a small molecular weight oral drug that is designed specifically to treat patients who have a G551D mutation in at least one of their CFTR genes. Ivacaftor is the first approved CF therapy that restores the functioning of a mutant CF protein rather than trying to target one or more of its downstream consequences (Davis, 2011).

Cystic fibrosis patients are prone to recurrent chest infections, requiring treatment with antibiotics, bronchodilators, and chest physiotherapy. Inhalants help to clear purulent and tenacious secretions. Antiinflammatory agents such as macrolide antibiotics, ibuprofen, and systemic and inhaled steroids are used with the objective of controlling excessive and harmful inflammatory reaction in the lungs. Influenza and pneumococcal vaccines are used as preventive measures. Hypoxemic patients need supplemental oxygen. Some patients are considered for bilateral lung transplantation.

Because of the pancreatic insufficiency, **pancreatic enzyme replacement therapy (PERT)** is an important component of the management for CF patients to adequately absorb carbohydrates, protein, and fat. The pancreatic ducts are obstructed in approximately 85% to 90% of CF individuals, and this prevents pancreatic enzymes such as lipase, amylase, and protease from secreting into the small intestine. The build-up of these enzymes in the pancreas leads to auto digestion of the pancreas, and destruction of acinus. Pancreatic **acinus** is the secretory unit of exocrine pancreas, where pancreatic juice is produced. Destruction of pancreatic acinus, or **acinar** destruction, results in impaired secretion of pancreatic juice, which results in loose, oily, frequent stools and malabsorption. These individuals need PERT to combat the pancreatic insufficiency and maintain adequate absorption and digestion of nutrients (see *Focus On: PERT*).

Medical Nutrition Therapy

Medical nutrition therapy (MNT), critical to management of all the conditions described earlier, is vital in promoting longevity and positive outcomes. MNT begins with evaluation of the nutritional status of the patient (Baker et al, 2013) (see Chapters 4 and 7 and Appendix 22). CF patients frequently have growth failure, the cause of which is multifactorial: malabsorption, increased energy needs, and reduced appetite. There is a close correlation between pulmonary function tests (PFT) and nutritional status. All patients with CF should have regular

FOCUS ON

PERT

Pancreatic enzyme replacement therapy (PERT) is the first step taken to correct maldigestion and malabsorption. The microspheres, designed to withstand the acidic environment of the stomach, release enzymes in the duodenum, where they digest protein, fat, and carbohydrate. Pharmaceutical advancements have improved the medications. The quantity of enzymes to be taken with food depends on the degree of pancreatic insufficiency; the quantity of food eaten; the fat, protein, and carbohydrate content of food consumed; and the type of enzymes used.

Enzyme dosage per meal or snack is adjusted empirically to control gastrointestinal symptoms, including steatorrhea, and to promote growth appropriate for age. Following the manufacturer's directions about storage and administration of a particular brand of enzyme is important to emphasize. If gastrointestinal symptoms cannot be controlled, enzyme dosage, patient adherence, and enzyme type should be reevaluated. Fecal **elastase** (protein-digesting enzyme secreted by the pancreas and involved in hydrolysis of peptide bonds), fecal fat, or nitrogen balance studies may help to evaluate the adequacy of enzyme supplementation.

The acidic environment of the stomach does not allow the enzymes of the enteric coated PERT to be degraded. This normally occurs once the pH is above 5.5, usually when the PERT reaches the duodenal jejunum. A common practice is placing CF patients on proton pump inhibitors in order to increase the duodenal pH by decreasing gastric acid secretion (Rogers, 2013).

Intestinal abnormalities such as gastroesophageal reflux disease (GERD), meconium ileus (MI), **distal intestinal obstruction syndrome (DIOS)**, which is the blockage of intestines resulting from stool and intussusceptions, are some of the complications seen in patients (Katkin, 2014).

Hepatobiliary problems are seen more commonly now in this population because of an increased survival rate. In the liver, the CFTR is located in the biliary epithelium. Bile produced in patients with CF is thick and tenacious, causing blockage of the intrahepatic bile ducts. Blockage of these ducts eventually leads to cirrhosis. Use of ursodeoxycholic acid (UDCA) may delay the progression of liver disease (Kappler et al, 2012) (see Chapter 29).

nutritional assessments at 3-month intervals for early detection of nutritional status deterioration (see *Pathophysiology and Care Management Algorithm: Cystic Fibrosis*).

Children with CF should be monitored annually for parathyroid hormone (PTH) levels, 25 hydroxy-vitamin D levels, and serum calcium and phosphate levels. Older children should be evaluated for bone density using the dual energy x-ray absorptiometry (DXA) (see Chapter 24).

Major goals of nutritional therapy are increasing muscle strength, promoting optimal growth and weight maintenance and enhancing the quality of life. To achieve these goals, the objectives of treatment are to correct maldigestion and malabsorption and to provide nutrients that are commonly deficient.

Energy. Because body mass index (BMI) is more sensitive to lung function in CF patients than percentage ideal body weight (IBW), in 2011 the CF foundation discontinued using the %IBW as an assessment tool in CF patients. Instead recommendations are for maintaining a BMI at or above the 50th percentile between ages 2 to 19 and a median BMI of 22.1 kg/m² for adults 20 to 40 years of age (Culhane et al, 2013).

A broad range of energy requirements are reported in patients with CF, ranging from 120% to 150% of recommendations for the general population, depending on the CF mutation, the patient's age, and the current state of health (Rogers, 2013). Although an energy-dense diet is important, achieving that

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Cystic Fibrosis

ETIOLOGY

Autosomal recessive inheritance

Cystic Fibrosis Gene
Cystic fibrosis transmembrane receptor (CFTR)

PATHOPHYSIOLOGY

Cystic Fibrosis (CF)

Obstruction of Glands and Ducts

- Secretion of abnormally thick, tenacious mucus by exocrine glands

Affected Organs

- Respiratory organs
- Pancreas; gallbladder, liver
- Reproductive organs
- Sweat glands
- Salivary glands
- Intestines

Physical Growth

- Short stature
- Low body weight (children and adults)
- Low muscle mass
- Malabsorption

Medical Management

- Genotyping
- Oral or IV antibiotics
- Aerosol antibiotics
- Inhaled medications
- Chest and physical therapy

Nutrition Management

- Monitor ongoing nutrition status
- Supply pancreatic enzyme replacement therapy (PERT)
- Meet increased energy requirements
- Provide vitamin and mineral supplementation

FIGURE 34-6 Algorithm for diagnosis and management of cystic fibrosis.

with high-glycemic index (GI) carbohydrates can be a problem, because a high GI diet can promote **impaired glucose tolerance (CF-IGT)** and CFRD by exceeding the capabilities of insulin production in CF (Balzer et al, 2012) (see Chapter 30).

Fat-soluble Vitamins. In CF patients, liver disease and pancreatic dysfunction lead to fat malabsorption, which predisposes these patients to deficiencies of fat-soluble vitamins A, D, E and K. The deficiency of vitamins A, D, E, and K, which significantly affects CF patients, reduces their response to pulmonary infections. Because bone disease is common in patients with CF and progresses with age (Rana et al, 2014), the CF foundation recommends patients be treated with cholecalciferol (D₃). A daily vitamin D dosage of 1500 to 2000 IU is suggested by the Endocrine Society with dosages increasing to 10,000 IU daily for CF patients 18 or older (Rogers, 2013).

It is also recommended that the CF patient be supplemented with vitamin K. Taking at least 1000 mcg/day was found to achieve an optimal status of vitamin K (Rogers, 2013).

Fat-soluble vitamin testing is important in the identification of deficiencies in CF patients with pancreatic insufficiency. Fat-soluble vitamins are supplemented routinely and annually monitored. Patients may be noncompliant with vitamin supplementation or require higher dosages (Rana et al, 2014).

Salt. Excessive sodium loss in perspiration in patients with CF predisposes them to hyponatremic dehydration under conditions of heat stress. Most patients need supplementation of sodium chloride. The amount of salt supplementation should be increased under circumstances such as high temperature and humidity; a dry, desert climate; strenuous exercise in hot weather; excessive sweating; fever; and presence of diarrhea or vomiting.

High levels of linoleic acid (LNA) (an omega-6 fatty acid) and low levels of alpha linoleic acid (ALA) (an omega-3 fatty acid) are seen in the development of fatty acid alterations in CF patients (Katrangi et al, 2013). Although nutrition therapy consisting of a high caloric and high fat intake counteracts the effect of malabsorption in CF, no recommendations exist regarding the best type of fat for the diet. However, data suggest that the increased LNA:ALA ratio may contribute to the increased metabolic abnormalities of CF and CF-related inflammation. More research is needed to determine the role of specific fat sources in treating CF patients (Katrangi et al, 2013).

A challenging issue while working with CF individuals is the gastrostomy tube feeds and administration of pancreatic enzymes. Overnight enteral pump feedings often are required for CF patients in order to supplement the daytime oral intake and provide an additional 6 to 8 hours of energy intake. Questions still remain on the optimal level of enzymes to be provided with overnight feeds (Matel, 2012).

Tube feeding options include gastrostomy tube, nasogastric tube, and jejunostomy tube. The most common delivery option is the percutaneous endoscopic gastrostomy (PEG) tube (see Chapter 13). When CF patients have trouble maintaining sufficient caloric intake because of recurrent infections, abdominal issues, and increased breathing, supplemental enteral feedings are of great benefit; PERT is still required (Rogers, 2013).

ASTHMA

Asthma is a chronic disorder that affects the airways and is characterized by bronchial hyper-reactivity, reversible airflow obstruction, and airway remodeling. Asthmatic symptoms

include periodic episodes of chest tightness, breathlessness, and wheezing. Asthma has become more prevalent and has been increasing at the rate of 25% to 75% every decade since 1960 in westernized countries (Allan and Devereux, 2011).

Pathophysiology

Asthma is the result of a complex interaction between environmental exposures and genetics. When people are genetically susceptible, environmental factors exacerbate airway hyper-responsiveness, airway inflammation, and atopy (tendency to develop allergic reaction) that eventually leads to asthma.

Environmental factors that are linked to the development of asthma include indoor allergies (dust mites, animal allergies) and outdoor allergies (pollen and fungi). Increased risk of asthma development also has been linked to air pollution, tobacco smoke exposure, small size at birth, respiratory infection, and lower socioeconomic status (McCloud and Papoutsakis, 2011).

Clinicians identify three key areas when diagnosing asthma:

1. Airflow obstruction that is at least partially reversible
2. Airflow obstruction that recurs
3. Exclusion of other diagnoses

Symptoms such as wheezing, coughing, shortness of breath, and chest tightness occur in most patients, and symptoms that worsen at night is a common feature. Although allergic asthma or “extrinsic asthma” is due to chronic allergic inflammation of the airways, “intrinsic asthma” is triggered by nonallergic factors such as exercise, certain chemicals, and extreme emotions (Chih-Hung Guo et al, 2012).

A life-threatening situation with markedly narrow airways, known as status asthmaticus, can result when asthma has not been treated properly. Corticosteroid therapy is often prescribed, but chronic use may place the individual at risk for **osteopenia** (precursor to osteoporosis), bone fractures, or steroid-induced hyperglycemia (see Chapter 8 and Appendix 23.). Some evidence supports the effectiveness of sublingual immunotherapy in the treatment of asthma and rhinitis, but more studies are needed on optimal dosages (Lin et al, 2013).

Medical Management

The essential components of asthma therapy are routine monitoring of symptoms and lung function, patient education, control of environmental triggers, and pharmacotherapy.

Pharmacologic treatment must be tailored to the individual patient and is used in a stepwise manner. The medications and the regime chosen depend on the severity of the asthma, which can be classified as an acute attack, intermittent, mild persistent, moderate persistent, or severe persistent.

Quick relief and long-term controller medications are used as therapy for asthma. Although quick-relief medications include short-acting beta agonists (bronchodilators) and steroid pills, long-term controller medications include inhaled long-acting beta agonists and leukotriene modifiers.

Inhaled corticosteroids are the cornerstone of pharmacologic management with persistent asthma. Some younger patients with refractory asthma need maintenance doses of systemic steroids. Because steroids change bone metabolism and the development of osteoporosis, these children benefit from increased calcium intake (see Table 34-1). Two newer therapies are anti-IgE (anti-immunoglobulin E) therapy and

TABLE 34-1 Recommended Calcium Intakes for Children Receiving Steroids Compared with Those for Healthy Children

Age in Years	Recommendations for Healthy Children (mg/day)	Recommendations for Children Taking Steroids (mg/day)
1-3	700	1000
4-8	1000	1500
9-13	1300	1900
14-18	1300	1900

Adapted from McCloud E, Papoutsakis C: A medical nutrition therapy primer for childhood asthma: current and emerging perspectives, *J Am Diet Assoc* 111:1052, 2011. McEvoy GK, Snow EK: *AHFS drug information*, Bethesda, Md, American Society of Health System Pharmacists, 2015.

bronchial thermoplasty, which are used in selected cases of severe asthma. Immunomodulator therapies with anti-IL-5 (anti-interleukin-5) antibodies, anti-IL-4 alpha subunit antibodies, human necrosis factor TNF-alpha (tumor necrosis factor-alpha) inhibitors, and the use of macrolide antibiotics for their antiinflammatory actions are some of the experimental approaches (Wenzel, 2014).

Antibiotics for exacerbation of asthma are not recommended by current clinical practice guidelines, because respiratory infection triggering asthma attacks are more often viral rather than bacterial.

Medical Nutrition Therapy

When treating asthma, the dietitian nutritionist addresses the dietary triggers, corrects energy and nutrient deficiencies and excesses in the diet, educates the patient on a personalized diet that provides optimal levels of nutrients, monitors growth in children, and watches for food-drug interactions.

Modulation of antioxidant intake with nutritional supplementation has a beneficial effect on the severity and progression of asthma. Although a slight inverse association was seen between a low vitamin E intake and wheezing symptoms, no association was found between vitamin E and asthma. Further studies are required to understand the mechanism of vitamin E on the inflammation of the immune system (Fabian et al, 2013). Low blood carotenoid levels also have been linked with asthma. A diet rich in antioxidants and monounsaturated fats seems to have a protective effect on childhood asthma by counteracting oxidative stress (Garcia-Marcos L et al, 2013). Studies have also associated asthma with reduced selenium status (Allan and Devereux, 2011).

In the childhood asthma prevention study omega-3 polyunsaturated fatty acid (PUFA) fish oil was supplemented throughout childhood and wheezing was reduced. This effect did not continue into later childhood. Supplementation of vitamin C and zinc also have been reported to improve asthma symptoms and lung function (Allan and Devereux, 2011).

Conflicting results on the efficacy of vitamin D supplementation have been reported. In one study an insufficient serum level of less than 30 ng/dL of vitamin D was associated with an increase in asthma exacerbation in the form of ER visits and hospitalizations (Brehm et al, 2010). In another, high doses of vitamin D supplementation were not shown to have any protective effect (Litonjua et al, 2014).

A higher than desirable BMI during childhood is associated with a significant increase in the development of asthma.

Institution of diets that help with weight loss in asthmatic obese children seem to show improvements with the control of asthma, static lung function, and improved quality of life (Gibson et al, 2013).

Gastroesophageal reflux disease (GERD) and food allergens are the two most common dietary triggers for asthma. GERD is highly prevalent in asthmatic patients. A critical component of medical nutrition therapy for asthmatic patients is a diet free of known irritants such as spicy foods, caffeine, chocolate, and acidic foods (see Chapter 27). Limiting the intake of high fat foods and portion control can prevent gastric secretions, which exacerbate GERD.

Food allergens and food additives are other potential dietary triggers for asthma. An immunoglobulin E-mediated reaction to a food protein can lead to bronchoconstriction. Completely avoiding the allergenic food protein is the only dietary treatment currently available for food allergies. Some sulfites, such as potassium metabisulfite and sodium sulfide, used in the processing of foods, have been found to be a trigger for asthmatics (Gaur et al, 2013) (see Chapter 26).

Some asthma patients need maintenance oral steroids, and these patients are prone to develop drug-nutrient interaction problems (see Chapter 8).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is now the third most common cause of death in the world and is predicted to be the fifth most common cause of disability by 2020 (Burney et al, 2014). Smoke from cigarettes is a major risk factor, along with that from biomass fuel used for cooking and heating in rural areas of developing countries. Occupational smoke or dust, air pollution, and genetic factors are also factors in the development of COPD (see Table 34-2). Patients with COPD suffer from decreased food intake and malnutrition that causes respiratory muscle weakness, increased disability, increased susceptibility to infections, and hormonal alterations.

Pathophysiology

COPD is a term that encompasses **chronic bronchitis** (a long-term condition of COPD in which inflamed bronchi lead to mucus, cough and difficulty breathing) and **emphysema** (a form of long-term lung disease characterized by the destruction of lung parenchyma with lack of elastic recoil). These conditions may coexist in varying degrees and are generally not reversible. Figure 34-7 shows the overlap between these three conditions, asthma, chronic bronchitis and emphysema.

Patients with primary emphysema suffer from greater dyspnea and cachexia. On the other hand patients with bronchitis have hypoxia, **hypercapnia** (increased amount of carbon dioxide), and complications such as pulmonary hypertension and right heart failure (Papaioannou et al, 2013).

TABLE 34-2 Risk Factors for COPD

Definite	Probable
Tobacco smoking	Pulmonary tuberculosis
Occupational exposure	Repeated lower respiratory infection during childhood
Exposure to biomass fuel smoke	Poorly treated asthma
Environmental tobacco smoke	

Adapted from Gupta D et al: Guidelines for diagnosis and management of chronic obstructive pulmonary disease: Joint ICS/NCCP (I) recommendations, *Lung India* 30:228, 2013.

FIGURE 34-7 The overlap of asthma, chronic bronchitis, and emphysema making up COPD.

Alpha-1 antitrypsin deficiency is present in 1% to 2% of COPD patients and is likely underrecognized. COPD exacerbations can be caused by *Haemophilus influenzae*, *Moraxella catarrhalis*, *S. pneumoniae*, rhinovirus, coronavirus, and to a lesser degree, organisms such as *P. aeruginosa*, *S. aureus*, *Mycoplasma* spp., and *Chlamydia pneumoniae*. Allergies, smoking, congestive heart failure, pulmonary embolism, pneumonia, and systemic infections are the reason for 20% to 40% of COPD exacerbations (Nakawah et al, 2013).

Although cigarette smoking is considered a major risk factor for developing COPD, only about 20% of smokers develop the disease (Hirayama et al, 2010). Osteoporosis in COPD patients not only predisposes patients to painful vertebral fractures but also affects lung function by altering the configuration of the chest wall. Frequent acute exacerbations in COPD patients increase the severity of chronic system inflammation. This leads to bone loss by inhibiting bone metabolism. Lack of sun exposure and physical activity with COPD leads to a lack of 25-hydroxy vitamin D (25-OHD), which regulates bone metabolism by promoting the absorption of calcium (Xiaomei et al, 2014).

Factors that influence the prognosis of COPD are the severity of disease, genetic predisposition, nutritional status, environmental exposures, and acute exacerbations.

Medical Management

In general, COPD therapies have a limited effect compared with therapies in asthma. No disease-modifying medications exist that can change the progression of airway obstruction in COPD.

Inhaled bronchodilators remain the mainstay of treatment for COPD patients. Usually these are given by metered dose inhalers (MDI), but for severe dyspnea, may be administered in a nebulized form. Anticholinergic medications such as ipratropium bromide or Spiriva (tiotropium bromide), a long-acting anticholinergic agent with specificity for muscarinic receptors, can be added to the treatment. Theophylline continues to be used in some cases. Inhaled steroids and a trial of oral steroids may be required for some patients. Antibiotics often are prescribed when an exacerbation is considered to be due to bacterial infection.

Pulmonary hypertension is a risk factor that shortens life expectancy and is common in advanced COPD. The first step in treating pulmonary hypertension in patients with COPD is appropriate management of their obstructive lung disease as

mentioned earlier. The exact indication for pulmonary hypertension specific therapies in COPD patients is unclear. Current recommendations state that pulmonary hypertension specific therapies should be considered when pulmonary hypertension is persistent despite optimization of COPD management and when pulmonary hypertension is out of proportion to the degree of air flow obstruction (Minai et al, 2010).

Patients who are hypoxemic need supplemental oxygen. Pulmonary rehabilitation may be helpful in advanced COPD. Patients with severe COPD may suffer respiratory failure related to complications such as pneumothorax, pneumonia, and congestive heart failure, or due to uncontrolled administration of high-dose oxygen or narcotic sedatives. The patients in respiratory failure need mechanical ventilation (see Figure 34-8).

In addition to facing major physical impairment and chronic dyspnea, COPD patients are at an increased risk of developing depression that should be identified and treated.

Medical Nutrition Therapy

Malnutrition is a common problem associated with COPD, with prevalence rates of 30% to 60% due to the extra energy required by the work of breathing and frequent and recurrent respiratory infections. Breathing with normal lungs expends 36 to 72 kcal/day; it increases 10-fold in patients with COPD (Hill et al, 2013). Infection with fever increases metabolic rate even further (see Chapter 2). An independent predictor of increased mortality in COPD patients is low body weight. Weight loss in advanced COPD is considered an independent risk factor for mortality, whereas weight gain reverses the negative effect of decreased body weight (Berman, 2011).

Low body weight is due to poor nutritional intake, an increased metabolic rate, or both. Inadequate food intake and poor appetite are the primary targets for intervention in patients with COPD. These two issues mean COPD patients struggle to meet their nutritional needs. Depletion of protein and vital minerals such as calcium, magnesium, potassium, and phosphorus contribute to respiratory muscle function impairment. In severe malnutrition inadequate electrolyte repletion during aggressive nutrition repletion can lead to severe metabolic consequences related to refeeding syndrome (see Chapter 13).

There are two main goals in managing the hypermetabolism seen in stable COPD: 1) the prevention of weight loss, and

FIGURE 34-8 An ICU patient on ventilator.

2) the prevention of the loss of lean body mass (LBM). These goals can be achieved by ensuring the following:

- Small frequent meals that are nutritionally dense
- The patient eats the main meal when energy level is at its highest
- Adequate calories, protein, vitamins, and minerals to maintain a desirable weight - a BMI of 20 to 24 kg/m²
- Availability of foods that require less preparation and can be heated easily in a microwave oven
- Limitation of alcohol to fewer than 2 drinks/day (30 g alcohol)
- A period of rest before mealtimes

People with COPD suffer a poor prognosis when they have malnutrition that predisposes them to infections. The ability to produce lung surfactant, exercise tolerance, and respiratory muscle force are reduced in the presence of infection. Weight loss leads to an increased load on the respiratory muscles, contributing to the onset of acute respiratory failure (Hill et al, 2013).

Many factors affect nutritional status during the progression of COPD. Although body weight and BMI should be followed because they are easily obtained markers of nutritional status in patients, they can underestimate the extent of nutritional impairment (Hill et al, 2013).

Current evidence suggests that a prudent diet pattern helps in protecting smokers against malnutrition. A combination of nutritional counseling and nicotine replacement seems to optimize success (Hill et al, 2013).

Studies have shown an inverse relationship between dietary iron and calcium intake and COPD risk. Iron deficiency anemia is seen in 10% to 30% of patients with COPD. It has been seen that correcting the anemia and iron deficiency by either blood transfusions or intravenous iron therapy improves dyspnea in COPD patients (Silverberg et al, 2014). COPD patients are also at higher risk of developing osteoporosis resulting from steroid usage, smoking, and vitamin D depletion. Maintaining adequate levels of vitamin D (25-OHD) is a health-promoting strategy for COPD patients (Lee et al, 2013; see Appendix 45).

The primary goals of nutrition care for patients with COPD are to facilitate nutritional well-being, maintain an appropriate ratio of lean body mass to adipose tissue, correct fluid imbalance, manage drug-nutrient interactions (see Chapter 8 and Appendix 23), and prevent osteoporosis.

Nutritional depletion may be evidenced clinically by low body weight for height and decreased grip strength. Calculation of BMI may be insufficient to detect changes in fat and muscle mass. Instead, determination of body composition helps to differentiate lean muscle mass from adipose tissue and overhydration from dehydration. In patients with **cor pulmonale** (increased blood pressure which leads to enlargement and failure of the right ventricle of the heart) and the resultant fluid retention, weight maintenance, or gain from fluid may camouflage actual wasting of lean body mass. Thus for patients retaining fluids, careful interpretation of anthropometric measurements, biochemical indicators, and functional measures of nutrition status is necessary (see Chapter 7 and Appendices 21 and 22).

A combination of nutritional supplements and anabolic steroids can increase muscle mass and reverse any negative effects of weight loss. Exercise tolerance has been shown to improve with a dietary supplement that contains omega-3 PUFA, which has anti-inflammatory effects (Berman, 2011) (see Chapter 3).

Adipokines is a generic term for the bioactive proteins that are secreted by adipocytes. They include adiponectin, leptin, IL-6, and TNF-alpha. They play a vital role in influencing the

nutritional status and regulating the appetite. **Leptin** (satiety hormone) is secreted promptly in response to food intake, and plays a role in suppressing appetite and enhancing energy expenditure. It has been suggested that measuring levels of leptin in the sputum can be useful in determining the severity of lung disease because it has been shown to increase during acute exacerbations (Itoh et al, 2013). **Adiponectin** (a protein involved in fatty acid breakdown and glucose regulation), like leptin, is secreted from adipocytes, but has an opposite effect. Adiponectin enhances appetite, has an antiinflammatory, antidiabetic, and antiatherosclerotic effect and is considered beneficial. **Resistin**, another adipokine, induces inflammation and insulin resistance. In addition to being an appetite stimulant, **ghrelin** also stimulates growth hormone secretion, with antagonistic effects to leptin. Table 34-3 summarizes the functions and change in the blood levels of these adipokines in COPD patients, and how they can influence management and recovery (Itoh et al, 2013).

Macronutrients

In stable COPD, requirements for water, protein, fat, and carbohydrate are determined by the underlying lung disease, oxygen therapy, medications, weight status, and any acute fluid fluctuations. Attention to the metabolic side effects of malnutrition and the role of individual amino acids is necessary. Determination of a specific patient's macronutrient needs is made on an individual basis, with close monitoring of outcomes.

Energy

Meeting energy needs can be difficult. For patients participating in pulmonary rehabilitation programs, energy requirements depend on the intensity and frequency of exercise therapy and can be increased or decreased. It is crucial to remember that energy balance and nitrogen balance are intertwined. Consequently, maintaining optimal energy balance is essential to

TABLE 34-3 Blood Levels of Hormones and Adipokines in Patients with COPD

Hormone	Function	Changes in blood levels with COPD
Leptin	<ul style="list-style-type: none"> • Suppresses appetite • Promotes inflammation • Regulates hematopoiesis, angiogenesis, and wound healing 	Decreased in patients with a low BMI compared with patients with a normal and high BMI
Ghrelin	Stimulates appetite and release of growth hormone	Increased in underweight patients compared with normal weight patients
Adiponectin	<ul style="list-style-type: none"> • Stimulates fatty acid oxidation • Increases insulin sensitivity, and inhibits inflammatory process 	Increased during acute exacerbation Decreased levels in current smokers
Resistin	Promotes inflammation and insulin resistance by the production of IL-6 and TNF-alpha	Inversely correlated with predicted FEV ₁ %
TNF- alpha	Antagonizes insulin signaling, and promotes inflammation.	Increased compared with healthy individuals
IL-6	<ul style="list-style-type: none"> • Loss of appetite • Promotes inflammation 	Increased compared with healthy individuals

preserving visceral and somatic proteins. Preferably, indirect calorimetry should be used to determine energy needs and to prescribe and monitor the provision of sufficient, but not excessive calories. When energy equations are used for prediction of needs, increases for physiologic stress must be included. Caloric needs may vary significantly from one person to the next and even in the same individual over time (see Chapter 2).

Fat

Omega-3 and omega-6 are PUFAs that are essential fatty acids. The simplest forms of these fatty acids are the omega-6 linoleic acid (LA) and alpha-linolenic acid (ALA). The body is unable to synthesize them, and they must be consumed in the human diet. These fatty acids are desaturated to form long chain omega-3 PUFAs or omega-6 PUFAs. Docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) and alpha-linolenic acid (ALA) are the major omega-3 PUFAs, and the major long-chain omega-6 fatty acids are linoleic acid (LA) and arachidonic acid (AA). See Appendix 34 for the sources of these fatty acids in the diet. In theory, intake of long-chain omega-3 PUFAs, which reduces inflammation, should improve the efficacy of COPD treatments. PUFA supplementation is beneficial in COPD, but various factors such as supplement adherence, comorbidities, and duration of the supplementation play vital roles (Fulton et al, 2012).

Dietary supplementation of DHA and AA has been shown to delay and reduce risk of upper respiratory infections and asthma, with lowering the incidence of bronchiolitis during the first year of life (Shek et al, 2012). Data from various studies have shown the positive impact of long-chain PUFAs in initiating and providing resolution of inflammation in respiratory diseases (Shek et al, 2012). It has been shown that aspirin helps to trigger resolvin, a molecule naturally made by the body from omega-3 fatty acids. **Resolvin** resolves or turns off the inflammation in underlying destructive conditions such as inflammatory lung diseases (Dalli et al, 2013).

Protein

Sufficient protein of 1.2 to 1.5 g/kg of dry body weight is necessary to maintain or restore lung and muscle strength, as well as to promote immune function. A balanced ratio of protein (15% to 20% of calories) with fat (30% to 45% of calories) and carbohydrate (40% to 55% of calories) is important to preserve a satisfactory **respiratory quotient (RQ)** from substrate metabolism use (see Chapter 2). Repletion but not overfeeding is particularly critical in patients with compromised ability to exchange gases as excess feeding of calories results in CO₂ that must be expelled. Other concurrent disease processes such as cardiovascular or renal disease, cancer, or diabetes affect the total amounts, ratios, and kinds of protein, fat, and carbohydrate prescribed.

Vitamins and Minerals

As with macronutrients, vitamin and mineral requirements for individuals with stable COPD depend on the underlying pathologic conditions of the lung, other concurrent diseases, medical treatments, weight status, and bone mineral density. For people continuing to smoke tobacco, additional vitamin C is necessary (see Appendix 42).

The role of minerals such as magnesium and calcium in muscle contraction and relaxation may be important for people with COPD. Intakes at least equivalent to the dietary reference intake (DRI) should be provided. Depending on bone mineral density test results, coupled with food intake

history and glucocorticoid medications use, additional vitamins D and K also may be necessary (see Chapter 24).

Patients with cor pulmonale and subsequent fluid retention require sodium and fluid restriction. Depending on the diuretics prescribed, increased potassium supplementation may be required (see Chapter 8 and Appendix 23). And other water soluble vitamins, particularly thiamin, may need to be supplemented.

Patients are recommended to drink adequate fluids and stay hydrated to help sputum consistency and easier expectoration. The Parenteral and Enteral Nutrition Group (PENG) recommends a fluid intake of 35 ml/kg body weight daily for adults 18 to 60 years and 30 ml of fluid/kg body weight daily for adults over 60 years (PENG, 2011).

COPD patients report difficulties with eating because of low appetite, increased breathlessness when eating, difficulty shopping and preparing meals, dry mouth, early satiety and bloating, anxiety and depression, and fatigue. In addition to the above, inefficient and overworking respiratory muscles lead to increased nutritional requirements (Evans, 2012).

Patients in the Advanced Stage of COPD

Patients with advanced COPD are undernourished and in a state of **pulmonary cachexia**. The cause of cachexia in advanced COPD is poorly understood. The role for myostatin has been suggested. Myostatin is a member of the transforming growth factor-beta superfamily that functions as a negative regulator of muscle growth. This has been suggested by the significantly high levels of myostatin in patients with stable COPD compared with healthy individuals (Benedik et al, 2011).

These cachectic patients have anorexia as a typical symptom. Pulmonary cachexia is an independent risk factor and is common in the advanced stage of COPD. Pharmacotherapy and nonpharmacotherapeutic treatments such as respiratory rehabilitation and nutrition counseling are the mainstays of COPD treatment in such patients (Itoh et al, 2013). Sarcopenia and cachexia result from the accelerated loss of lean tissue (Raguso and Luthy, 2011). This muscle wasting has a detrimental effect on the respiratory function (Collins et al, 2012).

Osteoporosis exists as a significant problem in 24% to 69% of patients with advanced COPD (Evans and Morgan, 2014). Any sudden drop in height is a mark of developing osteoporosis. As COPD progresses, osteoporosis results because of immobility, which also leads to deconditioning and dyspnea. Smoking, low BMI, low skeletal muscle mass, and corticosteroid usage can lead to bone loss along with low serum vitamin D levels (Evans and Morgan, 2014) (see Box 34-2).

BOX 34-2 Planning the Diet for the Patient with Pulmonary Cachexia

Energy requirements during healing = 30 kcal/kg of usual body weight or 13.7 cal/usual body weight (pounds)
 Protein (gm)/day during healing = [(1.2 g – 1.4 g) × body weight (kg) or 0.55 × usual body weight (pounds)]
 Fluid requirements = body weight (lb)/2 = ounces per day **or** body wt (lb) × 9/16 = cups per day
 Fluid requirements are increased because of fever, chemotherapy regimen, oxygen use, and presence of COPD. Lack of energy or dehydration increases fatigue and constipation. Fluid deficits of 1% body weight lower metabolic function by 5%.

Levin RM: *Nutrition in the Patient with Lung Cancer*, Caring Ambassadors Lung Cancer Choices (website): http://lungcancercap.org/wp-content/uploads/2014/10/Chapter_8_2014.pdf, 2012. Accessed December 31, 2014.

TUBERCULOSIS

Mycobacterium tuberculosis, the causative organism of **tuberculosis (TB)**, is an intracellular bacterial parasite, has a slow rate of growth, is an obligate aerobe, and induces a granulomatous response in the tissues of a normal host.

Even though TB is not as common in the United States as in some other countries, there has been a resurgence associated with human immunodeficiency virus (HIV) and drug-resistant forms of TB (see Chapter 37). The World Health Organization (WHO) estimates approximately 630,000 cases of TB worldwide. In 2013 TB remained a major health concern with resistance to multidrug-resistant TB on the rise. Increase in relocation of this population of patients, the HIV pandemic, and increase in multidrug-resistant TB poses global concerns in the management of TB (Abubakar et al, 2013).

Pathophysiology

When an infectious TB patient coughs, the cough droplets contain tuberculous bacilli. Small particles penetrate deep into the lungs. Each of these tiny droplets may carry 1 to 5 bacilli, which are enough to establish infection. This is the reason why cases of active TB must be isolated till they become noninfectious. In about 5% of cases, the infection progresses and produces active tuberculosis. In 95% of cases when a host has an effective cell-mediated immune response, the infection is contained. When patients with active TB, are left untreated, they can die as a result of progression and complications (Hood, 2013).

Although there may be minimal symptoms and the diagnosis is suspected because of an abnormal chest radiograph, most patients with pulmonary TB present with chronic cough, prolonged fever, night sweats, anorexia, and weight loss.

Management

An important component of management is to place these patients in respiratory isolation to prevent spread of infection, until the smear for sputum acid fast bacillus (AFB) comes back negative. As soon as the diagnosis is established, treatment with four anti-TB medications - INH, rifampin, pyrazinamide and ethambutol - is started. Each drug has food-nutrient interactions (see Chapter 8 and Appendix 23). These medications are continued for 2 months, and then only rifampin and INH are continued for 4 more months. Duration of treatment may be longer in some patients.

Medical Nutrition Therapy

Malnutrition is common in patients with pulmonary TB, and nutritional supplementation is necessary. Markers of protein nutritional status are low levels of the inflammatory proteins (see Table 7-4), anthropometric indices, and the micronutrient status of TB patients (Miyata et al, 2013).

TB leads to or worsens any preexisting condition of malnutrition and increases catabolism. The WHO guidelines suggest hospitalization of patients who are severely undernourished in view of their mortality risk. Dietary supplementation is recommended until the patient achieves a BMI of 18.5 (Bhargava et al, 2013).

Active TB is associated with weight loss, cachexia, and low serum concentration of leptin. There is a synergistic interaction between malnutrition and infection. Recurrent infection leads

to worsening nutritional status and loss of body nitrogen. The resulting malnutrition, in turn, creates a higher susceptibility to infection (Miyata et al, 2013).

In the short term, malnutrition increases the risk of infection and early progression of infection to produce active TB. In the long term, malnutrition increases the risk of reactivation of the TB disease. Malnutrition also can lower the effectiveness of the anti-TB drug regime, which patients have to be on for several months. The efficacy of Bacillus Calmette-Guerin (BCG) vaccine can also be impaired by malnutrition.

Upon correction of nutritional deficiencies, malnutrition-induced loss of certain immune processes can be reversed rapidly. Nutritional intervention in combination with appropriate medications does improve the outcome of malnourished TB patients.

Energy

Current energy recommendations are those for undernourished and catabolic patients, 35 to 40 kcal/kg of ideal body weight. For patients with any concomitant infections such as HIV, energy requirements increase by 20% to 30% to maintain body weight.

Protein

Protein is vital in preventing muscle tissue wastage and an intake of 15% of energy needs or 1.2 to 1.5 g/kg ideal body weight, approximately 75 to 100 g per day, is recommended.

Vitamins and Minerals

A multivitamin and mineral supplement that provides 50% to 150% of the RDA is helpful, because TB patients have increased requirements that are impossible to meet with diet alone. Nutrients such as vitamin A, the B vitamins, vitamins C and E, zinc, and selenium are usually deficient in TB patients. These are vital for the integrity of the immune response. Vitamin D deficiencies are common with TB and result because of an insufficient vitamin D intake and limited exposure to sunlight (Desai et al, 2012; see Appendix 45).

Isoniazid is an antagonist of vitamin B₆ (pyridoxine) and is frequently used in TB treatment. It may cause rare instances of peripheral neuropathy resulting from the nutritional depletion of vitamin B₆. A standard procedure is to supplement adults with 25 mg of vitamin B₆ per day to overcome this drug-nutrient interaction. Vitamin B₆ supplementation is not routinely used with children, but if large dosages of isoniazid are used or the child has a low blood vitamin B₆ level, 25 mg of B₆ supplementation is recommended (Nutrition Information Center University of Stellenbosch [NICUS], 2009).

Studies have documented an increased prevalence of anemia with TB patients, which is associated with increased risk of death. To guide clinical decision making and provide treatment recommendations, factors that contribute to the TB-associated anemia have to be characterized. Although other causes do co-exist, iron deficiency anemia is the most important contributor in the development of anemia in TB patients (Isanaka et al, 2012).

Evidence indicates that excess iron supplementation may be dangerous to TB patients, and the use of iron therapy is not universally recommended. However, if iron studies show iron deficiency, iron therapy is then initiated (see Chapter 32 for management of iron deficiency anemia).

LUNG CANCER

Lung cancer remains the leading cause of cancer deaths for males and females in the United States. In 2012 1.8 million patients worldwide were diagnosed with lung cancer (Mannino et al, 2014).

Neoplasms of the lower respiratory tract are a heterogeneous group of tumors. The group commonly called **bronchogenic carcinomas** comprises squamous cell carcinoma, adenocarcinoma, small cell undifferentiated carcinoma, and large cell undifferentiated carcinoma, and account for 90% of all the neoplasms of the lower respiratory tract. Mortality is more common in males than females, although this difference is diminishing. While the female incidence rate is stabilizing, the male incidence rate seems to be decreasing (Baldini et al, 2014).

Pathophysiology

Often lung cancer is detected on a routine chest radiograph in an asymptomatic smoker. Other patients may present with symptoms related to the tumor itself, symptoms related to the local extension of the tumor or widespread metastases, or systemic symptoms such as anorexia, weight loss, weakness, and paraneoplastic syndromes.

Dyspnea is the most burdensome cancer symptom, and occurs in 15% to 55% of lung cancer patients at diagnosis. In addition to the tumor, other factors contribute to the symptom of dyspnea – factors such as pericardial effusion, anemia, fatigue, depression, anxiety, metastatic involvement of other organs, aspiration, anorexia-cachexia syndrome, and pleural effusion.

Patients with lung cancer suffer from progressive *weight loss* with changes in body composition. Malnutrition impairs the contractility of the respiratory muscles, affecting endurance and respiratory mechanics.

Cough is present in 50% to 75% of lung cancer patients at presentation and occurs most frequently in squamous cell and small cell carcinoma because of their tendency to involve central airways (Huhmann and Camporeale, 2012).

Pain and fatigue are common symptoms associated with lung cancer. The tumor may produce pleuritic pain because of tumor extension into the pleura, or musculoskeletal type pain because of extension into the chest wall. Bone pain may occur as a result of metastases to the bones. Bone metastases in patients with lung cancer account for 30% to 40% of the pain. About 50% of early stage cancer and 75% to 100% of advanced stage cancer patients report fatigue (Huhmann and Camporeale, 2012).

Pulmonary cachexia syndrome affects patients with advanced lung disease and is defined by a BMI of less than 20 or a weight less than 90% of IBW (Bellini, 2013). In lung cancer, weight loss is associated with increasing mortality, and weight loss of even 5% indicates a poor prognosis. Although anorexia and cachexia are two different entities they often are used interchangeably (Huhmann and Camporeale, 2012) (see Chapter 36).

Medical Management

The choice of definitive management for a particular patient is determined by numerous factors, such as the tumor cell type, tumor stage, resectability of the tumor, and suitability of the patient for general anesthesia and surgery. Some patients need general palliative care in terms of psychologic support, control of distressing symptoms, and palliative radiation. Nutritional support plays a very important role in the management of advanced lung cancer.

Medical Nutrition Therapy

The National Comprehensive Cancer Network (NCCN) guidelines include nutritional assessments, medications, and nonpharmacologic approaches to achieve the following:

1. Treat the reversible causes of anorexia such as early satiety
2. Evaluate the rate and severity of weight loss
3. Treat the symptoms interfering with food intake: nausea and vomiting, dyspnea, mucositis, constipation, and pain
4. Assess the use of appetite stimulants like megestrol acetate and Decadron (corticosteroids)
5. Provide nutritional support (enteral or parenteral) (Del Ferraro et al, 2012)

Cancer cachexia syndrome (CCS) is the presence of a metabolic state that leads to energy and muscle store depletion in lung cancer patients. When patients experience CCS, they lose adipose and skeletal muscle mass. Changes in hormone and cytokine levels, along with tumor byproducts, cause CCS. Weight loss seen with CCS, unlike starvation, is irreversible and continues to worsen despite increased nutritional intake (Huhmann and Camporeale, 2012) (see Chapter 36).

However, despite these findings, reversible causes of anorexia should be sought and treated. Although nutritional support does not improve spirometric values and arterial blood gas and does not stop weight loss, it does modestly improve clinical outcomes such as the 6-minute walk test, quality of life, and inspiratory and expiratory muscle strength (Bellini, 2013).

Nutrition repletion is problematic in advanced lung disease because fatigue and dyspnea tend to interfere with the preparation and consumption of food. Alterations in the taste of food because of chronic sputum production, early satiety resulting from flattening of the diaphragm, nausea and indigestion resulting from side effects of medications, and lack of motivation to eat because of depression make it difficult for the patient to take adequate nutrition by the oral route. However, accepted components of oral nutrition therapy are the following:

1. Small frequent meals that are high in fat and protein and low in carbohydrate
2. Provision of adequate calories that meet or exceed the resting energy expenditure (REE)
3. Rest before meals
4. Meals that require minimal preparation
5. Oral supplements with the ratio of fat: carbohydrate of 3:1 that are better tolerated because the respiratory quotient for carbohydrates is 1.0 and for fats is only 0.7 and thus results in decreased work of breathing (Bellini, 2013)

With pulmonary cancer cachexia syndrome, patients are unable to gain weight with nutritional interventions alone. Prokinetic agents for delayed gastric emptying can be used with careful consideration of side effects. Megestrol acetate, an appetite stimulant, may result in increasing appetite and caloric intake. **Ghrelin** (a growth hormone releasing peptide) lowers fat use and stimulates feeding through growth hormone independent mechanisms, thereby inducing a positive energy balance. Studies have shown that repeated IV administration of ghrelin improves body composition, lowers muscle wasting, and increases functional capacity (Bellini, 2013).

One study suggests that whole body protein metabolism in pulmonary patients may benefit from branched-chain amino acid (BCAA) supplementation. This study was the first of its kind in assessing the clinical benefits of supplementing BCAA in a preoperative pulmonary rehabilitation center; 6.2 g of

BCAA supplementation was the recommended daily dosage. However, the effect of BCAA supplementation for lung cancer patients has not been clarified and requires further study before specific recommendations can be made. A comprehensive pulmonary rehabilitation protocol includes nutritional support and physical exercise (Harada et al, 2013).

OBESITY HYPOVENTILATION SYNDROME

Obesity hypoventilation syndrome (OHS) is defined as a BMI of more than 30 kg/m² and alveolar hypoventilation defined by arterial carbon dioxide (PaCO₂) level of more than 45 mm Hg during wakefulness, which occurs in the absence of other conditions that cause hypoventilation (Piper and Grunstein, 2011).

Alveolar hypoventilation in OHS is related to the multiple physiologic abnormalities related to obesity: obstructive sleep apnea (OSA), increased work of breathing, respiratory muscle impairment, a depressed central ventilator drive, and reduced effects of neurohumoral modulators (e.g., leptin) (Koenig, 2011; Piper and Grunstein, 2007).

Obstructive sleep apnea (OSA) is a common chronic disorder, which is characterized by loud snoring, excessive daytime sleepiness, and witnessed breathing interruptions or awakenings because of gasping or choking. The presence or absence of OSA and its severity usually is confirmed by a “sleep study” (polysomnography, PSG) before initiating treatment. The PSG also serves as a baseline to establish the effectiveness of the subsequent treatment (Epstein et al, 2009).

Medical Management

Depending on the number of episodes of apnea or **hypopnea** (overly shallow breathing) per hour, OSA is graded as mild, moderate, or severe. The patients with OSA commonly are treated with **continuous positive airway pressure (CPAP)** provided by custom made oral appliances or with various surgical methods. These primary treatment modalities for OSA must be used in addition to weight loss because of the low success and low cure rates by dietary approach alone (Epstein et al, 2009).

Medical Nutrition Therapy

Weight reduction by medical nutrition therapy or, in morbid obesity, by bariatric surgery remains an important component of management of these cases (see Chapter 21).

A 13% weight reduction has been shown to decrease the upper airway collapsibility by modifying its anatomy and function. Even modest weight loss of 10% achieved by reduced caloric intake can lead to a reduction in the apnea-hypopnea index (AHI) from 55 to 29 per hour (Shah and Roux, 2009).

Chylothorax

Chylothorax is a rare cause of pleural effusion. It is caused by the disruption or obstruction of the thoracic duct, which results in the leakage of chyle (lymphatic fluid of intestinal origin) into the pleural space. The fluid typically has a milky appearance. A pleural fluid triglyceride concentration of more than 110 mg/dl strongly supports the diagnosis of a chylothorax (Heffner, 2013).

Chylothorax can result from nontraumatic causes such as sarcoidosis or benign idiopathic chylothorax. It can occur because of surgical trauma such as postoperative chylothorax or postpneumectomy chylothorax. A unique case of recurrent bilateral chylothoraces resulting from push-ups has even been

FIGURE 34-9 CT scan showing bilateral pleural effusions.

reported (Karnik and Patel, 2011). Figure 34-9 is a CT scan of the patient showing bilateral pleural effusion. It shows the milky white chylous fluid aspirated from the patient. The milky white color seen in chylothorax is because of very high triglyceride levels.

Medical Management

The principles of management of chylothorax are (1) treatment of the underlying condition such as sarcoidosis, infection, lymphoma, or metastatic carcinoma and (2) pleural drainage to relieve dyspnea. Those patients who do not improve by thoracentesis and dietary control measures may have to be treated by pleurodesis or thoracic duct ligation (Heffner, 2013).

Medical Nutrition Therapy

MNT is the primary therapy and includes manipulation of dietary contents aimed at decreasing the formation of chyle itself. For example, it has been shown that if a patient is placed on a long-chain fatty acid restricted diet, and medium-chain triglyceride (MCT) supplements are given, there can be resolution of pleural effusion as shown by serial chest radiographs over the course of as little as 4 days (Karnik and Patel, 2011). Because the MCTs are absorbed directly into the portal system rather than into the gastrointestinal lymphatics, using them for energy in the diet results in less lymphatic flow and thus faster healing of the thoracic duct.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is a clinical state in which patients develop diffuse pulmonary infiltrates, severe hypoxia, and respiratory failure. Underlying clinical events such as sepsis or trauma that lead to the development of ARDS also result in a hypermetabolic state that markedly increases nutritional requirements.

Pathophysiology

For normal gas exchange, it is essential that dry, patent alveoli be in close proximity to capillaries. When an injury produces diffuse alveolar damage, proinflammatory cytokines are released. These cytokines recruit neutrophils to the lungs, where they become activated and release toxic mediators, which produce further damage to the alveolar epithelium and capillary endothelium. This damage allows protein to escape into the interstitium. Alveoli get filled with bloody, proteinaceous fluid which interferes with gas exchange and severe, refractory hypoxemia results. Various clinical conditions can lead to the development of ARDS (see Table 34-4).

Patients with ARDS present with acute onset of shortness of breath, tachypnea, and hypoxemia, which is refractory to oxygen supplementation.

Medical Management

The principles of ARDS management are the following:

- Treatment of underlying cause such as sepsis, aspiration, or bacterial pneumonia
- Mechanical ventilatory support
- Ensuring hemodynamic stability
- Prevention of complications such as stress ulcers, deep venous thrombosis, and aspiration pneumonia
- Nutritional support (Saguil and Fargo, 2012)

Therapies with corticosteroids, exogenous surfactant, antioxidants, and inhaled nitric oxide have been used but have not shown consistent benefit.

Medical Nutrition Therapy

Malnutrition is common in these patients who require mechanical ventilation. Patients with advanced respiratory disease have increased metabolic needs, and require prompt initiation of supplemental nutrition. It is important to consider issues related to protein use, and excess carbon dioxide production in these patients (Bellini, 2013).

Nutrition support in ARDS patients is necessary for preventing cumulative caloric deficits, loss of lean body mass, malnutrition and deterioration of respiratory muscle strength (Krzak et al, 2011).

Patients with ARDS are at high risk for complications as a result of underfeeding or overfeeding (see Table 34-5). Reduction in respiratory muscle strength is a deleterious effect of underfeeding, which leads to problems in weaning from mechanical ventilation. In addition, poor wound healing, immunosuppression, and risk of nosocomial infections increase related to inadequate calories and protein. Overfeeding leads to undesirable

TABLE 34-4 Common Clinical Conditions Associated with ARDS

Most Common	Less Common
Pneumonia	Drug toxicity
Sepsis	Aspiration
	Inhalation injury
	Near drowning
	Respiratory Syncytial virus
	Transfusion related acute lung injury
	Trauma

outcomes such as stress hyperglycemia, delayed weaning from mechanical ventilation and delayed wound healing (Krzak et al, 2011). Effective MNT requires careful assessment and monitoring. Indirect calorimetry is a useful tool for determining and monitoring energy needs (see Chapter 2). See Chapter 38 for further discussion on MNT for metabolically stressed patients.

PNEUMONIA

An inflammatory condition of the lungs that causes chest pain, fever, cough, and dyspnea is called **pneumonia**. In the clinical setting there are various kinds of pneumonias, such as community-acquired pneumonia, which may be viral or bacterial; hospital-acquired pneumonia; pneumonia in an immune compromised host; ventilator-associated pneumonia (VAP); and aspiration pneumonia, which will be discussed here. Aspiration is a common event even in healthy adults and usually causes no deleterious effects. At least one half of healthy adults aspirate during sleep. However, when this aspirate results in pulmonary consequences, it results in **aspiration pneumonia** (see Box 34-3).

Pathophysiology

Two conditions must exist for aspiration pneumonia to develop. First, there is a breach in the normal defense mechanisms, such as failure of glottis closure or impaired cough reflex, and second, a large enough inoculum enters the lungs. The aspirate contains

BOX 34-3 Conditions That Predispose a Patient to Aspiration Pneumonia

- Impaired level of consciousness, with compromised closure of glottis and impaired cough reflex
- Dysphagia from neurologic conditions
- Gastric reflux, disorders of or surgery on the upper gastrointestinal tract
- Mechanical disruption of the glottis closure because of endotracheal tube, tracheostomy, bronchoscopy, and interference with the cardiac sphincter by gastroduodenal endoscopy or placement of a nasogastric tube
- Miscellaneous conditions such as protracted vomiting, feeding via gastrostomy at less than a 45-degree angle and persistent recumbent position

Bartlett JG: Aspiration pneumonia in adults. In Baslow DS, editor: *Wolters Kluwer: UpToDate*, Waltham, Mass, 2012. Accessed October 26, 2013. Retrieved from <http://www.uptodate.com/contents/aspiration-pneumonia-in-adults>

gastric acid, which has a direct toxic effect on the lungs, particulate matter that may cause airway obstruction and atelectasis, and oral bacteria, which can result in infection and pneumonia. Pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, gram-negative bacilli, and *Staphylococcus aureus* are virulent, and only a small inoculum is needed to cause pneumonia. By convention, aspiration pneumonia is caused by less-virulent organisms such as anaerobes, which are part of the normal oral flora, with predisposing situations (see [Box 34-3](#)).

Medical Management

Three clinical syndromes exist within the category of aspiration pneumonia: (1) chemical pneumonitis resulting from aspiration of acid, (2) bacterial infection, and (3) airway obstruction. The clinical features depend on which of these predominates, but often there is an overlap. The details of the management of these syndromes is beyond the scope of this chapter, but understanding of pathophysiology and predisposing conditions helps in the effective treatment and prevention of aspiration pneumonia.

Patients who are observed to have aspirated should be cleared of the fluids or food with immediate tracheal suction. However, this maneuver will not necessarily protect the lungs from chemical injury, which occurs instantly ([Bartlett, 2012](#)). The main treatment in this situation is to support the pulmonary function. Use of glucocorticoids in chemical pneumonitis is controversial.

Aspiration pneumonia usually presents with indolent symptoms. Many patients present with complications such as lung abscess, emphysema, and necrotizing pneumonia. Once a patient has been diagnosed with aspiration pneumonia, antibiotic therapy should include coverage for anaerobic pathogens because they may cause significant disease when present ([Allen et al, 2013](#)).

Medical Nutrition Therapy

As per the 2009 Society of Critical Care Medicine and American Society for Parenteral and Enteral Nutrition (SCCM/ASPEN) guidelines, nutritional interventions for preventing aspiration pneumonia and managing it when it exists in the patient in the acute care setting are the following:

- Direct tube feedings into the small bowel rather than the stomach
- Implement continuous feedings rather than bolus feedings recommended
- Elevate the head of the patient's bed to 45 degrees
- Use prokinetic agents
- Minimize use of sedatives
- Optimize oral hygiene
- Use naloxone to improve gut motility ([Allen et al, 2013](#))

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is a chronic neonatal lung disease that causes respiratory morbidity in preterm newborns. Bronchopulmonary dysplasia occurs in 25% to 42% of preterm neonates, who show impaired growth during early stages of infancy ([Jain and Bancalari, 2014](#)). BPD affects 20% of infants born prematurely and 60% of infants born before completing 26 weeks ([Ghanta et al, 2013](#)).

Common interventions have little impact on long-term outcomes, with respiratory care remaining supportive. Decreased

lung compliance and increased need for respiratory support exists in these patients ([Dani and Poggi, 2012](#)).

Medical Management

Management should minimize any further injuries, while providing an optimal environment for growth and recovery ([Adams and Stark, 2014](#)).

Ongoing pulse oximetry is used to monitor oxygenation, whereas intermittent blood gas sampling monitors pH and PaCO₂. Periodic attempts are made to progressively wean infants from ventilator support. Prolonged ventilation is associated with laryngeal injury and subglottic stenosis, especially with infants who require multiple intubations. Suctioning should be limited to only when needed because it is associated with tracheal and bronchial injury ([Adams and Stark, 2014](#)).

The use of supplemental oxygen is challenging in patients with BPD because of the need to treat hypoxemia on one hand and on other, to avoid exposure to excess oxygen. Increasing the inhaled oxygen concentrations could have a negative affect by increasing the risk of retinopathy, pulmonary edema, or inflammation.

Most infants are managed with a modest fluid restriction of 140 to 150 ml/kg per day. Although diuretic therapy may improve short-term pulmonary status, there is no evidence that it improves clinical outcomes. Use of diuretics leads to serum electrolyte abnormalities such as hyponatremia and hypokalemia ([Adams and Stark, 2014](#)).

Medical Nutrition Therapy

Using the criteria in [Box 34-4](#), assessment of the infant with BPD begins MNT (see [Box 34-4](#)). Energy needs of infants with BPD are 15% to 20% higher than those of healthy infants, and they benefit from 140 to 150 kcal/kg/day during active stages of the disease ([Dani and Poggi, 2012](#)). Inadequate caloric

BOX 34-4 Components of Nutrition Assessment for Infants with Bronchopulmonary Dysplasia

History	Hemoglobin
Birthweight	Hematocrit
Gestational age	Serum electrolytes
Medical history	C-reactive protein
Nutrition history	
Previous growth pattern	Feeding History
	Volume of intake
Medical Status	Frequency of feedings
Respiratory status	Behavior during feedings
Oxygen saturation	Formula composition
Use of medications	Use of solid foods
Emesis	Developmental feeding milestones
Stool pattern	Swallowing difficulty
Urine output	Gastroesophageal reflux
Urine specific gravity	
Ventilator dependency	Environmental Concerns
Nutrition-Biochemical Measures	Parent-child interaction
Anthropometrics	Home facilities
Weight	Access to safe food supply
Length	Community resources
Growth percentiles	Economic resources
Head circumference	Access to adequate food and nutrients

intake leads to a catabolic state and muscle fatigue of the diaphragm. Adequate nutrition is essential for lung growth, alveolar development, surfactant production, and protection against infections.

Infants with BPD have decreased lean body mass, indicating an inadequate protein intake. Treatment with corticosteroids also increases body fat and lowers protein, thereby altering the composition of weight gain. Protein intakes of 3.5 to 4.0 g/kg body weight in infants with BPD help in meeting the growth and anabolic needs (Dani and Poggi, 2012). Amino acids are administered within the first 26 hours of life because they are well tolerated, improve glucose tolerance, and create positive nitrogen balance. An amino acid requirement of 1.5 to 2 g/kg/day is suggested for term infants, 2 to 3 g/kg/day for infants at 30 to 36 weeks, and 3.6 to 4.8 g/kg/day for infants at 24 to 30 weeks (Dani and Poggi, 2012) (see Chapter 42).

Although lipids remain a vital component in providing essential fatty acids and meeting energy goals, the role of lipid administration remains controversial. Lipids are held or administered in small quantities because they can cause hyperbilirubinemia and increase the risk of kernicterus in these infants. Lipids result in less carbon dioxide production compared to carbohydrate and although high-fat formulas do not show a significant change in respiration in adults, infants who receive fat-free formulas exhibit decreased carbon dioxide production and improved respiration (Dani and Poggi, 2012). Further investigation is required to determine the optimal lipid intake for infants with BPD. The European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) recommends a reasonable range of 4.4 to 6.0 g of fat/100 kcal or 40% to 55% of caloric intake.

Sodium and potassium depletion are seen in infants with BPD who are treated with diuretics. Because sodium administration counteracts the action of diuretics, mild deficiencies in sodium and chloride are anticipated (Dani and Poggi, 2012).

Decreased bone mineralization is seen in infants with BPD. Urinary loss of calcium is increased with the administration of corticosteroids and diuretics. Osteopenia of prematurity is common in infants with BPD resulting from nutritional deficiencies of calcium and phosphorus. Enteral feeds are not useful in providing adequate amounts of calcium and phosphorus,

whereas parenteral feeds restrict the intake because of limited solubility of calcium and phosphorus.

Infants with BPD are monitored every 1 to 2 weeks for calcium, and phosphorus and it is recommended to supplement with vitamin D (Dani and Poggi, 2012) and milk fortifiers (see Chapter 42).

The use of vitamin A, corticosteroids, and caffeine have been shown to reduce BPD at 36 weeks of age. 5000 IU of vitamin A was administered intramuscularly three times a week for a month to show a significant reduction in BPD and death in those infants receiving the supplementation (Ehrenkranz, 2014).

Parenteral nutrition is continued along with enteral feeds till the feeding volume reaches 100 ml/kg/day. Starting enteral feeds earlier induces gastric motility and promotes progression to full enteral feedings. Better neurologic development in preterm infants with BPD can be accomplished with early nutrition support, appropriate enteral feeds, and parenteral feed selection (Dani and Poggi, 2012). See Chapter 42 for further discussion on feeding the low birthweight infant.

CLINICAL CASE STUDY

Esther is an 80-year-old widow who is a retired secretary. She started smoking when she was 15, and she smoked two packs per day until 7 years ago. She has been diagnosed with COPD and has been admitted to the rehabilitation center with a broken hip following a fall at home. Significant findings are weight 101 lb, height 5'3", blood pressure 127/65 mm Hg, heart rate 82/minute, respiratory rate 18/minute, temperature 98.6° F, oxygen saturation 95% on 3L of O₂. History and physical examination reveal severe dyspnea on exertion, including showering, carrying packages, making the bed, and pushing a vacuum cleaner; orthopnea (two or three pillows); and decreased breath sounds. Prescribed medications include theophylline (300 mg twice daily), prednisone (20 mg once daily in the morning), furosemide 20 mg twice daily, fluticasone (Flovent; 220 mcg, four puffs twice daily), albuterol and ipratropium (Atrovent; two puffs as needed). Over-the-counter medications include vitamin C (250 mg twice daily), and calcium (500 mg daily). She says she has no appetite and is eating very little. Her stated usual weight is 115 lbs and she admits to recent weight loss.

Nutrition Diagnosis Statement

Significant weight loss related to decreased food intake due to lung disease and surgery.

Nutrition Care Questions

1. What dietary interventions can you suggest to increase intake of calories and protein?
2. What are the interrelationships between chronic obstructive pulmonary disease, food intake, and nutrient metabolism?
3. Are there any food-drug interactions that are a concern for Esther?
4. What are the principles of medical nutrition therapy in this clinical situation? Explain the scientific rationale for each.
5. What do you think of Esther's nutrient supplementation program? Would you have her change it?
6. You are planning a session on nutrition for the clients and their families who participate in the Pulmonary Rehabilitation Program. What topics would you cover? What educational techniques would you use?

Medical Nutrition Therapy for Renal Disorders

*Katy G. Wilkens, MS, RDN, Veena Juneja, MScRD, RDN,
Elizabeth Shanaman, RDN*

KEY TERMS

acute glomerulonephritides	erythropoietin (EPO)	oliguria
acute kidney injury (AKI)	Fanconi syndrome	osteitis fibrosa cystica
acute renal failure (ARF)	fistula	osteomalacia
adynamic (low turnover) bone disease	glomerular filtration rate (GFR)	peritoneal dialysis (PD)
antidiuretic hormone (ADH)	graft	phosphate binders
azotemia	hemodialysis (HD)	protein-nitrogen appearance (PNA) rate
blood urea nitrogen (BUN)	hypercalciuria	pyelonephritis
calciophylaxis	hyperoxaluria	recombinant human EPO (rHuEPO)
chronic interstitial nephritis	idiopathic hypercalciuria (IH)	renal failure
chronic kidney disease (CKD)	intradialytic parenteral nutrition (IDPN)	renal osteodystrophy
continuous renal replacement therapy (CRRT)	intraperitoneal nutrition (IPN)	renal replacement therapy (RRT)
continuous venovenous hemodialysis (CVVHD)	Kidney Dialysis Outcome Quality Initiative (KDOQI)	renal tubular acidosis (RTA)
continuous venovenous hemofiltration (CVVH)	kinetic modeling	renin-angiotensin mechanism syndrome of inappropriate antidiuretic hormone (SIADH)
creatinine	Kt/V	ultrafiltrate
dialysate	metastatic calcification	urea reduction ratio (URR)
end-stage renal disease (ESRD)	nephritic syndrome	uremia
estimated glomerular filtration rate (eGFR)	nephrolithiasis	vasopressin
	nephrotic syndrome	

PHYSIOLOGY AND FUNCTION OF THE KIDNEYS

The main function of the kidney is to maintain the balance of fluids, electrolytes, and organic solutes. The normal kidney performs this function over a wide range of fluctuations in sodium, water, and solutes. This task is accomplished by the continuous filtration of blood with alterations in secretion and reabsorption of this filtered fluid. The kidney receives 20% of cardiac output, filtering approximately 1600 L/day of blood and producing 180 L of fluid called **ultrafiltrate**. Through active processes of reabsorbing certain components and secreting others, composition of this ultrafiltrate is changed into the 1.5 L of urine excreted in an average day.

Each kidney consists of approximately 1 million functioning nephrons (see [Figure 35-1](#)), consisting of a glomerulus connected to a series of tubules. Tubules consist of different segments: the proximal convoluted tubule, loop of Henle, distal tubule, and collecting duct. Each nephron functions independently and contributes to the final urine, although all are under similar control and coordination. If one segment of a nephron is destroyed, that complete nephron is no longer functional.

The glomerulus is a spheric mass of capillaries surrounded by a membrane, Bowman's capsule. The glomerulus produces the **ultrafiltrate**, which then is modified by the next segments of the nephron. Production of ultrafiltrate is mainly passive and relies on the perfusion pressure generated by the heart and supplied by the renal artery.

The tubules reabsorb the vast majority of components that compose the ultrafiltrate. Much of this process is active and requires a large expenditure of energy in the form of adenosine triphosphate (ATP). The tubule is a unique structure; differences in permeability between the various segments and hormonal responses allow the tubule to produce the final urine, which can vary widely in concentration of electrolytes, osmolality, pH, and volume. Ultimately, this urine is funneled into common collecting tubules and into the renal pelvis. The renal pelvis narrows into a single ureter per kidney, and each ureter carries urine into the bladder, where it accumulates before elimination.

The kidney has almost unlimited ability to regulate water homeostasis. Its ability to form a large concentration gradient between its inner medulla and outer cortex allows the kidney to excrete urine as dilute as 50 mOsm or as concentrated as 1200 mOsm. Given a daily fixed solute load of approximately

FIGURE 35-1 The nephron. (Modified from Patton KT, Thibodeau GA: *The human body in health and disease*, ed 6, Maryland Heights, Mo, 2013, Mosby.)

600 mOsm, the kidney can get rid of as little as 500 ml of concentrated urine or as much as 12 L of dilute urine. Control of water excretion is regulated by **vasopressin (antidiuretic hormone [ADH])**, a small peptide hormone secreted by the posterior pituitary. An excess of relative body water, indicated by a low osmolality, leads to prompt shut-off of all vasopressin secretion. Likewise, a small rise in osmolality brings about marked vasopressin secretion and water retention. However, the need to conserve sodium sometimes leads to a sacrifice of the homeostatic control of water for the sake of volume (see *Focus On: Syndrome of Inappropriate Antidiuretic Hormone (SIADH)*).

FOCUS ON

Syndrome of Inappropriate Antidiuretic Hormone

Syndrome of inappropriate antidiuretic hormone (SIADH) is seen when there is an excessive amount of antidiuretic hormone released from the pituitary gland. Common causes include head injury, meningitis, cancer, infection, and hypothyroidism. The result is hyponatremia caused by hemodilution. It is characterized by a serum sodium less than 135 mEq/L and a urine sodium concentration greater than 20 mEq/L. If left untreated it can result in seizures and coma. It is treated with fluid restriction, generally less than 1800 ml/day, and may require intravenous sodium administration. Oral sodium supplementation is contraindicated.

The minimum urinary volume capable of eliminating a relatively fixed 600 mOsm of solute is 500 ml, assuming that the kidney is capable of maximum concentration. Urinary volume of less than 500 ml/day is called **oliguria**; it is impossible for such a small urine volume to eliminate all of the daily waste.

The majority of the solute load consists of nitrogenous wastes, primarily the end products of protein metabolism. Urea predominates in amount, depending on the protein content of the diet. Uric acid, **creatinine (Cr)**, and ammonia are present in small amounts. If normal waste products are not eliminated appropriately, they collect in abnormal quantities in the blood, known as **azotemia**. The ability of the kidney to adequately eliminate nitrogenous waste products is defined as renal function. Thus **renal failure** is the inability to excrete the daily load of wastes.

The kidney also performs functions unrelated to excretion. One of these involves the **renin-angiotensin mechanism**, a major control of blood pressure. Decreased blood volume causes cells of the glomerulus (the juxtaglomerular apparatus) to react by secreting renin, a proteolytic enzyme. Renin acts on angiotensinogen in the plasma to form angiotensin I, which is converted to angiotensin II, a powerful vasoconstrictor and a potent stimulus of aldosterone secretion by the adrenal gland. As a consequence, sodium and fluid are reabsorbed, and blood pressure is returned to normal.

The kidney also produces the hormone **erythropoietin (EPO)**, a critical determinant of erythroid activity in the bone marrow. Deficiency of EPO is the primary cause of the severe anemia present in chronic renal disease.

Maintenance of calcium-phosphorus homeostasis involves the complex interactions of parathyroid hormone (PTH); calcitonin; active vitamin D; and three effector organs: the gut, kidney, and bone. The role of the kidney includes production of the active form of vitamin D—1,25-dihydroxycholecalciferol (1,25-[OH]₂D₃)—as well as elimination of calcium and phosphorus. Active vitamin D promotes efficient absorption of calcium by the gut and is one of the substances necessary for bone remodeling and maintenance. Active vitamin D also suppresses PTH production, which is responsible for mobilization of calcium from bone (see Chapter 24).

RENAL DISEASES

The manifestations of renal disease are significant. They can be ordered by degree of severity: (1) kidney stones, (2) acute kidney injury (AKI), (3) chronic kidney disease (CKD), and (4) end-stage renal disease (ESRD) (National Kidney Foundation, 2002). Objectives of nutritional care depend on the abnormality being treated.

Kidney Stones (Nephrolithiasis)

Nephrolithiasis, the presence of kidney stones, is a significant health problem in the United States. The prevalence of kidney stones from the National Health and Nutrition Examination Survey (NHANES) 2007 to 2010 data is 8.8% (Scales et al, 2012). It is characterized by frequent occurrences during the fourth and fifth decades of life and a high recurrence rate. The risk doubles in those with a family history of kidney stones; stone formers often have first-degree relatives with kidney stones. Increased frequency of obesity, diabetes, and metabolic syndrome have resulted in increasing rates of nephrolithiasis. Thought to be a predominantly male disease, its prevalence is fast increasing in women (7.1%) and in men at 10.6%, changing the male/female ratio. Kidney stones affect people of all ethnic groups. NHANES reveals a lower occurrence rate in black non-Hispanic and Hispanic individuals compared with white non-Hispanic individuals (Scales et al, 2012).

Health care cost of evaluation, hospitalization, and treatment of kidney stone disease in the United States exceeds 4.5 billion dollars per year. Preventing recurrence can have a significant cost-saving potential as a result of reduced stone burden. Medical nutrition therapy can play an important role in prevention (Morgan, 2016). A low urine volume is the single most important risk factor for all types of nephrolithiasis.

Pathophysiology

Kidney stone formation is a complex process that consists of saturation; supersaturation; nucleation; crystal growth or aggregation; crystal retention; and stone formation in the presence of promoters, inhibitors, and complexors in urine. A typical metabolic evaluation is described in Table 35-1.

Calcium stones are the most common: 60% of stones are calcium oxalate, 10% calcium oxalate and calcium phosphate, and 10% calcium phosphate. Other stones are 5% to 10% uric acid, 5% to 10% struvite, and 1% cystine.

TABLE 35-1 Baseline Information and Metabolic Evaluation of Urolithiasis

Information	Description and Data
History of urolithiasis	History of onset, frequency Family history Spontaneous passage or removal Retrieval, analysis of stone Current status with radiologic examination
Medical history, investigation	Hyperparathyroidism Renal tubular acidosis Urinary tract infection Sarcoidosis Hypertension Osteoporosis Inflammatory bowel disease, malabsorption syndrome, intestinal bypass surgery for obesity (Roux-en Y or gastric banding/sleeve gastrectomy) Metabolic syndrome or insulin resistance Diabetes mellitus Obesity
Blood tests	Serum—calcium, phosphorus, creatinine, uric acid, CO ₂ , albumin, parathyroid hormone, Hgb A1C
Urinalysis	Urine analysis with pH Urine culture
24-hr urine collection	Volume, calcium, oxalate, uric acid, sodium, citrate, magnesium, phosphorus Urea Creatinine Qualitative cystine
Medications and vitamins	Thiazide, allopurinol, vitamin C, vitamin B ₆ , vitamin D, cod liver oil, calcium carbonate, glucocorticoid therapy, potassium citrate, antacids
Occupation history and strenuous exercise	Dermal water losses Dehydration Low urine volume Type of job and activity level
Environment	Hard water area
Dietary evaluation	Intake of calcium, oxalate, animal protein, salt, purines, fructose, potassium Fruits and vegetables (related to urine pH) Herbal products; fish oils Volume of fluid intake Type of fluids containing citrate, malate, caffeine, fructose, phosphoric acid; mineral water; sports drinks

CO₂, Carbon dioxide; Hgb A1C, hemoglobin A1C.

Obese stone formers excrete increased amounts of sodium, calcium, uric acid, and citrate, and have lower urine pH. Obesity is the strongest predictor of stone recurrence in first-time stone formers. As body weight increases, the excretion of calcium, oxalate, and uric acid also increases. Patients with a higher body mass index (BMI) have a decrease in ammonia excretion and impaired hydrogen ion buffering. With increasing BMI, uric acid stones become more dominant than calcium oxalate stones, especially in men. Based on urinary supersaturation index and urinary risk factors total body fat and truncal fat mass are associated more strongly with uric acid stones than total body weight and lean body mass (Pigna et al, 2014).

Uric acid stones are common in the presence of type 2 diabetes. Hyperinsulinemia also may contribute to the development of calcium stones by increasing urinary calcium excretion.

In postmenopausal women as the amount not the intensity of physical activity increases, the risk of incident stones declines (Sorensen et al, 2014).

Weight control may be considered one of the preventive modalities and in stone formers, a BMI of 18 to 25 kg/m² is recommended.

With malabsorptive bariatric procedures such as Roux-en-Y gastric bypass (RYGB), urolithiasis is higher than in obese controls, probably because of the increased prevalence of hyperoxaluria and hypocitraturia in RYGB patients. However, restrictive gastric surgery (i.e., gastric banding or sleeve gastrectomy) is not associated with increased risk of kidney stones (Semins et al, 2010).

Agents added intentionally or unintentionally to food or drug products have led to the appearance of new types of stones containing melamine and indinavir (Zilberman et al, 2010) (see Table 35-2).

Calcium Stones. One third to one half of patients with calcium stones are hypercalciuric. **Hypercalciuria** describes a value of calcium in excess of 300 mg (7.5 mmol) per day in men, 250 mg (6.25 mmol) per day in women, or 4 mg (0.1 mmol)/kg/day for either in random urine collections of outpatients on unrestricted diets. The classic definition of hypercalciuria of upper normal limit of 200 mg per day is based on a constant diet restricted in calcium, sodium, and animal protein (Pak et al, 2011).

Idiopathic hypercalciuria (IH) is a familial disorder characterized by abnormal serum calcium in the absence of known causes of hypercalciuria, such as primary hyperparathyroidism, sarcoidosis, excess vitamin D intake, hyperthyroidism, glucocorticoid use, or renal tubular acidosis (RTA). Ninety percent of patients with IH never form a kidney stone. However, they are more sensitive to forming stones, as relatively small increases in urine calcium increase calcium oxalate supersaturation.

TABLE 35-2 Causes and Composition of Renal Stones

Pathogenetic Causes	Composition of Stone
Hypercalciuria, hyperoxaluria, hyperuricosuria, or hypocitraturia	Calcium oxalate
Primary hyperparathyroidism	Calcium oxalate
Cystinuria	Cystine
Infection	Struvite
Acid urine pH	Uric acid
Hyperuricosuria	Uric acid
Renal tubular acidosis	Calcium phosphate
Alkaline urine pH	Calcium phosphate

Formation of a stone in a person with IH can be triggered by an excessive dietary calcium intake, increased intestinal absorption of calcium that may or may not be vitamin D–mediated, decreased renal tubular reabsorption of calcium, or prolonged bed rest. Increased gut absorption of calcium even when on a restricted calcium, sodium and animal protein diet is noted particularly in patients with absorptive hypercalciuria. Urinary calcium levels higher than normal at any level of net calcium absorption suggests that some of the urine calcium is derived from the bone. Negative calcium balance appears to be greater in stone formers than in non–stone formers.

When challenged with a very-low-calcium diet, the loss of more calcium in the urine than is in the diet indicates a net loss of total body calcium. The source of this additional calcium is the skeleton (Krieger and Bushinsky, 2013). Patients with IH tend toward negative phosphorus balance even on normal intakes. The defective phosphate metabolism may lead to increased $1,25(\text{OH})_2\text{D}_3$ levels, and increased intestinal calcium absorption.

Bone loss can be high in patients with IH in whom low calcium intake exaggerates bone loss from increased net acid excretion (NAE). For decades low-calcium diets were recommended to reduce the hypercalciuria in these stone formers. However, chronic prolonged calcium restriction, deficient calcium intake, and increased losses from hypercalciuria decrease bone mineral density. The decreased BMD also correlates with

an increase in markers of bone turnover as well as increased fractures (Krieger and Bushinsky, 2013). Vertebral fracture risk increases fourfold among urolithiasis patients in comparison with the general population.

Undesirable bone resorption may be enhanced by a high protein intake of nondairy origin. An inadequate calcium intake along with high protein intake induces metabolic acidosis, increases calcium excretion, and lowers urinary pH. This acid load inhibits the renal reabsorption of calcium. A reduction in nondairy animal protein may be recommended (see *Clinical Insight: Urinary pH—How Does Diet Affect It?*).

Calcium supplements do not have the same protective effect against stone formation as dietary calcium. Widespread use of calcium supplements to prevent osteoporosis corresponds to an increase in kidney stones in women. A trial of combined calcium–vitamin D supplementation to prevent bone loss and fractures led to a 17% increase in new stone formation in women who increased their calcium intake to 2000 mg a day by adding a 1000 mg calcium supplement to their baseline diet (Wallace et al, 2011).

If calcium is taken as a supplement, timing is important. Calcium supplements taken with meals increase urinary calcium and citrate, but decrease urinary oxalate; thus the increase in citrate and decrease in oxalate counterbalance the effects of elevated urinary calcium. Therefore, if used by patients who

CLINICAL INSIGHT

Acid and Alkaline Diets

by Sheila Dean, DSc, RDN, LD, CCN, CDE

Dietary intake can influence the acidity or alkalinity of the urine (Berardi et al, 2008). It has been shown that excessive dietary protein (particularly high in sulfur-containing amino acids such as methionine and cysteine), and chloride, phosphorous, and organic acids are the main sources of dietary acid load. When these animal proteins, such as meat and cheese, are eaten concomitantly with other acid-producing foods and not balanced with alkaline-producing foods, such as fruit and vegetables, there is an increased risk of chronic acidosis. Acidosis (which is not to be confused with acidemia) has been linked to inflammatory-related chronic diseases such as urolithiasis, hypertension, insulin resistance, low immune function, and osteoporosis (Adeva and Souto, 2011; Minich and Bland, 2007).

Consequently, when working with higher protein intakes it is important to provide a diet balanced in high alkaline foods. The most abundant alkaline foods are plant-based foods; particularly vegetables and fruit abundant in alkalinizing micronutrients such as magnesium, calcium, sodium, and potassium. A more alkaline diet consisting of a higher fruit and vegetable intake is associated with a low potential renal acid load (PRAL) (Remer and Manz, 1995). Lower consumption of meat, which is also associated with a lower PRAL, may thus ameliorate not only the elevated blood pressure of hypertension but also the concurrent excess of morbidity and mortality of the concurrent cardiac, vascular, and metabolic aspects of the hypertensive state. Although acute acid loading may only temporarily disrupt acid-base equilibrium, a chronic perturbation occurs when metabolism of the diet repeatedly releases acids into the systemic circulation in amounts that exceed the amount of base released at the same time. To overcome the imbalance, the skeleton, which serves as the major reservoir of base, provides the buffer needed to main blood pH and plasma bicarbonate concentrations. To some degree, skeletal muscle also acts as a buffer. Other compensatory mechanisms occur as well, all in response to the acidic load (Pizzorno et al, 2010).

Remer and Manz developed a physiologically based model to calculate the PRAL of selected, frequently consumed foods. By means of these PRAL data, the daily net acid excretion can be calculated, allowing for an

accurate prediction of the effects of diet on acid load. This has been a reason to recommend animal protein limited diets, to control the dietary source of acids (Kiwull-Schone et al, 2008). The following food lists serve as a guide to influencing potential renal acid load (PRAL).

Potentially Acid Foods

Protein: meat, fish, fowl, shellfish, eggs, all types of cheese, peanut butter, peanuts

Fat: bacon, butternuts, walnuts, pumpkin seeds, sesame seeds, sunflower seeds, creamy salad dressings

Carbohydrate: all types of bread including cornbran, oats, macaroni, rice-bran, rye, wheat, and especially wheat gluten

Sweets: gelatin desserts (dry mix with and without aspartame), pudding (instant, dry mix)

Potentially Basic or Alkaline Foods

Fat: dried beechnuts, dried chestnuts, acorn

Vegetables: all types including legumes but especially beets, beet greens, Swiss chard, dandelion greens, kale, leeks, mustard greens, spinach, turnip greens

Fruit: all types, especially currants, dates, figs, bananas, dried apricots, apples, prunes, raisins

Spices/Herbs: all types, especially fresh dill weed and dried spices/herbs such as spearmint, basil, coriander, curry powder, oregano, parsley

Sweets: sorghum syrup, sugar (brown), molasses, cocoa (dry powder)

Beverages: coffee

Neutral Foods

Fats: butter, margarine, oils

Dairy: milk

Vegetables: corn

Sweets: sugar (white), most syrups, honey

Beverages: water, tea

cannot tolerate dairy products because of lactose intolerance, allergies, or preference, calcium supplements should be taken with meals. Urine calcium should be measured before starting the supplement and afterward to see the effect; if urine calcium increases, patients should increase fluid intake to dilute the urine concentration of calcium.

Higher dietary calcium from either nondairy or dairy foods is independently associated with a lower kidney stone risk (Taylor and Curhan, 2013). Therefore, based on DRI recommendations for age (see inside front cover), patients may select calcium from dairy or nondairy choices. Given recent concerns for increased risk for cardiovascular disease and kidney stones with increased use of calcium supplements, women should aim to meet DRI recommendations from a calcium-rich diet, taking calcium supplements only if needed to reach DRI goals (Manson and Bassuk, 2014). Calcium should be taken in divided doses, choosing a source with each meal to maximize oxalate binding. Low-fat dairy choices are good options for their lower saturated fat content.

Oxalate Stones. Hyperoxaluria (more than 40 mg of oxalate in urine per day) plays an important role in calcium stone formation and is observed in 10% to 50% of recurrent stone formers. Primary hyperoxaluria is a feature of an autosomal-recessive genetic defect of a hepatic enzyme that results in overproduction of oxalate and a urinary oxalate concentration three to eight times normal. Multiple stones occur in these children, causing renal failure and early death.

Patients with inflammatory bowel diseases or gastric bypass often develop hyperoxaluria related to fat malabsorption. The bile acids produced during the digestive process normally are reabsorbed in the proximal gastrointestinal (GI) tract, but when this fails to occur, bile salts and fatty acids increase colonic permeability to oxalate (see Chapter 28). The unabsorbed fatty acids also bind calcium to form soaps, decreasing availability of calcium in a soluble form. With less calcium available to bind oxalate in the gut and prevent its absorption, serum oxalate and thus urinary oxalate levels increase.

Urinary oxalate also comes from endogenous synthesis, proportional to lean body mass. Ascorbic acid accounts for 35% to 55%, and glyoxylic acid accounts for 50% to 70% of urinary oxalate. In patients with CKD, excessive vitamin C intake may lead to stone formation. Oxalate synthesis is not increased with a high protein diet (Knight et al, 2009). Because pyridoxine acts as a cofactor in the conversion of glyoxylate to glycine, its deficiency could increase endogenous oxalate production.

The bioavailability of food oxalate and urine oxalate are affected by salt forms of oxalate, food processing and cooking methods, meal composition, and the presence of *Oxalobacter formigenes* (OF) in the GI tract (Siener et al, 2013). Stone-forming patients who lack this bacteria have significantly higher urinary oxalate excretion and stone episodes compared with patients colonized with the bacteria. There is a 70% risk reduction in calcium-oxalate stone formers when there is OF colonization of their stool (Lange, 2014).

Administration of *O. formigenes* as enteric-coated capsules significantly reduces urine oxalate in patients with primary hyperoxaluria. Dietary advice for reducing urinary oxalate should include use of this probiotic and reduction of dietary oxalate, if needed, and simultaneous consumption of calcium-rich food or supplement to reduce oxalate absorption (Knight et al, 2009; see Box 35-1).

BOX 35-1 Foods to Avoid for a Low-Oxalate Diet

- Rhubarb
- Spinach
- Strawberries
- Chocolate
- Wheat bran and whole-grain wheat products
- Nuts (almonds, peanuts, or pecans)
- Beets
- Tea (green, black, iced, or instant)
- High doses of turmeric

Data from Siener R et al: Oxalate content of cereals and cereal products, *J Agric Food Chem* 54:3008, 2006.

Uric Acid Stones. Uric acid is an end product of purine metabolism from food, de novo synthesis, and tissue catabolism. Approximately half of the purine load is from endogenous sources and is constant. Exogenous dietary sources provide the other half, accounting for the variation in urinary uric acid. The solubility of uric acid depends on urine volume, the amount excreted, and urine pH (see Table 35-3). Uric acid stones form when urine is supersaturated with undissociated uric acid, which occurs at urinary pH less than 5.5.

The most important feature in uric acid stone formers is low urine pH resulting from increased NAE and impaired buffering caused by reduced urinary ammonium excretion. The former can be a result of low intake of alkali-producing foods or increased consumption of acid-producing foods (see *Clinical Insight: Urine pH—How Does Diet Affect It?*).

Inflammatory bowel disease results in chronically acidic urine, usually from dehydration. GI bicarbonate loss from diarrhea may predispose these patients to uric acid stones. Uric acid stones also are associated with lymphoproliferative and myeloproliferative disorders, with increased cellular breakdown that releases purines and thus increases uric acid load. Diabetes, obesity, and hypertension appear to be associated with nephrolithiasis; diabetes is a common factor in uric acid stone development (Scales et al, 2012). Besides diabetes management for patients with uric acid lithiasis and hyperuricosuric calcium oxalate stones, dietary purines also should be restricted.

Meat, fish, and poultry are rich in purines and acid ash and thus should be used in moderation to meet DRI for protein. Purines and metabolism of sulfur-rich amino acids, cystine and methionine, in animal protein confer an acid load to the kidney, thus lowering urine pH. PRAL value is assigned to groups of foods in terms of their positive or negative effect on acidic load (Trinchieri, 2012, 2013). Foods specifically high in purines should be avoided, including organ meats, anchovies, herrings, sardines, meat-based broth, and gravy (see Box 39-3). Dietary noncompliance or persistence of hyperuricosuria warrants use of medication such as allopurinol. Uric acid stones are the only stones amenable to dissolution therapy by urine

TABLE 35-3 Effect of Urine pH on Stone Formation

pH	State of Urate	Likely Stone Development
<5.5	Undissociated urate	Uric acid stones
5.5-7.5	Dissociated urate	Calcium oxalate stones
>7.5	Dissociated urate	Calcium phosphate stones

alkalinization to a pH of 6 to 6.5. Potassium citrate has been used as the therapy of choice. Sodium bicarbonate increases urinary monosodium urate and calcium and should not be used as a supplement.

Cystine Stones. Cystine stones represent 1% to 2% of urinary calculi and are caused by homozygous cystinuria. Cystine stones affect approximately 1 in 15,000 persons in the United States. Whereas normal individuals daily excrete 20 mg or less of cystine in their urine, stone-forming cystinuric patients excrete more than 250 mg/day. Cystine solubility increases when urine pH exceeds 7; therefore an alkaline urine pH must be maintained 24 hours per day, even while the patient sleeps. This is achieved almost always with the use of medication. Fluid intake of more than 4 L daily is recommended to prevent cystine crystallization. Lower sodium intake may be useful in reducing cystine in the urine. Restriction of animal protein is associated with lower intake of cystine and methionine, a precursor of cystine. Ingestion of vegetables and fruit high in citrate and malate, such as melons, limes, oranges and fresh tomato juice, may help alkalinize the urine (Heilberg and Goldfarb, 2013).

Melamine and Indinavir Stones. Kidney stones, ARF, and death have been reported in young children who received melamine-contaminated infant formula. Melamine is an organic base synthesized from urea. When added to liquid milk or milk powder, it deceptively increases the protein content. Melamine precipitates in the distal renal tubules, forming crystals and sandlike stones. Hydration and urine alkalinization help with stone passage.

The treatment of human immunodeficiency virus infection with protease inhibitors has led to the appearance of another previously unknown urinary calculus: indinavir. Hypocitraturia is universal in all patients with indinavir stones as well as decreased solubility in a low urine volume with a low pH. These stones are soft, gelatinous, and radiolucent and are not amenable to basket removal or ureteroscopy. Intravenous (IV) hydration and temporary cessation of indinavir should be the first choice of treatment (Zilberman et al, 2010).

Struvite Stones. Struvite stones are composed of magnesium ammonium phosphate and carbonate apatite. They are also known as triple-phosphate or infection stones. Unlike most urinary stones, they occur more commonly in women than in men, at a ratio of 2:1. They form only in the presence of bacteria such as *Pseudomonas*, *Klebsiella*, *Proteus mirabilis*, and *Urealyticum*, which carry urease, a urea-splitting enzyme. Urea breakdown results in ammonia and carbon dioxide (CO₂) production, thus raising urine pH and the level of carbonate. Struvite stones grow rapidly to large staghorn calculi in the renal pelvic area. The mainstay of treatment is extracorporeal shockwave lithotripsy (ECSWL) with adjunctive culture-specific antimicrobial therapy that uses urease inhibitors. The goal is to eliminate or prevent urinary tract infections by regularly screening and monitoring urine cultures. Because of their infectious origin, diet has no definitive role except avoidance of urine alkalinization.

Medical Management

Uric acid stones are the only type amenable to dissolution therapy, or dissolving of the stone by alkalinization of the urine. This is done with consumption of a more vegetarian diet, that is also lower in purines, or use of medication. Shockwave lithotripsy and endourologic techniques almost have replaced the open surgical procedures of stone removal of 20 years ago.

Struvite stones also are treated with adjunctive culture-specific antimicrobial therapy that uses urease inhibitors. Management strategies are now aimed at kidney stone prevention.

Medical Nutrition Therapy

After corrective treatment, nutrition assessment is needed to determine risk factors for stone recurrence. The risk in men and women rises with increasing urine calcium and oxalate and decreases with increasing citrate and urine volume. There is a continuum of risk related to increasing urinary calcium and urinary oxalate. For patients with no metabolic abnormality there is a graded increase in stone risk that begins when the rate of urinary excretion of calcium, oxalate, and citrate is still within the normal range (Curhan and Taylor, 2008). Because urine chemistries change from day to day based on changes in the environment and diet, two 24-hour urine specimens are needed based on a usual diet, one during a weekday and one on the weekend. Specific medical nutrition therapy (MNT) is then based on comprehensive metabolic evaluations. Nutrition counseling and metabolic monitoring can be effective (see Table 35-4).

When a patient passes a stone, it should be determined whether it is a new stone or a preexisting one and advisement given accordingly. The effectiveness of any MNT should be monitored with evaluation of subsequent 24-hour urine collections. This gives the nutritionist and patient a measure of the effect of dietary changes. Once diet therapy is initiated, the goal is to prevent new stones from forming and preexisting stones from growing (see *Pathophysiology and Care Management Algorithm: Kidney Stones*).

TABLE 35-4 Recommendations for Diet and 24-Hour Urine Monitoring in Kidney Stone Disease

Diet Component	Intake Recommendation	24-Hour Urine
Protein	Normal intake: avoid excess	Monitor urinary urea
Calcium	Normal intake: 1000 mg if age <50 years; 1200 mg if age >50 years Divide intake between three or more eating sessions. Choose from dairy or non-dairy sources	Calcium <150 mg/L (<3.75 mmol/L)
Oxalate	Avoid moderate- to high-oxalate foods if urinary oxalate is high	Oxalate <20 mg/L (<220 μmol/L)
Fluid	2.5 L or more; assess type of fluids consumed; provide guidelines	Volume > 2 L/day
Purines	Avoid excessive protein intake; avoid specific high-purine foods	Uric acid <2 mmol/L (<336 mg/L)
Vitamin C	Avoid supplementation	Monitor urinary oxalate
Vitamin D	Meet DRI for vitamin D intake. Use supplements to reach DRI	Serum 25(OH)D ₃ in acceptable range
Vitamin B ₆	40 mg or more per day reduces risk. No recommendation made	
Sodium	<100 mmol/day	Monitor urinary sodium

PATHOPHYSIOLOGY AND CARE MANAGEMENT ALGORITHM

Kidney Stones

ETIOLOGY

Co-Morbidities

- Metabolic syndrome
- Renal tubular acidosis
- Medullary sponge kidney
- Hyperparathyroidism
- Malabsorption syndromes
- Urinary tract infections
- Bariatric surgery (Roux-en-y)

Family History

Urinary risk factors

- Low urine volume
- Hypercalciuria
- Hyperoxaluria
- Hyperuricosuria
- Hypocitraturia
- Urine pH
- ↑ urine urea

Dietary Factors

- Low fluid
- Low calcium
- High oxalate
- High sodium
- Low potassium
- High animal protein
- High fructose
- High vitamin C

Kidney Stones

PATHOPHYSIOLOGY

Flank pain/Renal colic

Spontaneous passage of stone

Retrieval of stone

Locate stone and treat

MANAGEMENT

Medical Management

- Identify and treat medical cause
- 24 hour urine collection to identify risk factors
- Stone analysis
- Shockwave lithotripsy
- Surgical, endourologic stone removal
- Antimicrobial therapy
- Pharmacologic treatment

Nutrition Management

- Normalize urinary excretion of stone forming solutes
- Achieve daily urine volume >2 L
- Dietary calcium based on age
- Avoid high oxalate foods
- Lower salt intake
- Moderate animal protein
- Vitamin C not >500 mg/day

Fluid and Urine Volume. A low urine volume is by far the most common abnormality noted in the metabolic evaluation of stone formers, and its correction with a high fluid intake should be the focus with all types of kidney stones. The objective is to maintain urinary solutes in the undersaturated zone to inhibit nucleation; this is accomplished by an increase in urine volume and reduction of solute load. The goal is the amount of urine flow rather than a specified fluid intake. High urine flow rate tends to wash out any formed crystals, and a urine volume of 2 to 2.5 L/day should prevent stone recurrence. Fluid intake should change based on different rates of extrarenal fluid loss that affect rate of urine flow. The concentration of urinary risk factors is important, not the absolute amount excreted, the former will be high when the urine volume is low. The goal should be to maintain appropriate concentration of solutes per liter of urine.

Achieving a urine volume of 2 to 2.5 L/day usually requires an intake of 250 ml of fluid at each meal, between meals, at bedtime, and when arising to void at night. Hydration during sleep hours is important to break the cycle of the “most-concentrated” morning urine. Half of this daily 2.5 L should be taken as water. Even higher fluid intake, perhaps as much as 3 L/day, may be necessary to compensate for any GI fluid loss, excessive sweating from strenuous exercise, or an excessively hot or dry environment. Barriers to fluid intake success include lack of knowledge about the benefits of fluid or not remembering to drink, disliking the taste of water, lack of thirst, lack of availability of water, needing to void frequently, and not wanting workplace disruptions. Fluid intake behavior can be improved by specifically addressing barriers relevant to the individual patient.

Not all fluids are equally beneficial for reducing the risk of kidney stones. Cranberry juice acidifies urine and is useful in the treatment of struvite stones. Black currant juice increases urinary citrate and oxalate and, because of its urine alkalinizing effect, may prevent the occurrence of uric acid stones.

Tea, coffee, decaffeinated coffee, orange juice, beer, and wine have been associated with reduced risk of stone formation. Coffee and tea induce moderate diuresis because of their caffeine content. Because decaffeinated coffee has no caffeine, it is suggested that other mechanisms may be involved, such as phytochemicals with antioxidant properties. Alcohol also helps because of diuresis. Orange juice has citrate that delivers an alkali load (Taylor and Curhan, 2008a).

The oxalate content of tea brewed from regular black or green tea is 300 to 1500 $\mu\text{mol/L}$. Because of this high oxalate content of black tea, it should be taken with generous amounts of added milk; milk appears to reduce oxalate absorption by binding it in the gut lumen as calcium oxalate, making it less absorbable. Herbal teas have much lower oxalate content of 31 to 75 $\mu\text{mol/L}$ and are an acceptable alternative (Kaufman et al, 2008).

Animal Protein. Epidemiologic studies find a correlation between improved standard of living, high animal protein intake, and the rising incidence of kidney stones. Meat, fish, poultry, eggs, cheese, and grains are the primary contributors of acid; a LAKE (load of acid to kidney evaluation) score can be a simple and useful tool to evaluate dietary PRAL (potential renal acid load). Dietary modifications can be made to achieve LAKE reduction for the prevention of kidney stones. Fruits, juices, vegetables, potatoes, and legumes have negative PRAL values (Trinchieri, 2012) (see *Clinical Insight: Urine pH—How Does Diet Affect It?*). An adequate-calcium, low-animal

protein, low-salt diet (less than 4 g) reduces oxalate excretion more than a traditional low oxalate diet.

Oxalate. Because much less oxalate than calcium exists in urine (the ratio is 1:5), changes in oxalate concentration have a greater effect than changes in urinary calcium. However, oxalate absorption, which is 3% to 8% of the amount in food, is affected by the amount of dietary calcium. Dietary calcium reduces oxalate absorption, and appears to have more impact on urinary oxalate than the amount of dietary oxalate. The impact of dietary oxalate on urinary oxalate appears to be small. For many stone formers, restricting dietary oxalate may be a relatively ineffective intervention to decrease urinary oxalate excretion (Agarwal et al, 2011). On very low calcium intakes of less than 200 mg/day, oxalate absorption rises; it falls when more calcium (1200 mg) is ingested. Age is associated independently and inversely with urinary oxalate.

Dietary counseling to reduce oxalate absorption is beneficial for stone-forming individuals who have large intakes of high-oxalate foods and who excrete more than 30 mg (350 μmol) of oxalate per day. Based on the available evidence, severe oxalate restriction is not necessary. The oxalate content of foods can be found at <http://regepi.bwh.harvard.edu/health/oxalate/files/oxalate>. However, avoidance of excessive dietary oxalate intake is reasonable, and should be coupled with advice for increasing calcium intake (Agarwal et al, 2011). The patient is advised to add calcium to each meal to bind oxalate. The total calcium intake for the day can be divided between at least three meals or as many eating occasions as possible. It takes 150 mg of calcium to bind 100 mg of oxalate. Patients should include approximately 150 mg calcium in each meal, such as that found in $1/2$ cup milk, ice cream, pudding, yogurt, or $3/4$ oz cheese (Kaufman et al, 2008).

Potassium. Stone formers often have a low to normal potassium intake and high sodium intake that results in an adversely raised Na:K ratio. Potassium intake is related inversely to the risk of kidney stones. Estimation of fruit and vegetable intake should be included in the metabolic evaluation. Stone formers should be encouraged to increase the potassium in their diets by choosing low-oxalate fruit and vegetables many times throughout the day (see Appendix 51 and Box 35-1). Foods high in potassium are replete with alkali, which stimulates urinary citrate excretion. Every 20 mEq/day increase in urinary potassium is associated with a 17 mg/day decrease in urinary calcium (Nouvenne et al, 2010).

Magnesium. Magnesium is a low-molecular-weight inhibitor that forms soluble complexes with oxalate. Like calcium, it inhibits oxalate absorption and may have a role to play in hyperoxaluric patients.

Phosphate. Excess urine phosphate contributes to calcium phosphate stone risk, but it is not as important a risk factor as urinary pH, which determines how much phosphate will be in the form of hydrogen phosphate (HPO_4). Calcium phosphate stones tend to occur in pregnant women in the second and third trimester of pregnancy.

Sodium. The daily amount of sodium chloride in modern diets reaches excessive levels of up to 10 g/day. The amount of sodium in the urine and hypercalciuria are correlated directly because sodium and calcium are reabsorbed at common sites in the renal tubule. The risk for nephrolithiasis is significantly higher in hypertensive individuals compared with normotensive individuals. A low-sodium diet and water therapy lowered urine sodium, calcium, and oxalate in idiopathic hypercalciuric stone formers compared with controls on water therapy alone

(Taylor et al, 2009). Urine sodium is associated positively with urine calcium and urine volume and negatively with urine calcium-oxalate supersaturation. Increased volume may confer a protective effect.

Sodium intake should be lowered to less than 2300 mg/day in patients with hypercalciuria. Consumption of a diet modeled on the Dietary Approaches to Stop Hypertension (DASH) diet reduces the risk for kidney stones (Baia et al, 2012; Trinchieri, 2013). Higher DASH scores are associated with higher intakes of calcium, potassium, magnesium, oxalate, and vitamin C and lower intakes of sodium as the diet is moderately high in low-fat dairy products, fruits and vegetables, and nuts and low in animal proteins (see Appendix 26).

Citrate. Citrate inhibits urinary stones by forming a complex with calcium in urine. Thus less calcium is available to bind urinary oxalate, which helps prevent the formation of calcium oxalate or calcium phosphate stones. Distal **renal tubular acidosis (RTA)** is an acidosis accompanied by hypokalemia. RTA, malabsorption syndrome with enteric hyperoxaluria, and excessive meat intake (lower urine pH) are associated with decreased urinary citrate levels.

Many citrate-containing beverages have been tested for their effect on urine. Several diet sodas contain moderate amounts of citrate and malate, bicarbonate precursors; malate increases the total alkali load delivered, which augments citruria. One commercial sports drink tested in non-stone formers increased urine citrate as much as 170 mg/day, but many sports drinks contain too much fructose and do not increase urinary citrate. Melon juice has citrate and malate and a PRAL value more negative than orange juice (Kang et al, 2007). Fresh tomato juice has citrate and malate and is low in sodium and oxalate.

Hypocitraturia is most commonly idiopathic but also may be caused by acidosis accompanied by hypokalemia, malabsorption syndrome with enteric hyperoxaluria, excessive meat intake, and acid ash. Half of recurrent calcium stone formers have hypocitraturia (urinary citrate of less than 300 mg/day). Normal daily urinary citrate level should be more than 640 mg/day. Long-term lemonade or lime or lemon juice therapy in hypocitraturic stone formers results in increased urinary citrate levels and decreased stone formation rate (Taylor and Curhan, 2008b). Mineral water, with its magnesium and bicarbonate content, raises urine pH and stone inhibition.

Fructose. Fructose intake has increased approximately 2000% during the past 30 years from the widespread use of high-fructose corn syrup in foods. Fructose may increase urinary excretion of calcium and oxalate. It is the only carbohydrate known to increase the production of uric acid and its urinary excretion. Fructose also may increase insulin resistance, which is associated with low urine pH. Fructose intake has been positively associated with risk for all types of kidney stones (Tang et al, 2012). Increased fruit and vegetable consumption is recommended to increase potassium intake, but because of the fructose content of fruit, there should be more emphasis on vegetables.

Vitamins. Vitamin C supplementation at 1000 mg/day was associated with twofold increased risk of kidney stones in men. Compared with less than 90 mg/day vs. 1000 mg/day the latter results in 6.8 mg more oxalate in urine (Agarwal et al, 2011). In another study, which included women, total vitamin C intake and supplement vitamin C intake correlated with risk for stone formation in men, but not women. The same was observed for supplemental vitamin C intake, but not dietary vitamin C intake in both men and women (Ferraro et al, 2016). Thus individuals with

calcium oxalate stone disease and high levels of urine oxalate should avoid vitamin C supplementation greater than 90 mg/day.

Vitamin B₆ in the form of pyridoxal phosphate is a required cofactor in oxalate metabolism; marginal B₆ status should be avoided. Supplementing with 2 to 10 mg/day of vitamin B₆ may reduce urinary oxalate in some calcium oxalate stone formers.

The role of vitamin D in stone disease is controversial. From NHANES III data based on serum 25-OH vitamin D concentration, a high concentration was not associated with prevalent kidney stone disease in the participants (Tang et al, 2012). Vitamin D in doses producing desirable levels of 25(OH) D at 100 to 150 nmol/L or 40 to 60 ng/ml does not adversely affect components of kidney stones (Heany, 2013, <http://www.grassrootshealth.net>).

Omega-3 Fatty Acids. Elevated levels of arachidonic acid (AA) in cell membranes may promote hypercalciuria and hyperoxaluria. The intake of omega-3 fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) may decrease the AA content of cell membranes and reduce urinary excretion of calcium and oxalate. EPA is an inhibitor of AA metabolism resulting in decreased synthesis of prostaglandin 2 (E-2 (PGE₂)), a substance known to potentiate urine calcium excretion. EPA and DHA through fish oil supplementation did not reduce the risk of incident kidney stones and fatty acid intake of AA, and linoleic acid did not increase the risk of developing kidney stones in observational studies (Taylor et al, 2005). The use of fish oil (omega-3 FA at 1200 mg/day) in the treatment of hypercalciuric stone formers combined with empiric diet counseling resulted in a measurable decrease in urine calcium (24% became normocalciuric) and oxalate excretion, and an increase in urinary citrate. Calcium-oxalate supersaturation decreased in 38% of subjects (29). EPA at 1800 mg/day showed significant reduction in stone episodes (Yasui et al, 2008).

ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

Pathophysiology

Acute kidney injury (AKI), formerly **acute renal failure (ARF)**, is characterized by a sudden reduction in **glomerular filtration rate (GFR)**, the amount of filtrate per unit in the nephrons, and altered ability of the kidney to excrete the daily production of metabolic waste. AKI can occur in association with oliguria (decreased output of urine) or normal urine flow, but it typically occurs in previously healthy kidneys. Duration varies from a few days to several weeks. The causes of AKI are numerous and can occur simultaneously (see Table 35-5). These causes are generally classified into three categories: (1) inadequate renal perfusion (prerenal), (2) diseases within the renal parenchyma (intrinsic), and (3) urinary tract obstruction (postrenal).

A new form of classification to help clinicians assess the severity and progression of acute kidney injury, using the acronym RIFLE (Risk, Injury, Failure, Loss and ESRD), indicates the likelihood of a patient recovering or progressing to chronic renal failure. This, in turn, helps dietitians know whether to increase protein intake goals or be more moderate to preserve kidney function.

Medical Management

The ratio of **blood urea nitrogen (BUN)** to creatinine can be used diagnostically to assess the location of damage to the kidney. Depending on where the insult occurs, **BUN** is

TABLE 35-5 Some Causes of Acute Kidney Injury

Causes	Condition
Prerenal inadequate renal perfusion	Severe dehydration Circulatory collapse
Intrinsic diseases within the renal parenchyma	Acute tubular necrosis <ul style="list-style-type: none"> • Trauma, surgery • Septicemia Ischemic acute tubular necrosis Nephrotoxicity <ul style="list-style-type: none"> • Antibiotics, contrast agents, and other drugs Local reaction to drugs Vascular disorders <ul style="list-style-type: none"> • Bilateral renal infarction Acute glomerulonephritis of any cause <ul style="list-style-type: none"> • Poststreptococcal infection • Systemic lupus erythematosus
Postrenal urinary tract obstruction	Benign prostatic hypertrophy with urinary retention Carcinoma of the bladder or prostate Retroperitoneal or pelvic cancer Bilateral ureteral stones and obstruction Rhabdomyolysis

increased because of poor filtration and is more actively reabsorbed. In this situation, with a BUN/Cr ratio greater than 20:1, damage is prerenal (before the kidney). When damage is intrinsic (within the kidney), the BUN/Cr ratio decreases to less than 10:1. Generally, if careful attention is directed at diagnosing and correcting the prerenal or obstructive causes, AKI is short lived and requires no particular nutritional intervention.

Intrinsic AKI can result from causes listed in [Table 35-5](#); of these, a prolonged episode of ischemia leading to ischemic acute tubular necrosis is the most devastating. Typically patients develop this illness as a complication of an overwhelming infection, severe trauma, surgical accident, or cardiogenic shock. The clinical course and outcome depends mainly on the underlying cause. Patients with AKI caused by drug toxicity generally recover fully after they stop taking the drug. On the other hand, the mortality rate associated with ischemic acute tubular necrosis caused by shock is approximately 70%. Typically these patients are highly catabolic, and extensive tissue destruction occurs in the early stages. Hemodialysis (HD) is used to reduce the acidosis, correct the uremia, and control hyperkalemia.

If recovery is to occur, it generally takes place within 2 to 3 weeks after the insult is corrected. The recovery (diuretic) phase is characterized first by an increase in urine output and later by a return of waste elimination. During this period dialysis may still be required, and careful attention must be paid to fluid and electrolyte balance and appropriate replacement.

Medical Nutrition Therapy

Nutritional care in AKI is particularly important because the patient not only has uremia, metabolic acidosis, and fluid and electrolyte imbalance but also usually suffers from physiologic stress (e.g., infection or tissue destruction) that increases protein needs. The problem of balancing protein and energy needs with treatment of acidosis and excessive nitrogenous waste is complicated and delicate. In the early stages of AKI the patient is often unable to eat. Mortality in AKI is high, especially among those who are

previously malnourished ([Coca et al, 2009](#)). Early attention to nutritional support and early dialysis improves patient survival.

At the onset of AKI, depending on severity, some patients can be treated with medical management, other patients require **renal replacement therapy (RRT)** with standard **hemodialysis (HD)** or **peritoneal dialysis (PD)** to remove wastes and fluids until kidney function returns. In significant AKI, a patient in the intensive care unit (ICU) may require continuous treatments, rather than periodic dialysis. **Continuous renal replacement therapy (CRRT)** is the broad category term that includes a whole host of modalities (see *Focus On: Continuous Renal Replacement Therapy or CRRT*). Most often used are **continuous venovenous hemofiltration (CVVH)** and **continuous venovenous hemodialysis (CVVHD)**, which use a small ultrafiltration membrane to produce an ultrafiltrate that can be replaced by parenteral nutrition (PN) fluids. This treatment allows parenteral feeding without fluid overload.

FOCUS ON

Continuous Renal Replacement Therapy or CRRT

CRRT typically is used when patients develop anasarca (extreme generalized edema) or elevated blood pressure and are unable to excrete fluid or uremic wastes. It is the therapy chosen when periodic hemodialysis is to be avoided because rapid removal of fluid and wastes may put the kidney into a less active state causing decreased blood flow to the kidney and a delay in regaining of kidney function.

	CVVH-Diffusion	CVVH-Convection	CVVHD	SCUF
Definition	Continuous venovenous hemodialysis using diffusion	Continuous venovenous hemodialysis using convection	Continuous venovenous hemodiafiltration	Slow continuous ultrafiltration
Advantages	Good removal of small molecules. Do not need replacement fluids.	Better removal of middle weight molecules. Good fluid removal.	Best removal of fluid and middle weight solutes. Also used in treatment of severe sepsis.	Best treatment for fluid overload. Used primarily for fluid removal.
Contraindications	May add considerable calorie load, less effective removal of middle weight molecules.	10% to 15% protein losses in ultrafiltrate. Protein lost must be replaced, along with other fluid replacement.	Replacement fluids required. Considerable calorie load from dextrose solution possible.	Does not remove urea or other small or middle weight molecules well.

Protein. The amount of protein recommended is influenced by the underlying cause of AKI and the presence of other conditions. A range of recommended levels can be found in the literature, from 0.5 to 0.8 g/kg for nondialysis patients to 1 to 2 g/kg for patients receiving dialysis. With CRRT protein losses are

high, and estimated protein needs increase to 1.5 to 2.5 g/kg. As the patient's overall medical status stabilizes and improves, metabolic requirements decrease. During this stable period before renal function returns, a minimum protein intake of 0.8 to 1 g/kg of body weight should be given. This remains dependent on the patient's overall status and comorbidities and should be evaluated individually.

Energy. Energy requirements are determined by the underlying cause of AKI and comorbidity. Energy needs can be measured at the bedside by indirect calorimetry in most ICUs (see Chapter 2). If this equipment is not available, calorie needs should be estimated at 25 to 40 cal/kg of upper end IBW or adjusted IBW per day. Excessive calorie intake can lead to excess CO₂ production, depressing respiration (see Chapter 34). With newer solutions available, glucose can be either absorbed or lost, depending on the concentration or type of solution used, and can be a source of calorie loss or gain. Large intakes of carbohydrate and fat are needed to prevent the use of protein for energy production. For patients who receive PN, high concentrations of carbohydrate and lipid can be administered to fulfill these needs as long as respiratory status is monitored.

A high-calorie, low-protein diet may be used in cases in which dialysis or hemofiltration is unavailable. In addition to the usual dietary sources of refined sweets and fats, special high-calorie, low-protein, and low-electrolyte formulas have been developed to augment the diet. However, care must be taken with these products because hyperglycemia is not uncommon as a result of glucose intolerance, and additional insulin often is needed.

Fluid and Sodium. During the early (often oliguric) phase of AKI, meticulous attention to fluid status is essential. Ideally fluid and electrolyte intake should balance the net output. With negligible urine output, significant contributions to total body water output include emesis and diarrhea, body cavity drains, and skin and respiratory losses. If fever is present, skin losses can be excessive; whereas if the patient is on humidified air, almost no losses occur. Because of the numerous IV drugs, blood, and blood products necessitated by the underlying disease, the challenge in managing patients at this point becomes how to cut fluid intake as much as possible while providing adequate protein and energy.

Sodium is restricted, based on decreased urinary production. In the oliguric phase when the sodium output is very low, intake should be low as well, perhaps as low as 20 to 40 mEq/day. However, limiting sodium is often impossible because of the requirement for many IV solutions (including IV antibiotics, medications for blood pressure, and PN). The administration of these solutions in electrolyte-free water in the face of oliguria quickly leads to water intoxication (hyponatremia). For this reason, all fluid above the daily calculated water loss should be given in a balanced salt solution.

Potassium. Most of the excretion of potassium and the control of potassium balance are normal functions of the kidney. When renal function is impaired, potassium balance should be scrutinized carefully. In addition to dietary sources, all body tissues contain large amounts of potassium; thus tissue destruction can lead to potassium overload. Potassium levels can shift abruptly and have to be monitored frequently. Potassium intake must be individualized according to serum levels (see Appendices 29 and 51). The primary mechanism of potassium removal during AKI is dialysis. Control of serum potassium levels between dialysis

TABLE 35-6 Summary of Medical Nutrition Therapy for Acute Kidney Injury

Nutrient	Amount
Protein	0.8-1 g/kg IBW increasing as GFR returns to normal; 60% should be HBV protein
Energy	30-40 kcal/kg of body weight
Potassium	30-50 mEq/day in oliguric phase (depending on urinary output, dialysis, and serum K ⁺ level); replace losses in diuretic phase
Sodium	20-40 mEq/day in oliguric phase (depending on urinary output, edema, dialysis, and serum Na ⁺ level); replace losses in diuretic phase
Fluid	Replace output from the previous day (vomitus, diarrhea, urine) plus 500 ml
Phosphorus	Limit as necessary

GFR, Glomerular filtration rate; *HBV*, high biologic value; *IBW*, ideal body weight; *K⁺*, potassium; *Na⁺*, sodium.

administrations relies mainly on IV infusions of glucose, insulin, and bicarbonate, all of which drive potassium into cells. Exchange resins, such as sodium polystyrene sulfonate (Kayexalate), which exchange potassium for sodium in the GI tract, can be used to treat high potassium concentrations; however, for many reasons these resins are less than ideal. Table 35-6 summarizes MNT for AKI.

DISEASES OF THE TUBULES AND INTERSTITIUM

To a great extent, the functions of the kidney tubules make them susceptible to injury. The enormous energy requirements and expenditures of the tubules for active secretion and reabsorption often leave this part of the kidney particularly vulnerable to ischemic injuries. Many toxic drugs can destroy or damage various segments of the tubules. The high-solute concentration generated in the medullary interstitium exposes it to damage from oxidants and precipitation of calcium-phosphate product (extraosseous calcification) and favors the sickling of red blood cells in sickle cell anemia. Indeed, a wide variety of diseases or disorders of the tubules and interstitium exists. They share common manifestations and can be considered together with respect to nutritional management.

Chronic interstitial nephritis can occur as a result of analgesic abuse, sickle cell disease, diabetes mellitus, or vesicoureteral reflux and manifests primarily as inability to concentrate the urine and as mild renal insufficiency. A hereditary disorder of the interstitium, medullary cystic disease, also presents with this picture. Dietary management consists of adequate fluid intake, which can require several liters of extra fluid. This is generally well tolerated by the patient, except when intercurrent illness occurs.

Fanconi syndrome is characterized by an inability to reabsorb the proper amount of glucose, amino acids, phosphate, and bicarbonate in the proximal tubule, thus causing urinary excretion of these substances. Adults with this syndrome present with acidosis, hypokalemia, polyuria, or osteomalacia, whereas children present with polyuria, growth retardation, rickets, and vomiting. No specific medical treatment is available to treat Fanconi syndrome; therefore dietary treatment is the main form of management. Replacement therapy usually consists of large volumes of water and dietary supplements of bicarbonate, potassium, phosphate, calcium, and vitamin D.

Renal tubular acidosis (RTA), a defect in tubular handling of bicarbonate, can be caused by either a defect in the distal tubule (type 1) or a proximal tubular defect (type 2). Distal RTA leads to severe osteomalacia, kidney stones, or even nephrocalcinosis (calcification of the kidney). Distal RTA is treated with small amounts of bicarbonate, 70 to 100 mEq/day, with complete resolution of disease manifestations. Isolated proximal RTA in the adult is a benign disease, which often is made worse with bicarbonate and therefore should not be treated.

Pyelonephritis, a bacterial infection of the kidney, does not require extensive dietary management. However, in chronic cases the use of cranberry juice to reduce bacteriuria may be useful (Wang et al, 2012). Concentrated tannins or proanthocyanidins in cranberry juice and blueberry juice may inhibit the adherence of *Escherichia coli* bacteria to the epithelial cells of the urinary tract (see *Clinical Insight: Urinary Tract Infections and Cranberry Juice*). However, a study that reviewed 24 studies did find substantial benefit (Freire, 2013).

CLINICAL INSIGHT

Urinary Tract Infections and Cranberry Juice

Urinary tract infections (UTIs) are much more common in women than men because of the shorter female urethra. Elderly women have the highest incidence of UTI, and it is thought to be related to the loss of estrogen after menopause. Patients who are catheterized are also at high risk. The bacteria most commonly involved are *E. coli* resulting from the close proximity of the anus to a woman's urethra. Treatment is usually antibiotics to resolve the infection and phenazopyridine is used as an anesthetic to decrease symptoms. It temporarily changes the color of a woman's urine to bright orange or red. It is contraindicated in renal failure.

Nutritionally, tannins or proanthocyanidins in cranberry juice and blueberry juice may inhibit the adherence of *E. coli* bacteria to the epithelial cells. Coffee, alcohol, and sodas should be avoided because they irritate the urinary tract and cause dehydration. In normal kidney function drinking 6 to 8 ounces of water daily is recommended.

GLOMERULAR DISEASES

The functions of the glomerulus that are important with respect to disease are production of an adequate ultrafiltrate and prevention of certain substances from entering this ultrafiltrate.

Nephritic Syndrome

Nephritic syndrome incorporates a group of diseases characterized by inflammation of the capillary loops of the glomerulus. These **acute glomerulonephritides** are sudden in onset and brief and may proceed to complete recovery, development of chronic nephrotic syndrome, or ESRD. The primary manifestation of these diseases is hematuria (blood in the urine), a consequence of the capillary inflammation that damages the glomerular barrier to blood cells. The syndrome also is characterized by hypertension and mild loss of renal function. The most common presentation follows a streptococcal infection and is usually, although not always, self-limiting. Other causes include primary kidney diseases such as immunoglobulin A nephropathy (IgA); hereditary nephritis; and secondary diseases such as systemic lupus erythematosus (SLE), vasculitis, and glomerulonephritis (GN) associated with endocarditis, abscesses, or infected ventriculoperitoneal shunts.

Pathophysiology

Nephrotic syndrome comprises a group of diseases that derive from a loss of the glomerular barrier for protein. Large urinary protein losses lead to hypoalbuminemia with consequent edema, hypercholesterolemia, hypercoagulability, and abnormal bone metabolism. More than 95% of the cases of nephrotic syndrome stem from three systemic diseases: (1) diabetes mellitus, (2) systemic lupus erythematosus (SLE), and (3) amyloidosis; and from four diseases that are primarily of the kidney: (1) minimum change disease (seen only with electron microscopy), (2) membranous nephropathy, (3) focal glomerulosclerosis, and (4) membranoproliferative glomerulonephritis. Although renal function can deteriorate during the course of these diseases, it is not a consistent feature.

CHRONIC KIDNEY DISEASE

Many forms of kidney disease, two of which are described earlier, are characterized by a slow, steady decline in renal function and lead to renal failure in some patients, whereas other patients have a benign course without loss of renal function. It is unclear why some patients remain stable with **chronic kidney disease (CKD)** for many months to years, whereas others progress rapidly to renal failure and dialysis. The nature of this progressive loss of function has been the subject of an enormous amount of basic and clinical research during the past several decades and the subject of several excellent reviews (National Kidney Foundation, 2000; Yang et al, 2014). Medical nutrition therapy begins when the patient is diagnosed with the goal of preventing the progression of the disease as well as mitigating symptoms.

Pathophysiology

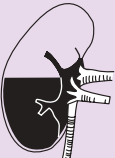

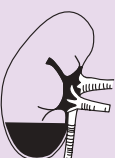

Once approximately one half to two thirds of kidney function has been lost, regardless of the underlying disease, progressive further loss of kidney function ensues. This is true even in diseases in which the underlying cause has been eliminated completely, such as in vesicoureteral reflux, cortical necrosis of pregnancy, or analgesic abuse. It is thought that, in response to a decreasing GFR, the kidney undergoes a series of adaptations to prevent decline. Although in the short term this leads to improvement in filtration rate, in the long term it leads to an accelerated loss of nephrons and progressive renal insufficiency. The nature of these adaptations involves a change in the hemodynamic characteristics of the remaining glomeruli, specifically leading to increased glomerular pressure. Factors that increase glomerular pressure tend to accelerate this process, whereas factors that decrease glomerular pressure tend to alleviate it (Grams et al, 2013).

Diabetes is the leading risk factor for CKD followed by hypertension and glomerulonephritis. The National Kidney Foundation (NKF) divides CKD into five stages related to the **estimated GFR (eGFR)** the rate at which the kidneys are filtering wastes (see Table 35-7). Stages 1 and 2 are early stages with markers such as proteinuria, hematuria, or anatomic issues. Stages 3 and 4 are considered advanced stages. Stage 5 results in death unless dialysis or transplantation is initiated.

Medical Management

The prevalence of CKD is now estimated at approximately 10% of adults in the United States, or greater than 20 million Americans. This estimated prevalence of CKD shows that 1 in

TABLE 35-7 Stages of Chronic Kidney Disease

Stage	eGFR	Description
1 	90-130 ml/min	Kidney damage, but normal to increased kidney function
2 	60-89 ml/min	Mild decrease in kidney function
3 	30-59 ml/min	Moderate decrease in kidney function
4 	15-29 ml/min	Severe decrease in kidney function
5 	Less than 15 ml/min	Kidney failure requires dialysis, transplantation, or medical management (death with dignity)

eGFR, Estimated glomerular filtration rate.

3 people with diabetes and 1 in 5 people with hypertension have CKD (CDC, 2014). Many states now urge clinical laboratories reporting serum creatinine also to report the patient's eGFR. Patients with a low calculated eGFR do not necessarily have CKD. They must have several blood samples drawn 3 months apart that are consistently low (showing eGFR of less than 60) (see Table 35-7). This testing alerts primary care physicians to monitor for possible presence of kidney disease. Further research using eGFR cystatin C followed by eGFR pairing cystatin C and creatinine is now recognized as the most precise measure (Inker et al, 2012).

An online eGFR calculator can be found at the NKF site at http://www.kidney.org/professionals/kdoqi/gfr_calculator.cfm. With screening tools such as the calculated eGFR and a greater awareness of the progressive nature of CKD, more attention has focused on its social, medical, and financial effects. For example, CKD is strongly linked with cardiovascular disease (see *Clinical Insight: Chronic Kidney Disease and Heart Disease—A Deadly Union*).

Medical Nutrition Therapy

With each level of CKD, a different nutritional therapy may be proposed. The primary objectives of MNT are to manage the symptoms associated with the syndrome (edema,

CLINICAL INSIGHT

Chronic Kidney Disease and Heart Disease—A Deadly Union

The presence of chronic kidney disease (CKD) increases the risk category for those with cardiovascular disease (CVD), and exacerbates existing CVD. An alarming fact is that most patients with CKD die of heart disease before they develop end-stage renal disease. Recommendations are that CKD patients should decrease their cardiovascular risks: quit smoking, increase exercise, choose healthy fats, increase intake of fruits and vegetables, and reach and maintain a normal body weight.

Fortunately, intervention makes a difference. The United States Renal Data System Dialysis M/M Study included 2264 patients with CKD. More than half had not seen a nephrologist in the year before needing dialysis, and a third had their first nephrologist encounter less than 4 months before starting dialysis. This late referral to nephrologists resulted in low serum albumin and hematocrit levels. Patients who had seen a nephrologist at least 2 years before dialysis had a decrease in mortality. Thus patients who have CKD and receive early nutrition counseling may postpone the need for dialysis, or come to dialysis better nourished. The expertise of the renal dietitian has been recognized by the Center for Medicare Services, allowing for physician-ordered medical nutrition therapy by registered dietitian nutritionist (RDN) providers for Americans with CKD who are not on dialysis.

hypoalbuminemia, and hyperlipidemia), decrease the risk of progression to renal failure, decrease inflammation, and maintain nutritional stores. Patients are treated primarily with statins to correct hyperlipidemia, low-sodium diets, and diuretics (Turner et al, 2012). Patients with an established severe protein deficiency who continue to lose protein may require an extended time of carefully supervised nutritional care. The diet should attempt to provide sufficient protein and energy to maintain a positive nitrogen balance and to support tissue synthesis while not overtaxing the kidneys. In most cases, sufficient intake from carbohydrate and fats is needed to spare protein for anabolism.

Some of the more common nutrition diagnoses in the CKD population include the following:

- Inadequate mineral intake
- Excessive mineral intake
- Imbalance of nutrients
- Excessive fluid intake
- Impaired nutrient utilization
- Altered nutrition-related laboratory values
- Food-medication interaction
- Food- and nutrition-related knowledge deficit

Depending on the nutrition diagnosis, MNT interventions are adjusted for various intakes of minerals, protein, and fluids. Some benefit has been seen in CKD with dietary interventions to lower inflammation. Cooking techniques, a more plant-based diet, and a focus on foods that lower inflammation are being studied (Abboud and Henrich, 2010).

Protein. The recommended dietary protein level for CKD patients has changed over time. Historically, these patients received diets high in protein (up to 1.5 g/kg/day) in an attempt to increase serum albumin and prevent protein malnutrition. However, studies have shown that a reduction of protein intake to as low as 0.8 mg/kg/day may decrease proteinuria without adversely affecting serum albumin. Serum albumin is a marker of inflammation, not protein malnutrition. Dietary protein has been championed as a factor that increases glomerular pressure and thus leads to accelerated loss of renal

function. Numerous studies in experimental models of moderate renal insufficiency demonstrate a significant decline in this process with protein restriction. Clinical studies demonstrate a role for protein restriction in the management of patients with mild to moderate renal insufficiency to preserve renal function. To allow for optimal protein use, 50% to 60% of the protein should be from sources of high biologic value (HBV), meaning that the body is easily able to digest and use the amino acids.

A large multicenter trial, Modification of Diet in Renal Disease (MDRD), attempted to determine the role of protein, phosphorus restriction, and blood pressure control in the progression of renal disease. Thus the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDKD) developed recommendations for the management of patients with progressive renal disease or pre-ESRD. Those recommendations for dietary protein intake in progressive renal failure are 0.8 g/kg/day with 60% HBV for patients whose GFR is greater than 55 ml/min, and 0.6 g/kg/day with 60% HBV for patients whose GFR is 25 to 55 ml/min.

The NKF's **Kidney Dialysis Outcome Quality Initiative (KDOQI)** panel suggests that patients whose GFR is less than 25 ml/min and who have not yet begun dialysis should be maintained on 0.6 g/kg/day of protein and 35 kcal/kg/day. If patients cannot maintain an adequate caloric intake on this protein recommendation, their protein intake should be increased to 0.75 g/kg/day. In both cases approximately 50% of the protein should be of HBV.

The potential benefits of protein restriction in the patient with moderate renal insufficiency must be weighed against the potential hazards of such treatment (i.e., protein malnutrition). If protein is restricted, careful monitoring and anthropometric studies should be carried out periodically as directed by the KDOQI guidelines.

Systemic hypertension, which aggravates the progressive loss of renal function, must be well controlled to produce benefits from protein restriction. Also important in the control of the progression of renal failure in people with diabetes is good blood glucose control. In a national multicenter trial, the Diabetes Control and Complications Trial (DCCT) showed that blood glucose control was more important than protein restriction in delaying the onset of renal failure in individuals who have diabetes (see Chapter 30).

Research continues about the use of more plant-based proteins in CKD, including tofu and legumes. Some benefits can be assessed looking at inflammation and improvement in mortality rates, but it is not yet conclusive if this is related to the plant-based proteins, or the nutrition and lifestyle associated with a more plant-based diet (Chen et al, 2016).

Energy. Energy intake should be approximately 35 kcal/kg/day for adults to spare protein for tissue repair and maintenance. In patients who are significantly overweight, some adjustment should be made to normalize requirements (see Box 2-1).

Sodium. Edema, the most clinically apparent manifestation, indicates total body sodium overload. In addition, because of low oncotic pressure from hypoalbuminemia, the volume of circulating blood may be reduced because of migration of fluid to interstitial space. Attempts to severely limit sodium intake or to use diuretics may cause marked hypotension, exacerbation of coagulopathy, and deterioration of renal function. Therefore control of edema in this group of diseases should be with dietary intake of 1500 g of sodium daily (Whelton et al, 2012).

Potassium. Potassium management is possible through use of medications such as diuretics, individualized diet prescription,

and rate of progression of CKD. Many patients in early-stage CKD take potassium-wasting diuretics (e.g., furosemide) that require supplementation of potassium. When urine output drops below 1 L/day, these same patients may require a change to potassium restriction as the kidney is no longer able to excrete all the potassium ingested. This typically occurs rather late in stage 4 CKD.
