DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

The publishers have made every effort to trace the copyright holders for borrowed material. If they have inadvertently overlooked any, they will be pleased to make the necessary arrangements at the first opportunity.

To purchase additional copies of this book, call our customer service department at **(800) 638-3030** or fax orders to **(301) 223-2320**. International customers should call **(301) 223-2300**.

Visit Lippincott Williams & Wilkins on the Internet: http://www.lww.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 a.m. to 6:00 p.m., EST.

We dedicate this book to our present and former students who have always kept us on our toes, and to our future students who will continue to challenge us to be the best teachers possible. We also dedicate this book to our families: Bonnie, Alissa, and Adam Bernstein; and Marsha, Joshua, Danielle, Eric Shelov, and their spouses and children for their patience and support. We also thank the late Drs. Henry Barnett and Lewis Fraad; Drs. Michael Cohen and the late Gerald Nathenson; the late Richard Kravath; and Abraham Rudolph; as well as Jen Clements for her artwork; and Susan Rhyner, Jennifer Verbiar, Catherine Noonan, and Joy Fisher-Williams at Lippincott Williams & Wilkins for their perseverance in seeing this educational adventure through to fruition.

PREFACE

A revolution is occurring in the world of medicine, one that will have profound effects not only on the way medicine is practiced, but also on the way medicine is taught to students at all levels. New terms and phrases such as managed care, health care reform, covered lives, evidence-based practice, insurance exchanges, and capitation have filtered into our vocabulary alongside more traditional terms such as tetralogy of Fallot, bronchopulmonary dysplasia, and thrombocytopenic purpura. For health sciences students, perhaps the greatest change will be in the venue in which patients are encountered. There has been a significant shift in health care delivery from the inpatient ward to the outpatient setting, whether a private office or satellite clinic, an ambulatory surgery unit, or a day hospital. The focus of most general pediatric care has shifted from the inpatient ward to the outpatient setting and also from episodic treatment to prevention. At the same time, biomedical and technological advances have made inpatient care even more complex and high-acuity, and have increased the number of vulnerable children with complex chronic diseases surviving into adulthood. In many settings, roles traditionally carried out by physicians are being performed by other health care providers such as physician assistants, nurse practitioners, and health care technicians.

Pediatrics for Medical Students was written in the midst of this health care revolution to serve as an introductory text for students during their clinical medical school experiences. It strives to do something no other text has attempted: to concentrate on evaluative skills and logical approaches to both common and uncommon pediatric problems and on the development of rational differential diagnoses, rather than serving as an exhaustive reference. In doing so, this text provides students with insight into the clinical diagnostic thinking of some of today's premier pediatric clinicians. To these experienced clinicians, the process of developing and refining a differential diagnosis is akin to solving an elegant puzzle. *Pediatrics for Medical Students* also stresses the essentials of modern pediatric medicine with a view toward the challenges of pediatric practice in the 21st century. It has links to a sophisticated companion Web site and a robust library of visuals now available as a result of Internet accessibility. It also contains revised questions based on Pediatric Content Specifications developed through the leadership of academic pediatrics and The American Board of Pediatrics. It emphasizes the pediatrician's unique developmental perspective and opportunity to actively prevent future illness by altering life habits at an early stage. Finally, it has received the endorsement of the American Academy of Pediatrics as its recommended textbook for medical students, and should also serve as a key resource for allied health professionals on their pediatrics rotations.

Contributors to *Pediatrics for Medical Students* have been chosen from the attending staffs at several major medical schools, based primarily on their communicative skills, teaching abilities, and agreement with the educational philosophy of the text. The contributors have imparted the sense of challenge and accomplishment associated with arriving at a well-conceived differential diagnosis and management plan.

Pediatrics for Medical Students is organized to help students make the transition from the systems-oriented approach of the preclinical years to the problem-oriented approach of the clinical years. Some chapters focus on the general practice of pediatrics; these allow students to appreciate the normal preventive visit, including extensive discussions of preventive strategies and anticipatory guidance. More traditional systems-oriented chapters describe a uniform, systematic approach to developing a differential diagnosis that will serve as a model for assessing all clinical problem situations. Other chapters focus on emerging areas of health care, including medical ethics, health care economics in the midst of health care reform, and social and cultural issues in pediatrics.

With the growing complexity of modern pediatric medicine, it is increasingly difficult for beginning students to master all the details of pediatric diseases. *Pediatrics for Medical Students* views pathophysiology as a key to students' understanding of disease; this approach helps students develop differential diagnoses and logical management. The text emphasizes differential diagnosis, which goes hand in hand with an appreciation of the appropriate use of diagnostic tests. Medical cost containment issues are interwoven throughout the text. By teaching sound medical practice, students automatically learn cost-effective medical practice. Finally, *Pediatrics for Medical Students* emphasizes, both in a separate chapter and in appropriate context, the medical, epidemiologic, and social implications of our multicultural pediatric population.

Suggested readings at the end of each chapter include several components: one or two recommended textbooks for those desiring a more detailed examination of the subject, several well-written review articles in easy-to-find journals such as *Pediatrics* or *Pediatrics in Review,* and several seminal journal articles in the field. These references are intended for those students whose interest has been piqued and who wish to explore the latest developments in both basic science and clinical research as applied to a particular pediatric illness.

Pediatrics for Medical Students has several unique features, including:

- **Pediatric pearls:** Each chapter contains several key, "take-home" pieces of information that all students should know.
- **Companion Web site:** Additional figures, diagrams, tables, and other information keyed to each textbook chapter.
- **USMLE-type questions:** Questions based on the subject matter in each chapter, with explanations of the answers, both correct and incorrect, are included on the Web site.
- **Updated references:** A combination of up-to-date review articles and seminal references that have made major advances to the field are included for each section of each chapter.

We hope that students enjoy these important learning tools, find the organization and content of the book useful, and enjoy working with children.

CONTENTS

INTRODUCTION

Steven P. Shelov and Daniel Bernstein

Being a medical student or student in the allied health professions nowadays is not easy. Not that it ever was "easy," for surely our selective memory of those years has protected us from remembering the difficult times and has permitted us to glorify the more convivial and rewarding times disproportionately. Nevertheless, we truly believe that current health care students have to contend with elements that did not confront students in the past.

Pediatrics for Medical Students is intended to present a large variety of pediatric "information" in as understandable and usable a fashion as possible, but it would be an error not to take some time to recognize a number of issues relating to education during clinical clerkships that often go unstated and unrecognized. Some of this material is drawn from a landmark article entitled, "The Vulnerability of the Medical Student," published in the journal *Pediatrics* in 1976 by Drs. Edwenna Werner and Barbara Korsch to honor the memory of their mentor, Dr. Lorin L. Stephens. This reference is one we continuously cite to our medical students, residents, and physician assistant students during the course of their training. Other material is drawn from the increasingly important issues of medical issues and accountability for adverse health care outcomes. Still other material is derived from our own cumulative experience of some 50 years of exposure to young trainees in this specialty. Finally, there is material that focuses on the medical student as a learner and an evolving teacher. Through a combination of these four sources, we hope to bring some context to the material offered in the chapters to follow.

DEALING WITH UNCERTAINTY

The majority of learning and teaching strives toward some sense of achieving certainty. The basic sciences, especially those assembled for your appreciation in preclinical training (i.e., the first 2 years of medical school), have emphasized the need to strive to a level where we are certain about what we do. Whether we are talking about biochemical pathways, the genetic determinants of sickle cell disease, or any of the many facts that you have committed to memory from those years of basic science, your teachers have stressed that there is a great deal of certainty about your evolving knowledge base.

In addition, you learned that the more you applied yourself, the more of these "certain facts" you would know. To be successful in medicine, you are repeatedly told that certainty is always the achievable goal. During the upcoming clinical years, many of your teachers will imply that certainty in clinical medicine is also an achievable goal. Thus, as you jump into that first clinical clerkship, you are no doubt eager to apply your newly mastered knowledge base from the basic sciences to clinical practice. However, you learn that you have not been well prepared for the wall of uncertainty that you encounter as soon as you begin to work up that first patient.

Indeed, you soon learn that clinical medicine is *far from certain* and that any attempt to make it certain quickly leads to a sense of frustration, disappointment, and confusion. Some of this confusion and frustration is avoidable if you recognize that *medicine is often uncertain* and that *in spite of this fact we can still do much for our patients and derive much satisfaction from the careful application of what we have learned.*

We believe that the simple recognition that certainty is not always attainable is an important first step for the beginning clinician. Once you realize that and yet strive to apply all that is known to achieving a more certain state, you will find a more livable sense of balance in your role as a health care provider and, no doubt, a more satisfying sense of who you are and what you can and cannot do (i.e., you have limitations).

The major reasons for the inability to achieve certainty all of the time (actually, much of the time) are our incomplete knowledge base and the fact that the subjects of our combined art and science are *real people,* not idealized textbook examples. Children with meningitis do not all present in the same way; some children with fever are truly more ill than others, yet we may not always know how to spot them. What is the best diagnostic approach?

What is the highest yield from a particular test? Parents differ in their ability to recognize developmental delay or aberrances in their child's behavior. How can you best advise them to change their child's behavior?

With those multiple-choice questions we have all spent so much time answering, the answers are *certain*; in clinical medicine, the answers vary. They vary sometimes because of things that may be measurable and other times because of things that are not measurable. The hallmark of a good clinician is the ability to account for these variables. As long as you are systematic in your thinking, eager to embrace alternative explanations, open to suggestions, and *willing to listen at all levels,* you will be successful. Each day you will learn more, experience more, and grow as a clinician, moving a little more from uncertainty to certainty. But be prepared to carry around with you a continued supply of uncertainty, and do not feel you are very different in substance from even the most senior of clinicians you meet; you are different only in degree.

IDENTIFICATION WITH THE PATIENT

Although it may be difficult to remember, you had another life before you became a health care professional. Throughout your past and present life, you witnessed much and incorporated many different experiences and observations into your present persona. You are a function of your parents and friends, your previous life situations, and your original makeup. These parts of you do not disappear when you encounter your first patient; they are, in fact, incorporated into every patient encounter you will have. It is inevitable that you will frequently and often unconsciously compare your present experiences with your previous ones, adapt to them, and allow them to alter your present makeup. Many of these changes occur consciously, but there are many others of which you are not aware.

Some clinical encounters are difficult situations that unconsciously remind you of your own fears, your past or present relationships, or your own family. Those situations, which evoke an overidentification response, are often the most complex. It may be difficult to identify and become conscious of them. Nevertheless, these reminders will play havoc with your sense of stability and create unease and anxiety that you may have difficulty sorting out. Often, overidentification with a patient or family results in a driving need to rectify or fix a problem for which there is no easy solution. To highlight the pitfall of overidentification, we often cite a special quote from the article by Werner and Korsch:

> I believe I would have been a better intern and a better young physician, and that I would have learned more and suffered less, if someone could have told me explicitly, repeatedly, and patiently that the dying at hand was not my own, that the patient whose death I attended was not, in fact, myself, nor was it my wife, nor my child, nor my parents, nor, fortunately, was it often my friend. And most important, I needed to be told and taught that the dying which I was attending did not, in itself, increase my vulnerability nor the vulnerability of those for whom I cared most deeply. The confusion involved in the sympathetic relationship, wherein identities merge and blur—this is what is intolerable and excruciating and blinding.

You can become aware of when this is happening to you if you are sensitive to your own feelings, realizing that some anxiety should be expected. However, you should recognize that if these feelings begin to affect you in such a way as to influence your satisfaction with your clinical role or your ability to make clear decisions, it may be stronger than you realize and needs to be dealt with in some way. One method that we have found useful is regularly scheduled mentoring groups with students or residents. When discussing overidentification and related issues, other members of the group, including faculty mentors, often share similar experiences and feelings. Once these feelings of anxiety related to overidentification become "fair game" for discussion, the resistance to discussion drops, and each participant is able to contribute his or her own experiences and reactions. The individuals in such a group often come to the realization that their past experiences are inextricably interwoven with their present situations. Because these encounters often deal with life-and-death matters, their relevance becomes highlighted. Recognizing that this is a shared experience with your colleagues is usually the first step in the course of regaining some control over these situations.

SENSE OF RESPONSIBILITY—DEALING WITH LIFE AND DEATH

For medical students, who are protected from the real world by the comfort of the classroom, the basic science years are often just a continuation of the years of college, just more intense and with greater stakes. The clinical years are a different story. Medical students in TV shows embody many of the responses characteristic of new clinicians. At times bragging and confident, at other times sheepish and lacking confidence, and at still other times frustrated when the role confusion is maddening—all are part of the clinician trainee's mental state.

You, too, are immediately thrust into a "real world" of sick people who may convey signals of helplessness, neediness, illness, anxiety, and uncertainty about their present or future existence, as well as an often overwhelming sense that without your help they will no longer be able to "make it." Much of this has to do with, and is created in response to, the multiple roles and responsibilities demanded of you in dealing with real people undergoing a traumatic loss of who they are because of illness. And you, with all of your newfound wisdom, are expected to make it all better.

The fact of the matter is that there is no way you can possibly do that. You are just at the stage of attempting to integrate your newly learned, although fragile, knowledge base into this whole new world of real patients. Each new clerkship places you in new settings that keep you enough off balance so that you often develop self-doubts. How are you ever going to be able to learn enough, be confident enough in your knowledge and decisions, and just be calm enough to see yourself through successfully in any of these new roles? You will succeed with time. That is why clinical training takes place over years, not months, and why clinical confidence in new roles is a graduated series of responsibilities rather than something you are immediately expected to succeed at in the first few months of clinical experience. Unfortunately, someone forgot to tell your sense of your own expectations about these reservations regarding your level of responsibility. To quote once again from the article by Werner and Korsch:

> The study of medicine is in fact the study of living and dying. No more central nor enormous concern seems to exist: or at least this seems so for the peculiar and puzzling species of men and women who elect to take upon themselves the role of physician. And the innermost mystery of all, the most frightening, the most compellingly interesting, the most inescapable truth encountered in this journey is that one cannot learn about living and dying only in others. One cannot help but make inferences about one's own life and death . . . it seems true beyond doubt that upon one's comprehension of living and dying depends one's ability to serve as a physician.

The solution is for you to feel that you are shouldering a level of responsibility appropriate for your present level of training. You may need some help recognizing this at times, and those more senior to you may also need to be reminded about it. Feeling that you have an overwhelming responsibility for particular patients or their patient outcome will interfere with some of the growth that is essential for your future security as a clinician. This is not to say that you should not eagerly and enthusiastically engage your clinical responsibilities head on. You will gain much more from clinical experiences in which you play an active role. However, being an active participant does not mean you have ultimate responsibility for all of the outcomes, good or bad. The time will come in the future where your level of responsibility will increase; with that will come the increased knowledge and experience and the comfort that is part of that seniority.

YOU, THE ADULT LEARNER AND MENTOR IN THE MAKING

It is important that you begin to fully apply those principles of adult learning that for your future will dictate your ongoing success. As such a learner, you will follow the principles of adult learning, made clear by Knowles (1970), which are the following:

1. Establish or be learning in a climate that is safe and comfortable to be fully expressive.
2. Involve yourself and other learners in understanding methods of developing curricular content.
3. Assess your own learning needs as well as those of others.
4. Encourage yourself and others to develop your learning objectives.
5. Identify resources and strategies for using those resources to meet your own and learning objectives of others.
6. Support other learners in carrying out their plans and seek support on carrying out yours.
7. Be prepared to evaluate your own learning and develop skills in self-reflection.

These adult learning skills are the framework by which you will learn throughout all of your clerkships, your residency training, and your ongoing education when you finish formal training. As you move further along the educational paradigm, you will also be asked to educate others along the way. In those important encounters with younger trainees, try to apply the SEVEN principles of good educational practice developed by Chickering. These practices are:

1. Encourage contact between yourself and the learner.
2. Develop a degree of reciprocity and cooperation among the learners.
3. Encourage ACTIVE learning.
4. Give prompt feedback.

5. Emphasize time on task.
6. Communicate high expectations.
7. Respect diverse talents and ways of learning.

Following these principles of education, based on adult learning theory, will prepare you for the clinical learning and teaching you will do over the next 2 years and beyond through residency. As Parcell and Bligh (2001) have described, clinical teaching is a major part of a clinician's professional life and development. If one learns to teach well, it will, by definition, allow for the exploration of new ideas and methods. Collaboration among learners and teachers is the key to being successful in both areas. The five questions you need to ask yourself are:

1. What do I need to know to be an effective clinical teacher?
2. What roles do I need to adopt?
3. What attributes do I need to possess?
4. What teaching strategies do I need to apply, and in what circumstances?
5. How do I know my clinical teaching is effective?

Finally, the following list includes ideas that students tell us they would like included as part of their clinical teaching experiences (Copeland and Hewson, 2000).

1. Increasing responsibility for patient care
2. Consistent observation and feedback
3. Appropriate probing questions to link existing and new knowledge
4. Opportunity to process technical and problem-solving skills
5. Clear and timely answers to problems
6. Seeing patients first
7. Enthusiastic teachers (interesting, stimulating and enjoyable)
8. Mentors (knowledge, skills, and attitudes)
9. Opportunity to reflect on clinical experiences
10. Encouraging self directed learning

Utilizing the previous principles with the needs expressed by students should serve as a template for how to approach every learning opportunity you will face during your clinical years.

TO ERR IS HUMAN . . . (ARE ERRORS PERMISSIBLE?)

In 1999, the Institute of Medicine issued a report entitled *To Err is Human: Building a Safer Health System.* This highly publicized and critiqued white paper brought the issue of the consequences of medical errors to the forefront. It gives a relatively scathing account of the dire consequences of medical errors in the hospital setting and challenges the universe of the health care setting to develop remedies for these problems. Although many experts have stated the data are poorly drawn from overly high-risk settings and do not pertain to *their* situation, the overwhelming consensus is that much of what the report contains is on target.

As students, you will be thrust into settings in which you have to grapple with health and safety issues as they pertain to a particular setting. Our advice is to learn from the approaches to system change that are taking place around you; apply the principles of critical self-study and change when necessary; and become part of the solution, not part of the problem. Hospitals are complex places, and great care is necessary to ensure that the systems work for the patients, not against them. Reducing medical errors is *everyone's business*. You are in an ideal setting to see the benefits of a positive approach to change. Take advantage of those opportunities to learn and grow.

COMMUNICATION IS THE KEY

> To write prescriptions is easy, but to come to an understanding with people is hard.
>
> Franz Kafka

It is not always easy to effectively find out the things you need to know about your patients. Many times it is even harder to tell them about things that are happening to them, especially the difficult things. Nevertheless, good patient communication is the key to becoming a good clinician. In addition, the most difficult and often least clear-cut issues revolve around the psychosocial aspects of a patient's condition. You will quickly discover that diseases are not often explained by one factor alone and that there is much truth in Engel's "unified concept

of disease," which holds that every disease has multiple components—a biologic, an emotional, and a social component. These components are the challenge to clinical medicine, and uncovering them depends on clear communication and the ability to recognize the importance of psychosocial issues. We also recognize that it is often harder to relate to patients who present with a predominance of these issues.

> In a county-type hospital, when everyone's social ills are really in a lot of ways more important than the immediate pneumonia, it is quite a distraction. At County Hospital a patient with terminal cancer is much easier for me to deal with than four or five chronic alcoholics that come in with another pneumonia, and they're starting a decompensate again. You know that no matter what kind of medical treatment you give these people, the society, for them at least, is such that they will be back again. . . . When I have a real patient with real ills that I can handle, I'm very happy.

It is important to combat any resistance that occurs, diminish your skepticism, and realize that the process is a dynamic one. You will come to realize that if you are open to hearing about these "other issues," your patients will feel well served and feel that they have truly made a connection to "their doctor."
Two quotes of Dr. Stephens', from the last two pages of the article by Werner and Korsch, are pivotal and should be required reading for all those who are students or teachers of clinical medicine.

> If the issues described above are disregarded or dealt with only incidentally or accidentally, the students, in large number, will stumble in their desperation into the maladaptive roles seen all around us in graduate physicians. The students will meet these issues by transmuting their patients into abstractions, which offer neither the pain nor gratification of human intimacy. They will take refuge from human responsibility in obsessive attention to detail, to the particular. They will, in futility and panic, resist what they perceive as encroachment on their territorial imperatives in the form of health-care delivery evaluation, or even physician review processes. They will find other sources of gratification than in professional excellence: the talk in the surgeons' dressing room more often concerns the Dow-Jones averages and the golf course than it does patients, for many reasons, but some of the above pertain. All-gullible, they will accept the force-feeding of the detail man or the latest surgical vogue as the treatment of the lesion. They will avoid the dying patient rather than threaten the protection afforded by their illusory defenses. They will continue to get inferior medical care for themselves. They will not allow themselves fascination with the infinite variety of patients' problems and physicians' solutions.

> There are those who will tell you that being a physician is a curse, a life of endless and ambiguous work, where at best we are consumed in a holding action—and all that, without experiencing appropriate appreciation of our sacrifice.

> I do not feel that way. Being a physician I consider the highest privilege I can imagine. Along with the joys from my family, my life as a physician has provided me with moments of epiphany, transcendental moments of lucidity . . . To be a physician—to be permitted, to be invited by another human being into his life in the circumstances of that crucible which is illness—to be a trusted participant in the highest of dramas—for these privileges I am grateful beyond my ability to express . . .

These statements reflect the caution and optimism that occurs as you embark on the long journey of becoming a clinician. It is with these thoughts, encouragements, and reflections that we welcome you to this, your introduction to the world of children's health and disease. Enjoy these times; it is our hope that the material enclosed will help make your journey toward certainty a little bit easier and a great deal more satisfying.

SECTION I

GENERAL PEDIATRIC PRACTICE

1

Approach to the Normal Newborn

Andrew P. Mezey

The arrival of a newborn infant is an extraordinary event for a family. It releases a flood of emotions ranging from great joy and great expectations to great fear. Families feel particularly vulnerable at this time, and all health care providers must be sensitive to this. A careless word or a seeming indifference to a question may cause great pain for the parents. This chapter sets forth an approach to evaluating the newly born infant and communicating with the family.

PRENATAL INTERVIEW

About 4 weeks before the expected date of birth, many pediatric providers offer a prenatal interview to expectant parents whom they have not met. Obstetricians, midwives, leaders of prenatal classes, or friends who have previously enjoyed this experience may refer the parents.

The prenatal interview is an effective way for prospective parents to meet the provider at a relatively unpressured time. It is best to schedule the interview at the end of office hours (i.e., at a time when the office is quieter and the pressure to keep seeing patients is no longer there). Because expectant mothers often work until their due dates, the end of the day is often convenient for both parents.

After the initial introductions and questions relating to how the couple was referred, the interview should take the form of a formal medical history of both prospective parents. This should include the following topics:

- The length of time the couple has been married
- How easy or difficult it was to achieve conception
- Problems that the parents experienced during this or previous pregnancies
- Medications now being used
- Alcohol and smoking habits
- Problems that they or other family members may have had with their children
- Medical and genetic problems of other family members
- Ultrasound results
- Results of maternal screening tests; for example, chromosomal/genetic disorders

Although in many cases the answers to these questions yield relatively little information, focusing the discussion in this way helps the pediatrician learn about how the couple interacts, how they deal with apparent tensions, and whether any information elicited from one parent is a surprise to the other. The interview is a good gauge of how well prospective parents communicate. The interview is also a good way for the parents to learn how the physician communicates.

In the average middle class American family, the expectant mother asks most of the questions, with the support of the husband. It is unusual if the man does most of the talking. In such instances, the pediatrician may need to provide the woman with a great deal of support in the first few months of her infant's life. She may be depressed, and this condition may become worse after delivery.

Pediatric Pearl: In some cultural groups, a woman does not speak much in the presence of her husband. This may pose problems in the prenatal interview when questions about parenting issues are discussed.

The next portion of the interview should focus on what the couple plan to do after the baby is born. Although much of this deals with breast-feeding versus bottle-feeding, safety and general care concerns warrant attention. Now is the time to provide information about car seat usage; the risks to the infant of passive exposure to cigarette smoke; fluoride, iron, and vitamin use; and crib safety, including the potential dangers of old cribs and how to determine proper mattress size. Questions about if and when the mother or father plans to return to work, the couple's plans for child care, and the availability of social support from family and friends are all appropriate at this time.

In closing, the pediatrician should ask the parents whether there are any issues that have not been covered or are unclear. After that, the pediatrician should explain how he can be reached after the delivery and when and how often the infant will be seen in the hospital. He should also ask the couple to phone him if they have further questions after leaving the office. If the pediatrician uses e-mail and/or a Web site for communication, this, too, should be discussed. An interview of this depth takes between 30 and 45 minutes, but it is well worth the investment of time, especially if any problems arise during or after the birth of the infant. **After a successful prenatal interview, the pediatrician has achieved credibility as someone who is concerned about the parents and the unborn child.** This interview makes it easier to discuss issues that may arise at the time of delivery, which occur at an emotionally charged time.

INITIAL EVALUATION OF THE NORMAL NEWBORN

For normal births, a pediatrician/neonatologist is not present at the delivery. Currently, most hospitals in urban settings will have a neonatologist on call to attend births when there is the likelihood of a complication, such as during preterm birth, multiple births, or another indication that someone be there to resuscitate and stabilize the infant. The management of the infant in these situations is covered elsewhere in this book.

In most cases, the infant is born without problems, and the hospital staff notifies the pediatrician's office of a birth in a routine manner. Hospital personnel call the office and leave a message, and the pediatrician appears at the nursery, usually within 12 hours after the birth, but certainly no longer than 24 hours. After arriving at the nursery, the pediatrician should first review the delivery record and the infant's chart.

Review of the Delivery Record

It is important to note the length of the delivery; the duration of ruptured membranes; the mother's course during labor, particularly temperature elevations that necessitate administration of antibiotics; and the condition of the infant at birth as described by the Apgar score. If a delivery has been long, the mother may be exhausted and perhaps dehydrated, which may interfere with her ability to begin breast-feeding. If the membranes ruptured 24 or more hours before birth, subtle symptoms or signs of infection in the newborn warrant closer attention. If the mother has a history of prolonged rupture of membranes in the presence of fever, it is essential to decide whether to perform a sepsis workup on the baby, even in the face of a well appearing infant. The actual management of such infants varies and is covered elsewhere in this book.

The **Apgar score** is the standard, time-honored method for evaluating the well-being of newborn infants at the time of delivery (Table 1-1). In practice, there are usually two Apgar scores, the first done at 1 minute after delivery and the second done at 5 minutes after delivery. Two points are given for each of five observations, for a potential total score of 10. Scores of 7 to 10 at 1 and 5 minutes are indicative of a stable infant. If the score is less than 7 at 5 minutes, another score is done at 10 and at 20 minutes. If the score remains low, a decision to observe the infant in an intensive care area is appropriate.

Even the most normal infant does not usually have an Apgar score of 10 at 1 minute; most infants have 1 taken off for color. Many parents are familiar with Apgar scoring and will ask about it, so even if the pediatrician is not particularly interested in whether the Apgar score is 8, 9, or 10, the parents will be. The pediatrician should be prepared to discuss it with them (see Table 1-1).

In addition to noting the Apgar score, it is important to be aware of the resuscitative efforts that have taken place in the delivery room. These may range from routine care to oxygen by face mask to endotracheal intubation. **The more aggressive the intervention, the more concerned the pediatrician should be about the effects of asphyxiation on the infant, even in the face of Apgar scores of 7 or more.**

Review of the Infant's Chart

It is important to review an infant's chart for the blood type and Rh factor of the mother; the infant's blood type and Rh status; the Group B streptococcal status of the mother; the serology and hepatitis B status of the mother;

TABLE 1-1

Apgar Score

Score	*0*	*1*	*2*
Heart rate	Absent	< 100 beats/min	> 100 beats/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Reflex irritability (catheter in nose)	Absent	Grimace	Grimace and cough or sneeze
Color	Blue	Body pink, pale; extremities blue	Pink

Adapted from Apgar V: Proposal for new method of evaluation of the newborn infant. *Curr Res Anesth* 32:260, 1953

the HIV status of the mother; the infant's vital signs, especially heart rate and respiratory rate; and whether the infant has urinated and passed meconium. If the mother is Rh-negative, the infant is Rh-positive, and the direct Coombs test is negative, the mother should receive RhoGAM within 72 hours of delivery. Comparison of the mother's blood type with that of the infant's determines whether there is a potential ABO incompatibility. The blood bank will report a positive Coombs test, but jaundice associated with non–Coombs-positive ABO incompatibility is possible (see Chapter 10). Therefore, careful observation for the early development of jaundice is necessary in all infants with an ABO setup. (If the mother is O-positive and the infant is type A or B, there is a possibility that the mother's antibodies may cause rapid breakdown of the infant's red blood cells [RBCs].)

If the mother's serology for syphilis is unknown, the test for syphilis should be requested on the cord blood. In many areas, serologic testing of cord blood for syphilis has become routine, even when the mother has been tested during pregnancy. It is also usual in almost all places to determine hepatitis B immune status as part of prenatal care. **The management of the infant of a mother who is a carrier of hepatitis B surface antigen requires the administration of specific immune globulin and hepatitis B vaccine within the first 12 hours after birth.** The American Academy of Pediatrics (AAP) now recommends that *all* infants be immunized against hepatitis B soon after birth. Standard practice is to administer the vaccine in the hospital nursery prior to discharge even when the mother is known to be HBsAg negative.

Most mothers now receive testing for HIV infection during pregnancy. **If the HIV status of the mother is unknown, it is essential to take a blood sample from the infant (not from the umbilical cord) as soon as possible after birth to determine the presence or absence of HIV antibody.** Depending on local law, this HIV test may or may not require consent from the parents. If the mother is HIV-negative, no further action is necessary. If the mother is HIV-positive, it is necessary to draw blood from the infant for HIV DNA polymerase chain reaction testing and to begin oral zidovudine within the first 8 to 12 hours of birth. Consultation with a pediatric HIV specialist is mandatory in all children born to HIV-positive mothers. If the mother is Group B streptococcus positive, she should have received two doses of amoxicillin prior to delivery. If she has not, protocols exist in all newborn services for the further management of the infant. This is covered in Chapter 10.

Examination of the newborn's chart to evaluate its cardiovascular status is also important. The normal range is 120 to 160 beats/min for the heart rate and 30 to 40 breaths/min for the respiratory rate. Noting deviations from this range helps focus the physical examination. Most infants urinate at or around birth; all should urinate by 12 hours. Failure to do so mandates a careful evaluation of the newborn for renal, bladder, and genital abnormalities, as well as the state of hydration. Most infants pass meconium within 12 hours after birth. Full-term infants who fail to pass meconium by 24 hours and in whom there is evidence of abdominal distension warrant evaluation for anal patency; Hirschsprung disease (congenital megacolon); intestinal obstruction; metabolic problems, including electrolyte abnormalities and hypothyroidism; neuromuscular diseases; and cystic fibrosis.

Until recently it was thought that late-preterm infants, defined as a gestational age of 34 to 36 weeks and 6 days, could be treated as normal newborns because they generally did not require care in a special care nursery. It has been shown, however, that these infants should not be viewed as normal, full-term newborns. They are more susceptible to hypothermia, hypoglycemia, hyperbilirubinemia, respiratory distress, and possible sepsis. In addition, we are now aware of the significant remaining growth of brain cortical tissue that has not occurred if the baby is delivered prior to 37 weeks. As a result of these and other significant issues, extra care should be

taken to address these issues, first with the obstetrician prior to delivery (especially if there is planned, elective induction), with nursery personnel, and with the parents should the baby be born as late preterm.

INITIAL PHYSICAL EXAMINATION

Most infants are born without visible major anomalies. If visible major abnormalities exist, the pediatrician's task is to determine whether any associated disorders such as cardiac or renal malformations are present, and if so, to deal with them as quickly as possible. If no major anomalies are apparent, the task of the pediatrician is to try to rule out any abnormalities by thorough physical examination (Table 1-2). It is important to note any minor problems, point them out to the parents, and explain their implications. Generally, these minor abnormalities are skin-related and obvious even to the casual observer.

General Appearance

Healthy newborns assume a typical position of flexion of the arms and legs when in the supine position because flexor muscle tone is greater than extensor tone. Infants who are not in the flexed position warrant evaluation for hypotonia, which may be a manifestation of many diseases of varying etiology (e.g., progressive spinal muscle atrophy [formerly known as Werdnig–Hoffmann disease], myotonic dystrophy, trisomy 21 [Down syndrome]), or may be related to birth trauma (see Examination of the Nervous System).

The head of a newborn may not be round because of the molding that occurs as the infant moves through the birth canal. The cranial sutures are not normally fused at birth. A newborn infant with a round head usually signifies that the mother had a cesarean section without a trial of labor. In addition to **molding of the cranium,** there may be swelling over the occiput, or **caput succedaneum,** which is due to accumulation of fluid in the soft tissues above the periosteum, secondary to pressure associated with delivery. Molding disappears within 24 to 48 hours (see Examination of the Head). Bruises may be visible on the infant's scalp and face if forceps were applied during delivery. These disappear quickly also but, when seen, should prompt the examiner to check carefully for evidence of facial asymmetry secondary to pressure injury to the facial nerve from the forceps. This condition is most often temporary and resolves completely, usually within the first week of life.

In addition, it is important to note an infant's color. Infants are born with hemoglobin levels in the range of 16 to 17 g/dL; therefore, they are ruddy in appearance when light skinned. Paleness may be secondary to anemia or to poor perfusion. **If a newborn infant appears plethoric (too ruddy), maternal diabetes should be suspected. If the infant is one of twins, twin-to-twin transfusion should be suspected.** Polycythemia in a newborn may be associated with neurologic symptoms, occasionally necessitating a decrease in hemoglobin by removal of some of the RBC mass.

Examination of the Skin

The skin of infants is thinner than that of older children, so blood vessels can easily be seen. The skin may have a mottled appearance known as **cutis marmorata,** a benign condition that will disappear. This condition may develop in older children when they are cold. Many infants have red markings on the upper eyelids, in the area above the nose, sometimes extending onto the forehead, and on the back of the neck. These are known by a variety of names—**nevus flammeus, vascular nevi, salmon patches, "stork bites"** when on the back of the neck, and **"crow's nests"** when above the eyes. These disappear with time or, as on the back of the neck, when they become covered with hair.

Sebaceous gland hyperplasia is characterized by small yellow papules that are often seen over the nose and cheek; these disappear spontaneously. **Milia,** which are white papules, smaller than those seen with sebaceous gland hyperplasia, also disappear without treatment. What appears to be acne is sometimes seen in newborns. This is probably related to endocrine influences from the mother and also disappears without treatment.

Strawberry or capillary hemangiomas are elevated strawberry-colored collections of capillaries that have a variable appearance in newborns. They may be flat and look only like a small red dot, or they may be large, elevated lesions. Single or multiple, they may occur anywhere on the skin. These interesting lesions have a life of their own, growing in size for 3 to 7 months, stabilizing, and then most often involuting completely, with no remaining scar or blemish. The pediatrician should tell parents that the involution most often begins by 1 year of age and is complete by 5 years of age. However, sometimes the lesions may not disappear until after 8 years of age. Leaving them alone, regardless of location, is the best course of action. An exception to this rule is the presence of a strawberry hemangioma on an eyelid, obscuring vision. In this instance, consultation with an ophthalmologist is required.

TABLE 1-2

Initial Examination of Newborns: A Checklist

System	*Important Questions*
General appearance	Does the infant appear comfortable? Is the infant pink? Are all four extremities flexed?
Skin	Are there any birthmarks?
Head	Is the head circumference normal?
Face	Does the face look normal? Are there any stigmata of a recognizable syndrome?
Eyes	Is the red reflex present bilaterally? Are the irises round and of the same color?
Nose	Are the external nares symmetrical?
Ears	Are the pinnae symmetrical and normal in shape?
Mouth	Is the palate intact? Are there any teeth or masses?
Chest	Are the respirations symmetrical and effortless?
Heart	Is a murmur audible? Is the heart rate normal and regular in rhythm?
Abdomen	Is the abdomen convex in shape? Are any masses palpable?
Genitalia	
Male	Is the penile meatus in the proper place? Are both testes palpable and the same size?
Female	Are the labia majora and minora present? Is the vaginal opening present?
Extremities	Does the infant have ten fingers and ten toes? Are the arms the same size? Are the legs the same size? Do the hips abduct fully?
Back	Is the spine straight? Are any dimples present in the midline?
Central nervous system	Is flexor tone greater than extensor tone? Are both hands fisted? Is the infant's cry strong?

Cavernous hemangiomas, which are much less common than strawberry hemangiomas, have a less predictable course. These collections of larger blood vessels are often sizable. They may initially appear as bluish masses under the skin, or they may be above and below the skin, or they may be present completely under the skin, occupying an organ such as the liver. When they are very large, they may be associated with thrombocytopenia or, even more rarely, with arteriovenous fistulas, leading to high-output heart failure. Often, they mature by themselves and disappear; at other times, they require treatment with corticosteroids or radiation.

Port-wine stains, also in the nevus flammeus family, are permanent discolorations of the skin that on occasion are associated with arteriovenous malformations in other organs. In **Sturge–Weber syndrome, a port-wine stain is present in the distribution of the first division of the trigeminal nerve,** with vascular anomalies in the brain. In von Hippel–Lindau syndrome, a port-wine stain of the face is associated with vascular lesions of the retina and brain. Congenital glaucoma on the side of the lesion may also be present.

Examination of the Head

The head circumference of newborns should always be measured and compared with standards. It should be within two standard deviations of the mean for gestational age. A measurement that is more than two standard deviations from the mean may be a sign of hydrocephalus. A normal, full-term newborn should have a head circumference of approximately 34 to 35 cm.

Pediatric Pearl: The correct measurement is the largest one that can be obtained when a tape is passed around the parietal bones, just above the ears. The units should be centimeters rather than inches because almost all pediatricians trained in the United States in the last 35 years have been taught to think of head circumference in terms of centimeters.

The chest circumference should be measured also and compared with the head circumference. In full-term infants, the chest circumference is 1 to 2.5 cm smaller than the head circumference. If the measurements deviate from these guidelines, consultation with a pediatric neurologist is advisable.

It is important to palpate the scalp for the presence, size, and feel of the anterior and posterior **fontanelles.** The anterior fontanelle is larger, is located at the juncture of the two frontal and two parietal bones, is flat, and sometimes pulsates. Variable in size, it usually measures no less than 1 cm × 1 cm and no larger than 3 cm × 3 cm at birth. If the anterior fontanelle is either larger or smaller, but the head circumference falls in the normal range, nothing more than routine follow-up measurements is necessary. If the head grows normally, the variation in fontanelle size is considered normal. If abnormalities are apparent, either in the newborn period or later, consultation with a pediatric neurologist is recommended. The posterior fontanelle should be present in all newborns, is found at the juncture of the parietal bones and the occipital bones, and is of fingertip size. It is difficult to appreciate fullness, tenseness, or depression over the posterior fontanelle. It is generally closed by 6 weeks of age.

It is also necessary to palpate the head for evidence of **caput succedaneum,** the boggy swelling in subcutaneous tissues (see General Appearance). Learning to appreciate what a "caput" feels like is worthwhile to differentiate it from more extensive subaponeurotic swellings, which may be associated with significant bleeding. Typically the caput will "pit" on palpation corroborating that this is edema of the scalp, resulting from birth canal pressure during a difficult vaginal delivery. Learning to appreciate closed-space bleeding of the scalp in newborns is essential because such bleeding may be associated with anemia and significant hyperbilirubinemia. **Cephalohematomas,** which affect between 1 in 10 and 1 in 20 newborns, are not typically seen at the time of the initial examination but are apparent between 24 and 48 hours after birth. Cephalohematomas are defined as blood below the periosteum; therefore, they are confined to a single bone. In the skull, the various bones have their own periosteum, making it easy to differentiate a cephalohematoma from a subaponeurotic bleed, which can spread over several bones, occurring as it does between the bones and the aponeurosis that covers them. In newborns, cephalohematomas almost always occur over the parietal bone and are associated with a fracture of this bone about 25% of the time. When they are palpated, they appear to be "ballotable" and bounce back under the examining fingers. They do not just pit as a caput does. However, when cephalohematomas are found in a newborn, it is unnecessary to obtain a skull radiograph to document the fracture because it is not associated with a depressed skull fracture. These hematomas often last more than 4 weeks, so it is important to document their presence in the newborn period.

Pediatric Pearl: Finding a new cephalohematoma in an older infant who comes in for a routine well-baby visit should make the examiner suspicious of child abuse.

If cephalohematomas are not reported in the newborn nursery but are found only after the infant has gone home, the parents may be falsely accused of child abuse. To avoid unnecessary concern about possible abuse, it is essential to note cephalohematomas at or before discharge.

Skull examination for the presence of symmetry is important. Asymmetric skulls may be associated with abnormalities of the brain or with premature closure of one or more of the sutures between bones. Suture closure in newborns is appreciated by an inability to ballotte the juncture of the two sides of the suture line. Normally, one can feel both sides move up and down in relation to each other. A ridge may also be palpable at the point where the two bones meet, although this finding is not always present when premature suture synostosis is diagnosed in the newborn. **The most common premature suture synostosis in infants is the sagittal suture, the suture separating the two parietal bones;** when pronounced, it is characterized by a lengthening of the skull in the anteroposterior dimension. However, in newborns, this lengthening may not be apparent. Therefore, part of all routine examinations of the skull should include an attempt to detect suture synostosis. It is best to discover this abnormality early, although premature single-suture synostosis is not usually associated with brain abnormalities or progressive damage to the brain. Early diagnosis allows corrective measures, including surgery, to be performed at a time when the best cosmetic results can be achieved.

Finally, it is necessary to examine the skull for bony defects and for tabes of the skull. **Tabes is a ping-pong ball feel of the skull;** depression of the skull by a finger yields this impression. It is a benign condition and disappears over time. Bony defects are usually in this category; they also disappear over time without sequelae. Skull radiographs should be taken to rule out any rare abnormality.

Examination of the Face

In newborns, almost more than at any other time, it is important to look carefully at the face. Look at the face straight on. Is the nose straight? Are the external nares symmetrical? During the birth process the nasal septum can be dislocated from its position in the vomerine notch. Marked asymmetry of the size of the external flares, which are normally of equal size and shape, is a sign of this abnormality. If recognized early, an experienced otolaryngologist can easily return the nasal septum to its normal position.

Look at the eyes. Are they slanting up or down? Do the eyes appear too big or too small? Does one eye appear larger than the other? Do they seem too far apart or too close together? If one eye appears too large or both eyes appear too large, the infant may have congenital glaucoma. **The large eye is called buphthalmos or "ox eye" and is enlarged by the increased pressure in the eye.** The earlier this condition is recognized and treated, the more likely it is that vision will not be impaired. **Eyes that appear too small may be seen in those with fetal alcohol syndrome as a result of narrowing of the palpebral fissures.** In this condition, the eyes may also appear to be too close together. Eyes that appear too far apart may be associated with midfacial abnormalities such as cleft palate syndromes.

Pediatric Pearl: Upward slanting of the eyes is seen in Down syndrome (trisomy 21); downward slanting is seen in Treacher Collins syndrome.

Look at the chin. Infants tend to have small chins, which grow larger as the child grows. However, if the chin is very small (micrognathia), the child may have **Pierre Robin syndrome,** a condition in which the small chin is associated with a small mouth, predisposing the infant to respiratory obstruction by the relatively large tongue. Look in front of the ears for a **preauricular sinus or skin tag.** These are important only from a cosmetic viewpoint in the newborn, but if the examiner fails to see it, the parents surely will. Failure to see these and explain their presence to the parents puts all the other assurances you have given them in doubt. Although preauricular sinuses may become infected later in childhood, they should not be removed in the newborn period. Skin tags can be removed for cosmetic reasons later in the child's life if the child or the parents wish it.

Look at the infant's face while she is crying. Is the face symmetrical? A condition known as **asymmetrical crying facies syndrome** is associated with aortic valve abnormalities. Because a murmur in a newborn may not be appreciated, even when it is associated with a serious cardiac malformation, consultation with a pediatric

cardiologist is warranted when asymmetry of the face is present. Facial asymmetry may also be associated with facial nerve palsy secondary to pressure on the facial nerve during the birth process. Even when the baby is not crying, this condition can be appreciated and is usually temporary.

Finally, look at the color of the infant's eyes and hair; look at how much hair there is, and look to see whether the face has any bruises or puffy areas. You should mention all these things in your conversation with the parents, reassuring them that any bruises will disappear within a few days and that sparseness of hair now does not mean that the baby will not have a full head of luxuriant hair later. Showing that you have paid attention to this kind of detail as part of your newborn examination assures the parents that you have paid equal attention to the other parts as well.

Examination of the Eyes, Ears, Nose, Mouth, and Throat

A description of a portion of the eye examination appears earlier (see Examination of the Face). The eyes of newborns may be opened or closed, and it is sometimes difficult to see the infant's opened eyes; this may be possible by holding the infant with one hand on its bottom and the other supporting the head. Slowly raising the infant from a supine to a more upright position may make the infant open its eyes. Further examination of the sclerae, conjunctivae, corneas, irises, and pupils is necessary. **Subconjunctival hemorrhage, either unilateral or bilateral, may be present;** this is not associated with internal damage to the eye, is secondary to the trauma of the delivery process, and disappears by the end of the first week of life. **Conjunctivitis** is not generally appreciated in the first 24 hours after birth. When it is seen that early, it is generally a manifestation of a chemical irritation when silver nitrate has been used for gonorrhea prophylaxis. **Acquired conjunctivitis,** as seen with gonorrhea, does not develop for several days because infection occurs during the birth process and takes time to become apparent. Conjunctivitis due to *Chlamydia trachomatis* is not usually seen until after the first week of life.

The sclerae in newborns are often blue as a result of their thinness. The **corneas should be clear** and no more than 12 mm in diameter. **Both irises should be the same color.** When they are not, the condition is called **heterochromia iridis** and is associated with **Waardenburg syndrome** or **rubella embryopathy,** causing atrophy of the iris. Both irises should be present; **aniridia** may be associated with **Wilms tumor** and genital abnormalities in boys. The pupils should be symmetrical, although **unequal pupils (anisocoria) may be seen in up to 25% of normal individuals.** The more severe abnormalities such as colobomas (defects) of the iris warrant the attention of an ophthalmologist.

Examination of both eyes for the presence of a **pupillary red reflex** is necessary. An ophthalmoscope is used, setting the lens at zero, standing at a distance of 12 in to 18 in, and shining the light first at one pupil and then at the other. A red reflection should be present bilaterally; if it is not, the possibility that something is blocking the passage of light from the cornea to the retina should be a concern. In infants, this is usually the sign of a **cataract.** The absence of a red reflex should be confirmed, and consultation with an ophthalmologist is appropriate. The list of causes of congenital cataract is long and includes congenital infections, metabolic disorders, and chromosomal abnormalities.

Although testing for extraocular muscular movements is not part of a formal examination in newborns, the movements and positions of the eyes are noteworthy. When the infant is looking straight ahead, the eyes are generally in the same position but may not stay that way with motion. This is not unusual. Persistent internal or external deviation is abnormal, although it is unusual to see this in the newborn period except in premature infants.

Examination of the ears for symmetry of size and for normal folding of the external ear is necessary. Abnormalities of the external ear may be associated with renal defects and hearing defects. **A small ear—microtia—is often associated with abnormalities of the middle ear, usually only on the side of the abnormality.** Otolaryngological referral is appropriate because the early assessment of hearing is more important than the management of the cosmetic problem. Inspection of the ears for the presence of external auditory canals is warranted, and it is important to make a gentle attempt to visualize the tympanic membranes. This is not easy initially because the eardrum is in a more horizontal position in newborns. When the membrane is visible, it tends to appear less translucent than in older children.

Examination of the nose should be for symmetry, as described earlier (see Examination of the Face). Inspection of the philtrum below the nose is necessary. **A flat, inadequately formed philtrum is associated with fetal alcohol syndrome.** In addition, inspection of the nares for patency, secretions, and masses with a nasal speculum is necessary. **With suspected choanal atresia, the clinician should attempt to pass a # 5 French catheter through the nostril.** If this attempt is unsuccessful, an otolaryngological consult is warranted.

Examination of the mouth and throat is next. The mouth of the newborn should not contain teeth. When natal teeth are present, they are usually removed after consultation with a dentist because they tend to be attached loosely to the gum. When these teeth are not removed, they are usually shed soon after birth; aspiration is a concern. Interesting but usually benign lesions can often be seen in the mouths of newborns. These include small inclusion cysts on the hard palate, generally in the midline, known as **Epstein pearls.** On the alveolar ridges, eruption cysts and mucoceles can sometimes be found; these are benign and disappear spontaneously. Careful inspection of the palate for evidence of a cleft is necessary. Large clefts are difficult to miss, but small ones may go unnoticed. Inspection of the uvula is also important; a bifid uvula may be associated with a submucous cleft of the palate, a condition that predisposes infants to middle ear infections.

The examination of the mouth should include an inspection of the tongue. The tongue generally looks normal, although there are still individuals who insist on making the diagnosis of **tongue-tie** in newborns. The frenulum that attaches the tip of the tongue to the floor of the mouth almost always appears to be short in newborns, compared with that in older individuals. Because of this, a diagnosis of tongue-tie would sometimes be made in the past and the frenulum clipped, without anesthesia, in the newborn nursery, using a small iris scissors. In almost all instances, this procedure is unnecessary. Although instances of actual tongue-tie do exist, they are rare. Before the diagnosis can be made, evidence that the shortening of the frenulum interferes with the functioning of the tongue (e.g., difficulty in sucking) should be present. In older individuals, the shortened frenulum may interfere with the ability to pronounce certain sounds.

A large tongue, **macroglossia,** can sometimes be seen. This condition may be seen in isolation or it can be associated with **Wiedemann–Beckwith syndrome, Down syndrome,** and **Cornelia de Lange syndrome.** Rarely, the tongue can be cleft and, even more rarely, absent; this latter condition is known as congenital aglossia.

At this point, inspection of the neck for evidence of an enlarged thyroid or for any other masses or abnormalities is appropriate. Midline neck masses may be **thyroglossal duct cysts.** Lateral masses may be **branchial cleft cysts.** Large, soft masses in the neck may be cystic hygromas.

Examination of the Chest

It is important to examine the chest for symmetry. The pattern of respirations should be noted. Most newborns breathe at an average rate of 40 times/min, but the pattern may not be regular. Breathing should appear effortless, without evidence of nasal flaring; without intercostal, subcostal, or supracostal retractions; and without grunting.

Breath sounds should be equal and present on both sides of the chest, although in newborns one can easily be fooled because sounds are transmitted very well from one area of the chest to the other. Therefore, if an abnormality in the pattern of breathing is found, a chest radiograph should be obtained, even in the face of normal breath sounds. It is unusual to hear rales, rhonchi, and wheezes, even in the face of severe respiratory distress.

The average heart rate in newborns is 140 beats/min. At this rate, it is difficult to appreciate the presence of a murmur unless one listens closely and for a period. Newborns with cardiac abnormalities, even the most severe such as a hypoplastic left heart, may not present with murmurs, or the murmur may be only of a grade 1 to 2/6 quality. In addition, a murmur audible in a newborn may not be of any clinical significance. Whatever is heard should be described carefully and correlated with other physical and historical findings such as the heart rate, quality of the heart sounds, and quality of pulses in the extremities, especially the femoral pulses.

Coarctation of the aorta or, more broadly, aortic hypoplasia is associated with diminished or absent femoral pulses. However, palpation of femoral pulses in the newborn is not easy. It takes practice before one can be confident that the failure to feel the femoral pulse is because it really is not there. If there is any question of the possibility of coarctation of the aorta, measurement of upper- and lower-extremity blood pressures is warranted. The blood pressure in the legs is lower than that in the arms in most patients with coarctation of the aorta.

A persistent finding of tachycardia or bradycardia should be brought into the attention of a pediatric cardiologist. Loud murmurs, evidence of central cyanosis, heart sounds more easily heard on the right side than on the left side, and difficult-to-hear heart sounds are all reasons to ask for a cardiac consultation, especially if these findings are appreciated in an infant who is less vigorous than expected.

Examination of the Abdomen

The normal appearance of the abdomen in newborns is full, protruding, and round. It should not be flat or sunken (scaphoid), nor should it appear tense.

Pediatric Pearl: A sunken or scaphoid abdomen is always a cause for concern. Where are the intestines? Is the flat abdomen due to a diaphragmatic hernia? Is it due to poor muscle tone from a neurologic insult or flaccid musculature? In any case, it is a cause for alarm.

A tense abdomen may signify an obstruction in the gastrointestinal tract or a perforation of a viscus, with resultant leakage of gas and the development of peritonitis and ileus. Intestinal malrotation resulting from a defect in development can predispose to volvulus. Intestinal atresias occur with greater frequency in infants with chromosomal abnormalities; these should be suspected in infants with abdomen-related problems who appear to have Down syndrome. **The anus may be imperforate, or there may be a defect in intestinal innervation, as seen in Hirschsprung disease.** Thick meconium may cause a special type of intestinal obstruction, **meconium ileus, which has a strong association with cystic fibrosis.** It is unusual to see a tense abdomen immediately after birth, for it takes some time for these conditions either to develop or to become manifest.

In addition, a newborn's abdomen has something not found in older individuals—an attached, although cut, clamped, or tied umbilical cord. The cut surface of the umbilical cord should be inspected; **two umbilical arteries and one umbilical vein should be present.** The presence of only one umbilical artery is sometimes associated with other anomalies such as renal malformations.

The abdomen should be palpated for the presence of masses. It is best to begin palpating in the right upper quadrant, feeling for the liver. The liver is often palpable up to several centimeters below the right costal margin. This is most often normal and related to the mobility of the liver rather than to an increase in size. Enlarged livers have a different feel to them, appearing closer to the surface and "fuller" on palpation. Congenital infection resulting from **to**xoplasmosis, **r**ubella, **c**ytomegalovirus, **h**erpes simplex, or **s**yphilis (the so-called TORCHS group of diseases) may cause hypertrophy of the liver. Other causes may involve masses within the liver such as cysts, vascular malformations, or tumors.

In the left upper quadrant and laterally, the spleen may also be palpable in newborns for the same reasons as the liver; it may be normal or enlarged as a result of the presence of a congenital infection. By moving deeper and more distal, it may be possible to feel the kidneys. Although kidneys of normal size may be palpable in some infants, it is difficult for the beginning examiner to appreciate this. However, enlarged kidneys are the most common cause of palpable abdominal masses in the newborn, most often as a result of obstructive lesions of the urinary tract. The presence of an enlarged abdominal mass requires further investigation, which is best accomplished in consultation with a pediatric radiologist and a pediatric surgeon or urologist.

Examination of the Genitalia

The genitalia of female newborns look a bit different from the genitalia of older sexually immature females because of the influence of maternal hormones. At times, **there may even be a bloody vaginal discharge within a few days after birth, resulting from withdrawal bleeding.** The labia majora and labia minora appear full and puffy. The vaginal opening can be seen, as can the hymen, which partially obscures the orifice. The clitoris should be contained within the preputial covering; if it is not, clitoral enlargement should be suspected. This may occur in **congenital adrenal hyperplasia** or, less commonly, in disorders of sexual differentiation. If abnormalities are encountered, consultation with a pediatric endocrinologist is warranted.

Examination of the male genitalia involves checking for the presence of both testes in the scrotum, the shape and size of the penis, the presence of a normal-appearing foreskin, and the position of the urethral meatal opening. The testes may feel enlarged in newborns; this is due to the frequent presence of **small hydroceles** in newborn males. When an enlarged, hard testis is felt, congenital torsion or tumor may be the cause. Consultation with a pediatric urologist is necessary.

The penis should be straight. If it appears to be bent downward (ventrally), **chordee of the penis** may be present. Chordee of the penis is associated with **hypospadias,** a condition in which the urethral meatal opening is displaced proximally on the ventral aspect of the penis. When a hypospadias is present, the foreskin is incompletely formed, appearing as a "hood" around the glans of the penis. **Epispadias,** a condition much less common than hypospadias, is diagnosed when the urethral opening is displaced to the dorsal aspect of the penis. Rarely, the penis may be very thin and small, a condition known as micropenis. Micropenis can be associated with either a local or a general (e.g., pituitary insufficiency) endocrine disorder. With chordee of the penis, hypospadias, epispadias, and micropenis, consultation with both a pediatric endocrinologist and a pediatric urologist is warranted.

Examination of the Extremities

Careful inspection of the fingers and toes with regard to number, size, and shape is necessary. Parents focus on these areas, and if the examiner fails to find an abnormality that is present, no matter how minor, credibility with the parents is lost. Extra partial digits, connected to a finger, usually the fifth by a pedicle of skin, are not uncommon. Webbing of the toes is often seen and may be familial. Webbing of the fingers is much less common. **Clinodactyly is an inturning of a finger, usually the fifth, and may be unassociated with anything else, but can be seen in Down syndrome.** It is usually due to hypoplasia of the middle phalanx of the fifth finger. Thumb abnormalities are seen in a number of dysmorphic syndromes.

Abnormalities of the hands are not common, and minor abnormalities of the feet are frequently seen. The most common of these is **forefoot adduction (metatarsus adductus), most likely secondary to intrauterine positioning** during fetal life. If the forefoot adduction is supple, meaning that the foot can be straightened easily, no treatment or consultation is necessary, and the foot will straighten over the succeeding months. If the forefoot adduction is rigid on physical examination, referral to an orthopedist is necessary. **Clubfoot is a combination of forefoot adduction, varus deformity, and shortening of the Achilles tendon.** Treatment of this condition should begin in the newborn nursery. The feet may appear to be convex at the sole, a condition known as rocker-bottom feet; this is usually associated with serious dysmorphic syndromes such as trisomy 18.

Congenital abnormalities of the arms are uncommon, whereas congenital abnormalities of the legs, although usually minor, occur more often. The most common abnormality is **internal tibial torsion, often seen in conjunction with forefoot adduction.** This condition most likely occurs secondary to intrauterine positioning and is likely to improve without treatment over a period of months, but can take up to 2 years to disappear. **External or internal versions of the hips also occur but are unlikely to be diagnosed in the newborn period. Developmental dysplasia of the hips** (formerly known as congenital dislocation or dysplasia) **occurs more commonly in female infants, particularly in those who have been in a frank breech position during pregnancy.** The condition has a 9:1 female-to-male predominance and a 20% positive family history, with around 60% occurring in firstborn children and 30% to 50% occurring in breech deliveries. Most often the hip is not actually dislocated but dislocatable. Initial imaging assessment is an ultrasound of the hips.

Pediatric Pearl: Developmental dysplasia of the hips is important to diagnose as early as possible because early treatment improves the prognosis.

To examine for this condition, the infant is placed in a supine position with the hips and knees flexed, and the middle finger of each hand is placed over the greater trochanter. The thumbs are placed on the inner aspect of the thighs, opposite the lesser trochanter. The hips are flexed and adducted, and a posterior force is applied. If the hip is unstable, it will dislocate; a clunk or a click may be felt or heard. In case of doubt, the maneuver can be done one side at a time by stabilizing one side of the pelvis and attempting the maneuver on the other side (Barlow sign). One should also test the range of motion of the hips; 180-degree rotation should be possible. The infant should also be placed in the prone position, and the buttocks should be examined for symmetry. Asymmetry of the buttocks may be due to a dislocated hip. If there is any possibility of the presence of hip dislocation, an immediate orthopedic consult is necessary. Diagnosis of developmental dysplasia of the hip at birth is not always possible; therefore, continued assessment during the first few months of life is mandatory. Hemihypertrophy or hemiatrophy of one or more extremities occasionally occurs. **Hemihypertrophy has been associated with Wilms tumor of the kidney.** Other rare skeletal dysplasias such as phocomelia and osteogenesis imperfecta may occur.

Acquired abnormalities of the arms are more common than congenital ones. The most common is a **fractured clavicle,** a condition that occurs in up to 3% of newborns. The diagnosis can be made by feeling for crepitus over the clavicle or by noting an incomplete Moro reflex on the side of the fracture. It is a benign condition, and even if the diagnosis is missed, the clavicle always heals, although it heals with callous formation. If the diagnosis is not made in the newborn nursery, a parent may find the "bump" when the child is several weeks old. When the "bump" is shown to the primary care provider, the question of possible child abuse may arise if the fracture was not documented in the nursery. Therefore, both initial and discharge physical examinations should involve careful searching for the presence of a fracture of the clavicle. **Brachial plexus palsies,** also known by the eponyms Erb and Klumpke palsies, are acquired abnormalities secondary to difficult deliveries. The diagnosis is not difficult to make because the affected arm is usually flaccid and extended and does not move as well as the unaffected arm. Treatment is supportive, with the arm placed in such a position as to prevent further stress

on the brachial plexus. The prognosis depends on how quickly function begins to return. Infants with a good prognosis will regain some muscle tone and begin to move the arm within the first few days after birth. When the diagnosis is made, consultation with a pediatric neurologist is necessary. Some pediatric orthopedists or neurosurgeons are skilled in making operative repairs of brachial plexus injuries.

The rest of the skeletal system, including the spine, is examined at the time the extremities are examined. **Congenital scoliosis** of the spine is rare; when it is seen, it is usually associated with abnormalities of the vertebrae (e.g., hemivertebrae). Neural tube abnormalities such as **meningocele** or **myelomeningocele** are now often diagnosed prenatally by ultrasound examination or by maternal screening for α-fetoprotein, although supplementation of the diet of pregnant women with folic acid seems to have decreased the incidence of neural tube defects. When present, consultation with a pediatric neurosurgeon is necessary. **Pilonidal sinus**, the most common abnormality of the spine, is found at the very base of the spine. This sinus does not communicate with the spinal canal and does not usually become infected before adolescence. Therefore, although the parents should be informed of its presence and apprised of its significance, no treatment is necessary. Other abnormalities of the spine such as sinuses, cysts, fatty tumors, or tufts of hair over the thoracic or lumbar areas are rare. When they are present, consultation with either a pediatric neurologist or a neurosurgeon is appropriate.

Examination of the Nervous System

When an infant has had a normal birth and when nothing abnormal has been noted in the delivery room, it is unlikely that any major abnormality of the central nervous system (CNS) will be found on physical examination. In fact, most pediatricians and other providers familiar with newborn examinations can tell at a glance the neurologic status of the newborn. What allows the experienced observer to do that is just that—observation.

Normal newborns, when supine and at rest, hold both upper and lower extremities flexed at the elbows, hips, and knees because flexor tone is greater than extensor tone (see General Appearance). If a newborn's arms or legs are in extension when the infant is not being stimulated, either extensor tone is increased or all tone is decreased. Infants with decreased tone are "floppy." Investigation of the cause of increased extensor tone or decreased generalized tone is essential, and a quick preliminary judgment is necessary. The cause may be (1) an insult to the CNS such as intracranial bleeding or infection, (2) a congenital disorder of the nervous system or muscles, or (3) sepsis.

It is important to make sure that motor responses are symmetrical. One of the easiest ways to do this is to elicit a **Moro reflex.** This can be done in a variety of ways; the most common is to put one hand below a supine infant's head, raising the head and back, and then to allow the head and back to drop while continuing to support the head and neck with the hand. Infants do not like this and respond by extending their arms and then bringing them back into flexion and into the midline. The legs generally are also extended and then flexed. All these responses should be symmetrical.

The hands of the newborn are kept fisted. The placement of two index fingers in the palms of the hands elicits a grasp reflex. The grasp reflex is so strong and the flexor tone so great that an infant can be lifted off the ground in this manner. When infants are grasped underneath both axillae and lifted up, the shoulder tone is strong enough to support their weight. If the shoulders and arms rise up with this maneuver, decreased muscle tone is present. When placed in a standing position, infants can be induced to "walk" or climb steps, the so-called **stepping reflex.** When the cheeks are stroked on the side of the mouth, the infant will "root" (i.e., demonstrate the **rooting reflex**), a major asset to the infant when placed on the breast of the mother.

The infant can normally handle its secretions; there should be no drooling when the infant is not taking from the breast or bottle. Evidence of an inability to swallow secretions could be due to neurologic problems or esophageal atresia.

Testing for pain sensation, sight, or hearing is not generally part of the newborn neurologic examination. However, fairly sensitive methods for screening for hearing in the newborn are now available, and this has become part of the routine in most nurseries because of state mandates for universal hearing testing at birth. The eyes may be open or closed, and it is important to check for the red reflex (see Examination of the Eyes, Ears, Nose, Mouth, and Throat). If infants are willing to keep their eyes open, they may be able to fix on an object or a light by the time of discharge.

MANAGEMENT IN THE HOSPITAL

In most cases, infants now spend no more than 24 to 48 hours in the hospital when born by vaginal delivery and no more than 72 to 96 hours in the hospital when born by cesarean section. As recently as 20 to 25 years ago, a

4-day hospital stay after vaginal delivery and a week-long hospital stay after cesarean section were routine. As a result, the management of issues after the birth of a child has become compressed. It is essential that several issues are discussed with the parents before the mother and infant leave the hospital. The short stay does not allow much time; therefore, organization is important.

Review of the Birth History and the Initial Physical Examination

After finishing the review of the birth record and performing the initial physical examination, discuss the results with the parents. These days, fathers are often present for most of the mother's stay in the hospital, especially if this is the firstborn child. If this is the pediatrician's first encounter with the parents, introductions are necessary. The pediatrician should be careful not to appear rushed—this is an important interview, and the parents will "hang on every word" that the physician says. An example of what the pediatrician should say follows:

> The baby is well formed and beautiful (or handsome). All the fingers and toes are present. The arms and legs are normal. The heartbeat is strong and regular. I did not see the color of the baby's eyes. (Or, the baby's eyes are blue, but they may not remain that color.) His hair is black. (If you know the baby's first name refer to the baby by name.) The bruises on the face will disappear within the next few days. The head will become rounder in the next few days. The marks you see above the eyes and on the back of the neck are very common and will disappear slowly in the course of the next year. The Apgar scores were good. (If necessary, explain what is meant by the Apgar score.) The examination of the reflexes and nervous system is normal.

Ask whether the parents have any questions about what they have noticed about their infant or about what transpired during delivery or in the labor room. Ask how they plan to feed the baby (see Chapter 4). Many, if not most, women breast-feed their infants in the hospital, often beginning immediately after delivery. The pediatrician must encourage and be supportive of the mother's decision to breast-feed, must be able to supply information about techniques of nursing, and must make sure that the mother is provided with assistance if necessary. Support by the nursing staff or the hospital's lactation consultant is essential if the mother is breast-feeding for the first time.

Inform the parents about what they can expect to happen in the hospital. Explain that you will make sure to find out the infant's Rh factor if the mother is Rh-negative. Tell when and where their infant will receive hepatitis B immunization and explain why. In current practice, the first dose is given in the newborn nursery. The next two doses are given at the 2- and 6-month visits. In addition, a state-mandated blood test will be drawn for neonatal screening for a large number of genetic disorders, including phenylketonuria, hypothyroidism, sickle cell disease, and numerous others. The test is usually done at 48 hours after birth to allow for any abnormal metabolites to build up. If the baby is discharged prior to 48 hours, the tests may not be accurate. A listing by state can be found at the Web site for the National Newborn Screening and Genetics Resource Center (http://genes-r-us.uthsca.edu). If the blood is not sent from the nursery, arrange for the parents to come to your office for this procedure. If any problems have come to light, explain how they will be handled.

Make sure to tell the parents how you can be reached if they need to ask you any questions, and tell when you will return to see them. If you use e-mail or if your office has a Web site, inform the parents of this. Sometimes the initial hospital visit is the only visit. Arrangements should be made for them to call you the next day to discuss any problems—there are always problems—and to make arrangements to bring the child in for an office visit. When the infant is discharged from the hospital after only 24 hours, a visit to your office in the next 24 to 48 hours is appropriate, if only to examine the infant for the presence of jaundice. If the infant stays 48 hours or more and there is no evidence of jaundice, the office visit can be scheduled when the infant is 1 to 2 weeks old.

Review of the Hospital Stay and the Discharge Examination

Before the mother and infant are discharged from the hospital, it is necessary to review the hospital stay, discuss the discharge physical examination, and make plans for seeing the family afterward. The review of the hospital stay and the discharge physical examination focus on different aspects of care than the initial assessment did. It is a good idea to ask the following questions:

- Is jaundice present?
- How much weight has the baby lost?
- Is the baby taking to the breast or bottle?
- How easy or difficult is the baby to feed?
- Does the baby retain her feeds?

- Is the infant urinating and moving her bowels?
- What is the baby's temperament like? For example, does the baby calm easily, seem regular, and like to be held?
- Are there any new findings on the physical examination, such as the presence of a cardiac murmur, a rash, or a hip click?

Jaundice is common in newborns. Is the jaundice sufficient to warrant obtaining a bilirubin determination? Any infant with jaundice appearing within the first 24 hours of life requires evaluation. Discharge from the hospital should wait until the evaluation is complete and the bilirubin rise has stopped.

Pediatric Pearl: The appearance of jaundice in the first 24 hours of life may never be diagnosed initially as being physiologic jaundice of the newborn, a condition in which jaundice generally does not appear before the third day of life.

A determination of how far down the body the jaundice extends is an approximate gauge of the level of jaundice. If the jaundice appears after 24 hours of age and is mainly on the face and upper chest, the total bilirubin is probably below 8 mg/dL. If the jaundice extends to the abdomen and upper thighs, the total bilirubin is generally in the range of 12 to 13 mg/dL. If the infant is over 48 hours old and appears to have only minimal jaundice, it is not necessary to obtain a serum bilirubin determination. Infants with moderate jaundice, corresponding to bilirubin levels in the range of 12 to 13 mg/dL, require observation to make sure the level stabilizes. In most cases, infants with bilirubin levels at or above 15 mg/dL receive phototherapy. Most nurseries now use transcutaneous bilirubin measurement as an initial assessment of bilirubin level.

If the jaundice appears within the first 48 hours of life and if the infant is going home, arrangements for next-day follow-up must be made. Some full-term infants develop jaundice sufficient to require a therapeutic intervention, most commonly phototherapy. The complete differential diagnosis of jaundice and the indications for this treatment are discussed elsewhere in this book (see Chapter 10). **The usual causes are jaundice related to excessive hemolysis, most often resulting from an ABO incompatibility, exaggerated physiologic jaundice, or breast milk jaundice.** Whatever the cause, the presence of jaundice produces great apprehension in the parents. Even if they do not know from previous experience why jaundice is a concern, the fact that tests to discover its etiology and severity are being performed engender great anxiety, much advice from concerned relatives and friends, and many questions as to what harm the jaundice can cause the infant. The clinician should address all of these concerns with a great deal of patience and concern, although the jaundice may be of little actual significance.

It is necessary to ask the mother whether she has any issues concerning breast-feeding; if there are, arrangements must be made to assist her with these concerns after the hospital stay. In many hospitals, a member of the staff is assigned as a breast-feeding coordinator. That individual is responsible for holding breast-feeding classes and for making sure that educational literature about breast-feeding is available and that a member of the nursing staff is available to help the mother in the techniques of breast-feeding her baby.

- How comfortable is the mother with the process?
- Does the baby get on the breast easily?
- Does the baby suck well?
- Has the mother's milk "come in" yet?

In many parts of the United States, "lactation consultants" are available for this purpose, especially for mothers who are breast-feeding for the first time. Some women have significant quantities of milk by the end of the second day, but it often takes about 3 to 4 days before milk flow becomes established. In older mothers it may take longer. Prior to that time the mother has a supply of colostrum. The mother should be aware of this.

Regardless of the method of feeding, either breast or bottle, parents want to know how much the baby weighs. There is an obligatory weight loss in almost all infants because total body water at birth approaches 80% of body weight, dropping to 65% to 70% of body weight in the first few days of life. On average, for full-term newborns, this means that weight loss is about 3 to 5 oz the first day and another 3 to 5 oz the second day. The weight then levels off for a few days, after which the baby starts to gain about an ounce per day. It takes about 7 to 10 days for bottle-fed infants and about 10 to 14 days for breastfed infants to regain their birth weight. It is necessary to explain all this to the parents.

Introducing the concept of **infant temperament** to the parents is worthwhile. They grasp this idea easily, for they "see" that their own infant does seem to have his own personality. Some babies appear very calm. When hungry, they cry but not with great intensity. When comforted, they are easy to console. After feeding, they fall asleep quickly, awakening only for their next feeding. Other babies cry with a great deal of intensity, not just when hungry but also with minor disturbances. They are difficult to console and, after feeding, these "difficult" babies may fuss for a while before going to sleep, then awakening after a short period and crying once again.

Most infants fall in between these two extremes. Recommend to the parents that they purchase a "baby book" that discusses this and other aspects of their child's care. The author recommends *Caring for Your Baby and Young Child: Birth to Age 5* (edited by Steven P. Shelov and published by the AAP). It is important for parents to recognize the aspects of their child's temperament as being innate characteristics. An appreciation of this allows them to respond appropriately to the infant.

Any new findings on physical examination must be discussed with the parents. The examination should include remeasuring the head circumference and comparing it with the original measurement, repeating the entire physical examination, and noting any changes from the initial examination.

In addition, ask the parents to tell you of any new concerns they may have or old ones they feel have not been adequately addressed. If the mother is breast-feeding and requires pain medications or, for that matter, almost any medication other than antimetabolites or radioactive materials, she should be told that the usual doses will not affect her infant. Mention of any tests or procedures that have been performed during the hospital stay is appropriate, including the infant's blood type, the administration of hepatitis B vaccine, and the obtaining of blood by heel stick to screen for a variety of genetic disorders. In addition, most states require a hearing screen to be done in the newborn nursery prior to discharge. The results of this screening examination should be told to the parents. If the infant has failed the screening, arrangements must be made for follow-up testing. Most often the second test will be normal. If it is not, referral for specialized audiological evaluation is mandatory.

Finally, a discussion needs to take place about safety issues. These include "back to sleep," meaning that the infant should be placed on its back when sleeping for at least the first 6 months of life. This technique has been shown to reduce the incidence of sudden infant death syndrome by approximately two-thirds. The parents should be asked about car seat availability when leaving the hospital, exposure of the infant to second-hand smoke, avoidance hot liquids when holding the baby, enforcing hand washing before handling the infant, and avoidance of visitors with obvious infectious conditions.

SUMMARY

In summary, the evaluation of newborn infants at birth requires knowledge of not only many fields, but also, and perhaps most importantly, a sensitivity for and an understanding of the concerns parents have about the well-being of their own newborn. It is a new start in life, and the parents want it to be a good one for the infant and for themselves. Unlike other situations, in which minor events carry little weight, anything that happens to a newborn infant has great significance. The skillful practitioner recognizes this and incorporates it into all encounters. When this happens, even if difficult situations are encountered, parents will be forever grateful. It is likely that the trust formed between the parents and the pediatrician during this period will make dealing with issues that arise later in childhood easier.

Health Supervision Visit

Steven P. Shelov

INTRODUCTION

For the pediatrician, the skills, attitudes, and energy necessary for preventing disease and maintaining health come first. This focus on health supervision (formerly called health maintenance visit) is the centerpiece of a practice unique to the pediatrician, who has strong feelings about this approach, similar to a surgeon's belief in the ability to heal through procedural intervention. For the pediatrician, both physical and emotional factors play roles in preserving health. Recommendations about immunizations, nutrition, and developmental growth help the family cope with psychological setbacks; dysfunction; and problematic emotional periods, in which children make demands on parents. The completeness of the pediatrician's practice is testimony to the deeply held belief that the central, organizing influence for the child is the family; that is, a family that is healthy in all aspects helps ensure a healthy present and future for the child.

This chapter describes the pediatrician's approach to health supervision so that the reader can understand the importance of monitoring the growth of the child. The initial regular health supervision visit in the office or other ambulatory setting, which usually occurs at 2 to 4 weeks of life, focuses on aspects of physical and behavioral development. It is impossible to summarize all of well-child care in one chapter. Rather, it is intended that the reader apply the principles and outlined guidelines to all subsequent visits, using developmentally appropriate material from the figures, tables, appendix, and the available references identified in the text. The first visit at 2 to 4 weeks of age sets the stage for the elements for each subsequent visit. Throughout this first, detailed illustrative example of such a visit, summarized questions, topics of potential concern, developmental milestones and physical examination at subsequent ages through age 12, immunizations at different ages, tests and procedures for different ages, and topics in anticipatory guidance are presented.

The American Academy of Pediatrics (AAP) has recently developed extensive revisions of its approach to the health supervision visit for children. These core guidelines are contained in a thorough and extensive document titled *Bright Futures—Guidelines for Health Supervision of Infants, Children, and Adolescents.* Information on how to access the online material, including chapter questions, is available on the inside front cover of the book.

GENERAL ASPECTS OF A HEALTH SUPERVISION VISIT

Health supervision visits are essential anchors for parents to learn about their infant or child and to achieve an increasingly more satisfied level of competence as parents with each contact with the pediatrician. The overall purpose of these visits is for the pediatrician, through education and response to questions, to further empower each and every parent to be as knowledgeable, observant, nurturing, loving, and to feel as rewarded as possible. Although this goal may not be attainable at every visit, it should be the object of every encounter. The Bright Futures visit guidelines further enhance this desired outcome.

HEALTH SUPERVISION 2- TO 4-WEEK VISIT

– *Items indicated, by age and development, to invite discussion, gather information, address the needs and concerns of the family, always geared to that particular family and modified by the communication style of the provider*

What better place to begin a discussion of the health supervision visit than with the 2- to 4-week-old infant! Chapter 1 reviewed the elements of the newborn visit. The focus of the health supervision visit for the 1-month-old follows the important period of the first month of life and serves as the model for health maintenance visits to follow.

In the early days of parenting, **health supervision visits** and frequent telephone contacts in between office visits provide support and confidence-building interactions for new parents. The actual process of these important visits is one that the experienced pediatrician repeats so many times that they become second nature to every encounter with children and their families. The first health maintenance visit often serves as the paradigm for teaching in similar visits. Although the details of each visit, specifically the content of information sought and shared with the parents, is targeted to the developmental age and stage of the child, the process remains the same. Each of the health maintenance visits at each age has the following headings, the specifics of which are filled in month by month, year by year.

Context
Priorities for the Visit
    History/Interview
    Observation of Parent–Child Interaction
    Surveillance of Development
Physical Examination
Screening—Universal; Selective (Considering Risk Assessment); Developmental
Immunizations
Other Practice-Based Interventions
Anticipatory Guidance

Context

The new baby has just returned home 2 to 4 weeks ago. In addition to a number of different emotions and anxieties, family members have questions, which may include the following:

- Do I know enough to care for this new baby?
- Do I have enough love to go around between my other children and my new baby?
- How will I know if there is something wrong?
- Will I know when I need to call someone for help, and who should I call if I have any questions? It is important to make sure that parents have emergency numbers, especially those of the pediatrician for evenings and weekends.
- How do I know what my baby wants when he cries?

The anxieties of new parents, especially parents of first children, often obscure the intrinsic sense of their own competence and innate abilities. Anxiety often leads to uncertainty and, with that uncertainty, often a sense of being overwhelmed. One of the most important roles of the pediatrician, especially in the first few months of life of the new infant, is to relieve parents' anxiety, reassure and teach by being available and responsive to parents' needs and questions, and repeatedly support their own parental capabilities and instincts. The more the pediatrician can strengthen parents' sense of competence, the more happy and secure parents will be with their parenting role and the more confident they will be with their new baby.

As with any person-to-person encounter, making sure the mother and father feel comfortable in their initial visit is essential. This may mean ensuring that there is enough room for everyone, including anticipated baby paraphernalia (e.g., diapers, wipes, water, changing needs), and that there are a minimum number of interruptions. There is nothing worse than for a first conversation about a newborn infant to be repeatedly interrupted by a number of telephone calls or door-knocking intrusions. It is essential to ask nursing and clerical staff to hold all but necessary calls.

Different practitioners have different styles, but note taking during the interview is often the expected norm. It indicates to parents the importance of what they are saying and that the pediatrician is really listening to their issues and including them as part of their child's record. The physician should also make clear to parents that if they have a list of prepared questions, they should feel free to consult them at any time during this visit. It is important to reassure the parents that **no questions are silly or unnecessary.**

Within the first month, parents have spent increasing time learning to interpret the cues and signals of their new baby. The primary focus for the parents revolves around daily routine (or lack thereof), feedings, sleep and wake patterns, elimination, and gradual assimilation into the patterns of the family. As the pediatrician is the coordinator of "the medical home" for the family, if the baby has had a premature delivery or identified disabilities, then discussion of additional consultation or visits to other subspecialty providers will be part of this context.

The 1-month visit will encompass all aspects of health supervision, response to parental concerns, and, most importantly, encouragement and guidance regarding growth and nutrition, development, and transition to a more predictable sleep/wake pattern. Families experiencing difficulties related to postpartum adjustment will be identified and proper referral, if needed, will be discussed.

Priorities for the Visit

The first priority is to attend to the concerns of the parents and other child care providers. The priorities, in addition, as developed by the Bright Futures Infancy Expert Panel are the following:

- Parental (maternal) well-being, including health, emotional, and physical; return to work/school issues and plans for integrating care for the newborn into those plans
- Family adjustment (family resources, family support, parental roles, domestic violence, community resources)
- Infant adjustment such as sleep/wake schedule, sleep position (sleeping on back is strongly recommended), location of crib/bassinet, safety state modulation (crying, consoling, shaken baby), developmental changes (temperament discussion), tummy time
- Feeding routines, frequency, growth spurts, breast-feeding comfort issues, bottle-feeding queries, holding, burping, pacifiers
- Safety, infant car safety seat installation, crib type, toys with loops, mobiles

History

Interview

Patience is crucial at the very beginning. Getting adjusted, comfortable, and ready to listen while carrying a small, often 1-month-old, squirmy bundle usually takes time. At every visit during the first 6 months of life, it is necessary to ask some important questions at the beginning of the interview, such as:

- How are you doing with the baby? Are there any things at home that I should know about?
- What are your baby's routine and schedule like now?
- What are some of your best and most difficult times of day with the baby?
- Do you have any questions or concerns about the past several weeks?
- Are you enjoying your baby at least some of the time?
- Do you feel like you have settled into a routine, and if so, are you comfortable with it? Are you getting some rest at least part of every day?
- Have you been feeling tired or blue?
- Have any things changed since we last saw each other, either with the baby or in your home setting?
- How have you been handling the crying episodes? Is there a pattern to the crying, and what kinds of things seem to make your baby stop crying?
- What is the baby's sleeping pattern like? Does the sleep/wake cycle seem to be reversed?
- (For breast-feeding mothers): Has your milk come in, are you comfortable with breast-feeding, and do you have any excessive soreness, cracking, or discharge at the nipple?
- (For all mothers): Do you think your baby is satisfied after feeding? How often does she feed?
- Do you have any specific questions about the baby's condition (e.g., bowel movements, skin color [jaundice], eye discharge, umbilical stump oozing, excessive amounts of crying or fussiness, change in appearance or behavior)?

It is also important to learn about how life at home is proceeding in general. The pediatrician may ask:

- How are things going with the father of the baby? Are other people helping you with some of the house chores? Numerous studies now reinforce the importance of paternal involvement in all aspects of infant and child care. The earlier the involvement, the greater the child's and parents' satisfaction and the greater the positive influence on the child's development. The father's participation in care also allows for some rest time for the mother, which is much needed in the first several months of life, especially if she is breast-feeding.
- How are siblings (if there are siblings at home) handling the presence of the new baby? Are you spending time with your other children, who are probably feeling a little deprived of time with you? Classically, older siblings, especially those who are 2 to 4 years older than the new infant, regress somewhat when the new baby comes home. It is important for parents to take some separate time with older siblings to show that they have not forgotten their other children and that they are still as important as ever. (It should be noted that some breakdown in toilet training may even occur for a short period.)
- Are routine tasks around the house generally being taken care of (e.g., shopping, bill paying, odds and ends)?
- Are the grandparents, if present, too involved and intrusive, or are they helping just to the proper degree?

Pediatric Pearl: The questions about the first month are primarily focused on family adjustment to the new baby at all levels. The pediatrician will serve as the best monitor for any early warning signs that things are not going well.

The overall purpose of these initial questions is to establish a broad foundation for open and honest communication. There are no "unimportant questions." Initial questions are explorative, looking for any sources of additional stress that might be interfering with the initial, important bonding period with the new baby. In the first month, infants are not as easy to relate to as they are later. Their ability to make eye contact, be consoled, and relate to other individuals is usually quite variable, even from day to day. Infants usually do not have a responsive smile at this time (if it were there, it would help), so parents need even the smallest of signs of reassurance that they are doing a good job. Positive comments about how well the infant looks and how well the parents are doing are reassuring statements that pediatricians should repeat to parents during their first visit to the office.

Interview Questions at Subsequent Visits

It should be noted that the questions listed in this section are only a sample of those that may be appropriate. They relate to developmental milestones of which the parents should be aware. A more complete discussion of age-appropriate developmental milestones appears in *Bright Futures—Guidelines for Health Supervision* (see Suggested Readings).

Infancy: 1 to 6 Months

The clinician should ask the usual questions regarding home life with the infant since the last visit and whether there have been any changes that need to be discussed. In addition, some age-specific questions are appropriate, including:

- Is your baby on a more regular sleeping schedule and sleeping through the night? By age 3 to 4 months, most infants sleep through the night, much to everyone's relief.
- Are you putting your baby to sleep on his back?
- Is the feeding going all right? Have you been able to stop the middle-of-the-night feeding?
- Is your baby more responsive?
- Is your baby smiling?
- Is your baby making a variety of different sounds?
- Is your baby responding to sounds by quieting or looking at you?
- Are you carefully "baby-proofing" your home as your baby becomes increasingly active and mobile?
- Are you considering going back to work? If so, what child care arrangements have you worked out?
- Have you noticed your baby has developed more of a personality?

Infancy: 6 to 12 Months

- How are you handling your baby's increasing mobility? Have you adequately "baby-proofed" your home?

Pediatric Pearl: "Baby-proofing" is mandatory as the infant reaches 6 to 12 months of age. The kitchen, bathroom, changing table, and play areas are prime targets. For example, it helps to clean under sink cabinets and put the changing table in a corner.

- Is your baby sleeping through the night, or as the baby approaches his first birthday, has he begun to wake up? Sleeping through the night usually takes place around 3 months, but often at 9 to 10 months of age, infants start to wake up again during the night for a period.
- Are you introducing more variety of strained and then junior foods?
- Are you thinking about weaning your baby from the breast or bottle, and have you at least introduced him to the concept of the cup? Weaning usually takes place near the first birthday, although some parents like to continue breast-feeding well into the second year of life and occasionally beyond.
- Have you noticed your infant becoming more afraid of strangers and also more reluctant to leave you? Stranger anxiety is frequent during the last half of the first year. This normal developmental milestone reflects the increasing ability of the infant to distinguish the mother or other primary caregiver from a nonprimary caregiver. This normal phase may lead to some separation anxiety into the second year as well.
- How are you adjusting to your baby's increasing independence?

The Toddler Years: 1 to 2 Years

- Have you introduced your child to playmates, and how does she interact with them?
- Has your baby taken her first steps? Have walking and running created problems for you or the rest of the family?
- How are things going with the child's brothers and sisters (if applicable)?
- How are the new child care arrangements going (if the parent has returned to work)?
- What personality differences have you noticed?
- How are you handling the "terrible twos," the normal but difficult stage of development (if the child has entered this period)? Parents struggle with the bossiness and increasing independence of these often stormy months. Nevertheless, they are important stages of independence that a toddler must experience.
- Has disciplining your active toddler been a problem?
- What kinds of toys and games does your child now enjoy?
- Does your child enjoy books? It is never too early to read to children. Reading reinforces language, assists in object identification, and promotes attachment.
- How much television does your child watch, and what kinds of shows do you allow her to see? The earlier parents begin to limit television viewing to 1 to 2 hours per day at a maximum and indicate preferences concerning content, the earlier children start to develop their own appropriate television-watching habits.
- Is your child eating meals with you, and is her diet fairly well-balanced?
- Does your child still take a nap during the day? A morning and afternoon nap during these years is quite normal and expected, although not all children take such naps.
- Does your child sleep in her own room, and has your child "graduated" to a "real bed" from a crib? Sometimes, parents use the second birthday as the time to try a true bed. A junior bed may offer a more secure sleeping environment for the more fearful toddler.

The Preschool Years: 2 to 3 Years

- How are the discipline issues going? These issues are often the most pressing for parents. Several respected parent manuals or developmental texts contain numerous approaches to limit-setting.
- Have you started toilet training, and how is it going? The median age for toilet training is 33 months, with bowel control coming before bladder control.
- Does your child still wet the bed at night, although he is dry during the day? Often, nighttime wetting is still a normal finding until 4 to 5 years of age (see Chapter 5).

Pediatric Pearl: It is important to advise parents to minimize the fuss over bed-wetting. Bed-wetting beyond 6 years of age (primary nocturnal enuresis) often requires a separate approach, which is individualized to the family and never involves punishment. A variety of conditioning and positive reinforcement techniques are appropriate.

- Is your child starting to play more nicely with his playmates?
- Is your child starting to show lots of different emotions such as pleasure, anger, joy, protest, warmth, and assertiveness? Children begin to show different types of temperament, which are often displayed through different emotions. Children who are very quiet or very assertive often have different "personalities," and different ways of dealing with stress, anger, happiness, and sadness. Parents recognize this easily and know that they have to respond differently to their children, depending on the specific temperament.
- Is your child recognizing and naming lots of different objects?
- Does your child recognize letters and numbers?
- Is your child showing all of the developmentally active behaviors seen at this age? Running, going up and down stairs, and throwing a ball are three common examples. The Denver II is designed to assist the clinician in identifying children whose rate of development differs significantly from peers of the same age (Figure 2-1).
- Is he talking and using sentences of one, two, or three words?
- Is he beginning to learn how to take turns and to share?
- Are you finding time to just play and have fun with your active child?

Additional questions for the remainder of the preschool period and the school-age years can be found in *Bright Futures—Guidelines for Health Supervision of Infants, Children, and Adolescents, 3rd ed.*, 2008, published by the AAP, which contains many of the recommended developmental questions. Finally, the well-respected book for parents, *Caring for Your Baby and Young Child, Birth to Age 5, 5th ed.*, 2009, published by the AAP, is another good source for up-to-date developmental questions and advice (see Suggested Readings). You can also find development milestones on the *Bright Futures* website at http://brightfutures.aap.org/.

Observation of Parent–Child Interaction

The 2- to 4-week visit provides a unique opportunity for the pediatrician to observe the nature and substance of the parent–infant interaction. Some of the keys to guide these observations are as follows:

- Do the parents appear content, happy, distressed, anxious, or excessively fatigued?
- Do they appear to be overwhelmed and at a loss to ask additional questions?
- If they feed the baby during the visit, how comfortable does that appear to be?
- If both parents are there, which is great for the early visits, how do they appear with each other? Do they seem engaged and supportive, or are they distanced from each other? Does only one ask questions while the other is quiet or withdrawn?
- Do either appear nervous, anxious, and uncertain about interacting with the baby?

All of these observations will be key to advising each parent for the next month of care. If there appears to be a significant degree of being overwhelmed, then perhaps an earlier "check-in" visit might be useful during the next month rather than waiting until the 2-month visit.

Surveillance of Development

The next series of questions concerns the parents' view of their baby's development. Using the four categories of physical, social–emotional, communicative, and cognitive development, parents' observations will be explored. During the first month, the following might be some of the prompted questions:

- Physical development—While on his tummy, is he starting to lift his head off the surface? Are all four extremities moving equally, though randomly? Does the baby seem to startle when surprised (Moro reflex)?
- Social–emotional development—Is he becoming soothable during times of upset? Is he more responsive to calming actions?
- Communicative development—Is he able to follow faces and parents with his eyes across midline. Any verbal sounds will be few and very guttural and mostly as part of crying episodes.

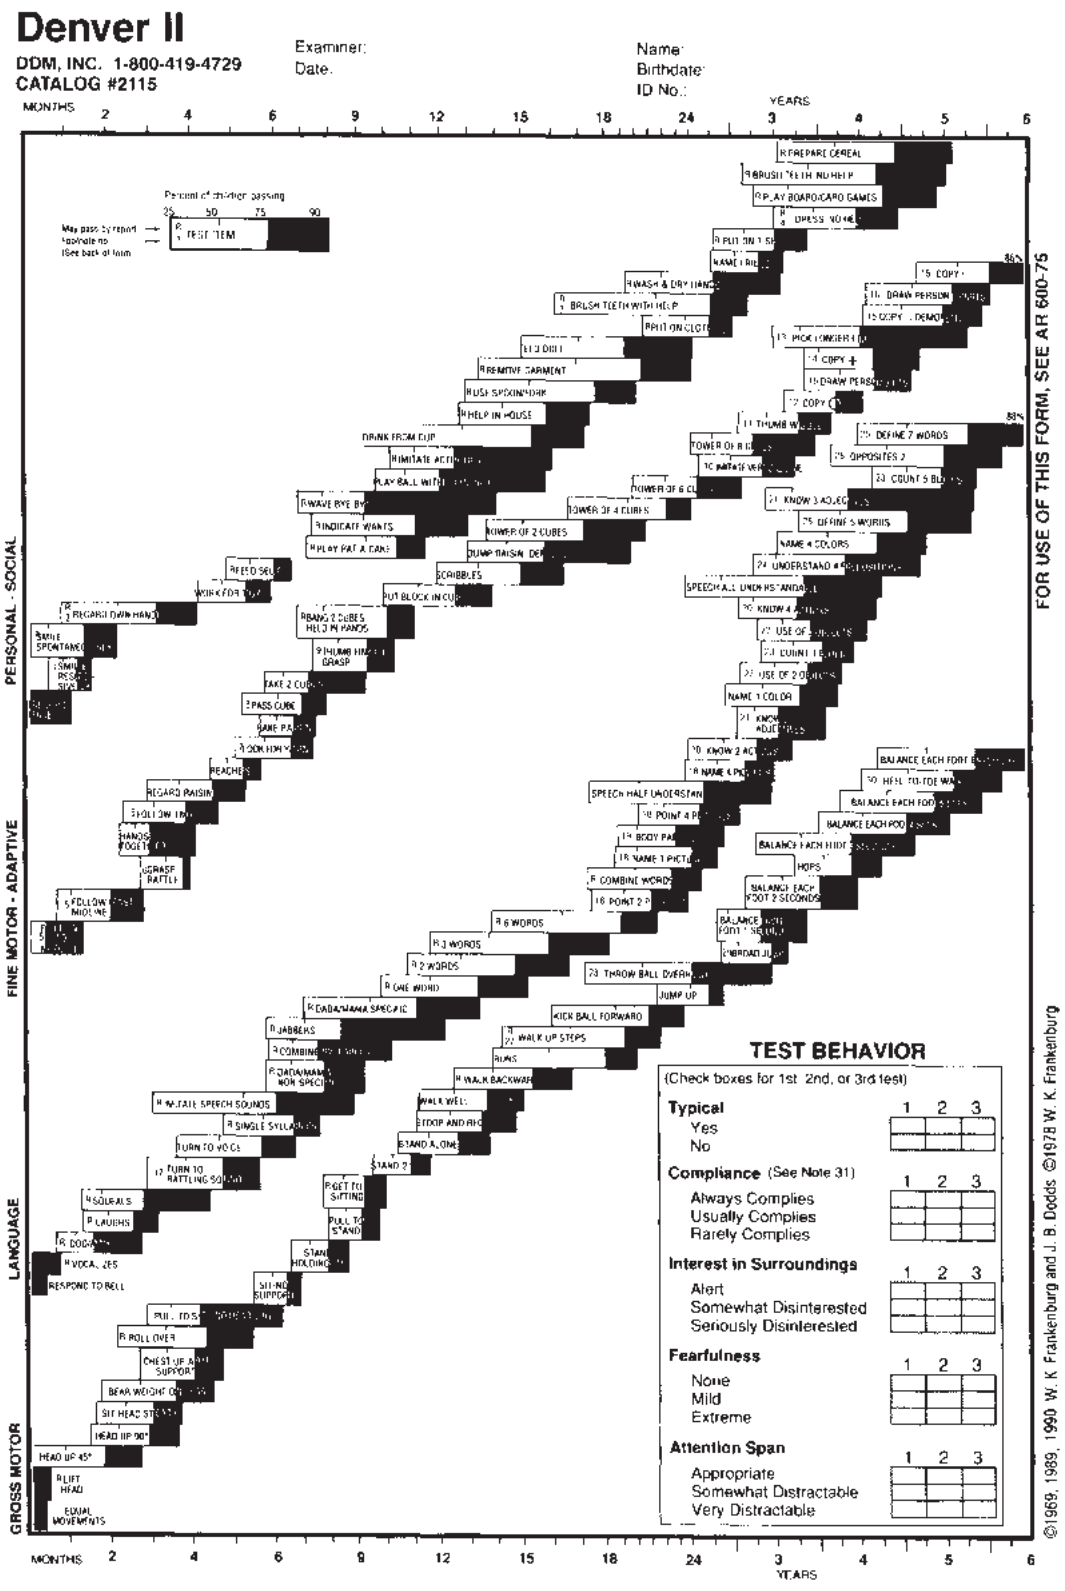

FIGURE 2-1. Denver II developmental screening test. From Frankenburg WK, Dodds J, Archer P, et al: The Denver II: A major revision and restandardization of the Denver Developmental Screening Test. *Pediatrics* 89:91–97, 1992.

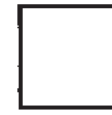
DIRECTIONS FOR ADMINISTRATION

1. Try to get child to smile by smiling, talking or waving. Do not touch him/her.
2. Child must stare at hand several seconds.
3. Parent may help guide toothbrush and put toothpaste on brush.
4. Child does not have to be able to tie shoes or button/zip in the back.
5. Move yarn slowly in an arc from one side to the other, about 8" above child's face.
6. Pass if child grasps rattle when it is touched to the backs or tips of fingers.
7. Pass if child tries to see where yarn went. Yarn should be dropped quickly from sight from tester's hand without arm movement.
8. Child must transfer cube from hand to hand without help of body, mouth, or table.
9. Pass if child picks up raisin with any part of thumb and finger.
10. Line can vary only 30 degrees or less from tester's line.
11. Make a fist with thumb pointing upward and wiggle only the thumb. Pass if child imitates and does not move any fingers other than the thumb.

12. Pass any enclosed form. Fail continuous round motions.

13. Which line is longer? (Not bigger.) Turn paper upside down and repeat. (pass 3 of 3 or 5 of 6)

14. Pass any lines crossing near midpoint.



15. Have child copy first. If failed, demonstrate.

When giving items 12, 14, and 15, do not name the forms. Do not demonstrate 12 and 14.

16. When scoring, each pair (2 arms, 2 legs, etc.) counts as one part.
17. Place one cube in cup and shake gently near child's ear, but out of sight. Repeat for other ear.
18. Point to picture and have child name it. (No credit is given for sounds only.)
    If less than 4 pictures are named correctly, have child point to picture as each is named by tester.

19. Using doll, tell child: Show me the nose, eyes, ears, mouth, hands, feet, tummy, hair. Pass 6 of 8.
20. Using pictures, ask child: Which one flies?... says meow?... talks?... barks?... gallops? Pass 2 of 5, 4 of 5.
21. Ask child: What do you do when you are cold?... tired?... hungry? Pass 2 of 3, 3 of 3.
22. Ask child: What do you do with a cup? What is a chair used for? What is a pencil used for?
    Action words must be included in answers.
23. Pass if child correctly places and says how many blocks are on paper. (1, 5).
24. Tell child: Put block **on** table; **under** table; **in front of me, behind** me. Pass 4 of 4.
    (Do not help child by pointing, moving head or eyes.)
25. Ask child: What is a ball?... lake?... desk?... house?... banana?... curtain?... fence?... ceiling? Pass if defined in terms of use, shape, what it is made of, or general category (such as banana is fruit, not just yellow). Pass 5 of 8, 7 of 8.
26. Ask child: If a horse is big, a mouse is __? If fire is hot, ice is __? If the sun shines during the day, the moon shines during the __? Pass 2 of 3.
27. Child may use wall or rail only, not person. May not crawl.
28. Child must throw ball overhand 3 feet to within arm's reach of tester.
29. Child must perform standing broad jump over width of test sheet (8 1/2 inches).
30. Tell child to walk forward, heel within 1 inch of toe. Tester may demonstrate.
    Child must walk 4 consecutive steps.
31. In the second year, half of normal children are noncompliant.

OBSERVATIONS:

FIGURE 2-1. ***(Continued)***

- Cognitive development—There may be the first signs of a smile. The first smile is often NOT responsive but spontaneous. Over the subsequent several weeks, responsive smiles start to be seen.

The milestones at this age are obviously very limited, and still largely dictated by the newborn reflexes (Table 2-1). Over the course of the next 2 to 3 months, these reflexes will become diminished and some will even disappear. With that neurologic maturation, more active and purposeful movements will unfold and the developmental observations will be much more robust.

TABLE 2-1

Newborn Reflexes[a]

Reflex	*Age When Reflex Appears*	*Age When Reflex Disappears*
Moro reflex	Birth	2 months
Walking/stepping	Birth	2 months
Rooting	Birth	4 months
Tonic neck reflex	Birth	4–5 months
Palmar grasp	Birth	5–6 months
Plantar grasp	Birth	9–12 months

[a] These reflexes are some that an infant performs during his first weeks. Not all infants acquire and lose these reflexes at exactly the same time, but this table gives a general idea of what to expect.

From *Caring for Your Baby and Young Child: Birth to Age 5* by Steven Shelov and Robert E. Hannemann, copyright 1991 by American Academy of Pediatrics.

The Denver II is a summary of those anticipated milestones until age 5. A more complete presentation of developmental milestones through childhood and adolescence can be found in *Bright Futures*.

Physical Examination

A complete physical examination is part of every health supervision visit. At this age the following elements must have particular focus. (Figures 2-2–2-6 are relevant charts.)

- Measurement and plotting (adjustment for gestational age) of height, weight, and head circumference
- Plot—Weight for length
- BMI for older children
- Vital signs including temperature, respiratory rate, and blood pressure should be recorded at every visit.

Specific Areas of Examination

HEAD. Careful examination of the head should start with a careful measurement of the occiput-frontal circumference with a tape measure. **It is important to measure the circumference at the same place each time to ensure consistency from visit to visit.** At birth, the normal occiput-frontal circumference is 35 cm, and increases each month, quite rapidly in the first few months, and then more slowly but predictably in the subsequent months of the first year of life.

Pediatric Pearl: A handy method to remember the increase in occiput-frontal circumference is:

- Increases 2 cm/month for the first 3 months
- Increases 1 cm/month for the next 3 months
- Increases ½ cm/month for the next 6 months

Therefore, the resulting head circumference at 1 year is about 47 cm, which is approximately the 50th percentile for all infants when plotted on the head circumference growth chart.

It is important to feel the anterior and posterior fontanelles carefully; both should still be open at this visit. The anterior should still be about 1 to 2 cm × 1 to 2 cm, but the posterior should, at best, be only a fingertip opening. The posterior fontanelle closes by 4 months of age, and the anterior fontanelle closes between 12 and 18 months of age.

In addition, it is necessary to examine the scalp for any evidence of cephalohematoma or other abnormality. The suture lines should still be quite open and should not have any evidence of fusion or ridging at this age. The skull should be symmetrical. There may not be much hair at this age; some of the newborn hair will have normally disappeared, and reassurance that new, more permanent hair will soon emerge is necessary.

EYES. Examination of the eyes should check for any discharge, suggestive of a **conjunctivitis**, a neonatally acquired ***Chlamydia* infection**, or evidence of a blocked tear duct or **dacryostenosis**. The pediatrician should elicit a **red reflex** to ensure that there are no cataracts. The eyes will normally have a slightly dysconjugate gaze, and the physician may need to reassure parents that this is normal in the first month or so.

EARS. Examination should look for any evidence of **otitis media** (OM). An otoscope with an air-insufflating bulb attached should always be used. After careful examination of the normal landmarks of the tympanic membrane, looking at the ear for normal landmarks (Figure 2-7), the examiner should introduce a slight puff of air into the ear canal with the attached bulb, making sure there is a good seal between the speculum and the external auditory meatus. This procedure should cause the tympanic membrane to move slightly (like a crinkling sail) and then snap back, provided there is no fluid behind the membrane. If no tympanic membrane movement is apparent, the possibility of otitis media warrants consideration.

MOUTH. It is necessary to examine the throat to check that there are no palatal abnormalities and that the gums are normal. No teeth should be present. Natal teeth should have been removed. Gums should be examined for any evidence of eruption cysts or any other abnormality. The tongue will frequently have the band of connective tissue attached toward the end, but rarely impinges on the thrust of the tongue.

HEART AND LUNGS. The pediatrician should listen carefully to the heart and lungs, both anteriorly and posteriorly. It is important to determine the respiratory rate and heart rate and to listen to the heart carefully for

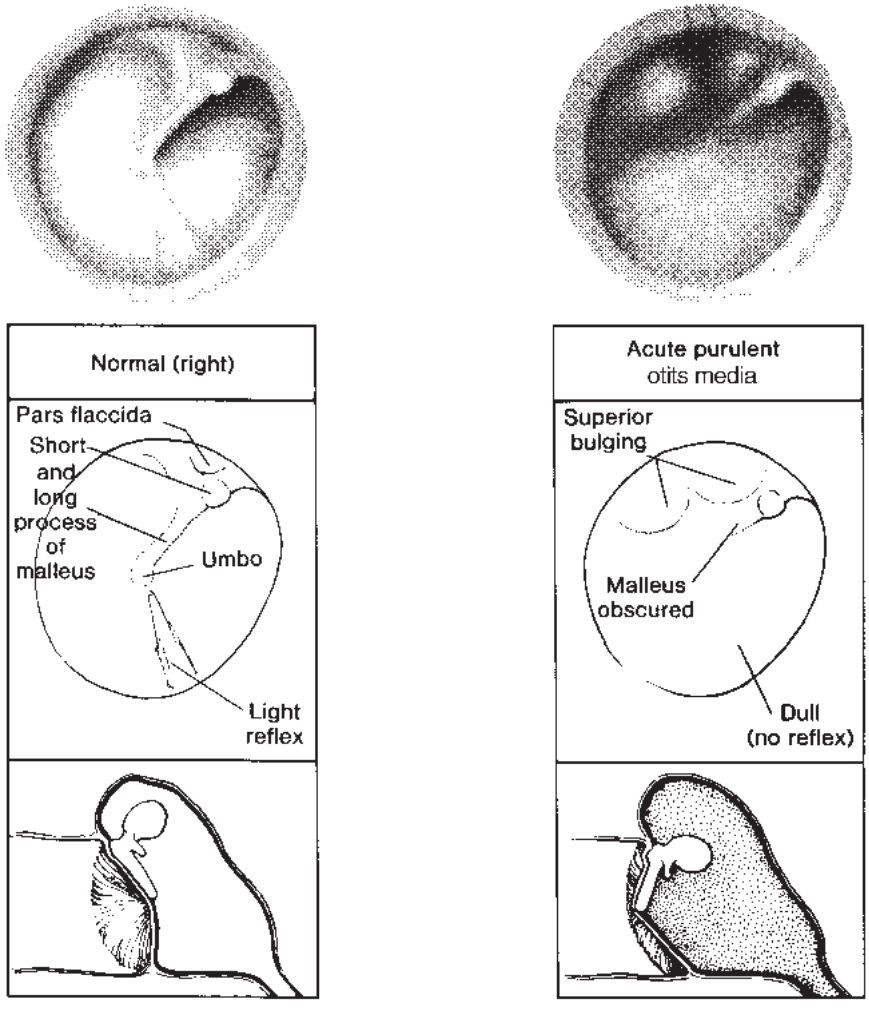

FIGURE 2-7. Drawings of normal tympanic membrane and acute purulent otitis media (OM). From Fleisher GR, Ludwig S (eds): *Textbook of Pediatric Emergency Medicine*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 740.

any evidence of murmurs. The normal respiratory rate is 36 to 40 breaths/min, and the heart rate is 120 to 140 beats/min. There should be evenness of breath sounds through the chest, with easily heard "whoosh" on inspiration and exhalation. There should not be any crackles or wheezing heard.

The examiner should thoroughly listen to the heart over the anterior chest, listening over aortic, pulmonary, sternal borders, midclavicular line, and at the point of maximum impulse. Occasionally, a murmur that was not appreciated in the newborn nursery may be audible. This often is a small **ventricular septal defect**. Careful auscultation over the back should also be routine; occasionally, a residual **patent ductus arteriosus** can be heard there. **ANY MURMUR HEARD AT THIS AGE IS CONSIDERED SUSPICIOUS AND REFERRAL SHOULD BE MADE TO A PEDIATRIC CARDIOLOGIST.**

ABDOMEN. A thorough abdominal examination should allow for palpation of any abnormal masses. The abdomen is usually quite soft when an infant is not crying. The pediatrician can therefore easily palpate the liver and right upper quadrant, the spleen and left upper quadrant, and both kidneys and, on deeper palpation, explore for any masses or other abnormalities. If the infant is crying and uncooperative, try working with the parent to calm the baby and examine in the parent's arms, allowing the opportunity for a complete and thorough examination.

Examination of the umbilicus should show a well-healed stump. If there is discharge and the mother states that she often sees blood at the top of the diaper, then this may indicate that an **umbilical granuloma** has developed at the site of the umbilical stump. This is easily cauterized in the office.

GENITOURINARY SYSTEM. The pediatrician will carefully examine the genitourinary area. In boys who have been circumcised, the prepuce should be completely healed with smooth, pink epithelium. Testicles should be both palpable and in the scrotum. In girls, it is necessary to spread the labia to ensure that there are no adhesions. The pediatrician should encourage parents to be sure to use warm water and cotton balls to carefully clean all of the creases and folds in which loose stool can easily become trapped.

MUSCULOSKELETAL. The pediatrician will examine all extremities, with special note taken of the examination of the hips. It is essential to perform Ortolani and Barlow maneuvers to be sure there is no **developmental dysplasia** of the hip (formerly known as **congenital dislocation of the hip**) (Figure 2-8). During a careful and complete examination of the hips, equal abduction and flexion should be evident.

SKIN. The pediatrician should examine the entire skin of the baby to look for any evidence of rash, discolorations, or abnormal marks. Special examination should focus on looking for hemangiomas. Often, a **hemangioma is *not* seen at the newborn examination because it may take a month or so for the abnormal vessels to become tortuous enough to show through the epidermis.** If a hemangioma is discovered, it is most important that the parents know that this will become larger over time and **that the best response is to "do nothing," assuming it is the usual kind of capillary hemangioma.** After enlarging during the first year or two of life, most capillary hemangiomas gradually involute and become smaller in the next several years.

The diaper area will also be closely examined for any evidence of rash, redness, or irritation. The pediatrician will review with the parent diaper area care and use of creams, ointments, and barrier creams to keep the area free from eruption.

NEUROLOGIC EXAMINATION. At the first-month visit, there are relatively few specific neurologic findings that do not relate to the developmental and reflex examination (see Developmental and Behavioral

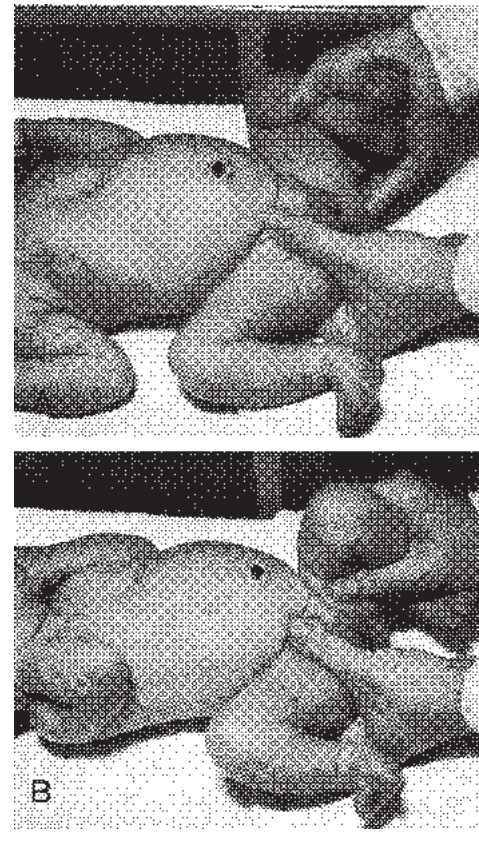

FIGURE 2-8. **(A)** Ortolani and **(B)** Barlow maneuvers. From Algranati PS: *The Pediatric Patient: An Approach to History and Physical Examination*. Baltimore, Williams & Wilkins, 1992, p 39.

Assessment, Chapter 5). Over the subsequent months and years, the neurologic and developmental examinations remain intertwined, and certainly abnormalities or deviations from the norm in the developmental assessment would suggest some underlying neurologic concern. However, cranial nerve, motor, sensory, and reflex examinations should be routine at every health maintenance visit.

The pediatrician should illustrate and discuss the newborn reflexes with the parents (Table 2-1). Concerns expressed should be discussed. Often, parents worry about the startle reflex (Moro) or even notice the fencer posture of the tonic neck reflex. Their normality and age when they disappear can be discussed.

The overall tightly flexed posture of the extremities of babies of this age can also be pointed out. Reassure parents that this degree of flexion gradually will loosen up as the baby achieves more motor control over his movements. With more active movement of the baby's extremities, the reflexes will also become less dominant.

Physical Examination in Future Visits

The actual physical examination changes little over the course of future health maintenance visits. However, the pediatrician should keep some points in mind as the child grows older, such as:

- Over the first 18 months of life, the pediatrician should develop the ability to perform the physical examination in the mother's arms as much as possible. Even at later visits, the parent should be nearby to lessen any anxiety the child may feel during the examination.
- Never start your physical examination too abruptly.
- Start with the least intrusive part of the examination first. Examine the abdomen first, then listen to the chest (use a warm stethoscope), perform the developmental assessment needed, and examine the head, eyes, skin, genitalia, and extremities carefully.
- Complete the examination with a careful look at the ears, performing tympanoscopy each time, and finally look in the mouth as efficiently as possible. When examining the ears, try having the mother hold the baby on one of her shoulders firmly while holding the head still and then looking at the "outside" ear. When this is complete, ask her to switch shoulders, and you can examine the other ear.
- While conducting the physical examination, ask the parents whether they have any questions. Certainly, if you see any abnormalities, point them out with an explanation immediately.

Pediatric Pearl: At older, appropriate ages from toddler to early childhood, engage children with lots of talk, conversation, puppet play, or whatever creative ideas you may have. Do not be afraid to "ham it up" a little; children love it, and parents do, too.

Screening

The pediatrician should review the newborn screening results with the parent. It is important for the pediatrician to be aware of the requirements for newborn screening as each state has different standards. For the most part, each state has a robust screen for potential congenital disorders, which include metabolic disorders, hemoglobinopathies, cystic fibrosis, endocrinopathies, neurologic disorders, and other conditions of genetic origin.

All infants require a hearing screen in the immediate newborn period. If the baby has failed the newborn hearing screen, then a follow-up with a more sophisticated hearing assessment must be scheduled within the first 6 weeks of life.

In addition to the universal screen of all newborns, certain babies should have selective screening for at-risk conditions. If the state does not uniformly screen for sickle cell disease, for example, and the newborn being examined appears to be at risk for that genetic defect, then such screening should be scheduled.

The use of developmental screening instruments has become increasingly important, especially as the young infant becomes a toddler and preschooler. The timely use of them serves as learning opportunities for the medical student trainee and teaching opportunities for parents by the pediatric provider. The screening instruments are completely discussed in Chapter 12. Infant toddler instruments include the ASQ, and school-age instruments include the Pediatric Symptom Checklist. Figure 2-10 illustrates the AAP recommendations for screening at different ages, including laboratory screening recommendations.

Immunizations

Immunization against many infectious diseases is routine in the United States, and pediatricians are the safeguard of this crucial public health measure. Their routes and age of administration vary. The newborn infant should have received the first immunization in the first days of life while still in the hospital. This first vaccine is the first dose of the **hepatitis B** vaccine, which is important to prevent acquisition of the hepatitis virus. This extremely safe vaccine, a genetically engineered product, is administered in three doses. The immunization for this 1-month of age visit should be the second of a three-shot series of hepatitis B vaccine. This may be given between 1 and 6 months of age.

The other recommended immunizations, which are also presented in Figure 2-9, include vaccines against **diphtheria (D), pertussis (whooping cough) (now in an acellular version, aP), and tetanus (T), which are combined as DTaP; polio (inactivated) (IPV); *Haemophilus influenzae* (Hib or *Haemophilus* conjugate vaccine); measles, mumps, and rubella (usually given as MMR); varicella; Rotavirus; and, for older children, the meningococcal vaccine.** Optimally, children should receive each immunization at a particular age (see Figure 2-9; Table 2-2). Certain reportable side effects of standard immunizations may occur (Table 2-3). The AAP recommends that each practitioner consult the specific vaccine insert for specific **contraindications** to a particular vaccine. Whenever a vaccine is administered, it is important to carefully explain to the parent the full rationale for the vaccine and the potential side effects. The AAP and the Centers for Disease Control and Prevention (CDC) also require that a written consent be obtained for each vaccine administered.

Detailed information about all the childhood vaccines is lengthy and beyond the scope of this overview of the health maintenance visit. The specific immunizations required by a schedule agreed upon by the Infectious Disease Committee (Red Book Committee) of the AAP and the Advisory Committee for Immunizations Practices of the CDC are summarized in Figure 2-9. Periodically, there are changes in the recommendations. These changes can be found at their respective Web sites for the most current recommendations. The Web sites are, respectively:

AAP: http://www.aapredbook.org

CDC: http://cdc.gov/vaccines

The practicing pediatrician often consults the complete report known as **"The Red Book,"** a resource published and available online for members of the AAP. The director of student education and program director should be members and should be able to access it during your rotation.

Other Practice-Based Interventions

There are two other interventions in older children that may affect the pediatrician's decision regarding what to incorporate into his particular practice. The first would begin during late infancy and involves promotion of the Reach Out and Read (ROR) model, especially for low-income children. Studies have shown a positive effect on parental reports of behavior, beliefs, and attitudes toward reading as well as improvements in language scores. One component of the ROR model includes anticipatory guidance about the importance of reading. Volunteers reading in waiting rooms for children age 5 months to 5 years reading culturally and developmentally appropriate books set an example for parents after they leave the office setting.

An additional program, titled Healthy Steps for Young Children, employs specifically trained Healthy Steps specialists. This program has been shown to result in positive outcomes in parent behavior (less severe discipline) and higher quality care. The components of such programs can be integrated into the office health supervision visit and at home as well.

Anticipatory Guidance

This category of issues is a significant component of every visit. Each set of topics is clearly outlined in the full text of the *Bright Futures* manual for pediatricians. Careful review of these questions is particularly useful prior to the beginning of each visit. The expert panel that constructed these questions did so with the intention of inviting discussion, gathering information, addressing the needs and concerns of the families, and building partnerships. The questions will vary depending on the particular age of the child at each visit and the communication style of the practitioner. Additionally, if there are needs or preferences of the culture or background of the patient, they must be considered as well.

The consistent topics to be covered in this anticipatory guidance section of each visit in anticipation of events that might occur prior to the next visit include:

- Parents (maternal) well-being
- Family adjustment

TABLE 2-2

Recommended Immunization Schedules for Children Not Immunized in the First Year of Life[a]

Recommended Time/Age	*Immunizations*	*Comments*
Younger than 7 years		
First visit	DTaP, Hib,[b] HBV, MMR	If indicated, tuberculin testing may be done at same visit. If child is 5 years of age, Hib is not indicated in most circumstances.
Interval after first visit		
1 month (4 weeks)	DTaP, IPV, HBV, Var[c]	The second dose of IPV may be given if accelerated poliomyelitis immunization is necessary, such as for travelers to areas where polio is endemic.
2 months	DTaP, Hib,[b] IPV	Second dose of Hib is indicated only if the first dose was received when younger than 15 months.
≥ 8 months	DTaP, HBV, IPV	IPV and HBV are not given if the third doses were given earlier.
Age 4–6 years (at or before school entry)	DTaP, IPV, MMR[d]	DtaP is not necessary if the fourth dose was given after the fourth birthday; IPV is not necessary if the third dose was given after the fourth birthday.
Age 11–12 years	See Figure 2-9	
7–12 years		
First visit	HBV, MMR, dT, IPV	
Interval after first visit		
2 months (8 weeks)	HBV, MMR,[d] Var,[c] dT, IPV	IPV may also be given 1 month after the first visit if accelerated poliomyelitis immunization is necessary.
8–14 months	HBV,[e] dT, IPV	IPV is not given if the third dose was given earlier.
Age 11–12 years	See Figure 2-9	

[a] Table is not completely consistent with package inserts. For products used, also consult the manufacturer's package insert for instructions on storage, handling, dosage, and administration. Biologics prepared by different manufacturers may vary, and package inserts of the same manufacturer may change. Therefore, the physician should be aware of the contents of the package insert being used.

[b] If all needed vaccines cannot be administered simultaneously, priority should be given to protecting the child against the diseases that pose the greatest immediate risk. In the United States, these diseases for children younger than 2 years usually are measles and *Haemophilus influenzae* type b infection; for children older than 7 years, they are measles, mumps, and rubella. Before 13 years of age, immunity against hepatitis B and varicella should be ensured. DTaP, HBV, Hib, MMR, and Var can be given simultaneously at separate sites if failure of the patient to return for future immunizations is a concern.

[c] Varicella vaccine may be administered to susceptible children any time after 12 months of age. Unimmunized children who lack a reliable history of varicella should be immunized before their 13th birthday.

[d] Minimal interval between doses of MMR is 1 month (4 weeks).

[e] HBV may be given earlier in a 0-, 2-, and 4-month schedule.

HBV, hepatitis B virus; *Var*, varicella; *DTaP*, diphtheria and tetanus toxoids and acellular pertussis; *Hib*, *Haemophilus influenzae* type b conjugate; *IPV*, inactivated poliovirus; *MMR*, measle-mumps-rubella; *dT*, adult tetanus toxoid (full dose) and diphtheria toxoid (reduced dose), for children 7 years of age or older and adults.

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2011

For those who fall behind or start late, see the catch-up schedule

Vaccine ▼ Age ►	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years
Hepatitis B[1]	HepB	HepB			HepB						
Rotavirus[2]			RV	RV	RV[2]						
Diphtheria, Tetanus, Pertussis[3]			DTaP	DTaP	DTaP	see footnote[3]	DTaP				DTaP
Haemophilus influenzae type b[4]			Hib	Hib	Hib[4]	Hib					
Pneumococcal[5]			PCV	PCV	PCV	PCV				PPSV	
Inactivated Poliovirus[6]			IPV	IPV	IPV						IPV
Influenza[7]					Influenza (Yearly)						
Measles, Mumps, Rubella[8]						MMR		see footnote[8]			MMR
Varicella[9]						Varicella		see footnote[9]			Varicella
Hepatitis A[10]						HepA (2 doses)				HepA Series	
Meningococcal[11]										MCV4	

Range of recommended ages for all children

Range of recommended ages for certain high-risk groups

This schedule includes recommendations in effect as of December 21, 2010. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm.** Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**.

1 **Hepatitis B vaccine (HepB).** (Minimum age: birth)
At birth:
- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

Doses following the birth dose:
- The second dose should be administered at age 1 or 2 months. Monovalent HepB should be used for doses administered before age 6 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg 1 to 2 months after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).
- Administration of 4 doses of HepB to infants is permissible when a combination vaccine containing HepB is administered after the birth dose.
- Infants who did not receive a birth dose should receive 3 doses of HepB on a schedule of 0, 1, and 6 months.
- The final (3rd or 4th) dose in the HepB series should be administered no earlier than age 24 weeks.

2. **Rotavirus vaccine (RV).** (Minimum age: 6 weeks)
- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
- The maximum age for the final dose in the series is 8 months 0 days
- If Rotarix is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** (Minimum age: 6 weeks)
- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.

4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).** (Minimum age: 6 weeks)
- If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- Hiberix should not be used for doses at ages 2, 4, or 6 months for the primary series but can be used as the final dose in children aged 12 months through 4 years.

5. **Pneumococcal vaccine.** (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])
- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- A PCV series begun with 7-valent PCV (PCV7) should be completed with 13-valent PCV (PCV13).
- A single supplemental dose of PCV13 is recommended for all children aged 14 through 59 months who have received an age-appropriate series of PCV7
- A single supplemental dose of PCV13 is recommended for all children aged 60 through 71 months with underlying medical conditions who have received an age-appropriate series of PCV7
- The supplemental dose of PCV13 should be administered at least 8 weeks after the previous dose of PCV7 See *MMWR* 2010:59(No. RR-11).
- Administer PPSV at least 8 weeks after last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant.

6. **Inactivated poliovirus vaccine (IPV).** (Minimum age: 6 weeks)
- If 4 or more doses are administered prior to age 4 years an additional dose should be administered at age 4 through 6 years.
- The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.

7 **Influenza vaccine (seasonal).** (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])
- For healthy children aged 2 years and older (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used, except LAIV should not be given to children aged 2 through 4 years who have had wheezing in the past 12 months.
- Administer 2 doses (separated by at least 4 weeks) to children aged 6 months through 8 years who are receiving seasonal influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
- Children aged 6 months through 8 years who received no doses of monovalent 2009 H1N1 vaccine should receive 2 doses of 2010–2011 seasonal influenza vaccine. See *MMWR* 2010;59(No. RR-8):33–34.

8. **Measles, mumps, and rubella vaccine (MMR).** (Minimum age: 12 months)
- The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.

9. **Varicella vaccine.** (Minimum age: 12 months)
- The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

10. **Hepatitis A vaccine (HepA).** (Minimum age: 12 months)
- Administer 2 doses at least 6 months apart.
- HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.

11 **Meningococcal conjugate vaccine, quadrivalent (MCV4).** (Minimum age: 2 years)
- Administer 2 doses of MCV4 at least 8 weeks apart to children aged 2 through 10 years with persistent complement component deficiency and anatomic or functional asplenia, and 1 dose every 5 years thereafter.
- Persons with human immunodeficiency virus (HIV) infection who are vaccinated with MCV4 should receive 2 doses at least 8 weeks apart.
- Administer 1 dose of MCV4 to children aged 2 through 10 years who travel to countries with highly endemic or epidemic disease and during outbreaks caused by a vaccine serogroup.
- Administer MCV4 to children at continued risk for meningococcal disease who were previously vaccinated with MCV4 or meningococcal polysaccharide vaccine after 3 years if the first dose was administered at age 2 through 6 years.

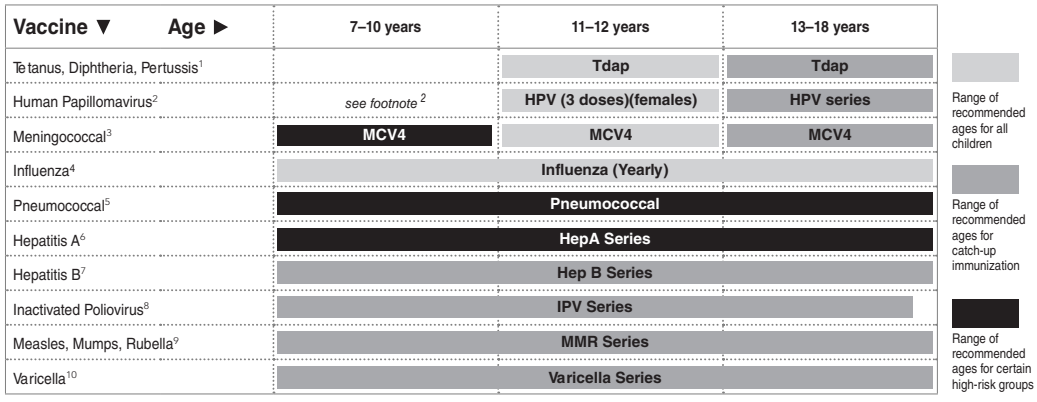
The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

Department of Health and Human Services • Centers for Disease Control and Prevention

FIGURE 2-9. Recommended immunization schedule for children (2011) according to the AAP.

Recommended Immunization Schedule for Persons Aged 7 Through 18 Years—United States • 2011

For those who fall behind or start late, see the schedule below and the catch-up schedule



This schedule includes recommendations in effect as of December 21, 2010. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm**. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967.**

1 Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap). (Minimum age: 10 years for Boostrix and 11 years for Adacel))
- Persons aged 11 through 18 years who have not received Tdap should receive a dose followed by Td booster doses every 10 years thereafter.
- Persons aged 7 through 10 years who are not fully immunized against pertussis (including those never vaccinated or with unknown pertussis vaccination status) should receive a single dose of Tdap. Refer to the catch-up schedule if additional doses of tetanus and diphtheria toxoid–containing vaccine are needed.
- Tdap can be administered regardless of the interval since the last tetanus and diphtheria toxoid–containing vaccine.

2. Human papillomavirus vaccine (HPV). (Minimum age: 9 years)
- Quadrivalent HPV vaccine (HPV4) or bivalent HPV vaccine (HPV2) is recommended for the prevention of cervical precancers and cancers in females.
- HPV4 is recommended for prevention of cervical precancers, cancers, and genital warts in females.
- HPV4 may be administered in a 3-dose series to males aged 9 through 18 years to reduce their likelihood of genital warts.
- Administer the second dose 1 to 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).

3. Meningococcal conjugate vaccine, quadrivalent (MCV4). (Minimum age: 2 years)
- Administer MCV4 at age 11 through 12 years with a booster dose at age 16 years.
- Administer 1 dose at age 13 through 18 years if not previously vaccinated.
- Persons who received their first dose at age 13 through 15 years should receive a booster dose at age 16 through 18 years.
- Administer 1 dose to previously unvaccinated college freshmen living in a dormitory.
- Administer 2 doses at least 8 weeks apart to children aged 2 through 10 years with persistent complement component deficiency and anatomic or functional asplenia, and 1 dose every 5 years thereafter.
- Persons with HIV infection who are vaccinated with MCV4 should receive 2 doses at least 8 weeks apart.
- Administer 1 dose of MCV4 to children aged 2 through 10 years who travel to countries with highly endemic or epidemic disease and during outbreaks caused by a vaccine serogroup.
- Administer MCV4 to children at continued risk for meningococcal disease who were previously vaccinated with MCV4 or meningococcal polysaccharide vaccine after 3 years (if first dose administered at age 2 through 6 years) or after 5 years (if first dose administered at age 7 years or older).

4. Influenza vaccine (seasonal).
- For healthy nonpregnant persons aged 7 through 18 years (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used.
- Administer 2 doses (separated by at least 4 weeks) to children aged 6 months through 8 years who are receiving seasonal influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
- Children 6 months through 8 years of age who received no doses of monovalent 2009 H1N1 vaccine should receive 2 doses of 2010-2011 seasonal influenza vaccine. See *MMWR* 2010;59(No. RR-8):33–34.

5. Pneumococcal vaccines.
- A single dose of 13-valent pneumococcal conjugate vaccine (PCV13) may be administered to children aged 6 through 18 years who have functional or anatomic asplenia, HIV infection or other immunocompromising condition, cochlear implant or CSF leak. See *MMWR* 2010;59(No. RR-11).
- The dose of PCV13 should be administered at least 8 weeks after the previous dose of PCV7.
- Administer pneumococcal polysaccharide vaccine at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. A single revaccination should be administered after 5 years to children with functional or anatomic asplenia or an immunocompromising condition.

6. Hepatitis A vaccine (HepA).
- Administer 2 doses at least 6 months apart.
- HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, or who are at increased risk for infection, or for whom immunity against hepatitis A is desired.

7 Hepatitis B vaccine (HepB).
- Administer the 3-dose series to those not previously vaccinated. For those with incomplete vaccination, follow the catch-up schedule.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB is licensed for children aged 11 through 15 years.

8. Inactivated poliovirus vaccine (IPV).
- The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR).
- The minimum interval between the 2 doses of MMR is 4 weeks.

10. Varicella vaccine.
- For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if only 1 dose has been administered.
- For persons aged 7 through 12 years, the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 4 weeks.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

FIGURE 2-9. ***(Continued)***

TABLE 2-3

Reportable Events Following Immunization[a]

	See package insert[b]	See package insert
Inactivated poliovirus vaccine	Anaphylaxis or anaphylactic shock Any acute complication or sequela (including death) See package insert[b]	24 hours No limit See package insert

[a] Events listed are required by law to be reported to the United States Department of Health and Human Services; however, the Vaccine Adverse Events Reporting System (VAERS) will accept all reports of suspected adverse events after the administration of any vaccine.

[b] Refer to the contraindication section of the manufacturer's package insert for each vaccine.

Aids to interpretation:

- Shock–collapse or hypotonic–hyporesponsive collapse may be evidenced by signs or symptoms such as decrease in or loss of muscle tone, paralysis (partial or complete), hemiplegia, hemiparesis, loss of color or change of color to pale white or blue, unresponsiveness to environmental stimuli, depression of or loss of consciousness, prolonged sleeping with difficulty arousing, or cardiovascular or respiratory arrest.
- Residual seizure disorder may be considered to have occurred if no other seizure or convulsion unaccompanied by fever or accompanied by a fever of <102° F occurred before the first seizure or convulsion after the administration of the vaccine involved, AND, if in the case of measles-, mumps-, or rubella-containing vaccines, the first seizure or convulsion occurred within 15 days after vaccination OR in the case of any other vaccine, the first seizure or convulsion occurred within 3 days after vaccination, AND, if two or more seizures or convulsions unaccompanied by fever or accompanied by a fever of <102° F occurred within 1 year after vaccination.
- The terms seizure and convulsion include grand mal, petit mal, absence, myoclonic, tonic–clonic, and focal motor seizures and signs.
- Encephalopathy means any substantial acquired abnormality of, injury to, or impairment of brain function. Among the frequent manifestations of encephalopathy are focal and diffuse neurologic signs, increased intracranial pressure, or changes lasting ≥6 hours in level of consciousness, with or without convulsions. The neurologic signs and symptoms of encephalopathy may be temporary with complete recovery, or they may result in various degrees of permanent impairment. Signs and symptoms such as high-pitched and unusual screaming, persistent inconsolable crying, and bulging fontanelle are compatible with an encephalopathy but in and of themselves are not conclusive evidence of encephalopathy. Encephalopathy usually can be documented by slow-wave activity on an electroencephalogram.

From Centers for Disease Control and Prevention: Vaccine adverse event reporting system—United States: Requirements. *MMWR* 39, 1990.

- Infant (or child) adjustment
- Feeding routines or nature of nutritional patterns
- Safety

Focusing on these particular sections for this first month visit, the following is a brief outline for issues/topics to be covered.

Parent (Maternal) Well-Being

This is the major focus of this visit, and hence why this visit may be a little longer than subsequent ones. There is much to talk about. Having completed the first month, are there any suggestions of depression, substance abuse, or complications after the delivery that need to be addressed for the upcoming period? If there have been issues concerning maternal depression, or excessive "down periods" for the mother, then discussion with the obstetrician should follow, with the permission of the mother. Postpartum depression remains a major issue for many women and needs to be addressed immediately if apparent. For mothers who plan to return to work, discussion as to logistics and readiness should be covered. What are the substitute child care arrangements that have been made and is the mother comfortable with them?

Family Adjustment

What are the family resources that need to be mobilized for the upcoming months? What roles are different family members playing? Is there any suggestion of domestic violence? What additional community resources need to be mobilized? Is the parental couple comfortable in their new roles?

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

Recommendations for Preventive Pediatric Health Care

Bright Futures/American Academy of Pediatrics

Bright Futures
prevention and health promotion for infants, children, adolescents, and their families™

Each child and family is unique; therefore, these **Recommendations for Preventive Pediatric Health Care** are designed for the care of children who are receiving competent parenting, have no manifestations of any important health problems, and are growing and developing in satisfactory fashion. **Additional visits may become necessary** if circumstances suggest variations from normal.

Developmental, psychosocial, and chronic disease issues for children and adolescents may require frequent counseling and treatment visits separate from preventive care visits.

These guidelines represent a consensus by the American Academy of Pediatrics (AAP) and Bright Futures. The AAP continues to emphasize the great importance of **continuity of care** in comprehensive health supervision and the need to avoid **fragmentation of care.**

1. If a child comes under care for the first time at any point on the schedule, or if any items are not accomplished at the suggested age, the schedule should be brought up to date at the earliest possible time.
2. A prenatal visit is recommended for parents who are at high risk, for first-time parents, and for those who request a conference. The prenatal visit should include anticipatory guidance, pertinent medical history, and a discussion of benefits of breastfeeding and planned method of feeding per AAP statement "The Prenatal Visit" (2001) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;107/6/1456].
3. Every infant should have a newborn evaluation after birth, breastfeeding encouraged, and instruction and support offered.
4. Every infant should have an evaluation within 3 to 5 days of birth and within 48 to 72 hours after discharge from the hospital, to include evaluation for feeding and jaundice. Breastfeeding infants should receive formal breastfeeding evaluation, encouragement, and instruction as recommended in AAP statement "Breastfeeding and the Use of Human Milk" (2005) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;115/2/496]. For newborns discharged in less than 48 hours after delivery, the infant must be examined within 48 hours of discharge per AAP statement "Hospital Stay for Healthy Term Newborns" (2004) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;113/5/1434].
5. Blood pressure measurement in infants and children with specific risk conditions should be performed at visits before age 3 years.
6. If the patient is uncooperative, rescreen within 6 months per the AAP statement "Eye Examination in Infants, Children, and Young Adults by Pediatricians" (2007) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;111/4/902].
7. All newborns should be screened per AAP statement "Year 2000 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs " (2000) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;106/4/798]. Joint Committee on Infant Hearing. Year 2007 position statement: principles and guidelines for early hearing detection and intervention programs. *Pediatrics.* 2007;120:898–921.
8. AAP Council on Children With Disabilities, AAP Section on Developmental Behavioral Pediatrics, AAP Bright Futures Steering Committee, AAP Medical Home Initiatives for Children With Special Needs Project Advisory Committee. Identifying infants and young children with developmental disorders in the medical home: an algorithm for developmental surveillance and screening. *Pediatrics.* 2006;118:405–420 [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;118/1/405].
9. Gupta VB, Hyman SL, Johnson CP, et al. Identifying children with autism early? *Pediatrics.* 2007;119:152–153 [URL: http://pediatrics.aappublications.org/cgi/content/full/119/1/152].
10. At each visit, age-appropriate physical examination is essential, with infant totally unclothed, older child undressed and suitably draped.
11. These may be modified, depending on entry point into schedule and individual need.
12. Newborn metabolic and hemoglobinopathy screening should be done according to state law. Results should be reviewed at visits and appropriate retesting or referral done as needed.
13. Schedules per the Committee on Infectious Diseases, published annually in the January issue of *Pediatrics.* Every visit should be an opportunity to update and complete a child's immunizations.
14. See AAP *Pediatric Nutrition Handbook,* 5th Edition (2003) for a discussion of universal and selective screening options. See also Recommendations to prevent and control iron deficiency in the United States. *MMWR.* 1998;47(RR-3):1–36.
15. For children at risk of lead exposure, consult the AAP statement "Lead Exposure in Children: Prevention, Detection, and Management" (2005) [URL: http://aappolicy.aappublications.org/cgi/content/full/pediatrics;116/4/1036]. Additionally, screening should be done in accordance with state law where applicable.
16. Perform risk assessments or screens as appropriate, based on universal screening requirements for patients with Medicaid or high prevalence areas.
17. Tuberculosis testing per recommendations of the Committee on Infectious Diseases, published in the current edition of *Red Book: Report of the Committee on Infectious Diseases.* Testing should be done on recognition of high-risk factors.
18. "Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) Final Report" (2002) [URL: http://circ.ahajournals.org/cgi/content/full/106/25/3143] and "The Expert Committee Recommendations on the Assessment, Prevention, and Treatment of Child and Adolescent Overweight and Obesity." Supplement to *Pediatrics.* In press.
19. All sexually active patients should be screened for sexually transmitted infections (STIs).
20. All sexually active girls should have screening for cervical dysplasia as part of a pelvic examination beginning within 3 years of onset of sexual activity or age 21 (whichever comes first).
21. Referral to dental home, if available. Otherwise, administer oral health risk assessment. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.
22. At the visits for 3 years and 6 years of age, it should be determined whether the patient has a dental home. If the patient does not have a dental home, a referral should be made to one. If the primary water source is deficient in fluoride, consider oral fluoride supplementation.
23. Refer to the specific guidance by age as listed in Bright Futures Guidelines. (Hagan JF, Shaw JS, Duncan PM, eds. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents.* 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2008.)

KEY

FIGURE 2-10. Recommendations for preventive pediatric health care according to the AAP.

How are the father and mother dealing with the new baby? Is there any tension in the interactions? Are parents comfortable in their new roles, or is there dominance of one versus the other? Is there a grandparent involved that is tipping the balance between father and mother making it uncomfortable for either or both of the parents?

All of these and numerous other questions are crucial in the discussion with the pediatrician, who can serve as a major facilitator to achieve solutions in problematic situations.

Infant Adjustment

What is the sleep/wake cycle for the baby, and how this will change in the coming month? The baby may move from bassinet to crib. The location and equipment should be discussed. If the baby has been difficult to console over the first month, what are additional techniques to try to make this easier? What consoling techniques have been successful? Discuss the need to place the baby on his tummy regularly each day. Explaining the issues related to "infant temperament" should also be part of this guidance. Temperament is the term used by developmental experts to describe the personality and qualities of interaction of even young babies. Often the first signs of what a child will be like are seen emerging during infancy. Is the baby slow to warm up, is he shy, withdrawn, or does he need more soothing to console? Is the baby very active and constantly on the go, does he sleep fretfully and rarely have "quiet times"? Is the baby placid, calm, and able to self-console and play by himself as he gets older? Each of these is normal, and may occur, and each description is a specific baby temperament.

Helping parents read their baby's temperament and adjusting their expectations of behavior to that temperament are important for them to gain a feeling of comfort and predictability as they react to their baby. Matching their responses and expectations to that of their baby's behavior and reactivity is key to a successful bonding and parenting experience. It is also important to remind parents that siblings often have different temperaments and just because their older child may have reacted in one fashion does not predict the behavior or reactivity of their new baby.

Feeding Routines

The feeding schedule during these first several weeks is often erratic. During the first month of life, infants, especially those who are breast-fed, may feed as often as every 2 hours or, sometimes, every 3 to 4 hours. Each day may also be different from the one before, which adds to the confusion of the first month. It is important that parents are aware that infants often lose weight until they are 3 to 4 days old, then regain weight to equal their birth weight by 10 days of age (possibly 2 weeks for breast-fed infants), and then start to gain weight predictably and quickly. There may be some days when they are especially hungry and others when they are less so (see Chapter 4 for more specific information on infant feeding).

Breast-feeding remains the feeding method of choice. During the first month, establishing a satisfying breast-feeding experience is an important goal. By this first visit, breast-fed babies are usually nursing every 3 hours or so and feed throughout the night. By now, the mother's milk supply should be well established, although there may have been some days of discomfort or engorgement during the first week at home, and infants and mothers are usually quite settled into a routine. The mother should have been able to find several comfortable positions for positioning the infant, and each feeding usually lasts 20 to 30 minutes, with approximately 10 to 15 minutes on each breast.

It is important to be very encouraging and supportive of the mother who is beginning to breast-feed her infant because if the mother can remain relaxed, comfortable, and reassured that the baby is growing and **gaining weight**, then she will feel that all of the initial adjustment has been worth it. Usually, after the first month, the feeding process becomes more predictable. Although there may normally be occasional days of sudden "surges in apparent hunger and appetite," infants generally take in approximately 110 to 150 kcal/kg, which is optimum for growth. This usually translates into 3 to 4 oz every 3 hours in the first month. At this time, it is a good idea to give mothers some referral material so they may find answers to some of their questions regarding the specifics of breast-feeding. Two excellent sources are *The Womanly Art of Breastfeeding*, a publication of La Leche League, and *Caring for Your Baby and Young Child: Birth to Age 5* (see Suggested Readings).

If parents have chosen the bottle-feeding method, several excellent **infant formula** preparations are available. These preparations have a cow's milk foundation that has been altered to provide a more suitable casein:whey ratio, a more digestible form of fat, and vitamin fortification. They can be purchased either in a "ready-to-feed" variety, which is quite expensive, or in a concentrate form, which requires reconstitution with water. Some of the formula preparations come in a powder formulation that is also convenient for travel purposes. There may be questions about preparation, storage, frequency of feeds, bottle cleaning, or other logistics.

See Chapter 4 for the types of formula and their specific contents with respect to type of carbohydrate, fat, and protein contained, as well as for a more detailed discussion of nutrition.

Safety/Injury Prevention

The following items will serve as the foundation of anticipatory guidance questions on this subject.

- All infants and toddlers should ride in a rear-facing car safety seat until they are 2 years of age or until they reach the highest weight or height allowed by their car safety seat's manufacturer. Proper installation of car safety seats according to manufacturer's recommendations is crucial. It is also necessary, regrettably, to check the car safety seat recall list to be sure parents are not purchasing a car safety seat that has been recalled. The Consumer Product Safety Commission (CPSC) or Consumers Union usually has an updated recall list.
- Are the parents using seat belts themselves **all the time?**
- Is the changing table in a safe place (preferably, in a corner with two walls on a side)? Are the necessary changing supplies near at hand?
- Is the **hot water heater turned down to 120° F**, especially if the infant bathes in a sink with a swing-out faucet?
- Is the infant never left alone in the house, car, or outside?
- Are pacifiers never attached with a string around the infant's neck? **Choking is a major hazard for infants,** especially those who have a string around the neck.
- Is the crib safe and approved according to national standards? Modifications made in 1985 include (1) a slat distance of 2 ⅜ in or less, (2) no cutouts in headboards, (3) no protruding corner posts, (4) a mattress that fits snugly against the side rail, and (5) a side-lowering mechanism that is not accessible to the infant.
- Is there a smoke detector in all appropriate places in the home?
- Are small objects kept out of the reach of the infant?

Obviously, as the baby becomes more mobile with increasing age, these child safety measures become increasingly important and need to be discussed at each visit. Appendix 2-1 contains a detailed list of age-appropriate safety measures. All of these areas are addressed in robust fashion and available online through *Bright Futures* (http://brightfutures.aap.org) or the toolkit that is accessible through your department where your training takes place.

CONCLUDING THE VISIT: OTHER KEY ISSUES TO DISCUSS

The closing of the health maintenance visit should have several goals:

- To reinforce your recognition of how well the parents have cared for the infant, how well they have observed certain factors, and how responsive they have been despite possible fatigue
- To make sure that the parents or children have no additional questions that they would like to have answered
- To be sure they know how to reach the pediatrician or the office if necessary or in an emergency
- To identify any remaining anxieties they may be feeling
- To confirm their next appointment and what to expect at that time

At the conclusion of the 1-month health supervision visit, it is important to ask again whether the parents have any other questions. The questions may be about issues that the pediatrician may have introduced or anything else that may come to mind. Often during the visit, additional topics may arise that remind the parents of problems they had not thought of earlier. This is an opportunity to discuss these issues further.

Two other key issues to be sure are not forgotten concern Sleep and Crying.

SLEEP. Infants at this age are naturally predisposed to sleep 12 to 14 hours a day but usually not more than 3 to 4 hours at a stretch. That means the baby *will not sleep through the night during this time*, and this leads to exhaustion, about which parents often complain. Therefore, it is crucial that the mother develops some arrangements that allow her to get some rest during each day. This is especially true if she is breast-feeding.

Pediatric Pearl: During the first months of life, it is recommended that infants be placed on their backs when going to sleep. The AAP recommends that infants not bed share during sleep (see Sleep Patterns, Chapter 5).

During the second month of life, the sleep pattern of infants usually becomes more regular, but they probably will still not sleep through the night. It is important to remind parents about the guidelines that recommend that they put their infants to sleep on their back, especially in the first several months of life. This recommendation is derived from the review of the research that may implicate the prone sleeping position in sudden infant death syndrome events. Although the research design has some distinct flaws, the expert panel convened at the AAP has concluded that it would be most responsible to advise parents of this possible association and to act accordingly.

Young infants also have two fairly long naps during the day, one in the morning and one in the afternoon. Usually, by 3 to 4 months of age, the sleep routine changes, and the majority of infants sleep through the night.

CRYING AND COLIC. Crying is particularly stressful for new parents. During the first month of life, infants often cry for up to 3 to 5 hours per day. In many cases, this fretting appears to occur for no reason; the parents have checked for soiled diapers, open diaper pins with cloth diapers, the need for additional feeding, or the rare but painful event of a hair getting caught around one of the infant's toes or fingers. Some of the techniques that may console a fussy infant include rocking, swaddling, nestling closely on the shoulder, or the judicious use of a pacifier. Occasionally, fussiness is due to a sensitivity to a specific formula or a food the mother has eaten that is passing into her breast milk. Over the course of the first few months these episodes generally diminish in frequency and intensity, but **occasionally, infants remain extremely fussy. These infants are sometimes referred to as colicky babies.**

The cause of these colicky episodes is not clear, and they appear to be particularly severe during the late afternoon or evening, often lasting 3 to 4 hours at a stretch. Recently, data derived from a number of carefully controlled studies have reinforced the understanding that colicky infants are simply more difficult to console. Because they appear to lack some ability to self-regulate their own state, they need additional soothing measures such as holding, rocking, and motion to help them self-regulate. Although no measures for handling this problem are guaranteed to be successful, these techniques may help bring both parents and infants through these mutually disruptive episodes. It is reassuring to know that these intense, fussy periods usually subside by the time the infant is 3 months of age.

With the completion of the first-month visit, subsequent visits will follow the same format, but obviously they will have different content depending on the age of the visit. Appendix 2-1 includes a summary of the developmentally appropriate items within each category. These can be further supplemented by careful review of the Bright Futures manual before each visit. Ideally, these items can be built into the electronic prompts for those practices where an electronic record is used for all health care maintenance documentation.

10 years	Firearm hazards	Sports safety Seat belt use Bicycle safety	Gold Child Survey Gold Safety Sheet (10–12 years)

Counseling Guidelines for the First Year of Life

Household Hazards	Counseling Guidelines
1. Do you put the crib side up whenever you leave your baby in the crib?	**Keep crib sides raised.** Crib sides need to be kept up and firmly secured to prevent falls. Even if your baby currently cannot roll over or pull up, there is always a first time.
2. Do you leave the baby alone on tables or beds, even for a brief moment?	**If you leave, even for a moment, place your baby in a playpen or a crib with the sides up.** Emphasize the necessity of anticipating developmental stages; the baby's first rollover should not lead to a fall.
3. Do you leave the baby alone at home?	**Provide constant supervision.** Never leave your baby alone in the home without a capable babysitter, at least 13 years old who can respond to emergency situations. Poisonings may occur in a matter of minutes; choking, falls, fires, and similar emergencies require immediate attention.
4. Do you keep plastic wrappers, plastic bags, and balloons away from your children?	**Keep plastic bags and balloons away from your children.** Plastic wrappers and bags form a tight seal if placed over the nose and mouth. Balloons can be inhaled into the windpipe and may cause death from choking.

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines for the First Year of Life *(Continued)*

Household Hazards	Counseling Guidelines
5. Does your child wear a pacifier or jewelry around his or her neck?	**Do not put anything around a baby's neck—objects around the neck may strangle the baby.** Necklaces, ribbons, or strings around a baby's neck may get caught on parts of furniture or other objects and cause strangulation. Drawstrings also should be removed from all children's clothing.
6. Does your child play with small objects such as beads or nuts?	**Do not allow your child to play with small objects.** Any small objects that can be placed in the mouth (including plant parts) are potential hazards. Even small pieces of food may cause problems; children should not run or play while eating. Parents should be informed about emergency treatment for the choking child. Use the AAP brochure *Choking Prevention and First Aid for Infants and Children*. Round or cylindrical food or objects are especially hazardous.
7. Are any of your babysitters younger than 13 years?	**Select an experienced babysitter.** All sitters should be at least 13 years old and mature enough to handle common emergencies. Use the AAP handout *Baby-sitting Reminders*.
8. How frequently is the heating system checked where you live?	**Check heating systems at least once a year.** This annual inspection helps prevent carbon monoxide poisoning, fires, and system malfunction.
9. Are your operable window guards in place?	**Place operable window guards on all windows in your home.** Window guards should be properly repaired and inspected regularly. Keep furniture away from windows that can give a climbing toddler access to a windowsill. Apartment windows should have guards above the second floor. The spaces above and below window guards should be less than 4 inches to prevent a child from falling through. Children leaning on screens can fall through and be seriously injured.
10. Do you ever place your baby in an infant walker?	**Do not place your child in a walker.** Every year, more than 8,000 injuries occur to children in walkers.
Burns	**Counseling Guidelines**
11. Does anyone in your home ever smoke?	**About one-third of home fires involving fatalities are caused by smoking.** Smoking in bed or improper disposal of ashes or butts endangers children sleeping in adjacent rooms who may be trapped in the event of fire.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines for the First Year of Life *(Continued)*

Burns	Counseling Guidelines
12. Do you have a plan of escape from your home in the event of a fire?	**Develop an escape plan in the event of a fire in the home.** Identify appropriate exit routes and a family meeting point away from the house.
13. Do you have working fire extinguishers in your home?	**Buy a fire extinguisher for the home.** The most common causes of home fires are cooking and heating equipment. Multipurpose dry chemical extinguishers should be available in the kitchen and in any room with a furnace or fireplace.
14. Do you have working smoke alarms in your home?	**Install a smoke alarm in your home.** Most fire-related deaths occur at night and are the result of inhaling smoke or toxic gas. There is a critical period of 4 minutes to get outside after the alarm sounds. Smoke alarms are recommended for each floor, but particularly for furnace and sleeping areas. Batteries should be checked monthly and replaced yearly.
15. Do you ever drink or carry hot liquids when holding your baby?	**Do not drink or carry hot liquids when holding your child or when children are nearby.** Scalds result from spilled hot food and drink; scalding injuries can be decreased by avoiding the use of tablecloths and keeping cups and saucers away from the edge of tables.
16. Do you ever use woodstoves or kerosene heaters?	**Erect barriers around space heaters.** The use of space heaters, woodstoves, and kerosene heaters has been associated with severe burns to toddlers. Appropriate barriers should protect children.
Water Safety	**Counseling Guidelines**
17. Do you leave the baby alone in or near a tub, pail of water, or toilet, even for a brief moment?	**Never leave a child alone in or near a tub, pail, toilet, or pool of water.** The bathtub is a source of severe scalding burns. If the phone or doorbell rings, do not leave an infant or toddler alone even for a moment. Young children can drown in less than 2 inches of water.
18. Do you have a pool or hot tub where you live?	**Fence in your pool or hot tub on all four sides.** Nationally, drowning is the leading cause of injury-related death in children younger than 1 year.

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines for the First Year of Life *(Continued)*

Auto Safety	Counseling Guidelines
19. Do you use a car safety seat in the car on every trip at all times?	**Your child should ride in a car safety seat during every trip, even if you will only be traveling a short distance.**
20. Does your car have a passenger air bag?	**NEVER place an infant in front of an air bag.**
21. Where do you place your child's car safety seat in the car?	**Seat a child in the rear seat of the car.** This is the safest place in the car. All infants and toddlers should ride in a rear-facing car safety seat until they are 2 years of age or until they reach the highest weight or height allowed by their car safety seat's manufacturer.
Bicycle Safety	**Counseling Guidelines**
22. Does your child ride on your bicycle with you?	**Do not carry children younger than 12 months on bicycles.** Infants too young to sit in a rear bike seat should never be carried on a bicycle. Children 12 months to 4 years old who can wear a helmet may ride in a rear-mounted seat. Use of backpacks or frontpacks is not recommended. Parents should avoid riding on busy streets. With small children, falls frequently result in head injuries. Children should always wear a helmet that meets Consumer Product Safety Commission (CPSC) or Snell Memorial Foundation standards.
Firearm Hazards	**Counseling Guidelines**
23. Is there a gun in your home or the home where your child plays or is cared for?	**Remove all guns from places children live and play.** More than 5,000 children and adolescents are killed by gunfire each year—injuries almost always inflicted by themselves, a sibling, or a friend. Handguns are especially dangerous. If you choose to keep a gun at home, store it unloaded in a locked place. Lock and store the ammunition in a separate place.

Counseling Guidelines from 1 to 4 Years (Part 1)

Household Hazards	Counseling Guidelines
1. Do you leave your child alone at home?	**Never leave small children alone in the home.** Parents should be aware of the child's rapid acquisition of new abilities.
2. Are any of your babysitters younger than 13 years?	**Select an experienced babysitter.** All sitters should be at least 13 years old and mature enough to understand parental instructions and handle common emergencies. Use the AAP handout *Baby-sitting Reminders*.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 1 to 4 Years (Part 1) *(Continued)*

Household Hazards	Counseling Guidelines
1. Do you keep plastic wrappers, plastic bags, and balloons away from your children?	**Keep plastic bags and balloons out of reach.** Plastic wrappers and bags form a tight seal if placed over the mouth and nose and may suffocate the child. Balloons can be inhaled into the windpipe and may result in death from choking.
2. Do you know how to prevent your child from choking?	**Small objects and solid foods such as hot dogs, peanuts, grapes, carrots, or popcorn may block your child's airway.** Any small objects that can be placed in the mouth are potential hazards. Children should not run or play while eating. Parents should learn cardiopulmonary resuscitation and emergency treatment for the choking child. Use the AAP brochure *Choking Prevention and First Aid for Infants and Children*.
3. Do you have mechanical garage doors?	**Mechanical garage doors may crush a child.** Install only garage door openers with sensors.
4. Are your operable window guards in place?	**Place operable window guards on all windows in your home.** Window guards should be properly repaired and inspected regularly. Keep furniture away from windows that can give a climbing toddler access to a windowsill. Apartment windows should have guards above the second floor. Windows should not be able to open more than 4 inches to prevent a child from falling through. Children leaning on screens can fall through and be seriously injured.
5. Is your child in the yard while the lawn mower is in use?	**Keep small children out of the yard while the lawn mower is in use.** Potential injury results from the machine itself and from objects thrown by the blade. Children should not be passengers on ride-on mowers.
6. Do you place gates at the entrance to stairways (for children younger than 3 years)?	**Use gates on stairways.** Use gates at the top and bottom of entrances to stairways because young children can quickly crawl or climb up the stairs from the lower level. Accordion-style gates are hazardous and can trap the child's head, causing death.
7. Is your baby's crib near a window or a drapery covering?	**Place your baby's crib away from windows.** Cords from window blinds and draperies can strangle your child. Tie cords high and out of reach.
8. Do you check for safety hazards in the homes of friends or relatives where your child may play?	**Check for hazards in homes your child may visit.** Other homes, especially those with no children or older children, may pose particular hazards from poisonings, falls, pools, and guns.

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines from 1 to 4 Years (Part 1) *(Continued)*

Household Hazards	Counseling Guidelines
9. Have any of your children ever had an injury requiring a visit to the doctor or hospital?	**Report any history of injuries to the pediatrician.** The pediatrician is able to explore the causes and discuss preventive measures. It has been shown that stressful family situations can be causally linked to repeated injuries in children (three or more injuries within 12 months). Also note that once an ingestion has occurred, another incident is likely within a year.
Firearm Hazards	**Counseling Guidelines**
10. Is there a gun in your home or the home where your child plays or is cared for?	**Remove all guns from places children live and play.** More than 5,000 children and adolescents are killed by gunfire each year—injuries almost always inflicted by themselves, a sibling, or a friend. Handguns are especially dangerous. If you choose to keep a gun at home, store it unloaded in a locked place. Lock and store ammunition in a separate place, and make sure to hide the keys to the locked boxes.
Poisonings	**Counseling Guidelines**
11. Do you keep household products, medicines (including acetaminophen and iron), and sharp objects out of the reach of your child and in locked cabinets?	**Keep medicines and hazardous products out of the sight and reach of children.** Household products, medicines, and sharp objects should be stored and locked in high places out of the child's sight. Keep household products in their original containers and never in food or beverage containers.
12. Do you dispose of old medicines?	**Dispose of old medicines.** All old medications should be safely disposed of by flushing them down the toilet.
13. Do you have safety caps on all bottles of medicine?	**Purchase medicines with child-resistant safety caps.** Remember to securely replace the cap and store the medicine out of the child's reach.
14. Does your child chew on paint chips or windowsills?	**Inspect walls for peeling paint.** Paint that is peeling and chipped or is on chewable surfaces is a potential lead hazard. Approximately 85% of all homes built in the United States before 1978 have lead-based paint in them. Housing built before the 1950s poses particular risk for exposure to lead.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 1 to 4 Years (Part 1) *(Continued)*

Poisonings	Counseling Guidelines
15. How frequently is the heating system checked where you live?	**Heating ventilation systems should be checked at least once a year.** This annual inspection helps prevent carbon monoxide poisoning, fires, and system malfunction. Carbon monoxide detectors also are available to provide an early warning before the deadly gas builds up to a dangerous level.

Counseling Guidelines from 1 to 4 Years (Part 2)

Burns	Counseling Guidelines
1. Do you use electrical appliances in the bathroom?	**Do not use electrical appliances within the reach of a child in the bathroom.** Electrical current hazards are increased by wetness. Appliances must be used with extreme caution in the presence of water.
2. Do you keep electrical appliances and cords out of your child's reach?	**Keep electrical cords out of a child's reach.** Mouth burns in children can result from chewing on the end of a live extension cord or on a poorly insulated wire. Cords should not be within reach of a child.
3. Do you keep matches and cigarette lighters out of the reach of your children?	**Keep matches and lighters out of the reach of children.** Annually, 5,600 fires are started by children younger than 5 years playing with matches and lighters. These fires cause 150 deaths per year.
4. Does anyone in your home ever smoke?	**Most deaths due to home fires are caused by smoking.** Smoking in bed or improper disposal of ashes or butts endangers children sleeping in adjacent rooms who may be trapped in the event of fire. Twelve percent of residential fires are associated with smoking.
5. Do you have a plan for escape from the home in the event of a fire?	**Develop an escape plan in the event of a fire in the home.** Identify appropriate exit routes and a family meeting point away from the house. Do not use elevators in apartment buildings if there is a fire. Ask your fire department for help in designing an escape plan. Use the AAP handout, Protect *Your Home Against Fire . . . Planning Saves Lives.*

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines from 1 to 4 Years (Part 2) *(Continued)*

Burns	Counseling Guidelines
6. Do you have working fire extinguishers in your home?	**Buy a fire extinguisher for your home.** The most common causes of home fires are cooking and heating equipment. Multipurpose dry chemical fire extinguishers should be available in the kitchen and in any room with a furnace or fireplace.
7. Do you have working smoke alarms in your home?	**Install a smoke alarm in your home.** The majority of fire-related deaths occur at night and are the result of inhaling smoke or toxic gas. There is a critical period of 4 minutes to get outside after the alarm sounds. Smoke alarms are recommended for each floor, but particularly for furnace and sleeping areas. Check the batteries monthly and change them once every year.
8. Have you checked the temperature of the hot water where you live?	**Check hot water temperature.** A third-degree burn can occur in only 6 seconds with a water temperature of 140° F. The temperature of a water heater should be set no higher than 120° F.
9. Do you keep the handles of pots and pans on the stove out of the reach of children?	**Keep hot pots and pans out of the reach of children.** Scalds in the kitchen are common; pot handles should be turned inward from the edge of the stove and be out of your child's reach. The kitchen is the most dangerous room for children. Keep children out of the kitchen when you are cooking, or put them in a playpen or high chair to keep them secure.
Water Safety	**Counseling Guidelines**
10. Do you leave your child alone in the bathtub?	**Do not leave your child alone in a tub, even for a moment.** The bathtub is a source of severe scalds and also poses a potential drowning hazard. If the telephone or doorbell rings, do not leave your child alone or in the care of another child, even for a moment.
11. Do you take your child on a boat?	**Always wear a Coast Guard-approved life jacket.** Everyone on the boat should wear a Coast Guard-approved life jacket. At least one adult swimmer should be present for each child who cannot swim. Use the AAP handout *Life Jackets and Life Preservers.*

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 1 to 4 Years (Part 2) *(Continued)*

Water Safety	Counseling Guidelines
12. Do you have a pool or hot tub where you live?	**Fence in your pool or hot tub on all four sides.** Drowning is the second leading cause of death of children nationally in this age group. Children most often drown when they fall into a pool that has not been completely fenced in on all four sides. Between 60% and 90% of drownings among children younger than 4 years occur in swimming pools.
13. Do you allow your child to swim unsupervised?	**Do not let children swim without supervision.** Never—not even for a moment—leave your children alone or in the care of another child in wading or swimming pools, spas, or other open standing water.
Bicycle Safety	**Counseling Guidelines**
14. Does your child ride on your bicycle with you?	**Use an approved child carrier.** Infants too young to sit in a rear bike seat should never be carried on a bicycle. Children 1 to 4 years of age who can wear a helmet may ride in a rear-mounted seat. Use of backpacks or frontpacks is not recommended. Parents should avoid riding in busy streets. With small children, falls frequently result in head injuries. Children should always wear a helmet that meets Consumer Product Safety Commission (CPSC) or Snell Memorial Foundation standards.
Auto Safety	**Counseling Guidelines**
15. How are your children restrained when they ride in a car?	**Children this age should always be properly restrained in a car safety seat. Select a car safety seat that fits your child's size and weight and that can be installed properly in your car.** Use it every time you are in the car. Remember that children should ride in car safety seats until they are about 4 years old and weigh about 40 lb. Children who weigh from 40 lb up to about 80 lb (or until they are about 4 ft 9 in tall) should ride in booster seats with lap/shoulder harnesses. Adults wearing seat belts are effective role models. Use the AAP brochure *Family Shopping Guide to Car Seats* for a list of car safety seats that meet federal standards.

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines from 1 to 4 Years (Part 2) *(Continued)*

Auto Safety	Counseling Guidelines
16. Do you leave your child alone in the car?	**NEVER leave a child alone in a car.** Children and car keys should always be removed from the car and the car kept locked. In addition to the many dangers of leaving children alone in the car, death from excess heat may occur in warm weather in a closed car in a short time.
17. Where do you seat your children in the car?	**Seat children in the rear seat of the car.** This is the safest place in the car. Never allow children to ride in the cargo area of a station wagon or truck.
18. Does your car have a passenger air bag?	**Never put children in front of passenger air bags.**
19. Do you lock the car doors before driving?	**Buckle up and lock up!** Before the car moves, all seat belts or child safety seats should be properly fastened and all doors should be locked.
20. Does your child play in the driveway or in or near the street?	**Young children should not play in driveways or near busy streets.** Parents should always walk behind the car before backing down a driveway. Children may not be seen in the rear view mirror and could be run over.

Toy Safety	Counseling Guidelines
21. Do you check your child's toys for safety hazards?	**Inspect toys for safety hazards.** Repair or discard broken toys. Inspect your child's toys for projectile and sharp parts or small detachable parts. Some toys may pose hazards from electric shock and burns. Toys intended for older children should not be accessible to toddlers and preschoolers. Follow age guidelines on toy packaging.

Counseling Guidelines from 5 to 9 Years

Firearm Hazards	Counseling Guidelines
1. Is there a gun in your home or the home where your child plays or is cared for?	**Do not keep guns in your home.** Guns, especially handguns, should be removed from the environments where children live and play. If firearms are in the home, they must be stored unloaded in a locked place and out of the reach of children. Guns are frequently involved in unintentional shootings in this age group, and homicides and suicides also occur. Parents should ask whether the homes where their child visits or is cared for have guns and how they are stored.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 5 to 9 Years *(Continued)*

Household Hazards	Counseling Guidelines
2. Do you let your child operate a power lawn mower?	**Never let children this age operate a lawn mower or ride with you on one.** Potential injury results from the machine itself and from objects thrown by the blade. Ride-on mowers are not recreational vehicles. Refer to the AAP Safety Slip *Lawn Mower Safety*.
3. Have any of your children ever had any injuries requiring a visit to the doctor or hospital?	**Report any history of injuries to the pediatrician.** The pediatrician is able to explore the causes and discuss preventive measures. It has been shown that stressful family situations can be causally linked to repeated injuries in children (three or more injuries needing medical attention within 12 months).
4. How frequently is the heating system checked in your home?	**Heating ventilation systems should be checked at least once a year.** This annual inspection helps prevent carbon monoxide poisoning, fires, and system malfunction.
Burns	**Counseling Guidelines**
5. Do you and your children know how to get out of your home safely in the event of a fire?	**Develop an escape plan in the event of a fire in the home.** Identify appropriate exit routes and a family meeting point away from the house. Do not use elevators in apartment buildings if there is a fire. Use the AAP handout *Protect Your Home Against Fire . . . Planning Saves Lives.*
6. Does anyone in your home ever smoke?	**A third of deaths due to home fires are caused by smoking.** Smoking in bed or improper disposal of cigarette ashes or butts endangers children sleeping in adjacent rooms who may be trapped in the event of fire. Twelve percent of residential fires are associated with smoking.
7. Does your child play with matches or lighters?	**Do not let children play with fire.** Keep matches and lighters out of the sight and reach of children. They commonly ignite flammable materials, which may result in severe burns and house fires.
8. Do you have working fire extinguishers in your home?	**Buy a fire extinguisher for your home.** Extinguishers should be available in kitchens and in rooms with a furnace or fireplace.

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines from 5 to 9 Years *(Continued)*

Burns	Counseling Guidelines
9. Does your child play with firecrackers or sparklers?	**Do not let children play with fireworks.** Firecrackers and sparklers can cause serious burns and injuries and should not be played with by children. Bystanders often are seriously injured by fireworks as well. An estimated 10,000 injuries related to fireworks are reported annually to the Consumer Product Safety Commission (CPSC).
10. Do you have working smoke alarms in your home?	**Install smoke alarms in your home.** Most fire-related deaths are the result of inhaling smoke or toxic gas. There is a critical period of 4 minutes to get outside the home after the alarm sounds. Smoke detectors are recommended for each floor, but particularly for furnace and sleeping areas. Be sure to test the alarm monthly to be certain that it is working. Change the batteries every year.
Water Safety	**Counseling Guidelines**
11. Does your child know how to swim?	**Teach children how to swim.** Swimming is an important life skill that all children should acquire. However, even if children know how to swim, there are still hazards. They may not retain their swimming skills in an emergency; even competent young swimmers should not swim unsupervised.
12. Does your child know the rules of water and diving safety?	**Teach and enforce the rules of swimming and diving safety.** Drowning is the second most common cause of death in children of this age. Knowledge of swimming is not enough to prevent drowning. Children should swim in supervised areas only. The "buddy" system is desirable. Teach your child to always enter the water feet first. Use the AAP handouts *Life Jackets and Life Preservers, Pool Safety for Children*, and *Water Safety for Your School-aged Child*.
13. Does your child wear a life jacket when on a boat?	**Be sure your child wears a life jacket when on a boat.** Everyone on the boat should use a Coast Guard–approved life jacket. At least one adult swimmer should be present for each child who cannot swim.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 5 to 9 Years *(Continued)*

Auto Safety	Counseling Guidelines
14. Does your child use a booster seat or seat belt when riding in the car?	**A booster seat should be used on every trip by all children who weigh from 40 lb up to about 80 lb (or until they are about 4 ft 9 in tall). Seat belts should not be used until the lap belt can be worn low and flat on the hips and the shoulder belt can be worn across the shoulder rather than the face or neck.** Shoulder belts should be installed in the back seats of cars that do not have them.
15. Does your car have a passenger air bag?	**Never seat a child in front of a passenger air bag.**
Pedestrian Safety	**Counseling Guidelines**
16. Do your children cross the street by themselves?	**Teach your child pedestrian safety skills.** More than half of motor vehicle-related deaths in school-aged children are caused by pedestrian injuries. All children should learn safe street-crossing skills and should demonstrate those skills to the parent before supervision ends. Children will still require supervision when crossing the street. Parents often think their children are able to handle traffic safety by themselves, but most children do not have the skills to handle these risky situations until at least 10 years of age. Parents should be reminded that children: • Often act before thinking and may not do what parents or drivers expect • May assume that if they see the driver, the driver sees them • Cannot judge speed like adults • Are shorter than adults and cannot see over cars, bushes, and other objects • Need a place to play away from cars and the street
Bicycle Safety	**Counseling Guidelines**
17. Has your child learned about bicycle safety?	**Teach and enforce bicycle safety rules.** Bicycle crashes can result in serious injury and death. Children should not ride in the street at this age. They should ride on bike paths, in parks, or in protected areas. They should never ride after dark. Bicycles should be equipped with coaster brakes at this age because the child may not be developmentally ready to use hand brakes appropriately. Use the AAP handout *Safe Bicycling Starts Early.* The size of the bicycle should be appropriate for the child. Use the AAP handout, *Choosing the Right Size Bicycle for Your Child.*

Continued

APPENDIX 2-1

Guidelines for Safety Counseling *(Continued)*

Counseling Guidelines from 5 to 9 Years *(Continued)*

Bicycle Safety	Counseling Guidelines
18. Does your child wear a helmet every time he or she rides a bike?	**Wear a bicycle helmet.** All children should wear a bicycle helmet approved by the CPSC. Parents should set an example by wearing helmets when they ride bikes as well.

Recreational Safety	Counseling Guidelines
19. Does your child participate in sports?	**Wear protective gear during sports.** Despite safety measures such as protective padding and helmets, the risk of injury is present in all sports. Children should be made aware of the risks that go with the sports they play. The chance of injury becomes greater with the degree of contact in a sport. Football, wrestling, gymnastics, soccer, ice hockey, and track/running have the highest rates of injury. Lower leg (knee and ankle) injuries are the most common injuries in major sports. Children should not participate in boxing because of the high risk of brain damage. Many serious sports injuries can be prevented if players wear protective equipment, particularly head and eye protection. Parents should encourage the use of such gear and teach their children that wearing protective gear increases the long-term enjoyment of the sport. If your child uses a scooter, skateboard, or rollerblades, a helmet, knee and elbow pads, and wrist guards should be worn. Use the AAP brochure *Sports and Your Child*.
20. Does your child participate in horseback riding?	**All children should wear an approved equestrian helmet when riding a horse.** All horseback riding activities should be supervised by an adult.

Counseling Guidelines from 10 to 12 Years

Firearm Hazards	Counseling Guidelines
1. Is there a gun in your home or any of your friends' homes?	**Do not play with guns!** More than 300 children die each year of unintentional gunshot wounds. BB guns and paint pellet guns often cause severe eye injuries. Air rifles are dangerous weapons that can kill.

Burns	Counseling Guidelines
2. Do you have working smoke alarms in your home?	**Check to see that your home has a smoke alarm.** Most fire-related deaths are the result of inhaling smoke or toxic gas. There is a critical period of 4 minutes to get outside the home after the alarm sounds. Smoke alarms are recommended for each floor, but particularly for furnace and sleeping areas. You should know appropriate exit routes and a family meeting point away from the house.

APPENDIX 2-1

Guidelines for Safety Counseling

Counseling Guidelines from 10 to 12 Years *(Continued)*

Bicycle Safety	Counseling Guidelines
3. Do you ever ride with passengers on your bike?	**Never ride with passengers on your bike.** This may impair your stability and visibility and lead to an injury.
4. Do you wear a helmet when you ride your bike?	**Always wear a helmet when riding a bike.** This protects you from head injury. Use the AAP handout *Safe Bicycling Starts Early*.
Auto Safety	**Counseling Guidelines**
5. Do you wear a seat belt in the car?	**Buckle up.** Seat belts save lives and should be used by all children. Remind your parents to buckle up as well.
6. Do you ride in cars that have passenger air bags?	Do not sit in front of a passenger air bag. The safest place for children to ride is in the back seat.
7. Where do you sit in the car?	The safest place for you to ride is in the back seat, buckled up.
Pedestrian Safety	**Counseling Guidelines**
8. When you want to cross the street, what is the first thing you should always do?	**Follow safety rules when crossing the street.** • Always stop at the curb, roadside, or at the outside edge of a parked car. • Always look left-right-left before entering the area of the road in which cars travel, even if a traffic light says "walk." • If a car is coming, wait until it passes and look left-right-left again. • Proceed to cross the street only when the road is clear.
Water Safety	**Counseling Guidelines**
9. When playing near water (e.g., rivers, ponds, lakes, oceans), is it OK to play alone?	**Never play near water without an adult nearby.** Even if children can swim, they should never play unsupervised near bodies of water into which they may fall because they may not retain their swimming skills in an emergency. Water conditions (rapids, tides) may overwhelm otherwise capable swimmers.
Farm Safety	**Counseling Guidelines**
10. Do you live or work on a farm?	**Farm equipment is very dangerous to children.** Parents may need to be counseled for this question.

[a] Safety sheets can be obtained from The Injury Prevention Program (TIPP) of the AAP.

3

Adolescent Medicine

Elizabeth M. Alderman and Warren M. Seigel

Adolescence, from the beginning of puberty until early adulthood, is a time of accelerated physical growth and maturity coincident with significant psychosocial and cognitive development. The chronologic boundaries of adolescence are roughly defined as between the ages of 12 and 21 years. Although most adolescents are healthy, an estimated 6% have chronic illnesses that limit daily activity, such as diabetes, cancer or other hematologic disorders, development disabilities, mental retardation, and asthma. However, the leading causes of morbidity and mortality in this age group are not these chronic conditions but rather injuries, homicide, and suicide, as well as the sequelae of early sexual activity and substance use.

This chapter contains a description of the physical and psychologic changes that occur during puberty. Following this is a discussion of several issues of importance during adolescence—violence, suicidal behavior, substance abuse, eating disorders, and sexual activity. The second part of the chapter addresses the special health concerns of adolescent athletes. Participation in sports—individually, community-based, or on school teams—provides young adults with a healthy venue to develop both physical and psychosocial skills.

ADOLESCENT PHYSICAL GROWTH AND DEVELOPMENT

The stages identified by J.M. Tanner are traditionally used to describe physical growth and development of the genitalia and secondary sexual characteristics of adolescents. Tanner stages describe female breast and pubic hair development (Figures 3-1 and 3-2), as well as male genitalia and pubic hair growth (Figure 3-3).

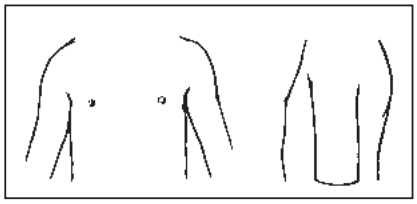
Girls

The earliest sign of puberty in girls is the appearance of the breast bud (thelarche), which may normally occur as young as 8 years of age. In fact, the average age of breast development has decreased over the past century. In the United States, Tanner 2 breast development occurs at about 9.9 years of age in Caucasian girls and 8.8 years of age in African American girls. Subsequent breast development involves further enlargement of the areola and breast (Tanner 3), appearance of the secondary mound (Tanner 4), and the mature female breast (Tanner 5). Simultaneous changes in the distribution of pubic hair occur, beginning with a sparse amount of long hair over the labia majora (Tanner 2), and progressing to darker, curlier, coarser hair (Tanner 3). Then, most of the mons pubis is covered with pubic hair (Tanner 4), and finally, an adult pattern of pubic hair (Tanner 5) is apparent. Breast development may take up to 4 years and pubic hair growth up to 2.5 years. Many fully mature women have Tanner 4 breast development or pubic hair.

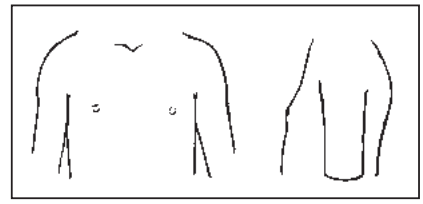
The average age of menarche, which is approximately 12.8 years for Caucasian girls and 12.16 years for African American girls, coincides with at least Tanner 4 breast and pubic hair development. In girls, the growth spurt usually occurs approximately 6 months before menarche and is coincident with the end of the Tanner 3 stage, a year after breast development begins. The peak of the growth spurt usually precedes menarche (Figure 3-4).

Boys

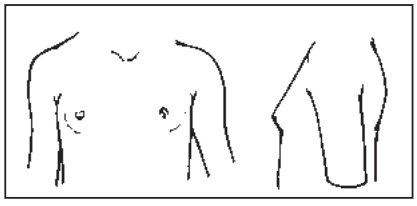
Physical maturity usually occurs approximately 6 months later in boys than in girls. The first signs of puberty are testicular and scrotal enlargement (Tanner 1 to Tanner 2), which occur at an average age of 11.5 years. Within a year of these changes, the penile length begins to increase (Tanner 3). Further growth of the testes and scrotum



Stage 1 Perpubertal: Elevation of papilla only.

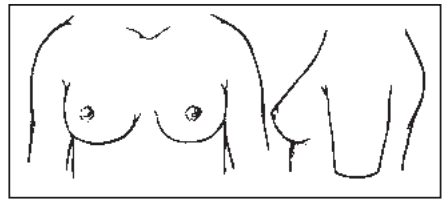


Stage 2 Breast bud: Areola widens. Elevation of small mound of subareolar tissue and erect papilla.



Stage 3 Continued enlargement of breasts and widening of areola, but without separation of contours.

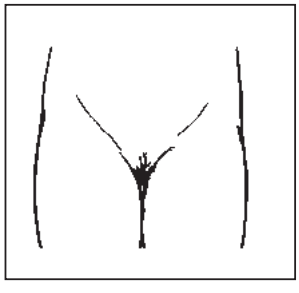
Stage 4 Areola and papilla separate from the contour of the breast forming a secondary mound.



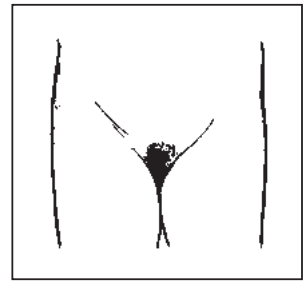
Stage 5 Mature female breast with areola and breast in same plane, erect papilla.

FIGURE 3-1. Tanner stages of female breast development. From Fleisher GR, Ludwig S (eds): *Textbook of Pediatric Emergency Medicine*, 3rd ed. Baltimore, Williams & Wilkins, 1993, p 1506.

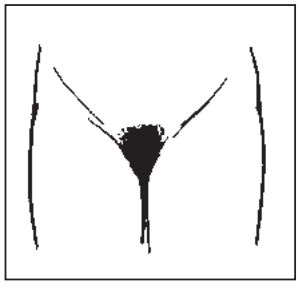
Stage 1 No pubic hair.



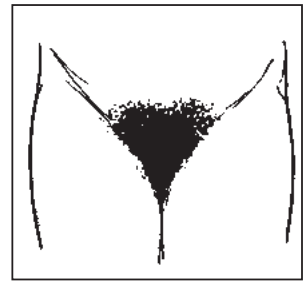
Stage 2 A sparse amount of long, somewhat pigmented hair over labia majora primarily.



Stage 3 Pubic hair darkens, coarsens and curls, and spreads sparsely over the mons pubis.



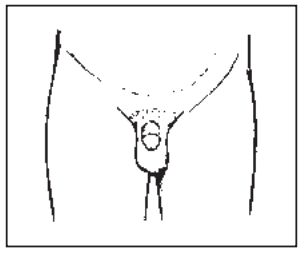
Stage 4 Abundant, coarse, adult-type hair limited to the mons pubis.



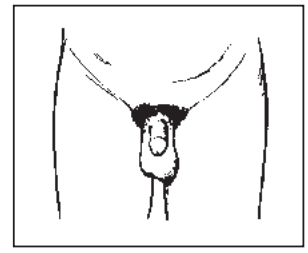
Stage 5 Adult-type and quantity of hair with spread to the medial aspect of the thighs.

FIGURE 3-2. Tanner stages of female pubic hair growth. From Fleisher GR, Ludwig S (eds): *Textbook of Pediatric Emergency Medicine*, 3rd ed. Baltimore, Williams & Wilkins, 1993, p 1506.

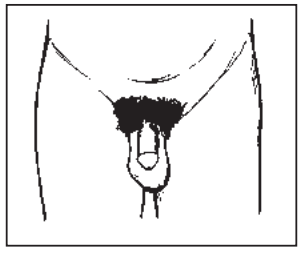
Stage 1 No pubic hair. Genitalia are prepubertal in size.



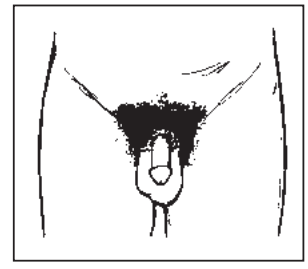
Stage 2 Sparse growth of long, slightly pigmented hair, at and lateral to base of penis. Testes and scrotum begin to enlarge, with pigmentation and thinning of scrotum.



Stage 3 Pubic hair darkens, coarsens and curls, at and lateral to base of penis. Penis lengthens and scrotum further enlarge.



Stage 4 Abundant, coarse, adult-type hair limited to the pubic region with no extension to the thighs. Further growth of testes and scrotum, with increased pigmentation of scrotum, and increase in width and length of penis.



Stage 5 Adult-type and quantity of hair with spread to the medial aspects of the thighs. Adult size and shape of genitalia.

FIGURE 3-3. Tanner stages of male genital development and pubic hair growth. From Fleisher GR, Ludwig S (eds): *Textbook of Pediatric Emergency Medicine*, 3rd ed. Baltimore, Williams & Wilkins, 1993, p 1506.

occurs, with increased scrotal rugae and penile diameter (Tanner 4), and eventually adult-size testicles (approximately 22 mL) and penis (Tanner 5). Simultaneous changes in the distribution of pubic hair occur, known as adrenarche, with growth beginning at the base of the penis (Tanner 2) and progressing to darker, coarser hair (Tanner 3). The hair then covers a much larger area (Tanner 4) and finally assumes an adult pattern (Tanner 5), which is usually attained by ages 14 to 16 (Figure 3-5).

The growth spurt in boys is usually coincident with Tanner 4 development of genitalia. On average, the growth spurt begins at approximately 11.5 years of age and is complete by 13 to 17 years. Nocturnal emissions or wet dreams are first noticed at Tanner 3. Change of voice usually occurs between Tanner 3 and 4 (see Figure 3-5).

Axillary hair development in boys begins at the same time as Tanner 4 development of pubic hair. One year later, facial hair develops and starts at the corners of the upper lip and spreads medially. Hair growth on the upper cheek, lower lip, and chin follows. Chest hair growth is a postpubertal event.

ADOLESCENT PSYCHOSOCIAL AND COGNITIVE DEVELOPMENT

Adolescence is not only a time of rapid physical growth and maturational changes, but also a period of behavioral metamorphosis; children who once relied solely on their parents and followed their wishes develop into autonomous adults who are now capable of making their own choices. The in-between period is marked by changes in body image, emergence of strong peer group influence, risk-taking behaviors, and the development of an adult pattern of sexuality and personal values. When discussing cognitive and psychosocial development, it is best to divide adolescence into early (12 to 14 years of age, or junior high), middle (15 to 17 years of age, or high school), and late (18 to 21 years of age, or college and/or employment) stages.

Early adolescence is characteristically a period of egocentricity. Experiencing rapid physical changes, adolescents wonder, "Am I normal?" and are very self-conscious. The peer group is also very important at this stage, with the opinions of friends being just as important, if not more so, than those of parents. This is the stage during which adolescents begin to behave independently and require a greater degree of privacy. Risk-taking behavior

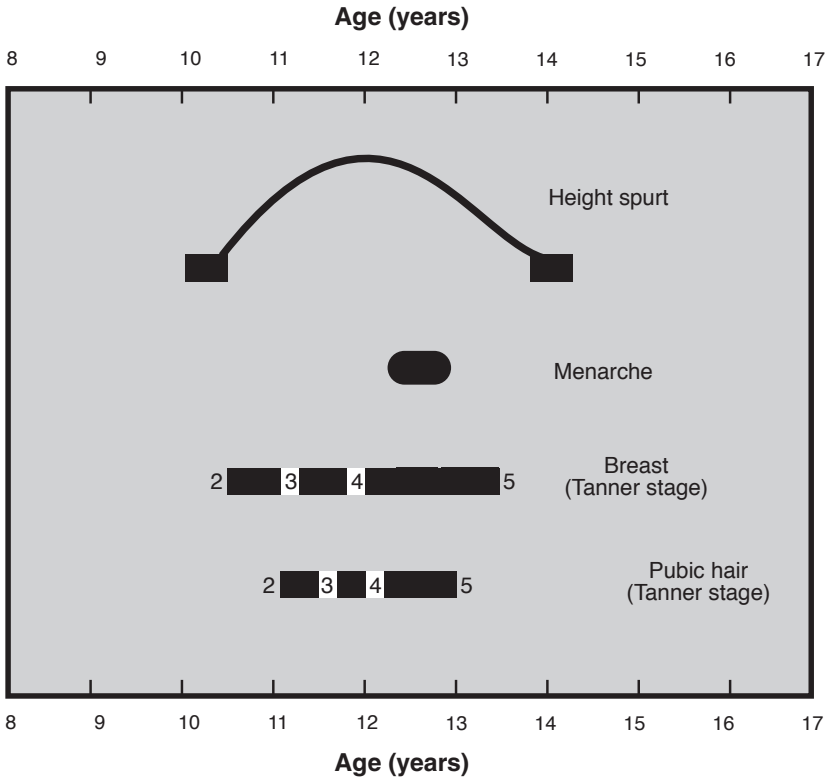


FIGURE 3-4. A summary of physical growth and development in girls, showing the sequence of pubertal events for average American girl. Adapted from Brookman RR, Rauh JL, Morrison JA, et al: The Princeton Maturation Study, 1976, unpublished data for adolescents in Cincinnati, Ohio.

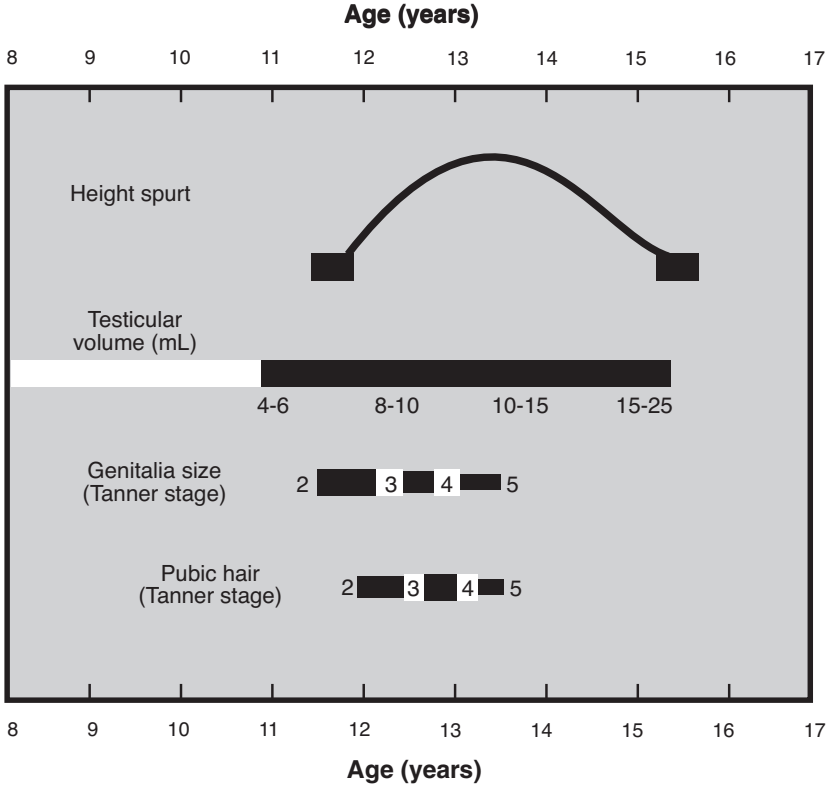

FIGURE 3-5. Sequence of pubertal events for average American boy. A testicular volume of less than 4 mL, as determined by an orchidometer (Prader beads), represents the prepubertal stage. Adapted from Brookman RR, Rauh JL, Morrison JA, et al: The Princeton Maturation Study, 1976, unpublished data for adolescents in Cincinnati, Ohio.

is likely as young adolescents try to establish independence and ensure peer approval. Cognitively, early adolescents still rely on concrete thinking and have difficulty conceptualizing the future well.

Middle adolescence is the stage of greatest turmoil. At this time, conflicts with parents are often most prevalent. During middle adolescence, teenagers may feel immortal and omnipotent, thus contributing to risk-taking behavior. Dating and romantic relationships with the same or opposite sex and the onset of sexual activity often begin at this time. The peer group remains important. Middle adolescents have a greater sense of self and are less preoccupied with pubertal changes. During this stage, adolescents acquire the beginnings of abstract thinking and can make decisions based on formal operational thought. Middle adolescents are frequently able to view global issues intelligently and can relate to the feelings of others.

Late adolescence is marked by separation from parents with an appreciation of parental values but with the distinct emergence of personal values. There is comfort with body image and the development of a full sense of self-identity. Cognitively, late adolescents have the ability to conceptualize and verbalize their thoughts fully, appreciate the ramifications of their actions, weigh alternatives in making decisions, and plan future vocational and educational goals. Issues of emancipation are very important and are the final tasks of adolescence. Older adolescents must learn to live on their own and become emotionally and economically self-sufficient.

MORTALITY IN ADOLESCENTS

The leading causes of death in adolescence are all **behavioral: motor vehicle crashes, unintentional injuries, homicide,** and **suicide.** Malignancy, the leading physical cause of death, finishes a distant fifth to these behavioral issues. Many, if not most, violent deaths are intertwined with issues of personal and family dysfunction, and do not occur as isolated events.

MOTOR VEHICLE CRASHES, INJURY, AND HOMICIDE

Injuries, due to motor vehicle crashes or unintentional injuries, are the leading causes of death in adolescents. Nearly 60% of all adolescent deaths are due to unintentional injuries. Boys are more at risk for unintentional injuries than girls. Older adolescents are more likely to die from motor vehicle injuries, whereas younger adolescents are at greatest risk for drowning and injurious death with weapons. Many of these injuries occur while teenagers are under the influence of alcohol. The combination of youthful drinking, learning to drive, risk-taking behaviors, and feelings of immortality all contribute to the exceedingly high rate of morbidity and mortality associated with automotive collisions.

Homicide is the second leading cause of death in adolescents in the inner city and the third leading cause in national reporting. It accounts for 11.3 deaths/100,000 teenagers, with the rate for African Americans five times higher than it is for Caucasians. High rates of homicide relate directly to the accessibility of guns; 9% of boys and 1% of girls in high school say they carry a gun. Many more have access to guns on a regular basis. Half of homicide victims know their assailant, and the fatal event usually occurs during an argument.

Clinical Evaluation: History

Taking a comprehensive psychosocial history from adolescents entails assurance of confidentiality in most circumstances. Exceptions involve circumstances in which the life of a particular adolescent or another person may be in danger or when involving reports of alleged physical, sexual, or emotional abuse by a parent or relative.

Pediatric Pearl: The **HEEADSSS** mnemonic (**H**ome, **E**ducation/Employment, **E**ating/Exercise, **A**ctivities, **D**rugs/Alcohol/Cigarettes, **S**exuality, **S**uicide/Depression, **S**afety (Sexual/Physical/Emotional Abuse), **S**pirituality may be used to help remember the important aspects of the psychosocial history that must be discussed with adolescents.

To evaluate adolescents for risk of death from injury, it is important to inquire about risk-taking behaviors and to take a history of previous accidents or injuries. Questions about drug and alcohol use, which may put them in jeopardy, are appropriate for all adolescents; inquiring about substance abuse and driving habits is necessary in older adolescents. Use of prescription drugs has become more prevalent in adolescents and this issue

should be specifically addressed. Questions about seat belt use (i.e., personal and family use) and possession of weapons are also important. The clinician should inquire about access to weapons both inside and outside the home, and whether the teenager has ever witnessed a murder or a shooting, and whether he belongs to a gang. Again, the key is anticipatory guidance. By asking these questions, while assessing the degree of risk to a particular teenager, the examiner can educate the adolescent about the dangers of weapons and the real possibility of getting caught in the line of fire.

Management

When working with adolescents who are at risk for injuries, **it is important not to scold, lecture, or be judgmental.** The physician should educate teenagers by providing anticipatory guidance about seat belt use and the risks of drinking and driving. Adolescents should realize the importance of assigning a designated driver whenever going out with friends and of providing for a safe ride home. Parents should discuss contingency plans if an adolescent is in a situation where the adolescent needs to be picked up by the parent. Establishing a code that the adolescent will use when calling a parent should be discussed. Emphasis of the importance of seat belt use in automobiles and helmet use when riding a bicycle, motorcycle, scooter, or minibike is critical. It is essential to encourage adolescents to steer clear of weapons and discuss alternatives for dealing with violence and confrontation. The health care provider should also speak to the parents of adolescents about the hazards of weapons in the home and emphasize strategies for addressing drinking and driving.

SUICIDE

Suicide is another leading cause of death in adolescents. In the last 30 years, the rate of suicide among teenagers has increased dramatically. Among high school students, 19% of girls and 10% of boys have seriously considered suicide or made a suicide attempt. Girls are more likely to attempt suicide, but the outcome in boys is five times more likely to be fatal. Girls are more likely to ingest medicines, and boys are more likely to use violent means such as weapons and hanging. Adolescents with preexisting psychiatric problems and those who abuse drugs and alcohol are more likely to attempt suicide. Young adolescents may not be able to conceptualize the consequences of a suicide attempt and may not have other coping strategies for their problems.

Clinical Evaluation

History

When taking a history, **the goal is identification of the risk factors** for suicide. Many adolescents who attempt suicide are depressed. Often, there is a conflict with parents, friends, or a romantic interest. Educational or legal problems may be a cause. If any of these situations exist, the physician should explore them further. Questions about depressive symptoms such as loss of appetite, anhedonia, sleep disturbance (too much or too little), and feelings of hopelessness or helplessness are important. It may be appropriate to ask teenagers whether they have ever thought about hurting themselves, have a suicide plan, or have ever attempted suicide, especially if they required medical attention. When asking adolescents about peers, suicide attempts on the part of friends can be a topic of discussion. Questions about substance abuse, which decreases judgment, increases impulsivity, and affects mood, thus aggravating the risk of attempting suicide, are also necessary.

Family health history is very important. Mental illness or alcohol or substance abuse in the family should alert the clinician to the possibility of depression and suicidal ideation.

Physical Examination

Few signs on physical examination point to the risk of suicide. Weight changes may occur with depression. The physician should look for any scars, especially on the wrists, that may have been due to a previous suicide attempt or physical abuse. Description of the physical signs of various drug ingestions is discussed in Chapter 23.

Management

Prevention is the key to the management of suicide. The goal of prevention is identification of those adolescents who are at risk for suicide (see History). If a particular adolescent is deemed to be at risk, other health care professionals should be consulted, such as a social worker experienced in working with teenagers and a child psychiatrist or psychologist. The physician needs to involve family and all other significant adults in counseling.

Pediatric Pearl: All adolescents who have suicidal ideation must be evaluated immediately by a mental health professional, and any adolescent who attempts suicide must be hospitalized.

Hospitalization not only provides a "cooling off" period for teenagers, but also allows the physician to determine the best course of treatment while the adolescents are in a safe environment where any further suicide attempt can be prevented. When adolescents are admitted to the hospital for attempted suicide, the physician must determine why it happened and decide, in conjunction with mental health professionals, the best course of treatment, whether outpatient counseling (individual, family) or inpatient psychiatric hospitalization. If a particular adolescent requires medication for major depression or psychosis, it will be initiated during the hospitalization. It should be pointed out that adolescents who have survived a suicide attempt have the greatest risk for death from suicide.

CAUSES OF MORBIDITY IN ADOLESCENTS

The major causes of morbidity in adolescents are substance abuse and sexual activity. In addition, obesity and eating disorders such as anorexia nervosa and bulimia nervosa, which have their onset during adolescence, are a source of significant psychologic and physical morbidity.

Adolescents experiment with drugs and develop sexual identity as part of their psychosocial and cognitive development. However, these behaviors put teenagers in jeopardy of accidents, injuries, violence, pregnancy, and acquiring sexually transmitted infections (STI), including HIV. The physician helps identify those teenagers involved with substance abuse and who are sexually active, which involves exploring why they are putting themselves at risk. Intervention should then occur to prevent the morbidity.

SUBSTANCE ABUSE

The majority of adolescents, who are well-adjusted, have experimented with cigarettes and alcohol, the most commonly used substances. Cigarette smoking, which often begins in middle school, is on the decline. This is attributed to intense public education about smoking and its adverse effects, the expense of smoking cigarettes, as well as disapproval of smoking with limitations on where one can smoke. In the most recent survey of high school students, over 44% have ever tried cigarettes and 20% smoke one or more cigarettes per day. White girls are the largest group to begin smoking and continue the practice.

Alcohol use is pervasive in adolescents and is the underlying cause of most mortalities related to motor vehicle crashes and unintended injuries. Surveys of high school seniors demonstrate that approximately 72% have tried alcohol and 39% had tried alcohol by the 8th grade. More than half of all high school seniors have been drunk at least once in their lives. Binge drinking is a large problem on college campuses.

Such surveys also indicate that about a third of high school seniors have tried marijuana. Many teenagers use drugs only on an intermittent basis, and drug use interferes with peer and family relationships in only a small minority of adolescents. Younger teenagers do not have the ability to link current behavior to long-term consequences and are more concerned about peer acceptance. Because these adolescents are not cognitively mature, they may make errors in judgment even while merely experimenting. Situations in which intoxication is associated with particular risk include sexual activity, violent behavior, delinquent behavior, transient depression that may lead to a suicide attempt, and, certainly, driving automobiles.

Clinical and Laboratory Evaluation

History

The mainstay of determining whether adolescents are on a collision course with substance use is by obtaining a thorough history.

Pediatric Pearl: Clinicians who evaluate adolescents should interview teenagers and parents separately.

The goal of the physician is to gain the trust of both the adolescent and the parents and ensure the confidentiality of the teenager. Adolescents respect the physician's knowledge and authority as long as this trusted adult is a good listener who can maintain confidentiality.

Talking to children and parents about drug use should begin at yearly health care maintenance visits at about age 10 years; surveys of high school seniors reveal that 24% had tried alcohol before age 13. Questions about what types of drugs are used and settings of usage are appropriate. The physician should also try to assess the degree of intoxication to determine whether drug use has ever put the teenager at risk. It is important to ask about drug use in friends and parents because this may be the only way to determine the teenager's risk of beginning drug use. Inquire about whether the adolescent uses medications that are prescribed for others such as Ritalin and painkillers.

School progress serves as an important clue to the possibility of drug use. Attendance problems or any decline in grades may suggest substance abuse as an etiology. Changes in family relationships (e.g., divorce, death) or disruption of the peer group (e.g., new neighborhood, breakup with a romantic interest) may lead to substance use. Questions about sexual activity or delinquent behavior are appropriate. Studies have shown the existence of a problem behavior syndrome (i.e., in many teenagers, risky behaviors are clustered).

As noted previously, it is important to screen for depression. Drug abuse may be a result of depression or a cause of it. Mood swings may also be due to drugs or an underlying psychologic problem that predisposes the adolescent to substance use.

When talking to parents, it is a good idea to ask about family relationships and if the teenager is stealing money, has sold possessions, has undesirable friends, or has had overt signs of drug use or intoxication. However, it is important to weigh the information ascertained from the parent against that obtained from the teenager. It is also important to inquire whether siblings or parents abuse illicit substances or are drinking alcohol to an excess as these factors influence the adolescent's risk for substance abuse and alcohol abuse.

Physical Examination

The findings on physical examination that indicate substance abuse are subtle and are most often only found in seriously addicted teenagers. In general, the physical examination is not of help in detecting previously unsuspected substance abuse. The clinician is most dependent on information gathered by history to suggest potential physiologic consequences of specific drugs.

Laboratory Evaluation

Either urine or blood may be screened for drug metabolites. Urine tests can identify cocaine, methadone, amphetamines, diazepam, opiates, and barbiturates. Blood tests or a breath alcohol test can detect only alcohol.[1] It is relatively easy to detect illicit substances in body fluids such as blood or urine, but drug testing in adolescents is controversial. At the center of this controversy is the belief that surreptitious testing is unethical and destroys the trusting physician–adolescent relationship. The American Academy of Pediatrics (AAP) condones such drug testing only if the particular adolescent is mentally incompetent to make an informed decision or the life of the adolescent is in danger.

Management

Management of adolescents who use drugs must address not only the drug abuse itself, but also the reasons for the abuse. If an individual teenager is merely experimenting with alcohol or marijuana in a social setting and it is not interfering with school, family, peers, or cognitive growth, then anticipatory guidance is important. It is also imperative to point out that even experimentation may place adolescents in risky situations, and the physician should help teenagers modify behavior so they avoid intoxication and they either do not drink while driving or they use a designated driver. In younger teenagers, the clinician should stress postponement of drug experimentation.

If it is determined that a teenager has a serious drug abuse problem—he is displaying signs of physical or psychologic dependence or drug use is interfering with normal adolescent development—initiation of treatment is essential. The primary care physician may offer this treatment alone or in consultation with a mental health professional with drug abuse expertise. Alternatively, referral to an ambulatory drug treatment program may be appropriate. Family therapy may be necessary, and peer support such as Alcoholics Anonymous is sometimes of help. However, if a teenager requires medically supervised treatment for an abstinence syndrome, has a less-than-optimal family environment, has an underlying psychiatric illness, or has not responded to outpatient therapy, then inpatient therapy or residential treatment is indicated.

[1] *Use of alcohol can only be detected in a clinical setting by a blood test. The breathalyzer test is only utilized in a law enforcement setting.*

There are two types of residential treatment: (1) an adolescent drug treatment unit in a hospital, and (2) a nonmedical therapeutic community. Selection among these alternatives is usually best left to a clinician with special expertise in drug abuse. The AAP has developed guidelines for assisting in the determination of the most appropriate treatment modality for a particular patient.

SEXUAL ACTIVITY

Close to 50% of high school students have been sexually active; 50% of all male students and 46% of all female students are sexually active. The health risks of early sexual activity are unwanted pregnancy and STIs such as syphilis, gonorrhea, chlamydia, and HIV. In the last 20 years, morbidities associated with sexual activity have increased in adolescents. Approximately 750,000 adolescent girls become pregnant each year, 25% of all sexually active teenagers acquire an STI, and over 2,000 test positive for HIV (http://www.avert.org/usa-race-age.htm). Many HIV-positive youth do not know their status because they have not been tested. The physician must identify those adolescents at risk for the consequences of early sexual activity and, if the adolescent is sexually active, provide options for effective contraception.

Clinical and Laboratory Evaluation

History

Beginning as early as 8 years of age, the physician should inquire in a developmentally appropriate fashion about sexuality and discuss the impending body changes of puberty with children and parents. Not only does this establish a trusting, open relationship between physicians and children, but it also encourages the parents to talk to their children about sex. As children reach adolescence, the physician should ask whether they are attracted to the opposite or the same sex, how this attraction is expressed, whether they are sexually active, and what types of sexual expression they have experienced. It is also important to ask whether their peers are having sex because this is a predictor of teenagers' behavior.

Pediatric Pearl: Young adolescents who abuse drugs, have a criminal record, or are having problems in school are more likely to become sexually active.

More detailed questions should follow (Table 3-1). It is also important to ask whether they have ever experienced physical or sexual abuse because this may predispose teenagers to early sexual activity and promiscuity.

Physical Examination

Sexually active adolescents require a more involved physical examination than non–sexually active teenagers. For all boys, a thorough testicular examination looking for lesions varicocele, hernia, hydrocele, and masses is imperative. Tanner staging should be performed for pubic hair and genitalia. Penile lesions or discharge and inguinal adenopathy, if present, must be noted, especially in sexually active boys. Although it is not recommended by Bright Futures, many physicians choose to provide instructions concerning testicular self-examination. For girls, an external genital examination to determine normal anatomy, Tanner staging, looking for lesions on the vaginal mucosa or for vaginal discharge should be performed. If a girl is sexually active and complains of a vaginal discharge or unexplained vaginal bleeding, a complete pelvic examination, including a speculum examination to visualize the cervix for lesions, discharge, and friability, is necessary. A Papanicolaou smear is generally not indicated until a girl is 21 years of age but may be indicated in a sexually active adolescent girl who is immunocompromised. A bimanual examination allows for assessment of uterine size, if pregnancy is suspected, as well as the cervical motion tenderness associated with salpingitis. It is also important to note the presence of adnexal masses or tenderness. An abdominal examination reveals a gravid uterus if the pregnancy is over 4 months.

Laboratory Evaluation

All sexually active adolescents require yearly urine testing for chlamydia and gonorrhea as well as serum screening for syphilis and HIV. In girls with a vaginal discharge, a wet prep (mixture of the discharge with normal saline or potassium hydroxide viewed under a microscope) may help distinguish yeast vaginitis, bacterial vaginosis, trichomoniasis, and cervicitis (Table 3-2). In teenagers with multiple partners, all STI screenings should occur more frequently—certainly if the adolescent is symptomatic.

TABLE 3-1

What to Ask Adolescents Regarding Sexual Activity

Ask adolescents whether they find themselves attracted to boys, girls, or both.
- Ask adolescents how old they were when they had voluntary sex, including vaginal, oral, and anal sex.

If have been sexually active:
- Ask about the number of current and lifetime partners. Ask which gender.
- Ask what they are doing to prevent STIs and pregnancy (i.e., if any form of contraception is used).
- Ask girls about the presence of any unusual vaginal discharge, and ask boys about any dysuria or penile discharge.
- Inquire about any lesions in the pubic area.
- Ask whether there has been any previous STIs or pregnancy.

Always ask adolescent girls whether they **menstruate**. If so:
- Ask at what age they began to menstruate and about the date of their last menses.
- Ask whether the interval between it and the previous menses and the duration were usual.
- Ask her whether she has painful menses. If so, ask if that has prevented her from going to school or work. Ask what medicines she uses for the pain.

STI, sexually transmitted infection.

If vaginal or penile lesions are suggestive of herpes infection, a culture of the lesion is necessary. If pregnancy is suspected, measurement of β-human chorionic gonadotropin (β-HCG) level is important. Serum β-HCG may be positive even before the occurrence of a missed menstrual period. If not previously immunized, all adolescents should receive immunizations to protect against hepatitis B and human papilloma virus. Hepatitis A immunization should be strongly considered for boys who have sex with boys.

Management

Sexually Transmitted Infections

Most STIs respond to drug therapy (Table 3-3). Making the diagnosis of an STI should be the springboard to talking to the teenager about the risks and consequences of unprotected sex and the need to use condoms for prevention of STIs as well as pregnancy.

Pediatric Pearl: Adolescents who are diagnosed with STIs are legally entitled to confidential care in all 50 states.

Concurrent treatment of the sexual partner is mandatory. Girls who are diagnosed with acute salpingitis should be admitted to the hospital for intravenous antibiotics if there is (1) the risk of noncompliance with

TABLE 3-2

Findings on Wet Prep

Infection	*Appearance*
Monilia (yeast) vaginitis	Hyphae, buds (revealed best by adding KOH)
Bacterial vaginosis	Clue cells (epithelial cells with cytoplasmic studding)
Trichomoniasis	Trichomonads
Cervicitis	Multiple white blood cells

KOH, potassium hydroxide.

TABLE 3-3

Treatment of Sexually Transmitted Infections

Infection	*Treatment*
Gonorrhea, cervicitis, urethritis	Ceftriaxone 250 mg IM single dose *or* Cefixime 400 mg PO single dose *or* Ciprofloxacin 500 mg PO single dose *or* Ofloxacin 400 mg PO single dose (check to see whether there is quinolone-resistant gonorrhea in your state, particularly in California or Hawaii)
Chlamydia trachomatis, cervicitis, urethritis	Azithromycin 1 g PO single dose *or* Doxycycline 100 mg PO bid × 7 days *or* Erythromycin 500 mg qid × 7 days **(if pregnant)**
Trichomoniasis	Metronidazole 2 g PO single dose Tinidazole 2 g PO single dose
Bacterial vaginosis	Metronidazole 500 mg PO × 7 days *or* Metronidazole gel 0.75%, 1 applicator intravaginally bid × 5 days *or* Clindamycin cream 2%, 1 applicator intravaginally qhs × 7 days
Vulvovaginal candidiasis	Topical clotrimazole, miconazole, terconazole, or nystatin at varying doses
Chancroid	Azithromycin 1 g PO single dose *or* Ceftriaxone 250 mg IM single dose Ciprofloxacin 500 mg PO bid × 3 days *or* Erythromycin 500 mg PO qid × 7 days
Lymphogranuloma venereum	Doxycycline 100 mg PO bid × 21 days *or* Erythromycin base 500 mg PO qid × 21 days **(if pregnant)**
Syphilis	
Early (primary, secondary, <1 year duration)	Penicillin G benzathine 2.4 million unit IM single dose *or* Doxycycline 100 mg bid × 2 weeks
Late (>1 year duration)	Penicillin G benzathine 2.4 million unit IM weekly × 3 *or* Doxycycline 100 mg PO bid × 4 weeks
Neurosyphilis	Aqueous liquid penicillin G 3–4 million unit IV q4hr × 10–14 days
Epididymitis	Ceftriaxone 250 mg IM × single dose *plus* Azithromycin 1 g PO × single dose *or* Doxycycline 100 mg PO × 10 days
Pelvic inflammatory disease	As inpatient: Cefoxitin 2 g IV q6hr *plus* Doxycycline 100 mg PO bid × 14 days *or* Erythromycin 500 mg PO qid × 14 days As outpatient: Metronidazole 500 mg × 14 days *or* Ceftriaxone 250 mg IM × 1 *plus* Doxycycline 100 mg PO × 14 days *with or without* Metronidazole 500 mg × 14 days

TABLE 3-3

Treatment of Sexually Transmitted Infections *(Continued)*

Infection	*Treatment*
Herpes simplex	
First episode	Acyclovir 200 mg PO 5×/day × 7–10 days *or* Acyclovir 400 mg PO tid × 7–10 days *or* Famciclovir 250 mg PO tid × 7–10 days *or* Valacyclovir 500 mg PO bid × 7–10 days
Prophylaxis	Acyclovir 400 mg bid *or* Famciclovir 250 mg bid *or* Valacyclovir 500 mg or 1 g qd
Recurrent episode	Acyclovir 400 mg tid × 5 days *or* 800 mg bid × 5 days *or* 800 mg tid × 3 days *or* Famciclovir 125 mg bid × 5 days *or* 1,000 mg bid × 1 day

Adapted from: http://www.cdc.gov/std/treatment/.

bid, two times per day; *IM*, intramuscularly; *IV*, intravenously; *PO*, orally; qd, every day; qhs, at night; qid, four times per day; q6hr, every 6 hours; tid, three times per day.

medications, (2) the patient is toxic or cannot tolerate oral medication, (3) the presence of a tubo-ovarian abscess or perihepatitis (Fitz–Hugh–Curtis), (4) the girl is pregnant, or (5) a failure of outpatient treatment.

Pregnancy

After a decline in adolescent pregnancy rates in the early part of the 21st century, rates began to go up again in 2006 and 2007. However, data for 2008 and 2009 show the decline resuming. Two-thirds of pregnancies are unintentional. One-half of girls continue the pregnancy to term, slightly fewer elect termination, and the rest experience miscarriages or stillbirths. Adolescent pregnancy is associated with a greater risk of complications, including low birth weight and maternal health and nutritional problems. The consequences of adolescent parenthood are unstable family formation and decreased chances of completing education. Therefore, all adolescents who are sexually active should be offered information on pregnancy prevention. Table 3-4 describes methods of contraception currently available in the United States. Moreover, adolescents should be made aware of emergency contraception that can be obtained without a prescription for those 17 years or older. Emergency contraception, in the form of a levonorgestrel pill, should be taken immediately after unprotected sexual intercourse but may be used 72 hours after. Some studies have shown efficacy of pregnancy prevention up to 5 days after the event.

The clinician should discuss the options available to pregnant girls in a developmentally appropriate way, usually with the assistance of a social worker or options counselor. If teenagers decide to continue the pregnancy, then early initiation of prenatal care, preferably in a teen pregnancy program, is mandatory. After the delivery, or if the pregnancy is terminated, a currently available contraceptive method must be initiated to prevent future pregnancies (Table 3-4). Girls who are sexually active may benefit from the oral contraceptive pill or injectable progestins, which are effective in preventing pregnancy. However, only barrier methods such as condoms prevent STIs, so concurrent condom use is usually recommended. Consideration of hormonal contraceptive options is appropriate when counseling teenagers (Table 3-5). Clinicians may prescribe contraception confidentially in most jurisdictions.

OBESITY

Obesity rarely contributes to mortality in adolescents, but it is a significant underlying cause of mortality in adults and creates medical morbidities in the adolescent age group. In adolescents, obesity, defined by a body mass index (BMI) greater than the 95th percentile for age and gender, is associated with dyslipidemia, hypertension, impaired glucose tolerance, type 2 diabetes mellitus, obstructive sleep apnea, polycystic ovary syndrome,

TABLE 3-4

Effectiveness of Contraceptive Options for Adolescents[a]

Method	*Typical Failure Rate (%)*
Condoms	15
Diaphragm	16
No contraception	85
Spermicide	29
Withdrawal	27
Combined pill, patch, ring	8
Injectable progestogen (DMPA)	3
Implants (levonorgestrel)	0.05
Levonorgestrel intrauterine system	0.2
Emergency contraception initiated within 72 hours	Reduces risk of pregnancy by 75%

DMPA, depot medroxyprogesterone acetate.

nonalcoholic fatty liver disease, gall stones, orthopedic problems such as slipped capital femoral epiphysis and Blount disease, as well as future risk of adult cardiovascular disease. Overweight is defined as a BMI between the 85th and 95th percentile. The incidence of obesity in children and adolescents in the United States has increased dramatically over the past two decades, concomitantly with the incidence of type 2 diabetes. It is now considered an epidemic with close to one-fifth of American children and adolescents obese. One-third of all adolescents 12 to 19 years of age are considered overweight. The incidence is higher in certain ethnic groups such as non-Hispanic African American girls and Mexican American boys and girls.

Clinical and Laboratory Evaluation

History

At every annual health care maintenance visit, adolescents should be evaluated for obesity. Always inquire about diet and exercise. Assess for family history of hypertension, diabetes, obesity, stroke, and hyperlipidemia. Sleep habits are important to ascertain. For adolescent girls ask about menstrual history and regularity of menses. On review of systems, headache may be due to pseudotumor cerebri and joint pain may be due to Blount disease. On HEEADDSSS assessment inquire about symptoms of depression and poor body image, which are common in obese adolescents.

Physical Examination

Height and weight should be measured, and BMI (weight in kilograms/height in meters^2) should be calculated and plotted on the BMI chart (http://www.cdc.gov/growthcharts/clinical_charts.htm) to determine whether a patient falls within the ranges for overweight or obese as previously defined. Blood pressure should be measured yearly for evidence of hypertension. Look behind the neck, axillary folds, intertriginal areas, and any skin fold areas for acanthosis nigricans, a sign of insulin resistance. Xanthomas may occur around the eyes due to dyslipidemia. Acne and hirsutism may be concomitant with polycystic ovary syndrome in adolescent girls. Abdominal striae may be present in obesity or Cushing disease. Abdominal pain on palpation may be due to gall bladder stones. An enlarged liver may be due to nonalcoholic fatty liver disease.

TABLE 3-5

Hormonal Contraception

Contraceptive Agent	*How It Works*	*Possible Side Effects*	*Contraindications*
Combined oral contraception (estrogen/progestin) Contraceptive patch Contraceptive ring	Inhibits ovulation Thickens cervical mucus Inhibits implantation	Spotting/breakthrough bleeding Amenorrhea Mood changes Weight change Headaches	Gallbladder disease Hepatic adenoma Active liver disease, including active mononucleosis Hypertension Pregnancy Breast cancer Estrogen-dependent neoplasia Liver tumor, cancer Previous thromboembolic event or cerebrovascular accident Ischemic heart disease Unexplained vaginal bleeding
Levonorgestrel implant	Suppresses ovulation for 3 years	Visible implants Spotting Amenorrhea Headache	Pregnancy Allergic reaction to components Same as oral contraception
Depo-Provera (medroxyprogesterone acetate)	Injection suppresses ovulation for 12 weeks	Pain of injection every 3 months Irregular bleeding Amenorrhea Mood changes Weight gain Osteoporosis	Pregnancy Allergic reaction to components Same as oral contraceptive pills
Levonorgestrel intrauterine system	Suppresses ovulation for 5 years	Spotting Amenorrhea Weight gain Headache Ovarian cysts	Pregnancy History of or at continued risk for ectopic pregnancy Allergic reaction to components

Laboratory Examination

Laboratory evaluation should include complete blood count as many obese adolescents are anemic. Serum electrolytes and liver function tests should be performed as well as fasting lipids and oral glucose tolerance test. Assessment for hyperlipidemia and type 2 diabetes should be done once a year. Referral to a nutritionist may be warranted to jump-start a patient's weight loss and to give the patient and family intensive guidance. Urineanalyis should be performed with spot protein. On initial evaluation, thyroid function tests are done to exclude hypothyroidism. The rest of the laboratory examination is guided by a history and physical examination to rule out comorbid conditions that might be present such as polycystic ovary syndrome, Cushing disease, cardiac disease, and orthopedic disease.

Management

There are simple things that patients can be encouraged to do, whether they are normal weight, overweight, or obese. The American Heart Association has dietary strategies that include eating breakfast, eliminating sugar-sweetened foods and beverages, as well as drinking whole milk in favor of skim or low-fat dairy products, reducing salt intake and eating more fish, whole grain foods, legumes, lean cuts of beef, as well as poultry without skin. Adolescents should be encouraged to perform 60 minutes of moderately intense physical exercise daily. The multifaceted management of obesity is beyond the scope of this text. Referral to a nutritionist may jump-start the patient and help the family work with the patient to develop a healthy weight loss diet plan. Multidisciplinary adolescent obesity programs with structured groups may also be helpful in the management of obese teens. Medical treatment for obesity should only be done when all other interventions fail. Two agents have been FDA approved for adolescents: Orlistat may be prescribed to patients over age 12, and sibutramine may be prescribed for adolescents older than 16 for use up to 2 years. Bariatric surgery has been done in teens who have failed medical intervention, have comorbidities, and are well beyond the end of puberty.

EATING DISORDERS

Eating disorders are another cause of morbidity and, sometimes, mortality in adolescents. Anorexia nervosa, which occurs in 0.5% of adolescent girls, is distinct from bulimia nervosa, which occurs in 1% to 3% of this population. Eating disorder not otherwise specified (ED-NOS) is a diagnosis used when the adolescent does not meet the criteria for a specific eating disorder; for example, if a patient meets the criteria for anorexia nervosa but has regular menses, or weight is in normal range despite large weight loss. A patient may meet the criteria for bulimia nervosa but binge eating/compensatory purging occurs less than twice a week for less than 3 months. Patients with ED-NOS might repeatedly chew and spit out food, not swallow it. Moreover, binge eating disorder is diagnosed in an adolescent who has recurrent episodes of binge eating but does not use laxatives, diuretics, enemas, or exercise to compensate. Each illness stems from an abnormal body image. The *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed., text revision (DSM-IV-TR) defines the criteria for diagnosis of these eating disorders. See Table 3-6 for the definitions of anorexia nervosa and bulimia nervosa.

Pathophysiology

Anorexia nervosa and bulimia nervosa affect almost every organ system. Vomiting, at times induced by ipecac, laxative abuse, or limited intake to lose weight, causes abnormalities of fluids and electrolytes. These electrolyte imbalances, which may be life-threatening, may be the first presentation of an eating disorder. Hyponatremia may be secondary to water intoxication in teenagers attempting to escape detection through rapid weight gain. Hypokalemia with a hypochloremic metabolic alkalosis occurs with vomiting. The hypokalemia develops with chloride and water depletion, leading to secondary hyperaldosteronism, and increases potassium excretion with sodium retention. Calcium, zinc, and magnesium deficiencies also occur. Starvation causes ketonuria and lower blood urea nitrogen than expected, resulting from decreased muscle mass.

Cardiovascular symptoms are usually precipitated by electrolyte disorders. Prolonged QT interval on electrocardiography (ECG), which results from hypokalemia, can cause sudden death. Hypotension and bradycardia occur as a result of decreased blood volume. In addition, ipecac may cause a cardiomyopathy.

Amenorrhea may result from a disturbed hypothalamic pituitary axis, presumably secondary to malnutrition. Hypoestrogenism and hypercortisolism in anorexia nervosa decrease bone mineral density, leading to osteoporosis.

Iron deficiency may develop in anorexia nervosa as a result of malnutrition. However, most female patients with anorexia nervosa are not anemic due to the fact they do not menstruate. Frequent vomiting may

TABLE 3-6

Criteria for Diagnosis of Anorexia Nervosa, Bulimia Nervosa, and Eating Disorder Not Otherwise Specified (From DSM-IV-TR)

Anorexia Nervosa

- Refusal to maintain body weight at or above a minimally normal weight for age and height (weight loss leading to maintenance of body weight <85% of expected or failure to make expected weight gain during period of growth, leading to body weight <85% of expected)
- Intense fear of gaining weight or becoming fat, even though underweight
- Disturbance in body weight/shape experienced, undue influence of body weight/shape on self-evaluation, or denial of seriousness of current low body weight
- Three consecutive cycles of amenorrhea in postmenarchal girls

Restricting type: No regular binge eating or purging behavior. Weight loss only through fasting, excessive dieting, or excessive exercise.

Binge eating or purging type: Regular binge eating or purging behavior

Bulimia Nervosa

- Recurrent episodes of binge eating is indicated. Binge eating characterized by both eating during a period an amount of food that is larger than most people would eat under similar circumstances and a lack of control over eating during the episode—a feeling that one cannot stop eating or control how much or what eating.
- Recurrent, inappropriate compensatory behavior to prevent weight gain is indicated such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- Triggers include stress, traumatic events, and self-evaluation of body shape/weight.
- Symptoms may occur after every meal on a daily basis or once every few months.
- There is no occurrence during episodes of anorexia nervosa.

Purging type: Self-induced vomiting (gag or using emetics) or misuse of laxatives, diuretics, or enemas

Nonpurging type: Use of other inappropriate compensatory behaviors after binge such as fasting or excessive exercise but not laxatives, self-induced vomiting, diuretics, or enemas

From American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition. Washington, DC, American Psychiatric Association, 1994.

cause reflux esophagitis, Mallory–Weiss tears of the esophagus, parotid gland enlargement, and tooth decay from enamel erosion. Constipation resulting from decreased intestinal motility is a hallmark of anorexia nervosa. This may also cause abdominal cramps and lead to increased laxative use.

Clinical and Laboratory Evaluation

History

When interviewing all adolescents, the physician should inquire about daily diet and exercise routines. Teenagers should also describe their body image as well as mood because many individuals with eating disorders have depressive symptoms. Menstrual patterns should be a topic of inquiry in girls.

With any suspected eating disorder, careful inquiry into weight patterns over the past few months, exercise, and typical daily diet is essential. The clinician should ask girls if they feel happy with their bodies. Do they think that they are too thin or too fat? The weight of family members is also a topic for inquiry. It is also important to know whether boys and girls make themselves vomit or use ipecac or laxatives. Knowledge of family psychiatric history is appropriate because many teenagers with eating disorders experience depression and affective or obsessive-compulsive disorders.

Physical Examination

Height and weight measurements are of paramount importance as part of the physical examination. A BMI less than the 5th percentile for age is a sign of anorexia nervosa. A patient with anorexia nervosa who has lost greater

than 15% of ideal body weight appears sick, but a patient with bulimia may look well nourished. Malnutrition causes lanugo; brittle hair and nails; dry, cold skin; loss of subcutaneous fat; and pedal or pretibial edema. Bradycardia, hypothermia, and hypotension may be evident.

Laboratory Evaluation

The purpose of laboratory tests is to determine whether a particular teenager with an eating disorder needs emergent medical attention. Usually, the history and physical examination allows for the diagnosis of an eating disorder. Blood tests include serum electrolytes, hemoglobin, hematocrit, and white blood cell count. Urinalysis is also necessary. The clinician should order an ECG to detect arrhythmias. Thyroid function tests are important if symptoms of hypothyroidism (e.g., bradycardia, thinning hair, cold intolerance) are present. Measurements of follicle-stimulating hormone and luteinizing hormone are usually suppressed, causing amenorrhea. If an adolescent girl has not gotten her menses for more than a year, a dual-energy X-ray absorptiometry scan should be performed to determine bone mineral density and whether osteopenia or osteoporosis is present.

Differential Diagnosis

Pediatric Pearl: Before making the diagnosis of an eating disorder, it is important to evaluate weight loss to exclude a systemic condition.

Weight loss or vomiting may not result from anorexia or bulimia. It may result from malignancy, malabsorption, inflammatory bowel disease, tuberculosis, cystic fibrosis, diabetes mellitus, and hyperthyroidism. Vomiting may be due to gastrointestinal (GI) obstruction, gastroenteritis, or increased intracranial pressure from a brain tumor, migraine headaches, or an aneurysm. Findings of weight loss or excessive vomiting together with an abnormal body image lead to the diagnosis of either anorexia nervosa or bulimia.

The female athletic triad includes disordered eating, amenorrhea, and osteoporosis. Always inquire about the level of physical activity and sports participation when an adolescent girl presents with amenorrhea as that might reveal behaviors such as disordered eating, which may lead to amenorrhea and osteoporosis.

Management

The management of adolescents with eating disorders is most frequently accomplished on an outpatient basis unless there are severe metabolic or cardiac disturbances, dehydration, or the necessity for inpatient psychiatric care. Treatment for eating disorders is multidisciplinary, with a team consisting of a pediatrician, mental health professional, and nutritionist. The goals of hospitalization are correction of physiologic abnormalities, weight gain, and initiation of psychologic evaluation.

Weight gain may occur on an outpatient basis, by having the adolescent eat food or nutritional supplements. If weight gain through oral feeding is not possible, then trials of inpatient nasogastric or intravenous nutrition must proceed. Weight goals should be established within a certain time frame. Ongoing psychotherapy and, sometimes, family therapy are necessary.

SPORTS MEDICINE

Physical activity during adolescence benefits the musculoskeletal and cardiovascular systems, and participation in team sports fosters psychosocial development. Improvements in strength, flexibility, endurance, bone mineral density, perceptual motor skills such as eye–hand coordination, and cardiopulmonary function result from regular physical activity. In addition to fitness, organized sports encourage good health behaviors and social and team skills. Participation in sports may produce lifetime benefits in terms of disease prevention and quality of life. Team sports, general physical activity, and parental encouragement in sport participation are the primary factors that contribute to an athletic self-concept that is reflected in a positive sense of appearance, competence, and importance.

There is an increasing focus on the impact that sports play has on adolescent health, both positive and negative. Although the number of publications addressing adolescent sports medicine has burgeoned, generalization and application of published results remain controversial given the extremely large number of variables inherent in such studies.

EXTENT OF SPORTS PARTICIPATION AND SPORTS-RELATED INJURIES

In the United States, sports participation and sports-related injuries are common in adolescents, and their incidence, estimated for many team and individual sports, is increasing. More than 30 million adolescents are enrolled in formal sports programs, and more than 30% of teenagers participate in competitive team sports (more than 15 million teenagers participate in organized play each year).

More than 3 million sports-related injuries occur each year in adolescents and about half of these require medical attention and temporarily restrict play.

Pediatric Pearl: Sports play is the most common cause of adolescent injury and the second most common cause of emergency room visits.

Sports-related injuries are second only to motor vehicle injuries as the cause of adolescent emergency department visits nationwide. Team-related sports (particularly football, basketball, baseball, soccer, volleyball, field hockey, hockey, and gymnastics) account for the greatest number of and the most serious injuries. Demographic statistics are now accumulating that also address injury rates due to participation in nonteam sports. There is now ample medical literature about in-line skating, trampoline use, weight lifting, surfing, martial arts, motor cross racing, snowboarding, skiing, running, hiking, weight training, golf, and equestrian sports (including high school rodeo) as related to adolescent sports injury. Musculoskeletal and neurologic injuries are best understood, but psychiatry and psychology as applied to adolescent athletes are now in an incipient stage. Other injuries that are common among teenagers but are less often addressed include eye and dental injuries. Injury rates vary widely by sport and reports stratify rates by type of sport, type and location of injury, hours of play, age, gender, and rate of recurrence.

There are also a few pathologic conditions that are unrelated to activity, or are nonspecific but characteristic of the athlete. The triad of amenorrhea, eating disorder, and osteoporosis is well described in competitive female athletes. Postexertional breast tenderness affects about three-fourths of female athletes independent of breast contact.

APPROACH TO ADOLESCENT ATHLETES WITH SPORTS-RELATED INJURIES

Sports-specific physical demands and technique and the adolescent sports "culture" all contribute to athletic performance and injury. Many intrinsic factors determine an athlete's susceptibility to injury. Extrinsic factors are also important to consider (Table 3-7).

A sense of invulnerability and risk-taking behavior can encourage athletes to attempt to exceed their abilities or previous performances. Their identity and self-esteem may be connected to physical fitness or a specific

TABLE 3-7

Risk Factors for Injury During Sports Play

Intrinsic Risk Factors	*Extrinsic Risk Factors*
Physiologic immaturity (close-packed viscera, reduced anaerobic capability, open epiphyses)	Required frequency and intensity of play
Limited strength/stability	Playing surface (bad friction, terrain)
Limited range of motion/flexibility	Poor equipment (fit, condition, support)
Poor endurance	Excessive contact force
Poor technique	Team sports
Sense of invulnerability	Ambient considerations (extremes of temperature, humidity, altitude)
Win-at-all-cost mentality	Low socioeconomic status
Obesity	

TABLE 3-8

Strategies to Prevent Sports Injury

Adequate warm-up, cool-down (including stretching)
Cross-training
Proper equipment, proper fit
Adequate preparticipation screening
Education (adolescent, others involved)

sport or team. This can foster actions such as the use of anabolic steroids and related substances, which may lead to injury. The use of ergogenic aids, including dietary supplements and steroids, is common among high school and college athletes. An estimated 6% to 10% of male high school seniors use, or have used, anabolic or androgenic steroids beginning at 16 years of age or younger. Use of creatine and anabolic or androgenic steroids is frequent in adolescents, despite the lack of proper guidelines.

Injury prevention is the first line of treatment (Table 3-8). Young athletes should avoid high-intensity training and sports specialization. This is contrary to the position taken by many serious athletes who exhibit a "win-at-all-costs" mentality resulting in intensive year-round practice of one sport. Cross-training is a valuable strategy to vary physical activity and avoid injury.

In September 2000, the Committee on Sports Medicine and Fitness of the AAP summarized one of the most significant behaviors that contributes to sports-related pathology. (Young athletes who specialize in just one sport may be denied the benefits of varied activity while facing additional physical, physiologic, and psychologic demands from intense training and competition.)

Pathophysiology

Several physiologic factors confer adolescent vulnerability to injury. Growing athletes have less fat and connective tissue, and, as a consequence, a lower shock absorption capacity than adults. As a result, the bone and viscera of adolescents receive a greater amount of force per unit area than in adults.

Pediatric Pearl: Injuries that affect the epiphyseal plate occur in adolescents as well as children. Young adolescent athletes are most susceptible to visceral and osseous injury, and older athletes have a greater vulnerability to soft tissue damage.

The viscera of physically immature athletes are more closely packed, and the frequency of multiple organ injuries during sports play is inversely related to the athlete's age.

Adolescent athletes have a lower anaerobic capability than adults. To meet physical demands, teenagers have a relatively greater oxygen consumption, higher heart and respiratory rates, and decreased cardiac stroke volume. This increases the metabolic cost for endurance activities and reduces the injury threshold in teenagers.

Clinical and Laboratory Evaluation: Preparticipation Screening

The preparticipation screening is a comprehensive medical and athletic history and physical examination that identifies risk factors related to the specific physical demands of intended play. Table 3-9 describes the key elements of the preparticipation physical. Screening can identify disqualifying medical conditions, diagnose previously undetected disease, and suggest interventions that will allow successful sports participation. Screening for factors associated with a high rate of injury may help avoid serious morbidity. The specifics, performance, and value of the preparticipation physical examination vary widely. Reportedly, it disqualifies the athlete or requires modification of the sport in 3.4% of junior high school athletes, 15.4% of high school athletes, and 33.9% of college-age athletes, with an overall disqualification rate of about 1.7%.

TABLE 3-9

Key Elements of Preparticipation Screening

History	*Physical Examination*
Medical history	Height, weight, and vital signs
History of prior injury	Limbs and trunk:
Details of training and play	Posture
Identification of risk factors	Range of motion
	Strength
	Cardiac screen
	Abdominal assessment

History

Key elements of the medical history include details regarding prior injury and treatment, general medical status, and the athlete's past performance. Training schedules, frequency of competition, and the number of years of play are noteworthy. The history can help the physician obtain a sense of the athlete's level of competitiveness and identify external pressures (from peers, coaches, or family) to which the athlete is subjected. It is important to note any sports-related goals such as securing a college athletic scholarship or playing in a professional league.

Questions about previous loss of consciousness or changes in memory, behavior, and personality are appropriate. Any prior surgery, allergies, exercise-induced asthma, medications, family history of sudden cardiac death, menstrual history, and lifestyle assessment (e.g., nutrition, substance abuse, performance anxiety) should be part of the athlete's medical record (Table 3-10).

Ambient factors such as temperature, humidity, or altitude as well as the specific challenges of athletic play, equipment, or the playing field that can present a hazard to the athlete should also be identified at this visit.

Physical Examination

The physical examination should begin with an assessment of posture. Check symmetry at rest and during movement (static and dynamic symmetry). Abnormalities in posture, alignment, limb girth, or trunk contour help provide a focus for the examination. The examination addresses strength, range of motion (ROM), and quality of motion. ROM should be full and smooth and proceed at a normal rate. Examine the neck, trunk, and joints of upper and lower extremities for ROM and strength. Look for swelling, tenderness, crepitus, or deformity. Whenever practical, direct observation of the athlete performing specific sport tasks can be very helpful.

Obtain the adolescent's height and weight. An overweight or obese adolescent is at twice the risk of injury (and at three times the risk for ankle injury) than their normal-weight peer. Perform an abdominal examination and check for organomegaly; this may help identify the risk for heat exhaustion or visceral injury during contact sports. The blood pressure and pulse rate, along with cardiac auscultation for murmurs or arrhythmia, generally suffice for cardiac screening. Further cardiovascular screening, such as exercise stress testing, remains controversial.

Laboratory Evaluation

If anemia is suspected in the female athlete on the basis of history (e.g., menorrhagia) or examination (e.g., pale conjunctiva or mucosa, delayed capillary refill), check the hemoglobin/hematocrit. No other laboratory studies are generally necessary. In special circumstances an athlete may be screened for doping (autologous transfusion to increase hemoglobin or hematocrit), steroid, or other drug use.

Imaging—generally plain films or magnetic resonance imaging (MRI)—is useful if there is a particular need to further assess bone or soft tissue, although most diagnoses can be made on a clinical basis.

Management

A knowledge of the demands of a particular sport allows the health care practitioner to work with athletes and coaches to develop strategies that minimize injury risk and, ideally, optimize performance. The generic management of adolescent sports injuries may be viewed as a three-staged intervention. The earliest effort seeks to

TABLE 3-10

Contraindications to Sports Participation

Relative Contraindications
Exercise-induced angina, syncope, family history of sudden cardiac death, exercise-induced arrhythmia, mitral regurgitation, or prior embolic event
Atlantoaxial instability (especially juvenile rheumatoid arthritis or Down syndrome) (contact or partial contact sports)
Coagulopathy
Detached retina
Fever or acute illness
Repeated spine or brain trauma with residual deficits
Conditions Requiring Restricted Contact or Other Accommodation
Congenital absence of one kidney
Cystic fibrosis
Acutely enlarged spleen

prevent injury. Education by the health care provider can help balance the emphasis placed on repetition and performance by trainers and coaches. Suggestions for maintaining strength and flexibility, warming up and cooling down, or managing minor aches and pains are valuable contributions that reduce injury and enhance athletic performance.

SPECIFIC TYPES OF SPORTS-RELATED INJURIES

MUSCULOSKELETAL INJURIES

Musculoskeletal injuries are the leading cause of morbidity in adolescent athletes. Although the growing skeletal system of adolescents is highly vulnerable, the preponderance of injuries involves muscles, ligaments, tendons, and bursae. Both osseous and soft tissue injuries occur more frequently during periods of rapid growth.

Sprains, strains, tendonitis, and muscle pain are the most common injuries affecting the adolescent athlete. Because these injuries correlate with the patterns of physical demand, they stratify according to sport. Low back pain, stress fractures, and compartment syndromes are less common injuries that must be identified to avoid long-term sequelae.

Pathophysiology

Sprain (tendon tear) and strain (a tear of muscle), as well as tendinitis, bursitis, and certain stress fractures result from cumulative trauma or direct trauma.

There are two patterns of tissue response to trauma: irritation/inflammation and loss of tissue integrity (e.g., laceration or fracture). Lesions of muscle, tendon, joint capsule, and bursa characteristically manifest as pain, swelling, erythema, and guarding as a consequence of inflammation. Muscles, ligaments, and tendons may tear, and bones may fracture. In these instances, the clinical presentation is usually more pronounced. When the injury is chronic or recurrent, long-term changes may become evident. These include shortening or incompetence of muscle, ligaments, and capsules with segmental changes in posture, instability, and degenerative joint disease.

Growing articular cartilage, as well as the physis and epiphysis of long bones, is especially vulnerable to both macrotrauma and microtrauma. During periods of accelerated growth (growth spurts), this vulnerability is greatest. Because skeletal maturity does not occur until late adolescence or early adulthood, the growth plates of young individuals are susceptible to injury. Until about 24 years of age, the strength of joint capsules and ligaments exceeds that of bone, which explains the unique collection of epiphyseal fractures and osseous avulsion injuries seen in adolescent athletes. In addition to fractures of the epiphysis and physis (Table 3-11), stress fractures of the spine, spondylolysis, and metacarpal bones have been reported in adolescent athletes.

TABLE 3-11

Salter–Harris Fracture Classification

Salter Classification	*Description of Fracture*
I	Epiphyseal separation from the metaphysis without bony fragment
II	Line of separation extending along physis and through portion of metaphyseal bone; metaphyseal bone fragment is seen (Thurston Holland sign)
III	Intra-articular fracture of the epiphysis, with cleavage plane extending from joint surface to physis and parallel to growth plate
IV	Fracture line beginning at articular surface, extending through epiphysis and segment of metaphysis
V	Crush injury of epiphysis

Significant joint disease can occur as repetitive wear of articular cartilage exposes joint surfaces. Osteoarthritis of the knee has been demonstrated in 50% of soccer players after 5 to 15 years of competitive play and may potentially affect late adolescents. Injury and subsequent degenerative change can be seen in the proximal interphalangeal joints of some teenage volleyball players.

Clinical and Laboratory Evaluation

History

Knowledge about an athlete's sport is important to both the prevention and understanding of the pathomechanics of injury. Sports may be classified as full contact (or impact), limited contact, or noncontact. The clinician should ask questions concerning the degree and type of effort involved in play: Do the necessary muscle contractions require a large or small degree of force? Is this force sustained or explosive? How long is this force applied? It is important to identify the set of movements required for play, the joints involved and the required ROM, the demands for flexibility, and whether the activity involves repetitive movement or exposure to excessive external force. Upper extremity injuries such as shoulder tendinitis and impingement and elbow/forearm epicondylitis or myositis most commonly result from repetitive motion. Lower extremity injuries from running may result from repetitive motion, whereas basketball injuries are often related to intermittent, explosive lower extremity use. Sprains, strains, and stress fractures of the foot, ankle, and knee, along with other lower extremity injuries, typically result from this type of trauma.

Physical Examination

Identify the joints involved and assess their ROM, strength of related musculature, and the athlete's overall endurance and flexibility. If possible, observe the specific activities of play and look for guarding, asymmetry, and the quality of motion. Note any swelling, tenderness, or ecchymosis (an indication of tissue disruption).

Pediatric Pearl: Osseous or articular pathology is painful with compression (pushing along axis), whereas ligament and tendon injuries are more painful with distraction (pulling).

Laboratory Evaluation

Joint instability, locking or buckling of a joint, crepitus with movement, or persistent pain on weight bearing may require imaging studies for precise diagnosis. Plain radiographs are appropriate initially.

Management

Treatment of acute injury follows the RICE protocol: **r**est, splint, or cast; **i**ce; **c**ompression or support; and **e**levation. The use of nonsteroidal anti-inflammatory agents or local corticosteroid injection should be considered.

If tissue disruption is suspected (e.g., fracture, tear of tendon or ligament), imaging or orthopedic referral for surgical evaluation is appropriate. If strength or sensory deficits are apparent, referral for neurologic evaluation is important.

During the subacute stage of management (week 2 to 4 after injury), bracing, taping, or splinting may provide stability or support to an injured body segment. Physical therapy can train the athlete in a balanced therapeutic exercise program of strengthening, stretching, and "work hardening." Repeated counseling about beneficial and harmful activities may be helpful. Involving athletes as well as coaches or trainers in setting goals and planning therapy is effective. The chronic stage of care focuses on modification of equipment, training, or competition strategies. Individualization of care is necessary for each athlete and injury.

NEUROLOGIC INJURIES

Central nervous system trauma affects the brain or spinal cord. Serious neurologic injuries are more common in athletes older than 12 years of age compared with younger children. The incidence of spinal cord injury increases dramatically between 15 and 18 years of age, and 4% to 14% of the reported spinal cord injuries occur as a result of participation in football, gymnastics, wrestling, or diving. Unfortunately, 30% to 50% of these injuries involve the cervical spine and result in quadriplegia and severe disability. The literature regarding closed head or traumatic brain injuries, concussion-related disorders, and postconcussion syndromes is extensive. Head trauma may affect performance, either physical or cognitive, and behavior (Table 3-12). One-fourth of all high school football players suffer a concussion each football season.

Fortunately, adolescent athletes more frequently sustain a less severe neurologic injury—the "burner" or "stinger." This injury is very common in high school and college athletes who play football, basketball, or hockey, or who engage in wrestling or weight lifting; in football players, it has a reported lifetime incidence of 18% to 65%. The condition is usually self-limited, but recurrences are common. With multiple recurrences, a permanent neurologic deficit may result.

Pathophysiology

Neurologic lesions can result from traction or compression. Axial compression of the spine when force is applied to the head with the neck in flexion may lead to quadriplegia. In "burners" or "stingers," damage to the C5 or C6 nerve roots, the brachial plexus upper trunk, or a peripheral nerve occurs. Most of these lesions result in neurapraxia, and they resolve if the athlete is not subjected to additional trauma.

Clinical and Laboratory Evaluation

History

Complaints of weakness, paresthesia (usually tingling in nature), decreased or altered sensation, or burning pain suggest neuropathology. A history of forced head flexion, traction on an abducted arm, or trauma to a peripheral nerve warrants further evaluation of the neurologic system (Table 3-13).

Physical Examination

Check muscle strength, light touch and position sense, tendon reflexes, motor control and coordination, and cognitive status. Between 15% and 20% of spinal cord injuries are spinal cord injuries without radiographic abnormality. The diagnosis of these injuries is made on the basis of clinical findings alone.

TABLE 3-12

Long-Term Sequelae of Repeated Head Trauma

Cognitive Sequelae	*Behavioral Sequelae*	*Motor Sequelae*
Memory loss	Emotional lability	Motor apraxia
Impaired learning	Disinhibition	Balance deficit
Dementia	Aggression or apathy	Other movement disorders

TABLE 3-13

Postconcussion Syndrome

History	*Signs/Symptoms*
Head trauma within 6 months	Attention deficits[a]
Loss of consciousness at injury	Memory deficits[a]
Posttraumatic amnesia	Rapid fatigue Disordered sleep Headache Dizziness Irritability Anxiety Depression Change in personality Apathy

[a] Required symptom.

Athletes who have suffered a concussion warrant evaluation for antegrade and retrograde amnesia (Table 3-14). Assessment should include the athlete's ability to understand and respond appropriately to questions; orientation to person, place, and time; and the presence of headaches or dizziness. With loss of consciousness due to head trauma, there may be an associated spinal injury.

Laboratory Evaluation

Any injury resulting in hypesthesia, paresthesia, weakness, or altered consciousness necessitates further evaluation. MRI (of head or spine) is the imaging study of choice. However, if the suspected injury is close to bone, computed tomography (CT) provides the best assessment. Electrodiagnostic studies (e.g., electromyography [EMG], nerve conduction testing, evoked potentials) may provide insight into lesion location, severity, and prognosis when performed at least 10 to 14 days following injury.

Management

Management initially follows the RICE protocol, with splinting and bracing as needed. In most instances in which there is an apparent neurologic deficit, timely neurologic consultation is essential (see Table 3-14).

TABLE 3-14

Concussion Severity and Activity Guidelines

Concussion Severity	*Return to Play*	*Termination of Season*
Mild (grade I): no LOC	After being asymptomatic for 1 week; if second concussion, after 2 asymptomatic weeks	Third concussion
Moderate (grade II): LOC < 5 minutes or PTA > 30 minutes	After being asymptomatic for 1 week; if second concussion, after 1 month of rest (must remain asymptomatic during play)	Third concussion
Severe (grade III): LOC > 5 minutes or PTA > 24 hours	1 month rest (must remain asymptomatic during play)	Second concussion

LOC, loss of consciousness; *PTA*, posttraumatic amnesia.

CATASTROPHIC INJURY

Catastrophic (emergent or life-threatening) injuries in adolescent athletes may occur, although they are uncommon. Direct contact or projectile contact trauma results in a wide range of injuries, including ophthalmologic emergencies. Emergent eye injuries result in about 40,000 emergency department visits per year.

Pediatric Pearl: Eye injuries are much more common in adolescent athletes than in adults.

The risk is greatest in baseball and basketball, followed by racket sports, hockey, combat sports, darts, archery, wrestling, the martial arts, and boxing. There are reports of sudden death due to chest wall trauma in adolescents competing in baseball. Reports of similar injuries in hockey, lacrosse, and softball are less common. Pneumothorax has been associated with running, tennis, golf, bicycling, wrestling, weight lifting, and rowing.

Most sudden deaths affect male athletes. The highest rates occur in football, with nontraumatic deaths due to cardiac causes and thermal injury, and traumatic causes relating to head and neck trauma. Sudden cardiac arrest is the leading cause of atraumatic death in adolescent athletes and can be the result of underlying cardiovascular disease (hypertrophic cardiomyopathy and congenital coronary artery anomalies being the most common). Careful screening (i.e., preparticipation physical examination) should identify adolescents who are at risk prior to sports participation (see Table 3-10). On-field automated external defibrillators should be available whenever possible as cardiac risk, albeit uncommon, may not have been identified during preparticipation screening.

Pediatric Pearl: Suspect sudden cardiac arrest in any event of collapse and unresponsiveness.

ADOLESCENT SPORTS MEDICINE AND CHRONIC DISEASE

Although adolescents with chronic disease may require close medical supervision for participation in competitive or recreational sports, they potentially derive substantial health benefits and pleasure from the experience. Exercise may be an effective part of the treatment plan for teenagers with diabetes mellitus, asthma, hypertension, and obesity. For these athletes, strategies to minimize risk and maximize performance are important. It is important to frequently monitor the serum glucose of adolescents with diabetes who participate in endurance activities until a baseline of glucose variation during play is established. The majority of athletes with asthma have exercise-induced disease, which may require premedication.

Exercise and sports play may not improve other conditions such as sickle cell disease, which requires careful attention to hydration and fatigue. However, with adequate medical supervision and care, affected adolescents can still participate and derive the cardiovascular, neuromuscular, respiratory, and psychosocial benefits associated with sports participation.

Adolescents with disabilities constitute a special category of athlete. Organized and supervised team and individual sports, wheelchair sports, or other athletic programs available to the athlete with disability can readily be identified on the Internet.

Principles of Pediatric Nutrition, Fluids, and Electrolytes

*Steven P. Shelov and Frederick J. Kaskel**

PRINCIPLES OF PEDIATRIC NUTRITION

This section of the chapter introduces medical students to the elements of nutrition and feeding of young infants and children that are useful beginning with the first interaction with parents. Often the discussion of optimum feeding practices begins at visits before an infant is born, with discussions about the advantages of breast-feeding versus bottle-feeding and what to expect in the first few days of the newborn's life. **These interactions are not just fruitful for establishing confidence and trust with parents, they are also a source of great satisfaction for pediatricians.**

In addition, this section also outlines the specifics of breast-feeding and formula-feeding in infancy, when and what to introduce as solid foods in the latter half of the first year, and elements of nutritional advice for toddlers and preschoolers. It also gives a brief overview of nutritional goals for school-age children. Several accessible, supportive references, listed at the end of this chapter, provide more complete information about any of these topics and can serve as resources for pediatricians and parents. **In addition, the American Academy of Pediatrics (AAP) maintains an active Web site (http://www.AAP.org), which is a source of continually updated nutritional advice.**

Breast-feeding

After a number of years, it now appears that the message that breast milk is the optimum food for infants is more effectively reaching professionals and parents. As recently as 10 years ago, fewer than 50% of new mothers stated that they were intending to breast-feed their new baby; most recent estimates now place this percentage at somewhere near 60% and apparently climbing. The AAP, longtime advocates for breast-feeding as the preferred method of infant nutrition, urges all of its 55,000 member pediatricians to reinforce this message at every possible encounter. It appears that the increasing percentage of women choosing this method of feeding their infant partially reflects a positive response to this strongly worded message.

Facts about Breast Milk

What are some of the advantages of breast-feeding? It is important to share several specific facts about breast milk and breast-feeding with new or expectant mothers:

- The nutritional components of breast milk, the carbohydrate (the sugar is lactose—a disaccharide of glucose and galactose), the protein (whey and casein in an 80:20 ratio), and the fat (cholesterol and a mixture of other triglycerides of varying lengths), are all of human origin and extremely well tolerated.
- The caloric content is 20 kcal/oz, ideal for the quantity ingested relative to weight.

We would like to acknowledge Charles L. Stewart, MD, for his contributions to the first edition of this chapter.

"Principles of Pediatric Nutrition" was written by Steven P. Shelov.

"Parenteral Fluid and Electrolyte Therapy" was written by Charles L. Stewart and Frederick J. Kaskel.

- Breast milk is less allergenic because the protein components (whey and casein) are human-based, not cow- or soy-based. This is significant, because cow's milk protein intolerance has been associated with eczema, allergy-mediated diarrhea and vomiting, colic irritability syndrome, and microscopic blood loss in the gastrointestinal (GI) tract.
- The presence of protective bacteriophagic elements, including macrophages and antibodies, is an important factor. In addition to local antibody (immunoglobulin A [IgA]) contributing to GI immunity as well as additional antiviral immunity (against poliomyelitis and influenza), the normally present macrophages in breast milk can synthesize complement, lysozyme, and lactoferrin, with the latter acting as an inhibitor to *Escherichia coli* growth in the intestine.
- Through its lower pH, breast milk contributes to a greater degree of lactobacillus growth in the intestine, which also may be protective against certain pathogenic intestinal bacteria (e.g., *E. coli*).
- Breast milk contains sufficient iron stores for at least 6 months and sufficient vitamin D and fluoride for at least 4 months.
- Breast milk is readily available and an important part of close bonding and maximal contact between the mother and her infant. The psychologic benefits of being able to provide the caloric sustenance through physical contact cannot be overemphasized. Breast-feeding on demand not only fulfills the infant's nutritional needs but also the baby's and mother's nurturing and skin contact needs.

Pediatric Pearl: Contraindications to breast-feeding include mastitis, severe fissuring or cracking of the nipples, and the need for pharmacotherapy (certain medications that enter breast milk and negatively affect the infant) (Table 4-1). However, for the most part, these contraindications occur very infrequently.

The Feeding Process

There is little need for special preparation of the breasts. Excessive nipple preparation or skin softening creams are only potentially injurious and sensitizing. In the first 2 to 3 days postpartum, the breasts secrete a thin, orange-tinted substance called colostrum, which is an electrolyte-, macrophage-, and nutrient-rich substance with a premilk composition. Colostrum is an extremely important component of the initial feeding experience of the newborn infant. With nursing taking place every 2 to 3 hours, the true milk supply usually comes in (i.e., milk is "let down") at about the third day postdelivery. The mother knows when this is happening because the breasts feel full, even engorged, quite quickly. It is most important that even with this initially slightly uncomfortable feeling, infants be encouraged to feed at 2- to 3-hour intervals to keep the milk flowing and to provide the continued stimulus for ongoing milk production.

At first, the feeding process is often a bit awkward but very quickly becomes comfortable and relaxed. Although the mother is either sitting or lying down, the infant is held and the face is brought directly facing the breast (Figure 4-1). Using the rooting reflex, the baby **latches onto the areola portion surrounding the nipple** and begins to suck (Figure 4-2). The sucking action is really a compression-milking action in which the milk is squeezed from the ductules into the ducts and then through the nipple into the baby's mouth. The infant may suckle in bursts and then take pauses in between. The first feedings usually last 5 to 10 minutes, usually with 5 minutes on each breast. **It is important that each feeding start on the breast on which the infant last nursed.**

In the course of the first month, the length of time for each feed, given a 2- to 3-hour interval between feedings, increases quickly to 20 to 30 min/feeding. Parents often want to be sure that the baby is getting enough milk. To reassure them that everything is going well, the clinician should ask the following questions: Is the infant wetting between four and six diapers each day? Is the infant gaining weight adequately? After each feeding, does the infant appear to be satisfied, or does the baby appear hungry by crying vigorously and sucking frantically on a fist? If there is any doubt about milk supply, it is often a good idea for the pediatrician to see the baby at about 2 weeks of age to be sure that the child has at least regained her birth weight.

The 2-week visit is also a good opportunity to talk to the parents about any problems they might have been experiencing and to support their efforts during these expectantly stressful times. Reassurance and support go a long way during these fatiguing and, at times, seemingly endless times of stress of the first weeks. Parents often need to hear several times how well you, the pediatrician, think things are going. **This period is often quite stressful for the new mother,** especially the first-time parent, because breast-feeding is not yet completely established, and there is often a high degree of anxiety focused on the feeding process. It is crucial that pediatricians support the mother's positive

TABLE 4-1

Effect of Maternal Drugs on Breast-fed Infants

Drug	*Effect*	*Comment*
Amoxicillin	None	Safe
Antimetabolites	Carcinogenic	Contraindicated
Aspirin	Rare complication of bleeding	Usually safe
Atenolol	None	Probably safe
Bromocriptine	Suppresses lactation	Avoid
Carbamazepine	Unknown	Probably safe
Cascara	Colic, diarrhea	Avoid
Chloramphenicol	Gray baby syndrome	Contraindicated
Codeine	Lethargy	Usually safe
Diazepam	Lethargy, apnea	High doses contraindicated
Digoxin	None	Safe
Ergot	Gangrene, vasospasm	Contraindicated
Furosemide	None	Safe
Gold salts	Hepatonephrotoxicity	Contraindicated
Meperidine	Lethargy	Avoid
Methimazole	Hypothyroidism	Contraindicated
Metoprolol	None	Probably safe
Metronidazole	Carcinogenic	Contraindicated
Phenindione	Hemorrhage	Contraindicated
Phenobarbital	Lethargy	Usually safe
Phenytoin	Usually none	May not be recommended
Prednisone	None	Probably safe
Propoxyphene	Lethargy	Usually safe
Propranolol	None	Probably safe
Propylthiouracil	Usually none; rare goiter	Probably safe
Radioactive material	Carcinogenic	Discontinue breast-feeding 1–2 wk
Tetracycline	Discolored teeth	Contraindicated

Adapted from Behrman RE, Kliegman RM: Nelson's *Essentials of Pediatrics*, 2nd ed. Philadelphia, WB Saunders, 1994, p 61.

attitude about her ability to breast-feed her baby successfully. Supportive literature or personnel (a doula or breast-feeding expert is a great resource) help the new mother through these often stressful first weeks. Often, previously successful breast-feeding mothers are great referrals for new mothers who may be struggling a bit with the process.

It is also important to remember that maternal fatigue is a major counterproductive force to establishing successful breast-feeding. The mother should get as much rest as possible and have help around the house with other chores. Minimizing fatigue allows her to relax more easily, and a relaxed mother can concentrate on the needs of both herself and her infant. It is essential to reduce such major disruptions as maternal fatigue, anxiety,

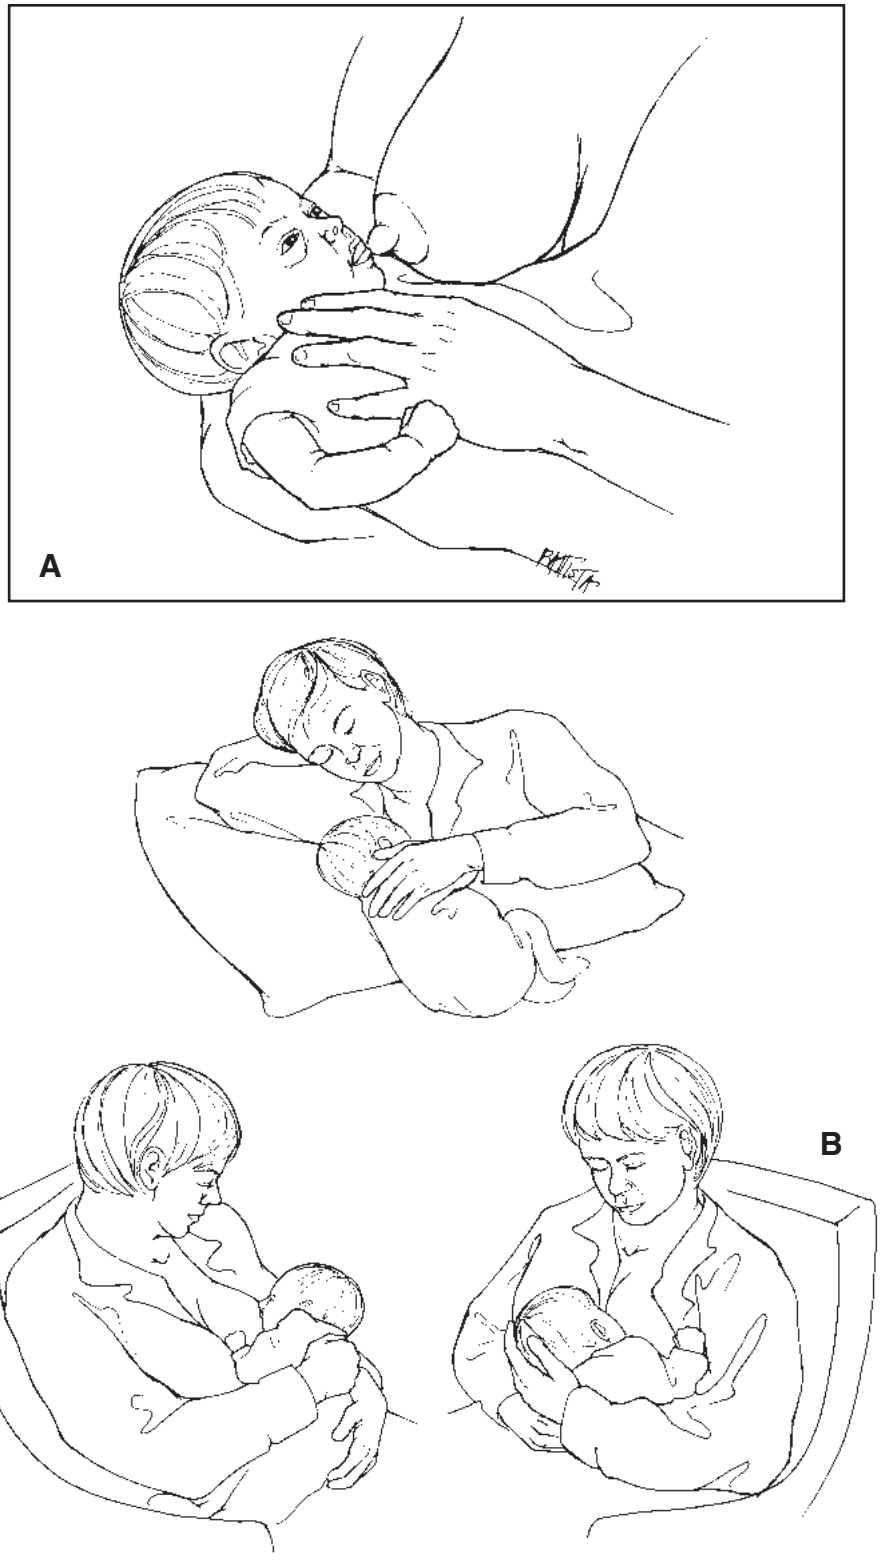

FIGURE 4-1. **(A)** The infant instinctively latches onto the nipple and begins to suck. **(B)** Different feeding positions. The infant's entire body, not just the head, should be facing the mother's body. From *Caring for Your Baby and Young Child: Birth to Age 5* by Steven Shelov and Robert E. Hannemann, copyright 1991 by American Academy of Pediatrics.

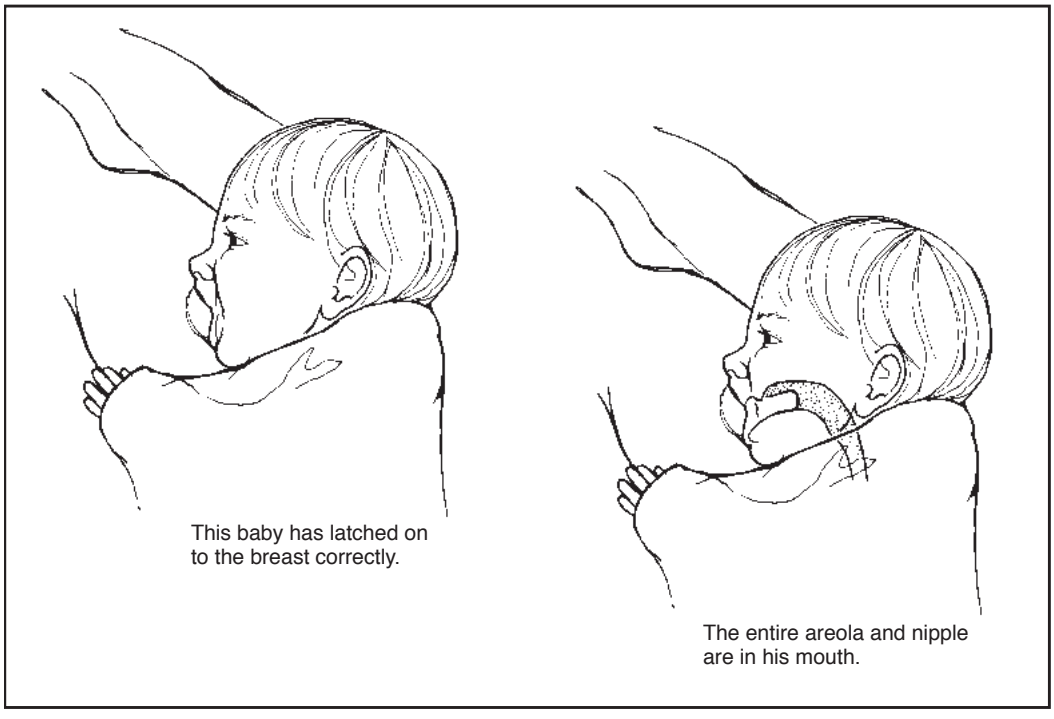

FIGURE 4-2. Latching on process. From *Caring for Your Baby and Young Child: Birth to Age 5* by Steven Shelov and Robert E. Hannemann, copyright 1991 by American Academy of Pediatrics.

and tension to ensure successful breast-feeding, and the pediatrician and the family can often creatively develop methods to accomplish these goals.

Breast-feeding is usually well established by the end of the first month. The routine is nursing every 3 hours or so with each feeding lasting around 30 minutes. It is reassuring to know that the majority (80%) of the milk at each feeding is probably consumed in the first 5 minutes of the feeding. This should help relieve some of the anxiety experienced when parents say that often their baby falls asleep after 10 or 15 minutes at the breast. Reassurance with continued good growth of the infant further helps reinforce the success of the breast-feeding, but the pediatrician must always remember that the need for such reassurance is often ongoing, especially in the first several months of the new baby's life.

Pediatric Pearl: In many instances, the breast-feeding process does not go well for many reasons, such as personal choice, difficulty with the process, and unrelenting anxiety about the baby "not getting enough milk." When these signs appear, provide further counseling and offer referral to a lactation specialist. A 2- to 4-week trial is usually sufficient to know whether breast-feeding is going to work for the mother and infant.

If breast-feeding continues to be "difficult" or anxiety-provoking, the optimum strategy is formula-feeding with equally justified support from the family and pediatrician. It is most important that the mother, especially a first-time mother, not be made to feel guilty about the switch. Many mothers feel the need to do this. Once the baby is on formula, both the baby and mother find greater satisfaction—the desired goal of any feeding process.

Formula-feeding

Formula is commercially prepared cow's milk–based infant feeding. For a variety of reasons, a large number of mothers (40% of new mothers by some estimates) choose not to breast-feed their new babies. There are some advantages to formula-feeding that some families find compelling and, as a result, would prefer to use it for their infants.

Facts about Formula

The excellent alternatives available to breast milk have become increasingly more sophisticated and more "breast milk–like." Fortunately, these preparations have been designed to be similar enough to breast milk and yet available in a variety of safe and easy-to-use formulations that they may serve as perfectly acceptable alternatives to breast milk as the basic nutritional source for proper infant nutrition. The three basic components of milk in formulas—carbohydrate, protein, and fat—are similar to those found in breast milk, although not totally identical. Formulas vary in terms of their exact composition (Table 4-2).

What are some of the more general similarities and differences?

- Both provide the same caloric content, approximately 20 kcal/oz (0.67 kcal/mL).
- Both breast milk and regular formula (those marketed as Similac [Ross Laboratories], Enfamil [Mead Johnson], SMA [Wyeth], Good Start [Carnation], and Gerber's) contain the **disaccharide** carbohydrate lactose (glucose and galactose).
- Both contain whey and casein as the principal proteins. Different formulas have varying whey:casein ratios, although all are less than the 80:20 ratio seen in breast milk. In addition, the protein in formula is cow's milk–based protein and not human, and although it has been hydrolyzed and altered somewhat to make it more digestible and potentially less allergenic (different brands do different things to the protein), the continued presence of cow's milk–based protein might trigger a sensitivity or allergy in those rare infants who might be allergic to cow's milk protein. For such situations, there are formulas available with a soy protein base that provide perfectly suitable nutrients for optimum growth.
- Both contain fats, but in formula, once the cow's milk is skimmed of all animal fat, which is quite poorly digestible, a variety of vegetable oils are added, including corn, coconut, and safflower oil, depending on the brand.
- In soy protein formulas, the protein is soy-based and not cow's milk–based, and the sugar is a corn syrup and sucrose, not lactose. Therefore, this type of formula is useful in lactose-intolerant situations and in which milk protein intolerance may be suspected.
- The mineral contents are variably different from breast milk (see Table 4-2). However, each formula contains iron and vitamin supplements, eliminating the need for any additional supplementation in the first 6 months and in the latter half of infancy, as long as the infant is then given additional sources of iron-containing food.
- Fluoride supplementation remains controversial. The Committee on Nutrition of the AAP does not recommend fluoride supplementation for breast-fed or formula-fed infants from birth to 6 months of age, regardless of the fluoride concentration in the community water. Currently, fluoride supplementation is recommended for children 6 months of age and older (Table 4-3).

The Feeding Process

Formula is available in three basic preparations. The most frequently used is a concentrate form, which requires an equal amount of water to be added to reconstitute it to full strength suitable for feeding to infants. The "ready-to-feed" preparations in various-sized bottles and cans are just that, ready to feed, but are more expensive; parents are basically paying for water. The availability of small (4 to 6 oz), ready-to-feed bottles that are very useful for travel or middle-of-the-night purposes are handy but are expensive as a regular, everyday procedure. Finally, many of the formula preparations come in a powder form that is also convenient for travel and comes with an easy-to-understand measuring spoon or scoop.

In the past, the AAP had recommended terminal heating for formula preparation in the first 3 months. This is no longer viewed as necessary given the safe nature of the water supply throughout most communities in the United States. Certainly, this method should be used in any household in which the risk of contamination of food is a reality.

In general, new infants are fed every 3 to 4 hours and take about 2 to 4 oz/feeding in the first several weeks. From the third week on, the feedings are increased in amounts (4 to 5 oz at a time) and generally follow a certain pattern (see Table 4-4). During the first 2 to 3 months, feeding usually continues every 4 hours or so through the night. Once infants are about 3 months of age, the evening feedings may be slightly increased in quantity to allow for a longer time between the late evening feeding and the early morning feeding, allowing the mother and infant (and father) to get a little longer stretch of continuous sleep. This first night that an infant "sleeps through the night" is usually heralded with much relief. The total amount of feeding per day usually approximates 150 mL/kg, which allows for approximately 120 kcal/kg, sufficient for good growth of the infant through these early months.

TABLE 4-2

Composition of Breast Milk and Infant Formulas

Homemade Formula

A small number of families continue to make formula from whole cow's milk rather than use commercially prepared formula. If this is the case with your patient, the recommendation is to use only evaporated milk (not condensed milk). An easy way for parents to prepare milk-based formula is the following:

1. All utensils required for mixing and storing of formula should be sterilized by boiling in water for 5 to 10 minutes.
2. Rubber nipples and caps should be boiled for no more than 5 minutes.
3. Wide-mouth glass bottles and a thoroughly cleaned quart (32 oz) bottle are easiest to use.
4. After thorough cleaning of the quart bottle, pour in 1 can (13 oz) of evaporated milk. Fill the remainder of the jar with tap water. Then add 2 tablespoons of cane sugar or 4 tablespoons of Mead's Dextrimaltose. Stir well.
5. Pour the formula, once made, into bottles as in the steps above and terminally heat. This will make enough formula for 1 day of the infant's needs. Each supply must be made no more than 1 day at a time.

Second 6 Months of Life: Introduction of Solid Food

Breast-feeding or formula-feeding should continue throughout the second half of the first year of life. Numerous studies have indicated an intolerance to whole cow's milk when ingested by infants under 1 year of age. This intolerance has resulted in occasional episodes of vomiting, diarrhea, and, most significantly, occult blood loss through the GI tract, resulting in an iron deficiency state.

Beginning at about 5 to 6 months of age, additional foods usually supplement nutrition provided by breast- or formula-feeding. The first food usually recommended is iron-fortified, single-grain infant cereal. This cereal, especially prepared for infants, can be rice, barley, or any other single grain. Initially, 3 to 4 level tablespoons can be diluted with

TABLE 4-4

Average Quantity of Feedings

Age	*Average Quantity Taken in Individual Feedings*
1st and 2nd week	2–3 oz (60–90 mL)
3 weeks–2 months	4–5 oz (120–150 mL)
2–3 months	5–6 oz (150–180 mL)
3–4 months	6–7 oz (180–210 mL)
5–12 months	7–8 oz (210–240 mL)

6 parts of breast milk or formula (about 108 kcal/dL) and fed to infants with a small baby spoon. Most often, this solid food supplementation is reserved for two feedings a day, but as additional solid foods are introduced, they can be spaced out into any of the feedings. The first feeding with the spoon is also a pretty sloppy affair, so parents should be warned to be prepared with lots of bibs and plastic on the floor. It takes a short while for infants to adjust.

After the introduction of cereals, additional specially prepared baby foods are introduced, one at a time, and again fed with a spoon. Although many parents have a tendency to put cereal and other foods into the bottle, this is not recommended; the potential for overfeeding of higher caloric dense solids is a common result. Strained fruits contain 45 to 70 kcal/100 g; strained vegetables, 25 to 65 kcal/g; and meat, 90 to 140 kcal/g. Some studies indicate that the addition of larger amounts of solid foods than calorically required can be one factor in the early predisposition to obesity later in childhood.

Toward the latter several months of the first year, the strained foods are generally less pureed and offered as "junior foods." However, as these commercially prepared baby foods are expensive and offer no advantage over homemade, freshly prepared and pureed foods, parents can certainly feel comfortable preparing their own foods for older infants, taking proper caution to keep all food preparation clean.

Feeding after the First Year: More Solid Food

With the beginning of the second year of life, infants become more mobile and active and motorically more facile. This means the feeding process is also a more active one. During this time, children show initiative with feeding, have food preferences, and have erratic food volume intakes, even from day to day. Unpredictable in their food choices as in their other activities, they may have a "favorite" meal one day and reject it totally the next day. They love to feed themselves; although self-feeding is often messy and disruptive, it should be encouraged.

They usually eat three meals and two snacks a day. In addition, their milk drinking (whole cow's milk is now acceptable, although 1% to 2% can be used after the second year) has generally been shifted to a cup that they can hold (unless, of course, they are still breast-feeding). With the addition of table foods at all of the meals, milk no longer occupies such a central place in the diet.

Pediatric Pearl: One guideline for milk volume per day is to never allow more than 1 quart of milk. If a child is drinking more than this, a loss of interest in other types of foods may result, and a risk for nutritional deficiency could occur.

The diet should include foods from all the different food groups, and parents should match the degree of chewing required to children's ability to chew. It is most important *not* to allow foods that require too much chewing; the risk for choking is probably greatest at this age. The basic food groups are:

- Dairy products—milk, yogurt, cheese, and milk products
- Meat, fish, poultry, eggs, and legumes
- Vegetables
- Fruits
- Cereal grains, breads, pastas, and rice

It is not necessary that children have representatives of all the food groups every day, but they should be in the diet at least two to three times per week. Although foods that are low in fat and cholesterol are recommended for adults, the AAP agrees that fat and cholesterol should not be limited until after 2 years of age.

The nutritional requirements of children in the preschool and school-age years are less specific and more reflective of the daily activities, personal and family likes and dislikes, and overall taste preferences. Regular meals, especially breakfast, are important not only as nutritional activities but also as social and family activities. In general, children's eating routines are integrally involved with the family. Continued attention to foods from the different food groups should guide nutritional food preparation, and now a greater watchfulness over the fat and cholesterol content of the diet should be a determining factor. There is no need for more than three cups of milk per day as a calcium source, and other milk and vegetable sources of calcium can consistently be ingested that are also sufficient.

It is also important to try and resist the natural temptation to replace some of the previously, established, sound eating principles with high-calorie snacks and fast foods. The eating of these foods is inevitable to some degree; ease, availability, and peer pressure are often hard to resist. It should occur as infrequently as possible. Even with the increased energy needs of children during the preschool and school-age years, the calories from

a more balanced diet are sufficient, and variations on those early dietary principles can be limitless and still maintain the majority of the good aspects of those early nutritional behaviors and habits. Finally, it is important not to minimize the influence that family and adult dietary habits have on children's determination of their own dietary needs and fancies. Discussions about family feeding and food preparation as a "family health item," by definition, include the children and incorporate them into this most essential part of growing up in the family.

PARENTERAL FLUID AND ELECTROLYTE THERAPY

All infants and children require an adequate intake of fluid and electrolytes to thrive. For most children, this is accomplished without difficulty by oral ingestion of food and fluids. The goals of an organized approach to fluid and electrolyte therapy in children are twofold: (1) to supply fluids and electrolytes used or lost as a result of normal metabolism and (2) to replace or repair abnormalities in fluid and electrolyte balance incurred by a disease process or a behavior. Physicians and other health care professionals should promote, whenever possible, the enteral route of fluid and electrolyte administration; they should reserve parenteral (intravenous) fluid administration for those children who cannot use enteral alimentation for medical or surgical reasons (Table 4-5). A major goal in the treatment plan for most children affected by the conditions listed in Table 4-5 is the resumption of enteral nutrition.

Fluid and electrolyte therapies (both enteral and parenteral) are frequently divided into several categories and subcategories, most commonly "maintenance" and "deficit replacement" phases. The following discussion of deficit fluid therapy focuses on diarrheal dehydration, although many of the concepts discussed apply to other causes of volume and electrolyte deficits as well.

TABLE 4-5

Conditions that May Require Parenteral Fluid and Electrolyte Therapy

Dehydration (see Table 4-10 for causes)[a]
Presurgical and postsurgical procedures Abdominal Neurosurgical Cardiovascular
GI diseases Bleeding Perforation of viscus Inflammatory bowel disease (uncommon)
Electrolyte abnormalities Hyponatremia (severe) (see Figure 4-3) Hypokalemia (severe) Hypernatremia Hyperkalemia
Acute hypovolemia, shock, or both Trauma Sepsis Gastroenteritis Hemorrhage (external or internal)
Metabolic abnormalities Diabetic ketoacidosis

[a] Enteral alimentation is preferred if feasible.
GI, gastrointestinal.

Maintenance Fluid and Electrolyte Requirements

Children admitted to the hospital for any reason are usually on "maintenance" fluids, often unregulated and administered via the oral route. It is necessary to modify this, of course, if they are overhydrated, dehydrated, or have acute renal insufficiency. Before certain surgical procedures, children may need to receive their fluid and electrolyte requirements intravenously, as do children who are in the early stages of recovering from surgical procedures, especially thoracic, abdominal, and central nervous system (CNS) surgery. Children undergoing bowel surgery may require more than maintenance fluids secondary to bowel wall edema or inflammation, also known as "third spacing." CNS surgery occasionally warrants a decrease in the "normal" maintenance fluids to ameliorate possible cerebral edema. Many acute and chronic diseases impair the child's ability to ingest food and water or significantly depress appetite or mental status and may make oral consumption of food and fluids dangerous.

The goal of parenterally administered maintenance fluids is to keep total body water and electrolytes at "even" or "zero" balance; that is, the amount of fluid and electrolytes utilized and expended by the body (through metabolism, growth, losses via skin, respiratory tract, GI tract, and urine output) should approximate the amount given to the child intravenously.

Methods for Estimating Maintenance Fluid Needs

Numerous methods are used to estimate maintenance fluid and electrolyte requirements in infants and children. The two most common techniques are based on either metabolic rate (the "caloric" method) or body surface area (the "per square meter" method). Each of these systems has many variations yielding similar but not the same results, and all methods must be considered estimates of actual requirements. Thus, each patient given intravenous fluid and electrolyte therapies requires frequent reassessment and monitoring and, sometimes, revision of the fluid prescription. This section of the chapter outlines the caloric method of fluid therapy.

The major components of maintenance fluid therapy are insensible fluid losses and urine output, with a small amount of fluid normally lost in feces (Table 4-6). Insensible water losses are related to energy expenditure by the body; under basal (resting) conditions, 45 mL of water are lost for every 100 kcal of energy metabolized per day. Two-thirds of these insensible losses occur through the skin (not sweat, which is an additional **source of insensible loss** of fluid), and one-third occurs via the respiratory tract.

Alterations in respiratory rate, ambient temperature, and inspired humidity may alter these values somewhat (Table 4-7). In general, few or no electrolytes are lost via the insensible route. The additional sources of water loss to account for the maintenance fluid requirements are free water losses in stool and urine. Normal solid stools account for a very small amount of water loss—about 5 mL/100 kcal metabolized (see Table 4-6). Urine output typically varies according to daily amount of fluid and solute intake. This component of maintenance requirements, estimated as 50 mL/100 kcal of metabolic energy, is derived from the amount of urine excreted under basal condition. In the absence of a significant alteration of the glomerular filtrate, its tonicity is close to that of plasma.

TABLE 4-6

Components of Maintenance Fluid Therapy

Water requirements (mL/100 calories metabolized/day)
Insensible Skin = 30 Lungs = 15 Stool = 5 Urine = 50
Electrolyte requirements (mEq/100 calories metabolized/day) Sodium = 2.5–3.0 Potassium = 2.0–3.0 Chloride = 4.5–5.5

TABLE 4-7

Conditions Altering Maintenance Fluid or Electrolyte Requirements and Ongoing Losses

Condition or Problem	*Fluid Adjustment Needed*
Increased metabolic rate	
Fever	Increase caloric estimate by 12% per °C rise in body temperature
Hypermetabolic states (hyperthyroidism, salicylism)	Increase caloric estimate by 25%–50%
Decreased metabolic rate	
Hypothermia	Reduce caloric estimate by 12% per °C fall in fever
Hypometabolic states	Reduce caloric estimate by 5%–15%
Sweat	
Mild to moderate	Increase fluid requirement by 5–25 mL/100 calories metabolized; increase sodium requirement by 0.5–1.0 mEq/100 calories metabolized
Mild to moderate (cystic fibrosis)	Increase fluid as above; increase sodium by 1–2 mEq/100 calories metabolized
Urinary losses	
Oliguria	Adjust fluid allowance to replace insensible losses plus output
Polyuria	Increase water allowance to replace output (may need to decrease dextrose in replacement fluids)
Sodium- or potassium-wasting states	Adjust sodium or potassium to equal losses
Sodium- or potassium-retaining states	Reduce or eliminate sodium or potassium intake

Adapted from Winters RW: *Principles of Pediatric Fluid Therapy*. Boston, Little, Brown & Company, 1982. pp 75, 78.

Pediatric Pearl: The estimate of insensible water losses (45 mL/100 kcal metabolized), when added to stool and urine losses (55 mL/100 kcal metabolized), causes the emergence of a simplified, one-to-one relationship of fluid requirements and caloric expenditure: 100 mL of fluid lost (and therefore required) for each 100 kcal expended.

The estimate of caloric requirements is based on body weight in kilograms, which is reasonable for infants older than several weeks of age (Table 4-8). Children who weigh 10 kg or less expend 100 kcal/kg (and thus require 100 mL of fluid/kg). Infants who weigh between 10 and 20 kg utilize an additional 50 kcal of energy/kg over 10 kg (thus, an additional 50 mL of fluid/kg are necessary). These children thus require 1,000 kcal of energy (or 1,000 mL of fluid) for the first 10 kg and 50 kcal (or 50 mL of fluid) for each kilogram between 10 and 20 kg. Children over 20 kg expend an additional 20 kcal of energy/kg in addition to the 1,500 kcal (or 1,500 mL) required for the first 20 kg (thus, they need an additional 20 mL of fluid for each kilogram).

The caloric method of estimating pediatric fluid requirements also allows for the estimation of sodium and potassium needs. Typically, children need 2.5 mEq of sodium and potassium (as chloride salts) per 100 kcal metabolized (see Table 4-6). If children are dehydrated, net losses of electrolytes along with fluids have already occurred, and it is necessary to estimate these losses and replace them. In addition, it is essential to assess and

TABLE 4-8

Caloric Requirements Based on Body Weight

Body Weight (kg)	*Calories Expended (kcal/kg body weight/day)*
3–10	100
10–20	1,000 calories + 50 per kg for each kg >10
>20	1,500 calories + 20 per kg for each kg >20

replace fluid and electrolyte losses that occur via vomiting, diarrhea, nasogastric tube, and surgical drains (often called "ongoing losses"). Typically, parenteral maintenance fluids are given for a brief period only, and enteral feeding is begun as soon as appropriate. Although clinicians estimate caloric requirements to calculate fluid needs, administered fluids rarely supply more than 20% of estimated caloric needs; if the GI route cannot be used for a prolonged period, consideration of parenteral hyperalimentation is warranted.

CASE 4-1

A 15-kg child requires intravenous fluid for several days following surgery. The child has normal hydration status, normal serum electrolytes, and normal kidney function. Assuming no unusual fluid losses, calculate maintenance parenteral fluid and electrolyte administration for 24 hours.

Maintenance fluids are 1,000 mL (100 kcal or 100 mL/kg body weight for the first 10 kg) plus 250 mL (50 kcal or mL for each kilogram between 10 and 20 kg), which equals 1,250 kcal or mL/24 h. Maintenance electrolytes are 2.5 mEq of sodium and potassium per 100 calories metabolized, with 1,250 kcal metabolized, which equals 2.5 times 12.5 or 31.25 mEq of sodium and 31.25 mEq of potassium to be given in the daily maintenance volume of 1250 mL.

The final 1 L infusion "bag" should then contain 5% dextrose with 25 mEq of sodium (as chloride) and 25 mEq of potassium to infuse at a rate of 52.08 mL/h. (Of course, the intravenous infusion rate should be reasonable; here, 52 mL/h.) To avoid pharmaceutical errors, fluids with standard electrolyte concentration are often preferred. D5 and half saline contains (150 mEq/L × 0.5) 75 mEq/L of NaCl, whereas D5 and 0.25 normal saline contains 37.5 mEq/L. Therefore, the latter (closer in value to 25 mEq/L) will be selected for infusion. In the absence of adequate urine output, potassium-containing fluid must be avoided.

CASE 4-2

Estimate maintenance fluid and electrolyte requirements for an infant weighing 6.8 kg.

Caloric expenditure is 100 kcal/kg/day for the first 10 kg of body weight; here, this would be 680 kcal. Thus, this child requires about 680 mL of fluid/24 h. The sodium and potassium requirements are 2.5 mEq of each per 100 calories metabolized; here, this is 17 mEq of sodium and 17 mEq of potassium per day. The final solution would therefore be 1 L of 5% dextrose with 25 mEq of sodium/L and 25 mEq of potassium/L, to infuse at 28.3 mL/h ("rounded off" to 28 mL/h).

Many factors may alter maintenance requirements (e.g., sweat, fever, and increased respiratory rate, which increase fluid loss), and sick children may have or develop abnormal ongoing losses (e.g., new development of vomiting or diarrhea). In these cases, intravenous fluid requirements need to be adjusted (Table 4-9; see Table 4-7).

Dehydration

One of the most common reasons that parenteral fluid and electrolyte therapy is used in children is **dehydration**, which has many causes (Table 4-10). For most children with dehydration, fluid loss occurs via the GI tract with diarrheal stools, frequently accompanied by vomiting. **Viral (e.g., rotavirus) or bacterial (e.g., *Salmonella*, *Shigella*, or cholera) infections of the GI tract (gastroenteritis), which are frequent in children, are the most common**

TABLE 4-9

Gastrointestinal Losses of Fluid and Electrolytes

Fluid	*Na^+ (mEq/L)*	*K^+ (mEq/L)*	*Cl^- (mEq/L)*	*HCO_3- (mEq/L)*
Gastric juice	50	515	110	0
Pancreatic juice	140	5	75	110

causes of dehydration in most parts of the world. Fluid loss via the GI tract is often accompanied by anorexia, with concomitant decreased intake of fluids. It should be emphasized that parenteral correction of dehydration is often not necessary, and oral rehydration has been successfully used in children with mild-to-moderate (and occasionally severe) dehydration.

Several important considerations in assessing and treating dehydration help formulate a reasonable therapeutic approach, such as:

- Is the child dehydrated, and if so, how much fluid has been lost?
- Does the child have an electrolyte disturbance (usually, hyponatremia or hypernatremia) in addition to the fluid loss?

TABLE 4-10

Causes of Dehydration

Inadequate fluid intake
Altered thirst (central nervous system lesion)
Physical impairment (cannot access fluids)
Altered mental status (lethargy, coma)
Dysphagia
Increased fluid needs
Increased GI fluid losses
Diarrhea
Vomiting
Ileostomy
Nasogastric drainage
Increased insensible fluid losses
Fever
Thermal injury (burns)
Sweating
Cystic fibrosis
Increased ambient temperature
Increased respiratory rate
Increased renal fluid losses
Osmotic diuresis (diabetes mellitus, mannitol)
Diabetes insipidus (central or nephrogenic)
Tubular concentrating defect (sickle cell disease, hypokalemia, hypercalcemia, congenital nephropathy)

GI, gastrointestinal.

- Does the child have an acid–base abnormality, and should the child be given specific correction for this?
- Is the serum (or, sometimes better, plasma) level of potassium normal?
- Are the kidneys responding to the fluid and electrolyte abnormalities appropriately?

Determining the Extent of Dehydration

At present, no particular laboratory test can quantify or estimate the severity of dehydration. The more reliable physical signs of dehydration are **reduced skin elasticity and prolonged capillary refill.**

Pediatric Pearl: Most commonly, the extent of dehydration (and thus the amount of fluid that needs to be replaced) is expressed as a percentage of body weight that has been lost acutely as a result of fluid loss (preillness weight minus admission or current weight, divided by preillness weight, multiplied by 100).

If a very recent preillness body weight is known, then the amount of weight lost when the child is seen for an acute diarrheal illness reflects the amount of body fluid lost. However, because the preillness weight is only rarely known, **the amount of fluid lost by the child is estimated based on physical examination and historical criteria** (Table 4-11); **it is usually expressed as a percentage.** Once the degree of dehydration has been estimated, an organized approach to the various components of intravenous (or oral) fluid therapy can be designed, with close attention paid to frequent reassessment of the patient after therapy is implemented.

Osmolar Considerations

An infant or child with dehydration **may have abnormalities in serum or plasma osmolality, usually resulting from hyponatremia or hypernatremia** that develop concomitantly with the dehydration. In the most common form of dehydration (iso-osmolar or isonatremic), the serum sodium concentration is normal or nearly normal (between 130 and 150 mmol/L). In these children, the amount of water and electrolytes lost from the body are proportional in concentration to electrolyte concentrations in the extracellular fluid space, or hypotonic fluid is lost from the body and is replaced orally with hypotonic fluid, so that serum sodium concentration remains

TABLE 4-11

Evidence of Dehydration Found on Physical Examination

Symptom/Sign	*Mild*	*Moderate*	*Severe*
Body weight loss			
Infants < 20 kg	5%	10%	15%
Older children	3%	6%	9%
Mucous membranes	Normal	Dry	Very dry, cracked
Tears	Normal	Absent	Absent
Urine output	Normal, concentrated	Decreased	Little or none
Capillary refill	Normal (<2 s)	Increased or normal	Increased
Skin elasticity	Normal retraction	Slow retraction	Delayed retraction, tenting
Blood pressure	Normal	Normal; may have orthostatic changes	Low
Heart rate	Normal or slightly increased	Orthostatic changes or increased	Increased; pulse is thready

TABLE 4-12

Estimated Fluid and Electrolyte Deficits in Iso-osmolar Dehydration

% Dehydration	*Water (mL/kg)*	*Sodium (mEq/kg)*	*Potassium (mEq/kg)*
5	50	4	3
10	100	8	6
15	150	12	9

stable. **Approximately 75% to 85% of dehydration episodes are isonatremic.** Proportional losses of electrolytes in children vary depending on the degree of isonatremic dehydration (Table 4-12).

Infants with **hyponatremic dehydration (Na^+ 130 mEq/L) have had more electrolyte losses than proportional water losses; these infants have more compromised intravascular volume (more signs of shock)** compared with infants with the same volume loss from isonatremia or hypernatremia. **Between 5% and 10% of diarrheal dehydration illnesses are hyponatremic,** and replenishing body stores of sodium is a major goal of therapy. It is possible to distinguish many other causes of hyponatremia on the basis of normal, reduced, or increased body fluid status (Figure 4-3). Significant hyponatremia results in certain clinical findings (Table 4-13).

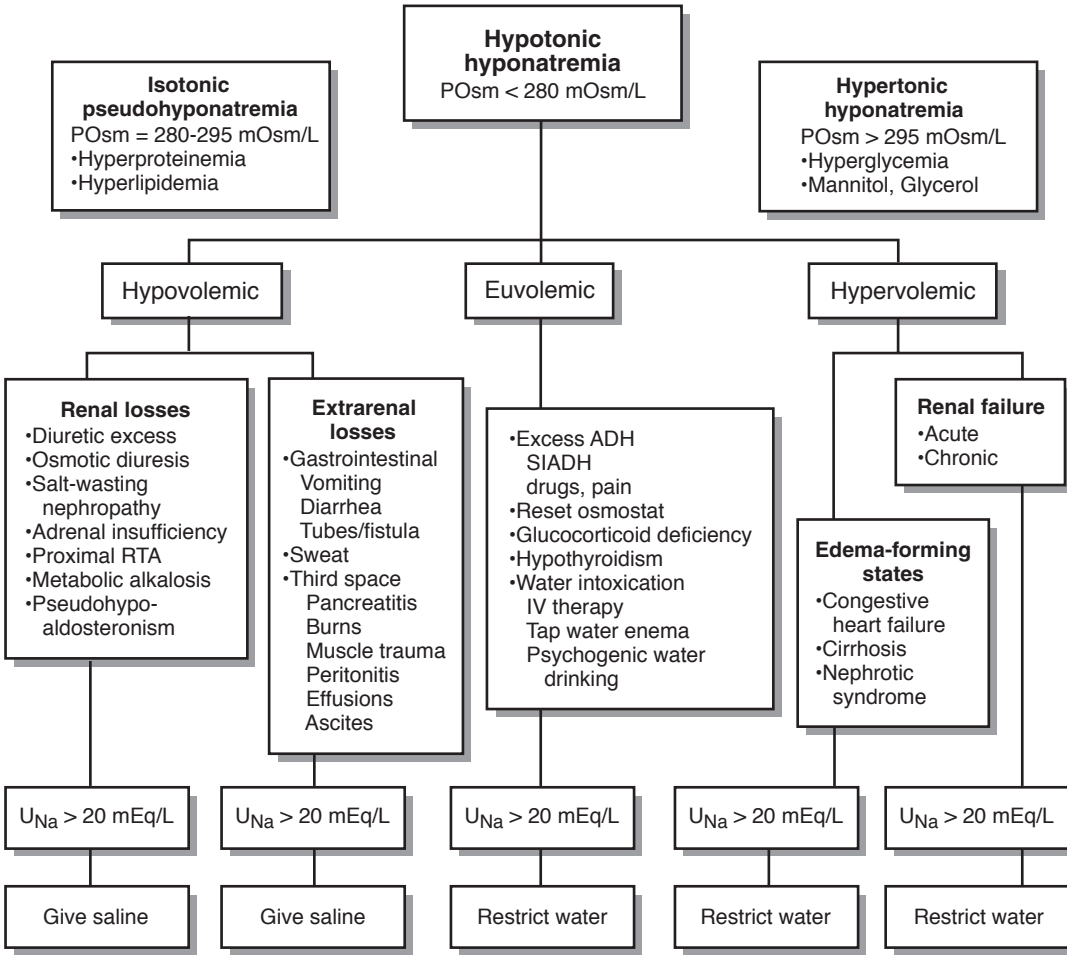

FIGURE 4-3. Classification, diagnosis, and treatment of hyponatremic states. *ADH*, antidiuretic hormone; *IV*, intravenous; *RTA*, renal tubular acidosis; *SIADH*, syndrome of inappropriate secretion of antidiuretic hormone. From Berry PL, Bel Sha CW: Hyponatremia. *Pediatr Clin North Am* 37(2):265–286, 1990.

TABLE 4-13

Osmolar Disturbance and Moderate Dehydration—Physical Findings

Symptom/Sign	*Isonatremia*	*Hyponatremia*	*Hypernatremia*
Mental status	Lethargic	Very lethargic	Irritable
Skin texture	Dry	Moist, clammy	Doughy
Heart rate	Increased	Markedly increased	Orthostatic or somewhat increased
Blood pressure	Normal or orthostatic	Low	Normal to orthostatic
Capillary refill(s)	1.5–3	>3	2–3

Hypernatremic dehydration accounts for 5% to 15% of diarrheal dehydration episodes; in such cases, intravascular volume is well maintained despite significant volume losses (caused by shifts of intracellular fluids into the extracellular and intravascular spaces because of the increased sodium concentration). **This results in fewer clinical signs typical of dehydration (i.e., less tachycardia and more preserved skin elasticity). Often, the skin texture in these infants has a "doughy" feeling. Hypernatremia can have significant CNS and metabolic sequelae,** both acutely and with correction of the hypernatremia. When hypernatremia develops gradually or has been present for some time, **the cells within the brain begin to generate new osmolar substances (so-called "idiogenic" osmoles, mostly amino acids such as taurine);** these osmoles help to prevent brain cell shrinkage and possible hemorrhage.

Because of possible neurologic sequelae and the newly formed osmoles, **most authorities recommend slow rehydration of infants and children with diarrheal hypernatremic dehydration.** Some young infants (often with poor sucking reflexes or with inexperienced mothers) have developed hypernatremic dehydration with breastfeeding, and several mothers have been found to produce milk with abnormally high sodium concentrations; certainly, incorrect mixing of powdered formulas may also result in hypernatremia. Other conditions may also cause hypernatremia (Table 4-14).

TABLE 4-14

Causes of Hypernatremia

Sodium excess
- Ingestion of seawater
- Excessive parenteral sodium administration
- Improperly mixed infant formula

Water loss or deficit
- Diabetes insipidus
  - Central
  - Nephrogenic
- Sweating
- Lack of access to water
- Lack of thirst
- Excessive sweat
- Diabetes mellitus

Water loss in excess of sodium loss
- Diarrhea (all causes)
- Osmotic diuresis
- Obstructive uropathy
- Renal dysplasia

Ketoacidosis
Renal insufficiency
Rhabdomyolysis
Ingestions
Salicylate
Methanol
Formaldehyde
Ethylene glycol
Paraldehyde

GI, gastrointestinal.

Acid–Base Considerations

In severe dehydration, which may be accompanied by peripheral circulatory failure, significant metabolic acidemia may ensue with a low blood pH (Table 4-15). Nevertheless, correction of the metabolic acidemia in this instance does not warrant bolus alkali therapy, but rather, a slower correction of the bicarbonate deficit. The bicarbonate deficit may be estimated as follows:

$$[HCO_3^- \text{ deficit}] = (\text{desired serum } HCO_3^-) - (\text{current serum } HCO_3^-) \times \text{Weight (kg)} \times V_d$$

where V_d is the volume of distribution of HCO_3^- (0.7 in infants; 0.6 in children and adults). Only one-half to two-thirds of the estimated deficit should be replaced.

Children with significant vomiting (as in pyloric stenosis) may have hypochloremic metabolic alkalosis. There is an associated urinary loss of potassium from the distal tubules in an attempt to retain hydrogen ions for the correction of the alkalosis. Chloride-containing solutions (5% dextrose plus 0.45% isotonic saline with added potassium chloride) are used to repair the fluid and electrolyte defects in accordance with the degree of estimated dehydration. Chloride-responsive metabolic alkalosis (e.g., in excessive loss of hydrogen and chloride ions from vomiting, gastric suction, diuretic therapy, and excessive sweat loss from cystic fibrosis) is usually characterized by urinary chloride concentrations less than 10 mEq/L. Chloride-resistant metabolic alkalosis (in primary or secondary hyperaldosteronism such as in renal artery stenosis) is reflected by urinary chloride greater than 20 mEq/L. Aldosterone increases the amount of hydrogen and potassium ions secreted from the distal renal tubules in exchange for sodium reabsorption.

Potassium Considerations

Most patients with diarrheal dehydration require oral rehydration therapy for fluid and electrolyte correction. Virtually all oral rehydration preparations contain at least 20 mEq/L of potassium supplement. Furthermore, the advantage of early feeding in diarrheal management includes gradual restoration of potassium balance. Even when parenteral fluid therapy is needed, intravenous replacement of potassium is unnecessary if enteral feeding is tolerated and serum potassium is within normal limits. Patients with protracted poor feeding, persistent frequent vomiting, or high stool output (>10 mL/kg/h) require 20 to 40 mEq/L of potassium

chloride (potassium acetate may be used if there is an associated metabolic acidosis; acetate is metabolized into lactate by the liver) added into the intravenous fluids, even if the serum potassium level is normal. The serum potassium level may not reflect the total body potassium (potassium is largely an intracellular cation); this is especially true for patients with failure to thrive or protein–energy malnutrition because of significant muscle wasting. Clinicians should add potassium to the intravenous fluids only after ensuring that urinary voiding has occurred.

It is essential to prevent iatrogenic hyperkalemia judiciously, because the danger of lethal cardiac arrhythmia is much greater with elevated serum potassium than with hypokalemia. Lethal arrhythmia is hardly ever seen in hypokalemic patients with normal hearts. Patients with rapid-onset severe hypokalemia and those with hypokalemia associated with life-threatening symptoms (severe muscle weakness with or without hypoventilation, electrocardiographic [ECG] changes, and cardiac arrhythmia) may require bolus treatment with 0.5 to 1 mEq/kg/dose given as an infusion over 1 to 3 hours (intravenous rate $<$ 1 mEq/kg/h). Intravenous bolus therapy of potassium should occur only in the intensive care unit (ICU) setting with a continuous cardiac monitor as well as frequent measurement of serum potassium (every 30 to 60 minutes).

Patients with chronic hypokalemia require slower correction of the deficit, and the daily requirement of potassium 1 to 2 mEq/kg is given as oral supplements. The dose is gradually increased according to the monitored serum level until normal potassium is achieved. Oral supplements can also be used to restore residual potassium deficit after intravenous correction in acute hypokalemia. Several useful oral preparations of potassium that contain sodium, potassium, and bicarbonate are available, including potassium chloride (40 mEq potassium = 3 g potassium chloride), potassium gluconate (40 mEq potassium = 9.4 g potassium gluconate), potassium phosphate, and citrate (Polycitra).

Renal Function Considerations

The most common cause of oliguria (urine output $<$1 mL/kg/h in infants; $<$0.5 mL/kg/h in children) is volume deficit, often secondary to dehydration. The resultant renal hypoperfusion may cause prerenal azotemia. Delay in treatment not only jeopardizes full recovery of renal function (with a progression to acute tubular necrosis) but may also cause damage to other major organs. Thus, aggressive fluid therapy is warranted in severe dehydration and peripheral circulatory failure. Furthermore, it may be difficult to differentiate between oliguria secondary to prerenal insufficiency and that due to (intrinsic) acute kidney injury. In the event of profound oliguria, it is safer to assume a prerenal insufficiency. It is necessary to give a fluid challenge with a crystalloid infusion using 20 mL/kg isotonic saline or lactated Ringer solution (preferred in diarrheal dehydration because it provides a bicarbonate supplement) over 30 to 60 minutes. Clinical signs of improved tissue perfusion are capillary refill greater than 2 seconds; decreased brachial pulse rate; increased blood pressure; and most importantly, enhanced urine output. In patients with altered mental status and those too young to allow accurate urine output estimation, urethral catheterization may be necessary. If oligoanuria persists despite one or two doses of bolus crystalloid infusion, it is necessary to give intravenous furosemide 2 to 5 mg/kg with a repeated fluid challenge.

In most cases, oligoanuria that persists after three boluses of fluid therapy (with or without furosemide) may suggest intrinsic renal failure (preferably called acute kidney injury). It is important to ascertain that the poor urine output is not due to accumulation of urine in the bladder from lower urinary tract obstruction. It is possible to palpate or percuss a distended bladder in the suprapubic region or perform catheterization.

Several biochemical parameters may be useful in the differentiation between prerenal and acute kidney injury (Table 4-16). It is essential to interpret these indices in line with other previously obtained clinical information. Some parameters are less useful than others, depending on the clinical situation; for example, blood urea nitrogen (BUN) is affected in hypercatabolic or nutritional deficiency states. Fractional excretion of sodium (FE_{Na}) is the most sensitive parameter. Most of the indices are derived on the basis of intact renal tubular concentrating capacity in prerenal failure (in contrast to the acute kidney injury). Thus, urinary specific gravity and osmolality are both elevated in prerenal failure, while urine sodium and FE_{Na} are low.

Pediatric Pearl: It should be noted that a primary glomerular disease (often distinguished by clinicobiochemical parameters) without significant tubular involvement may have a concentrated urine (low urinary sodium, high specific gravity, and urine:plasma osmolality ratio) and a low FE_{Na}, mimicking prerenal failure.

TABLE 4-16

Biochemical Parameters Used to Differentiate Oliguria

Laboratory Test	*Prerenal Failure*	*Intrinsic Renal Failure*	*SIADH*
Urine output	Oliguric	Oligoanuric/nonoliguric	Oliguric
Urine microscopy	Often normal	Granular/epithelial/RBC casts	Normal
Urine sodium (mEq/L)			
Children and adults	<20	>40	>40
Neonates	<40	>40	>40
Urine specific gravity			
Children and adults	≥1.020	<1.010	>1.020
Neonates	≥1.015	<1.015	>1.020
Urine osmolality (mOsm/L)			
Children and adults	>500	<350	>500
Neonates	>400	<400	>500
Urine:plasma osmolality ratio	>1.5	<1.5	>2.0
BUN (mg/dL)	>20	<10	>15
Creatinine (mg/dL)			
Children and adults	>40	<20	>30
Neonates	>20	<15	>20
BUN:creatinine ratio	>20	10–20	—
RFI			
Children and adults	<1.0	>1.0	>1.0
Neonates	<3.0	>3.0	>1.0
FE_{Na}			
Children and adults	<1.0	>1.0	1.0
Neonates	<2.5	>3.0	1.0

BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium $[(U_{Na} \times P_{Cr})/(U_{Cr} \times P_{Na}) \times 100]$; *RBC*, red blood cell; *RFI*, renal failure index $(U_{Na} \times 100/U_{Cr} \times P_{Cr})$; *SIADH*, syndrome of inappropriate antidiuretic hormone secretion.

Transfer to the ICU is necessary for patients with persistent oligoanuria in spite of seemingly adequate fluid therapy for central line placement and monitoring of central venous pressure. Pressures less than 5 cm H_2O imply persistent hypovolemia; therefore, more fluid may be necessary. It is necessary to perform a careful search for the etiology of the circulatory failure, which may include septicemia (redistributive shock), hypoglycemia, and drug poisoning. Pressures more than 10 cm H_2O suggest inadequate cardiac output in spite of adequate preload (cardiogenic shock).

On establishing the diagnosis of acute (intrinsic) kidney injury, oral and parenteral fluid replacement should be limited to insensible water loss and ongoing urine output (as well as fluid output from other

sources). In most pediatric patients, the daily amount of fluid required to maintain a zero balance can be calculated as:

$$M = UOP + ERL + IWL$$

where M is daily fluid requirement; UOP is urine output, or the estimated urine output of the previous 24 hours (electrolyte content may be determined); ERL is extrarenal fluid loss, or fluid loss (estimated and analyzed for electrolyte composition) replaced accordingly; and IWL is insensible water loss of 400 to 500 mL/m^2/day.

A shorter period of urine collection and measurement (16, 8, or 4 hours) may be chosen for determination of a more physiologic fluid replacement. The smaller time interval should be used for younger patients (especially neonates) in view of a high fluid turnover rate.

Adequacy of fluid therapy is monitored by a strict input–output analysis, daily weight, physical assessment, and serum sodium concentration. Most patients have a daily weight loss of 0.5% to 1% due to a high catabolic activity or inadequate calorie intake. In patients with a stable sodium consumption, hyponatremia in the face of oliguria may reflect a positive fluid balance, whereas hypernatremia signifies fluid deficit. Dilutional anemia may also indicate overhydration.

Approach to Parenteral Therapy in Dehydrated Infants or Children

Phases of fluid therapy in children are often described and provide a useful framework for organizing fluid therapy and (importantly) following the results of the therapy.

Phase 1

The aim of the first phase of therapy is **restoration of the circulating intravascular volume in children with severe dehydration and peripheral circulatory failure (shock).** If an infant or child has a history of volume deficit and is severely dehydrated or has signs of shock, **rapid intravenous infusion of a volume-expanding agent at 20 mL/kg body weight is appropriate.** (Usually this agent is isotonic saline, although lactated Ringer or 5% albumin may be used.) Continuous monitoring during this therapy is necessary, and intensive nursing and medical support are required. After the infusion, repeat evaluation of vital signs and physical examination are essential, and it is necessary to repeat the "bolus" of isotonic saline until cardiovascular stability (i.e., improved capillary refill, lower heart rate, higher blood pressure, improved mental status) ensues. Typically, between one and three such infusions are necessary.

Children in hypovolemic shock should not receive inotropic agents unless restoration of the intravascular volume fails to improve cardiac output. Although commonly practiced in the ICU setting, there is no clinical benefit from using low-dose dopamine to maintain urine output. Assessment of serum electrolytes, urea nitrogen, and creatinine should occur prior to fluid therapy because these help guide the subsequent phases of fluid therapy. **Children with dehydration but no evidence of shock do not require "bolus" fluid therapy, and phase 1 can be eliminated.** Many physicians recommend subtracting the initial fluid boluses given to the infant from the maintenance and deficit fluids calculated for the initial 24 hours; this is optional and depends on the individual patient.

Phase 2

Phase 2 in fluid replacement therapy requires attention to several components of fluid therapy as discussed previously (see Methods for Estimating Maintenance Fluid Needs). All children need maintenance fluid, and for children with isonatremic or hyponatremic dehydration, maintenance fluids should be calculated as described previously. Maintenance therapy for children with hypertonic dehydration is described in the following section. **In addition to maintenance fluids, replacement of losses from ongoing diarrhea, vomitus, or nasogastric secretions is essential.** Accurate replacement involves measurement of the electrolyte content of these body fluids in the clinical laboratory, volume measurement at the bedside, and administration of appropriate replacement fluids. Table 4-9 gives typical values for these ongoing losses, which can be used as guidelines. If these ongoing losses are significant, frequent replacement (every 1 to 2 hours) is necessary; for less severe losses, less frequent replacement may be appropriate.

Deficit therapy (replacement of previously lost fluids) can be calculated in several ways for children with isonatremic or hyponatremic dehydration. If accurate and recent preillness body weight is known, then the

amount of fluid needed to be replaced (as deficit) is simply the preillness weight minus the current weight (in kilograms). A body weight that decreases by 1 kg from diarrheal fluid loss requires 1 L of fluid replacement (1 L of water weighs 1 kg). **It is essential to give this and other deficit replacements in addition to "regular" maintenance fluids and replacement of ongoing losses.**

If preillness weights are not available, it is possible to estimate the percentage dehydration by using the physical examination criteria listed in Table 4-11. The preillness weight may be "back-calculated" according to the following formula:

$$\times \frac{\text{(preillness weight in kilograms)}}{\text{Current weight in kilograms}} = \frac{100}{100 - \%\ \text{dehydration}}$$

The amount of fluid lost in the acute dehydration episode that should be replaced is then estimated as *x* (preillness weight) minus the current weight, which equals the volume of fluid to be replaced. **Alternatively, the amount of fluid deficit can be estimated in infants based on the percent dehydration, as outlined in Tables 4-11 and 4-12.** Table 4-12 also gives proportional electrolyte replacement needs for children with isotonic dehydration.

Fluid Calculations in Isonatremic Dehydration

CASE 4-3

A male infant is seen in the emergency department because of diarrhea, decreased oral fluid intake, and irritability. The boy's weight at present is 8.1 kg; his mucous membranes are dry, and no tears are present when he cries. Parents report that the last urine output was about 12 hours prior to the emergency department visit. Blood pressure is 86/45 mm Hg, heart rate is 152 beats/min, capillary refill is 3 seconds, and skin elasticity is slow to retract. Based on these findings, you estimate the child to be 10% dehydrated and in need of urgent fluid resuscitation.

Question 4.3.1
What are the first steps in this child's rehydration therapy?

Answer 4.3.1
The first step involves obtaining vascular access and serum electrolytes. The second step involves giving 20 mL/kg body weight of isotonic saline and reassessing the child. The amount of isotonic saline is 20 mL/kg multiplied by 8.1 kg, or 162 mL; it should be given as quickly as possible (usually over 10–20 minutes).

The child responds to the fluid challenge with a decrease in heart rate to 115 beats/min and improved capillary refill of 2 seconds; and urine output, although scant, is obtained and is concentrated, with a specific gravity of greater than 1.035. The child's serum sodium is 135 mEq/L.

Question 4.3.2
Now that the child is more stable, how would you proceed with the fluid therapy?

Answer 4.3.2
Because the child now weighs 8.1 kg and you have determined that he is 10% dehydrated, the preillness weight can be calculated accordingly:

$$\frac{\times}{8.1\ \text{kg}} = \frac{100}{100} - 10?\ \text{(preillness weight)} = 9\ \text{kg}$$

Therefore, the amount of fluid lost (deficit fluid) is 9 kg minus 8.1 kg, which equals 0.9 kg (or, in fluid, 0.9 L or 900 mL). The amount of sodium and potassium in the deficit fluids is outlined in Table 4-12; here, the amount of sodium that should be given in the 900 mL of deficit fluid is 72 mEq. Maintenance fluids need to be given; 9 kg multiplied by 100 kcal (mL) equals 900 mL, with 22.5 mEq of sodium (see Table 4-6; 9 × 2.5 mEq sodium per 100 calories metabolized) for 24 hours.

The total 24-hour fluid estimation is then 900 mL (deficit) plus 900 mL (maintenance), which equals 1,800 mL/24 h (as mentioned, you may "subtract" the initial fluid bolus given, which reduces the 24-hour infusion volume to 1,638 mL). The total sodium content is 72 mEq (deficit) plus 22.5 mEq (maintenance), which equals 94.5 mEq of sodium per day. A 1-liter container of 5% dextrose, with 54 mEq sodium chloride added, set to infuse at 75 mL/h, gives 1,800 mL of fluid over 24 hours, with the required sodium deficit and maintenance (or run at 68 mL/h to give the total infusion minus the initial bolus therapy). This is approximately "5% dextrose with one-third normal saline," with potassium added to the intravenous solution after urinary voiding has been established.

Fluid Calculations in Hyponatremic Dehydration

As mentioned previously, children with hyponatremia often appear more ill than isonatremic children with similar volume deficits. The procedure for calculating the amount of fluid to be given is the same as described previously (see Methods for Estimating Maintenance Fluid Needs); in fact, the only difference is that more sodium is given. It is necessary to approach children as if they have an isonatremic dehydration requiring replacement of the fluid deficit. Maintenance fluid and sodium requirements are outlined in Tables 4-6 and 4-12. The sodium deficit may be estimated using the following equation:

$$(\text{Desired [Na]} - \text{observed [Na]}) \times \text{weight (kg)} \times 0.6 \text{ (volume of distribution of Na)}$$

It is recommended not to raise the serum sodium concentration more than 10 to 15 mEq/day to avoid neurologic complications such as seizures and pontine demyelination. Hyponatremia presenting with neurologic manifestations requires rapid correction with 3% sodium chloride not to exceed 1 to 2 mEq/L/h.

CASE 4-4

A previously healthy female infant who weighed 10 kg on a well-child evaluation during the previous week has had diarrhea with some vomiting for several days. On evaluation in the pediatric emergency department, she weighs 9 kg; in addition, she has sunken eyes, a capillary refill of 4 seconds, and dry mucous membranes. She is sleepy and lethargic. Blood pressure is 55/38 mm Hg with a heart rate of 160 beats/min. Laboratory studies indicate a sodium of 125 mEq/L, potassium of 3.8 mEq/L, chloride of 115 mEq/L, and bicarbonate of 9 mEq/L. Serum urea nitrogen is 32 mg/dL, and creatinine is 0.7 mg/dL.

Question 4.4.1
Should this child receive emergency fluid resuscitation?

Answer 4.4.1
The prolonged capillary refill and depressed mental status of this child, along with the clinical history, indicate significant hypovolemia and warrant emergency resuscitation. This child should receive 20 mL/kg body weight of isotonic saline (or lactated Ringer solution) rapidly (over 10 to 20 minutes); this should be repeated if the response is not sufficient.

Question 4.4.2
If a single infusion of isotonic saline of 20 mL/kg reduces capillary refill to 2 seconds, increases blood pressure to 90/48 mm Hg, and decreases heart rate to 124 beats/min, what would the fluid and electrolyte requirements be?

Answer 4.4.2
The maintenance fluid requirement for a child weighing 10 kg is 1,000 mL/day, and the maintenance sodium requirement is 25 mEq/day (2.5 mEq/100 kcal metabolized). Because 1 kg or 1,000 mL of fluid have been lost (in a child who is 10% dehydrated), the fluid deficit is 1,000 mL. Proportional sodium losses (as in isonatremic dehydration) are given in Table 4-12; there are 80 mEq of sodium (8 mEq of sodium/kg body weight in a child with 10% dehydration). Additional sodium losses are calculated based on the sodium deficit formula:

$$(\text{Desired Na} - \text{current Na}) \times \text{weight (kg)} \times 0.6 = \text{Na deficit}$$

Body weight (kg) multiplied by 0.6 is the commonly used formula for extracellular fluid volume of distribution for ions such as sodium. In this case, the sodium deficit is:

$$(135 - 125) \times 10 \times 0.6 = 60 \text{ mEq Na}$$

The total 24-hour fluid requirement is then 1,000 mL (maintenance) plus 1,000 mL (deficit) or 2,000 mL, and the total sodium requirement is 25 mEq (maintenance) plus 80 mEq (proportional losses) plus 60 mEq (sodium deficit) or 165 mEq sodium. This child could receive 2,000 mL of 5% dextrose over 24 hours in a solution that provides 165 mEq of sodium in that volume. The final 1-liter intravenous fluid container could include 5% dextrose with 82.5 mEq/L sodium, infused at a rate of 84 mL/h.

An alternative is to give one-half of this deficit–maintenance solution in the first 8 hours (900 mL in 8 hours = 112 mL/h) and the remainder over the ensuing 16 hours (900 mL in 16 hours = 56 mL/h), assuming there are no significant ongoing losses. This solution is very close to the commercially available 5% dextrose with one-half "normal saline." Potassium should be added to the intravenous fluids after urinary voiding is observed, usually at 20 to 40 mEq/L.

When an infant or child requires parenteral fluid administration, every effort should be made to resume enteral feedings as soon as possible. Often, the fluid bolus or first few hours of parenteral fluids are all that is necessary. The important point to remember is that these fluid calculations are at best estimates of fluid and electrolyte requirements, and frequent reassessment of physical examination, vital signs, and blood chemistries is imperative.

Fluid Calculations in Hypernatremic Dehydration

Causes of hypernatremia are listed in Table 4-14. Children with diarrheal dehydration and hypernatremia have lost both water and sodium from the body, but the water loss is proportionally less than the sodium loss. Because many children have diarrheal stools with sodium contents of between 30 and 60 mEq/L, **loss of this hypotonic (relative to the extracellular fluid) diarrhea without adequate enteral replacement of hypotonic fluids can result in hypernatremic dehydration.** With hypernatremic dehydration, it remains reasonable to replace volume deficits slowly and to adjust maintenance fluid requirements, as described in Case 4-5.

CASE 4-5

An infant boy with a recent weight of 10 kg has diarrhea and occasional vomiting and refuses all attempts at feeding. **He is becoming more irritable, and now has a somewhat high-pitched cry. His skin has a "doughy" feel,** the mucous membranes are dry, and muscle tone is somewhat increased. Capillary refill is slightly less than 2 seconds, blood pressure and heart rate are normal, and weight is now 9 kg. Blood pressure is 98/60 mm Hg, and heart rate is 122 beats/min. The urine output for the last 24 hours has been minimal. **Serum electrolytes demonstrate a sodium level of 165 mEq/L.**

Question 4.5.1
Will this child require emergency fluids?

Answer 4.5.1
This child is certainly dehydrated, **with dry mucous membranes, altered mental status, and decreased urine output.** However, capillary refill is not significantly prolonged, and blood pressure and heart rate are normal. **Some physicians would opt for treatment with 10 to 20 mL/kg body weight of isotonic saline because of the low urine output.** Because of the high serum sodium (and concomitantly high levels of antidiuretic hormone in response to the ensuing increase in osmolality), however, urine output is obligatorily low. The child may benefit from bolus infusion, but with this clinical scenario it is not mandatory.

Question 4.5.2
Assume that the attending physician did not want to give a bolus infusion but asks you to calculate maintenance and deficit replacement therapy for fluids and electrolytes. How would you do this for a child with hypernatremia?

Answer 4.5.2
Modifications in maintenance and deficit replacement fluids and electrolytes are required for children with hypernatremia. When the components of maintenance fluids were described earlier (see Methods for Estimating Maintenance Fluid Needs), the major components were insensible body losses (respiratory and skin) and an allowance for urine output that is reasonable to excrete waste products but not force the kidney to maximally concentrate or maximally dilute the urine. In hypernatremic dehydration with hyperosmolality and a maximal secretion of antidiuretic hormone, urine output is obligatorily small. It is therefore reasonable to allow 65 to 70 mL (rather than 100 mL)/100 kcal metabolized as daily maintenance fluids and an additional 30 to 35 mL/100 calories metabolized as deficit replacement. The total amount of fluid to be given would then be 100 mL/100 calories metabolized per day (which in "normal" situations are maintenance requirements). The sodium content of the intravenous fluids should be small (0.2% to 0.3% isotonic saline).

It is essential that this volume be given at a uniform rate over a 48-hour period with no bolus or increased volume in the first 48 hours. The danger with too rapid expansion of the extracellular volume with too dilute a solution is that it may lead to a precipitous drop in the serum sodium and too rapid fluid shifts intracellularly. Seizures and cerebral edema could result.

A prospective study compared the use of hypotonic dextrose and saline (5% dextrose with 0.2% isotonic saline) at 100 mL/kg (estimated rehydrated) body weight per day with 5% dextrose and 0.2% isotonic saline given faster (150 mL/kg/day) and 5% dextrose with 0.45 normal saline given faster (150 mL/kg /day). **Children given the fluids more rapidly and with more sodium had a significantly higher complication rate, with more seizure episodes during treatment and more edema.** Those given hypotonic saline more slowly had more controlled resolution of their hypernatremia with fewer adverse effects.

Children treated for hypernatremia require very close monitoring of their body weight, urine output, serum glucose, and calcium levels. **Hypocalcemia may require intravenous calcium replacement. In addition, hyperglycemia may require reducing the dextrose concentration to 2.5% rather than the usual 5%. Most physicians report that a sodium reduction of 0.5 mEq/L/h or between 10 and 15 mEq/L/day are reasonable goals.** Serum electrolytes should be obtained frequently (every 2 to 8 hours, depending on the original sodium concentration, the severity of clinical illness, and the response to fluid therapy). It should also be remembered that urine output will be quite low until serum sodium levels are near the normal range, and that urine output alone is not an adequate tool to monitor efficacy of therapy.

Approach to the Use of Oral Rehydration Solution

Oral rehydration solution (ORS) is necessary in all children with diarrhea or vomiting, except in conditions such as peripheral circulatory failure, frequent and persistent vomiting, and serious illness with or without altered mental status (Table 4-17). Early initiation of ORS may prevent dehydration in most patients. On initial contact with the patients, it is necessary to perform a goal-oriented history and physical examination. Assessment of dehydration status should be assessed based on suggested clinical parameters (see Table 4-11). The most sensitive of these parameters include loss of skin turgor, dry oral mucosa, sunken eyeballs, and altered mental status. The degree of dehydration can be estimated more accurately if the premorbid weight is known.

It is necessary to administer ORS to correct the calculated fluid deficit plus the maintenance and the ongoing fluid loss over 4 to 6 hours. Estimates of ongoing fluid loss for every diarrheal stool output are 50 to 100 mL and 100 to 200 mL for children younger than 2 years of age and older than 2 years of age, respectively. Alternatively, it is possible to weigh or quantify every stool output as 10 mL/kg body weight.

After 4 to 6 hours of rehydration, reassessment is appropriate. If the child is still dehydrated, it is necessary to administer a newly reestimated fluid requirement once again. Cycles continue until rehydration is adequate. Thereafter, ORS is given as the calculated maintenance requirement plus the ongoing fluid requirement.

For example, a 10-kg infant with a 10% weight loss following an acute onset of diarrhea that occurs every 3 hours would require a specific amount of ORS in the initial 6 hours based on the following calculations:

$$\begin{aligned} \text{Fluid deficit} &= 10\ \text{kg} \times 10\% \\ &= 1{,}000\ \text{mL ORS} \\ \text{Maintenance requirement} &= 100\ \text{mL/kg/24 h (first 10 kg)} \\ &= 25\ \text{mL/kg/6 h} = 250\ \text{mL ORS} \\ \text{Ongoing loss} &= 2\ \text{stools in 6 hours (10 mL/kg/stool)} \\ &= 200\ \text{mL ORS} \end{aligned}$$

TABLE 4-17

Guidelines for Oral Rehydration Therapy

Patient Eligibility
All ages
Any cause of dehydration
Avoid with shock or near-shock, intractable vomiting, or altered mental status
Method
Estimate fluid deficit based on previous weight (if known) and percent dehydration (see Table 4-11).
Use rehydration solution with glucose content of 2.0–2.5 g/dL and sodium content of 60–75 mEq/L.
Give 6–8 hours of maintenance volume plus deficit fluid volume.
If stool losses continue, replace with rehydration formula.
After rehydration, reassess. If patient is still dehydrated, estimate deficit fluid, add maintenance fluids, and give over 6–8 hours.
Continue breast-feeding.
If rehydration is successful, change to maintenance formula.
Do not use rehydration solution for more than 4–12 hours.
If patient is hypernatremic, give replacement fluids over 24 hours.
For maintenance phase: Use solution with glucose of 2.0–2.5 g/dL and sodium of 40–60 mEq/L. Give as tolerated, making sure enough is taken to supply maintenance needs and ongoing losses. Offer half-strength formula within 24 hours after starting rehydration therapy; advance to full strength within 24 hours.

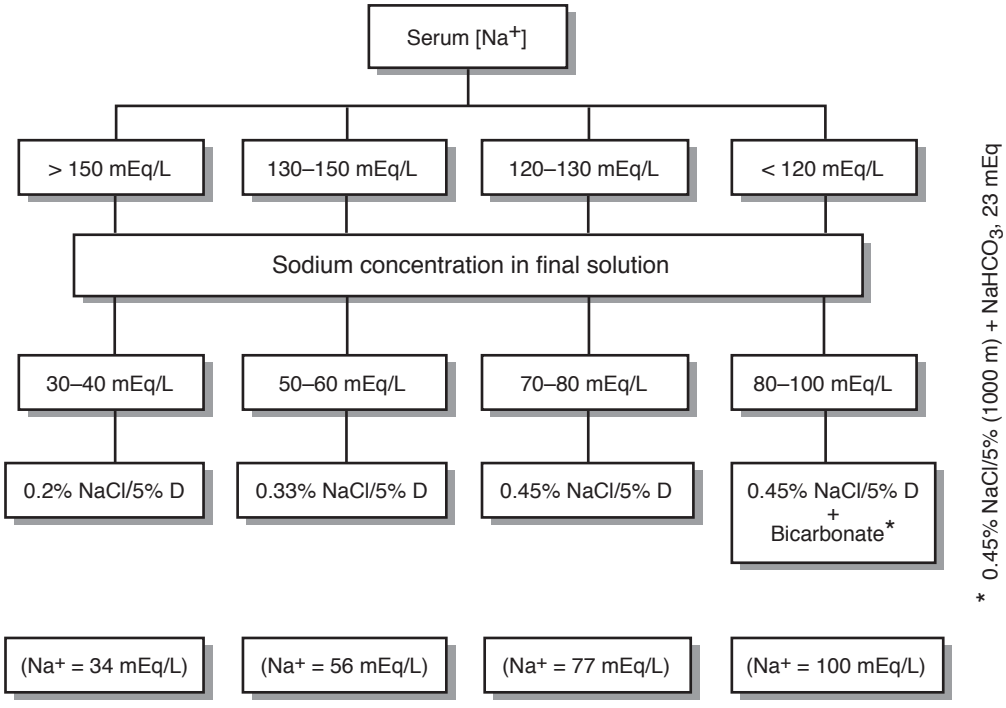

FIGURE 4-4. Decision tree for fluid therapy in dehydrated infants. *D*, dextrose. From Kallen, RJ: Diarrheal dehydration in infancy. *Pediatr Clin North Am* 37(2):265–286, 1990.

Therefore, the total amount of ORS required in the first 6 hours equals 1450 mL. On reassessment, the patient is well hydrated, and the diarrheal stool subsided after three bowel movements in the next 12 hours. Therefore, the "maintenance" and "ongoing" fluid replacement needed would approximate 500 and 300 mL, respectively. ORS can be given by spoon, cup, or bottle.

$$\begin{aligned}\text{Maintenance ORS (next 12 hour)} &= 25\ \text{mL/kg/12 h}\\ &= 500\ \text{mL}\\ \text{Estimate of ongoing loss} &= 3\ \text{stools/12 h (10 mL/kg/stool)}\\ &= 300\ \text{mL}\end{aligned}$$

Summary of Pediatric Fluid Therapy

The calculation of fluid requirements for dehydrated children can be complex, so a "decision tree" approach has been developed that works very well for children with moderate dehydration (Figure 4-4). Once the clinician has decided what fluids are necessary and has implemented administration, frequent physical examinations, vital signs (especially body weight), and certain "follow-up" laboratory parameters help ensure the achievement of the therapeutic goals of safe restoration of body fluid status and resumption of enteral alimentation.

Behavioral Pediatrics

Martin T. Stein

Attention to the behavior of children at each pediatric encounter is important for both clinicians and parents. Clinicians observe behavior as a way to determine severity of a physical illness (e.g., irritability or absence of a social smile in a febrile infant as a clue to sepsis) and to assess for specific behavioral condition (e.g., poor eye contact and lack of reciprocal social interactions in a child with an autistic spectrum disorder). Behavioral interactions between child and parent are also important observations. The manner in which a mother holds, feeds, and interacts with an infant may be a clue to the quality of early attachment. Excessive verbal abuse during an office visit may be a clue to inappropriate child rearing practices. From a primary prevention perspective, an observation of a child's behavior and the parent–child interactions as appropriate for age may be an opportunity to provide parents with positive feedback about the quality of their parenting. This technique is especially useful when a positive behavior is observed and the clinician comments simultaneously on the observation. Making use of behavior in this way strengthens the therapeutic alliance between physician and parent and enhances parental self-esteem.

Behavior and neurodevelopment are intertwined. The emergence of specific milestones of motor, language, and social development at each stage of development (see development, Chapter 2) is associated with a wide variety of different behaviors. As the brain matures in specific areas at a predetermined rate, skills develop that organize behavioral patterns. When an infant learns to sit without support and reach out for an object at 6 months of age, she can interact with her surroundings actively through exploratory learning with both people and inanimate objects. She becomes a "scientist in the crib" as she learns from successes and mishaps. These motor and cognitive skills impact on her behavior with parents and other caretakers. In the second year of life, new neurologic skills (walking, language, self-feeding, and eventually toilet training) reflect a growing inner sense of independence and autonomy. Although she is still dependent on her parents for nutrition, safety, and language stimulation, the toddler learns to master those neurologic milestones that add up to independence—a major shift from the dependant state of infancy. The predictable conflicts between autonomy and an earlier dependency are a major contributor to toddler temper tantrums. The response of parents to those tantrums shapes the child's behavior patterns.

Knowledge about the variations in normal behavior at each developmental stage during childhood and adolescence is a critical part of all clinical assessments. An example of this process occurs when a clinician differentiates normal and predictable fears and worries from anxiety disorders (Table 5-1). Understanding normal fears and worries begins the process of deciding whether a significant problem exists. Another example is bed-wetting, which is a behavior that is a reflection of maturation of the detrusser muscle, disordered sleep, or a small bladder capacity: at 3 years, about 75% of children wet their bed; at 5 years, 15% to 20%; at 8 years, 7%; and at 12 years, 2% to 3%. Bed-wetting is therefore normal before 6 years; when it persists into the eighth year, an evaluation for primary nocturnal enuresis is initiated.

BEHAVIORS, GENES, AND THE ENVIRONMENT

Behavior in children is an outgrowth of genes and environmental experience. A prominent principle in contemporary molecular biology is the idea that genes require an environment for expression. This process begins in fetal life. Healthy maturation of the fetal brain is dependent on adequate maternal nutrition; it is adversely affected by genetically mediated maternal illness (e.g., hypertension, diabetes) and environmental toxins (e.g., smoking alcohol, substance abuse, some prescription medications). Hypertension during pregnancy may result in a baby who is small in size for gestational age; these babies may be irritable and difficult to soothe, with significant feeding problems. Exposure to cocaine, amphetamine, and alcohol may also be associated with irritability after

TABLE 5-1

Anxiety in Children: A Developmental Perspective of Normal Fears

Infancy:	Separation anxiety
Toddler:	Fear of monsters
Preschool:	Fear of the dark; bodily harm
School age:	Fear of disapproval, animals, natural environment
Adolescence:	Fears related to identity, independence, and social acceptance

birth. It is important to recognize the neurobiologic and social/environmental influences on behavior during childhood (Table 5-2).

TEMPERAMENT

Variations in behavior are a reflection of a child's temperament. Understanding a child's temperament can be a useful tool in giving meaning to behavior. Temperament is a biologic trait that refers to the manner in which a child responds to new stimuli in the environment. It is an individual's way of responding to the environment based on differences in emotional reactivity, activity level, attention, and self-regulation that appear consistently across situations and are relatively stable over time. About 10% of babies are classified as temperamentally "easy" (i.e., maintain regular routines, are cheerful, and easily acceptable to others); 10% as "difficult" (i.e., are irregular, slow to accept change, and tend to respond negatively); 15% as "slow to warm up" (i.e., are mild, inactive, slow to respond, and have a neutral mood); and 35% with a mixture of temperament characteristics.

It is clinically useful to separate temperament (biologic and "hardwired") from environmental influences on behavior. Temperament cannot be changed but can be adapted to, whereas environmentally driven behaviors often respond to behavioral modifications. A discussion about temperament (and any inconsistency between the child and a parent's temperament) is often helpful when counseling parents about difficult behaviors.

TABLE 5-2

Neurobiologic and Environmental Mediators of Behavior in Children

Neurobiologic	*Environmental*
Genetic conditions	**Rearing practices**
Inherited temperament	Method of discipline
Inherited cognitive potential	Type of emotional climate
Genetically transmitted disorders	Consistency and structure
Prenatally or perinatally acquired conditions	**Family environment**
Congenital infections of the brain	Clothing, shelter, food
Drug or alcohol effects	Health care
Birth injuries	Presence of abuse or neglect
Postnatally acquired conditions	Relationships with parents and sibling
Injuries to the brain	**Community environment**
Diseases affecting the brain	Culture
Endocrine disorders	War, famine
Exogenous toxins such as lead	Natural disaster

A BEHAVIORAL HISTORY

One of the most effective questions to ask a parent is, "Do you have any *concerns* about your child's behavior?" A brief pause following the question is often followed by an expression of a concern. A behavioral history may then assess the details of the concern (when it occurs in relationship to specific activities), duration, effects on other aspects of development (including family and peers), and past treatments. A guide to an effective behavioral history uses the same principles of clinical interviewing as in other aspects of medicine (Table 5-3). Allowing a parent or child to tell his personal story not only provides the information necessary for an assessment, but is also therapeutic for children and parents. The process of active listening by a clinician builds on the trust of the relationship. As a complement to the behavioral interview, the Pediatric Symptom Checklist is an effective behavioral screening questionnaire for children and youth between 4 and 16 years old (see Chapter 2).

COMMON PEDIATRIC BEHAVIOR CONDITIONS

Infant Colic

All babies cry! When crying is more intense and of longer duration in the first 3 months life, it is called "infant colic." Colic in these infants is a more severe form of the diurnal behavior seen in most babies in whom crying is longer and more intense in the late afternoon and evening. The characteristics of infant colic are outlined in Table 5-4. Crying may be associated with many physical conditions as a result of pain, inflammation, or obstruction. A complete history and physical examination usually reveals a physical cause that is present in a small number of colicky infants. When the medical examination is negative and the behavior fits the pattern of infant colic, the clinician has an opportunity to describe to the parents the characteristics of this common, self-limiting condition. Teaching soothing techniques (e.g., use of a pacifier, gentle swinging in arms, and use of a cloth baby carrier) may relieve some of the crying. Formula changes are rarely helpful; eliminating cow's milk in the diet of a nursing mother decreases crying in some colicky infants. Careful education directed to the parents relieves guilt when it is given empathically and with a clear statement that the baby is healthy in all other ways. Most

TABLE 5-3

A Guide to Clinical Interviewing

Open and closed questions: Open-ended questions ("How is your baby doing?" or "What do you like about your baby?") encourage spontaneous, less structured responses than close-ended questions. They allow parents to express their concerns and an "explanatory model" of a problem or illness. Too many close-ended questions, especially early in an interview, inhibit spontaneity and assessment of the parent's agenda for the visit.

Pauses and silent periods: Pauses provide time for the parent or child to collect thoughts and express feelings at moments when stressful or when sad feelings emerge during an interview. This conveys the message that the clinician cares enough to take the extra time.

Repetition of important phrases: Repeating or interpreting a statement made by patient or a nonverbal observation often encourages further clarification and exploration.

Active listening: Most interviewing mistakes are due to too much talking by the clinician. Active listening is the process of giving undivided attention to a patient's words and body language. The empathic clinician practices active listening through her facial expressions, posture, hand movements, and head nodding. It is a skill that can be learned.

Transference: On some occasions, a parent (or older child) may experience the pediatrician as someone who is symbolically and psychologically identified with another important person (a mother, father, other relative, or person) in his or her life. The symbolic attachment is experienced at the time of deep emotional expression (e.g., joy, relief, anger, grief, or disappointment). Recognition of the transference process guides a clinician's insight and responses.

TABLE 5-4

Characteristics of Infant Colic

Episodes of crying lasting more than 3 hours a day, more than 3 days a week, for more than 3 weeks (Wessel's "rule of 3")
A pattern of crying more intense and more frequent than the normal crying in most infants in the first 3 months of life
Occurs in 10%–15% of infants
Normal physical growth
Starts in second week and resolves at the end of third month
Typically crying in late afternoon and early evening
Crying peaks at 6 weeks of age
Occurs in both breast-fed and bottle-fed babies; equally in boys and girls
Seen in all cultures

parents with a colicky baby benefit from additional social support that permits periodic breaks from child care. These measures are often necessary as persistent crying may lead to feelings of inadequacy about parenting, guilt, and a lingering sense that the child is fragile and vulnerable to physical illness.

Temper Tantrums

Temper tantrums, especially in the 1- to 3-year-old toddler period, are common. At this time in development, they often reflect frustration with emerging psychological independence as a result of new motor and language skills. Yelling, hitting, and saying "no" are frequent symptoms. Most oppositional behaviors respond to behavior management—reinforcing positive behaviors ("catching them at being good"), expectations for appropriate behaviors, and consequences for negative behaviors. Beyond the toddler period, temper tantrums require a careful history to assess for possible stress in the home, at school, or with peers. A complete physical (including neurologic) examination should be performed to rule out an occasional organic process.

Recurrent Abdominal Pain

Frequent episodes of abdominal pain occur in as many as 15% of school-age children; an organic cause is found in less than 10% of these patients. The pain is typically in the periumbilical area without nausea, vomiting, or change in bowel pattern. Anorexia, fever, weight loss, and other symptoms are not present. The most common behavioral causes are environmental stressors (e.g., a bully in school, family conflicts, or academic stress) and undetected anxiety disorders. The process of taking a careful history (letting the child and parent tell her story) and completing a physical examination (while narrating the negative findings) is often therapeutic. When a significant environmental stress or anxiety is detected, counseling (including education about the mind–body interactions and stress reduction and relaxation exercises) is often helpful. More severe anxiety may require a referral.

Attention-Deficit/Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) is the most frequently seen neurobehavioral disorder in school-age children. Core symptoms of hyperactivity, impulsivity, and inattention occur in 7% to 8% of children associated with impairments in academic achievement and/or social skills maturation. In addition, over half of school-age children with ADHD have coexisting conditions, including learning disabilities (e.g., dyslexia in which the acquisition of reading fluency and comprehension is delayed in the presence of normal general intelligence) and mental health disorders. Anxiety disorders and oppositional behavior disorder often accompany ADHD.

A diagnosis of ADHD is made by careful ascertainment of behaviors from parents and teachers; symptoms must occur in both environments. When core behaviors are found only at home or only at school, situational

stressors in one environment or the other are evaluated. The treatment of ADHD involves education of the patient and parents about ADHD, a discussion of therapeutic options, and a well-designed office-based follow-up system. Evidence-based treatments include behavioral management and medication. Stimulant medications (methylphenidate and amphetamine), atomoxitine, and guanfacine have been shown to ameliorate ADHD behaviors in at least 70% of school-age children and adolescents. Treatment with these medications requires careful monitoring for benefits and side effects (especially anorexia and weight loss). Classroom and home accommodations are often helpful (e.g., placing the child in the front of the room close to the teacher, providing smaller assignments, and finding a quiet place in the home for homework). The appropriate diagnosis and treatment often leads to improved educational achievement and more effective social interactions with parents, peers, and teachers.

Sleep Problems

Dysfunctional sleep patterns are common in childhood and adolescents. Delayed sleep onset (insomnia), frequent nighttime awakening, nightmares (frightening dreams during rapid eye movement [REM] sleep), night terrors (awakening in an inconsolable state of screaming and thrashing during non-REM sleep), somnambulism (sleepwalking), and persistent bed-wetting after 8 years of age (primary nocturnal enuresis) are among the common forms of sleep disturbances seen in children.

Sleep problems benefit from a proper diagnosis because, if left untreated, they limit the required physiologic rest period that enables healthy daytime physical and cognitive activities. Sleep-deprived infants and toddlers may be irritable during the day, may feed with difficulty, and may be an enormous challenge to effective parenting (at night and during the waking hours). A sleep problem in a school-age child may be associated with inattention in the classroom, poor social relationships, and underachievement. Some sleep problems are secondary to physical disorders (e.g., common conditions such as asthma, medications, obstructive sleep apnea, or uncommon conditions such as a brain tumor and nocturnal epilepsy). A standard complete medical history and physical examination will usually detect these problems.

For many sleep problems, counseling about appropriate sleep hygiene before bedtime is helpful. Infants should be placed in the crib prior to falling asleep during a feeding; in this way, when they experience normal periods of nighttime awakening, they will not have a sleep-awakening association (i.e., mother's breast milk or a formula bottle) that prevents them from going back to sleep. Older children benefit from a quiet environment at bedtime (e.g., no TV in the bedroom, no loud music, reading with only a night-light). School-age children may benefit from a progressive relaxation technique that simultaneously relaxes the mind and body. Psychosocial stress at school or in the home must be ascertained and addressed as a potential source of an abnormal sleep pattern. Sleep matters! It is essential to include a sleep history when evaluating most behavioral problems in children.

ANXIETY DISORDER AND DEPRESSION

Anxiety refers to excessive fears and worries that are more chronic, intense, and impairing compared to the normal fears and worries at different stages of development (see Table 5-1). Anxiety disorders in children include social anxiety, separation anxiety (persisting after 2 years old), selective mutism, obsessive–compulsive disorder, phobias (including school refusal), and panic disorder. The prevalence for anxiety disorders is 8% to 9% at some time during childhood and adolescence; a family history for anxiety is often present. Children and youth who respond positively to the following questions may manifest an anxiety disorder:

- I get really frightened for no reason at all.
- I am afraid to be alone in the house.
- People tell me that I worry too much.
- I am scared to go to school.
- I am shy.

Children with anxiety disorders often present to their doctor with physical symptoms (Table 5-5). Mild-to-moderate anxiety often responds to education, supportive care, and follow-up office visits. Evidence-based treatments, including cognitive-behavioral therapy and/or a serotonin reuptake inhibitor, are effective for moderate-to-severe anxiety disorders.

Depression is a mood disorder that usually presents as sadness, irritability, or boredom. Depressed children may feel a sense of hopelessness, worthlessness, or guilt. Effective screening questions for depression (adjusted

TABLE 5-5

Anxiety and Somatic Symptoms

In 128 children (6–17 years old) with anxiety disorders:
- Restlessness occurred in 74%
- Stomachache occurred in 70%
- Blushing occurred in 51%
- Palpitations occurred in 48%
- Muscle tension occurred in 45%
- Sweating occurred in 45%
- Trembling/shaking occurred in 43%

for the age of the child) include, "Do you feel sad or lonely most of the time? Do you blame yourself unnecessarily when things go wrong? Have you been able to laugh and see the funny side of things?"

Depression may be associated with somatic symptoms (e.g., abdominal pain, headaches, difficulty sleeping), but these symptoms are less frequently seen in anxiety disorders. Depression occurs in 2% of school-age children and between 3% and 8% of adolescents. Major depression is much less common in children than the temporary experiences of sadness, grief, or depressed mood that occurs during the course of most children's lives. Divorces, death of a grandparent, departure of a close friend, family discord, or a failed relationship are common and upsetting causes of temporary sadness.

A persistent disturbance of mood that is associated with functional impairment (i.e., deterioration of school or social function) should raise the suspicion of a major depressive disorder. Adjustment disorders secondary to a specific stressor usually respond to supportive counseling that focuses on problem identification and strategies that ease the stress. When family discord is prominent, problem-solving interventions should involve the entire family to improve compliance and reduce tensions. Major depression is treated with a combination of medication and psychotherapy.

Child Abuse

A physically abused child has experienced physical violence by a parent or other caretaker that results in injuries. The most common injuries seen in abused children are bruising, burns, fractures, and internal injuries such as intracranial bleeding. Child abuse is a result of living in a chronically stressed environment. It is seen among all socioeconomic classes, but poverty is associated with increased psychological stress that predisposes a child to abuse in a susceptible family. The abuser (either a parent or other caretaker) was often a victim of abuse as a child with unrealistic expectations and lack of understanding of the child's developmental abilities. This leads to frustration and anger, which may result in abuse. The absence of self-control in the abuser may be associated with substance abuse or alcohol. Social isolation and domestic violence are other contributing factors. A child with a difficult temperament (i.e., irritable, difficult to soothe, prone to tantrums) is also a risk factor.

A complete physical examination and behavioral observations of the parent and child are tools used in the assessment of child abuse. A frequent clinical clue to child abuse is when the clinician observes a discrepancy between the physical finding and the explanation provided by the parent (e.g., multiple fractures in different stages of healing associated with a history of "falling from the couch" or a nonmobile child with unexplained bruising). Most parents and kids are anxious when taken to an emergency room or doctor's office after an injury. When the anxiety (in the parent or child) is excessive and out of context for the injury, child abuse may be considered. Illogical or changing explanations for the injury may be expressed by some parents. Both chronic and acute stress in a child may manifest as sadness and withdrawn behavior, new fears and anxieties, and acting out with anger and aggression.

Conducting a nonjudgmental medical history is the first important step in determining the nature of the injury. Allowing the parent to tell her story without being rushed yields the best information. When abuse is likely, it is critical that the clinician evaluating the child suppress any anger directed toward the perpetuator. Verbal children should be interviewed separately by asking open-ended questions and avoiding direct or leading questions.

A completed physical examination, radiographs when indicated, and clotting studies when bruising is seen or internal injuries are suspected are the physician's responsibility. When child abuse is substantiated or suspected, an immediate referral to the child protection agency (CPS) is the next step. A social worker or other mental health specialist in the emergency room may be helpful by expanding the psychosocial history and offering support to the family until the CPS personnel arrive.

Socioeconomic and Cultural Issues in Pediatrics

Fernando S. Mendoza

Traditionally, the role of the pediatrician is to maintain children's health by preventing disease and curing illness. Yet, in the 21st century, pediatricians have begun to adopt a broader role in maintaining children's health based on the definition of health proposed by the World Health Organization (WHO): Health is a state of complete physical, mental, and social well-being, not merely the absence of disease or infirmity. This definition of health requires pediatricians to understand not only the science behind the disease process, but also the nonbiological family and community factors that may affect a child's health. The WHO definition encourages pediatricians to not only treat disease and illness, but also, in many situations, become child advocates to improve the environment in which children and their families live to maximize their physical, mental, and social well-being. Yet, in a society that is becoming more diverse, providing this form of comprehensive health care to children and their families requires an understanding of their physical and social surroundings. This necessitates an appreciation of the number of nonbiological factors that can affect children's health, such as social class, race, ethnic-cultural background, family structure, residential status, and even the physical environment. Both the American Academy of Pediatrics and the Future of Pediatric Education II Task Force acknowledge the importance of the family's socio-cultural background, and its influence on the child's health. Consequently, both recommend that the training of the next generation of pediatricians, whether as generalists or subspecialists, should be enhanced by expanding their knowledge of children's home environments, including their family's culture and community.

This chapter will review the socioeconomic and ethnic-cultural characteristics of children in the United States and how these characteristics may increase or decrease risks for poor health. In doing so, this chapter will highlight the health disparities associated with social class, race, ethnicity, and immigration status.

SOCIOECONOMIC DIVERSITY

The most common measures of socioeconomic diversity are family income and parental education. Among these two, family income is the most robust indicator in assessing the socioeconomic status of a family. Family income can be used either as a threshold measure or as a continuous one. For example, the poverty threshold assesses the adequacy of a family's income to support their basic needs. The federal government establishes the poverty threshold (also called the poverty line), by defining the income needed to support a family of four with food and shelter. At present, the poverty threshold or poverty line for a family of four is $22,050. Unfortunately, this does *not* include health insurance nor does it account for variation in the cost of housing, which can be significantly different from one part of the country to another.

Studies have shown that children who live below the poverty threshold have a higher probability of growth and developmental problems as well as a greater prevalence of disease. In reality, the relationship between income and health seems to be a linear one rather than a threshold phenomenon because it appears that those with higher income at whatever level have better health than those at lower incomes. For instance, those children from families that have incomes three times the poverty threshold demonstrate better health than those below the poverty threshold. Yet, those same children appear to have a higher risk for poor health compared to upper income children (defined as 10 times poverty threshold incomes). Differences in access to health care, the healthiness of their living environments, or their family–community risk for poor health behaviors related to income may be the

cause of these observed differences. Consequently, the number of children who live below the poverty threshold in a community is only an approximate measure of those who are at risk for health problem from socioeconomic factors. Studies by Marmot in the United Kingdom show that this socioeconomic health differential occurs throughout the economic ladder and holds for both children and adults.

In times of economic decline, the percent of children living in poverty usually increases because of the greater risk for economic instability among families with children. For example, from 2000 to 2008, the percent of children living in poverty increased from 16% to 19%, a 19% increase or an additional 2.5 million children in the United States (National Center for Children in Poverty). Yet, among certain racial and ethnic groups, there are a disproportionate number of children living in poverty. Thus, when an economic decline occurs, these groups are even more impacted. For instance, in 2008 the percent of non-Hispanic white children living in poverty was 11%. In contrast, for Black, Hispanic, and Native American children it was approximately three times as much—35%, 31%, and 31%, respectively. This disparity in the proportion of children living in poverty is a major contributing factor to the disparities in health seen among these children.

Family structure can also significantly affect the rate of poverty. The economic resource available to a two-parent versus one-parent household is apparent in all racial and ethnic groups; poverty rates are lower in two-parent families. Among all families with children, those headed by a woman are six times more likely to live in poverty than those headed by a married couple (36% versus 6%). African American and Hispanic households with children and headed by a woman are significantly more likely to live in poverty than their non-Hispanic white counterparts (46% versus 25%). In 2008, the percent of single parent families among non-Hispanic whites, Hispanics, Blacks, Asians, and Native Americans was 23%, 38%, 65%, 16%, and 50% respectively. Finally, although children constitute only 25% of the U.S. population, they make up 35% of all individuals living in poverty. This is a fact that has continued to be a major contributor to the poor health of children in our country.

RACIAL AND ETHNIC DIVERSITY

Currently, about one-third of all children in the United States are children of color: African American, Hispanic, Asian, and Native American. In addition, mixed race and ethnic children are also increasing in numbers. The U.S. Census Bureau predicts that by the year 2020, approximately one-half of all U.S. children will be children of color. In certain states, such as California, this prediction has become a reality. At present, 40% of all children in California are Hispanic, 15% are Asian, and 10% are African American. This demographic trend is also evident in many urban areas in other states. The demographic shift is the result of two factors: higher birth rates among women of color and immigration. In the United States, non-Hispanic Caucasian women in the 15- to 45-year age group have the lowest fertility rate, 58 births/1,000. Birth rates are higher in all other groups: Mexican American (112 b/10^3), Puerto Rican (76 b/10^3), African American (73 b/10^3), Native American (71 b/10^3), and Asian–Pacific Islander (64b/10^3). These higher fertility rates have a major implication for patient populations in obstetrics and pediatrics, particularly in those states and regions where these groups are concentrated. Moreover, higher fertility rates set the stage for continued diversification of the U.S. population independent of any changes in immigration.

Over the last 20 years, the number of children in the United States who are immigrants or whose parents are immigrants has increased significantly. The report of the Institute of Medicine (National Academy of Sciences) on the health and well-being of children in immigrant families noted that one of every five children in the United States (14 million children) is an immigrant or has immigrant parents. The great majority of these immigrants are from Latin America and Asia. However, every country in the world contributes to the immigrant population of the United States. A picture of this diversity is the entering kindergarten classes in California that have more than 100 different dialects spoken by the children in these classes. Thus, the practice of pediatrics is and will be even more in the future, a practice of medicine that will be global in nature, necessitating pediatricians to adjust to the language and culture of patients and their families. Consequently, the ability for pediatricians to speak more than one language and become culturally competent will be a significant asset in the practice of pediatrics, either as a generalist or specialist.

Beyond understanding the patient's language and culture, however, immigrant children and their families may also have an immigration experience that needs to be assessed by their pediatricians to provide comprehensive health care. This requires an understanding of the immigrant experience with respect to the health issues families encountered in their country of origin and the issues they face in adjusting to their host communities. These factors can influence the health of immigrant children and may require interventions by the pediatricians. For example, for some immigrant children, prior economic impoverishment and psychological trauma can present with problems in physical growth and emotional well-being. Management of these clinical issues begins

with understanding that they might be present and by asking immigrant families about their child's health and well-being in their country of origin. Such information can be both instructive and useful in developing an appropriate care plan for a child in an immigrant family. Likewise, understanding how the immigrant family is adapting to the host community's cultural norms may also reveal issues that will need to be addressed by the pediatrician. Not infrequently, the processes of acculturation may create tensions in the family that can influence the emotional and social development of the child. Consequently, although pediatricians cannot be experts on all the cultures of their patients, they can ask the appropriate questions that will guide them in enhancing the health care they deliver to children. The growing global economy and the flow of immigrants has made understanding the effects of cultural diversity on children's health a central issue for pediatrics, particularly as we all strive to improve the quality and efficiency of health care.

HEALTH DISPARITIES IN CHILDREN

If all children throughout the world were equal in socioeconomic class, lived in similar environments, and families and society treated them equally, then their genetic predisposition would be the basis for difference in diseases and illness seen among children. Unfortunately, this is not the case, and thus, pediatricians need to understand the various factors that contribute to poor health outcomes, and how they lead to health disparities seen among children—that is, the disproportionate distribution of disease and illness based on income and other factors.

Socioeconomic Disparities

As noted, living in a lower socioeconomic class environment increases the probability of health disparities in children. Children living in impoverished environments are more likely to be exposed to infectious and environmental agents, which, along with limited food or lack of health resources, can cause or contribute to disease processes. Using various national data sources, Starfield found that in the United States, children from lower-income families were two to three times more likely than children from higher income families to suffer from a variety of illnesses and conditions (Table 6-1). The effects of social class on children can begin before birth. For example, poor mothers have a higher risk of nutritional and health problems and limited access to quality prenatal care. These higher risk factors among poor women make it more likely for them to deliver low birth weight or premature infants that are twice as likely to die in the first year of life.

Beyond infancy, the environment of poverty can significantly affect children's health. The most common health problem directly related to the degree of economic impoverishment is malnutrition that results from inadequate caloric and nutrient intake. Worldwide, malnutrition affects one out of every four children (150 million), with 70% of malnourished children living in Asia, 26% in Africa, and 4% in Latin America. Over the past decade, 37% of immigrants to the United States have come from Asia and 41% from Latin America. Consequently, it is common for pediatricians in the United States to see newly arrived immigrant children with some degree of malnutrition, and therefore, they need to assess these children for this clinical condition by an appropriate anthropometric assessment (e.g., weight, height, body mass index, and skin folds).

Among those children born or raised in the United States, severe malnutrition is much less common; however, hunger, an attenuated form of malnutrition, is significant and affects the well-being of children. In 2008, the U.S. Department of Agriculture reported that 16.7 million children in the United States, or 22.5% of all children, suffer from hunger or **food insecurity**, meaning that they did not have access to enough food to meet their growth needs. Some children in the United States who suffer from hunger also suffer from the condition known as "failure to thrive," the inability to maintain a normal growth velocity. This condition is estimated to occur in as many as 10% of U.S. children. Quite often, children with failure to thrive also demonstrate significant developmental delays that relate to their relative malnutrition and impoverished environments. Yet, most children who suffer from food insufficiency have no evidence of physical growth abnormalities, but instead experience problems in concentrating and learning in school because of hunger. This can add an additional obstacle in achieving educational success for poor children, a goal that is vital for children's futures. Thus, in assessing patients, questions about diets need to go beyond the types of foods taken to include questions about the availability and quantity of food for the child.

Evaluating a child for malnutrition involves examining two basic parameters: (1) weight-for-height (a measure of **wasting,** or thinness for height), and (2) height-for-age (a measure of **stunting,** or shortness for age). Although other anthropometric assessments such as skin folds can be used, weight and height are the most common measures used by pediatricians to assess the nutritional status of children. For example, as poor

TABLE 6-1

Differences in Health Status Among Poor and Nonpoor Children

Increased Frequency in Poor Versus Nonpoor	
Low birth weight	Double
Teenage births	Triple
Delayed immunization	Triple
Asthma	Higher
Bacterial meningitis	Double
Rheumatic fever	Double to triple
Lead poisoning	Triple
Increased Severity of Health Problems in Poor Versus Nonpoor	
Neonatal mortality	1.5 times
Postneonatal mortality	Double to triple
Child deaths	
Due to accidents	Double to triple
Disease related	Triple to quadruple
Complications of appendicitis	Double to triple
Diabetic ketoacidosis	Double
Complications of bacterial meningitis	Double to triple
Percent with conditions limiting school activity	Double to triple
Lost school days	40% more
Severely impaired vision	Double to triple
Severe iron deficiency anemia	Double

From Starfield B: Childhood morbidity: Comparisons, clusters, and trends. *Pediatrics* 88(3):519–526, 1991.

children are more inclined to have an inadequate diet, pediatricians can assess their adequacy of caloric intake by assessing their degree of wasting (less than fifth percentile in weight for height) and stunting (less than fifth percentile in height for age). Depending on the degree and duration of malnutrition, stunting may persist for years, even after establishing adequate nutritional intake; that is, although linear growth may show some catch-up growth after improved nutrition, the height that is achieved is usually not what would have been the child's "normal" height with proper nutrition. In contrast, given adequate nutrition, wasting may resolve (i.e., weight increasing to a normal value) in a much shorter period. Because weight may catch up more quickly than height, previously malnourished children may have a tendency to achieve a greater weight-for-height (i.e., they may become overweight). Thus, although it may seem somewhat counterintuitive, some previously malnourished children may be overweight and present with a short, stocky physique.

Persistent poverty from one generation to another can be associated with persistent malnutrition and stunting. Consequently, not infrequently, parents are stunted because of malnutrition when they were children and their children are stunted because of the family's persistent state of poverty and malnutrition. However, if children live in a more favorable socioeconomic environment than their parents did as children, then they can become taller than their parents. Evidence for this is apparent in children in the United States who have grown taller each generation because of improved economic circumstances. For instance, Mexican American children who as a group have a high poverty rate have shown significant increase in heights from 1968 to 1980, suggesting an improvement in overall socioeconomic conditions.

Internationally, the effects of social class and malnutrition on children are very evident. The growth patterns of children from developing countries show that the heights of children from upper socioeconomic classes are similar to U.S. norms, whereas the height of children living in poverty varies from the norm in proportion to the severity of poverty. For example, the heights of children in rural China are 1.5 standard deviations below U.S. norms; that is, 50% of rural Chinese children have a height below the 15th percentile of U.S. norms, and 35% of these children have a height below the fifth percentile. In contrast, the height of children in urban China is only 0.6 standard deviations below U.S. norms. As a result of less poverty, urban Chinese children grow taller than those who live in rural areas.

These findings are important because they indicate that all children are capable of growing to U.S. norms and that U.S. norms should be used with all children independent of race, ethnicity, or country of origin. Indeed, the WHO has recommended that all studies of children's growth should use the U.S. growth curves developed by the National Center for Health Statistics and compare children to these curves by using Z scores (standard deviations). This recommendation emphasizes that genetic potential for growth is generally equally distributed among children from all countries.

Thus, pediatricians have a unique opportunity to work with children who suffer from malnutrition and food insecurity (hunger). Usually, prolonged and multidisciplinary interventions are necessary to improve this clinical condition. Management may involve the participation of nutritionists, social workers, public health nurses, and mental health workers, as well as nonprofessional support groups in the community. As health professionals, we should recognize that malnutrition is as much a social problem as a medical one and act accordingly in our roles as clinicians and child advocates.

Malnutrition is not the only health problem that may affect children from poor backgrounds. Children who live in poverty are also at greater risk of developing diseases from infectious and pathogenic environmental agents. This is because poor children are more likely to live in crowded, substandard housing, with increased exposure to individuals who may have untreated infectious diseases. In addition, if children are malnourished, they are at greater risk for contracting infectious diseases because of the probability of having an impaired immune system secondary to malnutrition. Limited access to health care and isolation from the health care system also contribute to the increased risk of transmission of contagious diseases among poor individuals. Outbreaks of tuberculosis, pertussis, and measles in poor and immigrant populations occur commonly in the United States as well as in the country of origin for immigrants from developing countries. Although simple preventative measures such as immunization can have a major impact on the spread of infectious diseases among poor and immigrant children, these children tend to be among those most often unimmunized. Thus, while we should be concerned about the immunization of all children, immunizing poor and immigrant children serves two purposes, to improve their health and to lessen the probability of spreading contagious diseases to the public.

Exposure to environmental toxins is also more frequent among poor children as they often live in substandard housing that exposes them to deteriorating housing materials and other toxic agents. In urban areas, lead is the most common environmental toxin. According to the latest national survey, elevated lead levels (10 μg/ dL) have significantly decreased due to a concerted public health effort. However, they continue to be higher in poor and minority children, particularly among African American children 1 to 5 years of age who have among the highest proportion of elevated lead levels, 3.1%. An elevated lead level is considered to be a risk for neurobehavioral and developmental delays, and thus can further contribute to the poor growth and development of children living in poverty.

In rural areas, pesticides are environmental toxins of concern. Many poor and immigrant families live and work in close proximity to agriculture fields, so the risk of exposure is high. Pesticide exposure also has become a concern for children living in the inner city because of efforts to control pests. Children, particularly younger ones, are at greatest risk for health problems because of their developing physiology. Unfortunately, it is difficult to determine whether pesticide exposure has occurred as symptoms are usually nonspecific. The effects of these environmental agents on children are not fully understood at present, but clearly, young children are the most vulnerable because of their rapid growth and greater hand-to-mouth contact. It thus becomes the pediatrician's responsibility to question all families, but particularly the poor about environmental exposures in and round their homes and to assess whether the child has **pica** (the behavior of eating nonfood substances), particularly in children who are 3 years of age or younger. Pica is associated with high lead levels in children and is clearly a behavior that should be reviewed with parents to avoid the increases the risk of exposure to environmental toxins.

With regard to chronic illness, the socioeconomic class of children has a variable effect. Most commonly, the occurrence of chronic illness in children is the result of genetic predisposition for a particular disease. For example, sickle cell anemia or cystic fibrosis affects children because of their genetic profile. However, some chronic illnesses in childhood are linked with socioeconomic background, specifically, those chronic illnesses

that are the result of untreated infectious or acute illness. For example, the lack of treatment of pulmonary tuberculosis in a child may lead to an infection that subsequently spreads to the brain, resulting in meningitis and significant long-term consequences. Another example is chronic lead ingestion, which, if untreated, can cause learning and developmental problems that may be irreversible.

Yet poverty can also modify chronic illnesses that have a significant genetic component. Asthma, the most common chronic illness in childhood, has a genetic basis, but poverty can increase its prevalence and severity. This is particularly true for African American and Hispanic children who live in urban areas. Investigators have proposed a mechanism for this effect involving differences in access to health care, patterns of medical care, psychosocial stress, and environmental exposure. The National Cooperative Inner City Asthma Study (NCICAS), a study of poor inner city children with moderate-to-severe asthma, found that although most children had routine health care, 50% had difficulties obtaining follow-up care for their asthma, suggesting that their care was fragmented. Furthermore, only 50% received treatment according to the recommended national guidelines, indicating that the care may have been less than optimal. In addition, psychosocial stress in children and mothers in the NCICAS was high, with 50% of mothers and 35% of children meeting the criteria for referral to a mental health professional. Significantly, maternal and child psychosocial stress levels were correlated with each other and with the child's morbidity from asthma. Exposure to a higher level of environmental pollutants and allergens, a characteristic feature of poverty, may also have affected the prevalence and severity of asthma in children in the NCICAS. Of particular importance was exposure to cockroach antigen, which was found in 90% of homes. The study reported that 50% of the homes in which poor children lived had levels of exposure considered clinically detrimental.

Other external environmental factors beyond the children's own households may also have an impact on their health and development. Neighborhoods can be a positive influence on child development by providing a safe, nurturing environment for play and school. Unfortunately, poor neighborhoods suffer not only from substandard housing, but also frequently from crowded and neglected schools, lack of safe play areas, and high levels of crime. In a study by Campbell and Schwarz of children attending suburban and urban middle schools in metropolitan Philadelphia, they reported that children in poorer urban schools had higher rates of exposure to crime, having known or witnessed someone being robbed, beaten, stabbed, shot, or murdered. Of children who attended a middle school in a poorer neighborhood, 96% knew someone who had witnessed one of the previously mentioned events, and 88% had witnessed such an event. For middle class suburban school children, these same values were 89% and 57%, respectively. Sixty-seven percent of children attending middle school in the poorer neighborhood reported being victimized themselves: 48% robbed, 21% stabbed, and 3% shot. Ninety-four percent of poor neighborhood children had heard gunfire in their neighborhood and 24% had been caught in gun crossfire. Whereas the children from the poorer neighborhoods reported more violent events and experiences, the children from the middle class suburban neighborhoods also reported a greater-than-expected number of events. Although the findings from this study should not be generalized to all poor neighborhoods, understanding the living environments of children is key to providing appropriate health services and working with families to ensure children are safe and nurtured.

Unfortunately, violence involving children is a major public health issue in the United States, and disproportionately affects poor children and adolescents. Children who witness a violent event experience fear, anxiety, sadness, anger, confusion, shock, empathy for the victim, and a desire to become involved in the altercation. These children and adolescents have symptoms of somatization, depression, and posttraumatic stress syndrome, including stomach pains, headaches, trouble sleeping, trouble remembering, nightmares, nervousness, sadness, and a sense of a foreshortened future. Children rarely discuss these events with a health or mental health professional. Thus, health care professionals should be more proactive in seeking a history of exposure to violence, particularly among poor children. They should be alerted to the exposure to violence among children and should receive training about dealing with children and families who have been traumatized by violence. It should be remembered that not infrequently, the complaint of stomach pain might be a symptom of posttraumatic stress from witnessing a violent event. With homicide one of the leading causes of death of school-age children and adolescents, particularly in urban areas, pediatricians need to be involved in helping families protect their children. This starts with identifying the risk for violence.

Racial and Ethnic Disparities

In addition to socioeconomic factors, children's racial and ethnic backgrounds may also influence their health. Discrimination based on racial, ethnic, and other characteristics as a factor affecting health is infrequently discussed, but the presence of discrimination in our past and current society necessitates acknowledging this as a

factor influencing children's health. Discrimination, whether overt or covert, may affect the health of children in one or more of the following ways:

- By forcing families to live in neighborhoods in which health risks are greater
- By causing stressful experiences involving discrimination
- By forcing children and families to develop under an imposed stigma of inferiority
- By causing bias (unintentional) on the part of health care providers (i.e., when a particular provider deals with patients of a different racial or ethnic group)

Discrimination, and in some cases, housing practices designed to limit integration of racial and ethnic groups, have led to the segregation of neighborhoods on the basis of race and ethnicity, as well as income. Such separation can reinforce children's feelings of isolation from the rest of society and may have a negative health effect on the people who live in the neighborhood by producing a stigma of inferiority and visible signs of discrimination. Although there are now laws against housing discrimination, the results of historical racial discrimination still are apparent in some communities. In these communities, families may feel less empowered to change their lives or those of their children. Therefore, although changing the effects of discrimination may seem overwhelming for any one person, as child advocates, pediatricians can give families a sense of empowerment over their children's health through parental education and family involvement. This, along with engaging supportive resources both inside and outside of their local community, can be a first step in empowering families who have suffered from discrimination.

Although the segregation of neighborhoods can have negative health effects, the concentrations of people of similar cultural and ethnic backgrounds may also have positive health effects. For example, maintaining the culture of the country of origin for immigrants appears to have a positive health effect. For instance, infants of immigrant Mexican American mothers appear to do better with respect to low birth weight and infant mortality than infants of later generation or more acculturated mothers, even though immigrant mothers have higher rates of poverty, lower levels of parental education, and less access to health care. In fact, over the past two decades, the prevalence of low birth weight and infant mortality among children born to immigrant Mexican American mothers were similar to nonpoor, non-Hispanic Caucasian mothers. This has been termed the "Immigrant Paradox." The paradox being that poor immigrant mothers can have outcomes similar to higher socioeconomic status (SES) mothers. This phenomenon is seen among a number of immigrant groups and suggests a positive health effect from maintaining cultural health habits with respect to pregnancy and child health. Moreover, this implies that cultural health habits may buffer the detrimental effects of poverty. However, it is important to note that as immigrant women become acculturated to American society, the health parameters of low birth weight and infant mortality appear to worsen and approach the norms of later generation poor mothers. Therefore, this suggests that the cultural buffer to the detrimental effects of poverty that exists for these mothers and children appears to lessen as American cultural practices replace those of the country of origin. Thus, if the "Immigrant Paradox" is a result of positive, culturally based family health practices, then pediatricians should become familiar and supportive of the positive cultural health practices of their patients' families. A community that is supportive of the family culture and provides children and their families with a positive self-image and identity may be a significant health resource and may create a positive psychosocial environment for poor children and families.

Finally, in the health care system, bias among health care providers, although unintentional, should be recognized and eliminated to the extent possible. It should not be unexpected that health care providers exhibit biases and stereotypes, because they were raised in the same society that created them. A review of the literature by the Institute of Medicine (National Academy of Sciences) affirms that one of the reasons for health disparities among minorities is physician bias and prejudice, usually unintentional. Nevertheless, physicians are called upon to rise above these prejudices. In order to do so, they must understand their own biases, and how biases can affect their care of patients. This is a challenge for all of us, independent of our backgrounds, but one that needs to be met for the benefit of our patients.

Disparities in Access to Health Care

The principal determinant of children's access to health care is the ability to obtain health insurance, which in turn depends on the parent's ability to obtain health care coverage, usually from their employer. It is frequently assumed that if parents work, their jobs offer health insurance, or that, if the parents are unable to work, then their children qualify for a social welfare program that provides access to health care. Unfortunately, neither of these two assumptions is necessarily true. In a recent analysis using national data, investigators found that ethnic minorities were much more likely than non-Hispanic Caucasians to be uninsured. Hispanics were the most likely to be uninsured (37%), followed by African Americans (23%), Asian Americans–Pacific Islanders (21%), Native Americans–Alaskan

Natives (17%), and non-Hispanic Caucasians (14%). Although 87% of uninsured Hispanics work, they are much less likely to receive employment-based health insurance, regardless of how much they work or the size of their firm or industry. Likewise, African Americans have lower rates of job-based health insurance compared to non-Hispanic Caucasians, 53% versus 73%. When Hispanic children were categorized by their residential status, non-U.S. citizens are very likely to be uninsured (58%), but even Hispanic U.S. citizens have a high rate of being uninsured (27%). Among children alone, the relative numbers of uninsured were similar to those for all individuals in their group: Hispanic (29%), African American (19%), Asian Americans–Pacific Islanders (15%), Native Americans–Alaska Natives (13%), and non-Hispanic Caucasians (11%). This translates into less acute care and preventive care for children. In addition, uninsured patients are less likely to follow minimum care recommendations.

If children are not able to obtain health insurance through their parents' employment, they may receive financial assistance for medical care depending on their family's income and on their immigration status (i.e., whether a child is a U.S. citizen or a legal resident). States usually determine income eligibility. In many states, an income of up to 250% of the poverty threshold qualifies a family for health care insurance through a state or federal program. A family of four can make as much as $42,625 per year and qualify for a government health insurance program. (This may seem high, but a family of four living in the San Francisco Bay area needs $46,000 just to meet basic housing and living needs.) The requirement for citizenship or legal residence also has been a major deterrent, particularly for children of immigrant families. In the mid-1990s, welfare reform excluded immigrant children from participation in federal and many state programs. For example, in California, undocumented immigrant children were ineligible for the state's Medicaid program except in emergencies. However, they do have access to a preventive health screening program (Children's Health and Disability Prevention program) and to a program to aid families with chronically ill children (California Children's Services).

Although Congress recently passed the Health Care Reform Bill, it does not cover immigrant children, particularly those who are not legal residents. If children are valued, then all children should receive health care, both for their health and the health of society. One should note that three-fourths of all children in immigrant families are U.S. citizens. However, immigrant families, fearful of obtaining government-sponsored health insurance even for their U.S. citizen children because of the implication it has for their efforts to obtain citizenship, are deterred in obtaining care for their citizen children. Accordingly, it is important that pediatricians become familiar with various state and federal programs, especially those addressing the needs of poor and immigrant children, so that they can better serve as health care providers and advocates for our diverse population of children.

TREATING CHILDREN FROM DIVERSE BACKGROUNDS

The information that has been presented hopefully encourages future pediatricians to learn how to adapt their clinical care to meet the sociocultural needs of children and families. Presently and in the future, socioeconomic class, race, ethnicity, and immigration status will define patients' diversity. Each can affect the physician–patient interaction through the processes of verbal and nonverbal communication and differences in the health beliefs between the health care provider and patients and their families. Ultimately, the opportunity exists for more effective interactions with families from diverse backgrounds, but it requires the physician to bridge the diversity gap by effectively communicating and understanding the patient's point of view when it comes to health.

Communication: Verbal and Nonverbal

Obtaining an accurate and comprehensive history from patients is the cornerstone of clinical medicine. The history not only provides the data necessary to understand a patient's complaint and disease process, but it also allows physicians to assess the patient's understanding and response to treatment. In pediatrics, this also necessitates understanding a family's knowledge of and reaction to a child's disease. Obtaining a pediatric history involves an interaction between several individuals: the physician, the patient, the parents, and, on occasion, other caregivers. As with any human interaction, each party has its own set of communication skills, expectations, unspoken understandings, and personal biases. Thus, part of the initial discussion with families from diverse backgrounds should include defining their expectations and understanding who beside the parents are important in making decisions for the child.

To do this, it is necessary to determine whether patients, parents, and providers are fluent in the same language. Frequently, they may not be. In such situations, it is essential to obtain the services of an accurate and culturally sensitive interpreter. Although this seems obvious, too often no interpreters are used in clinical interactions with limited-English-speaking families. Yet, federal law mandates interpreter services. In 2000, President Clinton issued Executive Order 13166 that supplemented Title VI of the Civil Rights Act of 1964. It mandated that all groups receiving federal funds needed to comply with improved access to services for persons of limited

English proficiency. Unfortunately, for reasons of expediency, health providers sometimes will rely on the use of either family members or ad hoc interpreters (i.e., nonmedical personnel working in the area) to provide interpretation to non–English-speaking patients and families. In a review of the literature, Flores found that the lack of a professional interpreter in the pediatric setting has a significant negative impact on parents' understanding of their child's disease and on parents' satisfaction with their child's care. In a clinical study of emergency room care, Flores found that the inability to communicate with parents effectively resulted in errors in diagnosis and in increased morbidity among pediatric patients.

However, even when professional interpreters are available, using them in a clinically effective manner requires conscious understanding that an interpreter is a tool to establish a relationship with the patient, and should not be used just to gather information from the patient. The personal relationship of the pediatrician with the patient or parent is the basis of all clinical interactions, and as such, nonverbal communication is part of the patient's conversation with the physician that can enhance the understanding between the two parties. Table 6-2 provides guidelines for use of interpreters.

TABLE 6-2

Guidelines for the Effective Choice and Use of Interpreters in Clinical Settings

Interpreter Choice
Always use a trained interpreter unless thoroughly fluent in the patient's language. This can be either an interpreter present in person or a telephone interpreter. Hospitals and clinics receiving federal funds should provide at least a telephone interpretation service.
Avoid using strangers from the waiting room or untrained staff as interpreters because of potential problems with accuracy, confidentiality, and medical terminology.
In emergency situations, if trained interpreters are not available, the use of adult relatives or friends brought specifically to translate may be temporarily acceptable alternatives, but problems with accuracy, confidentiality, medical terms, and disrupted social roles may occur. A professional interpreter should be sought as soon as possible to confirm the patient's information.
Children should not be used as interpreters because of problems with disruption of social roles, sensitive issues, and accuracy.
Always ask the patient whether a designated interpreter is acceptable.
Interpreter Use
Position the clinician, interpreter, and patient/parent in an equilateral triangle so that important nonverbal cues can be appreciated.
Speak to and maintain eye contact with the patient/parent, not the interpreter.
Ask the interpreter to translate as literally as possible.
If mistranslation or misunderstanding is suspected, return to the issue later using different wording.
Emphasize key instructions and explanations by repetition.
Use visual aids (charts and diagrams) whenever possible to verify the quality and comprehension of the translation, and have the patient/parent repeat information through "back translation."
At End of Medical Visit
Have the interpreter write lists of instructions for the patient/parent, particularly for prescriptions and other therapeutic interventions.
Indicate to pharmacists that prescription instructions should be printed in the patient's/parent's language.
Always have an interpreter accompany the patient/parent to schedule follow-up appointments with the receptionist.

Adapted from Flores G: Culture and patient-physician relationship: Achieving cultural competency in health care. *J Pediatr* 136:14–23, 2000.

In the end, physicians should see the office visit as an interaction between two cultures, that of the patient and the physician's own. Helping patients and their families develop their health literacy is a key component to quality health care today. Clinicians should be cognizant of the historical, political, and economic factors of patients' families that may affect health literacy. They should recognize that patients have unspoken understandings about the role of the physician. If both the physician and the patient are from similar sociocultural backgrounds, these understandings about roles and expectations usually coincide. However, if they are not, then socioeconomic, racial, or ethnic biases may lead to misperceptions that, in turn, may cause problems in communication. Some sociocultural misperceptions are transmitted unconsciously through nonverbal communication. For example, in some cultures, respect for physicians does not encourage asking questions. Thus, patients or parents who are silent after being asked whether they have any questions, or who nod their head in response to a question may not necessarily agree with the physician, but instead, may have significant concerns about what the physician has said. Having a socioculturally sensitive interpreter who can interpret nonverbal signs or by directly asking parents or patients about their satisfaction with care helps the pediatrician acknowledge these misperceptions, which lowers the barriers to effective health care.

Health Beliefs

Everyone has a notion of what it means to be healthy, and in some ways, an understanding of what keeps us healthy or makes us sick. Depending on their exposure to Western medicine, many people share some of the same views about medical treatment. However, based on individual health beliefs, people frequently use alternative therapies (complementary and alternative medical care [CAM]). About 33% to 50% of adults in the United States report using CAM therapy, and among some ethnic groups, folk remedies or CAM therapies may be more common. This is particularly true for new immigrants, who bring their health beliefs and therapies from their country of origin with them. Although at times these CAM therapies may seem exotic and contrary to Western medicine, practitioners should acknowledge these attempts on the part of parents to help their children. If these measures are not harmful, clinicians should try to integrate them into the medical management of the patient. Clearly, parental education is necessary to prevent the use of folk remedies that have any harmful effects (i.e., lead-containing folk remedies, such as *greta*, *azarcón*, or albayalde treatment for *empacho* in Mexican Americans).

Unfortunately, parents or patients often never tell physicians about the use of alternative treatments because they feel uncomfortable relaying such information. Therefore, pediatricians need to open discussions by asking patients or parents what they believe is wrong with the child's health, what they think is causing it, and what have they done to make it better. It is also useful to normalize the use of folk or alternative medicines by saying, "Many people use. . . for your child's condition. Have you heard of it? Have you used it?" In these ways, physicians may make themselves aware of the patient or his parents' health beliefs, thus enabling the physician to integrate them into the therapeutic plan.

In summary, the role of the pediatrician is key to the healthy development and well-being of all children. Becoming aware of the uniqueness of every child and his or her family will allow each pediatrician to fulfill that role and to enjoy the practice of pediatrics.

Ethical Issues in Pediatric Practice*

Alan R. Fleischman

Pediatricians play a special role in society because they are both caregivers of children and advocates for their best interests. The practice of pediatrics involves concern for the physiologic health of children as well as the emotional and psychosocial development of children within families. This role is quite different from the responsibilities faced by physicians caring for adults and creates significant challenges. Pediatricians are often faced with ethical dilemmas and conflicts of values or conflicts of duties when they care for children and make recommendations for their treatment. Sorting out ethical dilemmas is not just a matter of personal opinion; it requires a rational process to determine the best course of action in the case of conflicting choices.

In the past 30 years, the role of the physician in American society has changed from that of the highly respected and rarely questioned paternalistic decision maker, to that of a collaborator who is expected to provide recommendations for health care decisions made by patients and families. Patients have become consumers of physicians' services, expecting to be fully informed and increasingly responsible for decisions about their own health care. This respect for a person's fundamental right of self-determination or autonomy has resulted in the practice of allowing adults to make health care decisions for themselves, even if the physician disagrees and, more importantly, even if the physician perceives that the decision is not in the patient's best interest. This principle, known as "respect for persons," incorporates two ethical convictions: that individuals should be treated as autonomous agents and that persons with diminished autonomy are entitled to protection. This fundamental idea maintains that all persons capable of participating in decision making have the right to determine what happens to their own bodies. Furthermore, individuals with diminished autonomy who are incapable of participating in decision making for themselves are entitled to additional protection from harm. In general, society believes that children, at least very young children, have diminished autonomy and require protection.

The doctrine of informed consent, an expression of this respect for a person's right of self-determination, assumes that patients can understand the risks and benefits of alternative treatments and can make informed choices. When the process of informed consent relates to children or to individuals who lack the capacity to decide for themselves, it involves the use of a proxy or surrogate. Any proxy consent is based on another person's perception of the appropriate choice, not on an individual's choice. Many people have argued that the respect for a person's fundamental right of self-determination should extend to the family, who could be viewed as an autonomous unit. In this view of self-determination, the judgments of family members could substitute for those of members who cannot participate in decision making.

Although pediatricians should respect the important role of parents in providing informed consent for their children, unquestioning acquiescence to parental wishes can sometimes be problematic. The principle of informed consent for autonomous adults is extremely powerful; it allows capable adults to refuse treatments despite negative consequences. However, parental refusals of treatments that are deemed clearly beneficial for their child do not carry the same weight as refusals by competent adults for treatments for themselves. Parental refusal of necessary therapy does not relieve physicians or other health care providers from an ethical duty to the child, particularly if the refusal of such treatment puts the child at significant risk.

This ethical duty derives from the principle of "beneficence," which states that ethical treatment involves not only respecting the decisions of patients and protecting them from harm, but also making efforts to secure

**Parts of this chapter were adapted from Fleischman AR, Nolan K, Dubler NN, et al: Caring for gravely ill children. Pediatrics 94:433–439, 1994.*

their best interests or well-being. Beneficent actions attempt to maximize possible benefits and to minimize possible harms. Both physicians and parents have beneficence obligations to a child. To fulfill beneficence obligations to children and to preserve their future right to autonomous decision making, another concept, known as the principle of the "best interests of the child," has evolved. This principle promotes decision making for the benefit of the child, even if, in rare occurrences, it conflicts with parental beliefs. The "best interests" standard presupposes that decision makers are able to consider the interests of children as primary, regardless of their own interests and those of other family members.

Although the "best interests of the child" is the appropriate standard for treatment decisions, it is important to realize that what is in the best interest of any individual is often uncertain. When faced with a lack of clarity about what is effective or beneficial, it can be argued that those who bear the burden of the decision (e.g., in the case of a child, the family) should play the major role in making the choice. Families play an important, if not vital, role in deciding the future outcome of children. Their input and support is crucial to optimize the environment in which children live. Thus, it seems that the "best interests" standard for children must incorporate recognition of the interests of families and a commitment on the part of society to provide the resources that allow families to support children's interests without creating an undue burden.

ETHICAL ISSUES IN NEWBORNS

CASE 7-1
The pediatric team is called to the delivery room to resuscitate a 550 g (1¼ pound), 24-week-gestation, premature male infant who has just been born. This infant, just past the threshold of viability, has a reasonable (50%) chance to survive with aggressive intervention and greater than a 50% chance of being normal if he survives. He may suffer all the complications of prematurity, including cerebral palsy, mental retardation, impaired vision and hearing, and chronic lung disease. Should the pediatricians resuscitate the infant? Should the medical team allow the family to choose whether treatment is initiated? If treatment begins, under what circumstances may the clinicians withdraw it? Who should make these decisions and by what process?

Dramatic changes in the technologic care available to newborn infants have resulted in the capability of saving the lives of the majority of even the sickest, smallest neonates. In most neonatal centers, the survival rate of newborns as young as 24 weeks gestational age and weighing above 500 g is greater than 40%. Infants born at 1,000 g and 28 weeks gestation, thought to be at the threshold of viability in the 1960s and 1970s, now have up to a 95% survival rate. In addition, the development of new surgical techniques in the past two decades has allowed for the correction or amelioration of congenital anomalies of the heart, kidneys, intestine, liver, and brain. With intravenous parenteral nutrition, infants can grow and gain weight with normal development for weeks, months, or years without oral intake. These advances in neonatal medicine have enhanced the lives of countless children, yet at the same time they have also resulted in saving the lives of some children who are left with severely disabling and handicapping conditions. (See Chapter 10, Neonatology.)

All decisions for critically ill children in a neonatal intensive care unit are made in the face of great uncertainty as to long-term outcome. It is frequently difficult to predict which infants will survive and thrive with a good future quality of life and which infants will suffer irreversible damage, resulting in devastating chronic illness. American author, Jeff Lyon, in his book *Playing God in the Nursery*, graphically portrays the dilemma of this uncertainty:

> *If it is hard to justify creating blind paraplegics to obtain a number of healthy survivors, it is equally hard to explain to the ghosts of the potentially healthy that they had to die in order to avoid creating blind paraplegics.*

In general, American neonatologists have evolved a decision-making strategy that deals with this uncertainty by ranking the death of an infant who could have lived a reasonable life as worse than the saving of an infant who becomes devastatingly disabled. Both outcomes may be viewed as tragic. In general, pediatricians believe that neonates with a chance of survival deserve resuscitation in the delivery room, followed by stabilization in the neonatal intensive care unit (NICU) until data increasing the certainty about future outcome become available. When death or signficant impairment of future quality of life seems likely, physicians may

recommend withdrawing treatment or withholding future treatment. This approach to the uncertainty of neonatal outcome contrasts with the vitalist approach, which advocates aggressive intervention for all infants until death is certain, or a statistical approach, which seeks to minimize the number of infants who die slow deaths or live with profound handicaps by treating only those infants who satisfy minimum weight or gestational age criteria.

At the core of all discussions concerning appropriate treatments for critically ill neonates is the question of how much people value members of society who have disabling and handicapping conditions. Each infant has an inherent worth that deserves respect, regardless of the extent of their physical defect or future cognitive impairment. Physicians should discuss all treatments that may potentially enhance the interests and well-being of infants with family members. However, this respect for infants does not mean that because a treatment is available, a physician must provide it.

Assessment of what is in the best interests of a particular infant includes analysis of the potential benefits and burdens of the treatment plan, the likely prognosis, the future expected quality of life of the child, and the views and values of the family. If the potential for ultimate survival is small, the burdens of a proposed treatment great, or the future quality of life likely to be poor, a recommendation not to provide a particular treatment may be appropriate. The parents of neonates should be the ultimate decision makers, unless they are choosing a course of action that is clearly against the best interests of the child. The birth of an abnormal newborn may be tremendously stressful for parents, but it is possible to educate almost all parents about their infant's condition so that they can make decisions in the child's best interest.

Hospitals now have bioethics committees that are available to review complex, value-laden decisions in order to assist parents and professionals in the determination of what is in the best interests of infants. These multidisciplinary committees include physicians, nurses, social workers, ethicists, clergy, and other professionals who are interested in protecting and promoting the interests of particular children. Some physicians have resisted the use of bioethics committees; they contend that the best person to make such complex decisions is the treating physician at the bedside, who is most knowledgeable of the medical facts as well as the infant's interests and the family's wishes. However, most clinicians who have used infant bioethics committees believe that the committees enhance the decision-making process by reviewing the medical facts and protecting infants' interests while invoking ethical principles, and not merely intuition, in decision making. Infant bioethics committees may also enhance the role of parents in decision making by supporting parental choices in ambiguous cases in which it is uncertain as to what is in the best interest of a particular child. In addition, such committees can provide ethical comfort to both families and health care professionals who are ultimately responsible for both making and implementing difficult decisions.

When parents refuse what the health care providers and the ethics committee believe to be clearly in a child's interests, procedural mechanisms involving the courts have been developed to override parental choice. These legal approaches are the embodiment of the physician's beneficence obligations to a child, protecting an infant from inappropriate cessation of treatment. An example of this type of intervention is the court-ordered administration of blood products to save the life of a child whose parents' religion prohibits transfusions.

Increasingly, a new type of ethical dilemma is occurring in NICUs. Physicians who become comfortable with families having the discretion to choose to withhold or withdraw life-sustaining treatments from critically ill newborns are concerned about families who insist that their infants receive life-sustaining treatments that are deemed by the professionals to have minimal, if any, benefit. What should happen when physicians disagree with a parental request for treatment that will be life-prolonging but possibly not life-enhancing? When a treatment has no potential benefit and will only inflict pain and prolong suffering, physicians are not obligated to provide or even offer such interventions even if requested by parents. However, when parents request a treatment that offers a low likelihood of benefit, even in the face of significant burden, health care professionals should not make this decision themselves.

In general, when caring, concerned parents request continued attempts to save or prolong the life of their child, physicians should not impose their views over the values of the family. Clinicians should give broad latitude to parental discretion regarding choices for children when there is honest uncertainty concerning the ratio of benefits to burdens of continued therapy. However, parental discretion in demanding treatment should not be unlimited. Physicians and other health care providers, based on their own strongly held personal beliefs, have the right to opt out of the care of children for whom they believe the benefits of treatment do not outweigh the burdens. In addition, society has the right through its laws, regulations, and institutions to limit individual resource allocation for patients unlikely or unable to benefit from continued treatment.

ETHICAL ISSUES IN YOUNG CHILDREN

CASE 7-2
A 6-year-old girl with juvenile diabetes no longer wishes to cooperate in testing her blood sugar and taking insulin injections. Lack of insulin will cause the child to lose weight and eventually become seriously ill. Her parents seek advice from the pediatrician on what to do. Should the pediatrician respect the child's refusal? Should the parents punish the child for noncompliance?

Although most young children lack the capacity to make binding choices, their individual needs, interests, and perspectives must still be a central focus of health care decisions. Certain aspects of treatment and decision making permit, and sometimes even require, the participation of young patients. The proper role of children in planning care depends less on chronologic age than on developmental and personal capacity. For example, although 10-year-old children are usually less able to understand abstract concepts than adults, some may act or think quite maturely. Children even younger than 10 years of age often have a keen appreciation of their own clinical situations and options. Although very young children may be unable to envision the future benefits of a treatment that may justify its associated burdens (e.g., pain, discomfort, hospitalization), adults should not ignore children's perceptions of those burdens. Physicians should encourage children to verbalize their feelings and to choose methods to enhance their comfort or acceptance of painful or unpleasant procedures.

As children become older and more perceptive, they should be involved more fully in decision making concerning their care. Children may have religious or other values that shape their responses to illness, and they often are able to articulate personal goals and even views of death that warrant respect. There is no simple formula for determining whether and to what extent children are capable of participating in planning their own care. Parents and pediatricians should jointly decide how much weight to give children's treatment preferences, taking into account not only the child's level of understanding and ability to anticipate future consequences of present actions, but also the gravity of the decision in question, the likelihood of benefit, and the probability and severity of the burdens of treatment. Adults should respect children's right to disagree. However, on occasion, parental wishes must prevail for the best interests of the child.

For example, take the case of the 6-year-old girl with diabetes who is refusing to cooperate with the treatment regimen. The girl's inability to fully assess the consequences of her actions is a sign of immaturity, and she is at significant risk of serious harm if her pediatrician and family accept her choices. The clinician, in concert with the family, must provide treatment while working with the child to help her understand why this particular regimen is being followed.

At the very least, physicians or parents should inform children, in terms appropriate to their developmental level, about the nature of their condition, the proposed treatment course, and the expected outcome. By asking children about their hopes and fears, health care professionals and families may gain understanding about what the illness means to an individual child, and it may also provide valuable insights into how well children process information and form opinions. Such efforts foster children's cooperation and involvement and increase children's feelings of self-esteem and respect.

Because of parents' desire to protect, they may object to informing their children about a disease, proposed treatment plan, or prognosis. Health care professionals have an obligation based on an independent relationship with children to ensure that they receive adequate information. At the same time, these professionals should help parents understand that a conspiracy of silence rarely succeeds, often leaves children with unanswered questions and fears, and may be harmful to children's development of trust.

Regardless of children's level of participation in planning care, physicians should give young patients as much control over actual treatment decisions as possible. Even 2- and 3-year-old children may be able to help manage their treatments or at least determine the order in which various procedures are performed. Physicians and parents should not mislead or deceive children about their degree of authority. If a negative answer is unacceptable, then health care professionals and caregivers should avoid asking for children's approval. If a procedure is necessary, honesty demands that physicians offer children a more limited but feasible range of options (e.g., choosing in what order to receive a series of tests or whether or not to have a parent present).

Many childhood illnesses are chronic in nature with acute exacerbations and times of quiescence of disease. Young children faced with such chronic illnesses may develop and articulate clear sets of values and desires concerning future treatments and future quality of life. The child's perspective should be an integral part of

planning care. The goal for health care of chronically ill children should be to prolong and normalize their lives, optimize their functioning, and enhance their future potential productivity. These goals are not always attainable, and some physicians and parents may wish to provide all available therapeutic interventions, even those that offer only the slimmest possibility of achieving short- or long-term survival. Aggressive treatments that hold out little hope of success may be excessive and cause children to suffer pain, fear, and isolation for little potential benefit. Physicians and parents must deal with the difficult issue of knowing when to decrease technologic intervention and to increase palliative and comfort care. Continued unsuccessful attempts at treatment may divert children and families from integrating the inevitability of impending death.

An increasing number of chronically ill children are dependent on technology such as respirators, intravenous feeding, and dialysis machines. These infants and children are often "graduates" of neonatal and pediatric intensive care units and beneficiaries of new life-saving technologies. Because they will require technologic assistance for many years, perhaps for the duration of their lives, many people contend that these children are better off living at home. Thus, programs that allow for the home care of technology-dependent children have developed throughout the United States.

Many families have accepted the responsibility of caring for technology-dependent children in the nurturing environment of the home. Such families are motivated by a clear desire to have their children at home as part of the family, and for the most part, the family provides the majority of the child's care. It has become increasingly clear that it costs less to care for technology-dependent children at home than at an acute care hospital or chronic care facility. This realization has created an important ethical dilemma. In order for society to spend fewer dollars for the care of children, it has become common to ask families to assume the burden of care, with consequent family cost and disruption.

Society must address and define the limits of parental obligation to chronically ill, technology-dependent children. Those families who make great sacrifices deserve praise, but at the same time, do those who do not wish to or cannot provide this extraordinary level of commitment to their child warrant condemnation? Should society take custody of a child away from parents because they cannot provide adequate home care for a technology-dependent child? Even if a family has the ability to provide such care, does this imply that they are obligated to keep their children at home when this will dramatically affect the lives of others in the family? If home care for children is a good that society wishes to foster, families should receive adequate social support and financial incentive to make caring for children within the family an experience that enhances the interests of all concerned. Families who object should not be forced to care for children at home; society should provide creative alternatives to care for such technology-dependent children while allowing parents the ability to maintain their legal and emotional ties to their children.

SPECIAL PROBLEMS OF ADOLESCENTS

CASE 7-3

Samantha is a 15-year-old girl newly diagnosed with leukemia. She and her family want her doctors to do everything to cure her of this serious disease. However, she and her parents are Jehovah's Witnesses and will not accept blood or platelet transfusions if they should become necessary secondary to complications of the aggressive chemotherapy required to eradicate the leukemic cells. Should the pediatrician respect the adolescent's and family's wishes concerning transfusion? Should the pediatrician allow the family and the child's wishes to result in her death?

Adolescence is a period of intense physical growth and maturation, accompanied by rapid changes in cognitive capacity, abstract thinking, and moral development. As children move into adolescence, they interpret the values inculcated by their family and develop opinions of their own. They shape their opinions first through comparisons to their peer group and later by a firmer sense of self and the ability to assess options and understand the consequences of actions. Increasingly, they base moral choices on abstract values, but peer influences sometimes override internal concepts of right and wrong. Adolescents are well-known for an increased propensity for risk-taking behavior, which results from their curiosity, sense of omnipotence, and a drive to establish independence from parents and other authority figures. Illness itself may be a major influence on adolescent development and the capacity to make health-related decisions. Although certain diseases or therapies may impair cognitive function and

limit the ability to participate in decision making, experience with an illness over time may empower adolescents with clear understanding of both the choices and consequences of a given health care decision.

Age alone is not a sufficient determinant of intelligence, experience, maturity, or perception, and physicians and parents should not use age as the sole criterion when deciding whether teens are capable of participating in health care decisions. Even cognitive ability alone is not sufficient. The combination of maturity and the ability to weigh the risks and benefits of alternative courses of action with an understanding of future consequences is the key to assessing the ability of adolescents to make independent decisions. Decisions of adolescents about their own health care deserve great consideration if they are able to:

- Make virtually all decisions about their daily affairs
- Fulfill school or work obligations
- Make and keep medical appointments
- Articulate needs and follow recommendations
- Appear to understand the benefits and risks of proposed treatments

Physicians should respect the wishes of this 15-year-old girl, unlike those of the 6-year-old girl in Case 2, if the teenager has a fully developed view of her religious beliefs and the ability to understand the consequences of her choices. Careful assessment of the adolescent's ability to make decisions and an assessment of her independence from parental coercion must be performed before deciding to allow her view to prevail. Adults are given the right to refuse any treatment based on respect for their autonomy, including the right to refuse treatment even with grave consequences. It may be difficult for pediatricians to accept that adolescents have reached the level of maturity required to make such choices, but many teenagers do have the capacity to make hard decisions, and their views warrant respect. This is particularly true when adolescents and their parents are in agreement, as in this case, and their views and values conflict with physicians' recommendations.

Ideally, decisions concerning adolescents should be collaborative and include patients, parents, and health care professionals. If adolescents disagree with their parents about the best course of treatment, and health care professionals believe that this choice is reasonable, physicians should respect the young person's position after a careful assessment of the adolescent's capacity and mental health. At the same time, clinicians should attempt to work with the families to develop a reasonable plan of management. Pediatricians should not accept parents' surrogate decision making for patients whom they believe to be functionally autonomous.

If adolescents request confidentiality in an attempt to prevent their parents from learning of impending death or to hide certain behaviors that have resulted in an illness or injury, health care professionals are faced with another ethical dilemma. Physicians should explain the full scope of the problem to their patients, emphasizing that it may be more difficult to maintain confidentiality as the condition progresses, and there will be an increasing need for continuous support from a caring adult, preferably a parent. Most often, adolescents will benefit from the emotional support of parents and other family members, and health care professionals can help young people by explaining this and creating a plan that ensures family involvement. Many professionals who work with adolescents believe that if teenagers insist on maintaining confidentiality, physicians should comply with their patients' request not to share information with parents. Physicians who are unwilling to maintain confidentiality should explain this to adolescents. Clinicians should not violate an adolescent's trust by informing the parents and asking the parents not to tell a child of their knowledge of the matter.

Some adolescents are, by law, considered emancipated minors capable of making legal and binding decisions concerning their own health care. In general, these emancipated minors live independently, are in the military, or are parents of their own children. In addition, in most jurisdictions, even adolescents who are not emancipated may legally consent to medical treatment for sexually transmitted diseases, pregnancy and its prevention, and abortion services. It is clear that many older adolescents possess sufficient maturity and should be allowed to consent to or refuse care without parental involvement. The appropriate role of health care professionals who are caring for adolescents is to respect their patient's evolving autonomy and foster the young person's role in decision making whenever possible.

END-OF-LIFE CARE

Sadly, there may come a time in the care of critically or chronically ill children when parents and health care professionals may need to question the appropriateness of continued treatment or the initiation of new treatment. Concerned adults may value children's intrinsic worth and want to support their interests, but they must also face the reality of the impending death of a child.

When considering allowing children to die, many physicians believe that withdrawing a treatment is legally and morally less justified than withholding one, but this distinction is erroneous. In the real world, bad deeds seem to occur more often because of someone's action rather than from lack of action. However, in the physician–patient relationship, with its implied contract to help and provide appropriate treatment, there is no moral difference between withholding and withdrawing a treatment if the expected result of either action is the death of the patient. If there is a good reason to withhold a particular treatment from a particular patient, then it is equally defensible to withdraw that treatment if it is ineffective after it has begun. Conversely, if a treatment is morally indicated, it is just as wrong to withhold that therapy as it would be to withdraw it. There is no question that it is psychologically more difficult to withdraw a treatment than to withhold one, but this psychologic difference does not create an ethical distinction. In addition, although many physicians believe that there is a legal difference between withholding and withdrawing treatments, in the opinion of most legal scholars, nothing in the law makes stopping treatment a more serious legal issue than not starting it in the first place.

In recent years, some medical professionals have contended that withdrawing a treatment after a time-limited trial of efficacy is morally superior to withholding a treatment because of its uncertain effectiveness. Physicians often make decisions to withhold therapy in emergent situations in which uncertainty of outcome is quite great and contemplative discussion is impossible. On the other hand, they may base decisions to withdraw a treatment after a trial of therapy on additional information and perhaps more thoughtful discussion with patients or parents.

Some parents regard survival of severely ill or debilitated children as undesirable, and they sometimes resist proposed therapies that are unlikely to fully restore their child's health and function. Other parents believe that life has value under any circumstances, regardless of suffering, disability, or handicap, leading to requests for any and all treatments that can conceivably prolong children's biologic survival. Ascertaining what constitutes the best interests of children in these uncertain circumstances can be extremely difficult.

Perhaps the clearest example of such a case is that of children who have been diagnosed as brain-dead and whose organ functions can be maintained only by technologic support. In virtually all jurisdictions in the United States, determinations of death are possible after the irreversible cessation of circulatory and respiratory functions or the irreversible cessation of all functions of the entire brain, including the brainstem. There are specific brain death criteria for children; a degree of caution is necessary when applying them in very young infants. After a competent determination of brain death, children are deemed to be dead and, therefore, to have no interest in continued treatment. In such circumstances, most experts believe that no treatment should be provided even if requested by parents. Technologic intervention may continue for a short period of time for psychosocial support of the family or for maintaining organs for transplant donation but not in the interests of the deceased child.

Children who have no cortical function and no conscious ability to respond to the external environment but who do not fulfill the criteria for brain death (e.g., a child in a persistent vegetative state) present a more complex case. The only possible benefit of continued treatment is the prolongation of physical survival or the hope of an error in the diagnosis of irreversibility. Careful neurologic examination and testing with reference to the cause and circumstances of the illness or injury can make misdiagnosis extremely unlikely. Because such children presumably cannot experience either suffering or joy or interact with the environment, they have few interests, if any, to which a "best interests" standard might apply, except the interest in being maintained in a comfortable and dignified manner. In these cases, in which there is no interaction with the environment and yet no pain and suffering, the "best interests" standard requires a supplementary standard that considers the presence or absence of basic human capacities. The ethical principle that justifies this additional standard is the proposition that biologic human life is only a relative good in the absence of certain distinctly human capacities such as self-consciousness and the ability to relate to others. Professionals may counsel parents faced with such tragic circumstances to withhold or withdraw all life-sustaining medical treatments from their children on the basis of a perception of the child's interests and possible future quality of life, as well as the potential minimal benefits of continued treatment. However, it remains the parents' choice whether treatment should be withdrawn or continued.

Decision making is more complicated when the prospect of successful outcome is less certain or the degree of burden is high. Parents, physicians, and others may quite reasonably become distressed by the pain and suffering caused by treatments expected to be of marginal usefulness. A small statistical chance of survival may not seem worth the agony of such treatment, especially if the course of therapy is prolonged. At some point, acceptance of likely death by physicians and parents, as well as children, may be preferable to exerting all efforts to avoid it. There is no easy way to determine when the burdens of treatment become sufficiently great to warrant a change in management away from attempts at cure solely toward the promotion of comfort. However, sound

decision making requires that parents and their children, in consultation with health care professionals, make a judgment about the proportion of benefits to burdens. When it is recognized that attempts at cure or restoration of function are no longer reasonable, the promotion of comfort becomes the primary goal of medical management; the health care team must devote its efforts to helping children and their families cope with the process of dying. Providing adequate pain relief is crucial in this endeavor, because both pain and the fear of pain create tremendous suffering for everyone involved. In the care of terminally ill children, when promotion of comfort is the primary goal, most health care professionals do not hesitate to utilize full and effective doses of pain medication, even if a possible secondary effect is sedation, depression of respiration, and the possible hastening of death. Careful titration of pain medication is intended to promote comfort and should not be mistaken for an act of killing.

In addition, it is important to determine where children should spend their last days. Many children experience a less traumatic and more comfortable death at home than in the hospital. If families receive adequate support and are prepared to deal with pain relief and the signs and symptoms associated with impending death, home care may be appropriate. Many hospices offer support services to aid families who wish to support dying children at home. Alternatively, the hospital or inpatient hospice may be the appropriate setting for children whose families do not wish to cope with a terminally ill child at home. Death in the midst of loved ones and without the burdens of technologic intervention is possible in a hospital, either in an inpatient hospice unit or through special arrangements on pediatric units. It is important to develop an environment that facilitates continuing emotional and spiritual support for children and families before the child's death; this should continue through the grieving process to assist families in coping with the profound impact of a child's death.

Health Care Economics and the Future of Health Care Organization

Steven P. Shelov and Elizabeth K. Kachur

Health care economics is rarely discussed in traditional textbooks for medical students because it does not seem to be relevant to clinical medicine. However, current times clearly dictate a broader orientation for the successful practice of medicine. **Systems-based practice** is a core competency for all physicians-in-training and practicing clinicians. It is defined by the Accreditation Council for Graduate Medical Education (ACGME) as actions that "demonstrate an awareness of and responsiveness to the larger context and system of health care, as well as the ability to call effectively on other resources in the system to provide optimal health care." Systems-based practice requires at least some understanding of the economics of health care in our current world.

It is important for medical students to become familiar with the language of health economics (Appendix 8-1). The Internet provides many additional glossaries, some of which are updated periodically (see Suggested Readings). As the health care system changes, some terms fall into disuse and new concepts emerge. Yet, all health care providers must keep up with this terminology to effectively negotiate the system for their patients, their teams, and themselves. Without a firm understanding of who pays for health care, how insurance companies determine what they can provide, how the health care market works, and what life is like in local and national practice environments, future pediatricians will find themselves at a distinct disadvantage.

Pediatric Pearl: Without being both competent in systems-based practice and knowledgeable of the local and national health care environment a physician is at a distinct disadvantage.

This chapter provides some of this necessary information and background. It begins with a description of how the health care market differs from other markets and who pays for health care. It then continues with a discussion of the major forces (e.g., private industry and government) that have shaped the current system. Finally, the chapter will address how physicians will need to adapt their practice to the unfolding priorities of emerging health care systems.

HEALTH CARE: AN ATYPICAL MARKET

The health care market is intrinsically different from the traditional supply-and-demand market because the products are never guaranteed and they often affect society in addition to the individual. Typical market purchases result in direct satisfaction to the consumer with few externalities (e.g., secondary gains or spillover effects). Usually buyers are knowledgeable about the items they purchase, make rational choices, and are fairly certain about the outcome. For example, buying a lawn mower typically involves doing research and purchasing the most suitable machine available. The lawn mower will cut grass and the consumer knows what they are "getting for their money." Although variations in price may influence the type of machine people buy, no one would buy more than one lawn mower just because they are becoming less expensive.

Purchasing health care involves an entirely different series of decisions and rationales.

TABLE 8-1

Characteristics of Typical Markets and Atypical Health Care Markets

Typical Market	*Atypical Health Care Market*
• Direct satisfaction to customer	• Satisfaction from health, not medical care per se
• No externalities or spillover effects	• Externalities or spillover effects
• Well-informed consumer (certainty concerning outcome of purchase)	• Poorly informed consumer (little knowledge about competence of provider; significant degree of uncertainty about outcome)
• Rational consumer	• Health is not a rational series of choices

Pediatric Pearl: It is health that gives satisfaction, not the purchase of health care. Unfortunately, consumers are not able to predict how much "health" they will achieve by purchasing a specific amount of health care.

Buying more health care may be an attempt to achieve good health, but it certainly does not guarantee it. In addition, the purchase of health care may have many spillover effects. For example, not only are families who receive immunizations healthier, but they also do not infect others who might be susceptible. (Buying a particular lawn mower has little effect on anyone but the consumer.)

There is no perfect guide to the purchase of health care, and consumers may be poorly informed. Although current health care–related information is certainly better than it used to be, there are still few guarantees and many differences of opinion. In the past, people depended on providers and believed this was sufficient. Now, they seek information from insurance companies, advertisements, the Internet, the media, and other patients. Yet their education is rarely comprehensive, which may contribute to the excessive or needless purchasing of health care services.

The purchase of a computer may simulate the atypical health care market most closely. In many cases, people still derive a sense of satisfaction when they buy a fancy computer with extensive capabilities well beyond their level of need. Often there is excessive buying or upgrading with marginal improvement in computer literacy.

Health does not permit a series of rational choices. When it comes to their health, many people say, "there is no limit to what I would spend." However, the purchase of more health care services does not always result in better health or an improved quality of life. For all of these reasons, the **health care market is atypical** (Table 8-1).

HOW MUCH DOES HEALTH CARE COST?

Health care expenditures have changed greatly since the beginning of the 20th century. In 1929, $3.6 billion was spent on health care that accounted for 3.5% of the gross national product (GNP), which is now referred to as gross domestic product (GDP). In 2008, national health expenditures exceeded $2 trillion, or 16.2% of the U.S. GDP. The average per capita expenditure, also known as the personal healthcare expenditure, rose dramatically as illustrated in Figure 8-1.

Although there has been a rise in health care costs worldwide, the curve has been steeper for the United States. However, there has not been a significant gain in national health status. Even though the United States spends more money per capita than any other nation, it ranks only 37 out of 190 countries on the 2000 World Health Organization (WHO) health care systems performance list (based on population health and health system efficiency). In comparison, France held the 1st place but spent only 9.6% of its GDP on health care in 2000, and Japan holds the 10th place but spends only 7.6% of its GDP on health care.

Pediatric Pearl: Each year, health care costs have increased by 5% to 11%. This has created an environment in which consumers and providers need to seriously examine the sources of these increases and develop methods for limiting them.

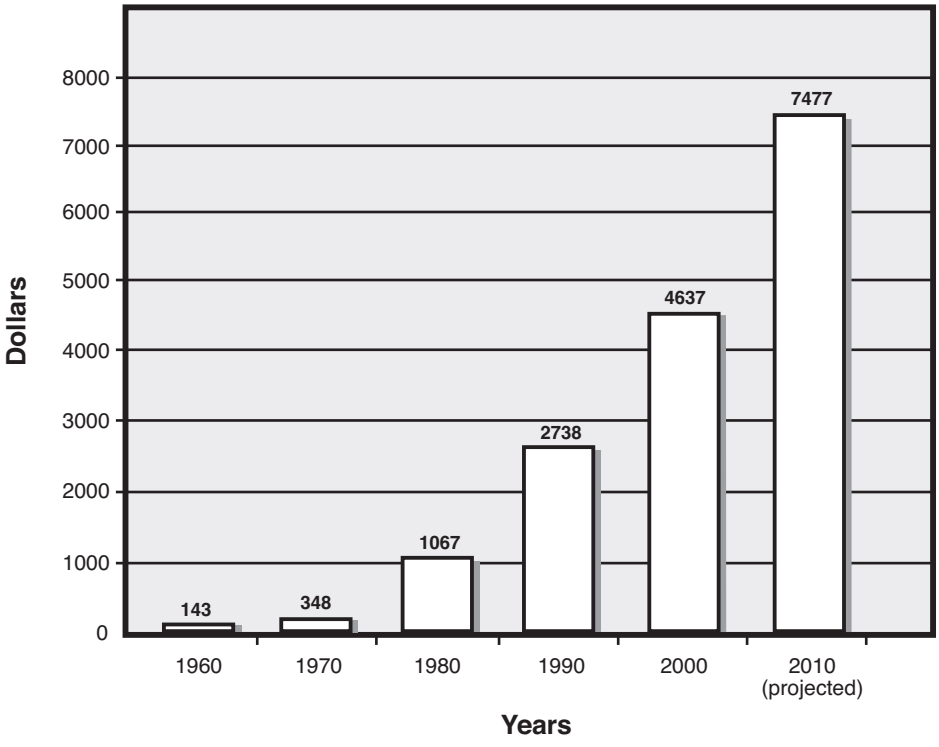

FIGURE 8-1. Personal health care expenditures. What is the per capita cost for health care in the United States? In 1960, each person spent an average of $143 on health care. By 2000, that amount had risen to an average of $4,637, and it is expected to almost double by 2010. The sharpest rise occurred between 1970 and 1980, when the individual amount paid for health care tripled.

Physician services account for a significant percent of health care costs, but not the majority (Figure 8-2). Over the past 50 years, expenses for physicians have amounted to an average annual increase of 10% to 11%, which has remained steady compared with other health care costs. In 2008, physician and clinical services accounted for 21% of the health care dollar spending. Hospital care has been costing more (31% of every health care dollar in 2008). In 2000, although physician and clinical services accounted for $286 billion, hospital costs accounted for $412 billion; in 2008, these two figures were $496 billion (physician and clinical) and $718 billion (hospital care). Both categories together accounted for 52% of all health care dollars spent. As everyone has become concerned about the inflationary spiral of health care costs, these expenditures have become obvious targets of reform.

WHO PAYS FOR HEALTH CARE?

Just as important as the increase in costs are the shifts in who pays for health care. In 1929, individuals and families paid for health care almost entirely out of their own pockets. The government accounted for only 4% of the payments, mostly for those veterans who had fought in previous military conflicts. In 1960, the sources of payment for growing health care costs shifted markedly to include a rising private insurance business (22%) and government support (24%). However, individuals continued to carry the majority of the burden. The Medicare and Medicaid legislation of 1965 changed those ratios once again, setting the stage for the dramatic shift in who pays for health care (Figure 8-3).

Before 1965, the poor and the elderly were often forgotten in their health care needs. Both the Kennedy and Johnson administrations recognized this mandate for reform and the resulting Medicare and Medicaid legislation of 1965 changed the health care landscape forever for the nation and providers at all levels. By 1970, federal, state, and local governments (in combination) paid for 38% of all health care costs, and the individual contribution dropped to 33%. By 2008, the share of the health care dollar paid for by the government accounted for almost 50%, and private health insurance paid for the remainder, about 34%. Individuals assumed only about 12% of the cost (see Figure 8-3). Nonetheless, such expenses can far exceed individual budgets. A 2007 national study showed that about 62% of personal bankruptcies had medical causes, even though three-quarters of these individuals had health insurance.

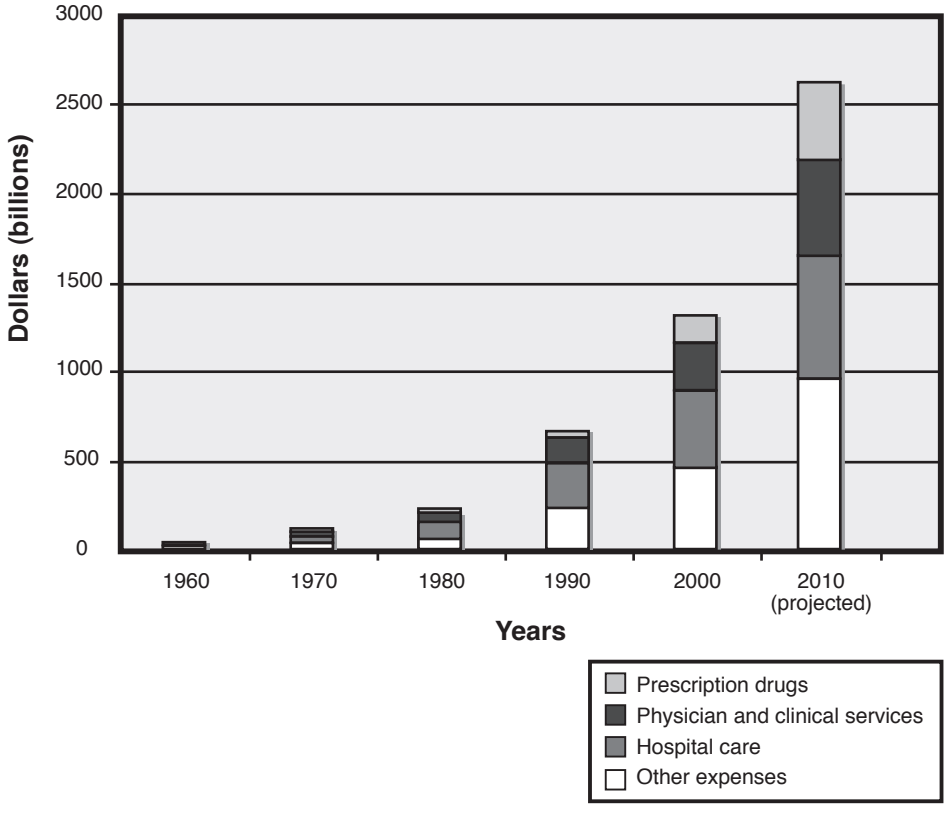

FIGURE 8-2. National health expenditures. How much money does the United States spend on health care? This graph illustrates the sharp rise in national health care expenditures over the past 50 years. The breakdown into different types of expenses illustrates that some are rising more quickly than others. Most expense categories double each decade, but the monies spent for prescription drugs seem to triple during these periods and are of special concern. "Other expenses" include dental services, nursing homes, durable medical equipment, and government public health activities.

Health care expenditures are not evenly distributed among the population. They vary based on age, health condition, population group, and payer. Although the financial burden for individual families to care for a sick child can be devastating, in general, children incur fewer health care expenses than individuals 65 years and older. In 2002, only 5% of the total health care costs were incurred by patients who were 18 years or younger. In 2007, the five most costly health conditions in pediatrics (ages 0–18) were mental disorders ($10 billion), asthma/chronic obstructive pulmonary disease (COPD) ($7.8 billion), trauma-related disorders ($6.4 billion), congenital anomalies ($5.2 billion), and acute bronchitis/upper respiratory infections (URI) ($4.8 billion). Private insurance companies provide the largest payments for all of these conditions, ranging from 15.9% (for congenital anomalies) to 73.1% (for acute bronchitis/URIs). Medicaid payments range from 10.3% (for acute bronchitis/URIs) to 82.9% (for congenital anomalies), in the reverse order.

Pediatric Pearl: The five most costly health conditions in U.S. pediatrics are mental disorders, asthma/chronic obstructive pulmonary disease, trauma-related disorders, congenital anomalies, and acute bronchitis/upper respiratory infections.

When sorting the population into how much money for health care is spent per year, government data from 2002 showed that those who spend the most amount of money (the top 5%) are responsible for 49% of all health care costs. In contrast, the bottom 50% (those who spend the least money for health care) contribute to only 3% of the national health care costs per year. This pattern has been fairly stable over the past few decades. Hence, sharing the cost for providing health care with the least sick and lowest utilizers (e.g., those

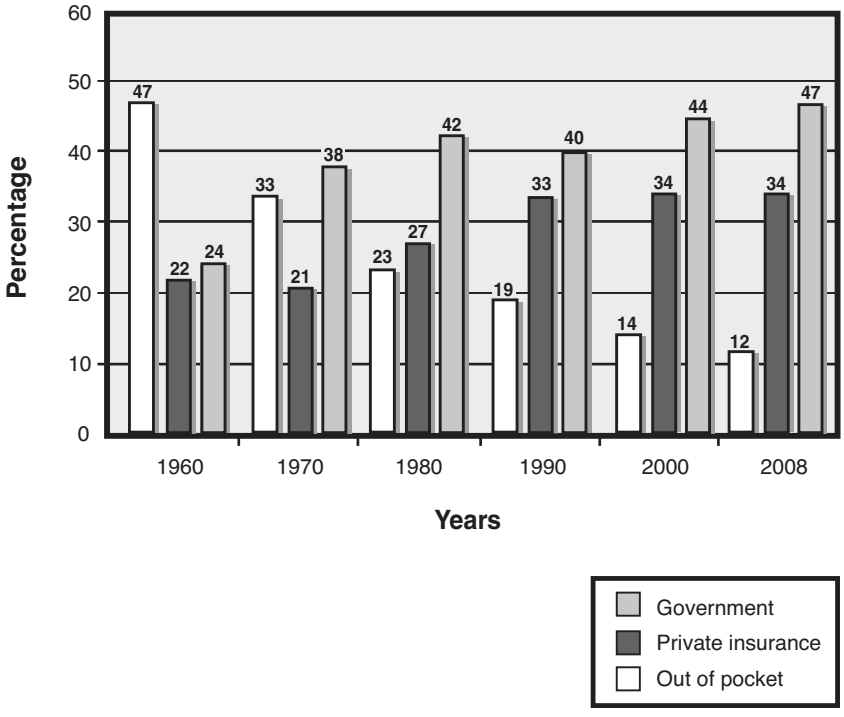

FIGURE 8-3. Sources of health care payments since 1960. The bar graph shows the dramatic rise in coverage of health care payments by private insurance as well as federal and state programs. By 2008, almost half of all health care was being financed by the government. In addition to out-of-pocket and private insurances there are also other private sources that have covered health care expenses (e.g., foundations, charities). Consistently over the past decades, these amount to 7% to 9% of the yearly health care expenditures.

under age 50) allows for decreasing the felt costs for older populations who often would be unable to pay their fair share. Intergenerational spreading of cost can provide a shared benefit for all. This would follow the same principle that underlies the paycheck deductions for Social Security and Medicare.

FUNDING FOR GRADUATE MEDICAL EDUCATION

The Medicare and Medicaid legislation of 1965 also instituted additional support for graduate medical education (GME). Many people still do not realize how broad in scope that legislation was. The creators of that landmark ruling envisioned that physicians-in-training at academic health centers would provide much of the health care for individuals older than 65 years of age or those who were very poor. These trainees would receive supervision from senior physicians, who would be spending their time educating and not providing patient care. If not subsidized, maintaining residents would be extremely costly because they are inherently less efficient, utilize more tests, and burden the system in other indirect ways.

Pediatric Pearl: Medicaid and Medicare pay academic hospitals for training residents through direct reimbursements (i.e., salaries and fringe benefits) and indirect reimbursements (i.e., teaching costs).

The government assumed the financial responsibility of many of these GME costs by allocating money through Medicare and Medicaid. Teaching hospitals receive a special amount per resident that varies by geographic region and poverty level of the population served. GME dollars are divided into two basic bundles: direct medical education (DME) reimbursement, which includes the salaries and fringe benefits for the residents themselves, and indirect medical education (IME) reimbursement, which covers the costs resulting from excessive test ordering, partial salaries of teaching physicians, and other inherent inefficiencies of a training

program. DME and IME payments, which have become an integral and growing part of the government's support of health care expenses, now account for over $7 billion of reimbursement to training programs annually.

HOW DID HEALTH CARE GET TO BE SO EXPENSIVE?

The marked change in who pays for health care in the United States, as indicated, has had a profound impact on every element of the health care industry: consumers, health care providers, insurance companies, businesses, and all levels of government. Until concerns about raising health care costs came into national consciousness, the various groups who had a stake in health care engaged in behaviors that in many ways aided and abetted the inexorable increase in annual expenditures. All participants in the health care setting played some role in the rising costs. For example, employers/businesses raised prices for goods and services to cover premium increases; insurers were eager to cover low-risk patients and reluctant to insure those with potential health care needs; physicians tried to see more patients and provide more services to receive more payment from third-party payers; hospitals could usually pass on increased costs to payers (government or private insurance); and consumers (formerly called patients) were protected by insurance companies from understanding the true cost of health care.

Insurance has permitted health care consumers to utilize increasing amounts of services. Only deductibles and copayments force patients to assume some real costs for their health care, which may reduce excessive utilization. If the cost of health care is completely assumed by the consumer, then the quantity demanded is low. If health care is completely covered (i.e., no cost to the consumer), demand for health care is at a maximum. Imposing a "deductible" forces consumers to pay up to a certain amount before their insurance takes effect. If insurance picks up a significant portion of the costs, and consumers are responsible only for the "copayment" (e.g., as little as $5), they are likely to want more health care than if they had to pay full price. Suffice it to say that price (cost) is a powerful influence on the purchase of health care.

Pediatric Pearl: Factors such as deductibles and copayments influence how people purchase health care and are one way that insurance companies have attempted to influence the excessive utilization of health care—to limit the number of dollars spent.

Because there is no real way to determine whether health itself is actually being purchased, there is a tendency to simply buy more. For example, parents may insist on antibiotics when their child suffers from a common cold, even though it is neither necessary nor appropriate. This extra amount of health care purchased probably does not result in better health but only generates waste or loss to the greater society (e.g., high cost of antibiotics, drug resistance risks).

By passing along health care charges to other groups with little insight into the true implications of this practice, every stakeholder in the health care system contributed to the sense that the growing expenses for increased utilization and technology could be ignored. It took a while before people realized that excessive health care use, with little regard for quality of outcomes and true gain, was no longer affordable. Although some of the key factors of health care inflation are unavoidable due to population changes and technical advances, there are many factors that are amenable to intervention (Table 8-2). Stakeholders (e.g., businesses, government programs, hospitals, physicians, patients) have to modify their behaviors to make spending practices conform to a more rational and disciplined model of care. From the physician's perspective, this includes taking on a population-based practice approach that looks beyond the needs of a single patient to the well-being of the community.

The next two sections describe how the health care industry, as well as the government, tried to halt the rampant health care inflation. Some of these corrections have been excessive and some have been insufficient; the situation is still evolving.

HEALTH CARE INDUSTRY EFFORTS TO CHANGE THE SYSTEM

In response to steadily increasing costs, physicians were forced to begin to look at their practices with a greater degree of financial accountability. They began to form different types of group practices, partially in response to payer shift and partially out of a desire to maintain quality and income. Hospitals, the greatest source of health care expenses, began to impose increasing restrictions on spending, personnel, and equipment. Capital purchases and building projects came under greater scrutiny, and personnel inefficiency and excessive technology purchases were sharply curtailed or altered. However, there was no sweeping effort to change the system until managed care became a prominent force.

TABLE 8-2

Causes of Health Care Inflation

Unavoidable Factors	*Discretionary Factors*
• Aging of population	• Medically uneducated, insufficiently price-sensitive consumers
• Technology and its success in prolonging life	• Highly fragmented insurance industry with little expertise in medical management
• Service cost inflation	• Massive excess hospital capacity, exacerbated by the proliferation of outpatient care
	• Wildly varying standards of medical practice
	• Resource focus on acute rather than preventive care
	• Insufficient medical outcome data
	• Oversupply and overuse of physician specialists
	• Heroic attempts to save virtually hopeless cases
	• Malpractice fears and pressures
	• Few effective pharmaceutical formularies

Managed care arose from the desire to "manage" care, to make it more organized, coordinated, and efficient than what it had become. In *Principles of Managed Care*, the American Medical Association (AMA) defines managed care as the "processes or techniques used by any entity that delivers, administers, or assumes risk for health services in order to control or influence the quality, accessibility, utilization, cost and prices, or outcomes of such services provided to defined populations."

Managed care originated in 1929 when Michael Shadid, MD, created a prepaid group practice insurance plan for a farmer cooperative in Elk City, OK. In the same year two other physicians, Donald Ross and H. Clifford Loos, started a prepaid plan for the Los Angeles Department of Water and Power. After these modest beginnings other plans developed. Some of the pioneers were Kaiser Permanente (1945) and the Health Insurance Plan of Greater New York (HIP) (1947). However, it was not until the second half of the 1990s that managed care grew substantially and became a major force that encompassed many new concepts and strategies. Figure 8-4 illustrates some of the buzzwords that emerged and that are still shaping the way we think about health care today.

Not only did the managed care system make payers and providers scrutinize costs more carefully, it also created entirely new reimbursement strategies (Table 8-3). They range from minimal cost and quality control in fee-for-service (FFS) plans to a maximum of structure and control in staff model health maintenance organizations (HMOs). The seemingly simple change in the payment system from FFS to prepayment resulted in a redistribution of risks and a revamping of emphasis from paying providers to deliver diagnosis and treatment to paying them for keeping patients well. Each provider receives a preset amount of money (capitated payment) to care for a predetermined number of patients (a population) in a given period of time. A provider who does less work (e.g., because patients are healthy or services become more efficient) can keep the extra money. In contrast, another provider, whose patients are ill more frequently, may have to work more, thus exceeding the fees received.

At first, many hospitals and physicians found these methods onerous, and they tried to hold on to the status quo that had proved profitable for health professions for so long. These care providers are now being blamed for having squandered valuable opportunities for the medical profession to take an active stance in improving the health care system. Because corporate entities demonstrated more responsibility for cost containment and a better appreciation of service outcomes, much of the control over spending on health care is now out of the hands of physicians and physician groups and in the hands of corporations.

Many physicians who initially resisted the movement toward managed care were later forced into participating because of growing competition. If they did not join a plan or collaborate to create one of their own, they were at risk for losing many of their patients. With the overall tightening of the economy also came a major

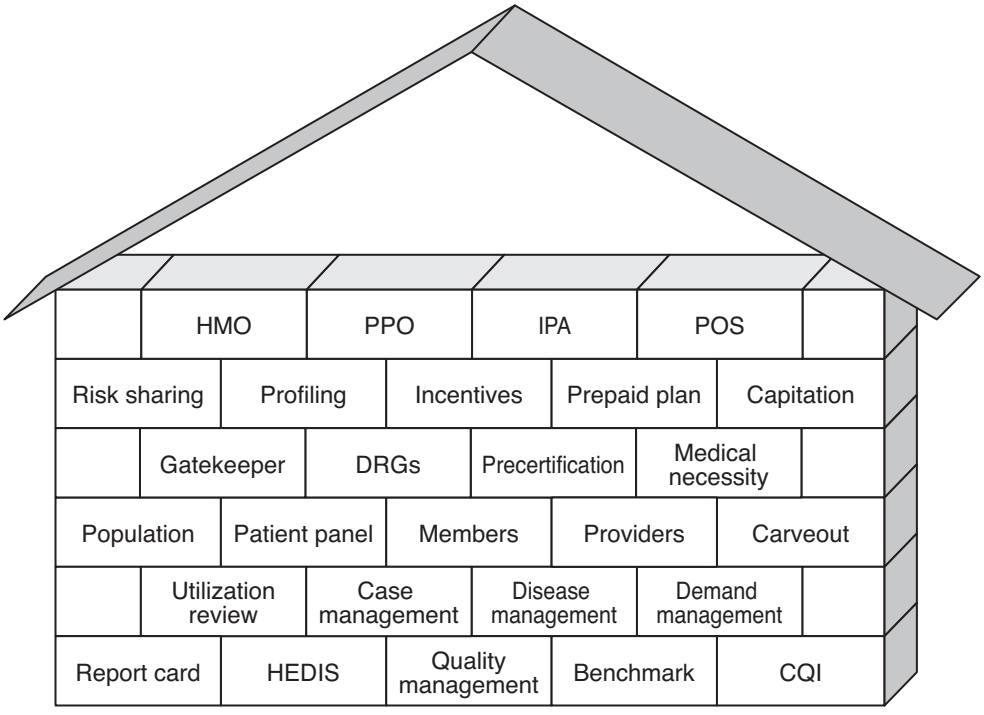

FIGURE 8-4. Key concepts and strategies developed by managed care. *CQI*, continuous quality improvement; *DRG*, diagnosis-related group; *HEDIS*, Health Plan Employer Data and Information Set; *HMO*, health maintenance organization; *IPA*, independent practice association; *POS*, point of service; *PPO*, preferred provider organization.

push to managed care plans from employers, who eagerly embraced newly emerging organizations that promised health care delivery for a lower cost. Indeed, in the mid-to-late 1990s, there was a sharp drop in employee premiums. However, that cost is increasing again, and now, the corporate world is contemplating its general ability to offer health care benefits.

With HMOs, the financial risk of having to expend health care resources shifted to providers and hospitals rather than remaining with insurance companies. Because physicians are a key element in the distribution of health care, the overutilization of health care resources that had been a problem in the past quickly became a concern about underutilization. Health care providers were encouraged to order fewer rather than more tests, and to prescribe less expensive rather than more expensive medications—not always on the basis of scientific evidence.

Pediatric Pearl: Physicians are a key element in the distribution of health care. If medical decisions are not based on scientific evidence, but rather on economic incentives, there are risks for under- and overutilization.

Initially, it was assumed that because health care plans had an incentive to keep their members healthy, they would heavily invest in prevention. However, the combination of requiring care by a selected number of providers and having health care insurance linked to employment created a problem. Members (i.e., the contracted patients) were not long-term participants; they were disenrolled when they lost their jobs or changed employment or when they got older or sicker. This reduced the incentive to invest in prevention, which requires a long-term perspective.

Many of the HMOs that started in the 1940s to 1960s were not-for-profit. In comparison, some of the newer companies were for-profit, and thus their central focus became stockholder shares, rather than investing in patient care. Methods of cost control entailed the exclusion of sicker patients, micromanagement of clinical decisions, denial of beneficial but expensive care to some patients, perverse incentives for providers, and pitting

TABLE 8-3

Types of Health Care Organizations

Increasing Control of Cost and Quality

Indemnity, Fee-for-Service Plan (FFS)	*Preferred Provider Organization (PPO)*	*Point-of-Service Plan (POS)*	*Health Maintenance Organization (HMO)*
Provider is reimbursed for number and type of services performed	Selected panel of providers who agree to discounted fee schedule	Combines HMO and indemnity options	Prepaid, comprehensive health coverage for hospital and physician services
Provider's income is directly related to volume and intensity of units of service rendered	Provider reimbursement is FFS	Selection is made when need arises	Members are required to use participating providers
Insurer may pay percentage of charges or utilize predetermined fee schedule	Patients are not required to have primary care provider or seek prior authorization for services	Additional costs to patient if non-HMO providers are used	Primary care providers act as gatekeepers
	Patients can obtain care from providers outside of plan but have higher copayments	All provider reimbursement is FFS	In staff model HMOs, physicians are employees (e.g., Lovelace Health Systems of New Mexico)
			In group model HMOs, physicians work in a group practice and contract with HMO (e.g., Kaiser Permanente)
			In an Independent Practice Association (IPA) model HMO, physicians maintain their independent offices while contracting with an (or) the HMO

specialists and primary care physicians against each other. New ethical concerns about "squeezing care to expand profits" arose quickly. Although it is unacceptable to waste resources, it is just as unethical to withhold them unnecessarily. The "gag rule," which forbids providers to take any actions or make any communications that could undermine the confidence of enrollees or the public in a health care plan (e.g., reveal incidences in which cost-cutting measures would inhibit proper care), was quickly abandoned. The initial efforts to control the resources through gatekeepers was met with much resistance by patients and resulted in a gradual relaxation of such rules.

After a steep rise in popularity in the late 1990s the managed care approach to health care delivery came in disrepute. New concepts and terms emerged, with accountable care organization (ACO) being one of them. An ACO is defined as a group of primary care physicians, specialists, and hospitals that have been incentivized

with a system of rewards (or penalties) to join forces to more efficiently and effectively deliver their services to a specific population (e.g., through the development of "medical homes"). With the help of new names, some people hope it will be possible to capitalize on the many positive innovations of the past few decades and make the still much-needed health care reforms.

GOVERNMENT EFFORTS TO CHANGE THE HEALTH CARE SYSTEM

In parallel to industry efforts to curb health care spending, the government also stepped in repeatedly in an effort to ensure accessible and affordable health care for its population. Table 8-4 summarizes some of the key events in the last few decades.

By taking on a good portion of the health care expenditure through Medicaid and Medicare, it was possible to impose changes in reimbursement strategies that would have a nationwide impact. Moving away from straight-cost reimbursement to other methods such as diagnosis-related groups (DRGs), it was possible to scrutinize lengths of stay as well as question procedures, tests, and other heretofore unchallenged elements of medical practice. As a result, health care costs as a political agenda began to gather momentum, which culminated in Bill Clinton's successful run for the presidency in the early 1990s. Health care became a legitimate target for change; patients, providers, hospitals, employers, and payers (including federal, state, and local governments) had a stake in seeing these costs come under control. As previously mentioned, the United States has spent billions of dollars on health care, but the country does not fare well in terms of public health indicators such as longevity, child survival, and immunization rates.

The old health care system was inaccessible to millions of people, rewarded costly interventions as opposed to prevention and fiscal prudence, and allowed individual providers to work and provide care regardless of practice conventions and scientific evidence. The Clinton administration attempted to pass legislation to create a universal health care system that would permit risk sharing among the entire population and would bring in those people who increasingly slip through the health care safety net. The purpose of universal

TABLE 8-4

Selected Governmental Influences on Health Care Systems and Health Care Economics

1965	The Medicare and Medicaid acts were passed by the U.S. government.
1971	The Nixon administration initiated a new grants and loan program to foster the development of HMOs.
1973	The HMO Act was passed by Congress to allocate funds for HMO development. It preempted state laws that banned prepaid groups, and required companies with at least 25 employees to offer a federally qualified HMO.
1980	The Reagan administration discontinued the Office of Health Maintenance Organizations, which oversaw 118 federally qualified HMOs.
1993	The Clinton administration tried to revamp the health care system, but concerns about excessive government involvement pushed toward a resolution of the health care crisis in the market place, bringing managed care to the forefront.
1997	The State Children's Health Insurance Program (SCHIP—now just referred to as CHIP) was initiated to cover more uninsured children whose family income was too high to qualify for Medicaid but inadequate to afford private health insurance. This state-level program is financed through cigarette taxes.
2001	The Patient Bill of Rights was debated in Congress. It would have provided rights similar to the Consumer Bill of Rights, but the initiative failed in 2002.
2010	Congress passed the "Affordable Healthcare for America" Act, which was promoted by the Obama administration. It seeks to reform health care insurance and health care oversight.

HMO, health maintenance organization.

coverage is to allow all individuals to have health insurance, including those with the highest risk for developing a medical condition.

Pediatric Pearl: By having everyone in the same pool, the premiums from low-risk individuals (those less likely to get sick in any given year) could cross-subsidize those who are at high risk.

Spreading out the risk pool through universal coverage could achieve a lower per capita cost that would be financially bearable for all individuals except the poor. Government funding would underwrite the costs for the truly indigent population. Although that legislation failed, the focus on health care expenditures became a national imperative.

In March 2010, after extensive debates and political challenges, the Obama administration was able to push through the 2010 Healthcare Reform Bill. Although it did not promise a unified health care system (as some had hoped), it did include some major reform packages that should allow for better coverage and better brakes on health care spending. Some of the key issues underlying the debate were: Is health care a "right" or a "privilege?" Who should have access to health care and under what circumstances? Who should be required to contribute toward the cost of providing health care? What should be done about those who do not have insurance? This uninsured and underinsured group includes many needy children and families who are above the Medicaid level, not eligible for SCHIP, and who cannot afford private insurance, even if it provides only minimum benefits.

Pediatric Pearl: Over 6 million children remain uninsured or poorly insured, and certain subpopulations (e.g., minorities) are even more at risk for poor health coverage and health outcomes.

The following section outlines some key elements that will determine future health care systems and financial strategies.

THE FUTURE OF HEALTH CARE ORGANIZATIONS

Gradually, the health care system will stabilize. Not all corporate entities are motivated by the potential of making money; many see our current crisis as an opportunity to increase access and advance health care delivery. Laws and regulations are being enacted to ensure that the rights of patients and health care providers are not compromised. Consumers also seem to be able to exert more influence.

Given the still rising health care costs and still increasing percentage of GDP occupied by health care spending, the recent push to truly reform health care's organization and payment methodology has taken on new urgency. Simultaneously, a new category of concerns has arisen that will influence the practice of medicine as well as health care economics in all settings. This concern is **quality.**

In 1999 and 2001, the Institute of Medicine (IOM) issued two comprehensive reports that have revolutionized the expectations the public has towards physicians, hospitals, and payers. "To Err is Human: Building a Safer Health System" details the different types of medical errors and their costs, both financial and human, as they occur throughout the United States. Two years later, that report was followed by "Crossing the Quality Chasm: A New Health System for the 21st Century," which described the core elements of system change that must occur if we, as a nation, are to achieve the quality of health care we desire for our population. This report outlined six elements that our organized health care system **must** achieve if it is to be the leader in health care worldwide (Table 8-5).

These important goals set forward by the IOM have become the cornerstone of providing optimum care in what will be the new health care system that will eventually come to pass within the United States. Many international health care systems have already moved squarely in that direction, and the United States has trailed far behind on many outcome measures. This cannot be allowed to continue.

Pediatric Pearl: Quality of care is likely to become the central element of the U.S. health care system. Patients will demand it and third-party payers will make it the basis for their reimbursements.

TABLE 8-5

Institute of Medicine (2001): Performance Expectations of a High-Quality Health Care System

A health care system must be:

1. **Safe**—The avoidance of injury and harm from care that is supposed to help patients.
2. **Effective**—The reliable matching of evidenced based care with actual care. In other words, providing services based on scientific knowledge to all who could benefit and, most importantly, refraining from offering services to those not likely to benefit.
3. **Patient centered**—The provision of care that is respectful of and responsive to individual patient's needs and values by exploring them and incorporating them in clinical decisions.
4. **Timely**—Care is provided in a timely fashion, which, by definition, avoids unnecessary delays in instituting it.
5. **Efficient**—In this increasingly costly medical world, any avoidance of waste or unnecessary tests or treatments are vital to cost savings and to giving appropriate care.
6. **Equitable**—It is crucial that all care provided to patients is done on an equal basis across all demographics and all patient populations, regardless of ethnicity, gender, geographic location, and, of course, socioeconomic status.

It is vital that health care provisions are increasingly examined from the patient's perspective. Ten percent of children's diseases are now chronic diseases in which care is complex and must be coordinated across a number of different subspecialties and disciplines. From the family's perspective, quality care typically means that it is:

1. **Continuous**—Care should be available throughout the year and not just during encounters with physicians. This will mandate specific care measures that the patient or patient's family can provide themselves. Disease management is a health care strategy that is geared toward ongoing support and tertiary prevention.
2. **Collaborative**—From the patient's perspective, the physician is no longer the only person capable of providing care. The complexities of new tests, new treatment modalities, and new expectations will require teams of physicians and nonphysician clinicians (e.g., pharmacists, nurses, nutritionists, physical therapists) to collaborate in the provision of care. Clearly, parents or other caregivers will also need to be part of the team in order to ensure maximal outcomes.
3. **Informative**—Using the tenets of patient- and family-centered care, the best informed patient will make the best patient (and caregiver as it is typically the case in pediatrics). It is most important that physicians guide the information stream so that patients and their families can be directed toward the best sources, rather than just any. As the popularity of medical programming in the media demonstrates, health literacy is becoming a national concern.
4. **Reliable**—Patients need to be assured that they receive the best possible care with all the services (e.g., diagnostic procedures, medications, prophylaxis) needed to improve their health. If an intervention is not offered, it must be made clear why it is not indicated and that it is not omitted because of oversight or cost considerations.
5. **Proactive**—Pediatricians have always been at the forefront of prevention on behalf of their patients. Given the complexity of health care in the 21st century, proactive care (e.g., anticipatory guidance, immunization) is now even more important.
6. **Safe**—Patients want to feel safe when receiving care. Diagnosis and treatment should make them feel better, not make them sicker. Safety has to become a key element of medicine. Whether it is in the inpatient or the outpatient setting, we have to remain committed to ensuring safety for all patients and their families.

With the six tenets of the IOM report and the six practices that patients (our consumers) will be considering essential for optimum care, pediatricians of the future will have to face complex medical environments

and decisions with a new sense of mission and vision. Future success will be aided by a number of other important new measures on the forefront of medicine. These will include: (a) user-friendly electronic medical records that will be integrated between all settings (inpatient, outpatient, also private practices) to allow information sharing among all providers for optimally coordinate care; (b) total transparency about all interventions for patients and their families by allowing them access to the electronic record system; (c) more thorough reviews of patients' progress to monitor quality and effective use of resources by third-party payers; and (d) the imposition of potential penalties for not adhering to certain qualities of care measures. Overall, there will be an effort to diminish variability in care and to optimize quality of care (e.g., by following evidence-based medicine guidelines) and to reduce costs and maximize outcomes. Pay-for-performance is a financial strategy to achieve this goal. Providers are remunerated according to how well they comply with the standards and how much they achieve the desired outcomes.

In order to bring costs down there will also have to be a refocusing from individual patients to the welfare of populations. This is likely to create some tension. What a single patient may want for him/herself in terms of health care resources may not be beneficial for the common good. Physicians will find themselves in a new role that includes advocacy for social justice. Population-based medicine does not come naturally to a profession that prescribes to an oath that puts the single patient "front and center." However, it will be necessary for controlling health care inflation and for moving medicine to the next level.

HOW TO PREPARE FOR THE FUTURE

Because of the changes in health care delivery systems, the training of physicians requires adjustments. As part of the IOM Quality Chasm Series, an effort has been made to identify the educational needs of all health care providers. The 2003 IOM report "Health Professions Education: A Bridge to Quality" postulates that all health care providers have to learn to (a) provide patient-centered care, (b) employ evidence-based practice, (c) apply quality improvement (which includes the elimination of waste), (d) work in interdisciplinary teams, and (e) utilize informatics. Residency programs (and, with increasing frequency, medical schools) now require the demonstration of competence in systems-based practice.

The case described in Table 8-6 is one example of the shift in thinking that all physicians must make if the health of individuals and our society is to improve and if we are to achieve a level of quality seen in other Western countries. It illustrates how care can be effective, efficient, family-centered, evidence-based, proactive and safe. Better management of the disease and prevention will result in significant costs savings in the long run (e.g., reduction in emergency department visits and hospital stays). As indicated previously, asthma/COPD is the second costliest condition in pediatrics in the United States. For the patient, having fewer illness episodes will result in financial as well as emotional and social benefits (e.g., minimal loss of school time, improved ability to play and socialize with other children, increased sense of normalcy). As such disease management models are rolled out across all patient conditions and across all populations, the savings potential multiplies and the risk of adverse outcomes or errors drops significantly.

The self-assessment tool in Table 8-7 provides an opportunity to develop a learning agenda in this area of medical expertise. The government (e.g., The Center for Medicare & Medicaid Services, The Agency for Healthcare Research and Quality, The White House) as well as private foundations (e.g., The Robert Wood Johnson Foundation, The Commonwealth Fund, The Kaiser Family Foundation) provide valuable resources for understanding current developments and future directions in the health care market.

Pediatric Pearl: Many foundations and governmental agencies provide online support for keeping up-to-date with the continuous changes in the U.S. health care system.

Until recently, pediatrics has been relatively unaffected by the national health care changes. In part, this can be attributed to the fact that proportionally less money is needed for the care of children because they are less likely to require costly interventions. In addition, some experts argue that there has been a lack of extensive outcome data. First, fewer drug trials assess whether one medication is better and more cost-effective than another in children. Second, Medicaid, the primary governmental insurer of children, is administered by the individual states, which makes the accumulation and sharing of information more difficult and less useful. This is unlike Medicare, which is a federal agency.

TABLE 8-6

A Child with Asthma: Example of How a Patient May Receive Effective and Efficient Medical Care[a,b]

A 5-year-old boy with no significant past medical history is brought to the emergency department by ambulance. The mother says that her son is usually in good health. However, 3 days ago, he developed a mild cough that progressively worsened. He was playing outdoors when he suddenly came inside the house and told his mother that he found it difficult to breathe. The patient's mother noted that he was coughing and short of breath. She became scared and called for an ambulance. The boy received one treatment of albuterol nebulizer from the emergency medical technicians on the way to the hospital.

In the emergency department:

1. Vital signs are as follows: temperature, 98.8°F; heart rate, 140 bpm; and respiratory rate, 32 breaths/min.
2. Oxygen saturation is 90% on room air.
3. Physical examination shows that the patient is alert but in moderate respiratory distress. HEENT, within normal limits; chest, symmetric with intercostal and supraclavicular retractions; lungs, diffuse wheezing bilaterally; cardiovascular system, normal S1 and S2, with no murmurs; abdomen, benign.
4. The patient receives the following medications: albuterol nebulizer × 3, ipratropium bromide × 2, and prednisolone × 1.
5. The chest radiograph shows hyperinflation bilaterally with increased peribronchial markings.
6. The diagnosis is reactive airway disease. The boy is admitted for further management, and he stays in the hospital for 24 hours. Both parents are educated about asthma management prior to discharge.

Under a new and improved health care system, the following services are also routinely available for patients with asthma:

1. Enhanced asthma education for parent and patient prior to hospital discharge.
2. Regular visits to the primary care physician for checkups. The frequency of visits varies with the severity of asthma.
3. Provision of an individualized, written asthma action plan.
4. Telephone services to provide support from medical staff.
5. Enrollment in a disease management program that includes parent and patient support groups and a visiting nurse to inspect the home for environmental triggers.
6. Peak flow scores for children 5 years of age or older, according to the ability of the child.
7. Referral to a specialist if the asthma is poorly controlled despite the primary care physician's and parents' efforts.
8. Reviews of the patient's medications, emergency department visits, and hospitalizations by the National Committee on Quality Assurance or a similar organization. There is some increased accountability for quality of care provided and adherence to standards for preventive strategies. The primary care physician is contacted and instructed to make adjustments if the quality of care is viewed as less than ideal. These organizations also monitor the number of patients who:
   - Receive a written asthma action plan
   - Use medications with a spacer
   - Use a home peak flow meter

TABLE 8-6

A Child with Asthma: Example of How a Patient May Receive Effective and Efficient Medical Care[a,b] *(Continued)*

- Receive instructions on the correct use of inhalers
- Receive counseling on the role of environmental irritants
- Receive annual pulmonary function tests

[a]This case was created by Valerie A. London, MD, when she was completing a managed care rotation during the third year of her pediatrics residency at Maimonides Medical Center in Brooklyn, New York. Tragically, she died in 2005, several years after completing her residency.

Health care economics continues to evolve as a science. Children and families must become a national priority. Despite some governmental efforts, too many children do not have needed health care coverage. Pediatricians remain the primary advocates for children's health; their outspoken voices on behalf of children are a crucial building block for the overall health of children in the United States and throughout the rest of the world. It is hoped that the next decades will see a truly accessible, effective, and efficient health care system evolve to benefit children, their families, providers, and society.

TABLE 8-7

Systems-Based Practice Learning Needs Assessment

Please indicate where you stand in each of these competency domains.[a]

Competency Domains Important for Systems-Based Practice	*Know little/Need to start learning about it*	*Know something but need to learn more*	*Know a lot/No need to include in my current learning agenda*
1. Work effectively in various health care delivery settings and systems	❒	❒	❒
2. Coordinate patient care within the pertinent health care system	❒	❒	❒
3. Incorporate considerations of cost awareness and risk-benefit analysis in patient and/or population-based care as appropriate	❒	❒	❒
4. Advocate for quality patient care and optimal patient care systems	❒	❒	❒
5. Work in interprofessional teams to enhance patient safety and improve patient care quality	❒	❒	❒
6. Participate in identifying system errors and implementing potential systems solutions	❒	❒	❒

[a]These competencies were derived from the ACGME description of competencies (see Suggested Readings).

APPENDIX 8-1

Selected Terms Used in Health Care Economics*

Accountable Care Organization (ACO)—Group of health care providers (primary care physicians, specialists, and hospitals) that has been incentivized with rewards (or penalties) to collaborate on delivering their services more efficiently and effectively (e.g., through implementing *medical homes*).

Benchmark—Measurable variable used as baseline or reference in evaluating the performance of an organization or program.

Capitation—Fixed amount paid per enrollee per month to cover a defined set of services over a specific period of time, which may be more or less than the cost of the actual services provided.

Continuous quality improvement—Form of *quality management* that uses a systems approach and targets internal operating procedures to improve efficiency and effectiveness.

Coordination of benefits—Procedure that prevents double payment for services when a subscriber has coverage from two or more sources (e.g., additional insurance from spouse).

Copayment—Cost-sharing arrangement in which the patient pays a flat charge for a specific service.

Current procedural terminology—Five-digit codes for all types of physician services and procedures, used for reporting and billing.

Deductible—Amount a patient has to forfeit directly to a provider before an insurance plan begins to pay benefits.

Demand management—Decision and behavior support system (e.g., self-care intervention, health promotion, educational tools, telephone help lines) for encouraging patients to use medical services appropriately.

Diagnosis-related groups (DRG)—Classification system instituted by the *Healthcare Financing Administration (HCFA)* to establish *Medicare* hospital reimbursement rates. Patients are categorized by principal diagnosis, type of surgical procedure, presence or absence of significant comorbidities or complications, or other relevant criteria to determine the amount that *Medicare* will pay for their treatment.

Direct medical education (DME) reimbursement—Part of the graduate medical education payment that hospitals receive for training residents. DME consists of salaries and fringe benefits for trainees.

Disease management—A systematic approach to provide care to a group of patients with a certain condition (usually chronic) for the purpose of managing their health problem over time, improving outcomes, and lowering costs. Such management programs may involve patient and provider education, guidelines for applying alternative therapies, patient monitoring, and outcome assessments.

Enrollment—Recruitment of *members* to an insurance plan.

Externalities (spillover effects, secondary gains)—Costs or benefits that impact society but are not included in the market price of a good or service. Negative externalities have negative consequences (e.g., pollution), and positive externalities have positive consequences (e.g., the cost of immunizing one child does not include the extra benefits of preventing the spread of disease in the community).

Fee-for-service plan (FFS)—Insurance system in which providers and hospitals receive direct payment for their billed charges, either from the patient or from the insurance company (see Table 8-3).

Formulary—List of selected pharmaceutical agents believed to be most useful and cost-effective for patient care. Closed formularies limit clinicians to prescribing the drugs on the list, whereas open formularies serve more as a recommendation.

For-profit entity—Company or organization that aims to benefit financially from the services it provides; opposite of non-profit or *not-for-profit*.

Gatekeeper—First contact provider (usually primary care practitioner), who determines the appropriate level and delivery of care for each patient by making the initial diagnosis; administering treatment; and authorizing referrals, tests, and hospitalization.

Graduate medical education (GME) reimbursement—*Medicare* and *Medicaid* funds that are given to hospitals that train residents. The reimbursement consists of two portions: direct medical education and indirect medical education payments.

Gross domestic product (GDP)—Current terminology for the total market value of all goods and services produced within a country during a given period, usually 1 year. The GDP equals the *gross national product* plus income from other countries. In the United States, this figure is tabulated and reported by the Department of Commerce.

Continued

APPENDIX 8-1

Selected Terms Used in Health Care Economics* *(Continued)*

Gross national product (GNP)—Total market value of all goods and services produced by the citizens of a country during a given period, usually 1 year. The GNP was once the official measure of how much output the U.S. economy produced. In the early 1990s, the term was replaced by *GDP*, which does not include foreign income.

Healthcare Finance Administration—Branch of U.S. Department of Health and Human Services that administers *Medicare* and oversees the state-run *Medicaid*. This agency, which introduced the *DRGs*, also provides *GME* reimbursements.

Health maintenance organization (HMO)—Managed care organization that provides comprehensive health care to a certain population of patients for a prepaid, fixed sum (see Table 8-3).

Health Plan Employer Data and Information Set (HEDIS)—Standard measures of health plan performance (e.g., access, patient satisfaction, membership, utilization).

ICD-9-CM *(International Classification of Diseases, 9th edition, Clinical Modification)*—List of diagnoses and identification codes used by physicians to report patient diagnoses to health plans. The next version, ICD-10, is already being scheduled for rollout.

Indemnity plan—Insurance plan in which the insured person or provider is reimbursed for all or part of the covered expenses after a service is provided; the opposite of a *prepaid plan*.

Independent Practice Association (IPA)—Type of *HMO* that contracts with physicians who see its *members* in their own offices, together with their other patients (see Table 8-3).

Indirect medical education (IME) reimbursement—Part of the *GME* payment that hospitals receive for training residents. It covers expenses incurred from excessive test ordering and other inefficiencies. IME also supplements the salaries of attending physicians for their teaching activities.

Intermediate care facility—Facility that provides less comprehensive care than hospitals or skilled nursing facilities but more comprehensive care than can be given at home.

Management services organization (MSO)—Company that provides administrative, managerial, financial, and managed care contracting services to providers, especially those in group practices. MSOs are used by hospitals to assist their affiliated physicians.

Medicaid—State-sponsored health insurance for poor individuals. Medicaid is administered by state health departments but is overseen by the *HCFA*, a federal agency and its organizational bureau, Center for Medicare & Medicaid Services (CMS).

Medical home—Approach to providing comprehensive primary care that facilitates partnerships between individual patients, their families, and their personal providers. This concept was first introduced by the American Academy of Pediatrics in 1967.

Medical necessity—Judgment by a clinical expert that specific care is required to preserve the life or health of a patient.

Medicare—Governmental health insurance for individuals older than 65 years of age and those with a permanent disability. It is centrally administered by the *HCFA*, a federal agency and its organizational bureau, Center for Medicare & Medicaid Services (CMS).

Member—Person enrolled in a managed care plan.

Not-for-profit entity—Organization or company that reinvests the majority of its profits in itself. It does not focus on enriching its owners or shareholders. Such institutions are subject to special regulations, but they also receive special tax benefits.

Patient panel—*Members* assigned to a single provider or a group of health care providers.

Pay for performance—Payment strategy that rewards hospitals, physicians, or other health care providers with financial and nonfinancial incentives based on performance on select measures (e.g., quality, safety, efficiency, patient experience, information technology adoption).

Per member per month—Measurement unit for operating statistics: one *member* enrolled in a *HMO* for 1 month (whether or not the *member* receives services). Two member months may be one *member* who enrolls for 2 months or two members who sign up for 1 month each.

Personal health care expenditure—Average amount of money spent on health care by an individual in a given year.

APPENDIX 8-1

Selected Terms Used in Health Care Economics* *(Continued)*

Physician hospital organization—Collaboration of physicians and a local hospital or group of hospitals to contract with managed care organizations.

Point-of-service plan (POS)—Managed care plan in which *members* can choose from a *HMO*, *preferred provider organization*, or *indemnity plan* at the time health care is needed. Thus, they do not have to make a decision at the time of enrollment (see Table 8-3).

Practice guidelines—Systematically developed statements on medical practices that assist with clinical decision making for specific medical conditions.

Precertification—Prospective review for the purpose of granting or withholding permission for diagnosis or treatment coverage.

Preferred provider organization (PPO)—Managed care plan that contracts with independent providers who render services to members at discounted rates (see Table 8-3).

Premium—Amount paid to an insurer or health care plan for providing coverage for a certain level of services during a specific time period. It may be paid by either an individual, or an employer or it may be shared by both parties.

Prepaid health plan—Entity that contracts to provide certain medical services to enrollees in exchange for *capitation* payment.

Profiling—Systematic method for collecting and analyzing patient data to develop provider-specific practice information.

Provider—Health care professional or organization that offers health care services.

Quality management—Formal set of activities (e.g., quality assessment, corrective actions) to ensure the quality of services provided.

Report card—Tool for policy makers and health care purchasers to understand and compare the performance of health plans or providers (e.g., quality and utilization, consumer satisfaction, administrative efficiency, financial stability, cost control).

Risk sharing—Apportionment of chance of incurring financial loss by insurers, managed care organizations, health care providers, and patients.

Systems-based practice—One of six core competencies required of all residents, regardless of specialty. It is mandated by the Accreditation Council for Graduate Medical Education and includes a working knowledge of the health care system and the ability to utilize system resources to optimize care.

Third-party payer—Insurance plan (e.g., *HMO, Medicaid, Medicare*, traditional insurance company) that pays providers for care. It acts as intermediary between the employer (who pays for health coverage) and the individual/*member* (who uses health care services).

Utilization review—A process that measures the use of resources (e.g., professional staff, facilities, services) to determine cost-effectiveness and conformity to criteria of optimal use.

*Italicized terms are also defined in the appendix.

PEDIATRIC SUBSPECIALTIES

9

Infectious Diseases

Kathleen Gutierrez

APPROACH TO THE EVALUATION OF THE FEBRILE CHILD

Physicians routinely encounter children with febrile illnesses. Fever is not harmful in itself; it is a symptom of underlying disease. Most fever in children results from underlying infection. Autoimmune disease, drugs, and neoplastic processes are less common causes. Rare causes of fever include central nervous system (CNS) abnormalities, thyrotoxicosis, and overheating (heat stroke).

Fever is an elevation in body temperature that occurs when the thermoregulatory center in the anterior hypothalamus is reset to a higher level. Cytokines produced in response to infection or inflammation, induce production of prostaglandin E2 and mediate fever. Normal body temperatures are subject to diurnal variation, with slightly higher (0.5° C to 0.9° C) [0.9° F to 1.6° F] core temperatures in the afternoon compared to early morning. Temperatures taken by a rectal thermometer reflect true core temperature, whereas oral and axillary temperatures are approximately 0.5° C and 1.0° C (0.9° F and 1.8° F) lower, respectively. The upper limit of normal body temperature in children is 37.9° C (100.2° F); a rectal temperature greater than 38.0° C (100.4° F) represents fever. Temperature elevation rarely exceeds 41.1° C (105.9° F) even in the absence of antipyretic therapy. Very young infants, unlike older children, are often unable to mount a febrile response to infection and may instead become hypothermic.

Viral infections cause most febrile illnesses in children. However, **serious bacterial infections (SBIs)** affect a small proportion of children. By definition, SBIs include meningitis, pneumonia, bone and joint infection, urinary tract infection, bacterial gastroenteritis, and sepsis and occult bacteremia. Children with **occult bacteremia** usually have only high fever but no other localizing findings on the basis of a careful history and physical examination. Some cases of occult bacteremia resolve spontaneously without antibiotic therapy, whereas others lead to development of SBIs.

Pathophysiology

Infants less than 1 month of age are prone to bacterial infection with pathogens acquired around the time of delivery, when colonization by organisms present in the mother's rectal or vaginal area occurs. *Escherichia coli, Klebsiella pneumoniae, Enterococcus* species, and *Streptococcus agalactiae* (group B streptococci) are the usual pathogens. In addition, *Listeria monocytogenes* may cause bacteremia and meningitis. Infants 1 to 3 months of age are still at risk for infection with these pathogens in addition to infection with *S. pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae*.

Older infants and children between 3 and 36 months of age are prone to infection with encapsulated bacteria such as *N. meningitidis*, and, in incompletely immunized children, *H. influenzae* type b and *Streptococcus pneumoniae*. Both methicillin-susceptible (MSSA) and -resistant (MRSA) *Staphylococcus aureus* may cause bacteremia. Frequency of infection with *Streptococcus pyogenes* (group A β-hemolytic streptococcus [GABHS]) increases as children reach school age.

Pediatric Pearl: Widespread use of *H. influenzae* type b conjugate vaccine and pneumococcal conjugate vaccine (PCV) makes bacteremia caused by these organisms less common in the completely immunized child. Therefore, a careful evaluation should include details of the patient's immunization history.

In older children and adolescents, bacteremia is infrequent, and *N. meningitidis* and *S. aureus* are the most common causes of serious infections.

The likelihood of SBI varies depending on age. The usual cause of fever is viral rather than bacterial (58% versus 8%, as reported in one study). In febrile infants less than 3 months of age, the incidence of bacterial infection ranges from 0.7% to 18.5%, with the highest risk in infants less than 1 month of age. In febrile children between 3 and 36 months of age, the risk of occult bacteremia ranges from less than 1% to 5%, depending on whether the child is completely immunized. The organism most commonly isolated from blood culture is *S. pneumoniae*, although isolation of this organism has become less frequent since the heptavalent PCV7 was implemented for routine vaccination of infants in 2000. Since then, infections caused by the seven *S. pneumoniae* serotypes contained in the vaccine have decreased significantly. The 13 valent pneumococcal vaccine (PCV13) was licensed in 2010. It is expected that the expanded coverage against the additional six serotypes should further decrease childhood infections caused by *S. pneumoniae*. Infections with serotypes not contained in the vaccine do still occur, as well as infections with other organisms such as *N. meningitidis, Salmonella* spp., and MSSA and MRSA.

Clinical and Laboratory Evaluation

Information used to determine risk of SBI or occult bacteremia includes the clinical appearance of the child and the results of laboratory tests. The chance of obtaining a positive blood culture increases with high fever (over 39.0° C [102.2° F]), ill appearance, and abnormal laboratory findings. Other factors associated with increased risk of SBI include underlying chronic illness and immunodeficiency.

However, neither laboratory studies nor careful observation is totally sensitive for detection of serious illness in febrile children. Therefore, each child warrants careful, thoughtful evaluation. It is necessary to make every attempt to avoid unnecessary laboratory testing and overuse of antibiotics while providing appropriate care and antibiotic therapy for patients identified as high risk.

History

Identifying febrile children at risk for occult bacteremia or SBI requires conscientious attention to parental concerns. It is necessary to question parents regarding duration and height of fever, method of measurement, and use of antipyretics. Inquiries about the child's behavior, appetite, and activity level are also appropriate. Previously healthy children who interact well, are playful and consolable, and have the ability to drink or eat and are interested in doing so are less likely to be seriously ill. Signs of serious illness include irritability, poor eye contact, failure to recognize parents, and poor interaction with people or the environment.

Physical Examination

Abnormalities in vital signs include fever or hypothermia, tachypnea, irregular respirations, apnea, tachycardia or bradycardia, and hypotension. It is important to examine the skin and mucous membranes for cyanosis, poor perfusion, and petechial or purpuric rash. The clinician should also examine the child for signs of meningeal irritation (Kernig and Brudzinski signs), pneumonia, heart murmur, abdominal infection, and musculoskeletal infection.

Careful documentation in the medical record of specific findings on physical examination is important. It is better to avoid more general terms and to note, for example, that instead of being "responsive," a child smiles, plays with the stethoscope, or takes a bottle from his mother. Similarly, use of the word "toxic" is less informative than saying the child is difficult to awaken and has cyanosis and poor capillary refill.

Laboratory Evaluation

Febrile infants less than 1 month of age should have a **sepsis evaluation**, which includes a complete blood cell count (CBC), blood culture, urinalysis and urine culture, as well as examination of spinal fluid with culture. If diarrhea is present, a stool sample for polymorphonuclear (PMN) cells and bacterial culture is appropriate. Infants with respiratory symptoms should have a chest X-ray (CXR) performed.

Recommendations for laboratory evaluation of febrile children between 1 and 3 months of age vary. A complete sepsis evaluation is necessary in ill-appearing children. The extent of testing necessary in non–ill-appearing children depends on the risk of SBI. Children with low risk of SBI include those with a white blood cell (WBC) count of 5,000 to 15,000 cells/mm^3, a normal urinalysis, and no PMN cells on stool examination (if diarrhea is present). Laboratory findings associated with occult bacteremia or SBI include an elevated or depressed WBC count (greater than 15,000 or less than 5,000 cells/mm^3), an elevated sedimentation rate (ESR) or C-reactive protein (CRP), and an abnormal urinalysis or stool examination. A CXR should also be considered in children with a high WBC because physical examination findings for pneumonia may be subtle in this age group. Children with a high

risk of disease should have a full sepsis evaluation. Recent studies show that elevated serum levels of procalcitonin may also be useful in predicting the presence of a SBI, although not many laboratories currently offer this test.

Suggested guidelines for laboratory evaluation and management of *nontoxic-appearing* febrile children between 3 and 36 months depend on whether their temperature is above or below 39.0° C (102.2° F). In general, non–ill-appearing children with a temperature less than 39.0° C (102.2° F) and no focal findings on physical examination can be observed without laboratory evaluation. The laboratory evaluation of children with a temperature greater than 39.0° C (102.2° F) depends on the child's clinical appearance. Some clinicians defer initial laboratory tests and observe the child carefully; others choose to obtain a screening CBC. If the WBC is greater than 15,000 cells/mm^3, a blood culture, urine culture, stool culture, and chest radiograph may be appropriate. As a practical matter, many clinicians choose to obtain a blood culture at the same time the CBC is drawn. Any child who is very ill-appearing should have a full sepsis evaluation, including lumbar puncture.

Differential Diagnosis

Infants less than 2 months old appear ill and have fever as a result of neonatal herpes simplex virus (HSV) 1 or 2 infection. The spectrum of neonatal HSV infection ranges from skin, eye, and mucous membrane disease to disseminated infection and CNS disease. Neonatal HSV infection can be difficult to distinguish from bacterial sepsis. Signs and symptoms may include fever or hypothermia, vesicular skin or mucous membrane lesions, keratitis, seizures, pneumonia, hepatitis, and abnormal coagulation studies. Consideration of this diagnosis is important as patients must be managed with intravenous antiviral (acyclovir) therapy.

In older infants, a careful history and physical examination often reveals the presence of a readily identifiable viral illness (e.g., croup, chicken pox) or bacterial infection (e.g., acute otitis media [AOM], pneumonia, cellulitis). A well-appearing child between the ages of 6 months and 2 years with high fever with no source may have roseola caused by infection with human herpes viruses 6 or 7 (HHV-6, HHV-7) (see Roseola). Typically, the rash appears just as the fever resolves. Meningitis carries a high risk of morbidity and mortality and requires early antibiotic therapy, so it is often considered in the differential diagnosis of children with fever or signs of sepsis.

Management

Important management considerations include age, clinical appearance, reliability of the family, and results of screening laboratory tests. **Antibiotics should never be initiated until appropriate cultures are obtained and should not be used in well-appearing older children whose laboratory results are unremarkable.** Hospitalization for intravenous antibiotics or careful observation pending culture results is appropriate for all infants less than 1 month of age with fever. Hospitalization and empiric parenteral antibiotic therapy is also recommended for high-risk children between 1 and 3 months of age (see Laboratory Evaluation). Hospitalization and empiric intravenous antibiotics are warranted for ill-appearing children over 3 months of age. Antibiotic therapy is a consideration in nontoxic-appearing children over 3 months of age with high fever and elevated WBC pending blood culture results.

Unimmunized or incompletely immunized children are at higher risk for bacteremia with *S. pneumoniae* and *H. influenzae* type b. Parenteral (IM) ceftriaxone may prevent progression of bacteremia to focal infection with these organisms. Therefore, in selected unimmunized or incompletely immunized non–ill-appearing older infants and children (over 3 months) who have elevated WBCs, outpatient parenteral antibiotics may be considered pending culture results, if follow-up within 24 hours is guaranteed. There is no evidence that oral antibiotic therapy is effective in preventing meningitis.

It may be possible to identify a focus of infection on the basis of history and a physical examination. If so, management proceeds according to recommended guidelines for the specific infection.

Antipyretics are indicated for febrile children who are uncomfortable. However, infants should not receive antipyretics until they have undergone a complete medical evaluation for the source of fever. Several different preparations of antipyretics are available. It is crucial that parents and physicians appreciate the differences between formulations made specifically for infants and children, including "junior strength" preparations. They should use only the dosing instructions that accompany the product. Acetaminophen inhibits centrally mediated prostaglandin formation and release; the recommended dose is 10 to 15 mg/kg/dose every 4 to 6 hours, not to exceed five doses in 24 hours or more than a total dose of 4 grams/day. Ibuprofen exerts its antiprostaglandin effect peripherally; the recommended dose is 5 to 10 mg/kg/dose every 6 to 8 hours. Aspirin is not recommended as an antipyretic in children because of the associated risk of Reye syndrome. Many over-the-counter cold and cough preparations may contain acetaminophen or ibuprofen, and parents should take this into account before giving additional antipyretic therapy. Over-the-counter cough and cold medications should not be given

to children 2 years of age and younger because of potentially serious adverse effects. In addition, research shows that these preparations are not effective in children younger than 6 years and their use is discouraged.

ACUTE OTITIS MEDIA

AOM, the most common disease diagnosed in children, accounts for over 15,000,000 provider visits/year. In AOM, infection of the middle ear occurs when bacterial pathogens that colonize the nasopharynx multiply in the enclosed space. Studies show that more than 75% of children experience at least one episode of AOM. The primary reason for dispensing antibiotics is treatment of AOM. Several factors place children at risk for the development of AOM (Table 9-1). Additional risk factors for frequent AOM include underlying palatal or craniofacial abnormalities.

Pathophysiology

Young children are more prone to AOM because they have shorter eustachian tubes, which lie in a more horizontal position. The eustachian tube protects the middle ear from nasopharyngeal secretions, provides drainage of middle ear secretions into the nasopharynx, and equilibrates air pressure in the middle ear with atmospheric pressure. In AOM, viral upper respiratory tract infection causes swelling of eustachian tube mucosa and prevents normal drainage of fluid from the middle ear to the nasopharynx. Other factors that impede normal eustachian tube drainage include enlarged adenoids or functional obstruction associated with decreased cartilage support of the tube in infants.

The most common bacterial cause of AOM is *S. pneumoniae*. Vaccination with the conjugate pneumococcal vaccine in infancy appears to be associated with only a marginal decline in AOM. This is likely due to the fact that nonvaccine serotypes of *S. pneumoniae* also cause AOM. Prior to introduction of the conjugate heptavalent pneumococcal vaccine, the number of episodes of AOM secondary to drug-resistant *S. pneumoniae* paralleled the nationwide increase in isolates with intermediate (minimum inhibitory concentration

TABLE 9-1

Risk Factors Associated with the Development of Acute Otitis Media

[MIC] = 0.1–1.0 μg/mL) and high-level (MIC greater than or equal to 2.0 μg/mL) resistance to penicillin. Vaccination of infants has been associated with a decrease in carriage of some of the serotypes that were likely to be drug-resistant; however, nonPCV7 serotypes that are drug-resistant have emerged. Infection with some of these drug resistant serotypes may be prevented by the newer PCV13 vaccine. Risk factors for infection with drug-resistant *S. pneumoniae* include residence in a community with high resistance rates, day-care attendance, antibiotic use within the past 3 months, and age of less than 2 years. Nontypeable *H. influenzae* and *Moraxella catarrhalis* are two other organisms often isolated from infected middle ear fluid. Gram-negative enteric bacteria may also cause middle ear infection in neonates.

Recent evidence proves a specific viral etiology in many cases of AOM; respiratory syncytial virus (RSV) is isolated most frequently. Other viruses isolated from middle ear fluid include parainfluenza and influenza viruses.

Clinical and Laboratory Evaluation

The basis of diagnosis of AOM involves assessment of specific clinical findings and eardrum appearance.

History

Children with AOM often present with acute onset of fever, pain, or irritability. Older children complain of ear pain, whereas younger children may manifest only irritability. Affected children often have a history of preceding or concurrent upper respiratory tract symptoms.

Physical Examination

Physical examination of a child's ears requires practice and patience. If the patient is unable to remain still, it may be necessary to ask the parent for assistance in restraining the child. Complete visualization of the tympanic membrane often requires gentle removal of cerumen with an ear curette under visualization or irrigation of the ear canal with a cerumenolytic such as hydrogen peroxide diluted with water.

The correct diagnosis of AOM involves the use of a pneumatic otoscope. Physical findings seen on examination may include erythema and thickening of the tympanic membrane, engorgement of blood vessels around or crossing the tympanic membrane, loss of a normal light reflex and bony landmarks, abnormal position (retracted or bulging), an air-fluid level behind the tympanic membrane, decreased mobility of the tympanic membrane, or otorrhea.

Pediatric Pearl: Fever and crying cause the tympanic membrane to appear hyperemic. However, a diagnosis of AOM should not be made unless other features, particularly bulging or fullness and decreased mobility, are present.

Laboratory Evaluation

The diagnosis of AOM is made by clinical examination. Tympanocentesis to identify a specific bacterial pathogen is considered in immunocompromised children, in neonates, in the presence of a concomitant CNS infection, or in an infection that is refractory to multiple courses of antibiotics.

Differential Diagnosis

Conditions that warrant consideration in the diagnosis of AOM and ear pain are **otitis media with effusion (OME)**, otitis externa, mastoiditis, furuncle, foreign body, and referred pain (Table 9-2). It is essential to make the distinction between AOM and OME, which does not require the use of antibiotics (Table 9-3).

Management

The current standard of care for AOM is antibiotic therapy, which is indicated **only in children with evidence of AOM.** (See Chapter 25 for discussion of management of OME.) Several antibiotics are currently approved for treatment of AOM (Table 9-4). Amoxicillin, the drug of choice, is effective for treating infections with

TABLE 9-2

Differential Diagnosis of Ear Pain

Diagnosis	*Physical Examination Findings*	*Management*
Otitis externa	Swelling of external canal, discharge in canal Pain with movement of tragus, normal TM	Keeping canal dry and clean Antibiotic and steroid drops
Mastoiditis	Erythema and pain over mastoid Usually signs of acute otitis media ± otorrhea Anterior displacement of pinna	CT scan of mastoid Surgical evaluation IV antibiotics
Furuncle	Visible in external canal, normal TM	Oral antistaphylococcal antibiotics
Foreign body	Visible in external canal, normal TM	Removal of foreign body
Referred pain	Normal examination of external canal and TM Other source (e.g., dental abscess) found	Treating source of pain

CT, computed tomography; *IV*, intravenous; *TM*, tympanic membrane.

penicillin-susceptible or intermediate *S. pneumoniae* and β-lactamase–negative nontypeable *H. influenzae*. It has a narrow spectrum of activity. Higher-dose amoxicillin (80 to 90 mg/kg/day) is generally recommended.

None of the oral cephalosporins is reliable against resistant pneumococci. Cephalosporins are active against β-lactamase–producing *H. influenzae* and *M. catarrhalis*. Treatment of AOM with one to three doses of intramuscular ceftriaxone is as effective as several days of oral antibiotic therapy.

Children less than or equal to 5 years of age are at increased risk for treatment failure, and 10 days of treatment is recommended. Children 6 years of age or older may be successfully treated with shorter courses (5 to 7 days).

In untreated AOM, the tympanic membrane becomes erythematous. After 24 to 36 hours exudate behind the tympanic membrane appears. Perforation occurs in 5% of cases. Consequences of lack of treatment include delay in resolution of pain as well as concerns regarding reemergence of complications formerly commonly associated with AOM, including mastoiditis, meningitis, extradural abscess, subdural empyema, brain abscess, and lateral sinus thrombosis. Current evidence does not support a significant resurgence in these illnesses in children who are treated only symptomatically without antibiotics. Because spontaneous resolution occurs in 60% of cases of AOM, withholding treatment is a consideration in selected cases, particularly in older infants (over 6 months) and children with an uncertain diagnosis of AOM and/or nonsevere illness. Spontaneous resolution rates for *M. catarrhalis, H. influenzae,* and *S. pneumoniae* are 75%, 50%, and 15%, respectively. AOM caused by *S. pneumoniae* is least likely to resolve spontaneously, so it is most likely to be associated with suppurative sequelae. If initial observation rather that antimicrobial therapy is chosen, the child should have good access to medical care in order to be reexamined.

TABLE 9-3

Clinical Findings in Acute Otitis Media and Otitis Media with Effusion

Acute Otitis Media	*Otitis Media with Effusion*
Fever	Nonspecific signs of viral infection
Pain	Rhinitis, cough, diarrhea
Bulging yellow or red tympanic membrane	Middle ear effusion[a]
Middle ear effusion[a]	

[a]Always use pneumatic otoscopy or tympanometry to confirm middle ear effusion.

TABLE 9-4

Antibiotics Used for Treatment of Acute Otitis Media

Drug	*Daily Dose*	*Taste*[a]
Amoxicillin	80–90 mg/kg/day bid	+ +
Amoxicillin–clavulanic acid[b,c]	90 mg/kg/day amoxicillin component bid 6.4 mg/kg/day clavulanate bid	+ +
Second-generation cephalosporins		
Cefaclor	40 mg/kg/day tid or bid	+ +
Cefuroxime axetil suspension[b]	30 mg/kg/day bid	+
Third-generation cephalosporins		
Cefpodoxime[b]	10 mg/kg/day bid	+
Cefdinir	14 mg/kg/day q day	+ + +
Ceftriaxone (IM)[b]	50 mg/kg/day q day for 1–3 days	N/A
Macrolides		
Azithromycin	10 mg/kg/day on day 1 5 mg/kg/day q day on days 2–5	+ + +
Clarithromycin	15 mg/kg/day bid	+ +

[a] Most palatable (+ + +).
[b] Best activity against both *Streptococcus pneumoniae* and β-lactamase–producing bacteria.
[c] Dose of amoxicillin–clavulanic acid varies depending on formulation used.

PHARYNGITIS

Sore throat occurs as a result of inflammation or infection of the tonsils, uvula, soft palate, and posterior oropharynx. Pharyngitis is more likely in older children; it is uncommon in infants and children younger than 2 years of age.

Pathophysiology

Several microorganisms are associated with pharyngitis (Table 9-5). Viral infections cause most cases, which occur during the winter, when many respiratory viruses are circulating. *S. pyogenes* (GABHS) is the most common bacterial cause. Pharyngitis in children 2 to 5 years of age is most often the result of infection with respiratory viruses. Older children and adolescents are more likely to have GABHS or Epstein-Barr (EB) virus infection (infectious mononucleosis).

Clinical and Laboratory Evaluation

History

Viral pharyngitis occurs in association with other symptoms of respiratory tract infection. Children with a viral syndrome typically have fever, rhinorrhea, cough, and mild pharyngitis. Fatigue, anorexia, and abdominal pain may be present. Family members or playmates may be ill with similar symptoms.

GABHS pharyngitis frequently manifests as acute onset of fever, headache, sore throat, and abdominal pain. Rhinorrhea or cough is uncommon. There may be a history of classroom or family exposure.

TABLE 9-5

Infectious and Noninfectious Causes of Acute Pharyngitis

Viral	*Bacterial*	*Other*
Rhinovirus	*Streptococcus pyogenes* (group A)	Allergies
Adenovirus	β-hemolytic streptococci (groups C and G)	Chronic sinusitis
Coronavirus	*Mycoplasma pneumoniae*	Kawasaki disease
Parainfluenza	*Arcanobacterium haemolyticum*	Foreign body
Influenza	*Chlamydia pneumoniae*	Environmental irritant
Respiratory syncytial virus	*Neisseria gonorrhoeae*	Neoplasm
HSV-1 or -2	*Neisseria meningitidis*	Stevens-Johnson syndrome
Epstein-Barr virus	*Corynebacterium diphtheriae*	Behçet disease
Cytomegalovirus	*Francisella tularensis*	PFAPA
HIV	*Borrelia burgdorferi* (Lyme disease)	
Measles	*Streptobacillus moniliformis* (rat-bite fever)	
Rubella	*Salmonella typhi* *Treponema pallidum* *Coxiella burnetii* (Q fever) *Yersinia enterocolitica* *Yersinia pestis* (bubonic plague)	

HSV, herpes simplex virus; *PFAPA*, periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis (syndrome).

Physical Examination

Several clinical characteristics are associated with some of the organisms that cause pharyngitis (Table 9-6). Careful examination of the oral mucosa, tongue, and pharynx is important. The presence of an enanthem (lesions in the mouth), appearance of the tongue, tonsillar size, color, symmetry, and presence of an exudate are noteworthy.

Infection with enterovirus **(herpangina)** is associated with small ulcers on an erythematous base found on the tonsillar pillars, soft palate, and uvula. Vesicles in the anterior portion of the mouth and on the lips are associated with herpes simplex type 1 (HSV-1) infection. Lesions in some cases of primary HSV-1 infection extend to the posterior oropharynx. Large tonsils with exudate are common with EB virus infection. In GABHS, the tonsils initially appear beefy red. As disease progresses, a yellow-white exudate within the anterior tonsillar crypts is apparent. The tongue may become coated with a white membrane with protrusion of prominent red papillae ("strawberry tongue"). Anterior cervical lymph nodes are often enlarged and tender. In infectious mononucleosis, diffuse lymphadenopathy and splenomegaly are present.

Skin findings may be associated with different infectious causes of pharyngitis. In GABHS, a characteristic scarlatiniform rash may be evident (see Bacterial Exanthems). With infection caused by certain types of enteroviruses, a diffuse erythematous maculopapular skin eruption and vesicular or pustular lesions on the hands and feet may be present.

Laboratory Evaluation

The clinical distinction between viral and GABHS pharyngitis is sometimes difficult; cough, rhinorrhea, hoarseness, or diarrhea are more likely to be symptoms of viral infection. Throat culture is the diagnostic test of choice.

TABLE 9-6

Clinical Characteristics of Selected Infections Associated with Pharyngitis

Organism	*Clinical Findings*
Rhinovirus	Scratchy sore throat, rhinitis, cough
Coronavirus	Scratchy sore throat, rhinitis, cough
Adenovirus	Pharyngitis, often with significant pain, erythema and exudate, conjunctivitis
Coxsackie A	Summer/fall, prominent fever, coryza, vesicular lesions posterior pharynx, rash (including hands and feet)
Influenza A, B	Winter season, abrupt onset of high fever, myalgia, then pharyngitis, dry cough
EB virus	Infectious mononucleosis, with fatigue, anorexia, fever, headache, severe pharyngitis, lymphadenopathy, hepatosplenomegaly, palatal petechiae, tonsillar exudate, periorbital edema, rash with ampicillin/amoxicillin (younger children may be asymptomatic)
Cytomegalovirus	Similar to EBV except pharyngitis and lymphadenopathy less prominent, may have higher fever, more fatigue
HIV	Primary infection presents as mononucleosis-like illness with fever, pharyngitis, lymphadenopathy, rash, fatigue, arthralgia. Tonsils are red but no exudate is seen
Streptococcus pyogenes	Peak incidence late winter or spring, sudden onset sore throat, fever, headache, abdominal pain, tonsillar exudate, palatal petechiae, strawberry tongue, sometimes rash or urticaria
Neisseria gonorrhoeae	Sexually active adolescents or adults, rash, arthralgia
Corynebacterium diphtheriae	Nonimmunized patients, low-grade fever, mild sore throat, gray-white adherent membrane seen on tonsils and posterior pharynx, weakness, lymphadenopathy, "bull neck," respiratory distress, cardiac and neurologic abnormalities
Arcanobacterium haemolyticum	Seen in adolescents and young adults, exudative pharyngitis, scarlatiniform rash, no palatal petechiae or strawberry tongue, desquamation rare
Mycoplasma pneumoniae	Headache, fever, sore throat, cough, coryza, sometimes tracheobronchitis or pneumonia
Chlamydia pneumoniae	Fever, cough, sore throat

EB virus, Epstein-Barr virus.

The clinician should vigorously swab the patient's posterior pharynx and tonsils. If GABHS is present, β-hemolytic colonies of bacteria appear after 18 to 48 hours of incubation onto sheep blood agar. Definitive identification of GABHS is made by the presence of a zone of inhibition around a bacitracin disk. The sensitivity of the throat culture is greater than 90%; fewer than 10% of cultures are falsely negative. However, the number of colonies of GABHS cannot distinguish between true infection and a carrier state.

A number of rapid tests for detection of group A streptococcal antigen are available. These tests generally use immunoassay or latex agglutination techniques to detect the presence of group A polysaccharide antigen from the bacterial cell wall. The specificity of most rapid tests is excellent (over 95%), but the sensitivity is variable (70% to 85%). Accuracy of the test depends on the kit used, the skill of the person performing the test, and the quality of the throat swab. Newer tests utilizing optical immunoassay techniques or chemiluminescent DNA probes may prove to have greater sensitivity. A confirmatory culture is usually performed when a child with suspected GABHS disease has a negative rapid streptococcal test.

Serologic testing is sometimes used to confirm infection with GABHS. Rising antibody titers against streptolysin O or deoxyribonuclease (DNAse) B are seen during the first month after infection and decline to normal levels 6 to 12 months after infection. Antibody to DNAse B peaks later than the antistreptolysin O titer, and both tests can remain elevated for several months.

Other infectious causes of pharyngitis may be diagnosed by use of special culture techniques. *Arcanobacterium haemolyticum*, a gram-positive or gram-variable nonsporulating bacillus, is best isolated using human or rabbit blood agar incubated for 72 hours. *Corynebacterium diphtheriae* is isolated from nose, throat, and membrane swabs inoculated onto select media. *Neisseria gonorrhoeae* is isolated using selective agar (chocolate agar with antibiotics).

Most cases of viral pharyngitis are self-limited, and viral culture is not necessary. Specific circumstances in which viral culture may be useful include cases of suspected HSV-1 or HSV-2 gingivostomatitis or in possible enteroviral disease with other manifestations (meningitis).

Diagnosis of EB virus infection (**infectious mononucleosis)** is made by Monospot and specific EB virus serology. Infection with EB virus stimulates an immunoglobulin (IgM) heterophile antibody response. Serum from patients with infectious mononucleosis agglutinates sheep red blood cells (RBCs) after absorption with guinea pig kidney antigens. Production of heterophile antibodies is induced by EB virus, but the antibodies are not directed toward any known EB virus antigen. Several specific serologic antibody tests for EB virus are available. The Monospot test may be negative in children less than 4 years of age with infectious mononucleosis, who are less likely to generate a heterophile antibody response.

Differential Diagnosis

The differential diagnosis of sore throat is broad. Serious infections to consider include **peritonsillar abscess, retropharyngeal abscess,** and **epiglottitis**. Noninfectious causes of pharyngitis include allergy, trauma to the pharynx, burns, inhaled or swallowed toxins, smoke, psychosomatic illness, and referred pain.

A history of pharyngitis often precedes signs and symptoms of a **peritonsillar abscess,** which typically involves the superior pole of one tonsil. Children exhibit high fever, difficulty swallowing, and changes in speech. Physical examination reveals an acutely ill child with unilateral peritonsillar and tonsillar swelling. The uvula is displaced away from the affected tonsil, and the neck is often held in a rigid position with marked ipsilateral cervical adenitis. Bilateral abscess formation rarely occurs. Timely diagnosis is important to prevent rupture and possible aspiration of purulent fluid. Organisms within the abscess include GABHS, *S. aureus*, and aerobic and anaerobic mouth flora. Treatment includes intravenous antibiotics and surgical drainage.

A **retropharyngeal abscess** occurs when lymph nodes located in potential space between the prevertebral fascia and posterior pharyngeal wall become infected and suppurate. Symptoms of retropharyngeal abscess are similar to those of peritonsillar abscess. Children appear ill with high fever, dyspnea, and difficulty swallowing. Careful examination of the mouth and pharynx reveals swelling of the posterior pharynx. Lateral neck films reveal retropharyngeal swelling. Treatment is similar to that of a retropharyngeal abscess.

Acute epiglottitis, a rapidly progressive disease, is now uncommon because of universal immunization with *H. influenzae* type b vaccine. The disease usually occurs in unimmunized patients. *S. pneumoniae; S. aureus;* nontypeable *H. influenzae; H. parainfluenzae;* and groups A, B, and C β-hemolytic streptococci are rare causal organisms. Affected children have acute onset of high fever and sore throat, and within several hours they have difficulty swallowing and exhibit drooling and respiratory distress. Diagnosis is made by noting the appearance of a swollen, cherry-red epiglottis with direct laryngoscopy by an experienced physician.

Pediatric Pearl: If epiglottitis is suspected, it is imperative that a skilled physician perform the examination in a setting where emergent intubation or tracheostomy can be carried out.

Ideally, a pediatric anesthesiologist and surgeon are alerted to the situation and available at the time of the examination. After epiglottitis is diagnosed, intubation and observation in an intensive care unit with administration of intravenous antibiotics are necessary until swelling resolves.

The syndrome of **p**eriodic **f**ever, **a**phthous stomatitis, **p**haryngitis, cervical **a**denitis **(PFAPA)** is characterized by periodic high fever occurring at regular intervals of about 3 to 4 weeks. Fever (temperature greater than

or equal to 39.0° C [102.2° F]) continues for 3 to 6 days, during which time, the child appears remarkably well. Aphthous stomatitis occurs in two-thirds of patients. Ulcers are typically smaller and shallower than lesions seen in Behçet disease. Tonsils are moderately enlarged, erythematous, and without exudate. Cervical adenitis is often present. It is not known whether PFAPA is an infectious or immunologic disorder.

Management

Treatment of viral pharyngitis is symptomatic, with antipyretics (if the patient is uncomfortable), fluids, and rest. Treatment of GABHS pharyngitis involves antibiotics to decrease duration of symptoms, reduce spread of infection, and prevent **acute rheumatic fever**. Antibiotic therapy does not alter the course of **poststreptococcal acute glomerulonephritis** but may limit the spread of strains of bacteria that are associated with it. Penicillin remains the drug of choice for treatment of GABHS infections. It is safe, inexpensive, and has a narrow spectrum of coverage. In addition, it is proven to prevent both suppurative and nonsuppurative complications of infection with GABHS. When given within 9 days of onset of symptoms, penicillin prevents development of acute rheumatic fever. Therefore, a short delay while awaiting rapid antigen or culture results does not increase the risk of acute rheumatic fever. If compliance is a concern, intramuscular benzathine penicillin G is appropriate. Amoxicillin is an effective substitute for penicillin. No isolates of GABHS are yet resistant to β-lactam antibiotics. Narrow-spectrum cephalosporins such as cephalexin may be considered in patients who are allergic to penicillins, although cephalosporins should be avoided in patients with an immediate (type 1) hypersensitivity reaction to penicillin.

Macrolide antibiotics including erythromycin, clarithromycin, and azithromycin are used in β-lactam antibiotic–allergic patients, although strains of GABHS resistant to macrolides have become more common in recent years. Failure to respond to macrolide or clindamycin therapy should prompt consideration of susceptibility testing. Tetracyclines, trimethoprim, and sulfonamides are not effective.

Routine throat culture after treatment is not necessary. Some children continue to have small numbers of GABHS present in their oropharynx; they are carriers. Generally, they do not have symptomatic disease, rarely spread disease to others, and are not retreated with antibiotics. Rare circumstances in which eradication of the carrier state is considered include community outbreaks of acute rheumatic fever or poststreptococcal glomerulonephritis, family history of acute rheumatic fever, multiple or recurrent episodes of GABHS pharyngitis in families or closed communities, or a case of GABHS-caused toxic shock syndrome or necrotizing fasciitis in a family. Antibiotics used with variable success to eradicate the carrier state include clindamycin, amoxicillin–clavulanic acid, or penicillin plus rifampin.

UPPER RESPIRATORY TRACT INFECTIONS

Most children have as many as 3 to 8 colds each year. Several viral species cause the common cold (Table 9-7). Rhinovirus is the most common viral agent associated with colds; at least 100 different serotypes have been identified. Symptoms are due to primary infection or reinfection with the same antigenic type.

Pathophysiology

Infection is spread by airborne, droplet, or contact transmission. **Airborne transmission** is dissemination of evaporated microorganism-containing droplets, which are suspended in air for long periods. Organisms transmitted by airborne transmission include rubeola (measles), varicella-zoster virus (VZV), and *Mycobacterium tuberculosis*. **Droplet transmission** is the propelling of relatively large microorganism-containing drops from infected children into the host's conjunctivae or nasal mucosa by sneezing, coughing, or talking. Viruses that usually spread by droplet transmission include adenoviruses, coronaviruses, and influenza viruses. **Contact transmission** is the touching of infected secretions by a noninfected individual, who autoinoculates the eyes, nose, or mouth. Viruses spread by contact transmission include RSV, parainfluenza virus, enterovirus, and rhinovirus.

After a virus is inoculated onto the respiratory epithelium, local viral replication begins. This period, called the incubation period, typically ranges from 2 to 5 days. Symptoms of the common cold are due in part to production of inflammatory mediators such as histamine, kinins, and interleukins. Submucosal edema, vasodilation, and impaired mucociliary transport result in symptoms of nasal stuffiness, throat irritation, and sneezing. Subsequent sloughing of the respiratory epithelium results in nasal discharge. Local γ-interferon production limits the spread of infection to respiratory mucosa of the upper and lower respiratory tract, sinuses, and eustachian tubes. Viremia does not occur. Secretory IgA and serum IgG produced in response to infection prevent future

TABLE 9-7

Viruses that Cause Upper and Lower Respiratory Tract Infections

Organism	*Serotypes*	*Season*	*Clinical Manifestations*
Rhinovirus	>100	Year round, with autumn/spring peak	Rhinorrhea, malaise, headache, low-grade fever (common cold), mild pharyngitis, occasionally otitis media, wheezing
Coronavirus	2	First type (winter) Second type (winter)	Rhinorrhea, malaise, headache, low-grade fever (common cold) Mild pharyngitis, occasionally otitis media, wheezing
Respiratory syncytial virus	Subtypes A and B	November–April	Bronchiolitis/pneumonia in infants and young children Upper respiratory tract illness in older children and adults
Human metapneumovirus	Subgroups A and B	December–April	Lower respiratory tract illness in infants and young children Upper respiratory tract illness in older individuals
Parainfluenza	Types 1–4	Type 1 (autumn) Type 2 (autumn) Type 3 (spring/summer) Types 4A/4B (sporadic)	Croup, upper respiratory tract symptoms, bronchiolitis Bronchiolitis, croup Bronchiolitis, croup Mild upper respiratory tract infection
Adenovirus	51	Year round (increased in late winter/spring/early summer)	Common cold, pharyngitis, pharyngoconjunctival fever, otitis media, keratoconjunctivitis, croup, pertussis-like illness
Influenza	Three antigenic types (A, B, C)	Winter	Sudden onset of fever, headache, myalgia, nonproductive cough, then pharyngitis, rhinorrhea Abdominal pain, nausea, and vomiting occasionally seen

infection with viruses of the same antigenic type. Viral shedding is greatest during the first few days of illness, with the highest concentration of the virus present in nasal secretions.

Clinical and Laboratory Evaluation

History

Most respiratory viruses cause similar signs and symptoms. Children typically have low-grade fever and mild irritability. Other symptoms include nasal discharge, which progresses from clear to cloudy in a few days. An initially dry cough eventually becomes productive.

Physical Examination

Patients do not appear seriously ill. The presence of a mucopurulent nasal discharge, which is part of the normal progression of respiratory infection, does not necessarily imply an underlying bacterial sinus infection. The pharynx may be erythematous with mildly enlarged tonsils. Otitis media resulting from secondary bacterial infection

or viral infection is occasionally evident. The chest is usually clear but wheezes may be heard. A viral exanthem is seen in association with enterovirus or adenovirus. Adenovirus infection is sometimes associated with high fever, prominent pharyngitis, and conjunctivitis.

Laboratory Evaluation

Because of considerable overlap in symptoms caused by respiratory viruses, it is difficult to make a specific diagnosis. Viral culture is usually not performed. Results are typically not available for days to weeks after the child is evaluated and the illness has resolved. Rapid diagnostic tests are available for diagnosis of RSV, human metapneumovirus (hMPV), parainfluenza, influenza, and adenovirus. These tests are not used routinely in outpatient settings. However, they are useful in evaluation of severely ill, high-risk (e.g., former premature infants, those with chronic lung disease or congenital heart disease), or immunocompromised children.

Differential Diagnosis

Sinusitis is a possibility when symptoms persist beyond 10 to 14 days, particularly when the condition is associated with cough, low-grade fever, facial pain, headache, or bad breath. In children who have not received the diphtheria and tetanus toxoids and pertussis (DTaP) vaccine, **pertussis** begins as a mild upper respiratory tract illness (catarrhal stage) and progresses to severe paroxysms of cough (paroxysmal stage) associated with vomiting.

Management

Management of viral respiratory infections is supportive, with fluids and rest. Over-the-counter medications containing antihistamines, decongestants, cough suppressants, and expectorants are available but should not be used in children under the age of 2 and use is discouraged in children younger than 6 years. None of these preparations appears to have clear benefit in alleviating symptoms. Vitamin C may not prevent colds but may have modest benefit in reducing symptoms. Zinc gluconate inhibits viral replication in vitro, but studies of clinical benefit have shown mixed results. Antibiotics are not indicated for treatment of viral respiratory illness but are used if secondary bacterial infection such as AOM or sinusitis is present.

Pediatric Pearl: Good attention to handwashing, avoidance of touching mucous membranes, and decontamination of fomites decrease spread of infection.

BRONCHIOLITIS

Bronchiolitis is an obstructive pulmonary disease of infants and young children, caused most often by infection with RSV. Approximately 100,000 infants are hospitalized with RSV infection annually; mortality rates range from 0.5% to 1.5%. The severity of illness caused by RSV ranges from mild upper respiratory tract infection to bronchiolitis or pneumonia. Bronchiolitis is most common in children younger than 1 year of age, with a peak incidence at 2 to 6 months.

Pathophysiology

RSV is the primary cause of bronchiolitis. Recent evidence suggests that hMPV is also a significant cause of bronchiolitis in infants. Parainfluenza viruses and adenoviruses are less commonly associated with the disease. RSV, an RNA virus in the genus *Pneumovirus* of the family Paramyxoviridae, receives its name from the characteristic cytopathic effect (syncytial appearance) noted several days after inoculation of infected material into cell culture. The RSV genome codes for at least 10 polypeptides, including the envelope proteins F and G. Fusion protein (F) facilitates cell penetration and cell-to-cell spread in the respiratory tract, and the G protein helps with attachment to sialic acid residues on respiratory epithelial cells. RSV, which is divided into types A and B based on differences in the G protein, attaches to and infects respiratory epithelial cells.

Viral proliferation in the respiratory epithelium leads to edema and necrosis of the epithelial lining of the airway, sloughing of ciliated cells, and formation of mucous plugs. Intense peribronchial lymphocytic

proliferation occurs. Possible distal airway obstruction may lead to ventilation-perfusion mismatch, hyperinflation, atelectasis, hypoxemia, respiratory failure, and, in some cases, death.

High levels of functional neutralizing serum antibody to RSV F and G proteins correlate with protection against disease. Lower levels of maternal neutralizing antibody are associated with more severe disease in young infants. Appearance of RSV-specific secretory IgA coincides with termination of RSV shedding. By the age of 3 years, virtually all children have formed an antibody to RSV, although this antibody is not totally protective, and reinfection may occur. Severity of illness decreases as children become older, and infection involves primarily the upper respiratory tract in later life.

In the United States, RSV infection occurs during November through April. Types A and B strains may circulate together during a single respiratory season, although A strains are more virulent and tend to predominate. Recurrent infection with the same strain is possible. Children at highest risk for severe disease include premature infants and patients with unrepaired or complex congenital heart disease or heart failure, bronchopulmonary dysplasia, cystic fibrosis, congenital abnormalities of the airway, and neuromuscular disease. Also at risk for serious infection are immunocompromised children.

Clinical and Laboratory Evaluation

History

Clinical manifestations depend on the age of the child and underlying medical conditions. Infants may present with bronchiolitis or pneumonia. Lethargy, irritability, and apnea are major symptoms. Poor feeding results from increased work of breathing. Older children and adults have symptoms of the common cold (prolonged), wheezing, croup, tracheobronchitis, or pneumonia (uncommon). Alternatively, they may be relatively asymptomatic.

Physical Examination

The focus of the physical examination is to determine whether a child requires symptomatic treatment at home or closer observation in the hospital. Some children appear to be relatively well, with nasal congestion and mild cough. Those with more severe illness present with lethargy or respiratory distress. Vital signs reveal low-grade fever, increased respiratory rate, and increased heart rate. Children with significant respiratory distress feed poorly and have signs of weight loss or dehydration. AOM may be present, either from bacterial superinfection or RSV infection. Mucous membranes may be dry or cyanotic. It is necessary to observe the chest for supraclavicular, intercostal, and subcostal retractions. Rales, wheezes, rhonchi, or decreased breath sounds may be audible on auscultation.

Laboratory Evaluation

Diagnostic tests are generally not performed if children appear well. If testing is necessary, rapid diagnostic methods, including immunofluorescent and enzyme immunoassay techniques, are available. The sensitivity of most of these tests ranges from 80% to 90%. These rapid diagnostic tests are useful for appropriate isolation of children admitted to the hospital.

In addition, some laboratories are capable of testing for RSV by highly sensitive polymerase chain reaction (PCR) techniques. RSV is also isolated by conventional viral culture techniques, although results are not available for 3 to 5 days. Some laboratories offer RSV culture by shell vial (centrifugation) with results available in 48 hours.

Pulse oximetry or arterial blood gases are used to determine if hypoxia is present in children with respiratory distress. Abnormal findings on chest radiograph include hyperinflation and atelectasis (usually right upper and right middle lobes). An alveolar infiltrate is often present in immunocompromised children. An enlarged cardiac silhouette suggests a primary cardiac problem, although a concomitant acute infection with RSV may be present.

Differential Diagnosis

The differential diagnosis of RSV bronchiolitis includes infection with other viruses and some bacteria. Parainfluenza, adenovirus, hMPV, and rhinovirus cause similar symptoms. *Chlamydia trachomatis* infection may produce similar symptoms in infants between 1 and 4 months of age, although fever is uncommon. Bacterial superinfection is rare, but occasionally clinical and chest radiographic findings of RSV bronchiolitis or RSV pneumonia are similar to those of bacterial pneumonia. Congestive heart failure leads to respiratory distress that may be indistinguishable from bronchiolitis; infants and young children with heart failure often have wheezing instead of rales

on physical examination. Aspirated foreign body may manifest as respiratory distress, wheezes, and atelectasis on chest radiograph.

Management

In most cases, treatment of healthy infants and children with symptoms of upper respiratory tract disease is supportive.

Medical Treatment

Hospitalization may be appropriate for children who appear ill, dehydrated, in respiratory distress, or in whom it is not possible to rule out SBI. Inpatient treatment may also be necessary for children with congenital cardiac or pulmonary disease when RSV is suspected because of the potential for rapid deterioration. Supplemental oxygen is often required and some children may respond to bronchodilator therapy. Mechanical ventilation is sometimes necessary, particularly in premature infants or those with underlying cardiac or pulmonary disease.

Use of antiviral drugs is generally reserved for severely ill or immunocompromised children. Ribavirin, a synthetic nucleoside analog, has in vitro activity against RSV. Administration is by the aerosolized route. Corticosteroids are not routinely indicated, particularly in young infants.

Prophylaxis

Clinicians should consider prophylaxis against RSV disease in the following groups of patients: (1) infants and children less than 2 years of age with chronic lung disease or hemodynamically significant heart disease requiring medical therapy for their disease, (2) children born at less than 32 weeks' gestation, (3) certain infants with congenital abnormalities of the airway or neuromuscular disease and (4) certain infants between 32 weeks and 34 weeks 6 days of gestation. Children with severe immunodeficiency may benefit from prophylaxis. Currently, no vaccines for prevention of RSV disease are available.

Palivizumab is an RSV monoclonal antibody used to reduce the risk of serious lower respiratory tract disease caused by RSV. Palivizumab is a humanized mouse monoclonal antibody that binds to the F protein of RSV and is given intramuscularly on a monthly basis for a maximum of five doses during months when RSV is circulating in the community. Studies have found that it reduces hospitalization of selected high-risk infants with RSV by 45% to 55% depending on the risk category.

CROUP

Croup, or laryngotracheobronchitis, is a common childhood illness. Hospitalization occurs in fewer than 2% of children, and only 0.5% to 1.5% of these children require intubation. Most cases occur in boys in their first 3 years of life during late fall or early winter.

Pathophysiology

Croup is an acute respiratory illness resulting from inflammation and narrowing of the subglottic region of the larynx. In most cases, parainfluenza viruses 1, 2, or 3 are the causal agents. Less common causes are influenza, RSV, hMPV, adenoviruses, measles, and *Mycoplasma pneumoniae*. Viral infection of the upper respiratory tract spreads to involve the respiratory epithelium of the larynx and trachea. Swelling and edema contribute to narrowing of the subglottic space. Inflammatory debris, mucus, and exudate contribute further to vocal cord dysfunction and subglottic obstruction.

Clinical and Laboratory Evaluation

History

The history should focus on understanding the tempo of the illness, prodromal symptoms, and likelihood of possible foreign body aspiration. Preceding symptoms include several days of mild upper respiratory tract illness. Children have a barking (or "croupy") cough, hoarseness, and inspiratory stridor. Fever is almost always present. Illness gradually subsides within 3 to 7 days. Disease progression occurs in some children, with respiratory distress, hypoxia, and, ultimately, respiratory failure.

Physical Examination

The child should be comfortable and sitting during the examination. It is important to pay special attention to evaluation of the severity of airway obstruction to rule out potentially life-threatening causes of stridor and airway obstruction. Children may appear relatively well with only rhinorrhea, hoarseness, and a barking cough. However, they may be cyanotic with intercostal retractions and respiratory distress. Restlessness and agitation are signs of hypoxia. Fever, increased respiratory rate, and increased heart rate may be present.

Some clinicians use croup scores to assess severity of illness and response to therapy. Scoring systems assign points for abnormal findings on physical examination. Parameters evaluated include stridor, retractions, decreased air entry, cyanosis, level of consciousness, presence of cough or dyspnea, and increased heart and respiratory rates.

Laboratory Evaluation

The diagnosis of croup is mostly based on clinical signs and symptoms. When obtained, the CBC is usually normal. Neck radiographs and chest radiographs are useful for eliminating other causes of stridor such as retropharyngeal abscess, foreign body aspiration, or epiglottitis. It is possible to isolate virus from nasopharyngeal secretions using conventional virus cultures. Rapid antigen detection assays are available for diagnosis of parainfluenza virus infection or other viral etiologies; however, the sensitivity of tests varies.

Differential Diagnosis

Viral croup is one of several causes of airway obstruction and stridor. Other diagnostic considerations include *H. influenzae* type b epiglottitis (see Pharyngitis, Differential Diagnosis), bacterial tracheitis, retropharyngeal abscess, and laryngeal foreign body (Table 9-8).

TABLE 9-8

Differential Diagnosis of Stridor/Upper Airway Obstruction

	Viral Croup	*Epiglottitis*	*Bacterial Tracheitis*	*Retropharyngeal Abscess*	*Laryngeal Foreign Body*
Age	0.5–3 years	3–6 years	Any (usual 2–4 years)	<4 years	Any
Etiology	Parainfluenza Respiratory syncytial virus Influenza	*Haemophilus influenzae* type b	*Staphylococcus aureus* *S. pyogenes* *S. pneumoniae*	*S. aureus* *S. pyogenes* *S. pneumoniae* Anaerobic oral flora	Foreign object
History of onset	Viral prodrome	Abrupt	Viral prodrome, then sudden worsening of symptoms	Abrupt	Abrupt
Temperature	<39° C	>39° C	>39° C	>39° C	Afebrile
Respiratory distress	Mild	Moderate to severe	Moderate to severe	Moderate to severe	Mild to severe
Cough	Present	Absent	Present	Absent	Present
Voice	Hoarse	Muffled	Hoarse	Muffled	Occasionally aphonia
CBC	Normal	WBC↑	WBC↑	WBC↑	Normal

CBC, complete blood cell count; *WBC*, white blood cell count.

Management

Treatment of viral croup is supportive. Cool, humidified air is often used, but no studies have shown that it decreases subglottic edema or stridor. Humidified oxygen is helpful in the patient with hypoxia. Nebulized racemic epinephrine reduces airway obstruction in hospitalized patients. Corticosteroid therapy (parenteral, oral, or inhaled) decreases the severity and duration of symptoms and the rate of hospitalization. Specific antiviral therapy is not available.

INFLUENZA

Infections with influenza virus are common in children. A short incubation period of 1 to 3 days and a long duration of viral shedding (1 to 2 weeks) facilitate spread of influenza virus. School-age children have the highest attack rates. However, 90% of deaths occur in persons over 65 years of age. Hospitalization for conditions related to influenza (about 110,000/year) is more common in older persons (over 65 years) or in very young children (under 1 year).

Pathophysiology

The causal agent is the influenza virus, a single-stranded RNA virus in the family Orthomyxoviridae. Influenza viruses are classified by type (A, B, C), host of origin (if nonhuman), geographic source, strain number, and year of appearance. The viruses have important surface glycoproteins such as hemagglutinin (H) to facilitate attachment and neuraminidase (N) to facilitate release of viral progeny from infected cells. The M2 proteins that occur in influenza A strains maintain acidity of the Golgi apparatus in infected cells and allow the virus to be uncoated.

Influenza A viruses are classified into subtypes on the basis of the surface antigens H and N. Immunity to the surface antigens of influenza reduces the likelihood and severity of infection. Antibody against one influenza type or subtype gives little or no protection against another type or subtype.

Both influenza A and B are associated with significant clinical illness and yearly epidemics. Influenza A is found in a wide range of animals, including humans, birds, ducks, pigs, horses, and marine mammals. Influenza B is predominantly a human pathogen. Influenza C infection is asymptomatic or causes mild respiratory illness in humans. Influenza viruses circulate during the winter in temperate and subarctic regions and year round in warmer tropical and subtropical climates.

Influenza viruses undergo frequent antigenic changes. **Antigenic shift,** an abrupt change, occurs after a circulating influenza A subtype disappears and is replaced by a subtype with one or both surface proteins (H or N) new to humans. **Antigenic drift,** a gradual change, occurs in both influenza A and B and results from a series of genetic mutations. Both antigenic shift and antigenic drift allow influenza virus to escape host immune responses. As a result, humans are susceptible to influenza virus infection throughout their lives. Continual antigenic drift, which occurs more often than antigenic shift, causes seasonal **epidemics** of influenza. However, when antigenic shift does occur, large numbers of the population have no immunity to the virus. **Pandemics** result from the appearance of a novel influenza virus capable of rapid transmission in humans; in 1918, influenza type A subtype H1N1 led to more than 20 million deaths worldwide. New viruses with limited transmissibility are associated with relatively few cases of disease. A novel swine-origin subtype A H1N1 influenza virus appeared in the spring of 2009 that was easily transmitted, resulting in the declaration of a worldwide pandemic soon after the virus was first identified.

Infection of the respiratory epithelium by the influenza virus causes significant cellular necrosis, edema, and inflammation. The infection spreads rapidly to involve both the upper respiratory tract and the smaller airways of the lower respiratory tract. Systemic symptoms of malaise and myalgia relate to the production of interferon. Bacterial superinfections are more often seen with influenza infection than with other respiratory viruses. Otitis media occurs in 10% to 50% of cases. *S. pneumoniae* and *S. aureus* may cause pneumonia or bacterial tracheitis.

Complications, including viral pneumonia, myocarditis, meningoencephalitis, and Guillain-Barré syndrome, are more likely in individuals with underlying respiratory, cardiac, renal, neurologic, metabolic, or immune disorders or in the very young or elderly. Muscle pain (especially involving the calves), rhabdomyolysis, and, rarely, renal failure occur in association with influenza B infection. **Reye syndrome,** a hepatoencephalopathy, is associated with both influenza and varicella virus. This condition is more common in children who receive aspirin during the acute phase of influenza illness.

Clinical and Laboratory Evaluation

History

Young children have symptoms of influenza that are similar to those seen with infection with other respiratory viruses (see Upper Respiratory Tract Infections). Older children and adults typically have abrupt onset of fever, headache, myalgia, sore throat, and nonproductive cough. Gastrointestinal (GI) symptoms are more frequent in children. Fever is present for 3 to 5 days. Myalgia and cough persist up to 2 weeks.

Physical Examination

The patient with influenza appears ill with high fever. Special care is given to examination of ears, lungs, heart, abdomen, CNS, and musculoskeletal systems to identify complications of disease and to identify presence of bacterial superinfection.

Laboratory Evaluation

The diagnosis is based on history and physical examination. Viral cultures of nasopharyngeal secretions are positive after 2 to 6 days. Cultured isolates provide specific information on circulating strains of influenza virus. Several rapid diagnostic tests are available for detection of influenza A and B viruses. The sensitivity of these tests is 62% to 73%, and the specificity is 80% to 99%. PCR amplification of viral RNA has led to more sensitive rapid diagnosis of the virus. With this methodology it is possible to distinguish between circulating subtypes of virus and also to detect antiviral resistance. If bacterial superinfection is suspected, a CBC, blood culture, and chest radiograph warrant consideration.

Management

Supportive treatment is generally recommended for children with uncomplicated illness and normal immune function.

Antiviral Agents

Antiviral therapy decreases the severity of influenza and the duration of symptoms. Several antiviral drugs are available. Amantadine and rimantadine, which prevent viral uncoating by blocking ion-channel activity of the viral M2 protein, are effective against some influenza A viruses but not influenza B. Zanamivir and oseltamivir, analogs of sialic acid, inhibit the neuraminidase activity of both influenza A and B viruses. Both drugs are effective for treatment of influenza A and B infections; oseltamivir is approved for prophylaxis. Zanamivir, which is available as a dry powder for inhalation, is generally not recommended for use in patients with underlying respiratory disease because of reports of wheezing and decreased pulmonary function.

Resistance of circulating influenza viruses to antiviral therapy has become more prevalent in recent years and the selection of the appropriate antiviral medication depends on resistance patterns of circulating virus.

Antiviral prophylaxis may be appropriate in high-risk patients who were immunized after influenza A began circulating, in immunodeficient patients with poor antibody response to vaccines, and in persons in whom the influenza vaccine is contraindicated (e.g., individuals with anaphylactic hypersensitivity to egg protein).

Vaccination

Influenza virus vaccine is used to protect individuals from infection with circulating strains of influenza virus. It is now recommended that all children, age 6 months to 18 years receive annual influenza vaccine. Priority for vaccination is given to children who have underlying medical problems. Two types of influenza vaccine are available. The first is an injectable inactivated vaccine that consists of three viral strains (usually two type A and one type B), which are produced in embryonated eggs. Experts select viral strains based on worldwide surveillance of circulating strains. The injectable inactivated vaccine may be administered to any individual age 6 months and older who does not have a contraindication to influenza vaccine (see the following). The second type of influenza vaccine is a cold-adapted, trivalent live attenuated influenza virus vaccine (LAIV) that is administered intranasally. It also contains the three predominantly circulating strains of seasonal influenza. The LAIV vaccine is recommended only for use in healthy individuals between the ages of 2 and 49 years. Vaccine efficacy ranges between 50% and 95%, depending on how closely it matches circulating strains of virus. The optimal time for administration of vaccine is October through mid-November.

Adolescents and adults who receive the injectable influenza vaccine should receive whole virus vaccine, which is prepared from intact purified virus particles. Children under 13 years of age should receive the subvirion and purified surface antigen vaccines ("split-virus"), which have fewer side effects. Children over 9 years of age and children who have been previously immunized should receive one dose of vaccine, and children less than 9 years of age (no previous immunization) should receive two doses of vaccine 1 month apart. The immunization schedule for LAIV is similar to that of the inactivated vaccine.

Adverse effects of the injectable inactivated vaccine include local pain, swelling, and redness in 10% to 64% of recipients. Low-grade fever and myalgia may begin 6 to 12 hours after vaccination and persist for 1 to 2 days. Some individuals who receive the LAIV vaccine may have mild respiratory symptoms and low-grade fever. Contraindications to influenza immunization include a severe anaphylactic reaction to egg protein and a previous history of Guillain-Barré syndrome. In addition, individuals with any underlying illness such as asthma, those who are receiving immunosuppressive medications, and those who are pregnant or who require aspirin therapy should not be given LAIV.

PNEUMONIA

Pneumonia is infection or inflammation of the lung parenchyma. Most episodes of acute pneumonia in young children result from viral infection; a smaller percentage results from bacterial infection.

Pathophysiology

The organisms that cause viral pneumonia are also common causes of viral upper respiratory tract infections. The bacterial causes of pneumonia vary depending on age of the child (Table 9-9) and are similar to causes of other SBIs (see Approach to the Evaluation of the Febrile Child). Intracellular organisms such as Chlamydia trachomatis, *Chlamydophila pneumoniae,* and *M. pneumoniae* cause lower respiratory tract disease.

The lower airways are typically sterile. Infection occurs as a result of defects in host defenses protecting the lung, inhalation of a large inoculum of virus or bacteria, or infection of the lung by hematogenous dissemination. Infection of the bronchial epithelium is associated with cell death, sloughing, local inflammation, and edema with airway narrowing. Alveoli become filled with fluid, and infection spreads to involve adjacent lung parenchyma.

Recurrent bacterial pneumonia suggests underlying disease. Examples include immunodeficiency, anatomic abnormalities (e.g., cleft palate, tracheoesophageal fistula), cardiac enlargement due to congenital heart disease, foreign body aspiration, ciliary dysfunction, cystic fibrosis, and chronic aspiration.

TABLE 9-9

Age-Related Differences in Etiology of Infectious Pneumonia

Age	*Pathogens*
0–1 months	*Streptococcus agalactiae*, gram-negative enteric bacteria, *Staphylococcus aureus*, *Listeria monocytogenes*, *CMV, occasionally HSV*
1–3 months	Viral,[a] *S. agalactiae*, Enterobacteriaciae, *S. aureus, Streptococcus pneumoniae, Chlamydia trachomatis*
3 months–5 years	Viral,[a] *S. pneumoniae, S. aureus, Streptococcus pyogenes* (rare), *Mycoplasma pneumoniae*
>5 years	Viral,[a] *M. pneumoniae, Chlamydophila pneumoniae, S. pneumoniae, S. aureus, S. pyogenes* (rare)

[a] Viruses most often associated with pneumonia include respiratory syncytial virus, hMPV, influenza, adenovirus, and parainfluenza viruses. Cytomegalovirus and herpes simplex virus may cause severe pneumonia in infants or immunocompromised children.

CMV, cytomegalovirus; *HSV*, herpes simplex virus.

Clinical and Laboratory Evaluation

History

The presentation of **viral pneumonia** involves prodromal symptoms of rhinorrhea, cough, low-grade fever, and pharyngitis. Affected children may be lethargic, refuse to play, or have difficulty feeding because of tachypnea or cough. Very young children may become apneic. Pneumonia is suspected when symptoms progress to signs of increasing respiratory distress.

The typical presentation of **bacterial pneumonia** is more abrupt. Older children and adults present with acute onset of high fever, cough, chest pain, and shaking chills. Younger children and infants may have a several-day history of upper respiratory tract symptoms followed by an acute increase in fever and respiratory distress. Cough is initially nonproductive. As infection progresses, hypoxia and delirium may develop.

Pediatric Pearl: In some cases of bacterial pneumonia, particularly of the right lower lobe, abdominal complaints may predominate, so that intra-abdominal pathology such as acute appendicitis is often the initial suspicion.

Neck pain and stiffness are seen with upper lobe pneumonia. Systemic findings of sepsis, including shock and multisystem organ involvement, may occur in some cases.

Children with pneumonia often have coinfections with both bacterial and viral pathogens.

Physical Examination

Children with **viral pneumonia** may often be irritable, with nasal flaring, subcostal or intercostal retractions, and mucous membranes that appear cyanotic. Vital signs reveal fever (temperature usually less than 39.0° C [102.2° F]), tachypnea, and sometimes tachycardia. In young children in whom auscultation of the lungs is difficult, tachypnea may be the only sign of underlying pneumonia. Normal respiratory rates vary depending on the age of the child. Newborns have normal respiratory rates between 30 and 40 breaths per minute (bpm), children up to the age of 2 years have respiratory rates of 25 to 35 bpm, children 3 to 9 years have respiratory rates of 20 to 25 bpm, and children older than 9 years have normal respiratory rates of 16 to 20 bpm. Findings on auscultation include rales and wheezes. Mild hepatosplenomegaly may be evident in infants if the lungs are hyperinflated.

Children with **bacterial pneumonia** may be toxically ill or anxious, with high fever (temperature over 39.0° C [102.2° F]), tachycardia, tachypnea, and occasionally hypotension. Nasal flaring and cyanosis of mucous membranes or skin may be present. The signs and symptoms of *M. pneumoniae* pneumonia include fever, headache, and cough. Typically, children with *M. pneumoniae* do not appear to be very ill. Diffuse rales are evident on physical examination, and a rash is present in 10% of cases.

Careful examination of the lungs focuses on the **appearance** of the chest, **palpation, percussion,** and **auscultation**. The clinician should note the rate and rhythm of breathing and presence of nasal flaring and intracostal or subcostal retractions.

Palpation of the chest produces tenderness. **Tactile fremitus,** which refers to palpable vibrations transmitted through the chest when a patient speaks, is decreased when a pleural effusion is present and increased over consolidated lung. **Dullness to percussion** is present over areas of consolidated lung or with a pleural effusion.

Bronchophony is heard over consolidated lung and is an increase in the clarity of spoken words as heard through the stethoscope. **Egophony** describes the change in transmission of patient's "eee" sounds to "aay." **Bronchial breath sounds** are normally best heard over the trachea, but can be heard over consolidated or airless lung. Expiration is greater than inspiration and is unusually high-pitched and loud. **Rales** are crackling noises heard over the area of infection. As infection resolves, cough becomes more productive, and rales and rhonchi are more prominent.

Signs of dehydration such as tachycardia, decreased perfusion, decreased skin turgor, and history of poor urine output may be present. Fever, poor fluid intake, and increased respiratory rate often cause dehydration.

Laboratory Evaluation

The diagnostic laboratory workup for children with suspected pneumonia is extensive (Table 9-10). WBC counts are typically greater than 15,000 cells/mm^3, with a predominance of PMNs in bacterial pneumonia.

TABLE 9-10

Diagnostic Workup of Pneumonia

1. Complete blood cell count with differential
2. Blood culture (if bacterial pneumonia suspected)
3. Chest radiograph
4. Sputum (only useful in children >12 years of age) for Gram stain, bacterial culture, AFB smear, and AFB culture
5. Direct viral examination of nasopharyngeal specimens (if viral pathogen suspected)
6. *Mycoplasma pneumoniae* IgM and IgG
7. Pulse oximetry/arterial blood gas if children are ill-appearing, cyanotic, or in respiratory distress

AFB, acid fast bacilli; *Ig*, immunoglobulin.

Values of up to 40,000 cells/mm^3 are not uncommon with pneumococcal and staphylococcal pneumonia. Blood cultures are positive in 10% to 30% of cases of bacterial pneumonia. Typical chest radiographic findings for viral, mycoplasma, and bacterial pneumonia are distinctive (Table 9-11); however, overlap in findings occurs.

Infants less than 2 to 3 months of age are at risk for infection with *S. agalactiae*, gram-negative enteric bacteria, *L. monocytogenes*, and *S. aureus*. If bacterial pneumonia is a possibility, diagnostic workup includes blood and urine cultures, and lumbar puncture is considered.

A positive rapid diagnostic test for RSV, hMPV, parainfluenza, influenza, or adenovirus may suggest a viral etiology for pneumonia but does not definitively rule out a bacterial superinfection. Diagnosis of *M. pneumoniae* involves serology for specific IgM and IgG. A PCR test for *M. pneumoniae* is available in some institutions. *C. trachomatis* may be isolated from epithelial cells in tissue culture or noting the blue-stained intracytoplasmic inclusions in epithelial cells from conjunctival scrapings stained with Giemsa stain. Nucleic acid amplification is useful for evaluating urethral and cervical specimens but has not been evaluated adequately for detection of *C. trachomatis* in nasopharyngeal specimens. *C. pneumoniae* may be diagnosed serologically or with newer antigen detection or PCR methodology.

Pulse oximetry is useful for determining presence of hypoxia. If pulse oximetry is abnormal, arterial blood gas sampling is required. Bronchial alveolar lavage or lung biopsy may be necessary for diagnosis of complicated pneumonia not responding to empiric antimicrobial therapy.

Differential Diagnosis

Signs and symptoms of viral and bacterial pneumonia overlap considerably. Some features of the history and physical examination help distinguish between these two conditions (see Table 9-11).

Management

Antimicrobial treatment of bacterial pneumonia is appropriate (Table 9-12). Outpatient management may be sufficient. Close observation is necessary until children improve. Decisions regarding hospitalization are based on the severity of symptoms. It is usually appropriate to admit the following patients: (1) infants less than 2 to 3 months of age for observation or empiric antibiotic therapy pending culture results, and (2) children with underlying immunodeficiency, metabolic disease, or cardiopulmonary disease, who are at risk for complications of pneumonia, for parenteral antibiotics. Other criteria for admission include respiratory distress, hypoxia or hypercarbia, sepsis, dehydration, and poor compliance.

LYMPH NODE ENLARGEMENT

Infections causing enlargement of single or multiple lymph nodes are common in children.

TABLE 9-11

Distinguishing Features in Pneumonia: Bacterial Versus Viral

Organism	*Prodrome*	*Onset*	*Signs and Symptoms*	*Laboratory Studies*	*7p9.536*
Streptococcus pneumoniae	None or URI Influenza	Abrupt	Temp >39° C Mild-to-severe illness	WBC↑ Blood culture positive (10%–30%)	Lobar consolidation ± empyema Less common: bronchopneumonia, interstitial infiltrate, pneumatocele
Staphylococcus aureus	None or URI Influenza	Abrupt	Temp >39° C Moderate-to-severe illness	WBC↑ Blood culture positive (rare)	Lobar consolidation Empyema Pneumatocele/abscess
Mycoplasma pneumoniae	Malaise Headache	Subacute	Fever Cough Pharyngitis Lymphadenitis Mild-to-moderate illness	WBC normal	Patchy consolidation Interstitial Infiltrates Hilar adenopathy Effusion
Chlamydophila pneumoniae	Malaise Headache	Subacute	Fever Pharyngitis Hoarse voice Mild illness	WBC normal	Unilateral patchy infiltrate
Chlamydia trachomatis	Conjunctivitis	Gradual	Afebrile Staccato cough Rales/wheezes	WBC normal	Diffuse infiltrates Peribronchial thickening Lobar consolidation
Mycobacterium tuberculosis	None or fever	Gradual	Fever Weight loss Cough Mild illness	WBC normal + PPD or positive interferon-gamma release assay (IGRA)	Primary complex Hilar adenopathy Atelectasis/consolidation Cavitary lesion
Respiratory viruses	Rhinorrhea Cough	Gradual	Temp <39° C Mild-to-moderate illness	Normal WBC	Perihilar infiltrates Hyperinflation Patchy consolidation

WBC, white blood count; *URI*, upper respiratory infection.

Pathophysiology

Reactive lymphadenopathy, defined as diffuse mild inflammation of lymph nodes, occurs in response to systemic or local infection. The rubbery, mobile nodes have a diameter of less than 2 cm. Several conditions, both infectious and noninfectious, may cause reactive adenopathy (Table 9-13).

Lymphadenitis, defined as infection of the lymph node itself, occurs primarily as the result of bacterial infection; *S. pyogenes* and *S. aureus* cause 80% of cases. Affected nodes are poorly mobile, with associated soft tissue edema and erythema, and have a diameter typically larger than 2 cm. Illness is characterized by painful rapid enlargement of the lymph nodes. Tonsillar and anterior cervical nodes are primarily involved. When dental disease is the initial source of infection, anaerobic bacteria may be found in infected submental and submandibular nodes.

TABLE 9-12

Antimicrobial Treatment of Pneumonia

Etiology	*Treatment*
Respiratory syncytial virus	Supportive Consider ribavirin in severely ill children
Human metapneumovirus	Supportive
Parainfluenza	Supportive
Adenovirus	Supportive
Influenza	Influenza antiviral—choice depends on circulating virus
CMV	Ganciclovir IV plus CMV hyperimmune globulin in immunocompromised children
HSV	Acyclovir IV
Chlamydia trachomatis	Erythromycin[a] Azithromycin[a]
Chlamydophila pneumoniae	Erythromycin Doxycycline in children > 8 years Azithromycin
Mycoplasma pneumoniae	Erythromycin Doxycycline in children > 8 years Azithromycin
Streptococcus pneumoniae	Penicillin/amoxicillin Second- or third-generation cephalosporin
Staphylococcus aureus	Vancomycin (MRSA) Nafcillin/dicloxacillin First-generation cephalosporin Clindamycin

[a] Infantile hypertrophic pyloric stenosis is associated with erythromycin therapy in newborns and, in addition, has been reported rarely after azithromycin use. Physicians treating infants with macrolides should discuss potential risks with parents.

CMV, cytomegalovirus; *HSV*, herpes simplex virus; *IV*, intravenous.

Lymphadenitis is a common presentation of **catscratch disease.** Most patients have a history of a scratch by flea-infested cats or kittens, which are infected with the causal pathogen *Bartonella henselae;* young cats (less than 1 year) are more often infected with the bacterium. The incidence of disease is greatest in fall and winter. A characteristic red papule is present at the site of the scratch, with regional adenitis noted proximal to the injury. Children are often highly and persistently febrile. Infection can disseminate to cause retinal lesions, liver and spleen abscesses, bone lesions, and, rarely, encephalitis.

Lymphadenitis may also occur as the result of atypical mycobacteria in children less than 4 years of age. Submandibular, preauricular, anterior cervical, inguinal, or epitrochlear lymph nodes may be involved. Bilateral adenitis is not present. Affected children appear well with no fever or systemic symptoms. The lymph nodes are mildly tender with little warmth or inflammation, and after several weeks they become fixed and discolored. Spontaneous suppuration with formation of a sinus tract may occur.

Other bacteria associated with lymphadenitis include *Francisella tularensis* (the ulceroglandular form of tularemia), *Yersinia pestis* (bubonic plague), and *Pasteurella multocida. M. tuberculosis*, a cause of lymphadenitis in patients of any age, should always be a consideration (see Tuberculosis).

Juvenile idiopathic arthritis
Systemic lupus erythematosus
Chronic granulomatous disease
Infection-associated hemophagocytic syndrome
Sarcoidosis

[a] Diffuse or regional nodes less than 2 cm in size.

[b] In Kawasaki disease, lymphadenopathy is usually unilateral, node size >1.5 cm in diameter.

Clinical and Laboratory Evaluation

History

Important historical information includes rate of enlargement of lymph nodes, associated systemic illness, travel, illness in family members (e.g., tuberculosis), and animal contact (e.g., catscratch disease, tularemia, bubonic plague). The clinician should question sexually active adolescents about risk factors for HIV infection.

Physical Examination

Detailed examination of lymph nodes is necessary, along with a careful written description of the nodes involved, and their appearance, consistency, and mobility. Measurement of the size of the nodes is also essential. An understanding of the anatomy and regional drainage of lymph nodes helps discern possible sources of infection (Table 9-14). An enlarged spleen or liver suggests systemic infection with EB virus or CMV. A rash occurs in viral causes of reactive adenopathy such as rubella.

Laboratory Evaluation

The WBC count may be increased with bacterial lymphadenitis. The ESR is also elevated with bacterial lymphadenitis and adenitis caused by *M. tuberculosis*. The chest radiograph is often abnormal with *M. tuberculosis* infection but usually normal in infection with atypical mycobacteria. If tuberculosis is suspected, a purified protein derivative (PPD) test may be placed. Interferon-γ release assays for the detection of *M. tuberculosis* may potentially be of use in distinguishing atypical mycobacteral from tuberculous lymphadenitis in selected patients. Additional studies, based on results of the history and physical examination, include serology for *B. henselae*, toxoplasmosis, and EB virus. Culture of urine, nasopharynx, or peripheral blood mononuclear cells for CMV may be appropriate if the illness is similar to **infectious mononucleosis** (e.g., fever, pharyngitis, reactive lymphadenopathy, and splenomegaly), but EB virus serology is negative.

If the diagnosis is unclear and the patient does not respond to empiric therapy, biopsy or needle aspiration of the lymph node is appropriate, with material sent for pathology and culture. Incision and drainage of lymph nodes infected with *Mycobacterium* species may lead to chronic drainage and sinus tract formation. If these organisms are suspected, lymph node excision or fine needle aspiration is recommended.

Differential Diagnosis

The differential diagnosis of lymphadenitis includes the enlarged lymph nodes seen with **Kawasaki disease (see** Chapter 14**),** branchial cleft cyst, thyroglossal duct cyst, thyroid goiter, lymphoma or Hodgkin disease, and rhabdomyosarcoma.

Management

Management of reactive lymphadenopathy depends on the underlying illness. Specific management of lymphadenitis depends on the infectious cause (Table 9-15).

CENTRAL NERVOUS SYSTEM INFECTIONS

BACTERIAL MENINGITIS

Acute bacterial meningitis is a potentially life-threatening illness. Despite antibiotic therapy and supportive care, mortality is 5% to 10%. Almost 50% of survivors of bacterial meningitis have long-term sequelae that range from mild to severe. Mortality and neurologic sequelae are highest with *S. pneumoniae* meningitis.

The epidemiology of bacterial meningitis has changed significantly over the last 15 years. Historically, most cases of bacterial meningitis occurred in children under 5 years of age, and *H. influenzae* type b was the predominant pathogen, followed by *S. pneumoniae* and *N. meningitidis*. Immunization with *H. influenzae* vaccine has virtually eliminated *H. influenzae* type b as a cause of meningitis. In addition, immunization with the heptavalent *S. pneumoniae* conjugate vaccine (PCV7) has significantly decreased the incidence of invasive pneumococcal disease, including meningitis. Pneumococcal meningitis due to nonvaccine serotypes still occurs but may decrease with the institution of PCV13 in the childhood immunization schedule. As a result of infant vaccine recommendations in the United States, bacterial meningitis is now seen more often in adults than in young children.

TABLE 9-14

Regional Drainage of Lymph Nodes

Site of Infection	*Site of Drainage*
Nasal and oropharyngeal infections	Tonsillar and anterior cervical nodes
Superficial facial infection or cellulitis	Anterior cervical nodes, preauricular nodes, submental nodes
Scalp infection	Occipital, posterior cervical, preauricular and postauricular nodes
Conjunctival infection	Preauricular nodes
Teeth, gingivae, tongue	Submental and submandibular nodes
Neck	Anterior or posterior cervical nodes
Breast and chest wall	Anterior axillary nodes
Hand and arm	Midaxillary nodes
Back	Posterior axillary nodes
Fingers, hand, forearm	Epitrochlear nodes
External genitalia, anus, umbilicus, lower abdomen, lower back, buttocks, upper thigh	Inguinal nodes
Foot and lower leg	Femoral nodes

TABLE 9-15

Management of Lymphadenitis[a]

	Antibiotics		
Suspected Etiology	*Oral*	*Intravenous*	*Surgical Management*
Bacterial adenitis *Staphylococcus aureus*[b] or *Streptococcus pyogenes*	Dicloxacillin Cephalexin Amoxicillin–clavulanate Clindamycin	Nafcillin Cefazolin Ceftriaxone Clindamycin Vancomycin	Incision and drainage if no response to antibiotic therapy. Send material for culture and pathology.
Atypical mycobacteria	None	None	Surgical excision of affected nodes. (Incision and drainage may lead to chronic suppuration.)
Mycobacterium tuberculosis	Antituberculous medications		None
Bartonella henselae	Not necessary for mild cases		Usually excision is not necessary.
For more severe illness:	Azithromycin or rifampin or TMP/SMZ or ciprofloxacin or doxycycline (>8 years of age) or intravenous gentamicin		Needle aspiration is performed in some cases.

[a] Nodes larger than 2 cm in size.
[b] If MRSA is suspected or diagnosed vancomycin, clindamycin, TMP/SMZ may be appropriate depending on the susceptibility pattern. TMP/SMZ does not cover Streptococcus pyogenes.

TMP/SMZ, trimethoprim–sulfamethoxazole.

Pathophysiology

The bacteria that cause meningitis include enteric pathogens in infants and encapsulated bacteria in older infants and children (Table 9-16). To infect the CNS, bacteria must evade several layers of defense provided by the host immune response. Organisms initially colonize and invade respiratory mucosal epithelium. To attach to the respiratory epithelium, encapsulated bacteria make IgA proteases that render secretory IgA nonfunctional. After attachment, bacteria invade mucosal barriers by endocytosis or through separations in tight junctions of columnar epithelial cells.

Once bacteria enter the intravascular space, capsular polysaccharide enables them to evade the alternative complement pathway. The bacteria then replicate in the blood and eventually penetrate the blood–brain barrier and infect the cerebrospinal fluid (CSF). Small blood vessels that enter the brain carry the infection to the cerebral cortex. Thrombosis of intracerebral vessels leads to hypoxia and infarction. Intracranial pressure rises as a result of increased permeability of the blood–brain barrier, toxins released by bacteria or neutrophils, and decreased CSF outflow. Replicating bacteria induce local release of interleukin-1 and tumor necrosis factor. Stimulation of neutrophils migrating into the CSF results in their degranulation, releasing toxic oxygen metabolites. Some studies suggest the host inflammatory response to infection is responsible for the long-term sequelae of meningitis.

Meningitis is also the result of direct bacterial invasion of the CNS after penetrating trauma or through a congenital malformation. Congenital malformations that lead to increased risk of meningitis include **dermoid sinus tract** or **meningomyelocele**, which are associated with recurrent or polymicrobial meningitis. A fracture through a sinus or a skull fracture may lead to CNS infection with respiratory pathogens.

Clinical and Laboratory Evaluation

Even after a careful history and physical examination, the diagnosis of meningitis sometimes remains in question. Careful and frequent evaluation is then indicated.

History

A history of recent symptoms of viral upper respiratory tract illness, head trauma, recurrent bacterial infections, immune compromise, presence of a cochlear implant device or ventricular shunt, or contact with other ill individuals may be present. *N. meningitidis* and *H. influenzae* type b infection occur in clusters among family members or close contacts.

Symptoms in infants and young children include irritability, anorexia, vomiting, and inconsolable crying. As illness progresses, lethargy, seizures, or focal neurologic signs develop. Older children complain of headache, back pain, stiff neck, and photophobia, and may become increasingly confused and disoriented.

Physical Examination

Careful examination, focusing on the child's general appearance, vital signs, and neurologic status, is crucial. Observation of patients from across the room is helpful; children who happily play with toys in the waiting room but who are fussy when examined by a physician are less likely to have meningitis. Fever is present in most children with meningitis, but hypothermia may occur in infants. With increased intracranial pressure, bradycardia and hypertension develop.

Signs of meningeal irritation, including pain and limitation of range of motion of the neck, may not be evident in children less than 18 months of age. Positive Kernig and Brudzinski signs are indicative of meningeal inflammation. A **Kernig sign** is elicited by having a child lie on her back with the knee flexed and the hip flexed so that the thigh is perpendicular to the trunk. If meningeal irritation is present, extension of the knees causes pain. A **Brudzinski sign** occurs when the hips and knees spontaneously flex after passive flexion of the neck.

It is necessary to perform a detailed neurologic examination with assessment of mental status, examination of cranial nerves, reflexes, muscle strength, and gait (if applicable). A bulging anterior fontanel is sometimes apparent in young infants. Pulmonary, cardiac, abdominal, and bone and joint examination may reveal the presence of other sites of infection. Petechiae or purpura may be evident on skin examination. A careful retinal examination may detect presence of papilledema.

Laboratory Evaluation

Of children with bacterial meningitis, 99% have CSF abnormalities, and the initial diagnosis of acute bacterial meningitis is based on analysis of CSF findings (see Table 9-16). The normal range of cells, glucose, and protein

TABLE 9-16

Infectious Causes of Meningitis

		Typical Cerebrospinal Fluid Findings		
Organism	*Microscopic*	*Cell Count (/mm³)*	*Glucose (mg/dL)*	*Protein (mg/dL)*
Bacteria				
Age 0–1 months				
Streptococcus agalactiae	Gram-positive cocci in chains	>100 to several thousand, with >80% PMNs	<40	100–500
Escherichia coli	Gram-negative rods	>100 to several thousand, with >80% PMNs	<40	100–500
Enterococcus spp.	Gram-positive cocci	>100 to several thousand, with >80% PMNs	<40	100–500
Listeria monocytogenes	Gram-positive rods (negative in 60%)	5 to >1,000, with usually >60% PMNs	<40 in 40%	>45
Age 1–23 months				
S. agalactiae	See previous			
E. coli	See previous			
Streptococcus pneumoniae	Gram-positive diplococci	>100 to several thousand, with >80% PMNs	<40	100–500
Neisseria meningitidis[a]	Gram-negative diplococci	>100 to several thousand, with >80% PMNs	<40	100–500
Haemophilus influenzae type b[a]	Gram-negative coccobacillary organisms	>100 to several thousand, with >80% PMNs	<40	100–500
Age >2 years				
S. pneumoniae	Gram-positive diplococci	>100 to several thousand, with >80% PMNs	<40	100–500
N. meningitidis	Gram-negative diplococci	>100 to several thousand, with >80% PMNs	<40	100–500
Any age				
Mycobacterium tuberculosis	Negative Gram stain	10–500; PMNs early, lymphocytes later	<40	100–500
Viruses				
Enterovirus spp.	Negative Gram stain	Usually <1,000 with early PMNs, then mononuclear cells	Normal	20–100
Fungi				
Coccidioides immitis	KOH usually negative	50–1,000, lymphocytes, eosinophils	10–39	50–1000
Candida albicans	Gram-positive yeast			
Cryptococcus neoformans	Positive cryptococcal antigen test	>20 lymphocytes	<40	>40

[a] Small gram-negative coccobacillary organisms such as *N. meningitidis* or *H. influenzae* type b may be difficult to see.

KOH, potassium hydroxide; *PMN*, polymorphonuclear neutrophil.

TABLE 9-17

Normal Cerebrospinal Fluid Indices

Age	*WBC Count (/mm³)*	*PMNs*	*Glucose (mg/dL)*	*Protein (mg/dL)*
Preterm infant	0–25	0%–57%	24–63	65–150
Term infant	0–22	0%–61%	34–119	20–170
Older infant/child	0–5	0	40–80	5–40

WBC, white blood cell; *PMN*, polymorphonuclear neutrophil.

in the CSF varies by age and is shown in Table 9-17. In bacterial meningitis, the CSF is typically cloudy. The cell count is more than 1,000 cells/mm^3, with a differential revealing a predominance of polymorphonuclear neutrophils (PMN) (usually more than 80%). (Some authorities consider the presence of at least 1 neutrophil/mm^3 as possibly indicative of bacterial meningitis.) Protein is elevated as a consequence of disruption of the blood–brain barrier. Glucose is low because the transport mechanisms responsible for carrying glucose from the peripheral circulation to the choroid plexus and into the CSF are impaired. Gram stain shows organisms if more than 10^3 bacteria/mL of CSF are present. Culture of CSF is positive in virtually all cases of bacterial meningitis, provided the child did not receive antibiotic therapy prior to the lumbar puncture. If possible, an extra tube of CSF is obtained for additional diagnostic tests if routine tests do not confirm bacterial meningitis.

A CBC with differential shows a predominance of PMN cells and an increase in band forms. Blood cultures are positive in the majority of cases; however, because time to positivity ranges from 24 to 72 hours, they do not aid initial diagnosis. Serum electrolytes may show decreased sodium secondary to the **syndrome of inappropriate (secretion of) antidiuretic hormone (SIADH).** Electrolyte abnormalities may also be a consequence of diarrhea, vomiting, or poor fluid intake. PCR testing for enterovirus or HSV is helpful in cases of suspected viral meningitis.

Computed tomography (CT) or magnetic resonance imaging (MRI) scans detect complications of meningitis such as subdural empyema, venous thrombosis, infarction, and hydrocephalus. Routine CT scan before lumbar puncture is usually not necessary unless children have a history of a neurosurgical procedures, are comatose, have papilledema, or focal neurologic findings. If these findings are present, blood culture is obtained and empiric antibiotic therapy is started prior to the imaging procedure. If there is no evidence of cerebral edema or mass lesion on CT scan, lumbar puncture can be performed. Imaging studies are useful for identifying a contiguous focus of infection such as chronic otitis media or chronic sinusitis. MRI is useful in the diagnosis of some forms of fungal (*Coccidioides immitis*) and bacterial meningitis (*M. tuberculosis*) that show predominance of basilar and brainstem inflammation.

A bacterial meningitis scoring tool may be useful in predicting the risk of bacterial meningitis in children over 2 months of age who have CSF pleocytosis and who have not been pretreated with antibiotics. The risk of bacterial meningitis is very low if the child has **none** of the following: (1) positive CSF Gram stain, (2). CSF absolute neutrophil count (ANC) greater than or equal to 1,000 cells/μL, (3) CSF fluid protein greater than or equal to 80 mg/dL, (4) peripheral blood ANC greater than or equal to 10,000 cells/μL, or (5) history of seizures before or on presentation. The scoring system should be used in conjunction with a careful clinical assessment of the child in determining the need for antibiotic therapy.

Differential Diagnosis

Other causes of fever, headache, and abnormal neurologic signs include aseptic meningitis, fungal meningitis, encephalitis, brain abscess, or brain tumor. Viruses, as well as bacteria and fungi, may cause aseptic meningitis (Table 9-18). Enteroviruses are the leading recognizable cause of aseptic meningitis. In temperate climates, enteroviruses circulate during summer and fall and are transmitted by fecal–oral spread. Mild respiratory or GI symptoms or a rash precede development of meningeal signs.

In children with aseptic meningitis, CSF usually shows a predominance of mononuclear cells, and routine bacterial cultures are negative. Recent data indicate that many patients with enteroviral meningitis have a predominance of PMNs. With viral meningitis, the typical total number of WBCs in the CSF is less than 500 cells/mm^3. CSF glucose and protein are likely normal.

TABLE 9-18

Infectious and Noninfectious Causes of Aseptic Meningitis

Infectious		*Noninfectious*
Viruses	**Bacteria**	**Immunologically Mediated Diseases/Other**
Enteroviruses[a]	*Rickettsia* spp. (RMSF and typhus)	Sarcoidosis Kawasaki disease
Arboviruses	*Borrelia burgdorferi*	Systemic lupus erythematosus
EB virus	*Brucella*	Rheumatoid arthritis
HIV	*Treponema pallidum*	
LCM	*Leptospira* spp.	**Neoplasms**
Cytomegalovirus	*Bartonella* spp.	Leukemia
Adenovirus	*Mycoplasma pneumoniae*	Lymphoma
Influenza virus		Brain tumor
Measles virus	**Parameningeal focus**	
Parainfluenza virus	Brain abscess	**Drugs**
VZV	Epidural abscess Mastoiditis	Intravenous immunoglobulin OKT3
Fungi	Sinusitis	Isoniazid
Cryptococcus neoformans		Ibuprofen
Coccidioides immitis		

[a] Serotypes most likely to cause CNS infection include: coxsackie serotypes B2, B4, B5 and echovirus 4, 6, 7, 11.

EB virus, Epstein-Barr virus; *LCM*, lymphocytic choriomeningitis virus; *VZV*, varicella-zoster virus; *RMSF*, Rocky Mountain spotted fever.

Management

All children with suspected bacterial meningitis should have a lumbar puncture and be admitted to the hospital. Treatment of acute disease includes antimicrobial therapy and management of sequelae of CNS infection and inflammation. Research efforts are directed toward therapeutic approaches that decrease the inflammatory response in addition to treatment with antibiotics.

The initial empiric choice of antibiotic therapy depends on the age of the child (Table 9-19). Parenteral therapy is given for the entire duration of treatment to achieve adequate CSF concentration of drug. Duration of therapy depends on the organism and the child's response (see Table 9-19). CSF concentrations of antibiotics commonly used to treat bacterial meningitis are approximately 5% to 15% of serum levels.

Dexamethasone given before the first dose of antibiotic therapy may reduce the inflammatory response and prevent sensorineural hearing loss in *H. influenzae* type b meningitis. Studies have not clearly demonstrated the benefit of this agent in other types of bacterial meningitis in children. Some experts recommend considering its use in pneumococcal meningitis after carefully weighing potential benefits and possible risks. Children generally remain in the hospital until antibiotic therapy is complete. Seizures, SIADH, stroke, and subdural empyema may develop during treatment.

The most common sequela of meningitis is sensorineural hearing loss. Other sequelae of bacterial meningitis include seizures, hemiparesis, hydrocephalus, ataxia, behavior disorders, and cognitive abnormalities.

TABLE 9-19

Empiric Antibiotic Therapy for Bacterial Meningitis

Age	*Pathogen*	*Empiric Antibiotic Therapy*	*Duration of Therapy*
0–1 month	*Streptococcus agalactiae* *Escherichia coli* *Klebsiella pneumoniae* *Enterococcus* spp *Listeria monocytogenes*	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside	*Escherichia coli, K. pneumoniae, L. monocytogenes* and *Enterococcus* spp. 21 days (minimum) *S. agalactiae* 14–21 days
1–23 months	*S. agalactiae* *E. coli* *Neisseria meningitidis,* *Streptococcus pneumoniae* *(Haemophilus influenzae type b)*	Cefotaxime or ceftriaxone plus vancomycin[a]	*N. meningitidis* 7 days *H. influenzae* type b 7–10 days *S. pneumoniae* 10–14 days
2–18 years	*S. pneumoniae* *N. meningitidis*	Cefotaxime or ceftriaxone plus vancomycin[a]	

[a] Vancomycin is discontinued if culture is positive for *N. meningitidis, H. influenzae* type b, or *S. pneumoniae* susceptible to penicillin or third-generation cephalosporin using the appropriate susceptibility criteria.

ENCEPHALITIS

Encephalitis is an acute inflammatory process of brain tissue. Children and elderly adults are most often affected.

More than 100 different viruses are reported to cause encephalitis. HSVs are the leading cause of severe encephalitis. Encephalitis caused by either HSV-1 or HSV-2 is seen in infants less than 6 weeks of age, who acquire infection around the time of birth or in utero (rare) if the mother has genital lesions. Risk of infection is 33% to 50% after primary maternal infection as opposed to less than 5% if the mother has a history of recurrent HSV infection. Infants can acquire infection after contact with a caregiver with cold sores or herpetic whitlow. Older infants and children develop HSV-1 encephalitis after reactivation of latent HSV-1 in the trigeminal ganglion or after primary infection.

Arboviruses are RNA viruses that cause either aseptic meningitis or encephalitis. Transmission occurs during summer or fall via mosquito or tick bites. The number of cases of encephalitis reported each year ranges from 150 to 3,000. In the United States, the most common types of arboviral encephalitis are St. Louis encephalitis; western equine encephalitis; eastern equine encephalitis; California encephalitis (LaCrosse strain); and recently, West Nile Virus. Neurologic sequelae are most common after infection with eastern equine encephalitis and St. Louis encephalitis. Mortality is highest with eastern equine encephalitis infection.

Enteroviruses typically cause aseptic meningitis but occasionally cause infection with focal neurologic signs and obtundation more typical of encephalitis. The nonpolio enteroviruses most likely to cause CNS infection include enterovirus 71; coxsackievirus B5; and echoviruses 7, 9, 11, and 30. Infection is most common during summer or fall.

Pathophysiology

Initial viral infection occurs at a site distant from the CNS such as the respiratory tract or GI tract; arboviral infection involves direct inoculation into skin. The virus replicates locally and spreads to regional lymphoid tissue. Distribution throughout the body occurs during the primary viremic phase, with subsequent high-level viral replication. Symptoms of fever, malaise, and headache are associated with a secondary viremia. Some viruses reach the CNS by bypassing the blood–brain barrier during the secondary viremia. Other viruses such as HSV and rabies reach the CNS by retrograde axonal transport from peripheral sites. Direct viral infection of neural cells and associated perivascular inflammation leads to destruction of gray matter. Meningeal inflammation and CSF pleocytosis often accompany encephalitis.

A syndrome of **postinfectious encephalomyelitis** (acute disseminated encephalomyelitis) may follow infection with certain viruses or bacteria. It is possible to distinguish this autoimmune process from acute encephalitis by the primary pathologic finding of demyelination of white matter.

Clinical and Laboratory Evaluation

History

Important historical considerations include history of travel, recent insect bites, other illnesses in the family, and possible drug or toxin ingestion. Initial signs and symptoms of encephalitis are nonspecific and include fever, irritability, lethargy, and anorexia. Rhinorrhea, pharyngitis, cough, diarrhea, vomiting, or rash may be present. Several hours to days after the occurrence of these initial symptoms, abnormal neurologic conditions that range from mild to severe develop. These include headache, behavioral disturbances, cranial nerve deficits, hemiparesis, dysphagia, seizures, obtundation, and coma.

Physical Examination

A careful neurologic examination is performed to assess level of consciousness, presence of cranial nerve abnormalities, hemiparesis, movement disorders, and ataxia. It is necessary to examine skin and mucous membranes for signs of enterovirus infection or vesicular lesions consistent with HSV infection.

Laboratory Evaluation

In viral encephalitis, the CSF typically shows a lymphocytic pleocytosis, elevated protein levels, and normal or mildly decreased glucose levels. In some cases, the CSF is normal. MRI may detect focal abnormalities consistent with HSV encephalitis, including temporal lobe edema or hemorrhage. MRI findings suggestive of white matter demyelination on T2-weighted images assist in differentiating acute encephalitis from postinfectious encephalomyelitis. Tests used to identify a specific virus include culture, PCR, serologic studies, and immunocytochemical studies of brain tissue.

Differential Diagnosis

Noninfectious causes to consider in children with abnormal neurologic findings include intracranial hemorrhage, collagen vascular disease, metabolic disease, or exposure to drugs or toxins.

Management

Treatment of HSV encephalitis requires intravenous acyclovir for at least 3 weeks. Treatment of arboviral or enteroviral encephalitis is supportive; no antiviral drugs are licensed for therapeutic use in these conditions. In cases of suspected postinfectious encephalomyelitis in which acute viral, bacterial, and fungal infections have been reasonably excluded, some experts advocate a trial of steroid or immunoglobulin therapy.

BONE AND JOINT INFECTIONS

INFECTIOUS ARTHRITIS

Infection and inflammation of the joint is caused by bacteria, fungi, or viruses. **Pyogenic (or septic) arthritis** is the result of bacterial infection of the joint space (Table 9-20). **Reactive arthritis** is an inflammatory response in the joint space that occurs as the result of infection elsewhere in the body (Table 9-21).

Pyogenic arthritis occurs in all age groups but is most common in children younger than 3 years of age. Joints of the lower extremities, including knees, hips, and ankles are involved in more than 75% of cases. Usually, a single joint is affected. If multiple joints are infected, *N. meningitidis*, *Salmonella* spp., or *S. aureus* is suspected. Infection with *H. influenzae* type b and *Kingella kingae* often follows an upper respiratory tract illness.

Pathophysiology

Joint infection in pyogenic arthritis occurs as a result of hematogenous spread of bacteria to the vascular synovium. An inflammatory response to bacterial endotoxin occurs within the joint space. The release of cytokines,

TABLE 9-20

Bacterial Causes and Treatment of Pyogenic Arthritis and Osteomyelitis

Age	*Organism*	*Empiric Antibiotic Therapy*
0–3 months	*Streptococcus agalactiae,* gram-negative bacteria, *Staphylococcus aureus*	Vancomycin[a], clindamycin, or nafcillin plus cefotaxime
3 months–5 years	*S. aureus, Streptococcus pneumoniae, Streptococcus pyogenes, Kingella kingae*	Vancomycin,[a] clindamycin, or nafcillin plus cefotaxime or cefuroxime
5 years and up	*S. aureus, S. pyogenes, Neisseria gonorrhoeae*	Vancomycin,[a] clindamycin, nafcillin, or cefazolin. Ceftriaxone if *N. gonorrhoeae* suspected
Special circumstances		
Child with sickle cell disease	*Salmonella* spp., *S. aureus*	Vancomycin, clindamycin, or nafcillin plus cefotaxime
Puncture wound through sneaker	*Pseudomonas aeruginosa*	Antipseudomonas antibiotic ± *S. aureus* coverage
Bite wound	*Eikenella corrodens* (human bite) *Pasteurella multocida* (cat, dog) *S. aureus* and oral flora including anaerobes	Ampicillin–sulbactam

[a]Vancomycin is initiated empirically if local resistance patterns suggest that MRSA is common in the community. Once an organism is isolated and susceptibility results are available, change to the appropriate antibiotic with the narrowest spectrum of coverage.

TABLE 9-21

Infectious Causes of Reactive Arthritis

Organisms that cause both pyogenic arthritis and reactive arthritis
Streptococcus pyogenes
Neisseria meningitidis
Neisseria gonorrhoeae
Salmonella spp.
Organisms that typically cause primary infection elsewhere with associated reactive arthritis
Shigella spp.
Yersinia enterocolitica
Campylobacter spp.
Chlamydia trachomatis

including tumor necrosis factor and interleukin-1, stimulates production of proteinases by synovial cells. Leukocytes produce neutrophil elastases, which cause destruction of cartilage.

Pyogenic arthritis is less often the result of contiguous spread from adjacent osteomyelitis. The joint capsules of the hip and shoulder, which overlie the metaphysis of the femur and the humerus, respectively, allow extension of infection from the bone into the joint space. Contiguous spread of infection is more likely in infants or young children because of the presence of transphyseal blood vessels. Direct inoculation of organisms into the joint space after puncture wound, trauma, or surgical intervention less often leads to pyogenic arthritis.

Clinical and Laboratory Evaluation

History

It is important to focus the history on information that helps distinguish between acute pyogenic arthritis, reactive arthritis, and **juvenile idiopathic arthritis**. It is necessary to question caregivers regarding underlying illness (e.g., sickle cell disease, immunodeficiency), recent travel or exposure history (e.g., tick exposure, pet rats, or reptiles), recent illness (e.g., pharyngitis, scarlet fever–like rash, upper respiratory tract infection, diarrhea, weight loss, or previous joint pain), and history of trauma. Adolescents should be interviewed regarding their sexual history.

Children with pyogenic arthritis typically present with acute pain in the affected joint. Initial symptoms in very young children or infants include crying with diaper changes, refusal to move the affected limb, or refusal to bear weight or walk. Fever is usually present.

Physical Examination

A careful musculoskeletal examination reveals the source of infection. The affected joint is swollen, warm, and tender. Range of motion is decreased. It may be difficult to diagnose pyogenic arthritis of the hip, because no redness or swelling of the joint is often apparent. Pain may be referred to the knee. The child may prefer to hold the hip in a flexed, externally rotated, abducted position. Differentiation of pyogenic arthritis of the hip from other causes of hip pain (e.g., transient synovitis) is crucial, because treatment of pyogenic arthritis of the hip requires immediate joint space drainage and intravenous antibiotic therapy.

Additional important physical examination findings include weight loss (inflammatory bowel disease), presence of skin lesions or rash, heart murmurs (endocarditis), abdominal pain (inflammatory bowel disease), or abnormal eye findings (juvenile idiopathic arthritis or Behçet disease). It is necessary to perform a genital examination in adolescents to rule out sexually transmitted disease.

Laboratory Evaluation

The ESR, WBC, and CRP are elevated. Blood cultures are positive in 40% of cases. Analysis of joint fluid cell count, Gram stain, and culture is helpful in differentiating pyogenic from other causes of joint inflammation (Table 9-22). Gram stain and culture of joint fluid are diagnostic in 60% to 70% of cases of pyogenic arthritis. Isolation of *K. kingae* is enhanced by direct inoculation of joint fluid into a blood culture bottle.

Plain radiographs of the affected joint reveal soft tissue swelling and widening of the joint space. Ultrasound is sometimes used to detect fluid within the hip joint. MRI is a sensitive method for detecting fluid within the joint space and identifying associated bone or soft tissue involvement; however, it does not differentiate

TABLE 9-22

Typical Synovial Fluid White Blood Cell Counts Seen with Infectious Arthritis

	WBC (cells/mm³) [usual range]	*Polymorphonuclear Cells (%)*
Normal	<150	<25
Pyogenic arthritis	10,000–300,000 (>50,000)	>90
Lyme arthritis	180–100,000 (25,000–40,000)	>75
Viral arthritis	3000–50,000 (15,000)	<50

WBC, white blood cell.

between infectious and noninfectious causes of joint space inflammation. Technetium phosphate radionuclide scans are not recommended except in cases where physical examination and plain radiographs cannot localize the site of infection (as in infection of the sacroiliac joint).

Differential Diagnosis

Illnesses that present with limb pain or refusal to walk include pelvic osteomyelitis, disk space infection (diskitis), vertebral osteomyelitis, primary or metastatic malignancies, trauma, and reactive or autoimmune arthritis.

Management

Hospitalization is appropriate for children with pyogenic arthritis. Management should occur in conjunction with an orthopedic surgeon. Goals of therapy include decompression and sterilization of the joint space. Immediate drainage of an infected hip joint is crucial to prevent vascular compromise and subsequent avascular necrosis of the femoral head. Aspiration of other joint spaces is recommended to obtain synovial fluid for cell count and culture and to facilitate decompression.

Pediatric Pearl: Immediate drainage of an infected hip joint is crucial to prevent vascular compromise and subsequent avascular necrosis of the femoral head.

Empiric intravenous antibiotic therapy is based on age (see Table 9-20). Once culture results are available, antibiotic coverage is narrowed to treat the identified organism. Intravenous therapy is continued until fever resolves and joint swelling and tenderness improve. Because antibiotics penetrate into the joint space in high concentration, oral antibiotic therapy may be used to complete a course of therapy, providing the parents appear to be compliant and children take the medicine. Typical duration of antibiotic therapy (intravenous plus oral), which depends on the causal pathogen, ranges from 3 to 4 weeks. On appropriate therapy, serum CRP normalizes after about 7 days, and children display steady clinical improvement.

OSTEOMYELITIS

Inflammation of bone is usually the result of bacterial infection, although fungal organisms are occasionally responsible.

Pathophysiology

In children, osteomyelitis is usually the result of hematogenous dissemination of bacteria to bones, which are growing rapidly and have a rich vascular supply. Organisms deposited in metaphyseal capillaries replicate and spread to cortical bone. In some cases, a subperiosteal abscess forms and extension of infection into adjacent soft tissue may occur. Osteomyelitis may also occur as a result of contiguous spread of infection after trauma or from bite wounds. Anaerobic osteomyelitis of the skull or face is seen with extension of infection from sinuses, chronic otitis media, or dental abscess.

Approximately 50% of cases of hematogenous osteomyelitis occur in children less than 5 years of age. Males are twice as often affected as females. The long bones of the lower extremities are more likely affected. *S. aureus* (both MSSA and MRSA) is the most common cause of hematogenous osteomyelitis in all age groups. Other bacterial causes along with predisposing conditions are listed in Table 9-20.

Clinical and Laboratory Evaluation

History

Systemic symptoms of fever and malaise are usually present. Children may refuse to bear weight, walk, or move the affected extremity (**pseudoparalysis**). A past medical history of such underlying conditions as sickle cell disease or immunodeficiency is relevant. A history of travel may suggest infection with fungal organisms endemic in certain geographic regions (e.g., *C. immitis, Histoplasma capsulatum, Blastomyces dermatitides*). History of animal exposure leads to consideration of infection with *B. henselae* (cats) or *Salmonella* spp. (reptiles). A history of congenital heart disease suggests bacterial endocarditis as a possible source of infection. A recent history of pharyngitis or chickenpox leads to consideration of infection with *S. pyogenes.*

Physical Examination

Some children with hematogenous osteomyelitis are afebrile and relatively well-appearing, whereas others have high fever and are moderately to severely ill. A careful bone and joint examination is required to localize the infection. Often swelling, redness, and warmth are evident over the affected portion of bone. Palpation of the bone reveals the site of maximum tenderness.

In osteomyelitis of the pelvis or lower back, which is difficult to diagnose, gait abnormalities or referred pain to the hip or abdomen is present. Rocking the pelvic girdle or direct palpation of the affected vertebral body elicits pain. Range of motion of the hip is normal. Recent cases of MRSA infection have been associated with deep vein thrombosis and pulmonary infection.

Laboratory Evaluation

The WBC is either normal or elevated, with a predominance of PMN cells. The ESR and CRP are increased in more than 90% of cases, and blood cultures are positive in more than 50% of cases. A culture of infected bone increases the chance of making the appropriate bacteriologic diagnosis.

Plain radiographs reveal soft tissue swelling around the affected bone within the first few days of illness. Bone destruction is not noted until approximately 50% of bone is demineralized. Therefore, osteolytic changes are not seen until 10 to 20 days after onset of symptoms. Sclerosis of the bone is evident 1 month or more after onset of infection.

Radionuclide scans using technetium-labeled methylene-diphosphonate isotope are useful in the early diagnosis of osteomyelitis. Osteoblastic activity in the infected bone enhances uptake of the isotope. The sensitivity of the bone scan is 80% to 100%. A positive bone scan is not specific for infection because malignancy, infarction, trauma, or soft tissue cellulitis overlying the bone may cause increased uptake of the isotope. The bone scan may be falsely normal in neonates and very early in the course of infection.

MRI detects changes in bone marrow caused by infection. The sensitivity for detection of osteomyelitis is greater than 90%, but as with radionuclide scanning, similar marrow abnormalities are present with malignancy, fracture, or infarction.

Differential Diagnosis

Causes of bone pain other than osteomyelitis include trauma, bone infarction, bone tumors, leukemia, and lymphoma.

Management

Hospitalization for intravenous antibiotics and evaluation by an orthopedic surgeon is usually necessary. Empiric antibiotic therapy pending a bacteriologic diagnosis is outlined in Table 9-20. β-Lactam antibiotics, clindamycin, and vancomycin achieve levels in bone that are adequate for treatment of the usual pathogens. In cases of osteomyelitis caused by MRSA newer antibiotics such as linezolid have been used successfully. Theoretically, aminoglycosides are not used because of poor activity in an environment of tissue hypoxia and acidosis. Intravenous antibiotics are continued until the fever resolves; local findings of pain, warmth, and erythema improve; and CRP and ESR return to normal.

Eventually, it is possible to consider a change to oral antibiotic therapy. Factors to consider before initiating this change include the ability of children and families to be compliant with medication regimens and to attend follow-up appointments. The choice of oral antibiotic depends on the organism isolated, and it should have approximately the same spectrum of coverage as the intravenous antibiotic to which the child responded. The dose of oral β-lactam antibiotics used is approximately two to three times the usual recommended dose. However, because of the excellent bioavailability of antibiotics such as clindamycin and linezolid, it is not necessary to alter the recommended dose of the drug. Duration of therapy ranges from 4 to 8 weeks.

Surgical intervention is recommended in the setting of persistent fever, erythema, swelling, and pain. It is also recommended with a periosteal or soft tissue abscess, a draining sinus tract, or suspected necrotic bone.

VIRAL EXANTHEMS

Pediatric exanthems (rashes) may be viral or bacterial in origin. The classic viral exanthems result from infection with measles virus, rubella virus, HHV-6 and HHV-7, parvovirus B19, and VZV. Viral illnesses associated with exanthems have distinctive microbiologic and clinical characteristics (Tables 9-23 and 9-24).

TABLE 9-23

Viral Exanthems: Microbiologic Characteristics

Virus	*Disease*	*Transmission*	*Pathogenesis of Infection*	*Incubation Period*
Measles Paramyxovirus family	Measles	Droplet/airborne	Replication in respiratory tract → lymphatics → viremia → RES → secondary viremia → dissemination to multiple organs, including skin	8–12 days (rash may not appear until up to 18 days after exposure)
Rubivirus Togaviridae family	Rubella	Droplet/contact	Same as measles	14–23 days
Varicella-zoster virus Herpesviridae family	Chickenpox Varicella zoster (shingles)	Airborne/contact	Inoculation of respiratory tract → replication in lymph nodes → viremia → RES → secondary viremia → mononuclear cells transport virus to skin, replication in epidermal cells Latency established	10–21 days
Human herpes viruses 6, 7 Herpesviridae family	Roseola	Contact	Infects mature T lymphocytes Establishes latency	9–10 days
Parvovirus B19 Parvoviridae family	Fifth disease	Contact/droplet	Replicates in respiratory tract → viremia → infects RBC precursors	4–21 days
Enteroviruses[a]	Hand, foot and mouth disease	Contact (respiratory or stool)	Replicates in respiratory and GI tract → transient viremia → RES → secondary viremia to target organs (CNS, heart, skin)	3–6 days
Herpes simplex virus Herpesviridae family	Neonatal herpes simplex virus Herpes gingivostomatis Herpetic whitlow	Perinatal transmission Contact	Skin or mucous membrane penetration → neuronal spread → viremia → organ involvement → latency	2–14 days (neonatal herpes simplex virus presents from day of life to 6 weeks)

[a] Usually coxsackie virus A16, sometimes enterovirus 71 or other strains.

CNS, central nervous system; *GI*, gastrointestinal; *RBC*, red blood cell; *RES*, reticuloendothelial system.

TABLE 9-24

Viral Exanthems: Clinical Characteristics

Disease	*Prodrome*	*Enanthem*	*Exanthem*	*Complications*
Measles	Cough, coryza, conjunctivitis, high fever	Koplik spots	Red, raised morbilliform rash	Otitis media, pneumonia, croup diarrhea, acute encephalitis, death, subacute sclerosing panencephalitis
Rubella	Malaise, posterior auricular nodes, low-grade fever	Red macules, soft palate	Red, raised rash, less intense than measles	Congenital rubella syndrome, polyarthralgia, arthritis, encephalitis, thrombocytopenia
Varicella (chicken pox) Varicella zoster (shingles)	Malaise, anorexia, Headache (mild)	Vesicles may involve mucous membranes	Papules → vesicles → crusted lesions appear on scalp/face/neck Spread to trunk, extremities Varicella zoster (shingles) is characterized by pain and rash in a dermatomal distribution	Disseminated disease, pneumonia, hepatitis, coagulopathy, pneumonia, encephalitis, bacterial superinfection with *Streptococcus pyogenes, Staphylococcus aureus*
Roseola (HHV-6, -7)	High fever	Red macules soft palate	Red maculopapular rash on trunk Rash appears after resolution of fever	Seizures, (disseminated disease in immunosuppressed hosts) HHV-7 infection may be very mild or asymptomatic
Parvovirus (fifth disease)	Low fever, malaise	None	Slapped cheeks, lacy reticular rash trunk and extremities	Arthritis/arthralgia, transient aplastic anemia in patients with hemolytic anemia, fetal infection, chronic infection in immunosuppressed
Enteroviruses	Mild upper respiratory or gastrointestinal symptoms	Small vesicles or ulcers in posterior pharynx	Pustular or vesicular lesions on hands and feet, maculopapular rash	Aseptic meningitis, myocarditis
Neonatal HSV	Poor feeding, lethargy	Vesicular lesions	Grouped vesicles on an erythematous base	Disseminated infection causing hepatitis, pneumonia, disseminated intravascular coagulation, death, encephalitis

The pathogenesis of the rash varies depending on the inciting organism. Skin eruptions are caused by direct infection of the epidermis (measles), dermis (rubella), or vascular endothelium (rickettsial disease); circulating bacterial toxin (*S. pyogenes, S. aureus*); host immunologic response (parvovirus B19); or a combination of factors.

When assessing children with rashes, it is important to take a complete history regarding the rash. To establish the diagnosis, information regarding prodromal symptoms; the onset, spread, and evolution of the rash; and associated systemic symptoms is necessary. The clinician must obtain a history of travel, ill contacts, immunizations, allergies, medications, and insect or tick bites. It is essential to document the following characteristics of the rash: color and texture, location, and pattern (e.g., is it symmetrical?); involvement of the hands and feet; and manner and extent of spread. In addition, the clinician should also note whether the rash is painful, painless, or itchy; whether it blanches; and whether any mucous membranes are involved. Observation of abnormalities, such as fever, respiratory symptoms, pharyngitis, lymphadenopathy, heart murmur, and joint abnormalities aid in the diagnosis.

MEASLES (SEE TABLE 9-24)

Measles (also known as "hard" measles, rubeola, red measles, and 9-day measles) is highly contagious, with most cases occurring in winter or spring. In the United States, the incidence of measles has dropped dramatically since the vaccine was licensed in 1963.

Pathophysiology

Skin eruptions result from direct viral infection of the epidermis. Bacterial superinfection may develop, and complications may occur. Death due to either respiratory or neurologic complications occurs in 1 to 3 of every 1,000 cases in the United States. Mortality rates are higher in other countries. **Subacute sclerosing panencephalitis,** a progressive fatal degenerative CNS disease, occurs after wild-type measles. It is associated with a prolonged incubation period (9.8 years on average). Symptoms include progressive changes in behavior, cognitive deterioration, and seizures.

Clinical and Laboratory Evaluation

History

The history should focus on immunization status, travel, or contact with other individuals with rash-associated illnesses. Children are moderately to seriously ill, with symptoms of high fever, dry cough, coryza, and conjunctivitis with clear discharge. A distinctive rash develops following the prodromal symptoms.

Physical Examination

Measles is distinguished by a pathognomonic enanthem (**Koplik spots**) characterized by tiny white dots on a red base, which appears on the buccal mucosa 1 or 2 days prior to the onset of a rash. The mucous membranes and pharynx are red. The rash appears 3 to 4 days after onset of prodromal symptoms. The dark red raised morbilliform (measles-like) rash begins at the hairline and spreads to involve the trunk, arms, legs, and eventually hands and feet. Individual lesions become confluent as illness progresses. Lesions initially blanch but progress to darker nonblanching lesions as a result of capillary leak. The rash fades over 7 to 9 days with subsequent fine desquamation. Children appear ill and may complain of photophobia.

Laboratory Evaluation

A diagnosis is based on clinical findings, exposure, and immunization history, as well as positive serology. IgM antibody against measles is present for approximately 1 month after the onset of symptoms. Paired acute and convalescent sera demonstrating a significant rise in measles IgG are diagnostic. It is possible to culture measles virus from nasopharyngeal specimens, urine, and blood. It is important to notify the local health department immediately about suspected cases of measles to expedite processing of specimens and to identify possible sources and contacts.

Differential Diagnosis

The differential diagnosis of measles includes other viral and bacterial exanthems, Kawasaki disease, and drug allergy.

Management

Treatment

Supportive treatment is appropriate for most cases of measles. If bacterial superinfection is suspected, antibiotic therapy is necessary. Generally, specific antiviral therapy is not recommended. Ribavirin, which has in vitro activity against measles virus, has been used in intravenous or aerosolized form in some cases of severe disease.

Severe measles may occur in children with decreased serum levels of vitamin A. Although vitamin A deficiency is not a major problem in the United States, supplementation is considered in young children (at or over 6 months of age) who either have complications of measles, malnutrition, immunodeficiency, and impaired intestinal absorption, or who are recent immigrants from countries with high mortality rates due to measles.

Prevention

Effective prevention of measles involves vaccination. The American Academy of Pediatrics (AAP) recommends that children receive two doses of live attenuated measles vaccine—one at 12 to 15 months of age and one at 4 to 6 years of age (see Figure 2-10). The trivalent measles, mumps, and rubella vaccine (MMR) is most commonly used in the United States. The measles vaccine is a live attenuated vaccine, which means that it is not appropriate for immunosuppressed children and pregnant women, except in the case of HIV-positive children who are not severely immunologically impaired. Transmission of measles virus by vaccine does not occur, so there is no contraindication to immunization of household contacts. Adverse effects of vaccine include fever, rash, and thrombocytopenia.

The "Red Book" published by the Committee of Infectious Diseases of the AAP contains details about the measles vaccine, including guidelines for its use in epidemic circumstances or in susceptible adolescents and adults. Immunoglobulin products interfere with the serologic response to measles vaccine. Clinicians should consult the AAP recommendations if they have a patient who has received an immunoglobulin product or blood transfusion to determine the appropriate interval before a vaccine may be administered.

To prevent the development or to decrease the severity of symptoms of measles in exposed nonvaccinated individuals, intramuscular immune globulin is useful. To be effective, the agent must be given within 6 days of exposure.

RUBELLA (SEE TABLE 9-24)

Rubella (German measles, **third disease**) is a moderately contagious disease, with most cases seen in late winter or early spring. The disease is now uncommon in the United States. During 1964, an epidemic of rubella resulted in over 12 million cases of rubella and 20,000 cases of **congenital rubella syndrome**. After rubella vaccine was licensed in 1969, the number of cases of the disease declined by 99%. Most rubella infections are seen in unimmunized Hispanic young adults, and most recent cases of congenital rubella syndrome have occurred in children born to unvaccinated women born outside of the United States.

Pediatric Pearl: It is important to recognize and diagnose rubella infection because the transmission of rubella virus to pregnant nonimmune women often results in severe congenital infection.

Pathophysiology

Skin eruptions in rubella result from direct infection of the dermis. The most common complications of rubella are arthritis and arthralgia. Joint abnormalities are rare in children but occur often in adult women. Fingers, wrists, and knees are most frequently affected.

Rubella infection during the early part of pregnancy is disastrous, leading to fetal death, premature delivery, or multiple congenital anomalies. All fetal organs may be affected. Abnormalities seen in congenital rubella syndrome include sensorineural hearing loss, cataracts, heart defects (usually patent ductus arteriosus [PDA], pulmonic artery stenosis, pulmonic valve stenosis), microcephaly and mental retardation, splenomegaly, hepatitis, and thrombocytopenia. Diabetes mellitus and progressive panencephalitis are late complications of congenital rubella syndrome.

Clinical and Laboratory Evaluation

History

It is important to obtain an immunization and contact history about any child who presents with a nonspecific viral exanthem. The prodrome, which does not occur in all cases, consists of low-grade fever, malaise, lymphadenopathy, and upper respiratory tract infection.

Physical Examination

Children appear well or mildly ill. Lymphadenopathy involving posterior auricular, suboccipital, and posterior cervical nodes may be present; the nodes remain enlarged for several weeks. An often pruritic rash, which occurs 1 to 5 days after prodromal symptoms, begins on the face and progresses caudally. It is fainter than the rash seen with measles and does not coalesce.

Laboratory Evaluation

Diagnosis is difficult because many patients appear to have a nonspecific viral illness. Serology is the usual method for confirming a case of rubella. Reliable evidence of acute infection includes the presence of rubella IgM or a significant rise in rubella IgG demonstrated on paired acute and convalescent sera. Rubella virus is cultured from nasal specimens, throat swabs, blood, urine, and CSF. It is important to alert the laboratory about suspected rubella to facilitate appropriate testing. As with measles, it is necessary to notify local health departments about suspected cases of rubella.

Differential Diagnosis

The rash of rubella is difficult to distinguish from other viral rashes such as those seen with enterovirus, parvovirus B19, HHV-6, and EB virus infection.

Management

Supportive treatment is appropriate for rubella. Prevention involves vaccination. Rubella vaccine is a live attenuated viral vaccine administered as MMR at 12 to 15 months of age and 4 to 6 years of age (see Figure 2-10). All pregnant women have rubella serology as part of routine prenatal screening, and any woman found to be rubella nonimmune receives vaccine during the postpartum period. Vaccine is not appropriate for pregnant women. Recent administration of immune globulin preparations or blood products interferes with antibody response to vaccine. Children with altered immunity should not receive live virus vaccine during the time they are immunosuppressed. Adverse effects of vaccine include fever, lymphadenopathy, joint pain, and thrombocytopenia.

ROSEOLA (SEE TABLE 9-24)

Roseola (exanthem subitum, sixth disease), which results from infection with HHV-6 and occasionally HHV-7 virus, is an acute febrile illness followed by a rash. Infection with HHV-6 is common, and seroprevalence in most countries approaches 100% in children over 2 years of age. HHV-6 has two variants (A or B) based on genetic and phenotypic variations; variant B (HHV-6B) causes roseola. HHV-7 infections occur later in childhood and may be asymptomatic or mild or be associated with a typical roseala-like illness.

Complications are uncommon. Seizures occur in 10% to 15% of children during the febrile period (see Table 9-24). Occasionally, roseola infection in healthy children results in a mononucleosis-like syndrome characterized by lymphadenopathy and hepatitis.

Pathophysiology

Acute primary infection with the human herpes viruses occurs in children 4 to 6 months of age or older. Virus is acquired from close contact with infected saliva from parents or siblings. After primary infection, the virus remains latent in mononuclear cells and likely persists in other tissue. Replication of virus in salivary glands accounts for the salivary route of transmission. Reactivation of virus is rarely associated with symptoms unless children are immunosuppressed. Symptoms associated with reactivation include fever, bone marrow suppression, hepatitis, pneumonia, and encephalitis.

Clinical and Laboratory Evaluation

History

Parents report a history of few prodromal symptoms and abrupt onset of high fever. The fever lasts for 3 to 7 days. Disease is typically mild. Occasionally respiratory or GI symptoms are present.

Physical Examination

Children have a high fever and are mildly ill or irritable. Except for the high temperature, vital signs are normal. Cervical lymphadenopathy or acute otitis media may be present. Skin perfusion is normal. It is necessary to perform a careful examination to exclude SBI. Resolution of fever is followed by development of an erythematous maculopapular rash that resolves spontaneously. The rash may not appear until 1 to 2 days after fever breaks.

Laboratory Evaluation

Diagnosis of roseola is based on clinical findings. The CBC, if obtained, shows lymphocytosis and neutropenia. Serology is difficult to interpret because a significant increase in HHV-6 IgG is seen after both primary infection and reactivation of disease. Techniques for culture of virus from peripheral blood mononuclear cells or detection of virus by PCR are available in some research laboratories. So far no technique has proved useful in differentiating primary infection from reactivation. Diagnostic tests for HHV-7 are so far limited to research laboratories.

Differential Diagnosis

Conditions to be ruled out include occult bacteremia or another hidden source of bacterial infection such as a urinary tract infection.

Management

Supportive treatment, with antipyretic therapy, is appropriate.

PARVOVIRUS B19 (SEE TABLE 9-24)

Infection with parvovirus B19, which is known by a variety of different names, including **erythema infectiosum, fifth disease,** and **slapped cheek disease,** causes mild illness. Approximately 20% of infected persons are asymptomatic.

By the time they are 15 years of age, about 50% of children have an antibody to parvovirus B19, with increasing rates of seroprevalence through adulthood. The usual mode of transmission is by contact with respiratory secretions. In addition, transmission by percutaneous exposure to blood or by mother-to-fetus also occurs. Mother-to-fetus transmission causes fetal hydrops and death; however, risk is low (about 5%).

Pathophysiology

The rash associated with parvovirus B19 is the result of an immune-mediated response. Children are most contagious during the prodromal period before the rash appears. After initial infection of the respiratory tract, viremia occurs with subsequent viral attachment to the P antigen on RBC precursors. Appearance of parvovirus-specific IgG correlates with protection from disease.

Arthralgia and arthritis may develop in adult women as the result of infection with parvovirus B19. Commonly affected joints include those of the hands, wrists, and knees. Joint pain and swelling usually resolve after 1 to 2 weeks, although symptoms may persist for months.

Because parvovirus B19 infects RBC precursors, most infected children experience mild and transient anemia. Children with disorders characterized by increased RBC turnover (e.g., sickle cell disease, glucose-6-phosphate dehydrogenase deficiency, autoimmune hemolytic anemia) develop transient aplastic crisis. Patients with immunodeficiency are at risk for chronic parvovirus infection and bone marrow failure. Parvovirus B19 infection is also reported to cause neutropenia and thrombocytopenia and is increasingly identified as a cause of acute viral myocarditis.

Clinical and Laboratory Evaluation

History

Children come to medical attention only after the rash appears. Illness is usually mild. Most children have a prodrome of low-grade fever, upper respiratory tract symptoms, and mild malaise.

Physical Examination

Children are well-appearing, with a low-grade fever or sometimes none at all. A red, flat rash on the cheeks and a lacy, reticular, often pruritic, rash on the trunk and extremities is notable. The rash becomes more intense if children are exposed to warm temperatures (e.g., a bath). The duration of the rash is approximately 7 to 10 days.

Examination of the joints for presence of arthralgia or arthritis is warranted. Complications of erythema infectiosum are uncommon in healthy children.

Laboratory Evaluation

Diagnoses in healthy children are made by clinical signs and symptoms. Laboratory work reveals mild anemia and a low reticulocyte count. Severe anemia is present in aplastic crisis. Serum IgM is more than 90% sensitive in identifying recently infected individuals, and serum IgG indicates previous infection and immunity. Serum DNA PCR is the preferred method of detection of parvovirus B19 infection in immunocompromised hosts.

Differential Diagnosis

The differential diagnosis of parvovirus B19 infection includes rubella, enterovirus infection, and drug reaction. If arthritis is present, juvenile idiopathic arthritis or other collagen vascular diseases must be considered.

Management

Treatment is not necessary in most children.

Pediatric Pearl: In patients with parvovirus, when the rash appears, children are not contagious, and it is not necessary to keep them home from school or day-care facilities.

Isolation for 7 days is necessary for children with transient aplastic crisis, who often have no rash. Hospitalized, immunosuppressed children require isolation for the duration of hospitalization because of risk of prolonged viral shedding. Intravenous immune globulin may be effective in children with immunodeficiency or transient aplastic crisis. Intrauterine blood transfusion has been useful in the treatment of hydrops fetalis resulting from parvovirus B19.

CHICKENPOX (VARICELLA) (SEE TABLE 9-24)

Chickenpox results from primary infection with VZV.

Pathophysiology

Infection is characterized by a generalized pruritic vesicular rash. Children are contagious from 1 to 2 days prior to the onset of the rash until the lesions have crusted. During primary infection, VZV establishes latency in dorsal root ganglia. Reactivation of virus results in **herpes zoster** (**shingles**).

The most common complication of chickenpox is bacterial superinfection with *S. pyogenes* or *S. aureus*. Parents of children who suffer from this complication often report that children were improving and afebrile with crusting lesions when they developed a new fever late in the course of illness. SBIs include pyogenic arthritis, osteomyelitis, pneumonia, bacteremia, and necrotizing fasciitis. Nonbacterial complications of chickenpox include pneumonia, cerebellar ataxia, encephalitis, hepatitis, hemorrhagic varicella, and arthritis. Disseminated VZV infection may cause death in immunocompromised patients as well as in healthy patients with a history of recent steroid therapy.

Clinical and Laboratory Evaluation

History

Children with chickenpox have a history of contact with another infected person within the previous 10 to 21 days. Although mild cases of varicella may occur in children who have been vaccinated against the disease, children usually have no history of varicella immunization. Prodromal symptoms include fever and malaise.

Physical Examination

Fever is often present. The child appears mildly to moderately ill. In cases of disseminated chickenpox or bacterial superinfection, the child may appear very ill. The rash begins on the neck, face, or upper trunk and spreads outward over the next 3 to 5 days. Mucous membranes may be involved. Lesions initially appear as small papules on an erythematous base. The papules evolve into vesicles that eventually form crusts. The rash is often intensely pruritic. It is important to inspect the rash for signs of hemorrhage or infection.

Lung examination may reveal signs of pneumonia caused by VZV or bacteria. Careful examination of the bones and joints may indicate infection caused by *S. aureus* or *S. pyogenes*. Neurologic examination may reveal cerebellar ataxia.

Laboratory Evaluation

Diagnosis of varicella is based on clinical findings. If the diagnosis is uncertain, it may be necessary to send scrapings of the bases of vesicular lesions for direct fluorescent antibody testing specific for VZV. A Tzanck smear reveals multinucleated giant cells; however, it is not specific for VZV and is less sensitive and accurate than direct fluorescent antibody. It is also possible to culture virus from lesions, but results are not immediately available.

Blood culture is warranted if bacterial superinfection is suspected. Chest radiograph, CBC, coagulation screen, and liver enzymes may be appropriate in ill-appearing children.

Management

Supportive treatment is appropriate for uncomplicated chickenpox in normal hosts. Acyclovir is useful in immunocompromised patients or patients with complications of disease. Antibiotics with activity against *S. pyogenes* and *S. aureus* may be effective in cases of suspected bacterial infection.

Prevention involves varicella vaccine, which is a live attenuated vaccine. Two doses are given, one at 12 to 15 months of age and the second at 4 to 6 years of age. The vaccine is not recommended for use in immunocompromised individuals or pregnant women. VariZIG is used for passive immunoprophylaxis in patients exposed to varicella who are at risk for severe disease. VariZIG is a lyophilized purified human immune globulin prepared from plasma with high levels of varicella antibody. If VariZIG is not available, administration of intravenous immune globulin is recommended. Administration should occur within 96 hours of exposure. Candidates include susceptible pregnant women, newborns whose mothers develop chickenpox shortly before or after delivery, premature infants, and immunocompromised children. Chemoprophylaxis with oral acyclovir is also used in selected nonimmune patients 7 to 10 days after exposure to prevent serious disease.

BACTERIAL EXANTHEMS

STREPTOCOCCUS PYOGENES (SCARLET FEVER) INFECTION

The rash of **scarlet fever** results from the vascular effects of streptococcal pyrogenic exotoxins A, B, and C produced by *S. pyogenes*. This organism also directly infects skin and soft tissue, causing **impetigo, cellulitis, erysipelas,** and **necrotizing fasciitis**. Various clinical findings are associated with these conditions (Table 9-25).

Clinical and Laboratory Evaluation

History

Prodromal symptoms of scarlet fever include fever, pharyngitis, chills, and abdominal pain. The rash appears 1 to 2 days after initial symptoms.

TABLE 9-25

Skin and Soft Tissue Manifestations of *Streptococcus pyogenes* and *Staphylococcus aureus*

Organism	*Disease*	*Clinical Findings*
Streptococcus pyogenes	Scarlet fever	See text
(GABHS)	Impetigo	Afebrile, honey-crusted pustular superficial skin lesions
	Erysipelas	Fever, well-demarcated erythematous advancing superficial skin infection
	Cellulitis	Fever, pain, deeper infection of subcutaneous tissue
	Necrotizing fasciitis	Fever, pain out of proportion to skin findings, bullous lesions or erythema, tissue necrosis
	STSS	Fever, erythematous macular rash, hypotension, renal impairment, coagulopathy, liver dysfunction, respiratory distress, soft tissue necrosis
Staphylococcus aureus	Staphylococcal scarlet fever	Same as *S. pyogenes* scarlet fever except no pharyngitis or enanthem
	Impetigo	Afebrile, honey-crusted pustules superficial skin lesions
	Folliculitis Furuncle/carbuncle Abscess or cellulitis	Infection of hair follicle Infection of hair follicle(s) and surrounding tissue Infection of skin/soft tissue May appear to look like a spider bite (particularly with MRSA infection)
	Staphylococcal scalded skin syndrome	Fever, tender erythematous skin, bullous lesions, positive Nikolsky sign[a]
	Toxic shock syndrome	Fever, erythroderma (sunburn-like rash), hypotension, mucous membrane hyperemia, vomiting and diarrhea, myalgia, renal and hepatic dysfunction, thrombocytopenia, altered level of consciousness

[a] Nikolsky sign is when the top layer of skin slips away from the lower layers with gentle rubbing.

GABHS, group A β-hemolytic streptococcus; *STSS*, streptococcal toxic shock syndrome.

Physical Examination

Most children with scarlet fever are only mildly ill. The rash of scarlet fever is erythematous and blanching, with fine, sandpaper-like papules on palpation. It is most prominent in warm, moist areas such as the neck, axillae, and groin, and spares the area around the mouth (circumoral pallor). Other skin findings include petechiae and areas of hyperpigmentation in skin creases (Pastia lines). Approximately 1 week after the appearance of the rash, fine desquamation begins on the face and spreads to the trunk and extremities.

Laboratory Evaluation

See Pharyngitis.

Differential Diagnosis

Other causes of a rash resembling scarlet fever may occur after infection with *S. aureus* or *A. haemolyticum*. A scarlet fever–like rash may also occur in association with streptococcal disease other than pharyngitis (e.g., bone or joint infection, pneumonia, streptococcal toxic shock syndrome).

Management

Parenteral antibiotics administered in the hospital are necessary for treatment of serious infections associated with scarlatiniform rash (see Pharyngitis).

STAPHYLOCOCCUS AUREUS INFECTION

Infection with *S. aureus* causes a variety of skin manifestations (see Table 9-25). Strains of this bacterium produce an exfoliative toxin that cause **bullous impetigo, staphylococcal scalded skin syndrome,** or a **scarlatiniform eruption** similar to the rash seen with streptococcal scarlet fever. Skin and soft tissue infections with MRSA have become increasingly prevalent. These infections are characterized by skin abscesses, which may appear to look like spider bites. They are often recurrent and may also occur in household members or close contacts (e.g., sports teams). **Cellulitis,** which occurs after direct infection of skin and subcutaneous tissues with *S. aureus*, is usually the result of trauma to the skin but occasionally occurs with hematogenous dissemination of bacteria. A diffuse sunburn-like rash (**erythroderma**) is seen with staphylococcal **toxic shock syndrome** (TSS) caused by TSS toxin-1–producing strains of *S. aureus*.

Pathophysiology

Many individuals are asymptomatically colonized with *S. aureus* in their anterior nares, skin, rectum, or vagina. Pathogenesis of infection is either by direct invasion of tissue or by effects of toxin-producing organisms distant from the site of the skin lesion.

Clinical and Laboratory Evaluation (see Table 9-25)

S. aureus is easily cultured from skin lesions or other sources of infection. If *S. aureus* is isolated from skin abscesses, blood, tissue, or CSF, susceptibility testing to identify possible methicillin resistance is necessary. See Table 9-25.

Management

Treatment for **impetigo** is with either a topical antistaphylococcal ointment such as mupirocin or retapamulin, or with an oral antistaphylococcal antibiotic such as dicloxacillin or a first-generation cephalosporin. Skin and soft tissue abscesses may be managed with incision and drainage (I and D) alone or I and D plus oral antibiotics. If infection with MRSA is likely, trimethoprim/sulfamethoxazole, clindamycin or doxycycline (in children older than 7 years) may be effective. It is important to note that trimethoprim/sulfamethoxazole is not effective in treating skin and soft tissue infections caused by *S. pyogenes*. Treatment for more extensive **cellulitis** or other serious staphylococcal infection is intravenous antibiotics. Drugs used include nafcillin, cefazolin, and clindamycin. Vancomycin or linezolid is useful for suspected MRSA. Treatment for suspected toxic shock syndrome involves admission for supportive care and intravenous antibiotics, with identification and removal of the source of infection (e.g., tampon, staphylococcal abscess).

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (*Rickettsia rickettsii*) is rickettsial disease caused by an intracellular, gram-negative coccobacillary bacteria. The infection is associated with a characteristic rash. Despite its name, this disease is reported throughout the United States, although it is most commonly seen in Oklahoma, Kansas, Missouri, Arkansas, North Carolina, and Tennessee, particularly from late spring through fall.

Pathophysiology

Inoculation of *R. rickettsii* into the dermis, with subsequent infection of endothelial cells, occurs via a tick bite. The incubation period is 2 to 14 days. After replication and dissemination of bacteria, vascular inflammation is associated with a petechial or maculopapular rash. Unrecognized and untreated infection results in multisystem organ involvement, vascular obstruction, disseminated intravascular coagulation (DIC), and occasionally death.

Clinical and Laboratory Evaluation

History

Children may have a history of tick exposure in an endemic area. Prodromal symptoms are nonspecific and include headache, fever, and malaise. Nausea, vomiting, abdominal pain, and diarrhea may be present.

Physical Examination

Children are febrile and ill appearing. **The rash, which appears after the third day of illness, is unique in that it begins peripherally on the wrists, ankles, and lower legs and spreads centrally.** The soles and palms may be involved. Initial lesions are erythematous blanching macules or papules that evolve over several days into petechiae or purpura. A small percentage of patients with Rocky Mountain spotted fever do not have a rash.

Laboratory Evaluation

This organism does not grow on routine bacterial culture media. A rickettsial group-specific serologic test confirms the diagnosis. PCR testing, if available, can identify the presence of the organism in blood. A skin biopsy of petechial lesions detects *R. rickettsii* antigen. A CBC may reveal thrombocytopenia and leukopenia.

Management

Children with suspected Rocky Mountain spotted fever require admission to the hospital for administration of antibiotics, ideally, before day 5 of the illness. **Antibiotics used to treat other childhood bacterial infections (e.g., penicillins, cephalosporins, macrolides) have no activity against *R. rickettsii*.** Use of tetracyclines, including doxycycline, is generally not recommended for children younger than 8 years because of the risk of discoloration of tooth enamel. However, with suspected Rocky Mountain spotted fever, the benefit of using doxycycline outweighs the small risk of tooth discoloration.

NEISSERIA MENINGITIDIS INFECTION

N. meningitidis, a small gram-negative diplococcus, causes a spectrum of diseases, including acute bacteremia with sepsis, meningitis, localized infection (pneumonia, arthritis), and occasionally chronic bacteremia. Chronic meningococcal infection is characterized by recurrent episodes of fever, rash, and arthralgia.

Pathophysiology

N. meningitidis causes disease when bacteria disseminate through the upper respiratory tract into the bloodstream.

Clinical and Laboratory Evaluation

History

Children with acute bacteremia often have a prodrome of fever, pharyngitis, and headache. They may have a history of contact with a family member or friend with *N. meningitidis* infection.

Physical Examination

Children are febrile and appear mildly to severely ill. Hypotension, poor perfusion, and cyanosis may be present. Petechial or purpuric skin lesions occur in approximately 70% of children; clinicians have reported finding other types of rash, including maculopapular and pustular lesions. Signs of meningitis, pneumonia, or joint infection may be evident.

Laboratory Evaluation

Diagnosis of meningococcal disease is made by isolating the organism from blood or CSF.

Differential Diagnosis

Differential diagnosis of petechial rash includes enteroviral infection, rickettsial infection, idiopathic thrombocytopenic purpura, and leukemia.

Management

Hospital admission for antibiotics and supportive care is necessary. Penicillin remains the drug of choice for treatment for confirmed meningococcal infection. In the United States, some isolates with decreased susceptibility to penicillin have been reported and resistance is widely reported in other parts of the world. Third-generation cephalosporins are acceptable alternatives for therapy.

It is necessary to notify the local health department immediately about suspected or proven cases of meningococcal disease. Close contacts of index cases are at high risk for colonization with *N. meningitidis* and are candidates for prophylaxis. Antibiotics used for prophylaxis include rifampin, ceftriaxone, and ciprofloxacin. In recent years, isolates of *N. meningitidis* in some parts of the United States are reported resistant to ciprofloxacin; therefore, knowledge of local susceptibility patterns is imperative.

Vaccination with meningococcal conjugate vaccine provides protection against infection with meninogoccal serotypes A, C, Y and W-135 and two doses are recommended for all adolescents age 11 to 18 years. Children 2 years of age and older who are at higher risk for infection, including those with deficiencies of terminal complement or properdin, asplenia, or HIV infection may also benefit from vaccination.

OTHER INFECTIOUS DISEASES

PEDIATRIC HIV INFECTION

Since the beginning of the **HIV** epidemic, thousands of children in the United States have been infected with HIV. **AIDS** is the severe end of the clinical spectrum of disease caused by HIV. As of 2007, more than 8,000 cases of AIDS in children have been reported as a result of perinatal transmission of virus. An increasing number of adolescents acquire the virus through heterosexual and homosexual contact or intravenous drug use. Transmission of HIV through contaminated blood transfusion or blood products has virtually been eliminated.

The number of children with perinatally acquired HIV infection has decreased dramatically since the mid-1990s. The decline in the transmission of HIV that has occurred over the last 15 years is attributed to screening for HIV infection during pregnancy and to the use of zidovudine and other antiretroviral agents in pregnant women. Approximately 12% to 40% of infants born to untreated HIV-positive mothers are infected with the virus. Appropriate management of the infected mother with highly active antiretroviral therapy during pregnancy, prophylaxis during the time of delivery, prophylaxis for the infant after birth and the recommendation that HIV-positive mothers not breastfeed, has decreased the risk of transmission to less than 2%. In cases where HIV infection was acquired later in pregnancy, adherence to antiviral therapy is poor, or maternal viral load is high, the risk of transmission is likely higher.

Pathophysiology

HIV is a member of the Retroviridae family in the genus lentivirus. There are two types of HIV (1 and 2) that cause disease. Infection with HIV 2 is not common in the United States. The initial cellular targets of HIV are Langerhans cells in the genital mucosa; infected cells fuse with CD4 lymphocytes and spread to deeper tissues. After the virus is internalized in the host cell and uncoated, viral reverse transcriptase facilitates transcription of viral RNA into DNA. The DNA is transported into the nucleus of the host cell and subsequent synthesis of new viral polyprotein occurs. HIV protease must cleave the large polyprotein into several smaller proteins for newly synthesized virions to mature and become infectious. Mature HIV virions are released from the host cell and reinitiate the life cycle by infecting other CD4+ target cells.

The virus is detectable in regional lymph nodes within 2 days of infection and in plasma 4 to 11 days after infection. An initial rapid rise in plasma viremia occurs with a subsequent marked reduction in plasma viral RNA to a "viral set point." The amount of viral RNA (or viral load) is usually higher in infected infants than in older children and adults.

Clinical and Laboratory Evaluation

History

It is necessary to obtain a careful social history from the child's parents to elicit risk factors for disease. However, the absence of apparent risk factors does not rule out HIV disease. It is important to discuss previous HIV

test results and exposure history (e.g., intravenous drug use, sexual behavior, transfusions) in a sensitive and confidential manner. Partners and extended family members are often unaware of an individual's risk factors. A negative HIV antibody test during pregnancy is reassuring but does not rule out infection after testing was performed.

Pediatric Pearl: It is important to offer HIV testing to all pregnant women because appropriate antiretroviral therapy during pregnancy and delivery and antiretroviral prophylaxis for the infant is proven to prevent perinatally acquired HIV infection.

Signs of primary HIV infection are rare in infants. Adolescents and adults may be asymptomatic or have symptoms of an acute illness similar to infectious mononucleosis (Table 9-26). Children with perinatally acquired HIV infection are often asymptomatic at birth but develop signs and symptoms of disease as they grow older; most have historical and clinical findings of HIV infection by 18 to 24 months of age. A small number of infected children come to medical attention within the first 2 or 3 months of life when they develop *Pneumocystis carinii (jirovecii)* pneumonia or disseminated CMV infection. Medical history of the child may reveal poor growth, recurrent otitis media or respiratory infections, mild developmental delay, diarrhea, chronic thrush, or diaper rash.

Physical Examination

Several abnormalities are apparent on physical examination (Table 9-27).

Laboratory Evaluation

For **exposed infants,** testing involves the use of the PCR for HIV viral DNA or RNA. Testing is performed within 2 to 3 weeks after birth and repeated at 1 to 2 months and at 4 to 6 months of age. Some experts recommend testing within 48 hours of birth in order to diagnose infection acquired in utero. Serologic testing of perinatally

exposed infants confirms exposure but not infection, because a positive test may reflect transplacentally acquired antibody. It is necessary to repeat a positive HIV test to confirm the diagnosis.

For **children over 18 months of age**, standard serologic testing is sufficient. Serologic tests are negative until 3 to 4 weeks after acute infection. A positive enzyme-linked immunoassay test is confirmed by Western blot. For **adolescents** and adults, diagnosis of acute HIV syndrome involves detection of HIV viral RNA in plasma. Viral RNA is detectable in plasma 1 to 3 weeks before the antibody test is positive.

After establishing the diagnosis of HIV infection, it is appropriate to determine a child's immunologic status based on the percent of CD4+ lymphocytes and clinical symptoms (Table 9-28). Children infected with

TABLE 9-28

Clinical and Immunologic Categories of Pediatric HIV Infection

Clinical Classification			
N-	No signs of symptoms of illness		
A-	Mild signs and symptoms		
B-	Moderate signs and symptoms		
C-	Severe signs and symptoms		
Immunologic Category			
	CD4+ Count (μL) by Age (% lymphocytes)		
	<12 months	1–5 years	*6–12 years*
No evidence of suppression	≥1500 (≥25)	≥1000 (≥25)	≥500 (≥25)
Moderate suppression	750–1499 (15–24)	500–999 (15–24)	200–499 (15–24)
Severe suppression	<750 (<15)	<500 (<15)	<200 (<15)

HIV typically have a decrease in the number of CD4+ lymphocytes and an increase in the number of CD8+ lymphocytes, which results in an inverted CD4+:CD8+ ratio (usually less than 1.0). The normal number of CD4+ and CD8+ lymphocytes varies with age, with higher numbers seen in infants.

Routine laboratory tests are appropriate. A CBC may reveal mild leukopenia, anemia, or thrombocytopenia. Transaminases may be mildly elevated.

Management

Although there is no cure for HIV infection, the use of highly active antiretroviral therapy is successful in suppressing viral load and preventing destruction of CD4+ lymphocytes. Three classes of antiretroviral drugs are currently used most often in children.

The **nucleoside analog reverse transcriptase inhibitors** (NRTIs) prevent transcription of viral RNA into DNA. They compete with cellular deoxynucleoside triphosphates, and after being incorporated into the growing DNA strand, they cause premature termination of the HIV DNA intermediate. The **nonnucleoside analog reverse transcriptase inhibitors** (NNRTIs) prevent transcription of viral RNA into DNA by noncompetitive binding of viral reverse transcriptase. The **protease inhibitors**, which bind to specific cleavage sites on the HIV polyprotein, prevent viral protease from cleaving the larger polypeptide into smaller mature virions.

Recommendations for initial therapy should take into account the child's age, immunologic status, viral load, and ability and willingness to comply with medication regimen. Poor compliance contributes to the development of a resistant virus. In HIV-1 infected children, initial antiretroviral treatment typically includes two NRTIs plus either a protease inhibitor or an NNRTI. In infants born to HIV-positive women, prophylaxis with azidothymidine (AZT) is essential, and babies should receive oral AZT, 2 mg/kg/dose four times a day for 6 weeks. HIV virus is present in breastmilk; therefore, breastfeeding is not recommended. Treatment recommendations for antiretroviral therapy are constantly evolving. Children with HIV infection or exposure should be managed by a specialist in pediatric HIV medicine.

After the initiation of therapy, it is necessary to monitor children monthly for immunologic and virologic response and for adverse drug effects. During the first 3 to 6 months of treatment, the clinician may expect to see an increase in CD4+ lymphocyte count and significant decrease in viral load (often to undetectable levels). Adverse effects of antiretroviral therapy include anemia, elevated transaminases, pancreatitis, and hyperlipidemia. The most common complication of AZT prophylaxis in infants is anemia.

Children with HIV infection are at risk for opportunistic infections caused by pathogens such as *Pneumocystis jirovecii (PCP), Mycobacterium avium-intracellulare, Cryptococcus neoformans,* cytomegalovirus, and *Toxoplasma gondii*. Infants exposed to HIV at birth receive prophylaxis for *P. jirovecii* beginning at 4 to 6 weeks of age unless the child is presumed negative for HIV infection (based on specific diagnostic criteria). If the child is infected, prophylaxis is continued until 12 months of age. After 12 months of age, the decision to give PCP prophylaxis is based on the CD4+ lymphocyte count. (For specific recommendations concerning prophylaxis, see Suggested Readings.)

TUBERCULOSIS

M. tuberculosis infects approximately one-third of the world's population and is responsible for 2 million deaths annually. In the United States, there were more than 14,000 reported cases of tuberculosis and more than 100 deaths in children from 1993 to 2006. The incidence of tuberculosis is highest in nonwhite racial and ethnic groups, particularly in low socioeconomic populations or urban areas. Tuberculosis in young children differs from that of adolescents and adults. Children are at increased risk of extrapulmonary disease due to lymphohematogenous spread of bacteria. The risk of disseminated disease (miliary and CNS) is greatest in children younger than 4 years of age.

Pediatric Pearl: The diagnosis of tuberculosis infection or disease in a child is a sentinel event signaling the presence of other cases in the household or community.

The source of infection in children is usually a household contact. Casual contact such as in school or a day-care center is less frequently the source of transmission. Children younger than 12 years of age are unlikely to transmit infection because they rarely have cavitary lesions with large numbers of organisms, and they usually do not cough or produce sputum. It is worth noting that an individual whose sputum smear is positive for acid fast bacilli (AFB) is more contagious than one who has a positive culture but a negative sputum smear. *Mycobacterium bovis* also causes tuberculosis disease, frequently involving the GI tract. It is acquired from ingesting unpasteurized milk and dairy products.

By definition, children who have recently been in contact with a person who has contagious pulmonary tuberculosis have been exposed to the disease. Latent tuberculosis infection (LTBI) is defined as infection in a person with a positive tuberculin skin test (TST) or interferon-gamma release assay (IGRA), no symptoms, and a CXR that is either normal or shows only evidence of "old" or healed disease (e.g., calcification in the lung or lymph nodes). Individuals with tuberculosis disease have a positive TST or IGRA, symptoms, abnormal findings on physical examination, and an abnormal chest radiograph or evidence of extrapulmonary disease. Many clinical forms of tuberculosis exist (Table 9-29).

Pathophysiology

Tuberculosis is transmitted when a contagious person coughs and releases infected droplets of mucus into the air. Infection begins when the infected droplet nucleus reaches a pulmonary alveolus. A pulmonary macrophage or neutrophil ingests the bacteria, which begins to multiply. Within a few weeks, the pathogen spreads through regional lymphatics to the lymph nodes in the hilum. A few bacilli enter the bloodstream and are spread throughout the body. Approximately 3 to 12 weeks after infection, a T lymphocyte–mediated inflammatory response facilitates enhanced phagocytosis and killing of intracellular organisms. The inflammatory response corresponds to the time the TST becomes positive. At this time, a **primary complex** may be visible on the chest radiograph, consisting of a focus of infection in the subpleural area, hilar adenopathy, or a localized pleural effusion.

Clinical and Laboratory Evaluation

History

History focuses on travel and exposure to ill family members or friends. Recent immigrants, homeless children, or individuals who have been exposed to intravenous drug users or HIV-positive persons are at increased risk for tuberculosis.

TABLE 9-29

Selected Forms of Tuberculosis

Clinical Form	*Characteristics*
Pulmonary tuberculosis	
Primary	Asymptomatic, or cough, fever, weight loss Chest radiograph looks worse than patient Signs of partial bronchial obstruction such as atelectasis may be present
Progressive primary	May occur in immunosuppressed child Enlargement of primary complex, caseation, and cavitation Chest radiograph consistent with bronchopneumonia
Endobronchial tuberculosis	Partial or complete obstruction of bronchus Segmental collapse and consolidation
Reactivation	Classic "adult" form: results from growth of previously dormant bacilli in lung Upper lobe disease with cavity
Pleural	Less common in young children Occurs 6 months after primary infection Fever, chest pain Chest radiograph shows pleural effusion and primary parenchymal lesion
Pericardial	Pericardial effusion
Lymphadenitis	Difficult to differentiate from infection with nontuberculous mycobacteria Excision of node confirms diagnosis and cures nontuberculous mycobacteria (incisional biopsy may result in chronic drainage; some success with fine needle aspiration) Antituberculous therapy required
Miliary tuberculosis	Occurs early after primary infection Young children or immunocompromised patients Fever, hepatosplenomegaly, lymphadenopathy TST sometimes negative Chest radiograph reveals multiple small lesions Must exclude meningitis Good prognosis with therapy
Meningitis	Occurs early after primary infection Diagnosis difficult (40% of children with negative TST; 25% of children with normal chest radiograph) Cerebrospinal fluid • Initial polymorphonuclear cell response, usually 50–500 cells/μL • Initial diagnosis is often partially treated bacterial meningitis • As illness progresses, mononuclear cells increase, glucose decreases, protein increases

TST, tuberculin skin test.

The clinical manifestations of the disease are diverse and subtle. A history of cough, weight loss, night sweats, or chills may be elicited. Multiple foci of infection are sometimes present in children. *M. tuberculosis* may infect the eyes, ears, skin, bone (particularly vertebral bodies), genitourinary tract, and cause intra-abdominal infection. Mothers with untreated tuberculosis during pregnancy transmit infection to the fetus.

Physical Examination

Pertinent findings include weight loss, fever, lymphadenitis, hepatosplenomegaly, abnormalities on neurologic examination, and skin lesions (rare). Lung findings with pulmonary tuberculosis may include cough, decreased breath sounds, and dullness to percussion over the affected areas of the lung. Some infants and children with tuberculosis disease may appear relatively well early in the course of illness.

Tuberculous lymphadenitis (scrofula) is the most common extrapulmonary manifestation. Large, nontender, rubbery, matted anterior cervical, or submandibular lymph nodes are evident. Bilateral lymphadenopathy may be present. Signs of acute inflammation such as redness, warmth, erythema, and tenderness are absent. Over time, infected lymph nodes become fluctuant (softer) as nodes become necrotic. Spontaneous drainage and development of a sinus tract may occur.

Children with **miliary tuberculosis** often appear mildly to moderately ill. Fever is present, and hepatosplenomegaly with diffuse lymphadenopathy is apparent.

Diagnosis of tuberculous **meningitis** is often delayed because initial symptoms, including fever, irritability, and poor appetite, are nonspecific (stage I). As infection progresses, children develop vomiting, drowsiness, and cranial nerve palsies (stage II). Infants may have a bulging fontanel, and stiff neck is present in one-third of patients. Severe changes in mental status, seizures, focal neurologic deficits, and involuntary movements eventually develop (stage III). *M. tuberculosis* meningitis often involves the base of the brain and brainstem.

Laboratory Evaluation

Diagnosis of tuberculosis depends on clinical, radiographic, and laboratory findings. Two types of tests are available for determining whether an individual has been infected with tuberculosis. The first is the PPD TST. The second type of test is an interferon gamma release assay (IGRA).

A **positive TST** is indicative of tuberculosis infection. A positive test does not differentiate LTBI from tuberculosis disease. It is important to measure the area of induration (not erythema) in millimeters around the injection site 48 to 72 hours after intradermal injection of 5 tuberculin units of PPD and note it in the medical record. The definition of a positive TST depends on the age of the child, immune status, and risk factors for exposure (Table 9-30). The TST may be negative in infants and in children with miliary disease and immunosuppression.

TABLE 9-30

Definition of Positive Mantoux Tuberculin Skin Test[a]

Size of Induration (mm)	*Interpretation*
≥15	Positive at any age
≥10	Positive if: Underlying disease including lymphoma, diabetes mellitus, renal failure, malnutrition, children (<4 years of age) Increased risk of exposure through travel, birth in a country where disease is common, exposure to adults who are migrant farm workers, homelessness, HIV infection, incarceration, or use of intravenous drugs
≥5	Positive if: Close contacts of known or suspected contagious cases Children receiving immunosuppressive therapy or with immunosuppressive diseases Children with clinical or chest radiograph evidence suspicious for tuberculosis

[a] Five tuberculin units of purified protein derivative (PPD). Induration is measured 48 to 72 hours after placement of TST.

IGRAs are blood tests that measure ex vivo lymphocyte production of interferon-γ to specific antigens of *M. tuberculosis* complex. Recommendations for use of the test are similar to those for use of the TST. There is little data regarding performance of the test in children younger than 4 years, and therefore it should only generally be considered for use in children 5 years or older. The sensitivity of the IGRAs appears similar to the TST in older children. Because IGRAs measure the interferon-γ response to specific antigens of *M. tuberculosis complex*, they are useful in individuals who have received BCG vaccine in differentiating whether a positive skin test is due to BCG vaccine antigen versus *M. tuberculosis* infection.

It is necessary to obtain specimens of sputum for AFB smear and culture. In children unable to produce a good sputum sample, specimens of gastric acid are indicated. Gastric aspirates obtained early in the morning before respiratory secretions swallowed during the night pass out of the stomach are sufficient. Samples are collected as children awaken, before they are allowed to eat. Three specimens are obtained on 3 successive days.

Gastric aspirates are more sensitive than bronchial alveolar lavage for isolation of *M. tuberculosis*; the organism can also be isolated from urine, tissue, pleural fluid, and CSF (large volumes of CSF are required). Rapid diagnostic tests, including PCR amplification, are currently useful for rapid identification and susceptibility testing of the organism after it is isolated in culture.

Differential Diagnosis

Differential diagnosis of pulmonary tuberculosis includes bacterial or fungal causes of pneumonia such as *Streptococcus pneumoniae, Staphylococcus aureus, M. pneumoniae,* and *C. immitis.* Children with pulmonary tuberculosis typically have less respiratory distress than children with bacterial pneumonia.

Nontuberculous lymphadenitis is similar in presentation to tuberculous lymphadenitis (Table 9-31). Bacterial lymphadenitis is more likely associated with warmth, erythema, and tenderness of the affected node.

The differential diagnosis of tuberculous meningitis includes infection with fungal organisms such as *C. immitis* or partially treated bacterial meningitis.

TABLE 9-31

Selected Nontuberculous Mycobacteria

Organism	*Site of Infection*
Slow growers (>7 days for growth)	
Mycobacterium avium complex (includes *M. avium* and *M. intracellulare)*	Bronchopulmonary, lymphadenitis, disseminated (HIV-positive)
M. kansasii	Bronchopulmonary, skeletal, skin and soft tissue, disseminated (HIV-positive)
M. szulgai	Bronchopulmonary
M. scrofulaceum	Bronchopulmonary, lymphadenitis, skeletal
M. haemophilum	Skeletal, skin and soft tissue
Intermediate growers (7–10 days of incubation)	
M. marinum	Skin and soft tissue, less often disseminated disease
Rapid growers (< 7 days for growth on agar)	
M. fortuitum	Skin, soft tissue, disseminated, intravascular device
M. chelonae	Skin, soft tissue, disseminated, intravascular device
M. abscessus	Skin, soft tissue, skeletal, disseminated, bronchopulmonary, catheter

Management

If tuberculosis infection or disease is suspected based on exposure, clinical examination, TST or IGRA results, or chest radiograph, therapy is initiated pending culture results. *M. tuberculosis* grows slowly. Time to isolation and identification ranges from 2 to 10 weeks. Treatment involves the use of medications.

Natural resistance to currently available antituberculous drugs occurs at a fixed rate. Patients with large numbers of bacteria (e.g., with cavitary disease) are more likely to have organisms resistant to at least one antituberculous medication. For this reason, a combination of antituberculous medications must be used to effect a cure.

Current recommendations for initial treatment of pulmonary disease and lymphadenitis include three or four antituberculous medications (Table 9-32). With extrapulmonary disease, including meningitis, miliary, or bone and joint disease, treatment involves four drugs at first. In the case of suspected drug resistance, it is always necessary to add a fourth drug until results of susceptibility testing are known. Drug resistance is considered if the contact source is from Asia, Africa, Latin America, or resides in an urban area with a documented high rate of resistance. Previous treatment for tuberculosis and a history of homelessness are additional risk factors for drug-resistant tuberculosis. A specialist in infectious disease should be consulted to assist in management of all children suspected of having tuberculosis disease.

Duration of therapy depends on whether the disease is pulmonary or extrapulmonary. Pulmonary disease is typically treated with an intensive short-course therapy for 6 months. If only hilar adenopathy is present, a 9-month regimen with two drugs (isoniazid and rifampin) is acceptable. Treatment of extrapulmonary tuberculosis continues for 9 to 12 months.

TABLE 9-32

Drugs Commonly Used for Treatment of Childhood Tuberculosis[a]

Name	*Dose*	*Side Effects*
Isoniazid (INH)	10–15 mg/kg/day (max 300 mg q day)	Elevated transaminases, hepatitis, peripheral neuritis, rash, nausea/diarrhea
Rifampin (RIF)	10–20 mg/kg/day (max 600 mg q day)	Orange urine and secretions, hepatitis, decreased platelets, vomiting
Pyrazinamide (PZA)	30–40 mg/kg/day (max 2 g q day)	Hepatotoxic, hyperuricemia
Streptomycin (SM)	20–40 mg/kg/day IM (max 1 g q day)	Nephrotoxic, rash, vestibular toxicity
Ethambutol (EMB)	20 mg/kg/day (max 2.5 g q day)	Optic neuritis, decreased red/green color discrimination, nausea/diarrhea, rash
Treatment Regimens for Drug-Susceptible Tuberculosis[b]		
Pulmonary tuberculosis/Cervical lymphadenopathy		
Three to four drugs (INH/RIF/PZA plus consider SM or EMB) for 2 months, then INH/RIF[c] for 4 months (total duration of therapy is 6 months)		
For hilar adenopathy only: (INH/RIF) [total duration of therapy = 6 months]		
Meningitis/Miliary Disease/Bone or Joint Disease		
Four drugs (INH/RIF/PZA plus SM or EMB) for 2 months, then INH/RIF for 7–10 months (total duration of therapy is 9–12 months)		

[a] Directly observed therapy (DOT) is recommended for treatment of tuberculosis in the United States.

[b] If infection with drug-resistant *M. tuberculosis* is a concern, initial therapy with four drugs is given pending susceptibility testing of the organism.

[c] After the initial 2 months of therapy, twice weekly therapy may be appropriate. The dose of drug may be altered if twice weekly dosing is used; refer to recommendations in the AAP: "Report of the Committee on Infectious Diseases" ("Red Book").

Isoniazid (for drug susceptible *M. tuberculosis*) is indicated for children with a positive TST and no clinical or chest radiographic evidence of disease. Treatment with one drug is adequate because of the small number of tubercle bacilli present. For most infants and children, isoniazid therapy for 9 months prevents subsequent disease.

Children exposed to an infected household member must have a TST placed. If the TST is negative, isoniazid is indicated for 3 months until a repeat TST is placed. Isoniazid is discontinued if the second TST remains negative. If the initial TST is positive, it is necessary to perform a complete physical examination and obtain a chest radiograph to look for evidence of disease.

The only vaccine currently available for prevention of tuberculosis is bacille Calmette-Guérin (BCG) vaccine, which is prepared from live attenuated strains of *M. bovis*. The vaccine is given worldwide to infants to protect them from miliary or CNS tuberculosis; it has an estimated efficacy of 80%. BCG vaccine is less effective in the prevention of pulmonary tuberculosis. Use of BCG in the United States is not recommended, except in specific circumstances in which infants are at high risk for unavoidable exposure. Children who have received BCG immunization have a characteristic scar at the injection site, and their TST is often positive. It is not possible to distinguish positivity caused by BCG vaccination from true infection with *M. tuberculosis* in very young children with a positive TST and in whom an IGRA results may not be reliable. For that reason, it is necessary to evaluate all children with a positive TST for presence of disease using chest radiography and consider isoniazid prophylaxis.

LYME DISEASE

The cause of Lyme disease is infection with the spirochete *Borrelia burgdorferi*, which is carried by the disease-transmitting ticks *Ixodes scapularis* (deer tick) in the eastern United States and *Ixodes pacificus* (western black-legged tick) in the western United States. Over 90% of reported cases of Lyme disease occur in 13 states along the mid-Atlantic seaboard and the upper north-central region of the United States.

Principal risk factors for acquiring disease are residence in areas overgrown with tick-infested brush as well as occupational or recreational exposure. The estimated risk of *B. burgdorferi* infection after a tick bite in highly endemic areas is 1.4%.

Transmission

Ixodid ticks, which undergo three stages of development (larva, nymph, adult) in a 2-year period, become infected after feeding on small mammals such as the white-footed mouse. Ticks in all stages are capable of causing infection; however, nymphs are most likely to infect humans because they are present in relatively large numbers; are small in size, which allows them to escape detection; and have peak feeding activity coinciding with increased human outdoor activity (spring/summer). Transmission of *B. burgdorferi* requires prolonged tick attachment (over 36 to 48 hours). Coinfection with human granulocytic anaplasmosis or babesiosis may occur in same cases.

Clinical and Laboratory Evaluation

History and Physical Examination

Clinical manifestations of Lyme disease are divided into three stages: early localized, early disseminated, and late disease (Table 9-33). The hallmark of early localized disease is a rash called **erythema chronicum migrans (ECM).** The rash begins as a papule that increases in size over days to weeks to form a large lesion (greater than 5 cm in diameter), usually with some central clearing. Approximately 60% to 80% of infected individuals have ECM. Constitutional symptoms such as fever, headache, malaise, and lymphadenopathy are sometimes present during the first stage.

Symptoms in the second stage occur as a result of dissemination of the spirochete to multiple organs. Constitutional symptoms, including arthralgia, may persist or recur. Signs and symptoms of meningitis, cranial nerve abnormalities (especially cranial nerve VII), and, rarely, pseudotumor cerebri may be present. Cardiac abnormalities, including varying degrees of heart block, myopericarditis, and left ventricular failure, occur in 10% of cases.

Pauciarticular arthritis affecting large joints is the most common sign of late disease. Chronic arthritis is more likely among patients with human leukocyte antigen (HLA) types DR-2, DR-3, or DR-4. Late complications of CNS disease are rare in children but include encephalopathy and polyradiculoneuropathy (inflammation of multiple nerves) in adults.

TABLE 9-33

Clinical Manifestations of Lyme Disease

		Symptoms				
Stage of Disease	*Time after Tick Bite*	*Skin*	*Constitutional*	*Musculo-skeletal*	*CNS*	*Heart*
Early localized	3 days–4 weeks	ECM	Fever, malaise, headache, lymphadenopathy	Myalgia/arthralgia		
Early disseminated	3–10 weeks	Multiple ECM	Fever, malaise, headache, lymphadenopathy	Arthralgia	Cranial nerve palsies Meningitis Pseudotumor cerebri	Carditis
Late	2–12 months		Fatigue	Recurrent arthritis	Subacute encephalopathy Polyradiculoneuropathy	

CNS, central nervous system; *ECM*, erythema chronicum migrans.

Laboratory Evaluation

It is possible to diagnose Lyme disease clinically if a rash typical of ECM is present. Serologic tests are used as an adjunct to clinical findings. Testing for antibodies should take place in a reliable reference laboratory. Initial testing should include a reliable enzyme immunoassay (EIA) or immunofluorescent assay (IFA) test. Western immunoblotting is used to confirm positive or equivocal test results. Serology is not recommended for children with only nonspecific symptoms (e.g., fatigue); false-positive results are likely. In addition, such testing is not advisable after tick removal in asymptomatic children.

Management

Treatment of childhood Lyme disease depends on disease stage, nature of symptoms, and extent of organ system involvement. Children who receive appropriate therapy are unlikely to develop late complications. Antibiotics used include amoxicillin, doxycycline, penicillin, and ceftriaxone.

Prevention of Lyme disease and other tick-transmitted infections involves avoiding exposure to tick-infested areas. If this not possible, clothing that covers arms and legs should be worn, with pants tucked into socks. Clothing, not skin, may be sprayed with permethrin. Diethyltoluamide-containing insect repellent is effective when applied to skin, avoiding the face, hands, and abraded areas. It is essential to inspect children daily after possible tick exposure, with particular attention to the head and neck.

FEVER OF UNKNOWN ORIGIN

The diagnosis of fever of unknown origin (FUO) is made when a child presents with a history of fever (higher than or equal to 38.3° C) [100.9° F] for 2 weeks or more. Fever without localizing signs for less than 1 week usually results from a self-limited viral infection. The etiology of FUO is variable. Infections are the most common cause in children (30% to 40%), with autoimmune disease (7% to 10%), malignancy (2% to 5%), and other (e.g., factitious fever, drug fever, sarcoid, Kawasaki disease) causes in 2% of cases. The cause is never determined in nearly 50% of cases. In most of these, fever resolves spontaneously with no long-term sequelae. Causes may be infectious or noninfectious (Table 9-34).

TABLE 9-34

Infectious and Noninfectious Causes of Fever of Unknown Origin

Infectious Diseases	*Noninfectious Diseases*
Endocarditis	Juvenile idiopathic arthritis
Liver abscess	Systemic lupus erythematosus
Pyelonephritis	Kawasaki disease
Sinusitis	Malignancy
Pelvic abscess	Familial Mediterranean fever
Salmonella spp.	Inflammatory bowel disease
Brucella spp.	Drug fever
Mycobacterium tuberculosis	Factitious fever
Bartonella henselae (catscratch disease)	Sarcoidosis
Coxiella burnetii (Q fever)	
Rickettsia rickettsii	
Epstein–Barr virus (infectious mononucleosis)	
Cytomegalovirus	
Malaria	
Toxoplasmosis	

Clinical and Laboratory Evaluation

History

The diagnosis of FUO is often made by obtaining a thorough history. Important aspects of the history include questions regarding present and past medical history, a complete review of systems, family history of recurrent illness or infection, social history, medications, immunizations, allergies, travel, and animal, insect, and food exposure. Several animal and vector-borne infections may be the cause of the FUO (Tables 9-35 and 9-36). Changes in social behavior and school attendance should be noted.

Physical Examination

Pediatric Pearl: The cause of FUO often becomes apparent as symptoms of disease and signs on physical examination evolve over several days.

First, it is necessary to document the existence of fever either in the physician's office or at home, where a parent keeps a daily temperature record. The clinician should educate parents about the proper way to take a temperature. Sometimes hospitalization is necessary to document presence of fever. Second, it is important to note the child's general well-being. Weight loss and poor growth are signs of the existence of a significant medical problem. Third, a complete physical examination is necessary. The clinician should repeat it until the cause of the FUO becomes apparent or the fever resolves.

TABLE 9-35

Insect Vectors of Infectious Diseases

Organism	*Vector*	*Clinical Syndrome*	*Diagnosis*
Bacteria			
Spirochetes			
Borrelia burgdorferi	Tick	Lyme disease	Screening enzyme immunoassay Confirmatory Western blot
Borrelia hermsii	Tick	Relapsing fever	Visualization of spirochete on Wright-, Giemsa-, or acridine orange–stained blood smear Serum antibody test
Gram-negative bacteria			
Francisella tularensis	Tick, deerfly, horsefly	Tularemia	Serology Fluorescent antibody on infected material Culture[a]
Yersinia pestis	Flea	Plague	Serology Culture[a]
Rickettsia			
Rickettsia rickettsii	Tick	Rocky Mountain spotted fever	Serology, PCR, immunofluorescent stain of skin biopsy
Other intracellular bacteria			
Ehrlichia chaffeensis	Tick	Monocytic ehrlichiosis	Serology PCR Detection of intraleukocytic morulae (less sensitive)
Anaplasma phagocytophilum	Tick	Granulocytic anaplasmosis	Serology PCR Detection of intraleukocytic morulae (less sensitive)
Viruses			
Coltivirus	Tick	Colorado tick fever	Serology Viral isolation from blood
Arboviruses	Mosquito	Encephalitis[b]	Serology
Protozoa			
Babesia microti	Tick	Babesiosis	Visualization of organism on Giemsa- or Wright-stained smear
Plasmodium spp.	Mosquito	Malaria	Thick and thin blood smears PCR

[a] Notifiy laboratory that tularemia or plague is suspected so precautions can be taken to avoid infection of laboratory personnel.
[b] Eastern equine encephalitis, Western equine encephalitis, St. Louis encephalitis, California encephalitis, West Nile Virus encephalitis.

PCR, polymerase chain reaction.

TABLE 9-36

Infectious Diseases Associated with Pet Exposure

Animal	*Organism*	*Disease*	*Clinical Manifestations*
Cats	*Bartonella henselae*	Catscratch fever	Fever
			Lymphadenitis
			Microabscesses in liver and spleen
			Bone infection
	Toxoplasma gondii	Toxoplasmosis	Asymptomatic
			Mononucleosis-like syndrome
			Congenital toxoplasmosis
Reptiles	*Salmonella* spp.	Salmonellosis	Diarrhea
			Bacteremia
			Local infection (e.g., bone, joint)
Birds	*Chlamydophila psittaci*	Psittacosis	Interstitial pneumonia
Dogs	*Toxocara canis* *Bordetella bronchiseptica*	Visceral larval migrans (immunocompromised)	Lung, liver, eye infection Pneumonia, septicemia, sinusitis
	Leptospira spp.	Leptospirosis	Influenza-like illness or jaundice
	Microsporum canis	Tinea capitis/tinea corporis	Superficial infection of skin or hair shaft
Rats	*Streptobacillus moniliformis*	Rat-bite fever	Fever, arthritis, arthralgia, rash, endocarditis

Findings on physical examination may be subtle but may guide the diagnostic evaluation. For example, joint pain or swelling suggests infectious or reactive arthritis, collagen vascular disease, or malignancy. A heart murmur leads to the consideration of bacterial endocarditis or acute rheumatic fever. Palpation of a spleen tip is consistent with EB virus infection, endocarditis, or malignancy. A good neurologic examination can reveal abnormalities consistent with a CNS malignancy or brain abscess. Rectal examination may point to a previously unsuspected perirectal abscess or ruptured appendiceal abscess. Findings of eczema or seborrhea suggest immune deficiency or histiocytosis. Careful palpation of bony structures may reveal tenderness consistent with infection or malignancy. The presence of adenopathy, rash, conjunctivits, erythema and cracking of the lips, strawberry tongue, erythema and edema of the hands and feet, and less commonly symptoms of aseptic meningitis or GI symptoms suggests Kawasaki disease (see Chapter 14).

Laboratory Evaluation

The tempo of the diagnostic evaluation for FUO matches the clinical appearance of the child. A child who appears well or mildly ill may benefit from a limited initial evaluation and observation. The ill-appearing child with progressive worsening of symptoms may require hospitalization and multiple diagnostic tests.

Tests ordered are based on findings from the history and physical examination. Useful screening laboratory tests include a CBC, ESR, CRP, urinalysis and culture, and serum chemistries, including liver function

studies. An elevated platelet count, although present in many infections, may be an indication of Kawasaki disease. Chest radiography is useful for showing changes consistent with acute or chronic pulmonary disease, hilar lymphadenopathy, or abnormal heart size or shape. Abdominal ultrasound may reveal an intra-abdominal tumor, appendiceal abscess, liver abscess, or liver and spleen lesions consistent with catscratch disease or abnormalities of the kidneys. Further outpatient evaluation may include a TST, Monospot, and serology for EB virus, serology for *B. henselae*, an HIV antibody test or HIV DNA or RNA PCR, blood culture, stool for bacterial culture and ova and parasites, serum for antinuclear antibody and rheumatoid factor, or thick and thin blood smears if the travel history is suggestive for malaria.

Diagnostic tests considered include lumbar puncture, CT of the sinuses, repeat blood cultures, echocardiogram, ophthalmologic examination, and bone marrow aspiration. Serologic tests for unusual infections are helpful only if acute and convalescent serum is obtained or if IgM for a specific infectious agent is positive. Nuclear medicine scans are not usually diagnostic unless a probable focus of infection has been identified by history or physical examination.

Management

Empiric oral or parenteral antibiotic therapy is not used in nonimmunocompromised children with FUO unless patients have a strong likelihood of bacterial infection or appear very ill. In these circumstances, it is reasonable to begin broad-spectrum antibiotic therapy but only after appropriate cultures have been performed. A trial of nonsteroidal anti-inflammatory drugs (NSAIDs) is recommended if juvenile idiopathic arthritis is likely. Empiric use of steroids is never appropriate.

If fever persists and the outpatient evaluation is not diagnostic, hospitalization is recommended. Observation should document the presence and pattern of fever and any changes in physical findings. Further diagnostic workup may include evaluation by specialists in infectious disease, rheumatology, or hematology/oncology.

Neonatology

Ronald S. Cohen, Katherine R. McCallie, and William D. Rhine

PERINATAL AND NEONATAL ASSESSMENT

General Considerations

Neonatology is the subspecialty of pediatrics concerned with sick newborns, and neonatologists strive to understand how fetal development and pathology lead to illness in infants at birth. **Perinatology** is the area of obstetrics concerned with pregnant women and their fetuses, and perinatologists care about the well-being of infants after birth. Use of a common terminology by all practitioners concerned with the care of young infants facilitates effective evaluation and understanding of high-risk fetuses and newborn infants. **Gestational age** is the number of weeks of a pregnancy from the first day of the mother's last menstrual period to the date of birth. **Prematurity** is birth before 37 weeks' gestation; **postmaturity** is any birth after 42 weeks' gestation. The **neonatal period** is 0 to 28 days after birth.

Pregnancies may be classified as high risk on the basis of two groups of factors: underlying maternal conditions and fetal or obstetric complications.

- **Maternal conditions:** extremes of age; extremes of weight or weight gain; medical disorders, especially diabetes mellitus, hypertension, and congenital heart disease (CHD); use of tobacco, illicit drugs, and excessive alcohol; multiple gestation; history of multiple fetal losses; and delay or avoidance of obstetric care
- **Fetal or obstetric conditions:** premature labor, prolonged rupture of chorionic membranes (over 24 hours), intrauterine growth retardation (IUGR), polyhydramnios (excessive amniotic fluid) or oligohydramnios (decreased amniotic fluid), abnormal fetal position, maternal vaginal bleeding, infection (e.g., chorioamnionitis), and meconium staining of amniotic fluid

Antepartum Testing

Several methods are used to assess fetal health. Clinical markers of fetal well-being include fundal height and fetal movement. Other antepartum tests are also available (Table 10-1).

Neonatal Evaluation and Resuscitation

High-risk infants sometimes need assistance in making the transition from fetal to neonatal physiology at the time of delivery. Whenever possible, high-risk deliveries should occur in an environment in which the necessary equipment and appropriately trained personnel are readily available if resuscitation becomes necessary. Preparation is crucial for successful neonatal resuscitation, and communication between the neonatal care team and their colleagues in obstetrics is often the first step in this preparation.

The **Apgar scoring system** ensures proper evaluation of neonates at the time of delivery (see Table 1-1). Scores are obtained at 1 and 5 minutes after birth. If the score at 5 minutes is less than 7, scores are obtained every 5 minutes thereafter (for 20 minutes after birth) until two scores of greater than 7 are obtained. Skin color (including perfusion) is usually the first factor to be reduced in depressed neonates, followed by respirations, tone, reflexes, and pulse.

TABLE 10-1

Antepartum Tests Used to Assess Fetal Health

Test	*Use*
Ultrasound studies	Fetal growth, anatomy, and physiologic function; the latter is scored as part of a biophysical profile that includes fetal tone, movement, breathing, heart rate, and amniotic fluid volume; Doppler studies of cord blood flow
Amniocentesis (sampling of amniotic fluid)	Detection of chromosomal abnormalities; estimate of lung maturity
Chorionic villus sampling (first trimester)	Earlier screening for chromosomal or other genetic/metabolic analysis
Percutaneous umbilical blood sampling (ultrasound-guided)	Both diagnostic and therapeutic interventions (e.g., hematocrit measurement, fetal transfusion)
Fetal heart rate monitoring, either at time of delivery or during later part of third trimester: • In absence of contractions (nonstress test) OR • With induction of contractions by oxytocin (stress test)	Fetal well-being
Fetal scalp blood sampling	Measurement of blood gases; determines acidosis during labor

The Apgar score provides a guideline for the magnitude and duration of cardiopulmonary resuscitation (CPR), if necessary. However, it was not designed to predict neurologic outcome. In fact, most children with abnormal neurologic development have a "good" 5-minute Apgar score of greater than 7, and most children with a 5-minute score of less than 7 have normal neurologic outcomes. On the contrary, prolonged depression of Apgar scores (less than 4 over 10 minutes) does indicate high risk (greater than 50%) for death or abnormal neurologic development. Additional markers of potential illness at birth include prematurity and extremes of size—whether **small-for-gestational age (SGA)** or **large-for-gestational age (LGA).**

Initiation of neonatal resuscitation begins with the ABCs of CPR: **airway, breathing,** and **circulation.** Airway management may be initiated by proper head positioning and bag-mask ventilation. Mask or nasal continuous positive airway pressure (NCPAP) may be used in premature infants to stabilize the lung's functional residual capacity and to help overcome the physiologic impairments associated with lung immaturity. If additional oxygenation and ventilation are required, endotracheal intubation may be necessary. If meconium staining of the amniotic fluid is present and the infant is nonvigorous at birth, suctioning via an endotracheal tube is used to help clear the airways and prevent **meconium aspiration syndrome (MAS).** However, intubation should be reserved only for patients requiring this as part of the usual ABCs. Intubation is not indicated solely for the purpose of diagnosing or treating meconium in the airway. Rescue breathing for neonates requires 30 to 60 breaths/min with adequate pressure, which is demonstrated by good air entry on auscultation or by adequate chest excursion. Circulation is assessed by auscultation of heart rate and/or palpation of the pulse at the brachial artery, in the axilla, or even at the umbilical stump.

In addition to these ABCs, newborns have several unique resuscitation needs. They often need **stimulation,** which induces sympathoadrenal-mediated increases in respiratory and cardiac performance; **suctioning,** which removes amniotic fluid from the nasal and oral pharynx; and **drying and warming,** which reduce the oxygen requirements for maintenance of thermoneutrality. Umbilical vessel cannulation can provide: (1) arterial access for blood pressure monitoring and arterial blood gas (ABG) sampling, and (2) venous access for cardiopressor drip administration and estimation of central venous pressure. Noninvasive oxygen saturation monitoring should be used in the delivery room to guide the titration of oxygen therapy.

Neonates who are considered ill and in need of further evaluation and therapy should be transferred to a neonatal intensive care unit (NICU). Management of ill newborns includes knowledge of resources available at the treating facility. In the United States, virtually all nurseries participate in a hierarchical referral and education network. **Level 1** nurseries provide basic neonatal care, which may include parenteral antibiotics. **Level 2** nurseries offer more intensive care such as gavage feeds and ventilatory assistance of limited form or duration. **Level 3** nurseries provide the broadest range of neonatal care, including consultation from pediatric subspecialists, advanced respiratory support, and neonatal surgery.

FLUIDS, ELECTROLYTES, AND NUTRITION

Pathophysiology

The maintenance of normal fluid and electrolyte balance may have a positive effect on the outcome of many underlying disease processes. The problems involved in establishing proper fluid and electrolyte administration are commonly encountered in the neonatal period.

Several significant developmental differences in physiology must be taken into account when considering fluid and electrolyte management in the neonatal period. **Total body water** is 85% of birth weight in the third trimester and decreases to 78% at term, compared with 65% in older children; more than 50% of the water in term infants is extracellular (Figure 10-1). With growth, there are significant alterations in the balance between **extracellular fluid (ECF)** and **intracellular fluid.** During the first 7 to 10 days of life, most infants experience a physiologic 5% to 12% reduction in body weight due to loss of body water, primarily ECF. This reduction in ECF is accompanied by a maturation of renal function. If fluid or electrolyte loading occurs in the first week of life, the ECF compartment may remain expanded, which may result in pulmonary edema or symptomatic left-to-right shunting through a **patent ductus arteriosus (PDA)**.

The initial goal of fluid and electrolyte therapy is the maintenance of zero balance for fluids and electrolytes, assuming no preexisting deficits or excesses. The formulation of a reasonable management plan for intake of fluids and electrolytes requires an adequate determination of output in neonates. The four normal sources of fluid loss are **insensible water loss (IWL), urine output, sweat,** and **fecal water loss.** IWL, the loss of water

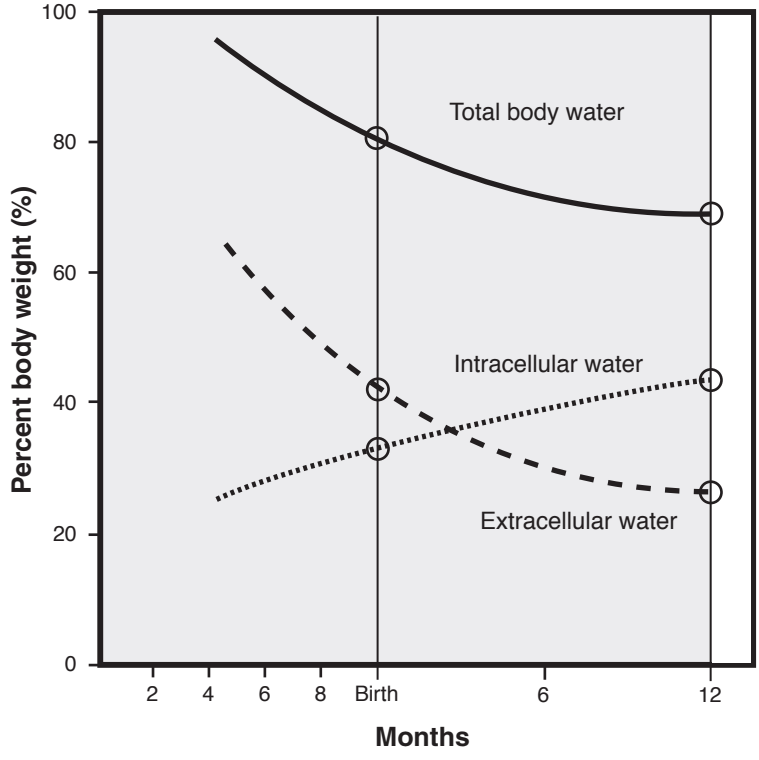

FIGURE 10-1. Changes in body fluid during fetal and neonatal life. From OH W: Fluid and electrolyte management. In *Neonatology: Pathophysiology and Management of the Newborn*. Edited by Avery GB. Philadelphia, JB Lippincott, 1987, p 776.

through the lungs during respiration and through the skin from evaporation, is greatest in infants of low birth weight and low gestational age because of increased skin permeability, larger body surface area per unit weight, and greater skin blood flow relative to metabolic rate. Other factors that affect IWL are respiratory distress, activity level, and environmental factors (e.g., open radiant warmers, phototherapy).

In neonates, who can maximally dilute their urine only to 50 mOsm/L and can concentrate it only to 800 mOsm/L, the intake of water and solutes primarily determines urine volume and osmolality. Sweat losses are almost nonexistent and fecal losses are low in newborns, which makes IWL and urine output the major sources of water loss, except for pathologic losses. Controlling the neonatal environment, including the use of radiant warmers, incubators, and ambient humiditiy, can help limit IWL.

Clinical and Laboratory Evaluation

History

Important historical factors include birth weight and gestational age, disease (e.g., respiratory distress, congestive heart failure, hyperbilirubinemia, meningitis, renal failure, gastroschisis), medications (e.g., furosemide, theophylline, indomethacin), fluid and solute therapy, and environmental influences (e.g., phototherapy, open radiant warmers).

Physical Examination

Important physical signs of hydration status include weight increase or decrease and skin turgor. Edema is a sign of overhydration, whereas a sunken fontanelle and loose skin indicate dehydration.

Laboratory Evaluation

The rate of weight gain should be checked regularly and related to a gestational-age normalized growth curve. In addition, electrolyte levels, urine output, and urine specific gravity should be assessed regularly. Normal urine output should average 1 to 3 mL/kg/h. Hypernatremia, a sign of dehydration, is not infrequent in infants who weigh less than 1,000 g because of their high skin permeability and increased IWL. Hyponatremia in the first few days of life more often reflects free water excess rather than inadequate sodium intake.

Differential Diagnosis

The differential diagnosis of fluid and electrolyte abnormalities should always include iatrogenic problems (inappropriate fluid or electrolyte therapy or medication side effect). Depending on the specific electrolyte imbalance, other diagnoses may be entertained, such as hyponatremia (syndrome of inappropriate secretion of antidiuretic hormone [SIADH], heart failure, hyperglycemia), hyperkalemia (congenital adrenal hyperplasia), hypochloremia (Bartter syndrome, cystic fibrosis), and hyperchloremia (dehydration).

Management

The goal of therapy is to restore fluid and electrolyte losses and to maintain a normal balance by calculating an appropriate maintenance intake. General treatment principles are similar to those used in older children (see Chapter 4). Decisions regarding fluid and electrolyte therapy should be made with the specific disease state in mind (e.g., the need for fluid restriction in heart failure or SIADH).

A weight loss of 5% to 12% is expected in the first week after birth and, if not present, suggests probable fluid overload. Fluid management is often more complex in infants who weigh less than 1,000 g at birth; weight measurements and serum electrolyte levels usually need to be obtained frequently during the first few days of life. These small, premature infants may have hypernatremic dehydration as the result of inadequate fluid administration or a symptomatic ductus arteriosus due to fluid overload.

Enteral feedings are usually attempted in newborns as soon as feasible. Maternal breast milk is the best choice for infants of all gestational ages; additional supplements provide needed increased calories, electrolytes, and minerals for premature infants. If breast milk is unavailable or contraindicated, special formulas designed for premature infants are generally appropriate for newborns who weigh less than 1,800 g; these formulas provide higher levels of calories, protein, and minerals. Donor milk banks are also available to provide pasteurized, voluntarily donated human milk for use in premature infants, generally those less than 1,500 g.

Newborns less than 34 weeks' gestational age lack a well-developed suck-and-swallow reflex, thereby necessitating gavage feedings. Newborns who weigh less than 1,000 g may require gavage feedings as often as

every 2 hours or by continuous nasogastric drip. Feeding volumes are generally advanced slowly to avoid feeding intolerance and **necrotizing enterocolitis (NEC)** (see Necrotizing Enterocolitis). The final goal is approximately 120 kcal/kg/day in premature infants and 100 kcal/kg/day in full-term infants.

Infants who do not tolerate optimal nutrition via enteral feedings within several days require **hyperalimentation**. A gradual daily increase in intravenous dextrose concentration of 1 to 2 mg/kg/min is necessary. Infants who weigh less than 1,000 g may not tolerate glucose in excess of 6 mg/kg/min, whereas full-term infants usually tolerate 8 to 10 mg/kg/min without developing hyperglycemia. The goal is to advance intravenous caloric intake to a level sufficient for growth (80 to 100 kcal/kg/day) to match intrauterine growth at a comparable gestational age. It is important to provide adequate protein intake early, especially in premature infants less than 1,500 g at birth, in order to prevent protein catabolism and a deficit. The goal is generally to achieve 3 to 4 mg/kg/day of amino acids as soon as possible in order to match intrauterine protein influx.

RESPIRATORY DISORDERS

RESPIRATORY DISTRESS SYNDROME

Pathophysiology

During fetal development, the lungs pass through a pseudoglandular stage (7 to 17 weeks) and canalicular stage (16 to 25 weeks) and, at about 25 weeks' gestation, enter the terminal sac stage that lasts until term. Alveolarization occurs mostly postnatally, with some alveoli present beginning at 28 weeks. During alveolarization, two major processes take place. First, pulmonary capillaries grow in closer approximation to the epithelium and a much larger gas-exchange surface is created. Second, the epithelial cells differentiate into type I and type II cells. It is the type II cells that produce surfactant. One of the major problems in infants with **respiratory distress syndrome (RDS) (hyaline membrane disease)** is surfactant deficiency, which markedly decreases lung compliance. Diffuse atelectasis results, accompanied by severe **ventilation–perfusion ($\dot{V}$ & Q) mismatch** and increased work of breathing. Despite advances in understanding the pathophysiology of RDS, specifically the role of surfactant, RDS remains the problem that most frequently affects premature infants.

Clinical and Laboratory Evaluation

History

The prevalence of RDS is inversely correlated with gestational age. Cases of RDS are uncommon at 37 weeks' gestation and beyond, whereas more than 70% of infants between 28 and 30 weeks' gestation have RDS. The critical risk factor is the stage of lung maturity at delivery, not the precise gestational age. Among the numerous factors that may delay lung maturity are maternal diabetes, male sex, second born of twins, and Caucasian race. Several conditions may accelerate lung maturity such as IUGR, severe pregnancy-induced hypertension, and maternal glucocorticoid administration.

Physical Examination

Within 6 hours of birth, infants with RDS typically exhibit the following clinical signs: tachypnea, retractions, nasal flaring, grunting, and cyanosis. The prominent retractions result from the compliant rib cage in newborns and the generation of high intrathoracic pressures that are needed to expand the poorly compliant lungs. The typical expiratory grunt, an early feature, is thought to result from partial closure of the glottis during expiration in an attempt to trap air and maintain functional residual capacity. Infants who weigh less than 1,000 g at birth may exhibit fewer of these signs if they are intubated immediately in the delivery room.

Pediatric Pearl: Visual inspection of the abdomen is necessary in infants with significant respiratory distress after birth. If the abdomen is scaphoid, the diagnosis is most likely congenital diaphragmatic hernia.

Laboratory Evaluation

The classic findings of RDS on chest radiograph are low-volume lungs with a **reticulogranular ("ground glass") pattern** and **air bronchograms** (Figure 10-2). It is important to note that RDS cannot be reliably differentiated from neonatal pneumonia by radiographic studies alone.

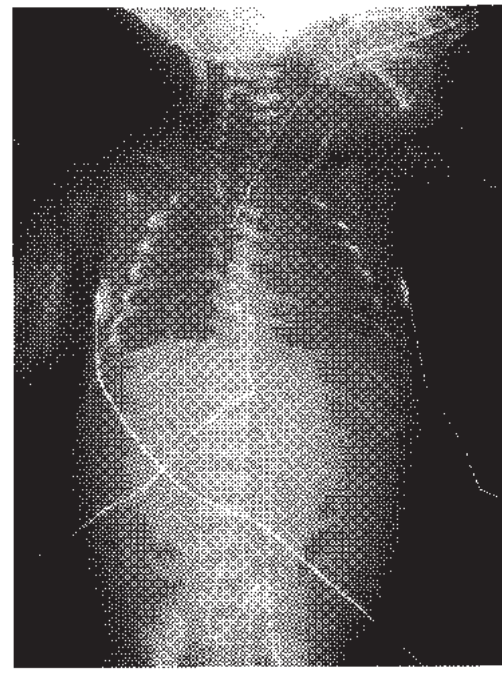

FIGURE 10-2. Chest radiograph of an infant with respiratory distress syndrome. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

Differential Diagnosis

The differential diagnosis of respiratory distress in the newborn period includes **pneumonia** and transient **tachypnea of the newborn (TTN);** for a complete differential diagnosis of neonatal respiratory distress, see Table 10-2. The lungs are the most common site of infection in neonates; infection may be acquired during the prenatal period, at the time of birth, or early in the neonatal period. In neonatal pneumonia, chest radiographs may vary in appearance; unilateral infiltrates or a diffuse pattern with air bronchograms may be seen. Furthermore, infection can lead to premature birth, and there can be both pneumonia/sepsis and RDS simultaneously. The difficulty in differentiating neonatal pneumonia from RDS has led to the frequent use of antibiotics in infants with RDS.

TTN, which tends to occur in term infants, is the delayed reabsorption of fetal lung fluid. It occurs more commonly after a cesarean section because the infant's thorax is not subjected to the same pressures as in a vaginal delivery. The symptoms, which usually last between 12 and 72 hours, consist of tachypnea, grunting, nasal flaring, and cyanosis. Because TTN has many overlapping features with RDS and pneumonia, it often presents a diagnostic dilemma. Chest radiography may be helpful diagnostically because films in TTN can show prominent perihilar streaking and fluid in the interlobar fissures (Figure 10-3).

Management

The central goal of management of RDS is the maintenance of adequate gas exchange to allow for normal tissue function and avoidance of the consequences of hypoxemia and hypercapnia. Routinely used therapies include the following:

- Oxygen supplementation with monitoring of blood gases
- CPAP
- Mechanical ventilation
- Exogenous surfactant replacement

Treatment must be provided in such a way as to minimize potential adverse consequences such as pneumothorax, pneumomediastinum, pulmonary interstitial emphysema (PIE), and lung injury with subsequent development of chronic lung disease (CLD).

MECONIUM ASPIRATION SYNDROME

Pathophysiology

MAS is characterized by staining of the amniotic fluid with meconium in association with respiratory distress. Meconium staining complicates 8% to 20% of all deliveries but is seen in up to 44% of postdates or other high-risk pregnancies. A leading theory of MAS contends that acute and chronic fetal distress lead to meconium passage in utero and then gasping by the fetus or newborn results in aspiration of meconium-stained amniotic fluid into the airway. The exact relationship between meconium staining and fetal distress is still unclear.

The pulmonary problems seen in MAS result from a mixture of complete and partial airway obstruction by the meconium. The completely obstructed areas become atelectatic, whereas the partially obstructed

TABLE 10-2

Neonatal Respiratory Distress

Airway/Pulmonary Anomalies	
Nasal/nasopharyngeal	Choanal atresia

Persistent pulmonary hypertension of the newborn (PPHN)	
Metabolic abnormalities (e.g., acidosis, hypothermia)	
Congestive heart failure	
Central nervous system anomalies	

airways develop a ball-valve effect, leading to air trapping with overexpansion. Air leaks, including pneumothorax, pneumomediastinum, pneumopericardium, and pneumoperitoneum, are often complications of MAS. The presence of meconium in the lungs is also thought to inactivate surfactant, further complicating the airway obstruction with decreased lung compliance. Other possible complications include **persistent pulmonary hypertension of the newborn (PPHN)** (see Persistent Pulmonary Hypertension of the Newborn), particularly in postdates babies.

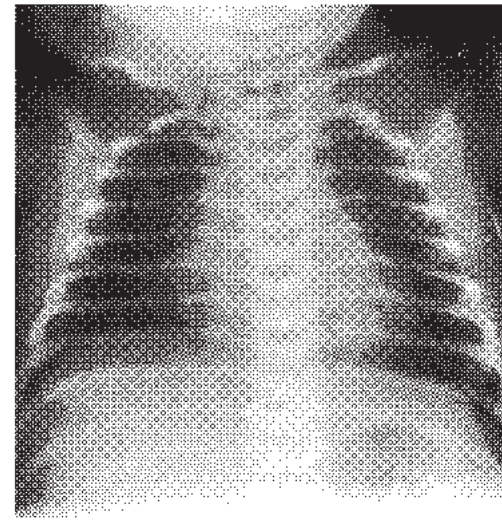

FIGURE 10-3. Chest radiograph of an infant with transient tachypnea of the newborn. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

Clinical and Laboratory Evaluation

History

MAS is most common in infants with a history of postmaturity, fetal distress, and/or meconium staining.

Physical Examination

Common features of MAS are meconium staining of the skin and nails, peeling skin, grunting, nasal flaring, retractions, marked tachypnea, and varying degrees of cyanosis.

Laboratory Evaluation

A chest radiograph should be obtained. Coarse, fluffy infiltrates with alternating areas of lucency are commonly visible (Figure 10-4). Air leak phenomena, such as pneumothorax or pneumomediastinum, and hyperinflation with flattening of the diaphragm are also frequently seen. ABGs identify hypoxemia and hypercarbia.

Differential Diagnosis

Conditions to be considered included blood or amniotic fluid aspiration and pneumonia.

Management

Intubation and suctioning of the trachea after delivery is indicated if the infant is depressed. Despite suctioning, most cases of MAS may not be preventable because of in utero aspiration.

Infants with MAS are at risk for increasing respiratory distress with hypoxemia and hypercarbia, which may also be further complicated by PPHN. The following modes of therapy are used to treat infants with MAS:

- Chest physiotherapy and suctioning
- Transcutaneous oxygen saturation monitoring with use of supplemental oxygen to prevent hypoxemia and hypoxic pulmonary vasoconstriction, which may result in PPHN
- ABG monitoring for prompt recognition and treatment of acidosis, hypoxemia, and hypercarbia
- CPAP or mechanical ventilation to maintain normal oxygenation and ventilation
- Sedation or neuromuscular paralysis for infants on high ventilator settings
- Routine administration of antibiotics due to possible secondary bacterial pneumonia
- Exogenous surfactant administration

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Pathophysiology

PPHN, also historically known as **persistent fetal circulation**, is the combination of pulmonary hypertension and right-to-left shunting of desaturated blood through fetal pathways (a patent foramen ovale [PFO] or a PDA) in a structurally normal heart. This pathologic process is due to a sustained elevation in pulmonary vascular resistance (PVR) after birth. Normally, the PVR falls rapidly after birth with the first breath. In contrast, the systemic vascular resistance (SVR) increases rapidly with cord clamping. These events result in functional closure of the PFO and constriction of the PDA with separation of the pulmonary and systemic circulations (see Chapter 13). When PVR exceeds SVR, right-to-left shunting can occur at the PFO or PDA, resulting in systemic hypoxemia. The elevation in PVR may be idiopathic or secondary to MAS, congenital diaphragmatic hernia, hyperviscosity, sepsis, or other causes. Acute hypoxia and acidosis at birth may cause pulmonary vasoconstriction and an elevation of pulmonary artery pressure.

A morphologic abnormality has also been identified in many infants who die of PPHN. Key features are an increase in the thickness of the media of muscularized arteries and extension of smooth muscle distally into normally nonmuscularized intra-acinar arteries. This abnormality results in a decrease in the cross-sectional area of the pulmonary vascular bed and an increased resistance to pulmonary blood flow. Experts have speculated that chronic hypoxia in utero may cause these vascular changes.

Clinical and Laboratory Evaluation

History

The occurrence of any condition associated with the various secondary causes of PPHN (MAS, sepsis, congenital diaphragmatic hernia, RDS, hyperviscosity) is relevant to formation of a diagnosis. In utero exposure to prostaglandin synthetase inhibitors (aspirin, indomethacin) may cause premature constriction of the PDA and secondary PPHN.

Physical Examination

No pathognomonic findings are encountered in infants with PPHN other than cyanosis, which may vary in severity.

Laboratory Evaluation

Preductal (right arm) and postductal (umbilical artery or leg) ABGs demonstrate a difference in PaO_2 of more than 10 mm Hg when there is right-to-left ductal (PDA) shunting, but this difference is not present when shunting occurs only at the level of the PFO. Two-dimensional echocardiography with color flow Doppler can demonstrate the right-to-left shunting pattern and rule out any structural heart defects (Figure 10-5).

Differential Diagnosis

Pulmonary processes such as RDS, MAS, congenital diaphragmatic hernia, and pneumonia should be considered. Cyanotic CHD (see Chapter 13) should also be ruled out.

Management

The management of PPHN has changed dramatically with recent medical advances. Modes of treatment include the following:

- Prompt correction of hypoxia and acidosis (both potent pulmonary vasoconstrictors) to reverse pulmonary vasospasm
- Supplemental oxygen administered by nasal cannula, hood, or NCPAP
- Intubation and mechanical ventilation if hypoxemia persists
- High-frequency ventilation (often used in term infants with PPHN)
- Volume expansion and/or administration of inotropic agents, such as dopamine, to ensure adequate cardiac output and to raise systemic pressure to counteract right-to-left shunting

For infants who do not respond to these therapies, additional treatment may be necessary. Clinical trials have found that infants with PPHN benefit from surfactant replacement therapy, probably because the initial lung injury has resulted in an inactivation of surfactant. Two large randomized clinical trials demonstrated the efficacy

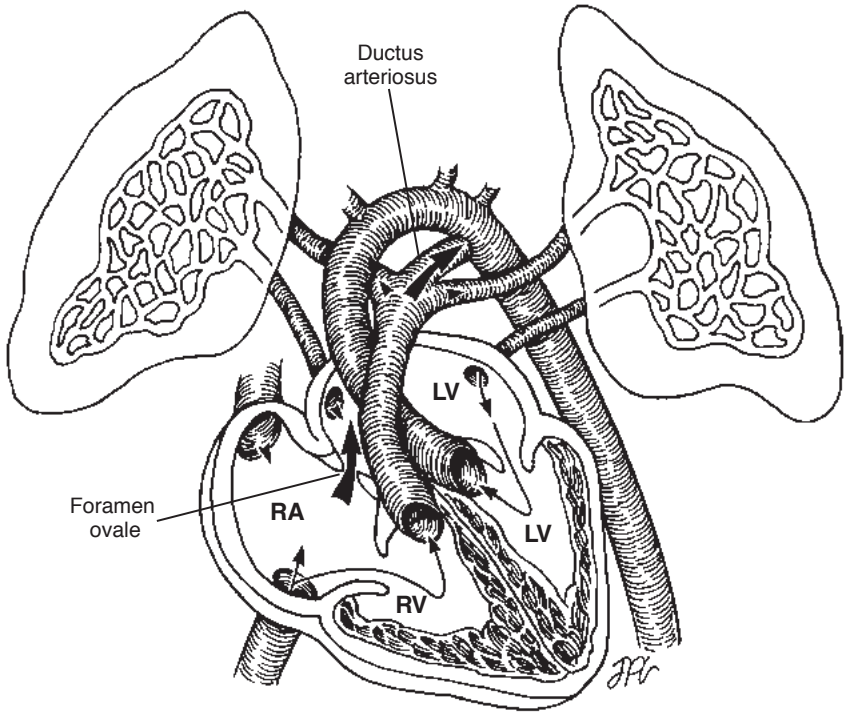

FIGURE 10-5. Right-to-left shunting patterns seen in infants with persistent pulmonary hypertension of the newborn. A shunt at the patent foramen ovale or patent ductus arteriosus may be present. *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

of inhaled nitric oxide in term infants with hypoxic respiratory failure, and, in 1999, the Food and Drug Administration approved this agent for such use. If infants fail to improve with surfactant replacement and inhaled nitric oxide, **extracorporeal membrane oxygenation,** a modified form of heart–lung bypass, continues to be successful in most cases. Intentional hyperventilation to induce marked respiratory alkalosis is no longer warranted, given the risk of lung injury as well as the strong association between this treatment and long-term hearing loss.

BRONCHOPULMONARY DYSPLASIA

Premature infants are diagnosed with **bronchopulmonary dysplasia (BPD) (also referred to as CLD)** if they continue to require oxygen or positive pressure support at 36 weeks gestational age. The incidence of BPD or CLD, which varies among institutions, is approximately 20% to 40% in infants who weigh less than 1,500 g at birth. Although artificial surfactant has reduced the mortality associated with RDS, it has not decreased the incidence of BPD.

Pathophysiology

The pathogenesis of BPD involves multiple etiologic factors, such as immature alveoli, barotrauma resulting from prolonged mechanical ventilation, oxygen toxicity with oxygen radical formation, infection, chronic aspiration caused by gastroesophageal reflux, pulmonary edema resulting from volume overload, and PDA.

Clinical and Laboratory Evaluation

History

Infants commonly have a history that includes prematurity, prolonged mechanical ventilation, the need for high inspired oxygen concentration, infection, and/or PDA.

Physical Examination

Physical findings include tachypnea, retractions, and failure to thrive.

Laboratory Evaluation

In BPD, ABGs commonly indicate mild-to-moderate hypoxemia and hypercarbia. Pulmonary function tests usually denote increased airway resistance and decreased dynamic lung compliance. Abnormalities apparent on chest radiography vary with the stage of BPD: stage I is indistinguishable from early RDS; stage II shows increased opacification; stage III shows bubbly lucencies, streaky densities, and mild hyperinflation; and stage IV is a nonhomogeneous pattern of hyperinflation mixed with dense streaky areas of atelectasis and collapse (Figure 10-6). The severe forms of BPD have been seen less commonly in recent years, and a typical progression is no longer evident.

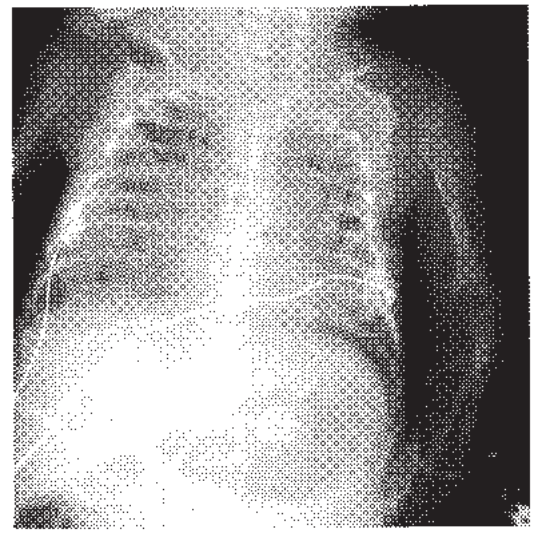

FIGURE 10-6. Chest radiograph of an infant with stage IV bronchopulmonary dysplasia. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

Differential Diagnosis

Diagnosis of BPD is made on the basis of clinical history and a typical radiographic appearance. Similar radiographic features can be seen with chronic pulmonary insufficiency of prematurity, Wilson–Mikity syndrome, PIE, CHD, and recurrent aspiration pneumonia (Figure 10-7).

Management

Just as the etiology of BPD is multifactorial, its treatment is multifaceted. Restriction of fluid intake is necessary until respiratory status has stabilized, although it is important to provide the calories necessary for adequate growth. Growth problems are common in infants with BPD, and intensive nutritional support is critical. Once infants are extubated, supplemental oxygen keeps the PaO_2 between 50 and 80 mm Hg during sleep, feeding, and other activities to avoid pulmonary hypertension and to provide adequate tissue oxygenation. Ventilator adjustments optimize blood gases and minimize the damaging effects of barotrauma and oxygen toxicity.

Pharmacologic management of BPD includes diuretics (e.g., furosemide or chlorothiazide and spironolactone) to treat excessive interstitial lung fluid; bronchodilators (e.g., nebulized albuterol) to reduce airway resistance; electrolyte supplements (e.g., sodium chloride, potassium chloride, ammonium chloride) to treat losses secondary to diuretic therapy; and antioxidants (e.g., vitamin A). Infants with BPD have lower plasma levels of vitamin A, and supplementation has been shown to reduce the incidence and severity of the disease. Corticosteroids have been shown to improve lung function in patients with BPD; however, they also have been associated with neurodevelopmental impairment, so their use should be limited to life-threatening, severe BPD with parental informed consent.

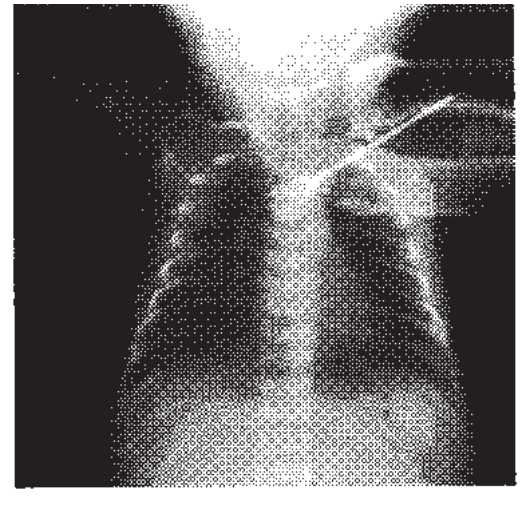

FIGURE 10-7. Chest radiograph of an infant with pulmonary interstitial emphysema. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

APNEA

Pathophysiology

Apnea, defined as the cessation of respiration for more than 10 seconds, occurs frequently in premature infants; the incidence decreases with increasing gestational age. Apnea affects approximately 25% of infants who weigh less than 2,500 g at birth and 84% of newborns who weigh less than 1,000 g. Experts believe that immaturity of central respiratory control is a key factor in the etiology of apnea in prematurity. Carbon dioxide responsiveness reflective of central chemoreceptor activity is not as developed in premature infants. In addition, hypoxia can result

in transient hyperventilation, followed by hypoventilation and apnea. Apnea is more frequent during rapid eye movement and transitional sleep when the respiratory pattern is irregular.

The presence or absence of upper airway obstruction distinguishes the three types of apnea. **Central apnea** (10% to 25% of cases) is characterized by no inspiratory effort; **obstructive apnea** (10% to 20% of cases) by airway obstruction with no nasal airflow; and **mixed apnea** (50% to 70% of cases) by elements of both types. In contrast, **periodic breathing** is defined as recurrent sequences of cessation of breathing of 5 to 10 seconds followed by 10 to 15 seconds of hyperventilation. This breathing pattern is normal in premature infants.

Clinical and Laboratory Evaluation

History

In infants born at more than 34 weeks' gestation, it is important to search for an underlying cause other than prematurity. History of feeding intolerance, vomiting, lethargy, temperature instability, seizures, and maternal history of infection or drug use may indicate an alternate cause of apnea (Figure 10-8).

Physical Examination

Bradycardia and, on occasion, cyanosis frequently accompany apnea. Other features that may be present include tachypnea, respiratory distress, congenital anomalies, or neurologic abnormalities such as lethargy, hypotonia, or jitteriness.

Laboratory Evaluation

Various blood studies (e.g., CBC, electrolytes, calcium, magnesium, glucose, drug toxicology screen) may be useful. Additional tests that may help determine the cause of the apnea include head ultrasound, head computed tomography (CT), genetic consultation, barium swallow or pH probe, and ABG analysis.

Differential Diagnosis

Several conditions may lead to apnea (see Figure 10-8).

Management

Identification of a potential cause of apnea such as hypoxemia, infection, or anemia warrants treatment of the causal condition. Exclusion of other etiologies leads to a diagnosis of idiopathic apnea of prematurity. Methylxanthines (e.g., theophylline and caffeine), the pharmacologic agents most widely used to treat apnea, act on the brainstem, producing central stimulation of respiratory drive. Serum levels of theophylline of 8 to 10 μg/mL and caffeine of 10 to 20 μg/mL are usually therapeutic. Side effects, which are seen with higher levels of theophylline, include tachycardia, irritability, vomiting and other gastrointestinal (GI) signs, and seizures. Apnea that is unresponsive to other therapies may require CPAP or mechanical ventilation.

NEONATAL INFECTIONS

CONGENITAL INFECTIONS

Pathophysiology

Congenital infections may occur any time during pregnancy, labor, and delivery. Transmission may occur through the placenta or may ascend into the amniotic fluid through the vaginal canal. First-trimester infections may affect virtually any of the developing organ systems and often lead to significant **IUGR**. The acronym **TORCH** (**t**oxoplasmosis, **r**ubella, **c**ytomegalovirus [CMV], and **h**erpes simplex) describes only some of the major causes of intrauterine infection; others include **HIV, enterovirus, parvovirus, varicella,** and **syphilis**. Some of these infections, as well as viral hepatitis, may arise from postpartum exposure through skin contact or via breast milk. The risk of peripartum transmission of herpes simplex is greatest with vaginal delivery in a mother with primary, not recurrent, genital herpes.

Clinical and Laboratory Evaluation

History

It is important to review maternal history carefully. Many severe congenital infections occur unexpectedly; they are often associated with mild, nonspecific illness in the pregnant woman. It is routine to screen most pregnant women for antibody titers against rubella and hepatitis B and occasionally for toxoplasmosis. Consumption of raw meat or, less commonly, exposure to cat feces increases the risk of toxoplasmosis. Risk of other congenital infections may have to be inferred. For example, intravenous drug use or history of sexually transmitted diseases increases the risk of viral hepatitis and HIV.

Physical Examination

The effects of congenital infection vary depending on the causative organism and the maternal and fetal hosts. Many affected fetuses are asymptomatic at birth. The most commonly shared sequelae include:

- Growth retardation
- Premature delivery
- Central nervous system (CNS) abnormalities, including microcephaly, intracranial calcifications, and chorioretinitis
- Hepatosplenomegaly, often with accompanying jaundice
- Bruising or petechiae that may accompany thrombocytopenia
- Skin lesions

Infants with congenital viral infections may also present with acute symptomatology such as interstitial pneumonitis, myocarditis, or encephalitis. Clinical findings specific for certain conditions are:

- Congenital rubella syndrome: cataracts, hearing loss, heart lesions, blueberry-muffin spots (palpable skin lesions associated with extramedullary hematopoiesis)
- Congenital herpes simplex: skin, eye, or mouth lesions; more severe systemic symptoms, including seizures or multiorgan system failure, usually occur after the first week of life
- Parvovirus B19: possible fetal marrow suppression associated with hydrops fetalis

Pediatric Pearl: Infants with hepatosplenomegaly and thrombocytopenia should be evaluated for congenital viral infection.

Laboratory Evaluation

The combination of careful review of maternal history with clinical evaluation of the affected newborn is the best guide to the selection of necessary diagnostic studies. Serologic testing is most helpful for rubella, toxoplasmosis, and herpes infections. However, repeat testing may be necessary because increased levels of immunoglobulin G (IgG) may result from passive transfer of maternal IgG or from neonatal production. IgM, which cannot pass through the placenta from mother to fetus, is often a more reliable indicator of true neonatal infection. Urine

cultures are best for demonstrating active CMV infection. Blood, cerebrospinal fluid (CSF), and skin lesion cultures or viral polymerase chain reaction testing are usually diagnostic for herpes and enteroviral infections. Specific electroencephalographic (EEG) changes, often accompanied by characteristic neuroradiographic findings on CT scan or magnetic resonance imaging (MRI), result from herpes encephalitis.

Differential Diagnosis

The differential diagnosis depends on the signs and symptoms at presentation. Growth retardation and multiorgan dysfunction may also signify a genetic syndrome or metabolic disease (see Chapter 11).

Management

Unfortunately, management of congenital infection is usually only supportive (e.g., provision of cardiopulmonary assistance or correction of coagulopathy). However, the following modes of treatment may be useful in specific conditions:

- Neonatal herpes infection: antiviral agents acyclovir and vidarabine to reduce mortality and morbidity
- Toxoplasmosis: a regimen of pyrimethamine, sulfadiazine, and folinic acid (neonates) or spiramycin (infected pregnant women)
- HIV infection: use of zidovudine in prophylactic treatment of HIV-exposed newborns (see Chapter 9)

BACTERIAL INFECTIONS

Pathophysiology

Bacterial infections may be blood-borne, crossing the placenta, or may ascend the vaginal canal, especially after **prolonged rupture of membranes**. The specific pathogen involved depends on maternal colonization. The agents that cause the most common neonatal bacterial infections are group B streptococcus, which colonizes the vagina or cervix of 15% to 25% of pregnant women; *Escherichia coli; Staphylococcus aureus;* and *Listeria monocytogenes*. Attack rates vary considerably over time and by geographic area. Other bacterial pathogens (e.g., coagulase-negative staphylococcus, *Klebsiella*, and *Serratia*) are more often associated with nosocomial (hospital-derived) infection, for which premature infants, with their relatively impaired immune function, are at higher risk.

Clinical and Laboratory Evaluation

History

It is important to obtain a complete obstetric history; maternal risk factors for neonatal bacterial sepsis include GBS colonization, prolonged or premature rupture of membranes associated with labor, chorioamnionitis, and urinary tract infection. Intrapartum evidence of infection includes otherwise unexplained fetal tachycardia, meconium staining of the amniotic fluid, maternal fever, and perinatal depression. Risk of nosocomial infection increases with extreme prematurity, hyperalimentation administration, prolonged intravascular access, and surgical procedures.

Physical Examination

Septic neonates may initially be asymptomatic, may present later with subtle findings, or may rapidly progress to cardiopulmonary shock. Early findings associated with bacterial infection include temperature instability (more often hypothermia than hyperthermia), tachypnea, labored respirations, and feeding intolerance. Physical findings may include lethargy or irritability, rales if there is an accompanying pneumonia, jaundice, or decreased perfusion. Other dermatologic findings such as petechiae or purpura occur rarely. Because respiratory symptoms are the most common presenting sign of neonatal sepsis, evaluation and treatment for this is imperative for neonates with respiratory distress even with other potential explanations, for example, prematurity and MAS.

Laboratory Evaluation

The approach to laboratory evaluation for potential bacterial sepsis is not standardized, and interpretation of laboratory data may depend on clinical evaluation. A positive blood culture confirms the diagnosis, but a negative blood culture does not rule it out. Small sample volume, the degree of bacteremia, or the inhibition of bacterial growth by antepartum maternal antibiotic administration may cause a negative culture result. White blood

cell counts may be either lowered or elevated in infected infants, with an increase in the percentage of immature lymphocytes, thrombocytopenia, or abnormal inclusion bodies.

Other tests may prove useful. Chest radiography may show evidence of an accompanying pneumonia. Lumbar puncture evaluates for meningitis. Urinalysis and culture are usually reserved for the evaluation of sepsis that occurs several days after birth because urinary tract infections soon after birth are usually hematogenous in origin and not necessarily a reflection of abnormal urinary structure or function. Antigen detection tests of serum, urine, and CSF lack the sensitivity and specificity to diagnosis neonatal sepsis accurately. Measurement of acute-phase reactants such as C-reactive protein may be useful in both ruling out neonatal sepsis and in helping determine the duration of antibiotic therapy.

Differential Diagnosis

The signs and symptoms of bacterial infection are relatively nonspecific. Viral or fungal infection (most commonly ***Candida***), often accompanied by cardiovascular instability, may also occur in neonates. In addition, cardiorespiratory or metabolic disease may manifest with systemic signs similar to infection.

Management

Often, a high degree of suspicion of infection is sufficient to lead to initiation of empiric antibiotic administration without a confirmatory positive blood culture. Therapy is usually started with two drugs: ampicillin (for possible *Listeria*) and an aminoglycoside (e.g., gentamicin) or a cephalosporin. In cases of nosocomial infection, broader spectrum coverage (vancomycin and a cephalosporin) against more resistant organisms, including coagulase-negative staphylococcus, may be needed. Results of culture and sensitivity tests may later alter the antibiotic choice.

Septic neonates may require significant intensive care support, including intravenous fluid therapy, respiratory support with supplemental oxygen and mechanical ventilation, and cardiovascular support with intravascular colloid volume or cardiopressor drugs such as dopamine. Transfusions of granulocytes, colony stimulating factor, or intravenous immunoglobin have not been proven to reduce mortality or morbidity in neonatal sepsis.

Pediatric Pearl: Infants diagnosed with *E. coli* sepsis should also be evaluated for galactosemia.

HYPERBILIRUBINEMIA

Pathophysiology

Approximately 50% of neonates have visible jaundice. It is necessary to understand bilirubin metabolism to distinguish "physiologic" from "pathologic" jaundice. Bilirubin is a degradation product of hemoglobin and, to a lesser extent, of myoglobin and other "non-heme" proteins. In newborns, the hemoglobin concentration is relatively high (15 to 18 g/100 mL), and any bruising from birth trauma or other sites of hemorrhage may exacerbate the expected baseline level of hemolysis. Markedly increased erythrocyte destruction leading to elevated bilirubin production may result from Rh or ABO isoimmunization, structural (e.g., hereditary spherocytosis) or metabolic (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency) erythrocyte defects, or infection.

Bilirubin occurs in two forms: **unconjugated** or **indirect**, most of which is bound to serum albumin; and **conjugated** or **direct**, which usually has one or two glucuronides. The enzyme **glucuronyl transferase** catalyzes bilirubin conjugation in the liver. Glucuronyl transferase activity is low at birth and increases to adult levels in the ensuing days to weeks; prematurity delays this maturation. Conjugated bilirubin is more soluble and excretable in the bile and urine. Bilirubin may also be reabsorbed from the intestines in a process known as **enterohepatic recirculation**. Critically ill newborns often have decreased intestinal motility or may not be receiving enteral feeds, which leads to higher levels of serum bilirubin via increased enterohepatic recirculation, which can be exacerbated by inadequate breastfeeding.

Excessive serum unconjugated bilirubin may lead to **bilirubin encephalopathy** or **kernicterus**. In this condition, yellow staining of the pons, basal ganglia, and other cerebellar structures is associated with permanent

neurologic injury. Conjugated bilirubin does not cross the blood–brain barrier and is therefore not associated with neurologic injury.

Clinical and Laboratory Evaluation

History

Historical factors may be important in the diagnosis and treatment of hyperbilirubinemia. This condition may be associated with prematurity, sepsis, ethnicity (more prevalent in Asian and Native American populations), poor enteral intake, dehydration, and inadequate breastfeeding.

Physical Examination

Serum bilirubin levels need be only 3 to 5 mg/dL to cause visible jaundice. The extent of jaundice roughly correlates with the severity of hyperbilirubinemia, with mild hyperbilirubinemia most noticeable in the face and sclerae, and with severe hyperbilirubinemia causing a deeper yellow hue throughout the body. Phototherapy removes bilirubin from the skin and thus impairs the ability to estimate serum bilirubin levels by exam.

Initial signs and symptoms of kernicterus include altered cry, seizures, obtundation, and opisthotonic (arched back) posturing. The long-term effects of kernicterus include the choreoathetoid form of cerebral palsy, mental retardation, high-tone hearing loss, and gaze palsy.

Laboratory Evaluation

The benchmark measures of hyperbilirubinemia are serum levels of total and direct bilirubin. When direct bilirubin is greater than 1.5 mg/dL and more than 10% of the total bilirubin, a patient is said to have conjugated hyperbilirubinemia. End-tidal carbon monoxide (CO) monitors have been used to measure exhaled CO, which correlates with the degree of hemolysis because hemoglobin degrades into bilirubin and CO on an equimolar basis. Transcuteanous bilirubinometers are being used more frequently to screen a wider population of newborns.

At any given level of hyperbilirubinemia, ABG analysis for acidosis and serum albumin measurement may help identify neonates at higher risk of brain injury. MRI of the brains of kernicteric patients may demonstrate characteristic changes in the basal ganglia and hippocampus.

A possible hemolytic etiology of hyperbilirubinemia is evaluated by comparing maternal and infant blood and Rh types, Coombs test, and reticulocyte count. Additional laboratory studies may be indicated to rule out other etiologies, including sepsis, hepatic disorders, and metabolic diseases (e.g., G6PD deficiency).

Differential Diagnosis

The differential diagnosis of unconjugated hyperbilirubinemia is extensive (Table 10-3). Several other diseases may cause conjugated hyperbilirubinemia, including extrahepatic biliary obstruction and intrahepatic cholestasis associated with infections, metabolic disorders, or hyperalimentation.

Management

Controversy exists about when to initiate therapeutic measures to lower serum bilirubin because permanent neurologic injury depends on more than serum bilirubin level alone. Serum bilirubin levels of greater than 20 mg/dL in conjunction with significant hemolysis have been found to be associated with kernicterus. Recent data suggest that otherwise healthy term infants may tolerate bilirubin levels up to 25 mg/dL with little, if any, risk of permanent neurologic injury.

Phototherapy, which induces isomerization of bilirubin to a more soluble form that is excreted in the urine, has been the mainstay of treatment. **Double-volume exchange transfusion** is reserved for higher levels of bilirubin, because of the attendant risks of catheter placement such as infection and embolic phenomena. Nomograms of normative bilirubin values over time are available for term and near-term newborns to help predict which patients may reach levels that might require phototherapy or exchange transfusion. For premature infants, phototherapy and/or exchange transfusion are generally undertaken at lower levels.

Other modes of therapy may be effective. Phenobarbital is sometimes used because it enhances bilirubin excretion from the liver, although it takes several days to induce the enzyme system. Recently, trials of metalloporphyrins have demonstrated that these agents decrease bilirubin production by competition for heme oxygenase, which catalyzes the first step in the breakdown of hemoglobin into bilirubin.

TABLE 10-3

Differential Diagnosis of Unconjugated Hyperbilirubinemia

Physiologic jaundice
Breast milk jaundice
Hemolytic anemia
• Congenital: hereditary spherocytosis, G6PD deficiency, pyruvate kinase deficiency, galactosemia, hemoglobinopathies • Acquired: Rh or ABO incompatibility, infection, drugs (e.g., vitamin K)
Polycythemia: chronic fetal hypoxia, maternal–fetal or twin–twin transfusion, delayed cord clamping, maternal diabetes mellitus
Hematoma or hemorrhage: birth trauma, pulmonary hemorrhage, intraventricular hemorrhage
Glucuronyl transferase defect
• Congenital: type I (Crigler-Najjar syndrome), type II deficiency, Gilbert syndrome • Acquired: drugs (e.g., novobiocin), Lucey-Driscoll syndrome
Metabolic disorders: galactosemia, hypothyroidism, maternal diabetes mellitus
Increased enterohepatic circulation: intestinal obstruction, ileus, swallowed blood
Alterations of bilirubin-albumin binding: aspirin, sulfonamides, acidosis

G6PD, glucose-6-phosphate dehydrogenase.

HEMATOLOGIC DISORDERS

ANEMIA (SEE CHAPTER 16)

Pathophysiology

Several changes in red blood cell (RBC) mass occur during the neonatal period. **Fetal hemoglobin,** which makes up 70% to 90% of hemoglobin at birth, binds oxygen more tightly, resulting in a shift of the hemoglobin–oxygen dissociation curve to the left in Figure 10-9. This shift benefits the fetus in utero by facilitating oxygen exchange from maternal to fetal RBCs. However, this feature proves disadvantageous to newborns because release to the tissues is impaired. In utero fetal oxygen saturation is approximately 65%, resulting in high levels of erythropoietin, reticulocyte counts of 3% to 7%, and steadily rising hemoglobin levels that reach a mean of 17.5 g/dL at term. After birth, with oxygen saturation in excess of 95%, erythropoietin levels and reticulocyte counts fall dramatically. The hemoglobin level increases slightly after birth as the result of hemoconcentration, usually returning to birth levels at 1 week and then progressively falling. The postnatal decline is due to the suppression of erythropoietin and expansion of the blood volume.

The usual **physiologic anemia of infancy** occurs in full-term infants at 2 to 3 months with hemoglobin levels of approximately 9 g/dL. In premature infants, the nadir occurs earlier (at 4 to 7 weeks) and is lower (7 to 8 g/dL). This anemia of prematurity is an exaggeration of the normal physiologic anemia resulting from a smaller RBC mass at birth, shortened RBC survival, more significant blood volume increase caused by growth, and, often, frequent phlebotomy for laboratory analysis. Consumption of iron stores during this period is rapid, and without supplementation, iron deficiency anemia will result.

Clinical and Laboratory Evaluation

History

It is necessary to obtain a complete obstetric history (e.g., for abruptio placentae or cord rupture), a family history (e.g., for anemia, jaundice, gallstones, splenectomy), as well as consider a history of blood loss, hemolysis, or frequent phlebotomy.

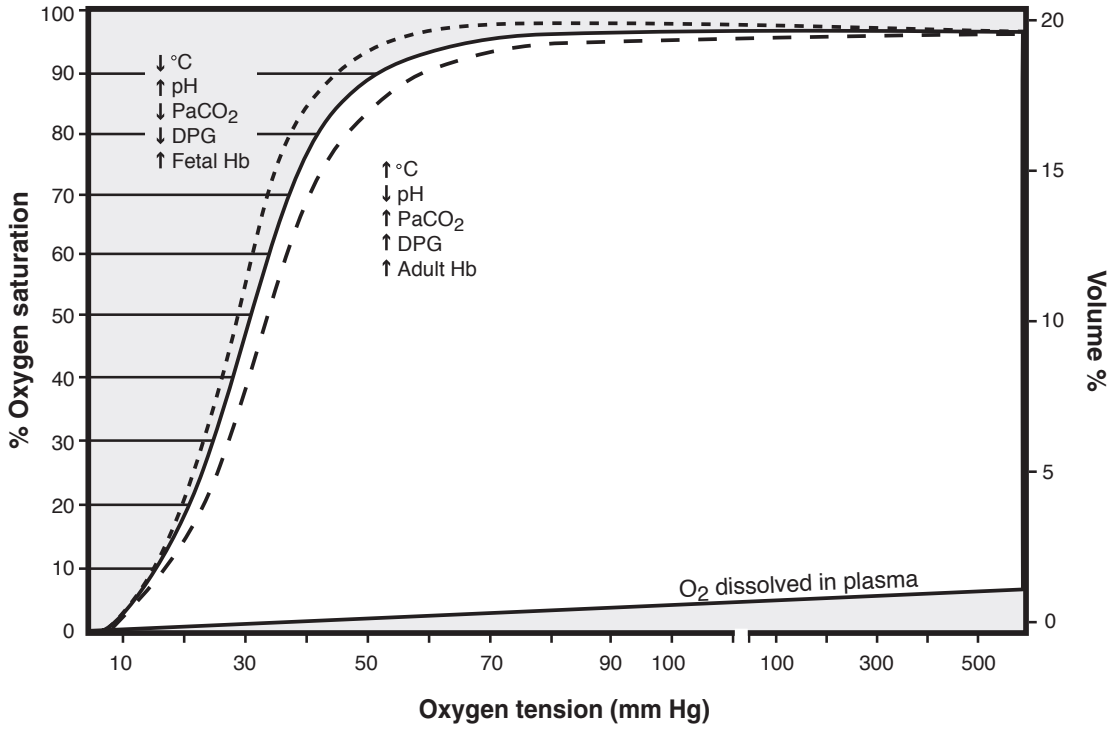

FIGURE 10-9. The oxygen dissociation curve of hemoglobin, which reflects the affinity of hemoglobin for oxygen. With a shift to the left, the affinity for oxygen increases, and less oxygen is released to the tissues. With a shift to the right, the opposite effect occurs. *DPG*, diphosphoglycerate; *Hb*, hemoglobin.

Physical Examination

Physical findings include pallor, tachycardia, tachypnea, hepatosplenomegaly, hypotension, and poor perfusion.

Laboratory Evaluation

A CBC, reticulocyte count, blood smear, Coombs test, bilirubin, Apt test, and Kleihauer-Betke test may be useful. In addition, ultrasound of the abdomen and head may identify sources of blood loss.

Differential Diagnosis

The causes of anemia include blood loss, hemolysis, and reductions in production of blood cells (Table 10-4).

Management

Specific indications for RBC transfusion depend on assessment of an infant's current physiologic status. Replacement of blood lost acutely is generally necessary, whereas replacement of blood drawn for laboratory evaluations is not required. Transfusions consisting of packed RBCs with a hematocrit of 60% to 70% are given in aliquots; 10 to 20 mL/kg is generally tolerated without symptoms of cardiovascular overload. Packed RBC transfusion may be necessary for infants with significant cardiorespiratory compromise, who may need higher hematocrits to optimize oxygen delivery. Promotion of more restrictive transfusion practices for premature infants reduces blood product exposure without any demonstrated evidence of compromising clinical outcomes.

POLYCYTHEMIA

Pathophysiology

Polycythemia is defined as a venous hemoglobin exceeding 20 g/dL or a hematocrit of over 65%. As the central hematocrit rises above 65%, blood viscosity increases exponentially, and capillary blood flow is reduced. Infarction and thrombosis may occur in the brain, lungs, intestines, or other organs. The causes of polycythemia

TABLE 10-4

Differential Diagnosis of Anemia

Blood Loss
• **Obstetric causes**
Abruptio placentae or placenta previa Cord rupture or hematoma Fetomaternal or fetoplacental bleeding Twin–twin transfusion Anomalous vessels (e.g., vasa previa, velamentous insertion)
• **Neonatal causes**
Iatrogenic (e.g., phlebotomy, surgical bleeding) Intracranial bleeding Cephalohematoma Gastrointestinal hemorrhage Rupture of liver or spleen
Hemolysis
• **Immune**
Rh, ABO, or minor blood group incompatibility Maternal autoimmune disease Drug-induced hemolysis
• **Nonimmune**
Hereditary RBC disorders RBC membrane defects (e.g., spherocytosis, elliptocytosis) Metabolic defects (e.g., G6PD, pyruvate kinase) Hemoglobinopathies
Infection Disseminated intravascular coagulation Vitamin E deficiency Microangiopathic hemolytic anemia (e.g., cavernous hemangioma)
Diminished Production of RBCs
Anemia of prematurity
Diamond–Blackfan syndrome
Congenital leukemia
Viral infections
Osteopetrosis

G6PD, glucose-6-phosphate dehydrogenase; *RBC*, red blood cell.

include increased erythropoietin in response to tissue hypoxia (e.g., asphyxia) and increased blood volume (e.g., twin–twin transfusion).

Clinical and Laboratory Evaluation

History

Historical factors are important in the diagnosis and treatment of polycythemia. Infants at risk for polycythemia include infants of diabetic mothers, SGA infants, recipients of in utero twin–twin transfusions, and infants with

delayed cord clamping. Polycythemia may result in feeding problems, NEC, hypoglycemia, seizures, renal vein thrombosis, and cerebral infarcts.

Physical Examination

Most infants with polycythemia are asymptomatic. However, tachypnea, congestive heart failure, cyanosis, plethora, jitteriness, hypotonia, lethargy, or jaundice are sometimes evident.

Laboratory Evaluation

A central venous hematocrit greater than 65% or hemoglobin greater than 20 g/dL is indicative of polycythemia.

Management

A partial exchange transfusion is performed to replace blood with crystalloid or colloid. The treatment is simple, but the timing of implementation is controversial. In general, treatment is performed in symptomatic infants with hematocrits greater than 65% and in asymptomatic infants with hematocrits greater than 70%. Intravenous hydration may be given to asymptomatic infants with hematocrits between 60% and 70%.

THROMBOCYTOPENIA

Pathophysiology

Thrombocytopenia is defined as a platelet count of less than 150,000/mm^3. The steady-state level of platelets in the blood reflects a balance between production and destruction. Platelet production can be evaluated by looking at the megakaryocytes in the bone marrow, whereas platelet destruction is studied by isotope labeling or by following the platelet count over time. Large platelets seen in the peripheral smear are indicative of increased destruction with young, larger platelets coming from the bone marrow.

Clinical and Laboratory Evaluation

History

Maternal history may be useful. A history of maternal thrombocytopenia, splenectomy, autoimmune disease, drug use, or infection may explain the neonatal thrombocytopenia.

Physical Examination

Physical findings may include petechiae, bruises, hepatosplenomegaly, jaundice, and congenital anomalies.

Laboratory Evaluation

The maternal platelet count should be checked. A low maternal platelet count suggests autoimmune thrombocytopenia or idiopathic thrombocytopenic purpura. If normal, platelet typing of the parents is indicated to diagnose neonatal alloimmune thrombocytopenia. A CBC, platelet count, prothrombin time, partial thromboplastin time, fibrinogen, and D-dimer are warranted in the infant.

Differential Diagnosis

The differential diagnosis of thrombocytopenia involves decreased platelet production, increased platelet destruction, and disorders of platelet function (Table 10-5).

Management

In general, platelet transfusions are appropriate for clinical bleeding and for infants at risk for complications such as **intraventricular hemorrhage (IVH)**. The exact platelet count at which prophylactic platelet transfusions are given is controversial and depends on several clinical variables (e.g., gestation age, severity of illness). Intravenous gammaglobulin may be used to mitigate immune-mediated thrombocytopenia. Treatment also depends on the specific cause of the thrombocytopenia.

TABLE 10-5

Differential Diagnosis of Thrombocytopenia

Decreased Platelet Production
Absent radii syndrome
Congenital cytomegalovirus and rubella
Trisomy 13 and 18
Methylmalonic aciduria, isovaleric acidemia, ketotic hyperglycinemia
Bone marrow infiltration (osteopetrosis, leukemia, histiocytosis, tumors)
Megaloblastic anemia (folate or vitamin B12 deficiency)
Wiskott–Aldrich syndrome
Increased Platelet Destruction
• **Immune**
Autoimmune (induction of platelet antibodies by maternal platelets) Maternal idiopathic thrombocytopenic purpura Maternal autoimmune disease Drug-induced (digoxin, chlorothiazide, quinidine)
• **Isoimmune** (induction of platelet antibodies, usually against platelet antigen PIA1)
• **Nonimmune**
Incidental maternal thrombocytopenia Peripheral consumption Disseminated intravascular coagulation Kasabach-Merritt syndrome Sepsis Drug injury (e.g., thiazides, hydralazine, aspirin) Hypersplenism (congenital hepatitis, congenital viral infection)
Disorders of Platelet Function
Bernard-Soulier syndrome
Gray platelet syndrome
May-Hegglin anomaly
Other Conditions
Thrombocytopenia after exchange transfusion or multiple transfusions

NEUROLOGIC DISORDERS

INTRAVENTRICULAR HEMORRHAGE

Pathophysiology

IVH usually starts in the **subependymal germinal matrix**. Bleeding may then extend within the ventricles to the **posterior fossa,** which may lead to **obliterative arachnoiditis** and **obstructive hydrocephalus**.

Autopsies of neonates as well as animal models have served as the basis of the neuropathology of IVH. About 15% of patients with IVH have a parenchymal lesion (i.e., hemorrhagic necrosis in periventricular white matter). Two-thirds of IVHs are unilateral; most of the remainder are asymmetric when they are bilateral.

IVH is classified using the Papile system as follows: grade 1, subependymal/germinal matrix bleed; grade 2, intraventricular bleed; grade 3, intraventricular bleed with ventriculomegaly; and grade 4, parenchymal hemorrhage.

The etiology of IVH is complex. Experts believe that IVH is not an extension of subependymal hemorrhage but rather a subsequent hemorrhagic venous infarction. Other possible etiologies or exacerbating factors include local potassium concentration, increased intraventricular pressure, and lactic acidosis. **Intravascular factors** implicated in the development of IVH include fluctuating cerebral blood flow, increased cerebral venous pressure, and platelet and coagulation factors (probably not very significant in most cases of IVH, although they may exacerbate any bleeding that is present). **Vascular factors** associated with IVH include tenuous capillary integrity and vulnerability to hypoxic-ischemic injury. **Extravascular factors** that affect IVH include deficient vascular support, fibrinolytic activity, and postnatal decrease in tissue pressure.

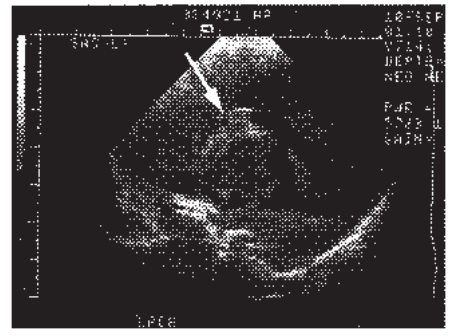

FIGURE 10-10. Head ultrasound showing a grade 3 intraventricular hemorrhage. The arrow indicates the location of the hemorrhage within a dilated left lateral ventricle. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

Long-term morbidity associated with IVH is quite variable. Minimal, if any, handicap is usually found with grade 1 and 2 bleeds. Grade 3 and 4 hemorrhages are associated with a 50% to 100% incidence of motor and mental deficits, including hydrocephalus, cerebral palsy, retardation, and seizure disorders. Neonates with severe IVH involving parenchymal hemorrhage often do not survive. In one study, 40% of infants with localized grade 4 IVH died, and 80% with extensive grade 4 bleeds succumbed. Bilateral lesions generally have a worse prognosis than unilateral.

Clinical and Laboratory Evaluation

History

IVH correlates most significantly with prematurity. In premature infants whose birth weight is less than 1,500 g, the incidence of all types of IVH is approximately 25%. Grade 3 and grade 4 diseases occur in about 10% of patients. Cardiorespiratory instability and, to a lesser extent, coagulopathy are also associated with a higher risk of IVH.

Physical Examination

Physical findings include cardiorespiratory instability, metabolic acidosis, hematocrit decline, a tense anterior fontanelle, and a change in neurologic status. Because these findings are neither very specific nor sensitive indicators of IVH, diagnosis requires neuroradiographic confirmation.

Laboratory Evaluation

Cranial ultrasonography is the most widely used neuroradiographic study for the detection of IVH (Figure 10-10). Descriptors of the laterality and magnitude of the IVH are also useful. Head CT and MRI can also be used diagnostically.

Differential Diagnosis

Other neuropathologies that occur in premature infants may accompany IVH or may develop independently. These include periventricular leukomalacia, a symmetric, nonhemorrhagic, ischemic white matter injury with a predilection for periventricular arterial border zones, as well as pontine neuronal necrosis, which is seen in as many as 50% of patients with IVH and is also associated with hypoxic-ischemic insult.

Pediatric Pearl: Newborn infants with seizures should be evaluated with a head CT or MRI to rule out congenital anomalies, hemorrhage, or infarct.

Management

Prevention of premature birth is the prenatal intervention most likely to decrease the incidence of IVH. Maternal transport to a center equipped for high-risk obstetrics and neonatology prior to premature delivery

may also decrease the likelihood of IVH by provision of optimal labor, delivery, and resuscitation. Recently, studies have found that administration of antenatal steroids to mothers delivering prematurely reduces the incidence and severity of IVH. Other drugs that have been studied to prevent development of IVH in premature at-risk neonates include phenobarbital, indomethacin, ethamsylate (a prostaglandin synthesis inhibitor), and vitamin E. Indomethacin has been used prophylactically to decrease IVH, but has not been shown to improve long-term outcome.

HYPOXIC-ISCHEMIC INJURY

Pathophysiology

Inadequate blood flow or oxygen delivery to the brain may cause **hypoxic-ischemic encephalopathy (HIE),** a clinical term preferable to the less specific "**perinatal asphyxia**." Prenatal origins of this hypoxia/ischemia may be maternal, placental, or fetal (Table 10-6). Hypoxic-ischemic injury may also develop any time after birth; for example, it may result from the cardiorespiratory insufficiency that may be seen in severe lung immaturity or with sepsis.

The extent and permanence of brain injury depend on the magnitude and duration of hypoxia and ischemia, as well as host factors such as the degree of prematurity. Partial asphyxia can lead to brain swelling and edema; necrosis of the cerebral cortex, basal ganglia, and thalamus; and alteration of the blood-brain barrier. Total asphyxia is more typically associated with damage to the brainstem and thalamic nuclei. The differentiation between these two modes of injury is not as well-defined clinically as it is in animal models.

Cerebral blood flow is normally autoregulated, with an increase in flow seen with elevation of PCO_2, with acidosis, or with decreased PO_2. Loss of cerebral blood flow autoregulation may lead to concomitant IVH. Recently, studies have found that extracellular glutamate is elevated after hypoxia and is associated with neuronal toxicity that can be ameliorated by specific chemical blockers to the membrane channels leading to glutamate release. Usually only a minority of the injury occurs immediately secondary to acute

TABLE 10-6

Causes of Hypoxic-Ischemic Encephalopathy

Maternal Causes
• Decreased maternal PO_2 (from heart or lung disease)
• Decreased uteroplacental blood flow (seen in hypotension)
• Hypertensive disease with vasospasm
• Uterine abnormalities
Placental Abnormalities
• Placenta previa
• Vasa previa
• Abruptio placentae
• Cord abnormalities Prolapse Compression Knot formation (may deprive fetus of adequate blood and oxygen)
Fetal Origins
• Hemolysis (e.g., from Rh incompatibility)
• Fetal–maternal transfusion
• Twin–twin transfusion

necrosis. The bulk of the CNS injury usually begins with reperfusion and is secondary to apoptotic changes (programmed cell death) over days to weeks; metabolic changes are detectable by magnetic resonance spectroscopy for weeks to months.

Clinical and Laboratory Evaluation

History

Review of the obstetrical history, particularly potential causes of IUGR, helps identify maternal or placental risk factors for hypoxia and ischemia. Cord pH and fetal heart tracings may also reflect the acidosis that can accompany hypoxia and ischemia.

Physical Examination

Three stages of HIE in neonates have been described: stage 1, mild irritability and hypertonia, usually associated with good outcome; stage 2, hypotonia and sometimes seizures, associated with variable long-term neurologic deficits; and stage 3, prolonged stupor and coma, usually leading to severe permanent neurologic injury. Classification of all HIE-affected newborns is not always straightforward because of individual variation in response to hypoxia and ischemia.

The neurologic examination may be limited or altered by other neonatal diseases or their treatment. Other organ systems are also frequently affected by hypoxic-ischemic insults:

- The kidneys, resulting in oliguria, proteinuria, and hematuria;
- The heart, resulting in tricuspid regurgitation and ventricular dysfunction;
- The lungs, resulting in pulmonary hypertension and impairment of function;
- The intestines, resulting in ileus or disruption of the brush border enzymes; and
- The bone marrow, resulting in thrombocytopenia.

Laboratory Evaluation

Several laboratory studies may provide useful information. A lumbar puncture and CSF analysis should rule out an infectious neurologic insult; bloody CSF may suggest an intracranial hemorrhage. Cranial ultrasound may show decreased ventricular size that may accompany the cerebral edema following an acute insult and can rule out associated IVH. In HIE, CT scanning and MRI imaging yield more information; cerebral edema, changes in gray-white differentiation, hemorrhage, and infarcts reflect acute changes. Focal or global atrophy are signs of the more chronic sequelae of HIE. EEG is quite useful in following patients with the disease. Abnormalities range from decreased amplitude with excessive sharp waves, to frank seizures, and finally to the most ominous patterns of burst-suppression or a flat, isoelectric tracing. Cerebral function monitoring utilizing continuous compressed and filtered EEG, known as amplitude-integrated EEG, has been increasingly used in neonates to assess neurologic injury.

Differential Diagnosis

Other neonatal neurologic insults may arise from congenital or neonatal infections, vascular accidents (e.g., subarachnoid hemorrhage), chromosomal or other genetic syndromes, maternal or neonatal drug exposure, and metabolic diseases.

Management

The best management strategy for HIE is prevention of hypoxic and ischemic stresses whenever possible. General supportive care ensures good cardiopulmonary function, glucose and electrolyte balance, and adequate renal function. Anticonvulsant therapy may begin prophylactically or after appreciation of seizures; phenobarbital, benzodiazepines, and fosphenytoin are the drugs of choice. Postinsult strategies once thought to decrease cerebral edema such as head elevation, hyperventilation, fluid restriction, and mannitol or other diuretic use have no proven benefit. Hypothermia, either systemic or localized with a head cooling device, has been shown in prospective, randomized, controlled trials to ameliorate CNS injury and improve prognosis. Other experimental therapies under consideration include erythropoietin, calcium channel blockers, N-methyl-D-aspartate antagonists (e.g., dextromethorphan), iron chelators (e.g., deferoxamine), and inhaled xenon.

DRUG EXPOSURE

Pathophysiology

Maternal drug exposure may lead to neurologic insult by any of several mechanisms. Drugs such as alcohol may have a direct teratogenic effect as seen in **fetal alcohol spectrum disorder (FASD)**, in which subtle interruption of facial development can occur, especially in the first trimester. **Cocaine** directly affects the fetus through interference with dopamine and norepinephrine uptake at the postsynaptic junction. This neurologic toxicity may not be reversible by cessation of cocaine use. Cocaine may also indirectly influence the fetus through uteroplacental and fetal vasoconstriction and hypoxia; these effects include premature birth, growth retardation, microcephaly, and neurologic insults from infarcts during development. Opiates (e.g., **heroin, methadone**) presumably alter opiate receptors associated with endorphin and enkephalin production. Any of these insults may be complicated by the socioeconomic and lifestyle problems that accompany drug abuse and that increase the likelihood of malnutrition, poor fetal growth, and sexually transmitted infections.

Pediatric Pearl: Infants born after a placental abruption should be evaluated for intrauterine drug exposure. Cocaine is a known cause of uterine vascular changes that increase the risk of abruptio placentae.

Clinical and Laboratory Evaluation

History

Maternal history is quite unreliable as a measure of recreational drug use. However, a nonthreatening manner on the part of the physician encourages self-reporting. The clinician may infer suspicion of drug use from behavior such as delayed or absent prenatal care. Unexplained placental abruption may raise the possibility of maternal cocaine use.

Physical Examination

Prematurity or SGA status may be the only sign of maternal drug use. Craniofacial anomalies, including hypoplastic philtrum, thin upper lip, decreased nose-to-midface length ratio, short palpebral fissures, and a flattened maxillary region, are primarily associated with FASD, although these findings may be less obvious in the neonatal period. Cardiac, renal, GI, and limb anomalies may also be linked to this condition. Mild facial dysmorphism or microcephaly, as well as limb reduction defects and urinary tract anomalies, may result from cocaine use.

Laboratory Evaluation

Maternal and neonatal drug screening offers insight into only relatively recent maternal drug abuse. Unfortunately, permanent injury from drugs may have occurred months before cessation of the drug habit. Toxicology studies from meconium or hair samples are more likely to demonstrate the presence of drugs even several weeks after last use.

Repeated observation by health care providers using an objective, quantifiable scoring system is the best method for the diagnosis of neonatal abstinence or withdrawal syndrome. Common signs and symptoms of withdrawal may be neurologic, including irritability or seizures; GI, including poor feeding, vomiting, and diarrhea; respiratory; and autonomic, such as altered cry, sneezing, and sweating.

Differential Diagnosis

The signs and symptoms of drug exposure or withdrawal are nonspecific. Neurologic symptoms such as jitteriness or seizures may arise from infectious or metabolic disease. GI symptoms that mimic narcotic withdrawal may also result from anatomic or infectious causes.

Management

Supportive care is appropriate for symptomatic drug-exposed neonates. Severe narcotic withdrawal may necessitate pharmacologic intervention, usually with an opiate such as morphine or methadone, which must be tapered slowly over several weeks. Long-term follow-up, together with parental behavioral modification and support classes, may be of help in achieving optimal developmental potential in drug-exposed infants.

OTHER DISORDERS AND ISSUES

NECROTIZING ENTEROCOLITIS

Pathophysiology

NEC, the most common serious GI tract disorder seen in the NICU, occurs in 1% to 5% of all NICU admissions and has an overall mortality of 20% to 40%. Its pathogenesis is unclear but appears to be multifactorial. Characterized by acute intestinal necrosis, NEC may be the final common response of the immature GI tract to multiple damaging insults such as ischemia, infectious agents, enteral feedings, and medications.

Clinical and Laboratory Evaluation

History

History is important in the diagnosis of NEC. Prematurity is the greatest risk factor, although 7% to 10% of cases occur in term infants. Suggested risks include perinatal asphyxia, IUGR, polycythemia, exchange transfusion, PDA, and rapid feeding practices. Over 90% of infants who develop NEC have received enteral feedings. Infants present with a history of feeding intolerance, vomiting, and heme-positive or grossly bloody stools.

The mean age of onset of NEC is 10 days. The clinical course of disease varies from a fulminant one with rapidly progressive signs of intestinal necrosis, sepsis, and shock to a more indolent one with gradual onset of abdominal distention, ileus, tenderness, and heme-positive stools. The potential long-term sequelae of NEC in survivors include strictures, short bowel syndrome, and failure to thrive.

Physical Examination

Abdominal examination may reveal progressive abdominal distention, tenderness, guarding, and/or abdominal wall erythema. Systemic signs of NEC include lethargy, apnea and bradycardia, irritability, temperature instability, and hypotension/hypoperfusion. In fulminant NEC, metabolic acidosis, respiratory failure, and disseminated intravascular coagulation can be seen.

Laboratory Evaluation

Stool, urine, blood, and CSF cultures are part of the work up for NEC. Laboratory findings in NEC may include hyponatremia, neutropenia, or leukocytosis with a left shift, thrombocytopenia, abnormal coagulation studies, and positive blood or CSF cultures. Other findings consistent with the disease are an abnormal bowel gas pattern suggestive of ileus, bowel wall edema, and a fixed loop. A careful review of serial radiographs is often necessary. **Pneumatosis intestinalis,** which indicates gas within the subserosal bowel wall, is pathognomonic (Figure 10-11). Portal or hepatic venous gas, associated with an increased mortality rate, can be visible in fulminant NEC. A left lateral decubitus or a cross-table lateral film is of help in determining whether intestinal perforation with pneumoperitoneum has occurred.

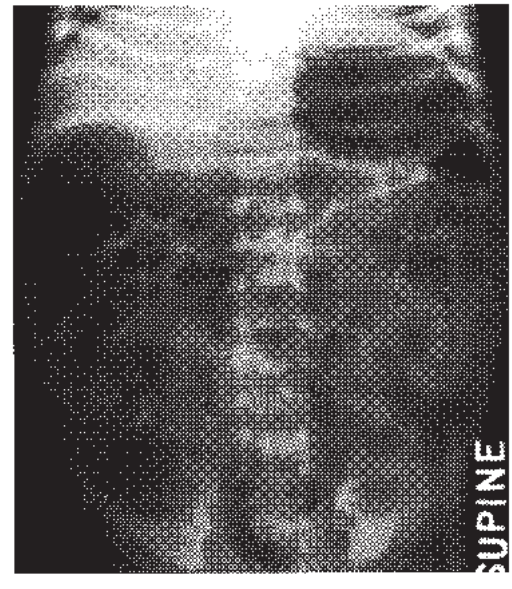

FIGURE 10-11. Abdominal radiograph of a patient with necrotizing enterocolitis. Courtesy of Richard Barth, M.D., Division of Pediatric Radiology, Stanford University.

Differential Diagnosis

The differential diagnosis of NEC includes sepsis or pneumonia with a resultant ileus, focal intestinal perforation, and other causes of a surgical abdomen such as malrotation, volvulus, perforation, and infectious enterocolitis. Early diagnosis is an important factor in the outcome, and it is important to maintain a high index of suspicion in a susceptible population.

Management

Treatment should be initiated promptly when signs and symptoms suggestive of NEC are present. Because the

condition varies in severity from a mild GI disturbance to a fulminant disease, specific treatment should be based on the severity of the clinical manifestations. Commonly, treatment for NEC includes:

- Bowel rest with a nasogastric tube.
- Intravenous fluid resuscitation to replace "third-space" losses and maintain adequate urine output (generally more than 2 mL/kg/hr).
- Hyperalimentation to maintain adequate nutrition.
- Administration of broad-spectrum antibiotics following the culturing of stool, urine, blood, and CSF, usually for a minumum of 7 to 14 days.
- Intubation, mechanical ventilation, and ABG monitoring, when respiratory distress and shock accompany NEC.
- Ongoing blood pressure support may necessitate volume boluses or inotropic agents such as dopamine.
- Correction of metabolic acidosis and coagulopathy due to necrotic bowel.
- Surgical intervention. (The only absolute indication for surgical intervention is pneumoperitoneum. However, pneumoperitoneum is underrecognized radiographically, leading many surgeons to operate when a progressive clinical deterioration occurs despite medical therapy.)

FOLLOW-UP OF THE NURSERY GRADUATE

As smaller and sicker infants survive as a result of advances in obstetric and neonatal care, the risk of chronic sequelae rises. Follow-up studies of infants born in the modern era of NICU care in the 1960s document a significant decrease in adverse neurodevelopmental outcomes. More recent studies show a continued decrease in mortality. However, the incidence of adverse neurodevelopmental outcome has remained unchanged, resulting in an increase in the absolute number of impaired survivors. Most NICU survivors are without severe handicaps but require substantial intervention to achieve an optimal outcome. The evidence that educational enrichment during infancy and early childhood might improve the outcome of high-risk infants, especially those from disadvantaged groups, is increasing.

Management of the postdischarge care of NICU graduates may be beyond the skill and expertise of some primary care providers. Thus, a neonatal follow-up program is an important part of every modern NICU, which provides an extension of the specialized care provided in the NICU and eases the transition to the home environment. The areas targeted for monitoring and intervention are growth and nutrition, neurologic development, psychomotor development, and vision and hearing. The central focus is enhancement of the functioning of newborns and families. Some issues that are commonly encountered at and following discharge include growth, CLD, neurodevelopmental assessment, retinopathy of prematurity (ROP), and hearing screening.

Growth Restriction

Extra-uterine growth restriction (EUGR) occurs in as many as 50% of very low birth weight (VLBW), or birth weight less than 1,500 grams infants and is also common in infants with NEC, and cardiac disease. NICU graduates may be difficult to feed because of tiring, have problems with regulation of state of arousal, or require the administration of multiple medications. Prolonged inadequate nutrition has a significant effect on brain growth and neurodevelopmental outcome. To promote growth, neonatal nutrition must be optimized. High-calorie formulas, particularly with increased protein content, are necessary for infants with obvious growth delays. Registered dieticians with NICU experience frequently review feeding practices and make recommendations to physicians and parents.

Catch-up growth normally occurs in the first 2 to 3 years of life. When plotting growth percentiles on standardized charts, correction for gestational age should be made during the first 2 years of life.

Chronic Lung Disease

After discharge, infants with CLD require close monitoring of respiratory status, including visits for drug and electrolyte levels, pulse oximetry, and blood gases. Approximately 50% of infants with CLD require rehospitalization during the first year of life. CLD usually improves by 2 years of age, although more subtle long-term changes in pulmonary function persist for longer.

Neurodevelopmental Delay

Infants most at risk for neurodevelopmental problems are those with severe asphyxia, periventricular hemorrhage (grades 3 and 4), meningitis, neonatal seizures, IUGR, EUGR, CLD, multiple congenital anomalies,

and VLBW. Many of these infants have transient neurologic abnormalities such as hypotonia or hypertonia. Identification of major neurologic problems is usually possible in the latter half of the first year of life—earlier if they are severe. Major neurodevelopmental handicaps are generally classified as **cerebral palsy** (spastic diplegia, spastic quadriplegia, spastic hemiplegia, or paresis), hydrocephalus, blindness, seizures, or deafness.

To assess the severity of neurodevelopmental problems, the Bayley Scales of Infant Development, the most common psychomotor evaluation used in high-risk children, is helpful. Usually, the reported percentage of premature infants with abnormal scores is 5% to 20%, but recent studies have found abnormal scores at 2 years of age in 37% of infants with birth weights of less than 1,000 g. These children have more neurologic dysfunction, lower intelligence quotients, and more behavioral difficulties than other NICU graduates. Even in VLBW children with normal intelligence, subtle neuroperceptual abnormalities that may result in school problems have been documented.

Retinopathy of Prematurity

ROP, a developmental problem of the incompletely vascularized retina that occurs in premature infants, may result in a range of outcomes varying from normal vision to blindness. The normal development of the retina is interrupted. Beginning at 15 to 18 weeks' gestation, the retinal vessels normally grow outward from the ora serrata. An injury such as hyperoxia or asphyxia may arrest this development. After the initial injury, proliferation of vessel growth in an abnormal fashion may form a ridge of tissue, which may either regress or worsen with the growth of fibrovascular tissue into the vitreous. With contraction of the neovascular tissue, the retina becomes distorted, forming a scar that may result in retinal detachment. This type of retinal detachment was formerly known as retrolental fibroplasia (RLF).

Which infants will experience regression or progression of the retinopathy is unclear, but some investigators have suggested that chronic hypoxia is a risk factor. Recent data analyses suggest that keeping the SpO_2 greater than 95% for infants with early ROP may prevent the need for laser surgery. Regular retinal examination beginning at 4 weeks of age, or 31 weeks PMA (whichever comes later) is necessary for all infants born before completing 30 weeks' gestation, and for select infants 30 to 34 weeks' gestation who were exposed to oxygen. At that time, information is recorded on the location, extent, and severity of retinal changes. Even infants with mild disease have a higher incidence of myopia, strabismus, and amblyopia.

The strongest predictors of ROP have always been gestational age and birth weight. Studies have found that ROP occurs in 66% of all premature infants with birth weights of less than 1,250 g, with 6% requiring laser photocoagulation to prevent retinal detachment. Laser retinal ablation is proven to reduce the incidence of poor visual outcome. Blindness due to ROP occurs in approximately 1% to 2% for infants with birth weights of less than 1,000 g.

Sensorineural Hearing Loss

NICU graduates have a substantial risk of sensorineural hearing loss. The numerous risk factors for hearing loss include gestational age less than 35 weeks, hyperbilirubinemia requiring exchange transfusion, ototoxic drugs, congenital viral infections, hyperventilatory alkalosis, and neurologic injury (e.g., intracranial hemorrhage, seizures, meningitis, or asphyxia). Generally, at-risk infants undergo a screening auditory brainstem–evoked response test prior to discharge, and periodic hearing examinations during the first 2 years of life. The incidence of hearing impairment is approximately 10% in infants with birth weights of less than 1,000 g.

Genetics

Robert W. Marion and Joy N. Samanich

Clinical genetics, a pediatric subspecialty, poses unique challenges. Because of the generalized nature of most genetic diseases, which affect many organ systems, the clinical geneticist must first be a generalist and then a subspecialist. In addition, contact with children with genetic diseases and congenital malformations can be a daunting experience for students. Individuals with genetic disorders are often very sick and may be disfigured in appearance. Finally, because these disorders often occur in infants born to parents who are about the same age as the medical student, dealing with these families may be psychologically difficult.

Congenital malformations are defined as clinically significant abnormalities in either form or function. Malformations result from a localized error in **morphogenesis**, an event that usually occurs early in the first trimester of pregnancy. Malformations differ from **deformations;** in deformations, early morphogenesis has progressed normally, but **environmental factors,** often external to the fetus, disturb the normally developing tissue. Thus, the presence of a malformation such as a cleft palate implies an abnormality that occurred during embryonic life, whereas a deformation such as congenital dislocation of the hip results from disturbances during the second or third trimester or, in some cases (e.g., dolichocephalic head shape in premature infants), even during early postnatal life. It is important to distinguish between these two conditions for prognostic reasons. Malformations often require aggressive surgical or medical management, whereas deformations often resolve on their own once the disturbing environmental force has been removed.

A **malformation sequence** occurs when a single malformation leads to other structural changes as a result of later, related developmental consequences. One example of such a disorder is the **Pierre Robin** malformation sequence, in which a single primary malformation, the failure of growth of the mandible during the first few weeks of gestation (**micrognathia**), results secondarily in a U-shaped **cleft palate** and **glossoptosis** (the presence of a posteriorly displaced tongue that falls backwards and obstructs the airway).

A **malformation syndrome,** which is defined as a recognizable pattern of anomalies that results from a single identifiable underlying cause, may involve a series of malformations, malformation sequences, and deformations. For example, in infants with Down syndrome, malformations of the central nervous system (CNS), craniofacies, heart, and limbs all result from the presence of an extra copy of chromosome 21 in every nucleated cell of the body.

An **association** differs from a syndrome because, although recognizable patterns of malformations appear repetitively, no common unifying cause of the pattern is yet known. For example, although certain features such as **v**ertebral anomalies, **a**nal atresia, **c**ardiac defects, **t**racheo**e**sophageal fistula, **r**enal anomalies, and **l**imb anomalies (VACTERL) occur more commonly together than would be expected by chance, no single causative agent has been identified.

Only about 50% of all infants in whom multiple congenital anomalies are present ultimately receive a diagnosis of an identifiable etiology or a particular malformation syndrome. Confirmation of a syndromic diagnosis is important for three reasons.

1. Identification of a diagnosis guides the physician during the remainder of the child's evaluation. Knowledge that specific internal malformations may be associated with the identified disorder, as well as information concerning the natural history of the entity, allows the physician to anticipate problems before they become evident.
2. Confirmation of a diagnosis improves communication between the physician and the family. It allows the parents, through a better understanding of the natural history of their child's disorder, to make informed decisions.

3. Confirmation of a diagnosis allows for proper genetic counseling, offering the parents an accurate recurrence risk and the potential for prenatal diagnosis in future pregnancies.

APPROACH TO THE CHILD WITH CONGENITAL MALFORMATIONS

Unfortunately, congenital malformations are not rare in children. Approximately 3% of all infants born in the United States each year have one or more birth defects that are discovered during the neonatal period. This figure is closer to 7% to 8% in a population of 1-year-old children, because some malformations such as congenital heart and renal anomalies remain clinically silent during the newborn period, only to manifest themselves later in the first year of life. Finally, it has been estimated that as many as 40% to 50% of all admissions to pediatric services are for children with congenital malformations. This section will provide a framework for evaluating children with one or more congenital malformations.

Clinical and Laboratory Evaluation

History

Infants do not begin their life histories at the time of birth. During the 38 weeks of intrauterine life, they have been growing and developing, and a great deal of information can be obtained about their health through careful questioning of the mother about her pregnancy (Table 11-1).

TABLE 11-1

Approach to the Dysmorphic Child: History

Questions about the Parents
How old are they? How many previous pregnancies did the mother have? Did she have any spontaneous abortions? Was there neonatal demise? Did the mother work outside the home during the pregnancy? Was she exposed to toxic chemicals? Does the mother have any underlying medical conditions (e.g., diabetes mellitus, seizure disorder)?
Did the mother take any medications during the pregnancy?
Did the mother smoke cigarettes or use alcohol or other drugs during the pregnancy?
How much weight did the mother gain during the pregnancy?
Questions about the Pregnancy
When did quickening occur? Was the pregnancy conceived naturally?
Were fetal movements active (as compared with previous pregnancies)?
Was any special testing performed (e.g., amniocentesis, chorionic villus sampling, sonography)?
Did mother have illnesses (e.g., infections, fever)?
Questions about Delivery
Was the infant full term, premature, or postmature?
Was the infant's size normal, large, or small (for gestational age)?
Were there any complications in the delivery room or nursery?
Questions about Family History
Does a complete pedigree contain any evidence of past congenital malformations, similar or dissimilar anomalies, neonatal demise, or pregnancy loss?

Physical Examination

While examining the child, the examiner should note all features, both those that appear normal and those that appear abnormal. This review highlights those features in which clues for the diagnosis of congenital malformation syndromes are most likely to be found.

GENERAL APPEARANCE. First, the clinician should carefully measure height and weight and plot the values on appropriate growth curves. This information helps categorize the underlying problem. Growth that is appropriate for age is consistent with the presence of a single gene disorder, a multifactorially inherited condition, or, most commonly, no genetic disease. **Growth restriction,** whether beginning pre- or postnatally, may result from a chromosomal abnormality or exposure to toxic, teratogenic agents. Finally, a larger-than-expected size suggests an **overgrowth syndrome** (e.g., Sotos cerebral gigantism or Beckwith-Wiedemann syndrome), or, in the newborn, a diabetic mother. The practitioner should also assess the child's body habitus. Is the child proportionate? If not, are the arms and legs too short for the head and trunk, implying the presence of a short-limbed bone dysplasia such as **achondroplasia**? Are the trunk and head too short for the extremities, suggesting a disorder affecting the vertebrae, such as spondyloepiphyseal dysplasia?

CRANIOFACIES. Careful examination of the craniofacial region is of crucial importance in the diagnosis of many congenital malformation syndromes. The head circumference should be carefully measured and plotted on an appropriate growth curve. It is also important to describe the overall shape of the skull. Is the child normocephalic? Is the head long and thin (dolichocephalic) or short and wide (brachycephalic)? Is the head lopsided (plagiocephalic)?

Pediatric Pearl: It is never helpful to describe a child's face as "funny-looking." The clinician should attempt to carefully describe what makes the facial features unusual.

Next, the examiner should concentrate on the face. An assessment of facial symmetry is essential. Asymmetry may be due to either a deforming process related to the intrauterine position of the fetus or malformations of one side of the face. For purposes of examination, the clinician may divide the infant's face into four regions and evaluate each region separately (Figure 11-1). Assessment of the forehead for both overt prominence (as is the case in **achondroplasia**) and deficiency (described as a sloping appearance, as occurs in children with **primary microcephaly**) is necessary. Examination of the midface, the region extending from the eyebrows to the upper lip and from the outer canthi of the eyes to the commissures of the mouth, is especially important. Assessment

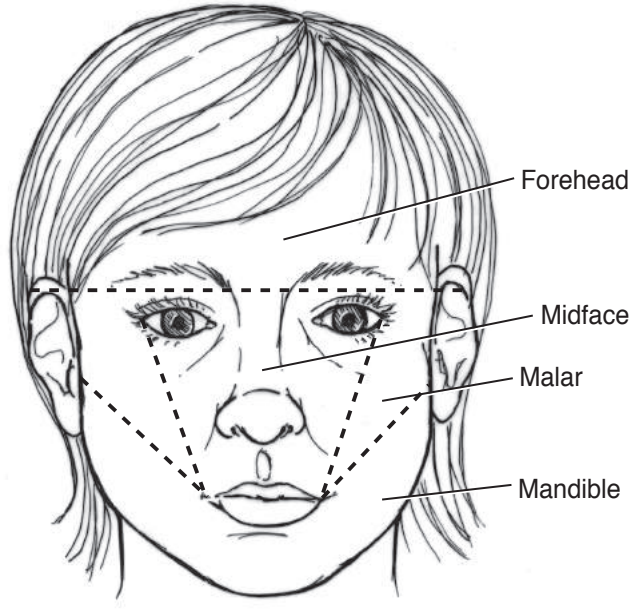

FIGURE 11-1. The four regions of the face.

of the distance between the eyes (inner canthal distance and interpupillary distance) confirms the presence of **hypotelorism** (eyes that are too close together, suggestive of an associated defect in midline brain formation) or **hypertelorism** (eyes that are too far apart). Measurement of the length of the palpebral fissures (measured from inner canthus to outer canthus) determines whether these structures are short (as in **fetal alcohol spectrum disorder**) or excessively long (as in the Kabuki syndrome).

The obliquity (or slant) of the eyes in either an upward (**Down syndrome**) or a downward (**Treacher Collins syndrome**) direction; the presence of epicanthal folds (Down syndrome or fetal alcohol spectrum disorder); the height of the nasal bridge (flat in Down, fetal alcohol, and other syndromes, and raised in **velocardiofacial syndrome**); the length of the philtrum (which should have a central depression surrounded by two pillars); and the upper vermilion border (the pink part of the lip) should be noted and recorded.

The third portion of the face to be examined, the malar region, extends bilaterally from the ear into the midface. It is essential to evaluate the ears; the clinician should measure their maximal length and plot the values on a growth curve. It is also necessary to examine the position of the ears; so-called **"low-set"** ears end below a line extended laterally from the outer canthus of the eye. Ears may be low set because they are microtic (unusually small) or because of anomalies of the mandibular region of the face. Description and notation of the architecture of each ear is essential.

The final portion of the face that warrants evaluation is the mandibular region, the area contained between the lower portion of both ears, including the mouth. The mandible should normally be slightly retruded in newborns; when viewed in profile, it should end slightly behind the level of the philtrum and upper lip. If this retrusion is exaggerated, the infant might be affected with micrognathia, a feature of the Pierre Robin malformation sequence.

EXTREMITIES. Anomalies of the extremities are common features of a vast number of congenital malformation syndromes. The pediatrician should conduct a brief examination of all joints. The presence of **single or multiple contractures** suggests either intrinsic neuromuscular dysfunction, as in the case of some forms of **muscular dystrophy**, or external deforming forces. Inability to pronate and supinate the elbow suggests **radioulnar synostosis**, an anomaly that occurs in fetal alcohol syndrome and in some of the X chromosome aneuploidy syndromes.

Close examination of the hands is extremely important. **Polydactyly** (extra digits) most often occurs as an isolated but fairly common autosomal dominant trait, but it can also be a prominent feature of a syndrome such as **trisomy 13**. In contrast, **oligodactyly,** a deficiency in the number of fingers or toes, is a less common finding. It may be part of a more severe limb reduction deficiency disorder, as occurs in patients with **Fanconi syndrome,** or may be secondary to an intrauterine amputation, as is the case in the **amniotic band disruption sequence**. Another disorder of the extremities, **syndactyly** (a joining of two or more digits) is fairly common in a number of syndromes.

GENITALIA. When examining the male genitalia, the clinician should briefly observe the penis and scrotum. If the penis appears short, measurement of penile length is necessary, and the practitioner should plot it on an appropriate growth curve. Ambiguity of the genitalia should suggest the presence of either an endocrinologic disorder such as **congenital adrenal hyperplasia,** a chromosomal disorder such as 45,X/46,XY mosaicism, or an inherited syndrome.

Hypospadias is a common congenital malformation, occurring in approximately 1 in 300 newborn males. This is most often an isolated malformation, but if it occurs in the presence of other anomalies, the possibility that the child is affected with a syndrome warrants consideration.

Laboratory Evaluation

In most children with multiple congenital anomalies, only a limited number of laboratory tests are necessary.

Pediatric Pearl: Karyotype analysis is warranted in any child who has three or more detected abnormalities.

Chromosome analyses are not indicated in the infant with an isolated cleft lip or palate unless other malformations are present. Chromosome analysis can be performed using three types of cells:

1. **Peripheral blood lymphocytes** stimulated to divide by use of mitogenic agents. Because this requires 2 to 3 days in culture, results are not available for at least 72 hours.
2. **Skin fibroblasts.** Results from fibroblast cultures usually require 2 to 3 weeks.
3. **Bone marrow cells,** which, because they are already rapidly dividing, can be analyzed immediately and yield results within 1 day.

The urgency of the situation dictates the type of cells used. When it is necessary to make critical management decisions, as in a child with features of trisomy 13 or 18, a bone marrow sample may be indicated. In the child with features of trisomy 21 or in whom no clear diagnosis is evident, peripheral blood lymphocytes are usually studied.

Any child with evident multiple external malformations should also have a careful evaluation to rule out the presence of associated internal malformations. Ultrasound evaluations of the head and abdomen are warranted; a chest radiograph, electrocardiogram, and echocardiogram are indicated in any child with anomalies who has an audible heart murmur or syndrome with a known risk for cardiac anomalies (e.g., Down syndrome).

In addition, specialized testing such as fluorescent in situ hybridization or direct DNA testing is necessary in the child suspected of having a syndrome known to be associated with a specific chromosome deletion (e.g., Prader-Willi syndrome, which is associated with deletion of chromosome 15q11.2) or a known single gene defect (e.g., fragile X syndrome, which is associated with a failure to express the FMR1 gene on the X chromosome).

The use of DNA-based microarray technology is quickly becoming the standard of care in the evaluation of children with multiple congenital anomalies, developmental delay, and/or autism. This test, known as chromosomal microarray analysis or array comparative genomic hybridization (aCGH), is used to compare the amount of DNA at thousands of loci throughout the genome between a patient and a control subject, and can thereby diagnose chromosomal microdeletions and microduplications too small to be seen on a standard karyotype. In this way, many known deletion/duplication syndromes such as Prader-Willi syndrome can be diagnosed, in addition to novel copy number changes anywhere throughout the genome. However, balanced chromosomal translocations will not be detected by this test, which relies on changes in copy number, and therefore performing a karyotype in addition to aCGH is still recommended.

Diagnosis

Although the presence of characteristic findings may sometimes make the definitive diagnosis of a malformation syndrome simple, in the majority of cases no specific diagnosis is immediately evident. Some constellations of findings are rare, and finding a "match" may prove difficult. In many cases, all laboratory tests are normal, and confirmation relies on subjective findings. Clinical geneticists have attempted to resolve this problem by the development of scoring systems, cross-referenced tables of anomalies that allow the development of a differential diagnosis, and computerized diagnostic programs.

Making an accurate diagnosis is important for three reasons. One, it offers an explanation for why the child was born with specific problems. Often, before a diagnosis is made, parents feel that in some way they were directly responsible for their child's problem. Providing a diagnosis often allays this guilt. Two, a correct diagnosis allows the physician to provide anticipatory guidance. Because the natural history of so many disorders is known, the health care provider can perform screening to check for problems known to occur in that condition, and at the same time, often reassure the parent about other complications that have not been reported previously. Three, an accurate diagnosis allows the pediatrician to provide genetic counseling concerning future progeny, when available. In addition, referral for prenatal testing may occur early in subsequent pregnancies.

Once a diagnosis is made, the clinician can provide the family with a wealth of educational material. The World Wide Web has become an important source of such information (Table 11-2). However, because the Web is not subject to editorial control, some of the information is inaccurate or inappropriate. Therefore, it is essential that the clinician screen the sites before encouraging a family to seek Web-based information. A good screening tool is the Web site of the National Organization for Rare Disorders. Because the field of medical genetics is expanding so rapidly, it is also difficult to remain current regarding the availability of testing for specific conditions. The GeneTests Web site, which provides constantly updated information regarding such testing, has become indispensable.

CHARACTERISTICS OF SOME GENETIC AND CONGENITAL MALFORMATION SYNDROMES

Congenital malformations can be classified into five categories (Table 11-3):

1. Chromosomal disorders, which account for 7% of all anomalies
2. Single gene disorders, which demonstrate Mendelian inheritance patterns and account for another 7% of the total

TABLE 11-2

Web Sites with Information About Common Genetic Disorders

General Sites

- Online Mendelian Inheritance in Man (OMIM)
  http://www.ncbi.nlm.nih.gov/omim/searchomim.html
  Maintained by McKusick–Nathans Institute for Genetic Medicine at Johns Hopkins University. Each entry contains a bibliography of all articles published in the medical literature about a given condition.
- Gene tests

3. Multifactorially inherited disorders, which result from an interplay of genetic and environmental factors, and account for 20% of all congenital anomalies
4. Teratogenically induced disorders, caused by exposure of the conceptus to a toxic environmental agent, accounting for 7%
5. Unknown causes, which presently account for 50% of all malformations

Because so many genetic disorders exist, only a handful of representative conditions will be discussed.

Chromosomal Disorders

Normal cells of humans contain 46 chromosomes. The chromosomes may be divided into two major types: the 44 autosomes and the 2 sex chromosomes. Occurring in pairs and numbered from 1 (the largest) to 22 (the smallest), autosomes are indistinguishable in males and females, who are genetically distinguished on the basis of their complement of sex chromosomes. Males have an X and a Y chromosome, and females have two X chromosomes.

Autosomal Aberrations

The impression that a chromosomal defect is present is strengthened by the presence of a group of cardinal features that are frequently found in such individuals, including

- Growth retardation, which may begin in utero
- Developmental retardation, which is often profound
- Structural defects of the craniofacies, CNS, and cardiovascular system, as well as other internal organ systems

For each of the common autosomal chromosomal aberration syndromes, a definite pattern of malformations is known to occur. However, although the karyotype may be the same from individual to individual, striking variability in expression may exist.

TABLE 11-3

Classification of Congenital Malformations[a]

Causes	*Number (%)*
Single gene mutations	8,400 (7.5%)
Chromosomal abnormalities	6,720 (6.0%)
Multifactorially inherited conditions	22,400 (20.0%)
Teratogenically induced conditions	7,200 (6.5%)
Unknown causes	67,200 (60.0%)

[a] Total number of births in 1987 was 3,600,000, of which there were 112,000 (3%) infants with malformations.

TRISOMY 21 (DOWN SYNDROME). This disorder, the most common and best known of all cytogenetic aberrations, occurs in 1 in every 800 births. Although the cause of the entity is always an extra copy of chromosome 21, the configuration of that extra chromosome is not always the same. In 92.5% of cases, straightforward trisomy 21 occurs. In 4.5% of cases, the extra chromosome is part of a Robertsonian translocation, a rearrangement of chromosomal material in which one chromosome 21 is attached to another chromosome (most commonly chromosome 14). In approximately 3% of cases, mosaicism occurs; there are two separate populations of cells, one with trisomy 21, and the other with a normal chromosome complement. Although it is widely believed that individuals with mosaic Down syndrome are more mildly affected, there are wide variations in clinical findings in mosaic individuals.

The diagnosis of Down syndrome is nearly always made in the newborn period. Affected children, who are often of normal birth weight and length, are strikingly hypotonic. This floppiness causes them to feed poorly and to seem less active than other babies. In addition to the hypotonia, several other external and internal characteristics are present (Tables 11-4 and 11-5). The facial appearance of affected children is striking (Figure 11-2).

FIGURE 11-2. Facial features of an individual with Down syndrome. From Gelehrter TD, Collins FS: *Principles of Medical Genetics*. Baltimore, Williams & Wilkins, 1990, p 173.

Life expectancy figures in individuals with Down syndrome are difficult to cite with confidence. In the past, premature death resulting from infectious diseases such as hepatitis was not uncommon, because many such children were placed in institutions at birth. With better care and with more aggressive treatment of congenital heart defects, it is expected that long-term survival will occur in the majority of children born with Down syndrome.

Although the cause of Down syndrome is well-known, the reason for the nondisjunction that leads to trisomy 21 remains a mystery. Down syndrome is commonly associated with advanced maternal age,

TABLE 11-4

External Characteristics of Children with Down Syndrome

Craniofacial Abnormalities
Hypoplastic midface
Flattened nasal bridge
Eyes Upward slanting palpebral fissures Epicanthal folds (flaps of skin) covering inner canthi of eyes Irides with speckled appearance caused by Brushfield spots
Flat occiput, causing brachycephalic appearance with flattened facial profile
Large tongue, often protruding from mouth
Flattened upper part of helices of ears
Extracranial Findings
Shortening of hands and fingers (brachydactyly) (most striking in fifth finger)
Simian crease (single crease across palm of hand) (50%)
Skin usually doughy in consistency
(Males only) Small penis (often)

TABLE 11-5

Internal Malformations in Children with Down Syndrome

Congenital heart disease (40%) Atrioventricular canal Ventricular septal defect, atrial septal defect Valvular disease
Gastrointestinal defects (10%) Duodenal atresia Tracheoesophageal fistula Annular pancreas Imperforate anus Hirschsprung disease
Growth retardation (90%)
Developmental retardation (99%) Mental retardation (primarily moderate; may range from borderline to profound)
Neurologic defects (99%) Hypotonia Seizures (10%) Presenile dementia (as early as third decade)
Endocrinologic abnormalities Hypothyroidism or hyperthyroidism (20%) Infertility in males (100%)
Hematologic abnormalities Leukemoid reaction during neonatal period Leukemia (all types) (risk increased >20-fold)
Skeletal abnormalities Joint hypermobility Atlantoaxial instability (10%–15%) Osteoarthritis of cervical spine

though exactly why this may lead to aberrant chromosomal development is not understood. It is currently recommended that prenatal screening and diagnostic testing be offered to all pregnant women, regardless of age, because of advances in the sensitivity, specificity, and safety of available tests.

There is some misunderstanding about the relationship between Down syndrome and maternal age. Only 25% of all children with Down syndrome are born to women older than 35 years of age. However, only 5% of all infants are born to these older women, so their risk of giving birth to a child with Down syndrome increases strikingly. Advanced paternal age appears to have little effect on the risk of trisomic births. In fact, researchers have recently shown that 89% of cases of trisomy 21 appear to result from nondisjunction occurring in either the first or second meiotic division in the ovum.

Several options exist for women wishing to have prenatal screening to identify those pregnancies most likely to be at risk for chromosomal abnormalities. Women can have first-trimester screening, consisting of blood testing for pregnancy-associated plasma protein A (PAPP-A), which is typically reduced and human chorionic gonadotrophin (hCG), which is elevated in Down syndrome, and of ultrasound measuring fetal nuchal translucency (NT; the fluid-filled space behind the neck). The advantage of this testing is that the woman has her test results early in the pregnancy. An alternative is integrated testing, incorporating the NT measurement and PAPP-A level in the first trimester with the measurement of maternal serum α-fetoprotein, unconjugated estriol, inhibin A, and chorionic gonadotrophin in the second trimester; test results are not available until the second trimester. Others choose sequential testing, where integrated testing is performed, but the results from

the first-trimester component are released to the couple, allowing for earlier diagnostic testing if desired. These screening tests are not definitive; they simply identify which women are at increased risk for having a child with Down syndrome. It is now recommended that amniocentesis or chorionic villus sampling, the more definitive tests for identification of fetal chromosomal abnormalities, be offered to all pregnant women who desire them, and particularly discussed with women at increased risk.

After the birth of a child with Down syndrome, the recurrence risk for future pregnancies depends on cytogenetic findings. With trisomy 21, the chance for recurrence based on empiric observation is approximately 1% for subsequent pregnancies (added to the age-specific risk); this risk is not just for Down syndrome but also for trisomy 18 or 13. If a translocation is discovered, it is essential that the karyotype of both parents be ascertained. Approximately two-thirds of the time, it turns out that the translocation has arisen de novo (a spontaneous event; the empiric recurrence risk following such an event is approximately 1%). In one-third of cases, one of the parents has a balanced translocation. This finding is often, but not always, accompanied by a history of recurrent pregnancy loss. The recurrence risk depends on which parent carries the translocation: If the mother is the carrier, the risk of recurrence is 10% to 15%; if the father is the carrier, the recurrence risk is only 2% to 5%.

TRISOMY 18 (EDWARDS SYNDROME). Trisomy 18, which occurs in approximately 1 in 5,000 live births, is the second most common autosomal trisomy. Unlike Down syndrome, trisomy 18 is almost universally lethal; less than 10% of affected individuals survive until their first birthday. Although survival into adolescence has been documented, such longevity is rare and is associated with severe or profound mental retardation and innumerable medical problems. As a result of the bleak prognosis, once the diagnosis has been confirmed, most authorities favor limiting the use of medical interventions for the prolongation of life.

Children with trisomy 18 have a characteristic appearance: small-for-gestational age, hypertonia, a characteristic facial appearance, and an unusual hand posture. More than 130 additional malformations have been reported. In addition, aberrant gestational timing occurs in trisomy 18. One-third of infants are born prematurely, another one-third are postmature. Information regarding recurrence risk and recommendations for genetic counseling are the same as for Down syndrome.

TRISOMY 13 (PATAU SYNDROME). Trisomy 13, which occurs in about 1 in 10,000 live births, is also nearly always lethal during fetal or early postnatal life. Affected infants have numerous malformations. They are small-for-gestational age and microcephalic. The midline facial anomalies, including cyclopia (single orbit), cebocephaly (single nostril), and clefts of the lip and palate that are often seen, are associated with midline defects of the brain such as alobar holoprosencephaly (failure of the cerebrum to divide into right and left hemispheres, resulting in a single cerebral holosphere). The forehead is sloping, the ears are small and malformed, and microphthalmia (small eyes) or anophthalmia (no eyes) occur. The hands show postaxial polydactyly and abnormal palmar creases, and the feet are malformed, usually with a clubfoot or rocker bottom deformity. Males have hypospadias and cryptorchidism, and females have hypoplasia of the labia majora. Internally, numerous malformations are encountered, including congenital heart disease, a nearly constant finding. Like the other autosomal trisomies, trisomy 13 is associated with advanced maternal age. Recurrence risk is similar to that of Down syndrome.

DELETION 5P SYNDROME (CRI-DU-CHAT OR CAT'S CRY SYNDROME). The cause of this syndrome is a deletion of part of the short arm of chromosome 5. Beginning in the newborn period and continuing through the first few months of life, children affected with this disorder have a striking cat-like cry that is caused by laryngeal hypoplasia. Other clinical features include low-birth weight and postnatal failure to thrive; hypotonia and developmental delay; microcephaly; and craniofacial dysmorphism, including ocular hypertelorism, epicanthal folds, downward obliquity of the palpebral fissures, and low-set malformed ears. Clefting of the lip and palate, congenital heart disease, and other malformations are occasionally seen.

The clinical severity of cri-du-chat syndrome appears to correlate with the size of the deletion: the larger the deletion, the more severe the expression. Most cases arise de novo. When such is the case, the deletion usually occurs in the copy of chromosome 5 inherited from the father. This finding is believed to be due to the phenomenon of imprinting.

Sex Chromosome Aberrations

Unlike the syndromes caused by anomalies of the autosomal chromosomes, sex chromosome abnormalities tend to be subtle and may remain undetected during early life. No generalizations can be made about the phenotype of such individuals; birth weight is frequently normal; external examination usually reveals no anomalies; and except for the genitourinary tract, internal anomalies are often not present. Sex chromosome anomalies are most often detected during the early teenage years because of the failure of affected individuals to begin puberty at the appropriate time.

Pediatric Pearl: It is important that patients newly diagnosed with Turner syndrome, Klinefelter syndrome, and related disorders receive appropriate and ongoing psychologic counseling for two reasons: (1) the later time of diagnosis and (2) the sensitive nature of the problems caused by such disorders.

TURNER SYNDROME (45,X). The entity now known as Turner syndrome, a relatively mild disorder, occurs in 1 in 5,000 live female births. In most cases, it is associated with normal intelligence, lack of significant disabilities, and normal life expectancy. It is not unusual for girls with Turner syndrome to escape detection during the newborn period. About one-third of affected girls are diagnosed at birth, another one-third during childhood as part of an evaluation for short stature, and the final one-third in the teenage years because of failure to develop secondary sex characteristics.

It has become clear that the 45,X karyotype is consistent with two very different phenotypic expressions, one seen prenatally and the other postnatally. Through studies of spontaneous aborted embryos and fetuses, researchers have discovered that 99% of conceptuses with a 45,X karyotype die early in pregnancy as the result of severe hydrops fetalis from lymphatic obstruction. Turner syndrome is the single leading cause of first-trimester spontaneous abortion, accounting for approximately 9% of all early pregnancy losses.

The newborn with Turner syndrome may have a characteristic appearance at birth with webbing of the neck and puffiness of the hands and feet, as well as an unusual facial appearance, a "shield" chest, cubitus valgus, short fourth metacarpals, and spoon-shaped nails. As these girls age, other features become apparent, including short stature and failure to develop secondary sexual characteristics as a result of failure of ovarian development. Internal anomalies are not uncommon in women with Turner syndrome. Cardiac defects, including coarctation of the aorta, aortic valve stenosis, and dissecting aneurysm of the aorta (a life-threatening complication), occur in approximately one-third of patients. Renal anomalies, including horseshoe-shaped kidneys and duplication of the collecting systems, are seen in more than half of affected patients.

Only half of liveborn individuals with Turner syndrome have a 45,X karyotype. Many girls have some variation of 45,X, including mosaicism and deletions of portions of one X chromosome. Although intelligence in women with Turner syndrome is usually normal, specific cognitive problems commonly occur, including defects in spatial perception, perceptual motor organization, and fine motor skills. Women with Turner syndrome are nearly always infertile. Estrogen replacement therapy may induce the development of secondary sexual characteristics, but unassisted reproduction has rarely been reported.

Recently, in vitro fertilization technology using donor eggs and hormonal therapy has allowed some women with Turner syndrome to bear children. Although assisted reproduction has offered hope of fertility to adult women with this disorder, great care must be taken, and close medical follow-up is essential. Recent evaluation has shown that pregnancy may have an adverse effect on the aorta, hastening the dissection of an aneurysm.

KLINEFELTER SYNDROME (47,XXY). Klinefelter syndrome, which occurs in 1 in 1,000 births, represents the most common genetic cause of hypogonadism and infertility in males. Nearly always normal throughout childhood, the male with Klinefelter syndrome usually remains undiagnosed until adolescence. At that time, males with Klinefelter syndrome are often notably tall, with long arms and legs. In addition, gynecomastia is present, and with the passage of time, central obesity occurs. Intelligence is usually normal, but affected individuals are said to manifest features of immaturity.

Pediatric Pearl: The most striking physical feature in adolescents with Klinefelter syndrome is the failure of growth of the testes.

In spite of the appearance of pubic hair and growth of the penis, the testes remain small, nearly prepubertal in volume, and feel soft and "mushy." This finding, in the presence of normal pubic hair distribution, is pathognomonic for this condition.

In men with Klinefelter syndrome, testosterone replacement therapy results in the development of secondary sex characteristics, including deepening of the voice; male body habitus and beard; and libido. Some affected males have additional X chromosome aneuploidy such as 48,XXXY and 49,XXXXY. As a general rule, the more X chromosomes present, the more abnormal the phenotype.

Nearly all men with Klinefelter syndrome are infertile, producing semen that contains few viable sperm. However, as in Turner syndrome, recent advances in assisted reproduction have allowed some affected men to

father children. Using intracytoplasmic sperm injection, a spermatozoa obtained through testicular biopsy is injected into an egg, producing fertilization. Thus far, all liveborn children fathered by men with Klinefelter syndrome using this technology have had normal chromosomal complements.

Single Gene Disorders

Humans are diploid organisms, and each gene is represented at its locus within the genome by two copies, one inherited from each parent. Genes, sequences of DNA, provide instructions to the cell to produce specific proteins. Among the 25,000 genes that compose the human genome, an occasional error (known as a mutation) occurs. Under the proper conditions, it may translate into a clinically distinguishable disease state. Such entities, referred to as single gene disorders, are often passed from parent to child over many generations.

In this section, three types of single gene disorders are discussed: autosomal dominantly inherited traits, which are expressed in individuals in whom at least one copy of a specific gene is errant; autosomal recessively inherited traits, in which two copies of the errant gene are necessary for clinical expression to occur; and X-linked recessive traits, in which the abnormal gene resides on an X chromosome.

In the 1960s, Victor McKusick, MD, began to catalog all reported human conditions caused by single gene mutations. The resulting treatise, *Mendelian Inheritance in Man*, has been constantly updated since then. The catalog is now maintained online (see Table 11-2). In this section, Online Mendelian Inheritance in Man (OMIM) entry numbers follow the name of each specific condition.

Autosomal Dominant Disorders

For autosomal dominant traits to be clinically significant, only one copy of an abnormal gene is necessary. These disorders are usually passed from affected parent to affected child, who, because they possess one normal and one abnormal gene, are said to be heterozygous. A pedigree of a family in whom an autosomal dominant trait is segregating (running through the family) illustrates certain rules (Table 11-6; Figure 11-3).

In genetics, as in life in general, rules are made to be broken. Phenomena such as skipped generations and individuals affected with autosomal dominant traits born into families in which no other members appear to be affected are commonly seen. Explanation of these observations involves use of the following terms.

Penetrance describes the frequency with which heterozygous individuals clinically express an errant gene. A mutant gene is said to be 100% penetrant if all heterozygous individuals express the abnormal phenotype. However, many disorders manifest decreased penetrance, with some individuals who are carriers of the mutant gene showing no ill effects. Such a situation would account for so-called "skipped generations."

Unlike penetrance, **expressivity** is the extent to which the clinical features of an autosomal dominant trait are expressed in the heterozygous individual. Mutant genes that show variable expressivity (such as the one that causes neurofibromatosis) result in clinical conditions that range from mild to severe. Thus, an errant gene that is 100% penetrant but is variably expressed shows some effects in all heterozygotes, but those effects may either be extremely mild or life-threatening.

Pleiotropy is defined as multiple, seemingly unrelated clinical effects that are caused by a single mutated gene or gene pair. For example, individuals with **Marfan syndrome** have abnormalities of their skeletal, ophthalmologic, and cardiovascular systems, all of which are clearly the result of a single gene defect; random occurrence of such conditions would be unlikely.

TABLE 11-6

Rules of Autosomal Dominant Inheritance

1. The trait appears in every generation.
2. Each child of an affected parent has a 1 in 2 chance of being affected.
3. No children of unaffected parents are affected.
4. Males and females are equally affected.
5. Male-to-male transmission occurs.
6. Traits generally involve mutations in genes that code for regulatory or structural proteins (e.g., collagen) and are associated with normal life spans.

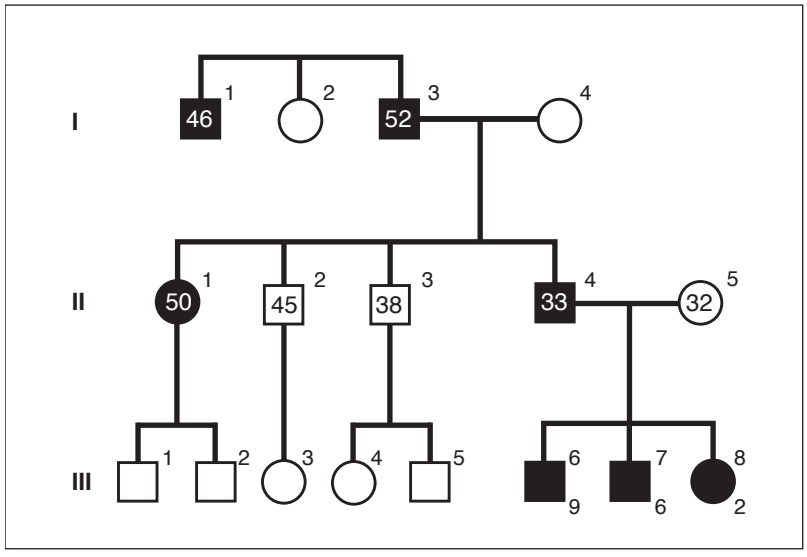

FIGURE 11-3. Pedigree of a family with autosomal dominant familial hypercholesterolemia. □, male; ○, female; ■, affected male; ●, affected female. From Gelehrter TD, Collins FS: *Principles of Medical Genetics*. Baltimore, Williams & Wilkins, 1990, p 29.

A spontaneous mutation is defined as any permanent inheritable change in the sequence of genomic DNA. If a mutation affects a gene, an individual with an autosomal dominant trait may be born into a family in which no other members are affected with that trait. Spontaneous mutations leading to the appearance of autosomal dominant traits are often associated with increased paternal age (over 35 years of age).

ACHONDROPLASIA (OMIM #100800). A defect of cartilage-derived bone, achondroplasia is an autosomal dominant disorder that leads to numerous phenotypic abnormalities, including short stature, macrocephaly, a flat midface with prominent forehead, and rhizomelic ("root of the limb") shortening of the limbs (i.e., the proximal part of the limbs are most strikingly affected). Occurring in approximately 1 in 12,000 births, achondroplasia is the most common bone dysplasia in humans.

The cause of achondroplasia is a mutation in the fibroblast growth factor receptor 3 (FGFR3) gene. Localized to chromosome 4p16, FGFR3 is expressed in early human development in the cartilage growth plates of long bones during endochondral ossification. Eighty percent of cases of achondroplasia are the result of spontaneous mutations. More than 95% of cases of achondroplasia are due to one of only two mutations in the same base pair (nucleotide 1138); this site is an extremely active mutational "hot spot" (a region where mutations appear to be more prone to occur).

As the child with achondroplasia grows, numerous related medical and psychologic problems may occur. In infancy, hydrocephalus and central apnea, both resulting from a narrowing of the foramen magnum, may occur. Later in childhood, bowing of the legs as a result of unequal growth of the tibia and fibula, dental malocclusion, and hearing loss from middle ear dysfunction are common. During late childhood and early adolescence, the psychologic effects of the marked shortening of stature are often seen for the first time. In adulthood, neurologic complications such as sciatica, resulting from nerve root compression, are often present. The expected life span of individuals affected with achondroplasia is normal. Although persons with achondroplasia usually have normal intelligence, societies have discriminated against them for centuries because of their appearance.

The basis of diagnosis of achondroplasia is the presence of the physical findings described previously as well as characteristic radiographic anomalies. Molecular testing should be performed only if the diagnosis is uncertain on clinical or radiologic grounds, or in cases in which prenatal diagnosis through amniocentesis is requested.

NEUROFIBROMATOSIS TYPE 1 (NF-1) [OMIM #162200]. NF-1, a common (1 in 4,000 births) autosomal dominant disorder, was originally described by von Recklinghausen in 1882. It was formerly known as "the elephant man's disease," but it is now clear that Joseph Merrick, the so-called Elephant Man, suffered from another disorder, Proteus syndrome. NF-1 is characterized by a large number of separate, seemingly unconnected clinical findings (Table 11-7).

Although the penetrance of NF-1 is high, the expression of the gene is extremely variable. In fact, many individuals who carry the mutated gene go through life unaware of their diagnosis. Most patients manifest only

TABLE 11-7

Criteria for Diagnosis of Neurofibromatosis Type 1 (NF-1)[a]

Café-au-lait spots Prepubertal: five or more (>0.5 cm in diameter) Postpubertal: five or more (>1.5 cm in diameter)
Axillary or inguinal "freckling"
Neurofibromas (dysplastic Schwann cell tumors) Two or more neurofibromas, or One or more plexiform neurofibromas
Lisch nodules (pigmented iridal hamartomas)
Optic glioma (one or more neurofibromas of the optic nerve) Skeletal manifestations, including: Scoliosis (often rapidly progressive) Pseudarthrosis (bowing of a bone due to skeletal defect) Bony rarefaction or overgrowth due to presence of plexiform neurofibroma Sphenoid wing dysplasia (5%)
Family history of NF-1 in parent or child diagnosed according to these criteria (additional features include developmental delay/learning disability, central nervous system tumors, hypertension)

[a] To make a diagnosis of NF-1, patients must fulfill at least two of these criteria.

café-au-lait spots (hyperpigmented areas); axillary or inguinal freckling; and small subcutaneous nodules, which represent Schwann cell tumors known as neurofibromas. Ten percent of individuals who carry the gene for NF-1 suffer more severe manifestations, including astrocytomas, optic gliomas and other brain tumors, craniofacial disfigurement, scoliosis, and pseudarthrosis (the presence of a false joint, usually in a long bone).

The staggering array of clinical features represents one of the best examples of pleiotropy known to exist in any autosomal dominant syndrome. Although the explanation of this phenomenon is still not clear, three major scientific breakthroughs have permitted the solution of at least part of the riddle of NF-1.

1. Mapping of the gene responsible for the disorder (in 1987) to the long arm of chromosome 17 (17q11.2).
2. Identification in different families of many different mutations, deletions, and insertions within this gene, providing one clue to the puzzle of the marked variability of clinical expression.
3. Identification of the protein responsible for the disorder. Named "neurofibromin," the protein is believed to function as a negative regulator or inhibitor to p21-ras, a proto-oncogene. Decreased production of neurofibromin leads to overexpression of this proto-oncogene, presumably causing the features of the disorder.

Molecular techniques for diagnosis of an isolated case of NF-1 are usually not helpful because of the large number of mutations that have been identified in the neurofibromin gene. As in achondroplasia, confirmation of the diagnosis of NF-1 is based on the presence of clinical features (see Table 11-7).

MARFAN SYNDROME (OMIM #154700). This autosomal dominant condition, which occurs in approximately 1 in 10,000 live born infants, is due to a single gene defect that causes abnormalities in several organ systems. Significantly, three systems are most often affected. In the skeletal system, dolichostenomelia (tall, thin body habitus), arachnodactyly (spider-like fingers and toes), pectus excavatum or carinatum, kyphoscoliosis, and joint laxity occur. In the ophthalmologic system, high myopia and a defect in the suspensory ligament of the lens, which leads to ectopia lentis, cause decreased visual acuity. In the cardiovascular system, a defect in the wall of the aorta leads to progressive dilatation of the ascending aorta, causing aortic insufficiency and, if untreated, ultimately resulting in dissecting aneurysm of the aorta with sudden death.

The fact that these systems are modified has led to the belief that a defect in some element of connective tissue common to these organs is responsible for Marfan syndrome. In the 1990s, a defect in the protein fibrillin 1, an essential element of the myofibrillar array of connective tissue, was documented in individuals with Marfan syndrome. The gene responsible for coding for this protein is located on the long arm of chromosome 15. Unlike

TABLE 11-8

Rules of Autosomal Recessive Inheritance

1. The trait appears in siblings, but not in their parents or offspring.
2. On average, 25% of siblings of the proband are affected (at the time of conception, each sibling has a 25% chance of being affected).
3. A "normal" sibling of an affected individual has a two-thirds chance of being a carrier (heterozygote).
4. Males and females are equally likely to be affected.
5. Rare traits are likely to be associated with parental consanguinity.
6. Traits generally involve mutations in genes that code for enzymes (e.g., phenylalanine hydroxylase, deficient in phenylketonuria) and are associated with serious illness and shortened life span.

achondroplasia, in which only a handful of mutations occur in the causative gene, Marfan syndrome is associated with many mutations. Virtually every family with a member with Marfan syndrome has a different mutation. As in NF-1, the diagnosis of Marfan syndrome is made based on the presence of characteristic clinical features.

Autosomal Recessive Disorders

Certain disorders follow an autosomal recessive pattern of inheritance. Unlike in autosomal dominant disorders, for an autosomal recessive disorder to be clinically significant, two copies of an abnormal gene must be present. An individual bearing two errant copies of the same gene is said to be **homozygous**. For a homozygous individual to be conceived, both parents must carry at least one copy of the errant gene and are, therefore, **heterozygous**. However, because a single errant copy of the gene is not sufficient to cause clinical abnormalities, heterozygous parents are nearly always asymptomatic. Thus, in most autosomal recessive disorders, the presence of a disease in a child is the first sign that an abnormality is segregating in a family.

The family pedigree in which an autosomal recessive trait is segregating illustrates the rules of autosomal recessive inheritance (Table 11-8; Figure 11-4).

SICKLE CELL DISEASE (OMIM #603903). Sickle cell disease is considered briefly here because of its autosomal recessive pattern of inheritance. (See Chapter 16 for more details.) Much is known about the genetic basis of sickle cell disease, the first human mutation to be elucidated. This mutation, which is caused by a single base substitution in the gene locus on the short arm of chromosome 11, results in the substitution of a valine residue for the glutamic acid residue that normally resides at position 6 in the β-globin molecule. This tiny defect leads to instability of the hemoglobin molecule, so that when oxygen saturation decreases, the hemoglobin molecule "collapses." This results in a deformation of the red blood cell (RBC) (sickle shape) and in occlusion of capillaries and smaller arterioles.

Individuals who are heterozygous for the sickle cell disease gene are said to have sickle trait. Such individuals, although clinically normal, have RBCs that sickle when subjected to low oxygen tension in vitro, a phenomenon that has allowed differentiation of these individuals from the rest of the population. The heterozygous state is present in approximately 1 of every 10 African Americans. As a result of this very high heterozygote frequency, the occurrence of newborns with sickle cell disease in this population can be easily predicted using the Hardy-Weinberg equation:

1. The chance of the mating of two individuals with the trait is approximately 1/10 × 1/10, or 1/100.
2. The chance that a child with sickle cell disease will be born to two parents, both of whom have trait, is 1/4.
3. Thus, the general incidence is 1/100 × 1/4, or 1/400.

As calculated, 1 of every 400 children born to parents of African American heritage will have sickle cell disease. The actual number is very close to the predicted frequency.

The reason that sickle cell disease, which causes such severe symptomatology in the homozygous affected individual, continues to be so prevalent in the population is that autosomal recessive traits depend only on the survival of the heterozygotes. It is not necessary for the gene's survival for homozygotes to reach childbearing age. This has led to a theory explaining why the sickle cell mutation has been maintained at such a high level in the

population. If instead of causing harm, a particular gene mutation present in the heterozygous state actually protects the individual in some way, the mutated gene has pressure to remain in the population. The mutation makes the carrier more fit and gives the heterozygote a selective advantage over homozygous unaffected individuals.

The first clue to the fact that sickle trait offered the heterozygote an advantage came from the observations that the sickle gene occurred in highest frequencies in regions where falciparum malaria is common. Epidemiologic studies have shown that heterozygotes are resistant to severe infection from the parasite *Plasmodium falciparum*. In Africa, individuals who have sickle trait become infected as frequently as do people who are free of the trait, but the former group has fewer complications resulting from the infection—the need for hospitalization is less, and deaths are far fewer. Physiologic studies have determined the reason for this increased survival. In individuals without sickle trait, the malaria parasite uses the RBCs of its host to proceed through its life cycle. In individuals with sickle trait, this process is interrupted, and the spread of the parasite is attenuated.

Sickle cell anemia, like some other autosomal recessive traits, occurs with markedly increased frequency within certain ethnic groups. This distribution pattern has raised the possibility of eradicating the conditions through directed screening programs, genetic counseling, and prenatal diagnosis. This approach has been used in Tay-Sachs disease, a condition that occurs most frequently in individuals of Ashkenazi Jewish background.

ELLIS–VAN CREVELD SYNDROME (OMIM #225500). Although some autosomal recessive traits are relatively common, the majority are rare disorders that occur infrequently in most populations. Ellis-van Creveld syndrome, also called chondroectodermal dysplasia, is one of these conditions. This disorder involves a combination of short stature (with disproportionately shortened extremities), polydactyly, a narrowed thorax, and congenital heart disease with abnormalities of the mouth (thickened frenula, defects in the alveolar ridge, and dental anomalies) and the nails (hypoplasia). Recently, researchers found that mutations within the EVS gene on chromosome 4p16.1 cause Ellis-van Creveld syndrome.

In 1964, McKusick discovered multiple cases of Ellis-van Creveld syndrome in an inbred Old Order Amish village in Pennsylvania. A study of trends within the Amish population explained why so many individuals with this disorder were concentrated in such a small area. The Amish tend to isolate themselves within small villages. When, through reproduction, the village becomes too crowded, one or two nuclear families break away from the main group and establish a new community some distance away from the original town. The founders

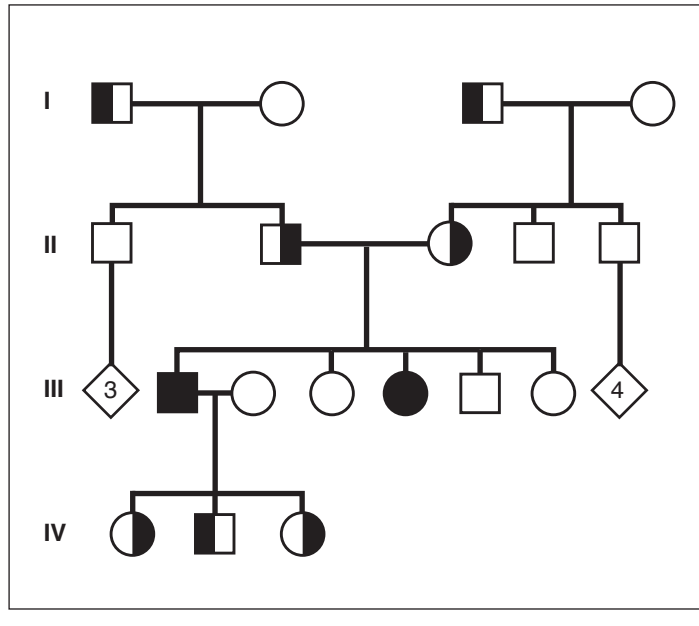

FIGURE 11-4. Pedigree of an autosomal recessive trait. Affected individuals are found in only one generation. Note that both parents of an affected child are obligate heterozygotes (designated by *half-shaded symbols*), as are all of the offspring of a mating between an affected individual and a homozygous normal individual. □, male; ○, female; ■, affected male; ●, affected female; ◧, heterozygous (carrier) male; ◑, heterozygous (carrier) female; ◇, sex not known. From Gelehrter TD, Collins FS: *Principles of Medical Genetics*. Baltimore, Williams & Wilkins, 1990, p 36.

of this new community reproduce, their children marry and in turn, reproduce, and eventually, the entire village is populated by descendants of the original founder couple. The founders bring with them their "genetic baggage," including the presence of one or more rare autosomal recessive traits carried in the heterozygous state. Through a few generations, the gene frequency of these rare traits increases dramatically, since most people never leave the home village.

X-Linked Recessive Disorders

Disorders caused by abnormalities of genes linked to the X chromosome have a distinct and unusual pattern of inheritance known as X-linked recessive. Heterozygous females, who display little or no effects, usually carry these disorders and pass them on to their sons, who are **hemizygous** because they have only one X chromosome. These males usually suffer severe manifestations.

The observation that males can survive with only one copy of the X chromosome, whereas females with one copy (Turner syndrome) have an increased prenatal mortality puzzled geneticists throughout much of the early part of the 20th century. In 1962, Mary Lyon postulated the explanation for this phenomenon. According to the Lyon hypothesis, at a very early stage in development, one of the two X chromosomes in every cell of the female pre-embryo becomes randomly inactivated. Thus, females are essentially mosaics, their bodies composed of two separate cell types, with each bearing a separate, active X chromosome. As the result of "lyonization," when an errant gene is present on one X chromosome, some cells express the abnormality, whereas others do not. Because inactivation of the X chromosome occurs randomly, it is possible that, by chance, one cell type may predominate over the other. Therefore, some women who carry an abnormal gene on one of their X chromosomes may, because of random inactivation of most of the X chromosomes bearing the normal gene, express symptoms of the disease caused by that abnormal gene.

The pedigree of a family in which an X-linked recessive inherited disorder is segregating illustrates the rules of X-linked recessive inheritance (Table 11-9; Figure 11-5).

DUCHENNE MUSCULAR DYSTROPHY (OMIM #310200). Duchenne muscular dystrophy, the most common form of muscular dystrophy, occurs in 1 in every 3,500 boys born in the United States. Among the clinical features of this condition are a "waddling" gait, usually discovered at about 3 years of age, and excessive falling (see Chapter 19). In most cases, pseudohypertrophy of the calf muscles is apparent on initial examination, and serum creatine kinase is markedly elevated. Affected boys show a slowly progressive downhill course. Death, usually from cardiopulmonary complications, occurs in the second or third decade.

Although Duchenne muscular dystrophy has long been known to be linked to the X chromosome, characterization of the gene responsible for the condition and the protein that codes for it occurred only in the late 1980s. Using a procedure known as "reverse genetics," researchers identified the protein dystrophin as the component of muscle cells that is deficient in men with this form as well as some other forms of muscular dystrophy. The characterization of dystrophin has led to major advances in both the diagnosis and potential treatment of Duchenne muscular dystrophy.

Mothers and sisters of affected males may or may not be carriers of the abnormal gene. In the past, counseling was offered based on statistical probabilities, which depended on several conditions, such as the number of other affected males in the family and the level of creatine kinase in the woman's blood. Fetal sex determination was the only possible method of prenatal diagnosis in women believed to be carriers. However, because the actual gene defect responsible for Duchenne muscular dystrophy has been discovered, counseling with certainty

TABLE 11-9

Rules of X-Linked Recessive Inheritance

1. The incidence of the trait is higher in males than females.
2. The trait is passed from carrier females, who may show mild expression of the gene, to their sons, who are more severely affected.
3. Each son of a carrier female has a 1 in 2 chance of being affected.
4. The trait is transmitted from affected males to all of their daughters. It is never transmitted from father to son.
5. Because the trait can be passed through multiple carrier females, it may "skip" generations.

is now available following testing of many of these female relatives. In addition, once a female has been identified as a carrier, direct prenatal diagnosis of the fetus involves either amniocentesis or chorionic villus sampling. Because of the inheritance pattern, men with Duchenne muscular dystrophy who reproduce will not have affected children. All daughters born to such men will be obligate carriers (and therefore, are at risk for having sons who are affected), whereas sons, having received the father's Y chromosome, will be completely free of disease.

HEMOPHILIA A. Hemophilia A is the most common hemorrhagic disorder occurring in children. The cause of this condition is a profound deficiency of factor VIII, an essential protein for coagulation. Most boys with classic hemophilia are diagnosed in early childhood after one or more episodes of unexplained bleeding. Because of their inability to clot, boys with hemophilia have recurrent episodes of hemarthrosis (bleeding into joint spaces) that can lead to chronic, painful arthritis. They develop intramuscular hematomas (see Chapter 16). Head trauma is a serious and potentially lethal problem because of the possibility of intracranial bleeding (see Chapter 23).

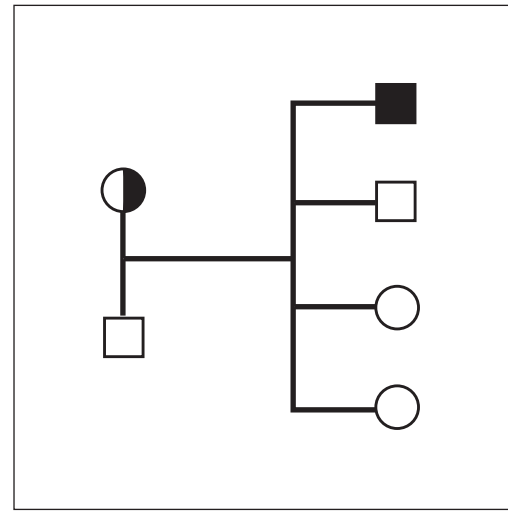

FIGURE 11-5. Pedigree of an X-linked recessive trait. Only male children of carrier females are affected. All girls born to hemizygous fathers are carriers; boys born to these men are never affected. □, male; ○, female (noncarrier); ■, hemizygous affected male; ◑, heterozygous (carrier) female.

The genetics of hemophilia is identical to that of Duchenne muscular dystrophy because it is an X-linked recessive disorder. Similarly, the gene responsible for producing factor VIII has been characterized, and direct DNA diagnosis is possible. As with Duchenne muscular dystrophy, the children of males affected with hemophilia are not themselves affected; however, all their daughters will be carriers and, as a result, should receive prenatal diagnosis during pregnancy if they wish. All first-degree relatives of affected males (i.e., mothers, sisters) should routinely have the opportunity to be tested and, if found to be carriers, should also be referred for counseling for consideration of prenatal diagnosis by either chorionic villus sampling or amniocentesis.

Multifactorially Inherited Disorders

Of the four etiologic categories of congenital or genetic disorders, multifactorial (also known as polygenic) inheritance is by far the most common. Such inheritance is responsible for 20% of all congenital malformations and also plays a role in determining susceptibility to most chronic disorders of adult life, including atherosclerosis and coronary artery disease, cancer, and diabetes. The cause of multifactorial inheritance is an interplay between multiple background genes and the environment in which those genes are expressed. Although multifactorial conditions tend to cluster in families, they do not conform to simple Mendelian patterns of inheritance.

Traits that are inherited in a multifactorial manner show a blending of features known as **continuous variations** (e.g., the bell-shaped distribution in the plot of the height of all medical students in the United States). When a trait such as height is the subject, excessive shortness or tallness is not necessarily considered a pathologic condition. However, for certain traits such as the timing of closure of the neural tube or the fusion of the palatal arches in the midline, distribution at the outer ends of the curve may have serious, life-threatening implications. Two relatively common congenital malformations that demonstrate multifactorial inheritance are discussed here.

Neural Tube Defects

Neural tube defects, consisting of anencephaly, meningocele, and meningomyelocele, are among the most common disabling birth defects that occur in humans. The embryology involved in the closure of the neural tube is well understood. At approximately 18 days after conception, the neural plate begins to involute. At first, an indentation known as the neural groove can be seen, but at 23 days after conception the edges of the neural groove meet to form the beginning of a tube. Over the next few days, this tube "zippers" closed; at the cephalad end, the tube becomes the brain; at the caudal end, the spine. For these structures to form normally, it is essential that complete closure of the tube occur by a specific time (known as the **threshold**). If closure of the cephalad end is not complete, abnormal brain development occurs, with anencephaly, a uniformly lethal condition. If closure of the caudal end is not complete, the child will be born with myelomeningocele (also known as spina bifida).

In 1990, it was estimated that myelomeningocele affected 1 in 1,000 liveborn infants in the United States. Anencephaly occurs with a similar frequency, although most of these infants are either stillborn or die in the neonatal period. Multiple factors, both genetic and nongenetic, dictate the speed with which the neural tube closes. Evidence for this comes from the following observations:

- Neural tube defects show ethnic differences in frequency. Far more common in the British Isles, they are much less common in Asia; in Ireland, the incidence is 1 in 250. These ethnic differences suggest a genetic component.
- Couples from the British Isles who come to the United States have a risk intermediate between the risks in the United Kingdom and in the United States, suggesting an environmental component.
- The occurrence of neural tube defects exhibits seasonality. Affected infants are more likely to be born during the late fall and early winter, again suggesting an environmental component.
- Parents who have one child with a neural tube defect are 20 to 40 times more likely to have a second affected child. This provides further evidence of a genetic component.

Pediatric Pearl: Periconceptual supplementation with folic acid has now conclusively been shown to significantly decrease the risk of having a child with a neural tube defect. This nutritional influence suggests yet another environmental component.

Children with myelomeningocele have an assortment of medical and surgical problems. They require neurosurgical procedures in the newborn period to close the spinal defect and, in as many as 90% of cases, placement of a ventriculoperitoneal shunt is necessary to alleviate obstructive hydrocephalus. Children with shunts require ongoing neurosurgical surveillance to evaluate for shunt obstruction. In 85% of patients, neurogenic bowel and bladder occurs as a result of the level of the spinal lesion; close supervision by both a urologist (who manages the bladder through clean intermittent catheterization) and a gastroenterologist is required. Numerous orthopedic problems occur, including joint contractures, clubfoot deformity, scoliosis, and paraparesis. Management by an orthopedic surgeon, in conjunction with a physiatrist and orthotist, is necessary. The pediatrician provides routine health care maintenance and coordinates the care provided by the numerous other members of the multidisciplinary team of health care professionals.

Because of the elevated recurrence risk associated with neural tube defects, prenatal diagnosis consisting of amniocentesis, α-fetoprotein screening, and sonography should be offered to the family. In recent years, researchers have demonstrated conclusively that folic acid reduces the risk of having either a first or subsequent child with a neural tube defect. Because the effect occurs only if folic acid supplementation begins at least 2 months before conception, the U.S. Department of Health and Human Services now recommends that all women of childbearing age take 0.4 mg of folic acid per day. Women who have had a previous child with a neural tube defect are at increased risk of recurrence, so they should take a higher dose of folic acid. It is recommended that first-degree female relatives of an individual with a neural tube defect take 4 mg of folic acid per day, beginning at least 2 months before planned conception. By following these recommendations, women may reduce the risk of bearing a child with a neural tube defect by up to 70%.

Pediatric Pearl: In recent years, clinicians have realized that an allergy to latex products develops in virtually all children with myelomeningocele. Before 1980, this allergy was almost unknown, but it has led to life-threatening complications due to anaphylaxis in affected patients. The Spina Bifida Association of America recommends that the use of latex products be avoided in all patients with neural tube defects.

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis is a disorder of historic importance in that it was the disease for which the multifactorial threshold model was actually developed. Although it originates in fetal life, because of its pathophysiology, hypertrophic pyloric stenosis is a condition that is usually not diagnosed until late in the first month after birth. Hypertrophy of the muscles of the pylorus leads to obstruction of the flow of partially digested food from the stomach into the first section of the duodenum. Vomiting becomes progressively worse and becomes

projectile in nature (see Chapter 25). At presentation, the child is usually dehydrated, has a significant electrolyte imbalance (hypochloremic alkalosis), and is extremely sick and irritable.

To the geneticist, the two most interesting features of hypertrophic pyloric stenosis are its sex distribution and its empirically derived risk of recurrence. Pyloric stenosis is five times more common in boys (5/1,000) than in girls. Furthermore, the recurrence risk is very different for males and females, with children born to affected women at much higher risk than those born to affected men. Assuming that the threshold for developing pyloric stenosis is lower for males than for females explains the observed sex distribution. Not only would more males be affected, but also the females who did have the disorder would be more severely affected. The more severely affected the parent, the higher the recurrence risk, thus explaining the observed data.

Teratogenically Induced Disorders

Defined as a chemical or environmental agent that has the potential to damage embryonic tissue primordia and resulting in one or more congenital malformations, teratogens are responsible for approximately 6.5% of all birth defects. Knowledge of these agents and their effect on the developing embryo or fetus is important for two reasons. One, this frequency is probably falsely low because of underreporting. As time passes, more is known about the effects of environmental agents on development, and it is likely that this frequency will significantly increase. Two, and perhaps more importantly, congenital malformations caused by teratogenic agents are all potentially preventable.

The first evidence that physical agents had the potential to harm developing humans came from Australia in 1941. N. McAllister Gregg, an ophthalmologist, noted a sharp increase in the number of infants born with congenital cataracts. On examining these children further, he noted a distinct pattern of abnormalities including sensorineural deafness, microcephaly with developmental delay, and congenital heart disease. By reviewing the pregnancy records, he discovered that all affected infants had been born to women who had been infected with German measles during their pregnancies. Rubella was the first known teratogen.

For nearly 20 years, people believed that most physical agents could not damage the developing human; viral agents might be a special case. This changed dramatically in 1960 when Pfeiffer and Kostellow reported the cases of two German children with phocomelia, a severe limb defect. Within a few months, an epidemic of phocomelia gripped Germany and other European countries. Epidemiologic evaluation soon uncovered the putative cause. Mothers of nearly all affected infants had been treated with thalidomide, a potent sedative and antiemetic, during early pregnancy. Before authorities withdrew the drug from the market, malformations occurred in 7,000 European and Australian infants. (Because of Food and Drug Administration regulations, the drug was never marketed in the United States.) The thalidomide saga opened the floodgates. Soon, physicians were attempting to attribute every observed malformation to some drug that had been administered to the mother during pregnancy. The truth probably lies somewhere in between.

Teratogenically induced disorders can be divided into three major groups: (1) those due to maternal factors, (2) those due to exposure to drugs and chemicals, and (3) those due to environmental agents.

Maternal Factors

From the time of Gregg's initial observation regarding the effects of the rubella virus, it has been known that the presence of maternal illness can have lethal or devastating effects on the conceptus. These illnesses may be further broken down into two categories: maternal infections and other maternal illnesses.

MATERNAL INFECTIONS. Some common infectious agents have harmful effects on the conceptus (Table 11-10). The effect each of these infectious agents has on the developing embryo or fetus is related to the timing of infection; generally, the earlier the infection, the more devastating the effects.

MATERNAL ILLNESS (OTHER THAN INFECTIONS). The conceptus is sensitive to a number of maternal metabolic disturbances. It is important to note that in most cases, strict control of the underlying metabolic abnormality in the mother will serve to protect the fetus. Two examples are maternal diabetes mellitus and maternal phenylketonuria (PKU).

Approximately 10% of infants of diabetic mothers are born with an abnormality in form or function that is detectable in the neonatal period. Malformations include the caudal regression sequence (a severe defect characterized by absence of the sacrum, defects of the lower limbs, imperforate anus, and abnormalities of the genitourinary tract) and the VACTERL association. The presence and severity of anomalies appears to be directly related to the degree of glycemic control during the first trimester of pregnancy.

PKU, an inborn error of metabolism caused by a deficiency of phenylalanine hydroxylase, has become a relatively innocuous disease as a result of a combination of neonatal screening and the institution of special

TABLE 11-10

diets. In the past, the tendency has been to limit intake of phenylalanine in affected individuals until late childhood, when liberalization of the diet has occurred. However, it was noted that offspring of women with PKU were at significant risk for mental retardation, microcephaly, and congenital heart disease. In the late 1980s, physicians began to return women in their childbearing years to low phenylalanine diets and found that if this change was instituted before the start of pregnancy, the fetus was at little or no increased risk for these anomalies.

Drugs and Chemicals

This category of teratogens has special significance because, to some extent, use of these agents by pregnant women is often regulated by their physicians. Therefore, it is essential for the physician to have a clear understanding of agents that can cause birth defects.

NONPRESCRIPTION DRUGS. This group of drugs includes alcohol, cocaine, heroin, and marijuana. Also considered as part of this group are caffeine and nicotine, agents that are believed not to have teratogenic potential. The teratogenic effects of two nonprescription agents, alcohol and cocaine, are discussed.

Features of **fetal alcohol spectrum disorder** include prenatal and postnatal growth deficiency, microcephaly with developmental delay, various skeletal and cardiac anomalies, and a characteristic facial appearance.

Pediatric Pearl: The full-blown syndrome occurs in 3 to 5/1,000 children, making fetal alcohol syndrome the most common teratogenic syndrome encountered in humans.

It is estimated that a pregnant woman has to drink at least 6 ounces of alcohol each day during the pregnancy to cause full-blown fetal alcohol syndrome. If alcohol ingestion begins after the first trimester (following the completion of organogenesis), the child is likely to have few of the physical features of fetal alcohol syndrome, but is at significant risk for the developmental and behavioral consequences of fetal alcohol exposure. This latter condition, termed fetal alcohol effects, is much more common than fetal alcohol syndrome and affects 20% to 30% of infants of alcoholic women. Therefore, alcohol is a behavioral teratogen as well as a structural teratogen. Because the effects are so variable the term fetal alcohol spectrum disorder has recently been employed.

More recently, attention has focused on the effects of other drugs of abuse on the developing embryo. A spectrum of anomalies has been observed in some offspring of women using cocaine, including intracranial hemorrhages leading to developmental disabilities and microcephaly, intestinal atresias, limb reduction defects, and striking urinary tract anomalies such as the "prune belly syndrome." The cause of these anomalies appears to be vascular disruption resulting from the vasoconstrictive effects of the drug occurring at critical times of gestation.

PRESCRIPTION DRUGS. These agents are important because their use is recommended by a physician. Thalidomide was the first prescription drug known to cause malformations. The effects of three other drugs, hydantoin, warfarin, and cis-retinoic acid, are described in this section.

Features of **fetal hydantoin syndrome** include a characteristic facies, mild mental retardation, and hypoplasia of the distal phalanges of the fingers and toes, with tiny or absent nails a striking characteristic of the disorder. In recent years, the pathogenetic mechanism responsible for the malformations has been described and appears to be related to the level of epoxide hydrolase, an enzyme in the mother's circulation, which is responsible for the breakdown of a metabolite of hydantoin. The risk of the syndrome is low; less than 10% of exposed embryos have features of the disorder.

Warfarin is also known to cause malformations. Deep vein thrombosis is a relatively common complication of pregnancy. The use of anticoagulant medication is critical to prevent pulmonary embolism, and warfarin is the oral medication most commonly used to treat this condition. In 1966, a pattern of malformations was described, including hypoplasia of the nasal bridge with upper airway obstruction, stippled calcification in the epiphyses of numerous bones, and mental retardation. The pathogenesis of these defects is unclear. Warfarin is contraindicated in pregnancy.

cis-Retinoic acid, a vitamin A congener, is an effective agent in the treatment of cystic acne. In the early 1980s, clinicians found that this drug was a potent teratogen. Up to 70% of pregnancies in which women received cis-retinoic acid during the first trimester were abnormal. Some ended in miscarriage, others ended in the birth of a child with what has become known as the Accutane embryopathy, a pattern of anomalies including severe craniofacial disorders (abnormalities of the skull, ears, eyes, nose and palate), cardiac defects, and the DiGeorge malformation sequence (hypoparathyroidism, T-cell deficiency).

Environmental Agents

In contrast to prescription and street drugs, exposure to chemicals and agents in the environment is not easily controllable. Some environmental agents clearly do not cause birth defects. Contrary to media reports, there is no convincing evidence that exposure to video display terminals, electromagnetic fields, caffeine, or inhaled cigarette smoke can induce malformations in fetuses. Two agents, radiation and methylmercury, are known to cause problems. They are described in this section.

RADIATION. From the experience in the Japanese cities of Hiroshima and Nagasaki, it became clear that radiation exposure during fetal life can have lethal or devastating consequences. In addition to a significantly higher rate of spontaneous abortion than normal, pregnancies exposed to high doses of radiation resulted in the birth of children with microcephaly, mental retardation, and skeletal malformations. The dose of ionizing radiation needed to induce these anomalies is more than 5 rads and probably closer to 25 rads. In contrast, the radiation dose used in diagnostic radiology examinations is extremely low, with most exposures in the range of a few millirads. Therefore, diagnostic radiologic procedures are probably safe in pregnancy.

METHYLMERCURY. An inadvertent spill of methylmercury into the water supply in the city of Minamata, Japan, in the 1960s led to an outbreak of congenital malformations in infants who were gestating during that period. These children were born with neurologic aberrations that included developmental retardation, cerebral palsy–like movement disorders, and, in some cases, blindness. This has raised concern about the possibility of abnormalities in the offspring of women who, because of diets rich in mercury-contaminated fish, ingest large amounts of this element.

Developmental Disabilities

D. Rani C. Kathirithamby and Maris D. Rosenberg

Monitoring children's development is a critical aspect of pediatric health care supervision. The pediatrician who suspects developmental problems in a child must be prepared to help the family gain access to evaluation services and obtain appropriate intervention. Early intervention has the potential to affect both the child's developmental outcome and the family's functioning. This chapter discusses developmental surveillance and screening and the presentation of developmental disabilities. It focuses on three developmental disabilities that manifest in infancy/early childhood: intellectual disability (formerly known as mental retardation), cerebral palsy, and autistic spectrum disorders; in addition, it highlights learning disability, which becomes evident during the school-age years.

DEVELOPMENTAL SURVEILLANCE AND SCREENING

It is critical to identify developmental delays as early as possible. Early identification of developmental disorders allows access to a range of therapeutic interventions geared toward maximizing a child's developmental potential. Identification of the etiology of the disorder also helps to identify associated medical conditions or other needs of the child and family.

In a 2006 policy statement, the American Academy of Pediatrics (AAP) published an algorithm for developmental surveillance and screening (Figure 12-1). Developmental surveillance is a longitudinal process, recommended at every health supervision visit. Developmental screening involves the periodic use of standardized screening instruments. One might imagine surveillance to be an ongoing movie chronicling a child's development, whereas screening is a series of snapshots.

Developmental surveillance has five major components (Table 12-1). While all children deserve careful monitoring, those with risk factors for developmental disability merit closer scrutiny. Table 12-2 lists prenatal, perinatal/neonatal, and postnatal factors that place children at risk for developmental disability.

The AAP statement recommends the use of developmental screening instruments at any point at which surveillance raises concern, and for **all children** at the 9, 18- and 30-month (or 24-month if a 30-month visit is not scheduled) health supervision visits. In addition, it recommends the use of specific screens for autistic spectrum disorders at the 18- and 24-month visits. Screening involves the use of standardized instruments that enable the pediatrician to monitor a child's developmental progress over time more objectively. It should be emphasized that screening procedures are not diagnostic for particular developmental disabilities and do not determine precise level of functioning. However, they are an important step in recognizing a potential problem and obtaining further diagnostic evaluation. The choice of a screening instrument should be based on a variety of factors such as the purpose of the screening (e.g., general developmental screening versus screening for a particular disorder, such as autism), characteristics of patients and families served (e.g., primary language, literacy level), and resources of the practice in which the screening instrument is used. Table 12-3 lists a few widely used developmental screening instruments.

PRESENTATION OF DEVELOPMENTAL DISABILITIES

Developmental disabilities present in an age-related manner. They manifest during the first year of life as motor delays, during the toddler and preschool years as language delays, and during school years as learning problems.

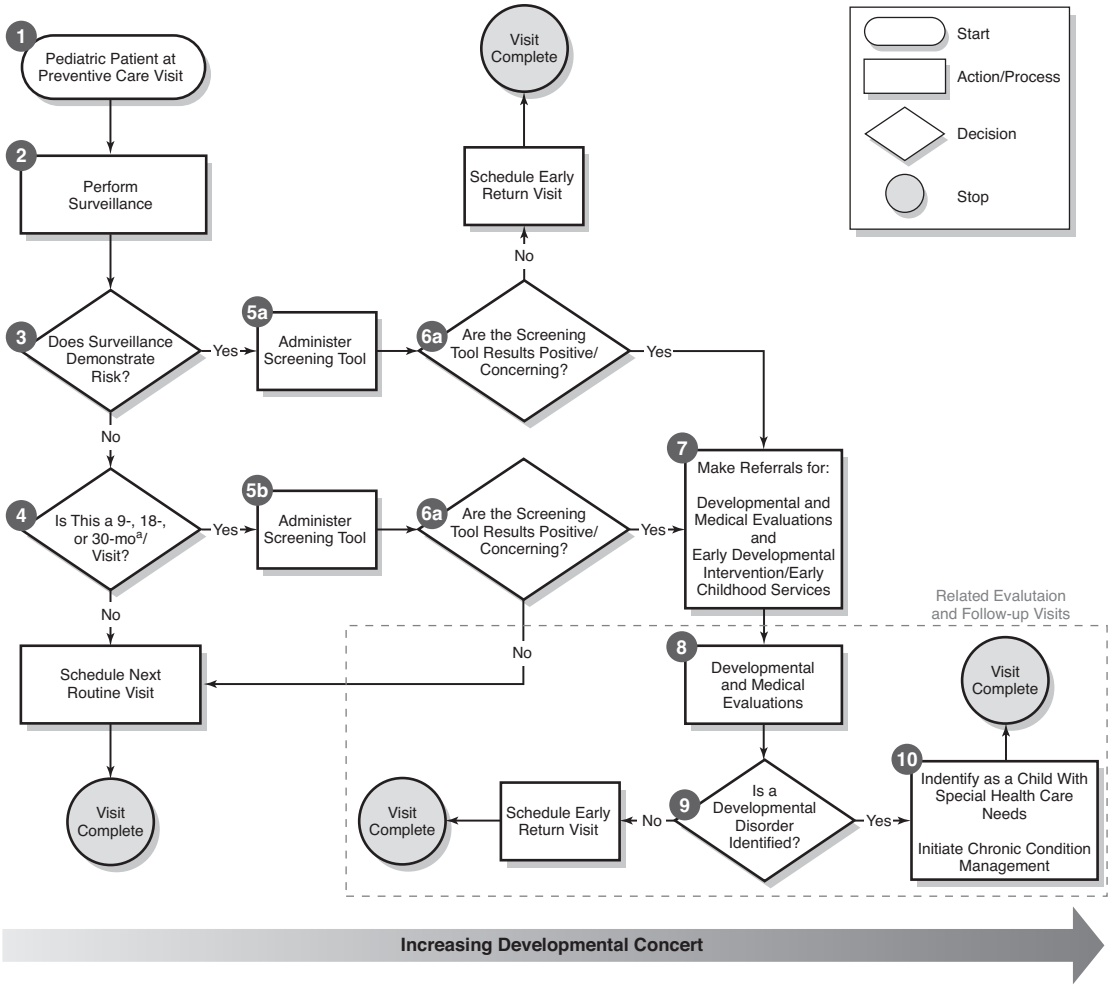

FIGURE 12-1. Algorithm for developmental surveillance and screening. Reprinted with permission from *Pediatrics* 118(1):407, 2006.

From the time of birth until the age of 1 year, the pace of motor development is rapid and proceeds in a predictable manner. Attainment of gross motor milestones depends on the symmetrical development of muscle tone and strength, which progresses cranially to caudally. In addition, motor development depends on the extinguishing of primitive reflexes and the emergence of postural reactions. Thus, the development of head control, the ability to roll over, independent sitting, and walking all occur in sequence at approximately 3 months, 4 to 5 months, 6 months, and 12 months of age, respectively. Deviations in development at this early stage tend to

ASD, autistic spectrum disorder.

present as motor milestone delays and may signify a neuromuscular, genetic, metabolic, infectious, or other abnormality. A careful medical evaluation is essential to determine the cause of developmental delay.

As children enter their second year, the development of communication becomes a sensitive indicator of overall development. Important communication milestones involve more than verbal communication. The phenomenon of **joint attention,** in which the child follows another individual's gaze or communicates by pointing, can be observed as early as 8 to 10 months. The act of pointing or gesturing to express desires or indicate interest is a critical milestone that should be present by 1 year of age. A child's single word vocabulary increases through the second year, with the emergence of two-word combinations by 2 years of age and three-word combinations by 3 years of age. Clarity of speech also improves, with 50% to 75% of speech becoming intelligible to strangers between 2 and 3 years of age. The quality and symbolism of children's play is also a valuable indicator of cognitive and linguistic development. Even with uncooperative children, watching them at play may yield a good deal of information.

Pediatric Pearl: The act of pointing or gesturing to express desires or indicate interest is a critical communication and social milestone that should be present by 1 year of age.

First and foremost, the evaluation of language delay in children must involve a thorough hearing assessment. Detection of hearing loss early can have a critical impact on later language development. In a policy statement published in 2007, the AAP recommends that the hearing of all infants should be screened at no later than 1 month of age. Many states mandate hearing screening in the newborn nursery. Infants who do not pass screening should have a comprehensive audiologic evaluation at no later than 3 months of age, and intervention

for confirmed hearing loss should begin before 6 months. As hearing loss can be progressive, ongoing surveillance of language development and hearing should take place during well-child care.

Pediatric Pearl: The evaluation of language delay in children must involve a thorough audiologic assessment.

Developmentally appropriate instruments are available to objectively measure hearing thresholds for critical frequencies for speech development. It is not enough to wave a rattle or clap the hands and judge a child's response. Electrophysiologic (e.g., evoked potentials) and otoacoustic techniques are available for children who are untestable using behavioral methods (e.g., visual reinforcement audiometry, play audiometry). Once the clinician determines that hearing is normal, she should try to discover whether the language delay appears to be part of a more global problem (e.g., cognitive delay), or whether it is isolated in the domain of speech and language. Language delay in the preschool years is a classic manifestation of intellectual disability, but coexisting delays in other domains such as fine motor-adaptive and personal-social skills may not be obvious until careful developmental screening has been completed. This is particularly true in children who are more mildly impaired. Other children may appear to have a limited ability to socialize and relate to others in addition to their delays in spoken language. These children may be manifesting autistic spectrum disorders. Conversely, many children do appear to exhibit delays that are limited to language. In such cases it is important to determine the degree to which receptive skills, expressive skills, and speech articulation are affected. These issues are critical in implementing intervention strategies that assist affected children in their communication development.

INTELLECTUAL DISABILITY

The term "intellectual disability" (ID) is now replacing the term "mental retardation."

An intellectual disability is a disability that involves significant limitations both in intellectual functioning and in adaptive behavior (social and everyday practical skills). By definition, ID originates before the age of 18. About 3% of the general population functions within the range of ID. Intellectual disability may be associated with other conditions (e.g., cerebral palsy, autistic spectrum disorders), and the varying degrees of severity affect the prognosis for ultimate functioning. Children with intellectual disability present as children who are functioning below age expectancy across all domains. In other words, they seem younger than their chronological age. Several classification systems, including that of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR), specify ranges of functioning that are helpful in anticipating intervention needs, rates of progress, and ultimate prognoses.

Mild ID, which affects about 85% of individuals with ID, is characterized by intelligence quotients (IQs) (developmental age divided by chronologic age) in the range of 50 to 70; the exact number varies with the standard deviation of the test being used. These children tend to present during the toddler or preschool years, often with no stigmatizing physical features. Academically, they tend to achieve up to a sixth grade level. Adults with mild ID can live independently, hold jobs, and raise children. They may require assistance in more complex tasks such as negotiating public transportation and arranging budgets and schedules, and they may need help coping during periods of stress.

Moderate ID affects about 10% of the intellectually disabled population. Children functioning in this range are likely to present somewhat earlier than mild ID, in the late infancy, toddler or early preschool years. These individuals are unlikely to progress beyond a second grade level academically. With training, they may attend to self-care needs and can work, usually in supervised settings.

Severe and profound ID encompasses the remaining 4% to 5% of the portion of this population. Children functioning in this range are likely to present with developmental delays in infancy. An identifiable medical etiology may be apparent on workup, with probable stigmatizing features and associated disabilities such as cerebral palsy, seizure disorders, or sensory deficits. These individuals have limited potential for independent living.

Psychological Assessment

It is necessary to document the subaverage intellectual functioning using culturally, linguistically, and developmentally appropriate standardized psychological tests. Such methods of assessment yield measures such as IQ. An IQ score of two or more standard deviations below the mean (generally 70 and under) satisfies this

criterion for diagnosis of intellectual disability. Examples of standardized tests commonly used in children are the Wechsler Preschool and Primary Scales of Intelligence (WPPSI), Wechsler Intelligence Scale for Children (WISC-4), and the Stanford-Binet Intelligence Scale.

Results of psychological tests reliably obtained after 2½ years of age are generally predictive of an individual's level of functioning and rate of learning and can be used as a basis for educational planning. Although assessment tools for infants and younger children are available (e.g., Bayley Scales of Infant Development), they do not yield results considered predictive of later functioning.

Clinical and Laboratory Evaluation

Medical evaluation of children with intellectual disability must involve a search for the cause of the condition. The many different etiologies all involve insult to the developing central nervous system (CNS). In 2006, the Committee on Genetics of the AAP published recommendations for the evaluation of children who present with developmental delays of unknown etiology (Figure 12-2). They recommend a clinical history, three-generation family history, dysmorphologic examination, neurologic examination, and genetic testing including chromosome analysis (greater than or equal to 650 bands) and fragile X molecular genetic testing. Fluorescence in situ hybridization (FISH) studies for subtelomere chromosome rearrangements and molecular genetic testing for typical and atypical presentations of known syndromes are recommended in those cases in which cytogenetic studies are normal. The newest diagnostic technology, molecular karyotyping using microarray comparative genomic hybridization, allows the detection of abnormal copy numbers of DNA sequences throughout the human genome (see Chapter 11 for complete discussion of genetic evaluation). It is estimated that copy number variants can be detected in as many as 10% to 20% of individuals with unexplained ID. Studies for metabolic disorders and neuroimaging are recommended only in instances where history or clinical findings support such studies.

Management

In discussions of the results of evaluation with parents, the clinician must carefully explain the meaning of the term intellectual disability, or "mental retardation", which is still in common use today. Parents may associate negative stereotypes involving behavioral and other stigmatizing conditions with this diagnosis. Without proper explanation, parents of mildly impaired youngsters may picture their child becoming wheelchair-dependent or otherwise severely impaired. Furthermore, parents who may not understand the difference between cognitive delay and emotional disturbance may believe that their child suffers from the latter condition. The pediatrician may be tempted to use other terminology such as "developmental delay," and while this may be more palatable, he must be careful to use the same diagnostic terminology that will be used in accessing services for the child. It is preferable for parents to hear the appropriate terminology, properly explained, rather than to see the diagnosis on paper for the first time without the benefit of the pediatrician's support.

The pediatrician is in a position to help parents interpret results of the diagnostic evaluation; particularly where findings suggest associated medical issues or etiologies with genetic significance. In providing a medical home for the child with intellectual disability, he must coordinate referrals to specialists and have knowledge of community resources. Monitoring the progress of a child with an intellectual disability is critical throughout the pediatric years. Any deterioration in functioning or progress that exceeds that predicted for a child's level of disability suggests possible confounding factors and mandates reevaluation. The pediatrician should bear in mind that each child, no matter what her level of functioning, can reach a certain potential, albeit at a slower rate than normal. The physician should help parents and other family members keep this realistically in mind while attempting to preserve optimum functioning of the family as a whole.

CEREBRAL PALSY

Cerebral palsy is a spectrum of disorders of movement and posture that continues to be the most frequent childhood motor disability. The incidence of cerebral palsy has remained constant at a rate of 2 to 3/1,000 live births during the last four decades.

Risk Factors and Classification

Cerebral palsy results from a nonprogressive lesion, an injury sustained during the period of brain growth, or a developmental deficit of the brain. Although motor deficits are the essential diagnostic feature of cerebral palsy, associated deficits resulting from the CNS pathology may occur. The brain lesions that lead to cerebral palsy

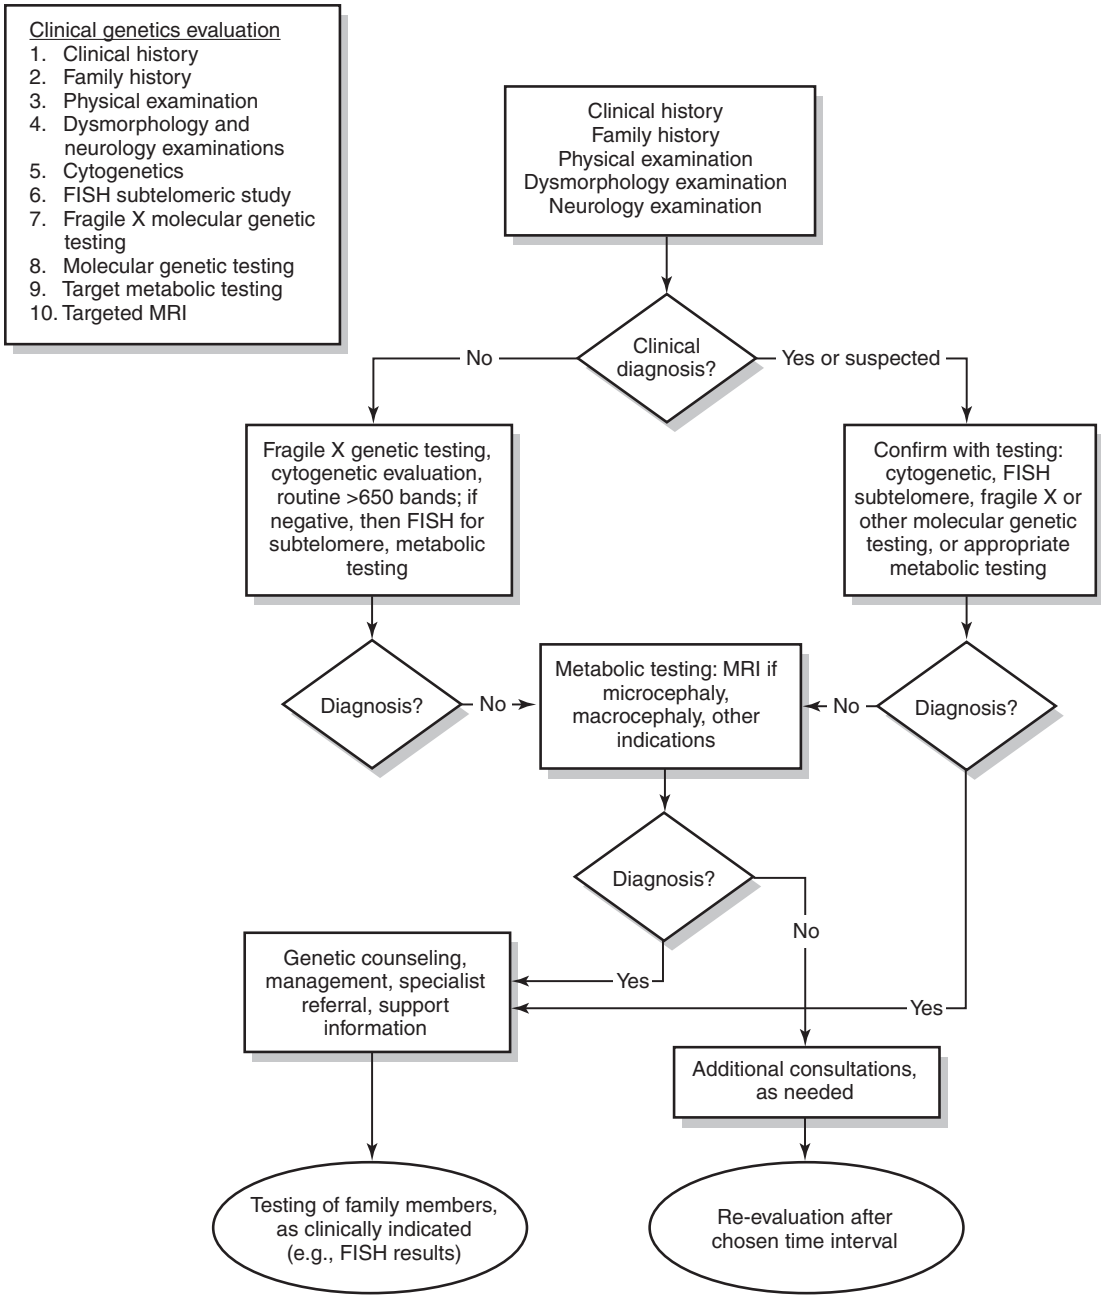

FIGURE 12-2. Recommended evaluation for children with intellectual disability of unknow etiology. Reprinted with permission from *Pediatrics*, Moeschler, J. et al, 117(6):2307, 2006. FISH, fluorescence in situ hybridization; MRI, magnetic resonance imaging.

may occur during the prenatal, perinatal, and postnatal periods. Risk factors for cerebral palsy are listed in Table 12-4. In most cases, there is no defined etiology. However, prematurity remains the greatest risk factor causing cerebral palsy. Based on movement and posture abnormalities there are three major types of cerebral palsy: **spastic, dyskinetic,** and **mixed** (Table 12-5). Rare types of cerebral palsy include atonic and rigid types.

A system of classification based on the ability of children with cerebral palsy to perform specific motor function has been developed by Palisano et al, called the Gross Motor Function Classification System (GMFCS), which is categorized into five groups (Table 12-6).

TABLE 12-4

Risk Factors Associated With Cerebral Palsy

Prenatal	*Neonatal/Perinatal*	*Postnatal*
Congenital malformations	Prematurity <32 weeks' gestation	Trauma
Social and economic factors	Birth weight <2,500 g	Infection
Maternal intrauterine infections	Growth retardation	Intracranial hemorrhage
Reproductive insufficiency	Abnormal presentation	Coagulopathy
Toxic/teratogenic agents	Intracranial hemorrhage	Metabolic
Maternal intellectual impairment	Infection	
Seizures	Bradycardia and hypoxia	
Hyperthyroidism	Seizures	
Multiple births	Hyperbilirubinemia	
Placental complication		
Abdominal trauma		

Adapted from Molnar GE, Alexander MA (eds): *Pediatric Rehabilitation*, 3rd ed. Philadelphia, Hanley & Belfus, 1999, p 194.

TABLE 12-5

Classification of Cerebral Palsy

Type/Subtype	*Involvement/Characteristics*
Spastic (most common)	
Spastic diplegia	Both upper legs
Spastic quadriparesis	Both upper arms and upper legs, but more severe in lower extremities
Spastic triplegia	Both lower legs and one arm
Spastic hemiparesis	One side of body, arm and leg (more involvement in arm)
Spastic monoplegia	One limb, usually mild, and very often a misdiagnosed hemiplegia
Dyskinetic	
Athetosis	Slow writhing movements of the face and distal extremities
Dystonia	Rhythmic twisting movements of trunk and proximal limbs with changes in muscle tone
Chorea (uncommon)	Rapid irregular jerky movements of face and extremities
Mixed	
Spastic athetoid	Spasticity and athetoid movements
Spastic ataxic	Unsteadiness, nystagmus, dyskinetic and uncoordinated movements

TABLE 12-6

Gross Motor Function Classification System (GMFCS)

GMFCS I	Walks, climbs stairs indoors and outdoors. No limitations.
GMFCS II	Walks indoors and outdoors, climbs stairs holding railings. Limitations on uneven surfaces and inclines.
GMFCS III	Walks indoors and outdoors, on level surfaces with assistive devices. Propels wheelchair.
GMFCS IV	Uses assistive device for ambulation and short distances. Uses wheelchair indoors and outdoors.
GMFCS V	Dependent in mobility.

Clinical and Laboratory Evaluation

History

The history should include a detailed prenatal, perinatal, and developmental history; family history; medical history; feeding history; and a review of systems. Early symptoms and signs that should arouse suspicion of cerebral palsy are delayed motor development and abnormal muscle tone, along with posture and movement patterns.

Physical Examination

The physical examination consists of a general examination (e.g., head circumference, height, and weight), an assessment of the musculoskeletal system (e.g., range of motion of major joints, leg length, spine assessment), and a neurologic examination (e.g., alertness, cranial nerves, muscle tone, posture reflexes). Gait, mobility, functional, and developmental assessments are essential. During the course of the examination, the clinician should remember that several medical conditions are associated with cerebral palsy (Table 12-7).

Laboratory Evaluation

As with other developmental disabilities, laboratory studies, neurodiagnostic imaging, visual/auditory evoked potentials, electroencephalograms (EEGs), and electrophysiologic studies may be appropriate as determined by the history and physical/neurological exam. Etiologic considerations should include metabolic and genetic

diseases, so that studies such as thyroid function, chromosomes, organic and amino acids, lactate, and pyruvate should be considered. Neuroimaging studies (magnetic resonance imaging [MRI], computed tomography [CT], and cranial ultrasound) may be necessary to rule out intracranial hemorrhages, congenital malformations, and periventricular leukomalacia. Evoked potentials may provide information regarding the integrity of visual and auditory pathways.

Clinical Course

The clinical course of cerebral palsy is diverse depending on type, severity, and clinical manifestations. Clinical findings at the time of diagnosis may change over the years due to growth and development or due to therapeutic intervention or lack of it. Initially, children may be hypotonic; later, they may become hypertonic or dyskinetic. Secondary adverse musculoskeletal effects due to muscle imbalance, abnormal posture, and abnormal muscle tone affect the functional outcome and tend to occur earlier in children with moderate-to-severe disability.

In **spastic hemiparesis,** children may have significant loss of function in the affected hand if sensory impairment is present in addition to the weakness and/or spasticity. This can lead to contractures and growth disturbances in the affected limb. However, most affected children can be independent in self-care, with adaptive utensils for bimanual fine motor skills. Almost all children with hemiplegia walk; however, they may need an orthosis to support a weak limb or to stretch tight muscles.

In **spastic diplegia,** children may have impaired hand function at the onset. With therapeutic exercises and functional training, they usually achieve independence in activities of daily living. With intensive physical therapy and the use of orthotic devices, walkers, and crutches, standing and walking may be possible. For long-distance mobility, wheelchairs may be necessary. Spasticity may lead to contractures of major joints and abnormalities of posture and gait. Orthopedic deformities may require surgical intervention.

In **spastic quadriparesis,** children have varying degrees of severity in motor deficits, which directly influence the acquisition of motor skills and functional independence. Persistent increased muscle tone in the extremities may cause hip dislocation, pain, and scoliosis, especially in nonambulatory children. Associated deficits such as mental retardation, seizures, hearing and visual impairments, and oromotor deficits may further compromise the acquisition of functional skills. Of children with spastic quadriparesis, 25% have minimal or no functional limitations in activities of daily living and walking, 50% have moderate involvement and need assistance in self-care and mobility, and the remaining 25% have severe deficits and require total care.

Pediatric Pearl: Intellectual disability is the most serious associated deficit in cerebral palsy, with an overall incidence of 30% to 50%. It is one of the main factors that preclude independent living skills in adults with cerebral palsy.

In **dyskinetic cerebral palsy,** children have prolonged hypotonia and persistent primitive reflexes. Between 18 months and 2 years of age, they develop athetoid movements in their distal extremities, which progress to dystonic movements with growth and maturation. Upper extremities are more involved than the lower extremities. About 50% of children walk independently, often after 3 years of age, and they develop upper extremity control adequate for self-care activities. Scoliosis may occur later in life.

Prediction of long-term outcome in cerebral palsy in the first few years of life is difficult. The outcome is determined by the severity of the motor deficits, presence of associated deficits (Table 12-8), and the effect of intervention. Overall, 75% of children with cerebral palsy walk either independently or with assistance. Failure to achieve independent sitting by 2 years of age and the persistence of primitive reflexes at 18 months of age has been shown to herald a poor prognosis for walking in children with cerebral palsy. The presence of intellectual disability, seizure disorders, and severe motor disability render functional independence less likely in adults.

Pediatric Pearl: Good prognostic indicators of independent walking are independent sitting by 2 years of age, and suppression of obligatory primitive reflexes by 18 months of age.

Because motor control is acquired gradually during the first year of life, it is difficult to recognize motor deficits at birth or in the child's first few months of life, unless the abnormalities are significant. As the

Associated Disorders in Cerebral Palsy

Intellectual disabilities	50%–70% overall Greater with increase in severity in motor impairment
Seizures	Overall common in severe cerebral palsy
Pulmonary disorders	Aspiration pneumonia, frequent infections
Speech and communication disorders	Articulation deficits, disathria
Oro-motor deficits	Poor sucking ability and tongue thrust, swallowing problems, excessive drooling
Vision impairment	Strabismus, myopia, cortical visual impairment, retinopathy
Hearing impairment	Common in athetoid type, sensory neural hearing loss
Learning disabilities	With associated language impairment
Behavior disabilities	ADHD, emotional lebility, anxiety, anger
Dental abnormalities	Malocclusions, periodontal diseases

ADHD, attention deficit hyperactivity disorder.

neuromuscular deficit and the abnormal movement patterns continue to evolve, the diagnosis can usually be confirmed at the end of the first year. In mild cases the diagnosis may be overlooked until much later when the abnormalities in walking and significant developmental delays are noted.

Management

Management of cerebral palsy involves the treatment of motor disabilities, the treatment of associated deficits, the promotion of good physical and emotional health, family support, appropriate educational and vocational services, integration into the community, and prevention or minimizing potential complications. Once the diagnostic workup is complete, the clinician should develop a therapeutic plan. Intervention must be initiated when there is evidence of motor delays or abnormalities of muscle tone. Table 12-9 summarizes treatment modalities used in the management of children with cerebral palsy.

The treatment of motor deficits involves various types of therapeutic systems. No one method is suitable for all children, and therefore development of individualized therapeutic regimens depending on age and the extent of involvement is necessary. Important components of physical therapy include stretching tight muscles, maintaining and improving the range of motion in joints, and strengthening weak muscles. In infants and young children these essential components are achieved by placing children in different positions to encourage the use of spastic muscle groups or through age-appropriate play and by use of adaptive toys and games. In addition to strengthening and stretching exercises, physical therapy involves training of postural and motor control to achieve age-appropriate developmental skills. Occupational therapy promotes achievement of self-care skills and fine motor skills. Speech and language pathologists encourage activities to improve oral motor functions such as feeding, swallowing, and articulation.

Orthotic Devices

Orthoses are used as an adjunct to physical and occupational therapy to maintain range of motion of joints, provide support in weightbearing or walking when the muscles are weak, or improve function such as in hand splints to assist in feeding. Orthoses may be necessary following surgery to maintain the surgical correction. Therapists may fabricate them using low-density plastic materials such as Aquaplast; usually, these devices are quite inexpensive and need frequent changing as children grow. Custom-fabricated orthoses made of laminated plastic or polypropylene are quite expensive. Periodic evaluation is necessary to ensure proper fit and to assess the need for continued use.

TABLE 12-9

Treatment of Cerebral Palsy

1. Therapeutic intervention
Physical therapy—Strengthening, stretching of tight muscles, improve trunk balance and mobility Occupational therapy—Improved fine motor skills, age-appropriate daily living Speech therapy—Improved receptive and expressive language skills, articulation, use of sign language and use of nonverbal communication devices Feeding therapy—Improved swallowing, chewing and oro-motor deficits, instruction of family
2. Orthotics devices: Static or dynamic
Upper extremity—Elbow splints, wrist/hand splints Lower extremity—Hip abduction orthosis, knee-extension splints, orthosis, ankle/foot orthosis and shoe inserts Spinal—Low-profile body jackets for scoliosis and kyphosis
3. Treatment of muscle tone abnormalities
Medications—Oral and intrathecal baclofen, dantrolene sodium, diazepam and tizanidine Chemodenervation—Botulinum toxins, alcohol, phenol intramuscular injections Selective dorsal rhizotomy—L2/S2 nerve rootlet resection
4. Orthopedic surgery
Muscle releases Tendon transfers Osteotomies/arthrodesis Scoliosis surgery
5. Treatment of associated medical conditions
Refer to Table 12-6
6. Assistive technology
Positioning—Adapted chairs, standers ADL—Feeder seats, bathing/toileting devices, specialized beds/cribs Mobility—Manual and power wheelchairs, strollers, walkers, canes, crutches Therapeutic—Body weight supported mobility systems (smart-walker, Hart-walker, light gait) Educational—Computers with specialized software, communication devices, eye-gaze systems and adapted toys, games, and books

ADL, activities of daily living.

Durable Medical Equipment

Durable medical equipment refers to devices used to achieve self-care, mobility, communication, vocational skills, and recreational activities in children where attainment of these skills may not be otherwise possible. An adapted bath chair may assist parents in bathing a child with poor head and trunk control who is unable to sit. An adapted stroller or a wheelchair can help transport a child to school. A walker or crutches can assist a child who has impaired balance to walk. When choosing equipment, it is important to consider the functional goals, prognosis, patient and family needs, and cost-effectiveness. Periodic evaluation is important, and as a result of children's growth and achievement of functional skills, repair and replacement of the devices may be necessary.

Early Intervention

These family-focused services, which are part of a multidisciplinary approach to the treatment of cerebral palsy, help establish effective parenting skills and improved infant–caregiver interactions. Services can be either

home-based or center-based. Parents receive instructions concerning handling and positioning as well as on feeding techniques. Trained physical, occupational, and speech therapists provide the teaching. The goal is to promote normal movement patterns and to enable young children with limited motor abilities to explore their environment. Families also receive psychosocial support to improve parents' coping abilities. Early intervention programs provide services until the child's third birthday. At that time, referrals to preschool programs for continuation of services are available if needed.

Orthopedic Surgery

Well-timed use of orthopedic procedures can improve function and prevent or correct deformities in children with cerebral palsy. Affected children usually do not have orthopedic problems at birth, but they develop deformities and limitations in range of motion due to spastic muscle imbalance and deforming forces. Prior to surgery it is essential that clear-cut goals and expectation for surgery are established and postoperative management is organized. Postoperative management usually includes physical therapy for range of motion, strengthening, gait training, and use of orthoses and casts to maintain surgical correction.

Several neurosurgical procedures have been used in the treatment of spasticity. Selective dorsal rhizotomy of L2 to L5 spinal rootlets followed by intensive physical therapy has been successful in decreasing spasticity. In children who are ambulatory, postoperative gait analysis has shown an increase in stride length and an improvement in hip and knee range of motion. In nonambulatory children, decreasing spasticity by selective dorsal rhizotomy has resulted in easier management by caregivers and an improvement in optimal positioning, thereby preventing decubiti and deformities.

Asymmetric muscle imbalance, poor posture, spastic muscles, and joint contractions all contribute to the development of spinal curvature. Serial radiographs should be taken at regular intervals to monitor the spine. Curves up to 20 degrees necessitate physical therapy for stretching of tight muscles and careful monitoring. Curves between 20 degrees and 40 degrees require use of a spinal orthosis in conjunction with stretching exercises and proper positioning to delay or control the rate of progression of the spinal curve during growth. When scoliosis is progressive in spite of adequate use of orthoses or when the curve is greater than 40 degrees, surgery is indicated. Progression of the curvature appears to be greater in children who are nonambulatory.

Spastic muscles of the hip can cause pelvic obliquity, decreased sitting balance, and gait deviations in children who are ambulatory. Deformities of the knees can cause crouch posture when standing and can interfere with sitting and walking.

Deformities due to spastic muscle imbalance of the calf muscles result in equinus deformity of ankles and toe walking. Surgery for correcting deformities of the lower extremities involves lengthening of tight muscles, tendon transfers, osteotomies, or arthrodesis in older individuals. Postoperative management includes immobilization in a cast for 6 to 8 weeks followed by the use of orthoses and gait training as needed.

Deformities of the upper extremities are due to dynamic muscle imbalance, spasticity, and contractures. Goals of treatment are to improve function and appearance. Prior to surgery, it is important to do a botulinum toxin A neuromuscular block of selected muscles to assess the effect. Postoperative intensive rehabilitation and use of casting as well as dynamic splints are important. Commonly used procedures include tendon lengthening of elbows, tendon lengthening of thumb, Z-plasty of first web space, and tendon transfer to improve supination and wrist extension.

Medical Management

An integral part of the management of motor disabilities includes treatment of abnormal muscle tone. Many modalities are available, including therapeutic heat, cold, biofeedback, and functional and therapeutic electrical stimulation. Although studies have shown that these treatments are effective in decreasing spasticity, the effects are of short duration and few validated studies are available.

Intramuscular blocks using botulinum neurotoxin A (Botox) reduce spasticity for 3 to 6 months when administered to selected spastic muscles. This treatment improves range of motion and decreases deformities, and it has proved especially useful in managing spastic triceps surae muscles in toe walking. Following the procedure, it is important to use an orthosis to maintain the range of motion and to continue physical therapy to increase the muscle strength and motor control.

Frequently used **oral antispastic medications** are benzodiazepines, tizanidine, dantrolene sodium, and baclofen, which decrease the muscle tone but do not necessarily improve function. When used in large doses in the treatment of moderate-to-severe spasticity, side effects that preclude long-term use include weakness, fatigue, and drowsiness.

In addition, Baclofen may be administered via a programmable pump that has been surgically implanted in the anterior abdominal wall and connected with a catheter to the spinal canal (intrathecal). This technique results in

improved function and reduced spasticity. Long-term efficacy in children with cerebral palsy has not been established. The advantages of this procedure include easy administration of the medication directly into the spinal canal with an ability to use very low doses to achieve the desired effects. The disadvantages are the prohibitive cost of the equipment and medication, as well as possible infection, cerebrospinal fluid (CSF) leaks, and kinking of the catheter.

The primary goals of intervention in cerebral palsy are to maximize functional skills, foster independence, and prevent or minimize complications. Periodic evaluation and assessment of physical growth and nutrition is essential, and appropriate educational placement with classroom adaptation to compensate for the disability and counseling for emotional and social adjustment is imperative. The primary pediatrician plays an important role in monitoring access to therapeutic services, subspecialty referrals, and other needs of the child and family within the medical home.

AUTISTIC SPECTRUM DISORDERS

The autistic spectrum encompasses a continuum of disability with core deficits in socialization, communication, and restricted behavioral repertoire. It is important to appreciate the wide variation in behavioral phenotype. Public awareness of the autistic spectrum has greatly increased, resulting in earlier recognition and greater availability of intervention services. Pediatricians need to be prepared to recognize the early signs of autistic spectrum disorder (ASD), and to address parental concerns as to whether their child may be on the autistic spectrum. The AAP recommends routine screening of all children for ASDs at the 18- and 24-month well-child visits (Figure 12-3). In addition, certain "red flags" should raise suspicion of the possibility of an ASD and initiate further evaluation as soon as possible. Among these are a family history of ASDs, delayed joint attention and communication, and parental concern regarding the child's attainment of milestones and/or social skills. The "Learn the Signs, Act Early" campaign initiated by the Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/ncbddd/autism/facts.html) offers excellent resources for early recognition of ASDs.

Presentation

Children on the autistic spectrum can present before the emergence of spoken language with impairments in **joint attention**. Joint attention involves sharing interest in an object or event by nonverbal means, such as gaze following or pointing, and should be evident before the end of the first year. ASDs may also present in the toddler to preschool years with histories of difficult to manage behavior and/or delayed speech and language development. There may be descriptions, often in retrospect, of remoteness or unusual placidity during infancy. As toddlers, autistic children may seem unusually independent. They may be insistent on following routines, resist transitions, and be unusually sensitive to sensory stimuli. Approximately one-third of parents report that their child's language or social skills appeared normal and then seemed to have regressed somewhere between 18 and 24 months of age. This phenomenon of autistic regression is currently under study.

Pediatric Pearl: Children on the autistic spectrum can present before the emergence of spoken language with impairments in joint attention.

Prevalence

Autistic spectrum disorders are common. The National Center on Birth Defects and Developmental Disabilities (NCBDDD) of the CDC has recently reported the prevalence of ASDs to appear in 1/110 children. More recently, Kogan et al reported the point prevalence of ASDs to be approximately 1/91 children.

Diagnosis

Diagnostic criteria have been defined in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR). The DSM-IV-TR terms this spectrum the **pervasive developmental disorders**, and defines diagnostic criteria in three domains (Table 12-10). Autistic disorder represents the severe end of the pervasive developmental disorder (PDD) spectrum. Other PDDs include Asperger syndrome, Rett syndrome, childhood disintegrative disorder, and PDD not otherwise specified, which all involve varying combinations of diagnostic criteria (see Differential Diagnosis, which follows).

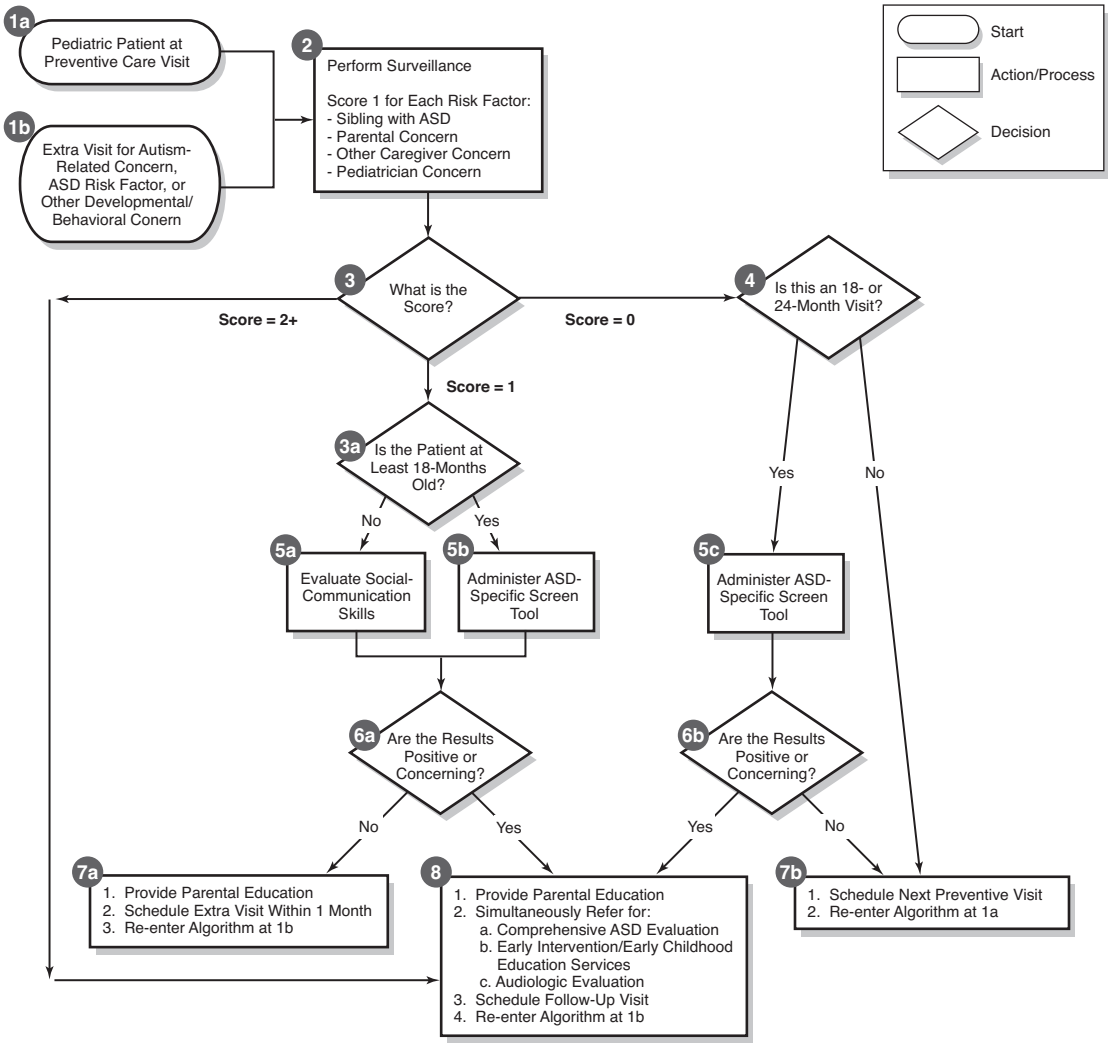

FIGURE 12-3. Algorithm for screening and evaluation of ASDs. Reprinted with permission from *Pediatrics*, Johnson CP. et al, 120(5):1196, 2007.

The diagnosis of autistic spectrum disorder is best made by a multidisciplinary team. Members of such a team might include medical specialists (e.g., developmental-behavioral pediatricians, pediatric neurologists, child psychiatrists), psychologists, speech and language pathologists, occupational therapists, and special educators. Instruments such as the Autism Diagnostic Observation Schedule (ADOS) (http://portal.wpspublish.com/) or Childhood Autism Rating Scale (CARS) (http://psychcorp.pearsonassessments.com) are often used to provide more objective assessments.

The intelligence of autistic children often falls in the intellectually deficient range. However, the language and social deficits that define the autistic spectrum disorders make it difficult to obtain an accurate estimate of an individual's intellectual potential using standardized psychological tests. Underlying cognitive level contributes significantly to the behavioral phenotype. Autistic individuals may have uneven cognitive profiles. Some autistic children with higher functioning may display unusual abilities or talents, amass facts about obscure subjects, or have unusually keen memories. Individuals functioning in the severe-to-profound ranges of intellectual disability may be labeled autistic when in fact their remoteness is due to significant cognitive impairment.

Autistic disorder implies a severe impairment in reciprocal social interaction. Awareness of existence, thoughts, or feelings of others may be markedly impaired. Children may seem to be "in their own world," showing little or no interest in social relationships. They may not seek to share pleasurable or painful experiences. Displays of affection may appear inappropriate in context. Eye contact may be limited but is not necessarily absent.

Communication is significantly impaired, with total lack of spoken language or atypical use of language. Comprehension is also severely affected. Autistic children may be unable to follow even simple verbal directions.

TABLE 12-10

Diagnostic Criteria for Autistic Disorder

Total of six (or more) items from (1), (2), and (3), with at least two from (1) and one each from (2) and (3):

1. Qualitative impairment in social interaction, as manifested by at least two of the following:
   a. Marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
   b. Failure to develop peer relationships appropriate to developmental level
   c. Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., lack of showing, bringing, or pointing out objects of interest)
   d. Lack of social emotional reciprocity
2. Qualitative impairments in communication as manifested by at least one of the following:
   a. Delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime)
   b. In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
   c. Stereotyped and repetitive use of language or idiosyncratic language
   d. Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
3. Restricted repetitive and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
   a. Preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or in focus
   b. Apparently inflexible adherence to specific, nonfunctional routines or rituals
   c. Stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, complex whole-body movements)
   d. Persistent preoccupation with parts of objects

Delays or abnormal functioning in at least one of the following areas, with onset prior to 3 years of age: (1) social interaction, (2) language as used in social communication, or (3) symbolic or imaginative play

Not better accounted for by Rett disorder or childhood disintegrative disorder

From American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition. Washington, DC, American Psychiatric Association, 1994.

They may communicate their desires by grabbing their caregiver's hand to point to an object. Children who do speak have severely impaired social rules of language **pragmatics,** which compromise or prevent the ability to engage in conversation. Language may be idiosyncratic, consisting of utterances of abnormal intonation, rate, or rhythm. **Echolalia,** the repetition of what was heard immediately or sometime in the past, may be prominent. Autistic children may repeat television commercials or favorite songs, or may appear to be reciting monologues or scripts. Play lacks symbolism and is often repetitive and devoid of imagination.

Autistic children may exhibit atypical patterns of behavior, interests, and activities, showing intense attachment to a particular object such as a piece of string or a magazine page. Insistence on routines or rituals is seen. Autistic children may engage in a variety of self-stimulatory behaviors such as rocking in place, spinning in circles, or flapping hands. Interruption of these patterns of behavior may cause severe distress. Temper tantrums, hyperactivity, self-injurious behaviors, aggression, and destructiveness are common.

Pathophysiology

Autism has no single known cause. A definite etiology is evident in only 10% to 20% of cases. Syndromes such as fragile X syndrome or tuberous sclerosis have been implicated but no definite association has been found. Genetics clearly plays a role; 80% to 90% of monozygotic (identical) twins, but only 10% of dizygotic (fraternal)

twins or siblings, tend to be diagnosed on the same spectrum. ASDs are thought to involve multiple genes as well as epigenetic factors (changes in gene expression that occur without changes in DNA sequence). Environment may also affect the expression of the phenotype, yet there is no scientific evidence for some media-driven theories to implicating factors such as vaccines, toxic exposures, or diet.

Medical Evaluation

History

The comprehensive assessment of a child with suspected ASD should include a thorough past medical and developmental/behavioral history. Current recommendations suggest that family history include information on at least three generations.

Physical Examination

Thorough physical and neurologic examination is indicated, as it is for all children with developmental delay. Special attention should be paid to the presence of dysmorphic features, neurocutaneous markings (aided by the use of a Wood's lamp), and neurologic abnormalities.

Laboratory Evaluation

Laboratory tests are indicated when a particular etiologic condition is suspected on the basis of history or physical exam. The yield of an etiologic evaluation is increased when ASD is associated with intellectual disability, and medical workup should follow the guidelines discussed in the context of intellectual disability, previously described. Recent advances in genetic technology offer the promise of greater diagnostic yields, leading many experts to suggest referral for genetic evaluation for all individuals with ASDs. The reader is referred to the recent American College of Medical Genetics practice guidelines (see Schaefer and Mendelsohn under Suggested Readings) for a discussion of the clinical genetic evaluation for etiology of ASDs.

Differential Diagnosis

Autistic disorder must be differentiated from other disorders on the PDD spectrum. **Asperger syndrome** involves impaired socialization without delay in language development or significant cognitive delay. **Rett syndrome** is now known to be caused by a mutation in the *MECP2* gene carried on the X chromosome. It was originally described as a disorder affecting only females, who manifest severe cognitive delays after a period of apparently normal development, with slowing of brain growth and hand mannerisms. The same mutation has been identified in males; however, it is more frequently lethal in utero or in early infancy. **Childhood disintegrative disorder** involves severe cognitive and social regression in children who were developing normally in the first 2 years of life. **PDD not otherwise specified** is the diagnostic terminology reserved for those individuals manifesting at least two diagnostic criteria on the PDD spectrum but not those for specific disorders.

Management

There is no cure for autism. The most effective intervention is individualized education aimed at promoting communication and socialization while minimizing negative behaviors. Programs using **ABA** (applied behavioral analysis) involve intensive individual instruction in a highly structured setting. Other interventions such as **DIR** (**d**evelopmental, **i**ndividual-difference, **r**elationship-based; also known as "floortime") or **TEACCH** (**t**reatment and **e**ducation of **a**utistic and related **c**ommunication-handicapped **ch**ildren) have also proven effective. Psychotropic medications can be beneficial in achieving behavioral control.

Prognosis for individuals with ASDs is generally determined by underlying cognitive potential, degree of communication impairment, and associated behavioral profile. Ultimate functioning in autism ranges from complete lack of communication skills and dependence on others to independent living and attainment of advanced educational degrees.

Parents of autistic children frequently receive promises of dramatic results from unconventional, inadequately studied interventions that may be time-intensive, costly, and offer little but false hopes. It is the pediatrician's responsibility to assist parents in gathering information and objectively interpreting what is known about new and unorthodox therapies. As with intellectual disability and other developmental disabilities, the pediatrician should serve as a source of information and support, guiding families in accessing services, monitoring their children's progress, and anticipating the needs of children and families.

LEARNING DISABILITIES

Learning disabilities refer to a broad range of disorders that cause difficulties in academic achievement well beyond those expected given an individual's level of intellectual functioning. The National Joint Committee on Learning Disabilities defines learning disabilities as a heterogeneous group of disorders manifested by significant difficulties in acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical abilities, or of social skills. These disorders are intrinsic to the individual, presumed to be due to CNS dysfunction, and may occur across the life span. Problems in self-regulatory behaviors, social perception, and social interaction may exist with learning disabilities but do not by themselves constitute a learning disability. Although learning disabilities may occur concomitantly with other handicapping conditions (e.g., sensory impairment, intellectual disability, serious emotional disturbance) or with extrinsic influences (e.g., cultural differences, insufficient or inappropriate instruction), they are not the result of those conditions or influences.

Learning disabilities affect an estimated 2% to 10% of children and adults, with a male-to-female ratio of approximately 4:1. The prevalence varies depending on the precise definition of the disability. Associated problems include perinatal injury, neurologic conditions, and chronic illness or genetic predisposition, but it is often impossible to account for a particular learning disability. Psychosocial stressors and underlying emotional disorders such as depression and anxiety must also be considered when a child does not appear to be meeting his academic potential.

Clinical and Laboratory Evaluation

History

Children with learning disabilities often present with difficulties in learning to read. Many have difficulty in associating letter symbols with sounds and blending sounds into words. These difficulties with **phonemic awareness,** which are often seen in children who have histories of language delays, are broadly termed **language-based learning disabilities.** After children have mastered basic phonics, language-based learning disabilities may affect children's comprehension of what they have read. Still other children have difficulty recognizing symbols or visually decoding written words. Such **nonverbal** or **perceptually based learning disabilities** also have profound implications for academic achievement. Learning problems may also result from difficulties with memory or attention. Inattention associated with attention deficit hyperactivity disorder (ADHD) can be a primary cause of academic failure or can be secondary to a student's inability to process the information presented in the classroom.

Children with learning disabilities may be puzzling to their parents and teachers. They are smart children who have trouble learning, who seem competent in other aspects of their lives; however, they perform poorly in school. Their parents may conclude that they are not working to their full potential (i.e., they are lazy). Such children may fidget, daydream, or "act out" because of long-standing difficulties keeping up with the pace of classwork. Thus, they begin to feel or may actually be labeled as "bad" as well as "stupid." Negative self-esteem is inevitably associated with learning disabilities.

Physical Examination

A physical examination should be performed to rule out chronic medical conditions that might predispose a child to problems with attention or an inability to focus in the classroom. Hearing and vision screening and neurologic examination must be completed. Episodes of staring, for example, either observed or reported, merit consideration of possible absence seizures.

Laboratory Evaluation

As is the case with other developmental disabilities, no routine laboratory assessment is indicated. Tests should be ordered only to confirm or rule out the clinical suspicion of contributory medical conditions.

Management

Careful multidisciplinary assessment is necessary in order to diagnose a learning disability. A standardized psychological assessment first documents cognitive potential. It is necessary to distinguish children with learning disabilities from "slow learners" (children whose intelligence falls in the borderline range; IQ that is one standard deviation below the mean). Although the pace of learning of borderline IQ children is somewhat slow, no one single area of deficit, such as in language, memory, or perceptual skills, is identifiable.

Educational evaluation should then pinpoint areas of strength and weakness, academic strategies, and areas that need remediation. Additional components of the evaluation such as speech and language, occupational therapy, and psychosocial assessments should be considered based on a child's particular problem. Multidisciplinary evaluation results in the formulation of an individual education plan (IEP), which delineates individual goals and implementation strategies. Under the law, parents have the right to be full participants in the educational planning for their children.

Although the pediatrician does not play the primary role in the diagnosis or management of learning disabilities, parents who are frustrated with their child's poor performance in school may consult the physician. Parents may mistakenly attribute school failure to behavioral issues or to factors that they perceive are under the child's control. Raising the possibility of a learning disability can be the first step in advocating for proper evaluation and for securing services aimed at helping the child learn.

ROLE OF THE PEDIATRICIAN IN CARING FOR CHILDREN WITH DISABILITIES

The pediatrician is in a position to serve as advisor and advocate for the child with a developmental disability and his or her family within the context of the **medical home**. Early on, the pediatrician must help the family access an appropriate evaluation for the child and must provide support and information as the family navigates through an often frightening and complicated process. There is ample evidence that children with disabilities and their families have better outcomes when developmental disabilities are identified and treated early. Thus, the pediatrician needs to identify delays as early as possible, monitor the necessary medical/diagnostic evaluation, and follow the child to ensure that appropriate services remain in place.

Mandatory federal education laws for children with disabilities began in 1975 with the passage of PL 94-142, the Education for All Handicapped Children's Act. Renamed the Individual with Disabilities Education Act (IDEA) in 1990 (http://www.idea.ed.gov), this legislation mandates "early intervention" services with a family focus for children 0 to 3 years who manifest or are at risk for significant developmental disability (Part C), and a free, appropriate public education, in the least restrictive environment, for all children 3 to 21 years (Part B). The pediatrician is in a position to inform parents of these entitlements, and must remain available for counsel and support once a disability has been confirmed and intervention services are accessed. Once services are in place, ongoing monitoring of progress, in collaboration with other members of a multidisciplinary treatment team, assures the child the best chance of meeting his or her maximal potential.

Cardiology

Daniel Bernstein

CONGENITAL HEART DISEASE

Congenital structural defects are the most common cause of cardiovascular morbidity and mortality in children, unlike in adults, in which diseases of the myocardium itself (e.g., ischemic cardiomyopathy secondary to coronary atherosclerosis) make up the largest portion of clinical cardiology practice. Other significant causes of cardiovascular disease in children include cardiovascular dysfunction associated with systemic illness, arrhythmia, and acquired heart disease. Congenital heart disease is present in 8/1,000 newborns; 50% of these are of sufficient severity to warrant cardiac catheterization or surgery in the first year of life.

Pathophysiology

Not all congenital lesions present with symptoms immediately at birth. Knowledge of the cardiovascular adaptations during the transition from fetal to extrauterine life is important in understanding the clinical presentation and pathophysiology of congenital heart lesions.

The **fetal circulation** places the right and left ventricles in a parallel circuit as opposed to the series circuit of the newborn or adult (Figure 13-1). In the fetus, the placenta provides gas and metabolite exchange. Three structures are important for maintaining this parallel circuit: the **ductus arteriosus,** the **foramen ovale,** and the **ductus venosus**. Venous return from the upper body enters the right atrium, the right ventricle, and then exits the heart via the pulmonary artery (see Figure 13-1A). Only 3% to 5% of right ventricular outflow enters the lungs. Because there is no gas exchange in the lungs, the pulmonary circulation is vasoconstricted. Instead, the majority of right ventricular blood supplies the descending aorta via the ductus arteriosus (right-to-left shunt in the fetus). Forty percent of fetal cardiac output goes to the placenta via the two umbilical arteries. Oxygenated blood from the placenta then returns to the fetus via the umbilical vein, entering the fetal inferior vena cava via the ductus venosus. This oxygen-enriched blood is selectively routed toward the left atrium by the eustachian valve, located at the inferior vena caval–right atrial junction, and by the flap of the foramen ovale. This blood then traverses the mitral valve, enters the left ventricle, and is ejected into the ascending aorta.

At birth, the mechanical expansion of the lungs combined with the increase in arterial PO^2 decrease pulmonary vascular resistance dramatically. Right ventricular outflow now flows entirely into the low-resistance pulmonary circulation (see Figure 13-1B). Because the pulmonary vascular resistance is now lower than systemic resistance, the shunt through the ductus arteriosus reverses (left-to-right shunt in the newborn).

Over the course of several days the high arterial PO^2 constricts the ductus arteriosus. The increased pulmonary blood flow returning to the left atrium increases left atrial volume and pressure sufficiently to functionally close the foramen ovale. The removal of the placenta from the circulation also leads to closure of the ductus venosus. Thus, within several days, an almost total transition from a parallel (fetal) to a series (adult) circulation is completed. When congenital structural cardiac defects are superimposed on these dramatic physiologic changes, they often impede this smooth transition and increase the burden on the newborn myocardium. Finally, because the ductus arteriosus and foramen ovale do not close completely at birth, they may remain patent in certain congenital cardiac lesions. These structures may either provide a lifesaving pathway for blood to bypass a congenital defect (e.g., in pulmonary atresia, coarctation of the aorta, or transposition of the great vessels) or may present an additional stress to the circulation (patent ductus arteriosus [PDA] or persistent fetal circulation associated with pulmonary hypertension).

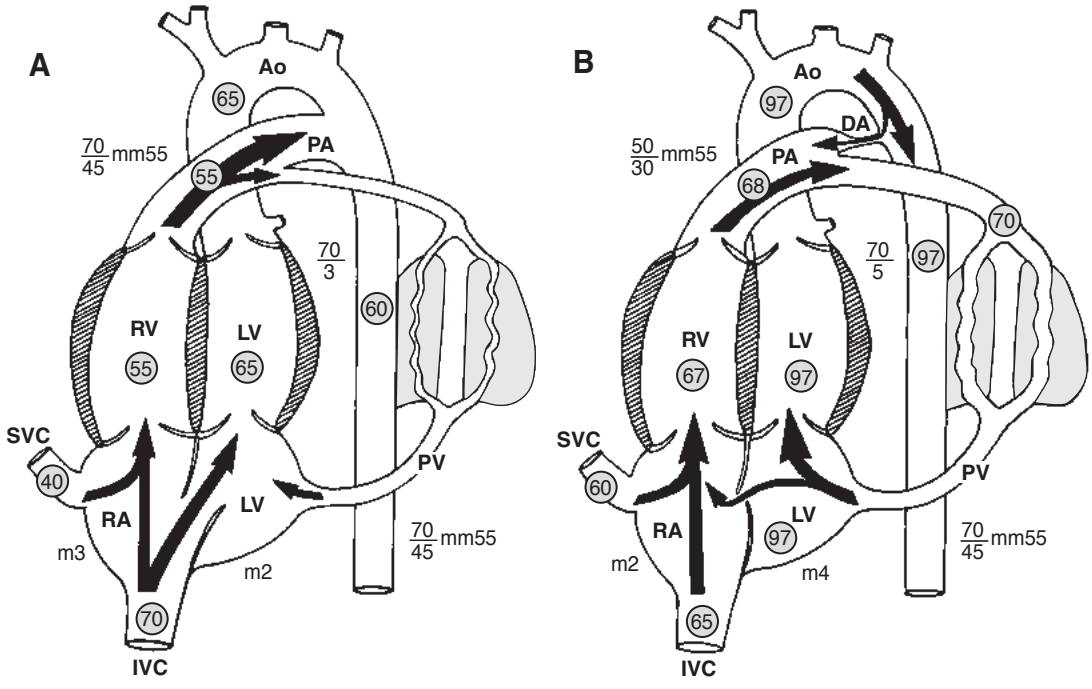

FIGURE 13-1. Transition of the fetal to the newborn circulation. **(A)** Fetal circulation and **(B)** early postnatal circulation. Rudolph, University of California, San Francisco.

Clinical and Laboratory Evaluation

History

The cardiac history should always begin with a careful review of the pregnancy, including exposure to potential teratogens as well as maternal history of infections or gestational diabetes, which can cause hypertrophic cardiomyopathy. A review of the perinatal period should focus on the Apgar scores, the occurrence of cyanosis or respiratory distress, and prematurity. If cardiac symptoms were present in infancy, it is necessary to inquire when symptoms began because the timing of presentation can provide a clue to the specific cardiac condition.

The symptoms of congestive heart failure are age-specific. In infants, **feeding difficulties** are common; feeding represents a significant stress for infants with congenital heart lesions. These problems may be manifest as falling asleep halfway through a feed, sweating with feeds, or frequent gastroesophageal reflux. Other symptoms and signs include rapid breathing, nasal flaring, periorbital or flank edema, irritability, and chest retractions. Cyanosis often goes unrecognized by parents, especially in newborns, unless it is severe.

In older children, the early stages of congestive heart failure may be manifested by difficulty in keeping up with peers during physical activities, requiring a nap after coming home from school, and poor growth. In older children and adolescents, complaints of anorexia, nausea, and abdominal pain are often more common than respiratory distress. Other frequent complaints include unusual weight gain and pedal edema.

Pediatric Pearl: Abdominal distress is one of the more common symptoms of congestive heart failure in older children and adolescents; feeding intolerance one of the more common symptoms in infants.

Physical Examination

GENERAL EVALUATION. The comprehensive cardiac examination begins before the clinician ever touches the patient. A novice examiner may place undue emphasis on cardiac murmurs; however, evaluation of the significance of a murmur is best performed in the context of the rest of the physical examination. Often other signs such as

the quality of the pulses, the presence or absence of growth retardation, the splitting of the second heart sound, or the presence of a ventricular heave allow the clinician to establish a specific cardiac diagnosis. With practice, not only will the examiner be able to diagnose a specific heart lesion, but the severity as well (e.g., the size of a ventricular septal defect [VSD] or the severity of aortic stenosis).

The examination should begin with a general assessment of the patient, with particular attention to the presence of **cyanosis, abnormalities of growth and development** (including head circumference in infants), **vital signs** (including both upper and lower extremity blood pressures), **quality of peripheral perfusion,** and evidence of **respiratory distress**. Cyanosis is usually best detected by examination of the nail beds, tongue, and mucous membranes (**central cyanosis**). Cyanosis is often incorrectly diagnosed in young infants because the color of the hands or feet is affected by cold (**acrocyanosis**).

Examination of the chest for equality of breath sounds and absence of **adventitious sounds** or **rales,** which could indicate pulmonary edema, is necessary. Many infants and young children who manifest **wheezing,** rather than rales, as a sign of pulmonary edema are often initially misdiagnosed as having bronchiolitis or asthma. The cardiac etiology comes to light once a chest radiograph reveals cardiomegaly.

The presence and degree of **hepatosplenomegaly** is worth noting, although in infants and younger children, the abdominal examination should occur after the chest is auscultated (for obvious reasons). **Edema** is evident in dependent regions: in infants, in the periorbital region and over the flanks; in older children, in the abdomen and lower extremities.

Palpation of the **peripheral pulses** is necessary in all extremities, with radial and femoral pulses felt simultaneously. Normally, the femoral pulse should occur immediately before the radial pulse. However, in children with **coarctation of the aorta,** blood flow to the descending aorta may derive predominantly through collateral vessels. This results in the femoral pulse being delayed until after the radial pulse, known as a **radial–femoral delay**. This is a very sensitive indicator for the presence of coarctation.

The quality of the pulses can also yield important information regarding the severity of congenital heart lesions. For example, as aortic stenosis becomes more severe, both the amplitude and rate of rise of the pulse becomes diminished. Pulses may also be weak in patients with left ventricular dysfunction such as in dilated cardiomyopathy (DCM) or in any condition that results in diminished cardiac output. Irregular pulses are a sign of arrhythmia.

CARDIAC EXAMINATION. The cardiac examination consists of three components: inspection, palpation, and auscultation. It begins with visual inspection of the precordium for evidence of a sternal or left precordial bulge, indicating chronic right or left ventricular enlargement. This is often best accomplished by standing at the foot of the examination table, with the patient lying supine. In children, the **point of maximal impulse** can usually be visualized directly.

The next step in the cardiac evaluation is palpation of the precordium for **thrills or heaves**. An increased impulse below the sternum or along the left sternal border is usually associated with right ventricular hypertrophy or enlargement, whereas left ventricular enlargement is manifested by an increased and laterally displaced point of maximal impulse. Palpation of the precordium for thrills should take place next. Thrills at the lower left sternal border are usually associated with a VSD, those at the upper left sternal border with pulmonary outflow tract stenosis, and those at the upper right sternal border with aortic outflow tract stenosis. Palpation of the suprasternal notch for thrills should also occur. Because the aortic arch lies directly under the notch, the presence of a thrill in this location may detect even mild degrees of left ventricular outflow tract stenosis (e.g., bicuspid aortic valve). Although palpation of a carotid thrill may be useful in older children, this examination is difficult in infants.

Only after the previous elements are completed should the clinician begin an examination for heart sounds and murmurs. It is helpful to warm the stethoscope briefly by rubbing it between your hands, especially when examining infants.

The examiner should first turn attention to auscultation of the heart sounds. The **first heart sound** (S_1), which may be split in some children, is best auscultated at the lower left sternal border or apex. The first heart sound may be muffled in conditions that result in decreased compliance of the left ventricle such as moderate-to-severe **aortic stenosis** or the **cardiomyopathies**.

The **second heart sound** (S_2) is heard best at the upper left and right sternal borders. Normally, it is physiologically split into aortic and pulmonic components, with the pulmonic component varying with respirations (Figure 13-2). With inspiration, there is a decrease in intrathoracic pressure and an increased return of blood to the right atrium. There is also a concomitant slight decrease in pulmonary venous return to the left atrium. The increased volume of blood flowing across the right ventricular outflow tract results in the pulmonary valve closing later in the cardiac cycle, which is heard as an increase in the splitting of S_2.

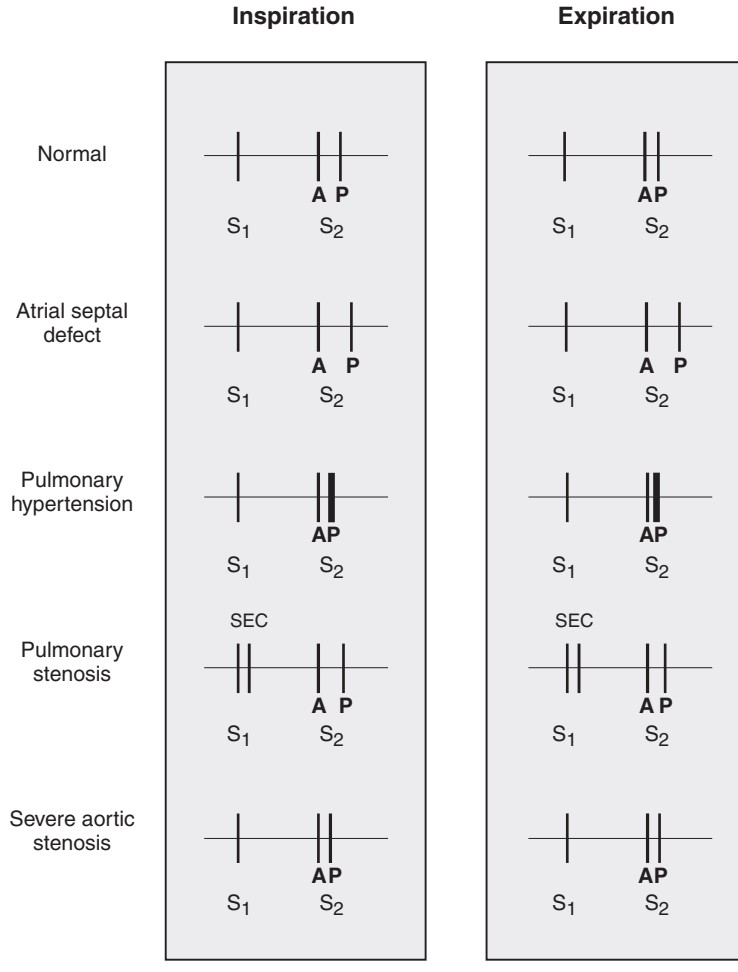

FIGURE 13-2. Variation of the heart sounds with respiration. *S_1*, first heart sound due to closure of the mitral and tricuspid valves, *S_2*, second heart sound due to closure of the aortic (*A*) and pulmonary (*P*) valves, *SEC*, systolic ejection click.

The quality of S_2 is quite important in the diagnosis of congenital heart disease. A single second sound may indicate absence or severe stenosis of one of the semilunar valves (**aortic or pulmonary stenosis or atresia**). A single second sound may also be audible in **transposition of the great vessels**. If systemic or pulmonary artery pressures are elevated that component of S_2 is increased. Thus, in evaluating patients for the presence of **pulmonary hypertension,** careful examination for the presence of a loud pulmonary component of S_2 is vital.

The splitting of S_2 also varies with congenital heart lesions (see Figure 13-2), the most common of which is the **atrial septal defect (ASD)**. Here S_2 is widely split and fixed in its splitting; that is, it does not vary with respirations. This results from the increased blood flow across the pulmonary valve (due to the left-to-right shunt) through all phases of the respiratory cycle and equilibration of pressures between the two atria. A widely split S_2 may also be heard in patients with **right bundle branch block** due to delayed activation of right ventricular contraction.

Ejection clicks are audible immediately following S_1 and are usually associated with mild-to-moderate degrees of stenosis of the aortic or pulmonary valve. Gallops (S_3 or S_4) are ventricular filling sounds. Many normal children have an S_3 gallop, whereas an S_4 is almost always pathologic. Rubs are a sign of pericardial effusion, although with large effusions the rub may disappear and the heart sounds become muffled.

Pediatric Pearl: Ejection clicks are often heard best directly over the superior part of the sternum, because bone transmits high-frequency sounds well. Ejection clicks that vary with respiration are usually due to pulmonary stenosis, those that do not, with aortic stenosis.

CARDIAC MURMURS. The subject of childhood murmurs could fill a complete book (Zuberbuhler's book is excellent [see Suggested Readings]). The common congenital heart lesions can be differentiated by the quality of the heart murmurs they produce (Tables 13-1 and 13-2).

To best appreciate the basics of heart murmurs, it is necessary to understand their relationship to the cardiac cycle (Figure 13-3). Murmurs may be heard in either systole or diastole alone, as two separate murmurs during both phases of the cardiac cycle (to-and-fro murmur), or continuously (Figure 13-4). The early phase of cardiac contraction (immediately after S_1 [i.e., closure of the tricuspid and mitral valves]) is known as **isovolumic contraction** because in this phase there is no egress of blood from a normal ventricle. Once the ventricular pressure rises to equal pulmonary arterial or aortic pressure, the appropriate semilunar valve opens, and the **ejection** phase of systole begins. It is important to note that a heart murmur that begins with isovolumic contraction (immediately after S_1) must involve egress of blood from the ventricle through a defect of some sort (either a VSD or via regurgitation of one of the atrioventricular [AV] valves) because at this point in the cardiac cycle, the aortic and pulmonic valves are still closed. Similarly, murmurs related to abnormal flow across the ventricular outflow tracts must begin during the ejection phase of systole, and there is a short space between S_1 and the murmur. If S_1 is easily audible in the presence of a systolic murmur, it is likely that the murmur is an ejection murmur.

It is essential to evaluate murmurs for several features, all of which aid in assessing not only the type of congenital heart lesion but also the severity. The "**shape**" of the murmur is determined by whether it is heard uniformly through a portion of the cardiac cycle (e.g., **pan or holosystolic**), rises and falls (**crescendo-decrescendo**) or falls only (**decrescendo**) (see Figure 13-4). The **length** of the murmur in the cardiac cycle is often a good indication of severity. For example, as pulmonic stenosis worsens, the time it takes for the volume of blood to leave the right ventricle lengthens, and thus the murmur becomes longer.

The **loudness** of the murmur is related to the pressure difference across the area that the blood flows. In ASDs, in which the pressure across the two atria is either equal or low (0 to 5 mm Hg), no murmur is audible due to the defect itself, but a flow murmur is heard across the right ventricular outflow tract due to the increased volume of pulmonary blood flow. In valvar stenosis, the more severe the stenosis, the greater the pressure drop across the valve, and thus the louder the murmur. The **tonal quality** of the murmur is also affected by pressure differences. Blowing murmurs are of low frequency and usually associated with low pressure differences such as across a large "nonrestrictive" VSD (large enough so that right ventricular pressure is equal to left ventricular pressure) or in tricuspid regurgitation (the difference between right ventricular and right atrial pressure is usually low). Harsh murmurs are of high frequency and usually heard best with the diaphragm. They are associated with high pressure differences such as in a small "restrictive" VSD (where the right ventricular pressure is much lower than left ventricular pressure), in more severe degrees of valvar stenosis, and in mitral regurgitation (because the difference between left ventricular and left atrial pressure is high).

INNOCENT MURMURS. Innocent or functional murmurs are common in children with a reported prevalence between 5% and 90%, depending on the population studied and the methods used. The job of the pediatrician and pediatric cardiologist is to distinguish the small percentage of these murmurs that represent organic heart disease, and avoid labeling normal children with cardiac diagnoses.

The most important steps in differentiating an innocent from an organic murmur include obtaining a history demonstrating an absence of cardiac symptoms, documenting normal growth and development, and noting the absence of other abnormalities on examination (e.g., heaves, thrills, abnormal heart sounds, alterations in the pulses, or cyanosis). If any of these factors is positive, the murmur must be considered organic until proven otherwise. If these factors are all negative, several features of the murmur itself can be used to confirm its innocent nature (Table 13-3).

Laboratory Evaluation

The comprehensive evaluation of the pediatric electrocardiogram (ECG) is beyond the scope of this chapter. However, **several aspects of the pediatric ECG are different from the adult ECG** and deserve special mention.

Interpretation of the ECG should begin with an assessment of heart rate and regularity of rhythm. Heart rate is high in infancy and gradually decreases with increasing age, so it is necessary to diagnose tachycardia or bradycardia by referring to normal values for age. Assessment of whether the rhythm is sinus includes the following criteria: P wave before every QRS, normal PR interval, and normal P-wave axis (P wave upright in leads I and aVF). An abnormal P-wave axis may indicate an ectopic atrial focus, atrial inversion (associated with congenital heart disease), or a junctional beat with retrograde P-wave conduction. It is important to examine the P wave for the presence of right atrial enlargement (P wave greater than 2.5 mm in lead II and aVR) or left atrial enlargement (notched or biphasic P waves in leads V_1 through V_2).

TABLE 13-1

Physical Findings in Common Acyanotic Congenital Heart Lesions

Congenital Lesion	*Palpation*	*Cardiac Auscultation*	*ECG*	*Chest Radiograph*
Left–to–right shunts				
Atrial septal defect (ASD)	RV impulse	Fixed, widely split S_2 Systolic ejection murmur ULSB Middiastolic rumble LLSB if large	Normal; occasionally RSR' in right precordial leads RVH if large	Large RA, LA, RV, PA Increased pulmonary markings
Ventricular septal defect (VSD)	LV impulse Thrill LLSB	±Widely split S_2 Holosystolic murmur LLSB Middiastolic rumble apex if large	Normal or LVH; RVH if large	Large LA, LV, PA Increased pulmonary markings
AV septal defect (AV canal or endocardial cushion)	RV impulse ± LV impulse	± Loud S_1 Holosystolic murmur LLSB Soft ejection murmur ULSB Middiastolic rumble LLSB or apex	Superior, counterclockwise axis (Q waves in leads I and avL)	Large RA, LA, RV, LV Increased pulmonary markings
Patent ductus arteriosus (PDA)	LV impulse Bounding pulses	Continuous murmur ULSB and subclavicular area	Normal or LVH; RVH is large	Large LA, LV
Obstructive lesions				
Pulmonic stenosis (PS)	RV impulse Thrill ULSB	Systolic ejection click (mild PS) Soft P_2 Systolic ejection murmur ULSB	RVH	Uptilt of cardiac apex (RVH)
Aortic stenosis (AS)	LV impulse Decreased pulses Thrill URSB, SSN, carotids	Systolic ejection click (mild AS) Soft A_2 Systolic ejection murmur URSB and MLSB	LVH	Dilated ascending aorta
Coarctation of the aorta	Decreased and delayed lower extremity pulses compared with upper extremities	Systolic ejection click (if bicuspid aortic valve) Systolic or continuous murmur LSB and left subscapular area	RVH, LVH	Collateral arteries (rib notching) Inverted-three sign Increased pulmonary markings

ECG, electrocardiogram; *LA*, left atrium; *LLSB*, lower left sternal border; *LSB*, left sternal border; *LV*, left ventricle (ventricular); *LVH*, left ventricular hypertrophy; *MLSB*, middle left sternal border; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle (ventricular); *RVH*, right ventricular hypertrophy; *SSN*, suprasternal notch; *ULSB*, upper left sternal border; *URSB*, upper right sternal border.

TABLE 13-2

Physical Findings in Common Cyanotic Congenital Heart Lesions

Congenital Lesion	*Palpation*	*Cardiac Auscultation*	*ECG*	*Chest Radiograph*
Lesions with decreased pulmonary blood flow				
Critical pulmonic stenosis	RV impulse	Single S_2 ± Systolic ejection murmur ULSB Continuous murmur ULSB (PDA or bronchial collaterals) Holosystolic murmur LLSB (tricuspid regurgitation)	RVH	Decreased pulmonary flow
Tetralogy of Fallot	RV impulse ± Thrill ULSB	Loud, single S_2 Harsh systolic ejection murmur ULSB and MLSB	RVH, RAD	Decreased pulmonary flow "Boot-shaped" heart Right aortic arch (25%)
Tricuspid atresia	LV impulse	Narrowly split S_2, soft P_2 Harsh systolic murmur LSB	LVH, left superior axis	Decreased or increased pulmonary markings Round cardiac silhouette
Ebstein anomaly of tricuspid valve		Triple or quadruple heart sounds Soft, holosystolic murmur LLSB	RAE, prolonged P-R, bundle branch block, preexcitation	Massive RA enlargement, globular cardiac silhouette
Lesions with increased pulmonary blood flow				
Transposition of the great arteries		Loud A_2, soft or absent P_2 ± Soft systolic ejection murmur MLSB	Normal in newborn period Later RVH, RAD	Normal in immediate newborn; increased pulmonary markings afterward, egg-shaped heart Narrow mediastinum
Truncus arteriosus	LV and RV impulse	Loud single S_2 Systolic ejection click, systolic murmur MLSB Continuous murmur—lungs	RVH, LVH	Cardiac enlargement, increased pulmonary markings Right aortic arch (25%)
Hypoplastic left heart (HLHS)	RV impulse Poor perfusion Poor peripheral pulses	± Soft midsystolic murmur LSB ± Middiastolic rumble LLSB	RAH, RVH	Cardiac enlargement, increased pulmonary markings, ± pulmonary venous obstruction
Total anomalous pulmonary venous return (TAPVR)	RV impulse	Gallop rhythm Soft systolic ejection murmur LSB Middiastolic rumble LLSB	RVH, RAH	Unobstructed: cardiac enlargement and increased pulmonary markings Obstructed: diffuse, dense, reticulated pulmonary markings

ECG, electrocardiogram; *LA*, left atrium; *LLSB*, lower left sternal border; *LSB*, left sternal border; *LV*, left ventricle (ventricular); *LVH*, left ventricular hypertrophy; *MLSB*, middle left sternal border; *PA*, pulmonary artery; *RA*, right atrium; *RAD*, right axis deviation; *RAE*, right atrial enlargement; *RV*, right ventricle (ventricular); *RVH*, right ventricular hypertrophy; *SSN*, suprasternal notch; *ULSB*, upper left sternal border; *URSB*, upper right sternal border.

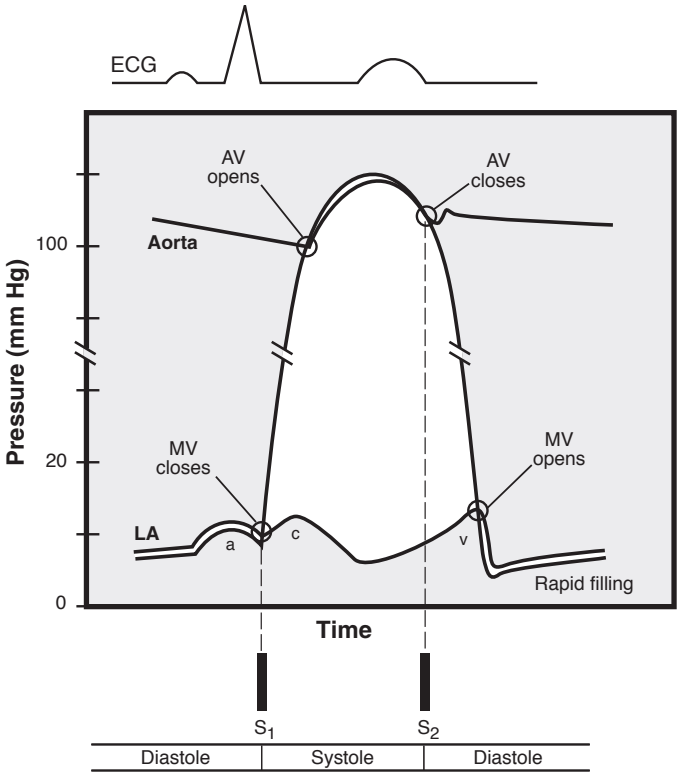

FIGURE 13-3. Events of the cardiac cycle. Systole is divided into two phases: isovolemic contraction and ejection. Diastole is divided into three phases: isovolemic relaxation, rapid ventricular filling, and atrial contraction. *a*, atrial contraction; *c*, ventricular contraction; *v*, atrial filling; *AV*, aortic valve; *LA*, left atrial; *LV*, left ventricle; *MV*, mitral valve. FIGURE 13-4. Timing and shape of cardiac murmurs. S_1, first heart sound; S_2, second heart sound, with aortic (*A*) and pulmonary (*P*) components.

TABLE 13-3

Qualities of Innocent Murmurs in Children

Murmur	*Characteristics*	*Differential Diagnosis*
Still murmur	Low-pitch systolic ejection murmur Best heard at mid-left sternal border with minimal radiation Not greater than grade III Vibratory or musical in quality Decreases with change in position (e.g., standing, lying prone)	Small ventricular septal defect (usually harsher, possible thrill) Mild pulmonic stenosis (radiates more to lungs, right ventricular impulse, ejection click) Atrial septal defect (fixed split second heart sound); HCM (increased left ventricular impulse)
Branch pulmonary stenosis	Usually heard in neonatal period Soft systolic ejection murmur at upper left sternal border radiating and often louder in lung fields (important to listen in both axillae) Disappears within first few months of life	Mild pulmonic stenosis (increased right ventricular impulse, systolic ejection click) Atrial septal defect (fixed split second heart sound)
Innocent pulmonary murmur	Soft systolic ejection murmur at upper left sternal border Blowing, nonmusical Higher pitched than Still murmur Often accentuated by fever or anemia Often present in pectus excavatum	Mild pulmonic stenosis (increased right ventricular impulse, systolic ejection click) Atrial septal defect (fixed split second heart sound)
Venous hum	Medium-pitched, soft blowing continuous murmur at upper right sternal border and infraclavicular area	

HCM, hypertrophic cardiomyopathy.

Next comes measurement of ECG intervals and durations (PR, QRS, and QTc [QT corrected for heart rate = $QT/\sqrt{RR}$]). To note abnormalities, it is necessary to compare the values with normal intervals based on age, and in the case of the PR interval, heart rate. An abnormally long QRS complex indicates either right or left bundle branch block; in the presence of this, ventricular hypertrophy is difficult to interpret.

By noting which lead is nearly isoelectric and finding the lead orthogonal to it, it is possible to assess the axis. Examination of voltages in the precordial leads is next; leads V_1, and V_5 to V_6 are compared with normal values for age. Finally, examination of ST and T waves for depressions, elevations, and polarity occurs; T-wave polarity is very age dependent. In the fetal circulation, both right and left ventricles are pumping against systemic pressure so that the right ventricular wall is relatively thick in the immediate perinatal period. Thus, most newborns have right axis deviation and increased right ventricular forces compared with older children. In the first 24 hours of life, a QR may be present in V_1, and the axis may be as rightward as 205 degrees. One of the most common pitfalls in interpreting newborn ECGs is the false reading of right ventricular hypertrophy.

The T wave in lead V_1 is an important indicator of right ventricular hypertrophy in children. In the immediate newborn period, the T wave is positive in V_1, becoming inverted at approximately 6 days of age. Until the age of approximately 6 years, the T wave in V_1 should remain inverted, and in many children, it remains inverted until the teenage years. However, if the T wave is positive in V_1 between the ages of about 6 days and 6 years, it strongly suggests right ventricular hypertrophy, even in the absence of specific voltage criteria. This is another common error in interpreting pediatric ECGs.

As part of the initial evaluation, the chest radiograph (both frontal and lateral views) may be valuable in making the diagnosis of congenital heart disease. A transcutaneous oxygen saturation measurement or arterial blood gases may easily confirm cyanosis. To differentiate pulmonary-based cyanosis from cardiac-based cyanosis, it is usually necessary to have the patient breathe 100% oxygen using a hood for several minutes and remeasure the arterial blood gases (hyperoxia test). If the etiology is pulmonary, the arterial PO^2 should increase to at

least above 150 mm Hg, whereas the PO_2 will not increase as dramatically if the etiology is cardiac, although this test is not 100% reliable. Two-dimensional echocardiography, magnetic resonance imaging (MRI), and computed tomography (CT) are useful for determining cardiac structure. Pulsed, continuous-wave, and color-flow Doppler echocardiography help assess blood flows and pressure gradients.

Differential Diagnosis

Congenital cardiac defects can be classified into two major groups based on the presence or absence of cyanosis (Figure 13-5). The chest radiograph can then be used to further refine the diagnosis based on whether the pulmonary vascular markings show evidence of increased, normal, or decreased pulmonary circulation (Figures 13-6 and 13-7).

Acyanotic Congenital Heart Lesions

This group of congenital lesions can be divided by physiologic principles into those that induce a **volume load** on the heart (most commonly due to a left-to-right shunt but may also result from AV valve regurgitation or abnormalities of the myocardium itself, i.e., the cardiomyopathies) and those that induce a **pressure load** on the heart (subvalvar, valvar, or great vessel stenoses). The chest radiograph is a useful tool for differentiating between these two major categories because both heart size and pulmonary vascular markings are usually increased in the left-to-right shunt lesions.

VOLUME LESIONS. The most common lesions in this group are the left-to-right shunts: **ASD, VSD, AV septal defect** (formerly called **AV canal or endocardial cushion defect), PDA,** and **aortopulmonary window**. The common pathophysiologic denominator in this group of lesions is a communication between the left and right sides of the circulation and the shunting of fully oxygenated blood back into the lungs. The direction and magnitude of a shunt across a defect such as a large VSD depends on the relative pulmonary and systemic pressures, and vascular resistances. Although pulmonary vascular resistance falls dramatically at birth, it remains moderately elevated for several weeks before declining to normal adult levels. Thus, in a lesion such as a large VSD, there may be little shunting or symptoms in the first week of life, and it is not unusual that a murmur is not heard in the newborn nursery.

As pulmonary resistance drops over the first month of life, the left-to-right shunt increases, and so does the intensity of the murmur and the symptoms. This is true for other left-to-right shunt lesions such as AV septal defect and PDA as well.

The increased volume of blood in the lungs is quantitated by pediatric cardiologists as the **pulmonary-to-systemic blood flow ratio** or **Qp:Qs**. A 3:1 shunt implies three times the normal pulmonary blood flow. This increase in pulmonary blood flow decreases pulmonary compliance and increases the work of breathing. Fluid leaks into the interstitium or alveoli causing pulmonary edema and the common symptoms: tachypnea, chest retractions, nasal flaring, poor feeding, rales, and wheezing (see Table 13-1).

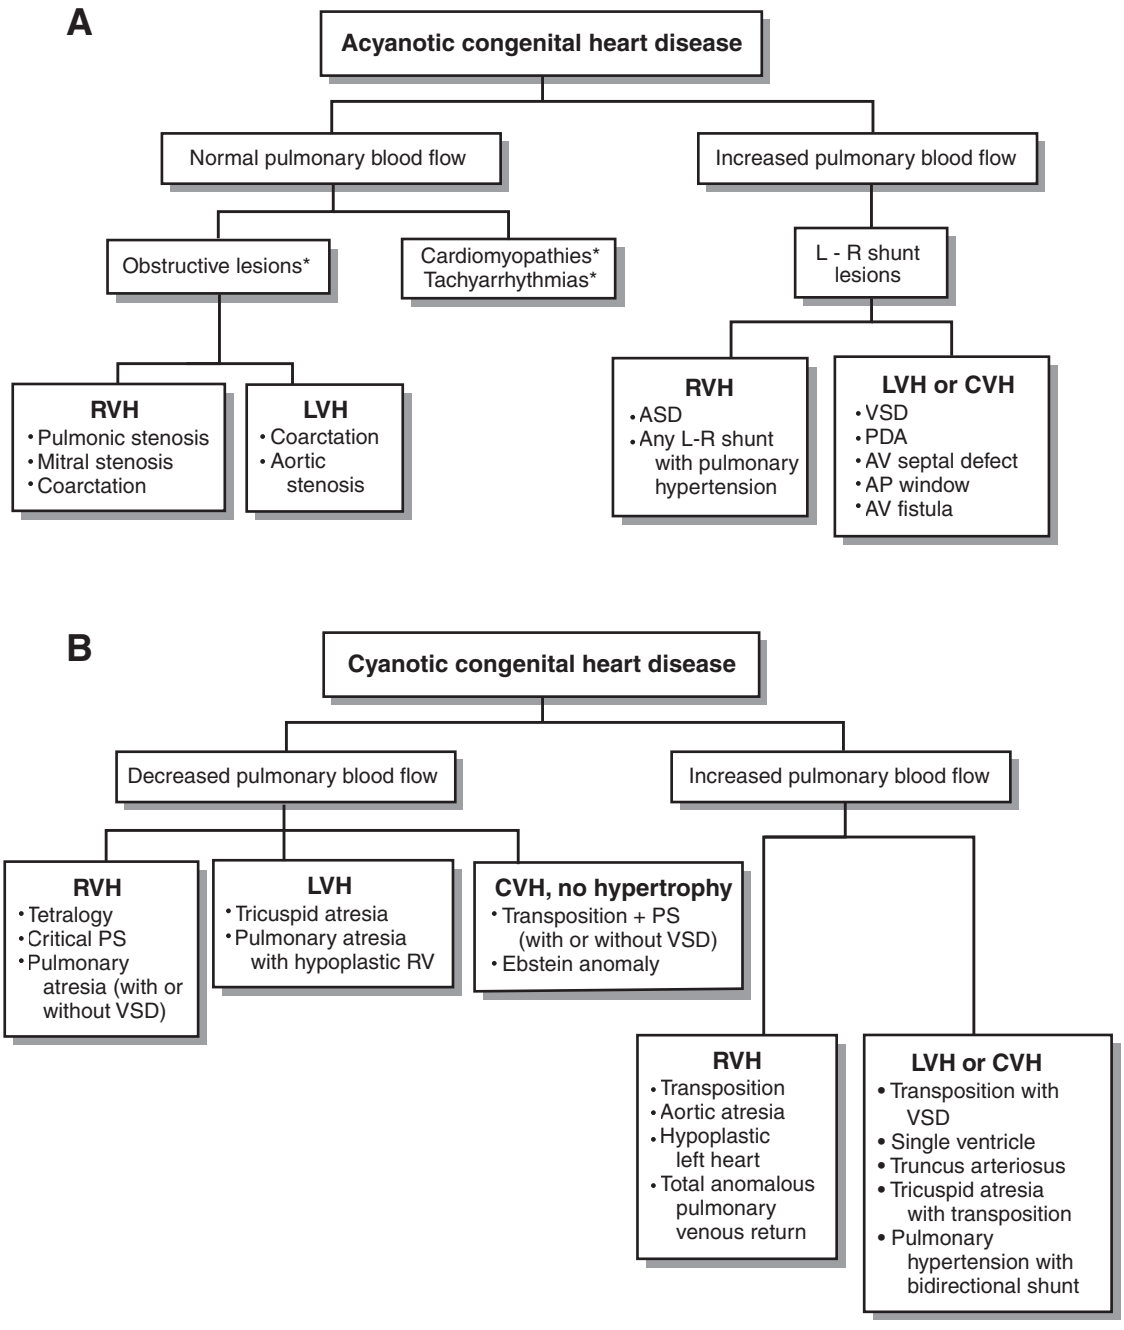
To maintain a left ventricular output, which is now several times normal (although most of this output is ineffective because it returns to the lungs), heart rate and stroke volume must increase, mediated by an increase in sympathetic stimulation. The increased work of breathing and the increase in circulating catecholamines lead to an elevation in total body oxygen requirements, taxing the oxygen delivery capability of the circulation. Thus, common symptoms include tachycardia, sweating, irritability, decreased perfusion, and failure to thrive.

While isolated valvular regurgitant lesions are less common, AV valve regurgitation is often a feature of complete AV septal defects. The combination of left-to-right shunt and valve regurgitation increases the volume load on the heart, and usually leads to earlier presentation and more severe symptomatology.

Unlike the left-to-right shunts, **cardiomyopathies** (see Cardiomyopathies) cause heart failure directly due to diminished cardiac muscle function. This leads to increased atrial and ventricular filling pressures as well as pulmonary edema secondary to increased capillary pressure.

OBSTRUCTIVE LESIONS. The most common obstructive lesions are **valvar pulmonic stenosis, valvar aortic stenosis,** and **coarctation of the aorta**. However, stenosis of the right or left ventricular outflow tracts can also be located at the subvalvar or supravalvar levels. The common pathophysiologic denominator of these lesions is that, unless the stenosis is severe, cardiac output is maintained; thus, in children, symptoms of heart failure are often not present. This compensation is accomplished by a marked increase in cardiac wall thickness (hypertrophy). Subtle radiographic changes in the cardiac silhouette (as compared to the volume lesions) may detect hypertrophy. However, the 12-lead ECG is best for detection of left or right ventricular hypertrophy.

Severe pulmonic stenosis in the newborn period (**critical pulmonic stenosis**) often leads to right-sided cardiac failure (hepatomegaly, peripheral edema), and to right-to-left shunting across a patent foramen ovale or



* For many obstructive lesions, cardiomyopathies, and tachyarrhythmias, the chest X-ray will show significant pulmonary edema; however, the pattern of this edema is usually subtly different from that in the L-R shunt lesions, being due to increased left atrial filling pressure as opposed to increased pulmonary blood flow. This pattern is often, but not always, more prominent in the perihilar regions.

FIGURE 13-5. Classification of congenital heart disease **(A, B)**. Determination of pulmonary blood flow is made by chest radiograph; determination of hypertrophy is made by electrocardiogram (*ECG*). *AP* window, aortopulmonary window; *ASD*, atrial septal defect; *AV* septal defect, atrioventricular septal defect; *AV* fistula, arteriovenous fistula; *CVH*, combined ventricular hypertrophy; L-R, left-to-right; *LVH*, left ventricular hypertrophy; *PDA*, patent ductus arteriosus; *PS*, pulmonary stenosis; *RV*, right ventricle; *RVH*, right ventricular hypertrophy; *VSD*, ventricular septal defect.

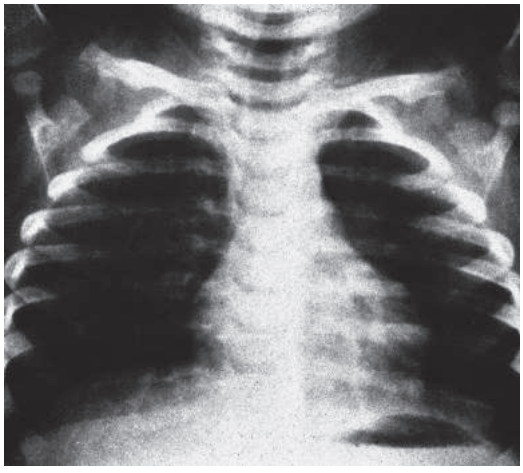


FIGURE 13-6. Normal chest radiograph.

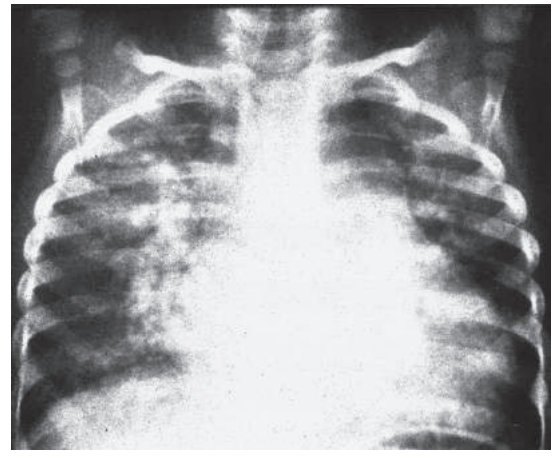

FIGURE 13-7. Chest radiograph in a patient with a large ventricular septal defect showing cardiomegaly and increased pulmonary vascular markings.

ASD; therefore, it is often classified as a cyanotic heart lesion. The pulmonary vascular markings on the chest radiograph are normal or decreased, and the ECG shows right ventricular hypertrophy. Severe aortic stenosis in the newborn period (critical aortic stenosis) presents with diminished pulses in all extremities and signs of left-sided heart failure (pulmonary edema), right-sided failure (hepatomegaly, peripheral edema), and often progresses to total circulatory collapse. If the ductus arteriosus is still open, the oxygen saturation may be decreased; in this case, aortic blood flow is supplied by a right-to-left ductal shunt. The ECG reveals left ventricular hypertrophy.

Coarctation of the aorta may present solely with a systolic murmur and with diminished pulses in the lower compared with the upper extremities. Thus, it is important to always palpate both the femoral and either the brachial or radial pulses simultaneously during a routine screening examination of any infant or child. A coarctation may be localized to the area of the descending aorta immediately opposite the ductus arteriosus (**juxtaductal coarctation**). In the first few days or weeks of life, the ductus arteriosus may remain partially patent and serves as a conduit for blood flow to partially bypass the obstruction at the level of the coarctation. Affected infants often become symptomatic when the ductus finally closes in the first few weeks of life. In more severe forms, coarctation involves hypoplasia of the transverse aortic arch, in which case it presents with a more significant obstruction to blood flow and usually causes heart failure and signs of poor perfusion in the neonatal period. In coarctation, especially in infancy, the ECG often shows a combination of both right and left ventricular hypertrophy.

Mitral stenosis is a less common lesion, and can be due to a supravalvar mitral ring or membrane, a hypoplastic mitral valve annulus, or a single papillary muscle (parachute mitral valve). Mitral stenosis is often seen in the setting of multiple levels of obstruction of the left side of the heart (e.g., combined with subaortic membrane, valvar aortic stenosis, and coarctation of the aorta [**Shone complex**]).

Cyanotic Congenital Heart Lesions

This group of congenital heart lesions can be divided by physiologic principles into those associated with decreased pulmonary blood flow (e.g., **tetralogy of Fallot, pulmonary atresia with intact septum, tricuspid atresia with pulmonary obstruction, total anomalous pulmonary venous return with obstruction**), and those associated with increased pulmonary blood flow (**transposition of the great arteries; various forms of single ventricle, including hypoplastic left heart syndrome, truncus arteriosus; tricuspid atresia without pulmonary obstruction; total anomalous pulmonary venous return without obstruction**). The chest radiograph is again an important primary initial diagnostic tool for differentiating between these two major categories (Figures 13-8 and 13-9).

CYANOTIC LESIONS WITH DECREASED PULMONARY BLOOD FLOW. Two basic pathophysiologic elements underlie all of these lesions. First is an obstruction to pulmonary blood flow at some level (tricuspid valve, subpulmonary muscle bundles, pulmonary valve, main or branch pulmonary arteries). Second is a means by which deoxygenated blood can flow right-to-left to enter the systemic circulation (patent foramen ovale, ASD, or VSD). It is important to remember that even with severe pulmonic stenosis, systemic desaturation does not occur unless there is right-to-left shunting at some level.

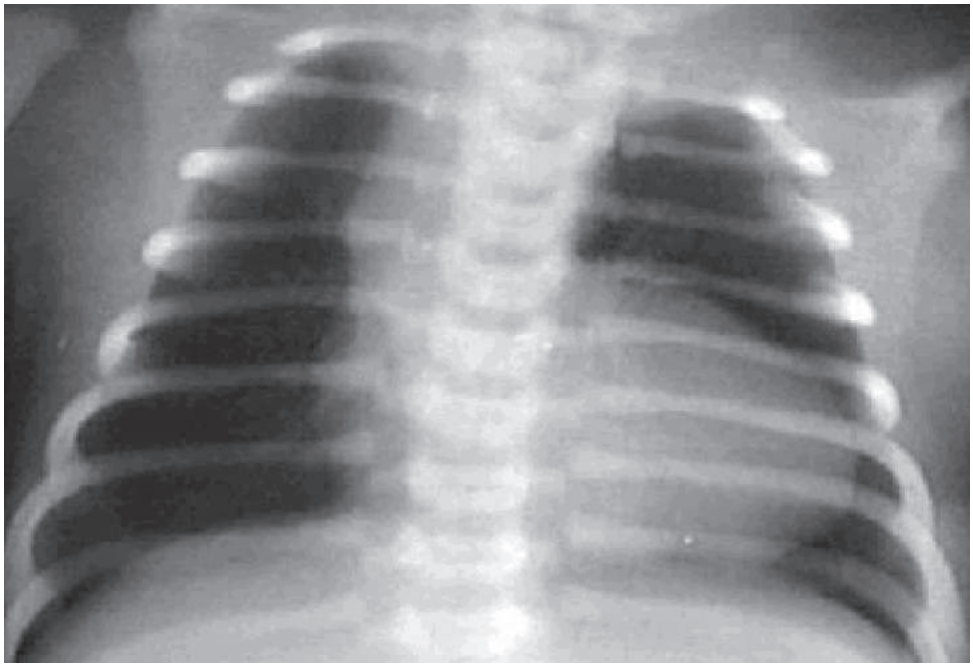

FIGURE 13-8. Chest radiograph in a patient with tetralogy of Fallot. The cardiac apex is tilted upward, signifying right ventricular enlargement; the left upper mediastinal shadow is narrowed due to hypoplasia of the main pulmonary artery segment; and the pulmonary vascular markings are decreased. This is the typical "boot shape" appearance of tetralogy of Fallot.

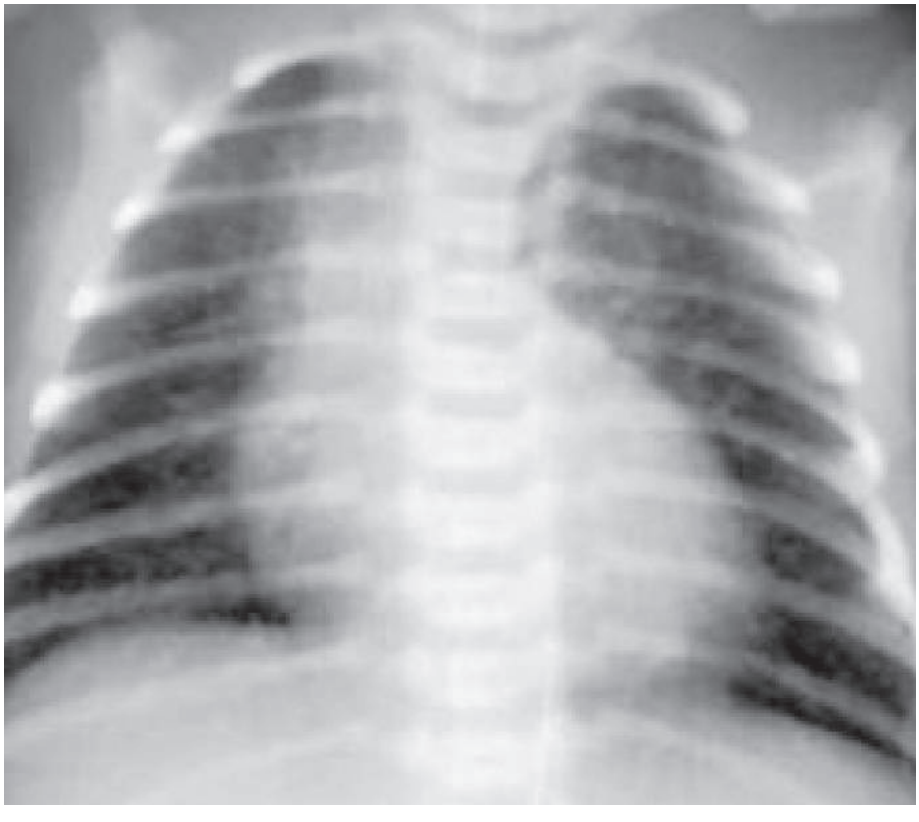

FIGURE 13-9. Chest radiograph in a patient with transposition of the great vessels. As opposed to the patient with tetralogy of Fallot (see Figure 13-8), it is easy to appreciate that this cyanotic patient has increased pulmonary vascular markings.

Tricuspid atresia involves the right-to-left shunting of deoxygenated blood across either a patent foramen or ASD to the left atrium, where it mixes with pulmonary venous return and enters the left ventricle. Blood enters the lungs either from the right ventricle (via a VSD) or through a PDA. Some patients with tricuspid atresia have pulmonary stenosis, resulting in decreased pulmonary blood flow, and moderate-to-severe cyansois. Others have a wide-open pulmonary outflow (especially those with tricuspid atresia combined with transposition of the great arteries), and these patients have increased pulmonary blood flow and only mild cyanosis.

Tetralogy of Fallot is a constellation of anatomic findings (subvalvar, valvar, or supravalvar pulmonic stenosis, VSD, aorta overriding the VSD, right ventricular hypertrophy). Deoxygenated blood shunts right to left across the VSD into the overriding ascending aorta. In these lesions, the degree of clinical cyanosis depends on the degree of obstruction to pulmonary blood flow. If the obstruction is mild, cyanosis may not be present at rest but only with stress (hypercyanotic episodes known as "Tet spells"). If the obstruction is severe, pulmonary flow may be totally dependent on the patency of the ductus arteriosus. These infants present with profound cyanosis in the newborn period and require pharmacologic treatment (**prostaglandin E_1**) to maintain ductal patency until surgical intervention.

CYANOTIC LESIONS WITH INCREASED PULMONARY BLOOD FLOW. Although pulmonary blood flow is more than adequate, only a small portion of this oxygenated blood can enter the systemic circulation because of the defect. **Transposition of the great arteries** is the most common lesion in this group. In transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Deoxygenated blood from the body returns to the right side of the heart and is pumped directly back to the body again. Oxygenated blood from the lungs returns to the left side of the heart and is pumped back into the lungs. If not for the persistence of fetal pathways such as the foramen ovale and ductus arteriosus, this lesion would not be compatible with life. These pathways allow for some degree of both left-to-right and right-to-left mixing of oxygenated and deoxygenated blood until surgical intervention takes place.

Pediatric Pearl: The most common cyanotic congenital heart lesions can be remembered as the `five Ts": tetralogy of Fallot, transposition of the great vessels, tricuspid atresia, truncus arteriosus, and total anomalous pulmonary venous return.

Cardiac lesions leading to a **single or common ventricle** are known as **total mixing lesions** because deoxygenated systemic venous blood and oxygenated pulmonary venous blood usually mix totally in the heart, resulting in equal oxygen saturations in the pulmonary artery and aorta. Unless pulmonary stenosis is present, pulmonary blood flow is torrential, and affected infants usually present with both mild cyanosis and heart failure. If pulmonary stenosis is present, then pulmonary blood flow is limited, and these infants usually present with more profound cyanosis without heart failure. Single ventricle physiology is present in patients with a large common ventricle, in some forms of **double outlet right ventricle** or **double inlet left ventricle**, and in patients with **hypoplastic left heart syndrome**. **Truncus arteriosus** also results in total mixing of systemic and pulmonary venous blood; however, in this case mixing occurs at the great vessel level.

One additional common lesion, **total anomalous pulmonary venous return with obstruction,** causes cyanosis and the appearance of pulmonary edema on chest radiograph. However, this finding is actually secondary to obstruction to blood flowing out of the lungs at the level of the pulmonary veins rather than to an increased volume of pulmonary blood flow. In contrast, **total anomalous pulmonary venous return without obstruction** results in increased pulmonary blood flow and cyanosis due to total mixing of systemic venous and pulmonary venous blood at the level of the right atrium.

Management

Congestive Heart Failure

Congestive heart failure in the pediatric age group may be associated with left-to-right shunt lesions and pulmonary overcirculation, to primary or secondary cardiomyopathies, or to arrhythmias such as supraventricular tachycardia (SVT). The ultimate management of congestive heart failure is directed at correcting the underlying cause. However, initial management strategies are aimed at lessening the symptoms of tachypnea, edema, and failure to thrive as well as improving the ability of the heart to maintain adequate systemic oxygen delivery. The therapeutic measures useful for treating congestive heart failure are directed toward improving myocardial contractile function, decreasing preload and afterload, and improving the balance between systemic oxygen consumption and oxygen delivery (Table 13-4).

TABLE 13-4

Techniques in the Management of Congestive Heart Failure in Children

Therapy	*Mechanism/Advantages*	*Disadvantages*
General supportive measures		
Oxygen	Improves systemic oxygenation in presence of pulmonary edema	May cause pulmonary vasodilation and increase left-to-right shunting
Salt and water restriction	Decreases edema and congestion	Often limits caloric intake and contributes to failure to thrive
Transfusion	Increases oxygen-carrying capacity Reduces left-to-right shunt	Risk of infection
Diuretics		
Furosemide	Ascending loop of Henle	Hypokalemia, hyponatremia
Chlorothiazide	Distal tubule	Hypokalemia, hyponatremia
Aldactone	Aldosterone antagonist	K^+ sparing
Positive inotropic agents		
Digitalis	Inhibits Na^+–K^+-ATPase and increases intracellular Ca^{2+}	Increases myocardial oxygen consumption, arrhythmogenesis
Dopamine	Acts at cardiac β-adrenergic receptor to increase contractility and heart rate, at low doses acts on peripheral β-adrenergic receptors to reduce afterload	At high doses, acts on peripheral α-adrenergic receptor to increase afterload Arrhythmogenic especially at high doses
Dobutamine	Acts at cardiac β-adrenergic receptor to increase contractility and heart rate; acts on peripheral β-adrenergic receptors to reduce afterload	Arrhythmogenic especially at high doses
Milrinone	Phosphodiesterase inhibitor; synergistic with β-adrenergic receptor agonists by increasing intracellular cAMP; positive inotrope and afterload reducer	Hypotension
Afterload reducing agents		
Hydralazine	Direct arteriolar vasodilator	Hypotension
Prazosin	Peripheral α-adrenergic blocker	Hypotension; reduced preload
Captopril or Enalapril	Angiotensin-converting enzyme inhibitor; does not cause reflex stimulation of renin	Hypotension; chronic cough
Nitroprusside	Powerful arterial and venous vasodilator	Hypotension; intravenous only

Cyanosis

CYANOTIC CONGENITAL HEART DISEASE IN THE NEWBORN. The management of most forms of cyanotic congenital heart disease is surgical, whether a palliative shunt procedure or anatomic repair. However, in the initial hours or days after birth and while awaiting further diagnostic evaluation such as cardiac catheterization, an infusion of **prostaglandin E_1** usually stabilizes the patient by keeping the ductus arteriosus patent pharmacologically. In lesions associated with decreased pulmonary blood flow, the ductus supplements pulmonary flow and may even be its only source (e.g., in pulmonary atresia). In the transposition group of lesions, the patent ductus allows mixing of oxygenated and deoxygenated blood between the right and left sides of the heart. In patients with transposition of the great arteries, a balloon-tipped catheter, introduced via the femoral vein at the time of cardiac catheterization, is used to improve the amount of mixing at atrial level by ripping a large hole in the atrial septum **(Rashkind atrial septostomy)**.
HYPERCYANOTIC SPELLS IN TETRALOGY OF FALLOT. **Hypercyanotic spells ("Tet spells")** are manifested by a marked increase in the level of cyanosis associated with agitation, crying, and hyperpnea. They may progress to loss of consciousness and if untreated may lead to seizures, stroke, or death. Precipitating factors include either an increase in oxygen demands, a decrease in systemic vascular resistance, a decrease in systemic venous return, or spasm of the infundibular subpulmonary muscle. Treatment of hypercyanotic spells can involve the following maneuvers: comforting the infant, placement in a knee–chest position to increase systemic venous return and increase peripheral vascular resistance, subcutaneous or intravenous morphine sulfate, intubation and general anesthesia, the β-adrenergic blocker propranolol, or intravenous phenylephrine to increase systemic vascular resistance.

CARDIAC DYSRHYTHMIAS

Pathophysiology

The cardiac conduction system is comprised of a group of specialized cells with unique depolarization properties (Figure 13-10). The sinoatrial **(SA) node,** located at the superior vena caval–right atrial junction, controls heart rate; it is modulated by both sympathetic and parasympathetic (vagal) input. Depolarization spreads from the SA node through atrial myocardium to the atriventricular **(AV) node,** located at the junction of the atria and ventricles near the mouth of the coronary sinus. The specialized cells of the AV node slow conduction, thus allowing an appropriate interval between atrial and ventricular contraction. During rapid atrial dysrhythmias, the AV node prevents conduction of every atrial beat, resulting in varying degrees of block, and protects the patient from a low cardiac output due to a rapid ventricular rate.

From the AV node, impulses travel to the ventricles via the **bundle of His,** located immediately posterior and inferior to the membranous portion of the ventricular septum. This location renders this portion of the conduction system vulnerable to damage during surgical repair of congenital heart lesions such as VSDs. From

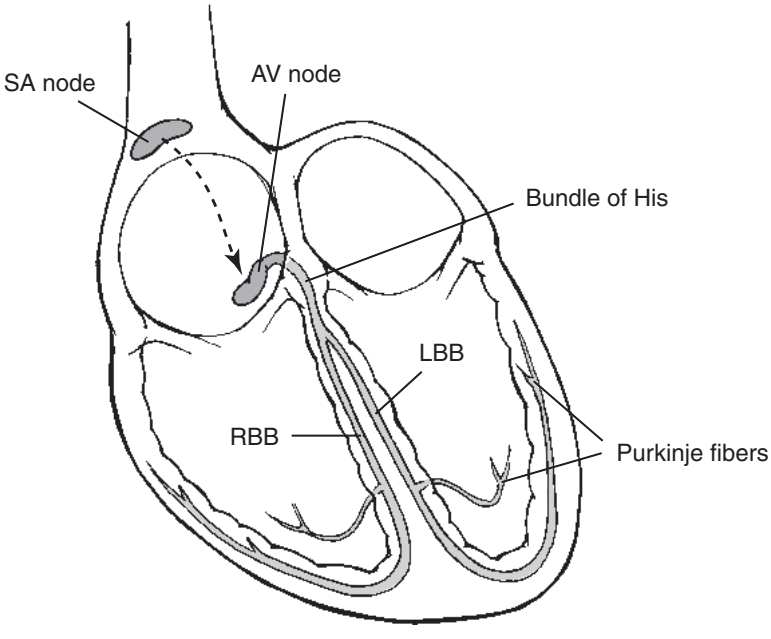

FIGURE 13-10. Cardiac conduction system. *AV* node, atrioventricular node; *LBB*, left bundle branch; *RBB*, right bundle branch; *SA* node, sinoatrial node

the bundle of His arise the **right and left bundle branches** leading finally to the **Purkinje fibers** that terminate in the subendocardium.

All cardiac cells are potentially capable of firing spontaneously. The orderly flow of impulses through the normal conduction system is thus dependent on higher foci (e.g., SA node) firing more rapidly than lower foci (e.g., ventricular cells), resulting in suppression of the more slowly firing cells. This property (called **overdrive suppression**) can be utilized clinically to treat certain dysrhythmias using a pacemaker.

Anatomic abnormalities of the specialized conduction system are responsible for many of the common pediatric dysrhythmias. **Heart block** may be due to damage of the AV node or bundle of His due to inflammation (maternal systemic lupus erythematosus, rheumatic fever), medications (digoxin), or surgical trauma. **SVT** may be due to the presence of a congenital accessory conduction pathway, leading to abnormal impulse conduction between atria and ventricles (see Atrial Dysrhythmias), to increased automaticity (spontaneous firing) of an ectopic atrial pacemaker (**atrial ectopic tachycardia** [**AET**]), or to intra-atrial reentry. In children, **ventricular tachycardia** often results from a global insult to the myocardium that renders individual ventricular cells irritable (hypoxia, electrolyte imbalances, myocarditis, drugs); a genetic abnormality in cardiac structure (hypertrophic cardiomyopathy) or ion channel function (long QT syndrome); or abnormal hemodynamics from palliated congenital heart disease (e.g., tetralogy of Fallot, single ventricle).

Clinical and Laboratory Evaluation

History

When evaluating a patient with a dysrhythmia, the clinician must first assess the degree of the patient's stability. If blood pressure and perfusion are abnormal, only minimal historical information is obtained before treatment is initiated: duration of symptoms, prior history of dysrhythmias or congenital heart disease, and exposure to medications or drugs.

Physical Examination

Assessment of the patient's general clinical status begins with the standard ABCs of emergency care: evaluation of the **a**irway, **b**reathing, and **c**irculation. The cardiac evaluation includes the patient's color (e.g., pale, cyanotic), peripheral perfusion, pulses, and blood pressure. In patients with a tachyarrhythmia, it may be difficult to evaluate heart murmurs, although a gallop rhythm is often audible. A thoracotomy or sternotomy scar is a clue that the patient has had prior surgery for correction of a congenital heart lesion.

Laboratory Evaluation

The most important laboratory tests are the 12-lead ECG and a long (2-minute) rhythm strip (usually lead II). A full 12-lead ECG should always supplement a single lead tracing from a monitor in the diagnosis of arrhythmia because it is not possible to evaluate the true morphology of the various waves and complexes using a single lead.

Pediatric Pearl: Common artifacts in a full 12-lead ECG are apparent because of their frequency: electrical artifacts are usually 60 cycles/s, and respirator artifacts occur at the rate at which the ventilator is set.

In the presence of ventricular dysrhythmias, it is necessary to obtain a "stat" blood sample for evaluation of electrolytes, calcium, and magnesium, as well as assessment of the patient's oxygenation (transcutaneous oximetry or arterial blood gas).

Differential Diagnosis and Management

An algorithmic approach is useful in the diagnosis of pediatric dysrhythmias (Figure 13-11). Characteristic ECG tracings typical of the more common dysrhythmias are shown in Figure 13-12. A brief discussion of these dysrhythmias follows.

Sinus Rhythms

Sinus arrhythmia, which is common in children, is a cyclic variation in heart rate associated with respirations. Usually the heart rate increases with inspiration and slows with expiration. The ECG is otherwise totally normal. The younger the child, the more pronounced the sinus arrhythmia.

Sinus tachycardia is also quite common in children and occurs as a result of stress (e.g., fever or dehydration) or pathologic conditions (e.g., congestive heart failure, anemia, hyperthyroidism). Some medications (e.g., certain cold preparations and β-agonists used for asthma) may cause sinus tachycardia. It is possible to differentiate sinus tachycardia from SVT based on several findings (Table 13-5).

Sinus bradycardia may occur during sleep, when it may be a normal finding. It is not uncommon for a sleeping child to have a heart rate less than 80 beats/min, although the heart rate will increase appropriately when the child is disturbed. Competitive athletes may also have a resting sinus bradycardia. Pathologic causes of bradycardia include hypothyroidism, increased intracranial pressure, hypothermia, hyperkalemia, and digitalis overdose.

Atrial Dysrhythmias

Premature atrial contractions (PACs) result from the firing of an ectopic focus in the atrium. PACs, which can be seen in many normal children, are one of the most common dysrhythmias in the newborn period. Although PACs are usually conducted, they will not be conducted if they occur too early in the cardiac cycle when the AV node is still refractory (**blocked PACs**). It is possible to differentiate PACs from **premature ventricular contractions (PVCs)** based on several ECG characteristics (Table 13-6). Isolated PACs do not require treatment. Frequent PACs in newborns usually resolve by 1 month of age.

TABLE 13-5

Sinus Tachycardia Compared with Supraventricular Tachycardia

	Sinus Tachycardia	*Supraventricular Tachycardia*
Heart rate (beats/min)	Usually <200	Usually >220
Heart rate variability	Present	Usually absent
History	Fever, dehydration, acute blood loss	Irritability, lethargy, poor feeding, tachypnea, sweating
Physical examination	Infectious source of fever; decreased skin turgor; absence of hepatomegaly; clear lung fields; source of acute blood loss	Signs of congestive heart failure: rales, hepatomegaly, respiratory distress, poor perfusion
Chest radiograph	Normal or small heart size; pneumonia as source of fever	Possible cardiomegaly or pulmonary edema

SVT can be divided into two major categories based on etiology: a **reentrant pathway (preexcitation syndrome)** or **an atrial ectopic focus (atrial ectopic tachycardia [AET])**. Preexcitation is more common and is usually due to an **accessory pathway** or **bypass tract** that leads to accelerated conduction between atria and ventricle. In patients with **Wolff-Parkinson-White syndrome,** an abnormal myocardial bridge lies between one of the atria and one of the ventricles. Cardiac impulses can travel anterograde (from atrium to ventricle) through the accessory bundle, which does not have the built-in time delay of the AV node. This leads to a shortened PR interval, and because one of the ventricles is excited before the other, the QRS complex is widened **(delta wave on the 12-lead ECG)**.

Pediatric Pearl: Examination of the T wave may reveal slight irregularities from one beat to the next that could represent a hidden P wave, thus indicating SVT or atrial flutter.

Patients with SVT typically present with heart rates of 200 to 300 beats/min (see Table 13-5). In children, atrial rates as fast as 300 beats/min may be conducted 1:1 to the ventricles. Most initial episodes of SVT occur in the first 4 months of life; however, SVT may develop at any age. Infants often present with irritability, tiredness, and decreased feeding, and occasionally with overt signs of congestive heart failure (sweating, labored

TABLE 13-6

Premature Atrial Complexes (PACs) Compared with Premature Ventricular Complexes (PVCs)

	PACs	*PVCs*
QRS timing	Premature	Premature
QRS duration	Usually normal; occasionally prolonged	Prolonged
QRS morphology	Usually the same as sinus rhythm QRS complexes	Different from sinus rhythm QRS complexes
ST-T abnormalities	Rare	More common
P wave	Usually precedes QRS complex	None; occasionally will follow QRS complex
Fusion beats	None	May be present
Compensatory pause	Not usually (but not reliable)	Usually (but not reliable)

TABLE 13-7

Treatment of Supraventricular Tachycardia

1. Vagal maneuvers (carotid massage, immerse face in ice water)
2. Adenosine 0.05–0.2 mg/kg by rapid IV push
3. Overdrive pacing (transesophageal or transvenous)
4. Synchronized DC cardioversion (0.25–2.0 W-s/kg) if patient is unstable

DC, direct current; *IV*, intravenous.

respirations, and decreased perfusion leading to shock). However, in the absence of heart disease, patients with SVT can often tolerate the dysrhythmia for 12 to 24 hours before these signs of heart failure intervene. Older children may complain of palpitations and dizziness.

The treatment of the SVTs involves several measures (Table 13-7). For patients who are stable, vagal maneuvers or pharmacologic management with antiarrhythmic drugs are the treatments of choice. However, for patients who have signs of decreased perfusion and shock, **synchronized direct current (DC) cardioversion** is warranted.

After the initial episode has resolved, infants and children are usually treated for 6 to 12 months with antiarrhythmic agents such as the β-blocker propranolol, or sotolol. Each of these drugs has its particular benefits and side effects that might limit treatment. Occasionally, use of more than one drug is necessary to maintain normal sinus rhythm. A trial without medications is appropriate in patients who are tachycardia-free for 6 to 12 months. **Cryoablation or radiofrequency catheter ablation,** which allows patients to be medication-free, is the recommended treatment option for children whose SVT is resistant to medications, and for all older children with Wolff-Parkinson-White syndrome as these patients develop an increased risk of complications as they grow older.

Atrial flutter (intra atrial reentry tachycardia) and **atrial fibrillation** are less common in children and usually encountered in the setting of congenital heart disease. If AV conduction is 1:1, symptoms of heart failure may rapidly develop. Often the AV node blocks extremely rapid conduction, and the atrial:ventricular rate is 2:1 or 3:1. The initial treatment of choice for either of these dysrhythmias is synchronized DC cardioversion followed by initiation of antiarrhythmic medication.

Ventricular Dysrhythmias

PVCs are often encountered in children hospitalized for other reasons such as patients in the pediatric intensive care unit (ICU) for trauma, infections, postoperative monitoring, or in those undergoing routine surgical procedures during anesthetic induction or recovery. For a comparison of PVCs and PACs on the basis of ECG findings, see Table 13-6. PVCs are usually considered benign when they occur singly, arise from a single ectopic focus (have the same morphology and axis), when the coupling interval (time between the previous normal QRS complex and the premature beat) is constant, and when there is no underlying heart disease (Table 13-8). Unifocal PVCs usually disappear if the patient exercises. Malignant PVCs warrant further evaluation and often require treatment.

TABLE 13-8

Benign Versus Malignant Premature Ventricular Complexes (PVCs)

	Benign PVCs	*Malignant PVCs*
Heart disease	Not usual	Often seen with congenital or ischemic heart disease
Coupling interval	Fixed	Variable
Baseline QT interval	Usually normal	May be prolonged
Focality of PVCs	Unifocal	Multifocal
R on T	Absent	Present
Response to exercise	Suppresses PVCs	Increases PVCs
Couplets or runs	None	May be present

Nicotine

Malignant PVCs and ventricular tachycardia often occur secondarily to another abnormality such as an electrolyte disturbance, hypoxia, or medication or drug (Table 13-9). Thus, the mainstay of treatment for any ventricular dysrhythmia is correction of the underlying abnormality. No pharmacologic agent is totally effective in treating ventricular dysrhythmias unless the underlying cause is also corrected. Other causes include myocarditis and a genetic predisposition (long QT syndrome, hypertrophic cardiomyopathy).

Ventricular tachycardia (VT) is defined as the occurrence of three or more PVCs in a row. When the ventricular rate is slow, patients may be minimally symptomatic. However, when ventricular rates are fast, cardiogenic shock rapidly ensues. Because of the possibility of degeneration into ventricular fibrillation, emergent treatment is necessary for all **ventricular tachycardias**. To confuse matters, with VT, the ECG may show P waves (with either retrograde conduction or AV dissociation), and with some SVTs, it may show aberrant conduction, and thus, wide QRS complexes. However, clinicians should almost always assume that children with wide complex tachycardia have VT and treat them appropriately (Table 13-10). When VT is seen in children who have one of the congenital **long QT syndromes (LQTS),** the ECG morphology is often an undulating wavy line alternating both above and below an imaginary baseline **(torsade de pointes)**.

Pediatric Pearl: It is important to search for underlying causes of PVCs or VT in pediatric patients (e.g., electrolyte abnormalities, hypoxia). Antiarrhythmic agents may not be completely effective unless these provoking factors are resolved.

Ventricular fibrillation (VF) manifests with absent pulses and shock. Immediate cardiopulmonary resuscitation is necessary. The ECG shows either a coarse or fine wavy line without recognizable QRS complexes. The treatment for VF is DC cardioversion, and as with VT, correction of the underlying cause (e.g., hypoxemia, electrolyte disturbance).

Conduction Disorders

First-degree AV block occurs when the PR interval is greater than normal values for both age and heart rate. First-degree block may occur in the presence of some congenital heart lesions (corrected transposition of the great arteries), and with myocarditis or rheumatic fever. Although first-degree AV block usually does not warrant

TABLE 13-10

Treatment of Premature Ventricular Complexes (PVCs) and Ventricular Tachycardia

1. Treatment of underlying causes (acidosis, hypoxia, electrolyte disturbances, intracardiac line)
2. Lidocaine 1 mg/kg IV bolus followed by 0.5–1.5 mg/kg/h drip
3. Amiodarone 5 mg/kg load, may repeat up to four times total, then 5–10 mg/kg/day drip
4. If patient is hemodynamically unstable; synchronized DC cardioversion (0.5–2.0 W-s/kg)

DC, direct current; *IV,* intravenous.

treatment, it does require follow-up monitoring for worsening block. The PR interval is usually slightly prolonged with digitalis treatment; this is not necessarily a sign of digitalis toxicity.

Second-degree AV block may be of two forms: Mobitz type I (Wenckebach) and type II. In **Mobitz type I,** there is progressive prolongation of the PR interval until a dropped QRS occurs. Thus, patients may have 2:1, 3:2, or 4:3 AV block. In **Mobitz type II,** QRS complexes are dropped in varying ratios (e.g., 2:1, 3:1, 3:2). Both of these dysrhythmias require cardiologic evaluation and may be an indication for a pacemaker.

Third-degree AV block or complete AV dissociation occurs when the atria and ventricles beat independently and there is not a regular relationship between the P waves and QRS complexes on ECG. This condition may occur congenitally (especially in newborns whose mothers have systemic lupus erythematosus) in association with underlying congenital heart disease (most commonly in corrected transposition of the great arteries), or after surgical repair of congenital heart disease (most commonly in VSDs, AV septal defects, or mitral or aortic valve replacement). If the heart rate is adequate to maintain a reasonable cardiac output, children are asymptomatic and treatment may not be indicated. However, if the heart rate is slow enough to result in symptoms such as exercise intolerance or syncope, pacemaker implantation is indicated. Additional patients requiring consideration for pacemaker implantation are asymptomatic infants with heart rates less than 50 beats/min and any child with long over pauses.

INFECTIVE ENDOCARDITIS

The incidence of infective endocarditis in children with congenital heart disease is approximately 1.5 cases per 1,000 patient-years. Given the serious morbidity and high mortality associated with endocarditis, prevention is a mainstay of treatment of children with congenital heart disease.

Pathophysiology

In the presence of congenital heart disease, turbulent blood flow causes damage to endothelial surfaces, allowing the deposition of fibrin and platelets. Within these tiny sterile thrombi, circulating bacteria initially adhere and then grow, partially protected from the cleansing action of laminar blood flow. Bacteria such as **streptococci** that produce glycoproteins are more easily adherent to these lesions, thus explaining their prevalence as causative agents. Lesions of infective endocarditis most usually occur on the downstream side of a lesion such as on the aortic surface of a stenotic aortic valve or on the right ventricular surface of a VSD. High-velocity lesions that produce more turbulence (e.g., small VSDs) are more susceptible to endocarditis than low-velocity lesions such as ASDs.

After correction of most congenital heart defects, the risk of endocarditis decreases. However, patients with prosthetic valves or artificial conduits such as Blalock-Taussig shunts may have increased susceptibility to infective endocarditis. Patients with rheumatic heart disease are also at risk.

Clinical and Laboratory Evaluation

History

A history of congenital or rheumatic heart disease is present in almost all patients with infective endocarditis. It is often possible to identify a source of infection such as a recent dental or surgical procedure, abscess, or

significant trauma. Indwelling urinary or intravenous catheters also put patients at risk. Persistent fever, anorexia and weight loss, malaise, myalgias, arthralgias, and worsening congestive heart failure may be presenting symptoms.

Physical Examination

A new or changing heart murmur may be audible. Splenomegaly is present in 60% to 70% of patients, and peripheral embolization of bacteria may cause petechiae, splinter hemorrhages, or small infarcts. Other skin manifestations are the result of circulating antibody–antigen complexes and include Osler nodes (painful red nodules on the fingers or toes), Janeway lesions (painless hemorrhagic lesions on the palms and soles), and Roth spots (retinal hemorrhages).

Laboratory Evaluation

Blood cultures demonstrate the specific organism, most often streptococci or staphylococci, although any bacterial strain may be involved. Gram-negative bacilli or enterococci are more common after genitourinary instrumentation or infection. *Candida albicans* is encountered in patients who develop endocarditis after open heart surgery, especially those with prosthetic valves. Additional laboratory findings include a mild leukocytosis, elevated erythrocyte sedimentation rate (ESR); anemia; and, quite commonly, microscopic hematuria. Echocardiography, if positive, is usually diagnostic; however, a negative echocardiogram, especially in younger children, does not eliminate the possibility of endocarditis. Transesophageal echocardiography may be required for the diagnosis in older children and adolescents.

Management

The primary strategy for management of infective endocarditis is prevention.

Prophylaxis for Subacute Bacterial Endocarditis

Prevention through maintaining good dental hygiene is still one of the mainstays of subacute bacterial endocarditis (SBE) management; however, the role of **prophylactic antibiotics** has undergone a major revision in recent years. The latest recommendations of the American Heart Association (AHA), published in 2007, have dramatically reduced the use of antibiotics for most congenital heart lesions. Prophylactic antibiotics are now only recommended for patients with prosthetic heart valves or prosthetic material used for valve repair, unrepaired cyanotic congenital heart disease, repaired congenital heart disease with prosthetic material or device within the first 6 months after the procedure, repaired congenital heart disease with residual defects such as patch leaks (which inhibit endotheliazation), and cardiac transplant patients with valve disease. The clinician should inform the parents of children with eligible congenital heart lesions about the risks of SBE as soon as the diagnosis is made and give them a card with the AHA recommendations for prophylaxis (Figure 13-13).

Treatment

The decision to initiate therapy before blood culture confirmation depends on the severity of the illness. In subacute cases, it may be appropriate to withhold antibiotics for a few days awaiting culture results. However, if clinical features are highly suggestive of infective endocarditis or if the patient is seriously ill, treatment usually involves a broad-spectrum antibiotic that covers the most likely infective agents.

Once the organism is positively identified, specific antibiotic therapy can begin, usually a 4- to 6-week parenteral course. Surgical management is reserved for resistant (usually fungal) organisms or those cases in which a vegetation affects function of a prosthetic heart valve. Despite recent advances in antimicrobial management, the mortality rate of infective endocarditis is still as high as 25%.

CARDIOMYOPATHIES

Pathophysiology

Diseases of the myocardium can be divided based on their etiology into infectious, metabolic, infiltrative, ischemic, and primary myopathic causes (Table 13-11). **Myocarditis,** one of the most common causes of myocardial disease, is an acute inflammation most often caused by a viral infection. Many viruses have been identified as etiologic agents; however, adenovirus, coxsackie B virus, and parvovirus are by far the most common in children.

PREVENTION OF INFECTIVE (BACTERIAL) ENDOCARDITIS
Wallet Card

This wallet card is to be given to patients (or parents) by their physician. Healthcare professionals: Please see back of card for reference to the complete statement.

Name: _____
needs protection from
INFECTIVE (BACTERIAL) ENDOCARDITIS
because of an existing heart condition.

Diagnosis: _____
Prescribed by: _____
Date: _____

You received this wallet card because you are at increased risk for developing adverse outcomes from infective endocarditis (IE), also known as bacterial endocarditis (BE). The guidelines for prevention of IE shown in this card are substantially different from previously published guidelines. This card replaces the previous card that was based on guidelines published in 1997.

The American Heart Association's Endocarditis Committee together with national and international experts on IE extensively reviewed published studies in order to determine whether dental, gastrointestinal (GI), or genitourinary (GU) tract procedures are possible causes of IE. These experts determined that there is no conclusive evidence that links dental, GI, or GU tract procedures with the development of IE.

The current practice of giving patients antibiotics prior to a dental procedure is no longer recommended **EXCEPT** for patients with the highest risk of adverse outcomes resulting from IE (see below on this card). The Committee cannot exclude the possibility that an exceedingly small number of cases, if any, of IE may be prevented by antibiotic prophylaxis prior to a dental procedure. If such benefit from prophylaxis exists, it should be reserved **ONLY** for those patients listed below. The Committee recognizes the importance of good oral and dental health and regular visits to the dentist for patients at risk of IE.

The Committee no longer recommends administering antibiotics solely to prevent IE in patients who undergo a GI or GU tract procedure.

Changes in these guidelines do not change the fact that your cardiac condition puts you at increased risk for developing endocarditis. If you develop signs or symptoms of endocarditis—such as unexplained fever—see your doctor right away. If blood cultures are necessary (to determine if endocarditis is present), it is important for your doctor to obtain these cultures and other relevant tests **BEFORE** antibiotics are started.

Antibiotic prophylaxis with dental procedures is reasonable only for patients with cardiac conditions associated with the highest risk of adverse outcomes from endocarditis, including:

- Prosthetic cardiac valve or prosthetic material used in valve repair
- Previous endocarditis
- Congenital heart disease only in the following categories:
  - –Unrepaired cyanotic congenital heart disease, including those with palliative shunts and conduits
  - –Completely repaired congenital heart disease with prosthetic material or device, whether placed by surgery or catheter intervention, during the first six months after the procedure*
  - –Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients with cardiac valvular disease

*Prophylaxis is reasonable because endothelialization of prosthetic material occurs within six months after the procedure.

Dental procedures for which prophylaxis is reasonable in patients with cardiac conditions listed above.

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth, or perforation of the oral mucosa*

***Antibiotic prophylaxis is NOT recommended for the following dental procedures or events:** routine anesthetic injections through noninfected tissue; taking dental radiographs; placement of removable prosthodontic or orthodontic appliances; adjustment of orthodontic appliances; placement of orthodontic brackets; and shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa.

Antibiotic Prophylactic Regimens for Dental Procedures

Situation	Agent	Regimen—Single Dose 30-60 minutes before procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin **OR**	2 g IM or IV*	50 mg/kg IM or IV
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—Oral regimen	Cephalexin**†	2 g	50 mg/kg
	OR		
	Clindamycin	600 mg	20 mg/kg
	OR		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone†	1 g IM or IV	50 mg/kg IM or IV
	OR Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

*IM—intramuscular; IV—intravenous
**Or other first or second generation oral cephalosporin in equivalent adult or pediatric dosage.
†Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema or urticaria with penicillins or ampicillin.

Gastrointestinal/Genitourinary Procedures: Antibiotic prophylaxis solely to prevent IE is no longer recommended for patients who undergo a GI or GU tract procedure, including patients with the highest risk of adverse outcomes due to IE.

Other Procedures: Procedures involving the respiratory tract or infected skin, tissues just under the skin, or musculoskeletal tissue for which prophylaxis is reasonable are discussed in the updated document (reference below).

In earlier years, it was often impossible to identify a specific viral agent, because peripheral serum titers were often nondiagnostic. More recent studies utilizing the polymerase chain reaction to analyze myocardial biopsy specimens have increased the ability to identify specific viral agents. Biopsy specimens reveal an acute inflammatory infiltrate and evidence of myocyte necrosis, often replaced later by fibrous scar tissue.

Common metabolic causes of myocardial dysfunction include electrolyte abnormalities such as hypocalcemia and hypomagnesemia, hypoglycemia, and hypothyroidism. Rarer causes relate to deficiencies of a specific

nutrient, an inborn error of metabolism, or are secondary to a toxin (see Table 13-11). Infiltrative myocardial diseases also occur with inborn errors of metabolism such as the abnormal glycogen deposition associated with type II (Pompe) glycogen storage disease. Ischemic heart disease is uncommon in children; however, it may occur with congenital abnormalities of the coronary arteries (e.g., anomalous origin of the left coronary artery from the pulmonary artery), in homozygous hyperlipidemias, and in postoperative patients after the repair of a complex congenital heart disease.

With use of new tools in molecular genetics and genomics, many cardiomyopathies formerly considered idiopathic are now being recognized as resulting from specific gene defects. Patients being evaluated for cardiomyopathy require a detailed family history and should be evaluated by a geneticist with expertise in this area. Genetic testing for cardiomyopathy has progressed significantly over the past decade, and several commercial laboratories now offer testing for the most common gene mutations. However, the correlation between genotype (the specific gene mutation) and phenotype (the patient's presenting signs, symptoms, and ultimate prognosis) is still a work in progress.

Cardiomyopathies can also be divided based on their physiology into dilated, hypertrophic, and restrictive subtypes. In **dilated cardiomyopathy** (DCM), the left ventricular end-diastolic volume is increased, and the ventricular wall is proportionally thin. The primary physiologic derangement is a decrease in *systolic* function (contraction or inotropy). In contrast, in **hypertrophic cardiomyopathy** (HCM, formerly known as idiopathic hypertrophic subaortic stenosis or IHSS), the end-diastolic volume is decreased and the ventricular wall is thickened, either eccentrically or concentrically. The primary physiologic derangement involves *diastolic* function (relaxation or lusitropy), although the subaortic muscle can often become thick enough to cause obstruction to the left ventricular outflow tract, a significant cause of symptoms. In **restrictive cardiomyopathy (RCM)**, the ventricular volume is normal to mildly decreased, and the wall thickness is normal or minimally increased. The primary physiologic derangement involves *diastolic* function due to extremely poor compliance (distensibility) of the ventricular chamber. The atria are typically markedly enlarged.

Clinical and Laboratory Evaluation

History

Children with myocarditis may present with either a rapid onset (more common in infants) or a more insidious onset (more common in older children) of symptoms of congestive heart failure. They may have a history of an upper respiratory tract infection or gastroenteritis within the previous month. Younger children may display evidence of decreased activity, irritability, or feeding intolerance. Older children may complain of difficulty breathing, chronic cough, easy fatigability, abdominal symptoms, dyspnea on exertion, orthopnea, or recent weight gain.

In patients with genetic myopathies, presentation is usually more insidious, although occasionally a family history of a specific metabolic disorder raises the index of suspicion and leads to an earlier diagnosis. Many patients may have been followed for weeks or months with a diagnosis of upper respiratory tract infection, pneumonia, chronic abdominal pain, or asthma. Occasionally, patients with hypertrophic or restrictive cardiomyopathy are first diagnosed when they present with syncope, or even with "missed sudden death," secondary to arrhythmia.

Physical Examination

General physical signs of congestive heart failure are similar to those described in the section on congenital heart defects (see Congenital Heart Disease). Findings include tachypnea, subcostal retractions, wheezes or rales, hepatosplenomegaly, and poor peripheral perfusion and pulses. Edema occurs around the eyes and on the back in infants and in the lower extremities in older children and adolescents. The cardiac examination may reveal diminished heart sounds, an increased cardiac impulse, a gallop rhythm, and often a holosystolic murmur of mitral or tricuspid insufficiency due to dilatation of one or both of the semilunar valve rings. The presence of a rub suggests pericardial involvement, which can be associated with myocarditis. Hepatomegaly is common.

Laboratory Evaluation

The chest radiograph is the best laboratory test for evaluation of cardiac chamber enlargement and the presence of pulmonary edema. The ECG is the best test for evaluation of chamber hypertrophy or signs of ischemia or inflammation. In myocarditis, the ECG may show low-voltage QRS complexes, ST-segment depression, and various degrees of heart block and other dysrhythmias. The hypertrophic myopathies demonstrate either isolated left or biventricular hypertrophy, and signs of ischemia or strain (e.g., T-wave inversion in lead V_6) may be evident. Some of the metabolic or infiltrative myopathies have distinctive ECG patterns such as the short PR interval and hypertrophy pattern associated with Pompe disease. In suspected viral myocarditis, serum viral titers

are only rarely diagnostic. A myocardial biopsy, performed transvenously in the cardiac catheterization laboratory, yields a specific diagnosis in most cases. MRI has also been used to detect myocarditis.

Differential Diagnosis

The differential diagnosis of acute myocardial dysfunction includes all of the conditions listed in Table 13-11. Endocardial biopsy sometimes allows a definitive diagnosis, but it often shows only fibrosis and compensatory

TABLE 13-11

Causes of Diseases of the Myocardium

Infectious Diseases
Viral myocarditis Adenovirus, coxsackievirus, parvovirus (most common) Mumps, measles, rubella, echovirus, cytomegalovirus, HIV, arbovirus, poliovirus
Nonviral myocarditis *Toxoplasma gondii, Mycoplasma pneumoniae, rickettsiae, Chlamydia trachomatis,* diphtheria toxin, *Trypanosoma cruzi* (Chagas disease)
Immunologic myocarditis Acute rheumatic fever Kawasaki syndrome
Metabolic Diseases
Electrolyte abnormalities Hypocalcemia, hypomagnesemia, hypokalemia, hyperkalemia, hypoglycemia
Endocrine abnormalities Infants of diabetic mothers, hypothyroidism, pheochromocytoma
Drugs and toxins Alcohol, cocaine, adriamycin, chloroquine, ipecac, radiation
Vitamin and trace metal deficiencies (thiamine [beriberi], selenium [Keshan disease], carnitine, taurine)
Infiltrative Diseases
Glycogen storage diseases (Pompe)
Glycolipid disease (Fabry)
Hemochromatosis (in patients receiving multiple transfusions)
Mucopolysaccharidoses
Cystinosis
Amyloidosis
Sarcoidosis
Neoplasms (lymphoma, rhabdomyoma [seen in tuberous sclerosis])
Primary Myopathic Diseases
Genetic forms of dilated cardiomyopathy (DCM) including muscular dystrophies (Duchenne, Becker)
Hypertrophic cardiomyopathy (HCM)
Restrictive cardiomyopathy (RCM)
Isolated noncompaction of the left ventricle

hypertrophy of remaining myocardial cells. These cases lead to a diagnosis of **idiopathic DCM**. Polymerase chain reaction analysis, usually performed in a research laboratory, has recategorized many of these "idiopathic" cases as the chronic stage of postviral myocarditis. Severe sepsis can lead to ventricular dysfunction, which is reversible when the infection is treated. Uremia in end-stage renal disease can also lead to ventricular dysfunction, which often improves with dialysis and management of hypertension, and can resolve fully after renal transplant.

Management

The treatment of acute myocarditis involves supportive therapy with diuretics, and in cases of hemodynamic decompensation, intravenous inotropic agents (e.g., dopamine, dobutamine, milrinone) or afterload-reducing drugs (e.g., nitroprusside, captopril). The inflamed myocardium is more sensitive to the arrhythmogenic effects of digitalis, so this agent is usually not used in this setting. Specific anti-inflammatory therapy with corticosteroids or other immunosuppressives or intravenous immune globulin (IVIG) is still controversial. For patients who do not respond to intravenous inotropes, several methods of artificial circulatory support are available, including extracorporeal membrane oxygenation and left ventricular assist devices. Cardiac transplantation is the only specific treatment available for children with the more severe forms of dilated or restrictive cardiomyopathy. Currently, the 1- and 5-year survival rates for pediatric heart transplant recipients are 90% and 75%, respectively.

For children with hypertrophic cardiomyopathy, surgical resection of subaortic muscle can reduce symptomatology and antiarrhythmics or an implantable cardioverter defibrillator can reduce the risk of sudden death secondary to ventricular arrhythmias. Transplantation is an option in the most severe cases.

RHEUMATIC HEART DISEASE

Improvement in public hygiene and standards of living, combined with the routine antibiotic treatment of streptococcal pharyngitis, has resulted in a marked decrease in the incidence of rheumatic fever in the United States. However, rheumatic fever is still a major public health problem in many developing countries. A worrisome resurgence of rheumatic fever began in the United States in the mid-1980s; the exact reasons for this are unknown.

Pathophysiology

Acute rheumatic fever is associated with an infection (usually of the pharynx) with **group A β-hemolytic streptococci** that triggers an abnormal immune response in genetically susceptible individuals. In these individuals, B-lymphocytes are sensitized by streptococcal antigens, leading to the formation of antistreptococcal antibodies. Immune complexes form that cross-react with antigens present on cardiac muscle, leading to inflammation and both myocardial and valvular disease.

Pathologic changes occur not only in the heart, but in connective tissue and in perivascular tissue. The characteristic pathologic lesion is the **Aschoff body,** consisting of an inflammatory focus surrounding disrupted connective tissue fibers. The initial acute attack leads to a **pancarditis** (involvement of pericardium, myocardium, and endocardium). Initial attacks of rheumatic fever result in valve thickening **(verrucous valvulitis),** leading to regurgitation, most frequently of the mitral and aortic valves. Pathologic changes also occur in the joints **(arthritis),** skin **(subcutaneous nodules, erythema marginatum),** and central nervous system (CNS) **(chorea)**. In the heart, recurrent attacks result in repeated scarring of the affected valves, usually resulting in the development of mitral stenosis.

Clinical and Laboratory Evaluation

History

Patients may present with a history of a recent episode of untreated or partially treated pharyngitis, although this history is variable. A complaint of **migratory polyarthritis,** usually affecting large joints with transient erythema and effusions, is often the major presenting symptom. Symptoms of **congestive heart failure** are less common. **Sydenham chorea** is also a less common presentation of acute rheumatic fever. The chorea consists of sudden abnormal movements of the extremities but may develop insidiously as clumsiness or deteriorating school performance. Muscle weakness and behavioral disturbances are common. A history of previous episodes of acute rheumatic fever is very significant, as recurrence risks are high.

Physical Examination

The physical examination should focus on detection of **arthritis** (e.g., joint swelling, redness, warmth, and pain) as opposed to **arthralgias** (pain alone). The cardiac examination may be notable for a friction rub secondary to a pericardial effusion, a gallop rhythm, or a new heart murmur of mitral regurgitation (holosystolic) or aortic regurgitation (decrescendo diastolic). The classical skin lesions are 0.5 to 1.0 cm, painless, **subcutaneous nodules** on the extensor surfaces of the hands, feet, scalp, or vertebra. The typical rash is **erythema marginatum,** although it occurs in only about 10% of patients, and consists of an evanescent erythematous macule with a clear center and serpiginous outline. Erythema marginatum is predominantly truncal, is also migratory, and is usually nonpruritic.

Laboratory Evaluation

The standard laboratory evaluation shows elevation of several acute phase reactants, including ESR and C-reactive protein; however, these findings are very nonspecific. A rising titer of antistreptococcal antibodies (antistreptolysin O antibodies, anti-DNAse B, antihyaluronidase) is very important in making the diagnosis. Culture of group A β-streptococci from the pharynx is also important.

The ECG may show a prolonged PR interval or first-degree heart block. The chest radiograph reveals cardiac enlargement in patients with active carditis and pulmonary edema in patients with congestive heart failure.

Differential Diagnosis

The diagnosis of acute rheumatic fever may be difficult, because most patients do not present with all of the textbook criteria. The AHA has guidelines for the diagnosis of rheumatic fever, known as the modified Jones criteria (Table 13-12). The differential diagnosis often includes several of the rheumatic diseases of childhood, such as rheumatoid arthritis and systemic lupus erythematosus (see Chapter 21).

Management

Treatment involves eradication of the streptococcal infection with penicillin. Benzathine penicillin G given as an intramuscular injection of 0.6 to 1.2 million units is the most effective because compliance is ensured. Anti-inflammatory agents such as aspirin, which are begun at 30 to 60 mg/kg/day in four divided doses, are

TABLE 13-12

Modified Jones Criteria for Diagnosis of Acute Rheumatic Fever[a]

Major Manifestations
1. Carditis (cardiomegaly, heart murmur, pericarditis, congestive heart failure)
2. Polyarthritis
3. Erythema marginatum
4. Subcutaneous nodules
5. Chore
Minor Manifestations
1. History of previous episode of rheumatic fever
2. Arthralgias
3. Fever
4. Increased acute phase reactants (ESR, C-reactive protein, WBC count, anemia)
5. ECG changes (increase PR or QT intervals)

ECG, electrocardiogram; *ESR*, erythrocyte sedimentation rate; *WBC*, white blood cell.

[a] The presence of two major or one major and two minor manifestations combined with evidence of recent streptococcal infection (positive throat culture, elevated antistreptolysin O titer, history of scarlet fever) are highly indicative of diagnosis of rheumatic fever.

continued depending on the individual's response, usually for 2 to 6 weeks. Corticosteroids are rarely used, although they may be beneficial in the treatment of patients with severe carditis and congestive heart failure. For patients in heart failure, other treatment modalities are used as needed (see Table 13-4). Clinicians no longer require strict bed rest. However, they still recommend a modified and gradual ambulatory program during the acute phase of the illness.

An important concept in rheumatic fever treatment is the prevention of future episodes. Once affected, children are at high risk for recurrent attacks and continue to receive penicillin prophylaxis. This involves either twice-daily penicillin G (250,000 units) or parenteral benzathine penicillin G (1.2 million units) given intramuscularly every 4 weeks. The latter is preferred if poor compliance is suspected.

KAWASAKI DISEASE

First described in 1967 in Japan, **Kawasaki disease** (also known as **mucocutaneous lymph node syndrome**) is a generalized vasculitis of unknown etiology. It is currently one of the leading causes of acquired heart disease in children. Although initial reports of Kawasaki disease were confined to Asia, the disease has now been described worldwide. It occurs in both endemic and epidemic patterns. Epidemics have usually taken place during the winter or spring. In the United States, the prevalence is approximately 9 cases per 100,000 children less than 5 years of age, with 80% of cases in children younger than 8 years of age. Kawasaki disease is more prevalent in children of Asian ancestry.

Pathophysiology

Coronary artery disease is present in 20% of untreated patients with Kawasaki disease. In untreated patients, there are four pathologic stages.

- **Stage 1** (first 2 weeks): An acute vasculitis, involving predominantly the coronary arteries, is present. A pancarditis, with inflammatory changes in the cardiac conduction system, may accompany the vasculitis.
- **Stage 2** (2 to 4 weeks after onset): The coronary vasculitis persists, and coronary artery aneurysms may occur. In some cases, thrombosis in the aneurysms may occur, with obstruction of coronary blood flow.
- **Stage 3** (4 to 8 weeks): Coronary inflammation begins to subside, although aneurysms may still be present. The myocardial inflammation is almost resolved.
- **Stage 4** (more than 8 weeks after onset): Scar formation and calcification of the coronary arteries, stenosis and recanalization of the coronary lumen, and myocardial fibrosis occur.

Other arteries may be involved and, rarely, peripheral arterial involvement may be severe enough to cause gangrenous changes in the extremities.

Clinical and Laboratory Evaluation

History and Physical Examination

Clinically, Kawasaki disease has three distinct phases: acute, subacute, and chronic. The acute febrile phase with typical skin and mucous membrane manifestations lasts up to 2 weeks (Table 13-13). The subacute phase is characterized by milder clinical disease and thrombocytosis, during which time coronary aneurysms may develop. This phase may last from the second to the fourth week of illness. The chronic phase, during which symptoms and laboratory abnormalities resolve, lasts up to 2 months after onset. During the acute phase, diagnosis is based on fulfilling five of six major criteria.

Additional clinical features may be present. Such symptoms include arthralgia or arthritis, cough, rhinorrhea, pneumonia, abdominal pain, diarrhea, jaundice, irritability, aseptic meningitis, and carditis.

The cardiac examination may be significant for the presence of a gallop rhythm. A flow murmur may be heard secondary to the high fever and mild anemia. A pericardial friction rub or distant heart sounds may indicate the presence of a pericardial effusion, which occurs in one-third of patients. Rarely, murmurs of mitral or aortic regurgitation are present when the carditis is severe.

Laboratory Evaluation

A complete blood cell count shows an elevated white blood cell count and mild anemia. During the early acute phase, the platelet count is normal, but becomes elevated during the second and third weeks of the disease. The ESR and other acute phase reactants are elevated. Urinalysis reveals sterile pyuria and proteinuria. If a lumbar puncture is performed, spinal fluid examination finds mild pleocytosis with normal glucose and protein levels. Abdominal ultrasound may show hydrops of the gallbladder.

TABLE 13-13

Classic Diagnostic Criteria for Kawasaki Disease[a]

Fever persisting for at least 5 days PLUS
Presence of at least four of the following five principal features
Changes in extremities: Acute: erythema and edema of hands and feet Convalescent: membranous desquamation of fingertips
Polymorphous exanthema
Bilateral, painless bulbar conjunctival injection without exudate
Changes in lips and oral cavity: erythema and cracking of lips, strawberry tongue, diffuse injection of oral and pharyngeal mucosae
Cervical lymphadenopathy (≥1.5 cm in diameter), usually unilateral

[a] From AHA Scientific Statement: Diagnostic guidelines for Kawasaki disease. *Circulation* 103:335–336, 2001.

The ECG may be normal or may show prolonged PR or QT intervals, low voltages, ST-T wave changes, or dysrhythmia. During the subacute phase, signs of coronary ischemia or infarction may be present (abnormal Q waves or ST segments). Clinicians usually obtain an echocardiogram at the time of initial diagnosis to establish a baseline with which subsequent studies can be compared and to detect a pericardial effusion. Occasionally, this initial echocardiogram reveals early coronary aneurysms. A repeat echocardiogram is then appropriate 3 to 4 weeks after onset; it demonstrates coronary aneurysms if present. If no aneurysms are evident at this time, a final follow-up echocardiogram at 6 to 8 weeks, and another several months later are usually warranted.

Differential Diagnosis

Several infectious diseases may present with symptoms and signs similar to those of Kawasaki disease, including measles, scarlet fever, staphylococcal scalded skin syndrome, toxic shock syndrome, and Rocky Mountain spotted fever (see Chapter 9). Other disorders worthy of consideration in the differential diagnosis include allergic drug reactions, Stevens-Johnson syndrome, myocarditis, rheumatic diseases such as juvenile rheumatoid arthritis, and mercury poisoning.

Management

Initial therapy of Kawasaki disease is directed at reducing inflammation and preventing development of coronary artery aneurysms. Chronic therapy is directed at preventing coronary artery thrombosis. When the diagnosis is first established, intravenous gamma globulin, given as 2 g/kg as a single infusion over 12 hours, is the standard treatment. If administered within the first 10 days of the onset of disease, gamma globulin has been shown to significantly decrease the risk of aneurysm formation. For resistant cases (i.e. those children whose inflammation does not subside after IVIG treatment), either a second dose of IVIG can be given or stronger anti-inflammatory agents (steroids, or the TNF-α antibody infliximab) can be used (usually with consultation of a pediatric cardiologist and rheumatologist).

During the acute phase, aspirin is also given at 80 to 100 mg/kg/day orally four times daily. Aspirin reduces systemic symptoms and also decreases the risk of aneurysm formation. When patients become afebrile, they continue to take aspirin at a lower dose of 3 to 5 mg/kg given once daily. Discontinuation of low-dose aspirin is appropriately 6 to 8 weeks after the onset of illness, unless coronary aneurysms are present. Patients with documented aneurysms should continue to take low-dose aspirin indefinitely. Patients with giant aneurysms or those who present with coronary thrombosis may require systemic anticoagulation with heparin or warfarin.

Long-term management of patients with aneurysms depends on assessment of the patient's risk, as determined by the site and size of the coronary aneurysms. Follow-up of these patients with ECGs and

echocardiograms at 6- to 12-month intervals are appropriate. Coronary angiography is warranted if these noninvasive tests are abnormal. Exercise stress testing is used to screen for coronary insufficiency and to guide recommendations regarding participation in sports activities.

CHEST PAIN

Chest pain is a very common complaint in general pediatrics. It ranks just behind headache and abdominal pain in frequency and becomes a more common problem in older children and adolescents.

Pathophysiology

The causes of chest pain are varied, ranging from musculoskeletal problems to functional causes. They are not all thoracic (Tables 13-14 and 13-15).

Clinical and Laboratory Evaluation

History

A careful and detailed history is critical to the proper evaluation of chest pain in children; often, physical findings and laboratory studies are not helpful. The examiner should be careful to acknowledge the patient's and parents' concerns and not try to rush the diagnosis because the success of chest pain relief often depends on the ability of the physician to reassure the family regarding the usually benign nature of the problem. The focus of attention should be on the location, duration, and quality of the pain, and, in particular, whether it is pleuritic in nature. Inciting circumstances and whether the pain occurs at rest or wakes the patient from sleep are important historical items. The coexistence of **palpitations** is suggestive of a dysrhythmia as the cause of the chest pain, although emotion-induced chest pain is often associated with tachycardia.

In addition, the physician should note the quality of interactions between child and family members, and search for possible hidden agendas or secondary gain. Often the pain is a manifestation of a fear (e.g., fear of dying in a child who has recently lost a friend or relative). Determining whether children have missed school and whether the pain occurs on weekends as well as school days is important.

Physical Examination

Inspection of the chest for signs of trauma, congenital abnormalities, or alterations in respirations is important. Examination of the back should include an evaluation for scoliosis. Palpation of all areas of the chest wall

TABLE 13-14

Common Thoracic Causes of Chest Pain in Children

Etiology	*Description*	*Evaluation*
Costochondritis	History of an upper respiratory tract infection or vigorous exercise; pain is often unilateral	Pain is reproduced by palpation or movement of arm
Tietze syndrome	Pain is intermittent but increased by coughing or movement	Unilateral swelling at sternoclavicular or sternochondral junction
Muscle strain	History of vigorous exertion or excessive weight lifting	Tenderness on palpation and on movement
Stress fracture	Often sports-related (tennis, rowing, football)	Tenderness on palpation and on movement; chest radiograph
Tussive trauma	Chronic cough; history of allergies or chronic illness	Reproduction with coughing
Herpes zoster (shingles)	Pain and burning along intercostal lines; vesicular rash	Tender to palpation along course of nerve

TABLE 13-15

Non-Chest Wall Causes of Chest Pain in Children

Pulmonary
Asthma
Bronchitis
Tracheitis
Pneumonia
Foreign body (including broken sternal wire in patient after repair of congenital heart disease)
Pneumothorax

Scoliosis and other spinal deformities
Psychogenic (anxiety, hyperventilation syndrome)

determines whether the pain is musculoskeletal in origin and whether cardiac signs (e.g., heave, thrill) are present. Careful auscultation detects pulmonary abnormalities (e.g., adventitious sounds, decreased breath sounds) as well as cardiac abnormalities.

Laboratory Evaluation

It is important to keep laboratory studies to an absolute minimum unless specific findings point to an organic cause, which requires further evaluation (e.g., rib fracture, pneumonia, pericardial rub).

Differential Diagnosis

Thoracic conditions are by far the most common causes of chest pain (see Table 13-14). A variety of other conditions may also result in chest pain (see Table 13-15). Cardiac disease rarely causes chest pain in children, but cardiac conditions that lead to such pain are usually severe. Congenital aortic stenosis or other forms of left ventricular outflow tract obstruction, mitral valve prolapse, or dysrhythmia may be present; diagnosis using cardiac auscultation is easy. Coronary artery problems are quite rare in children; however, if they are suspected, diagnosis is usually possible after careful examination of the ECG. The chest pain associated with pericarditis is often worsened by lying flat and is improved by sitting up.

Management

Management of chest pain in children and adolescents depends on the suspected cause. For thoracic conditions, analgesics and anti-inflammatory agents are usually curative. For suspected cardiac conditions, further evaluation may include ECG, echocardiography, and either treadmill or bicycle exercise stress testing. Once a specific cardiac diagnosis has been established, treatment may take place. Interventions may include surgery or valvuloplasty (for aortic stenosis), surgery or angiography (for coronary artery anomalies), or prohibition or physical activities (for cardiomyopathies).

SYNCOPE

Pathophysiology

Syncope is defined as a temporary loss of consciousness and postural tone. Causes of syncope include cardiovascular, CNS, and metabolic disorders as well as reactions to cardioactive drugs. These disorders may lead to a loss of consciousness due to a primary decrease in cerebral perfusion, to a global decrease in cardiac output, to an abnormality in peripheral vascular tone, or to a decrease in cerebral substrate delivery. Cerebral blood flow is normally autoregulated (i.e., it remains relatively constant despite wide fluctuations in blood pressure). Thus, systemic arterial blood pressure must fall precipitously in order for cerebral perfusion to decrease. Although some causes of syncope are intrinsically benign, they are dangerous because of the risk associated with the loss of consciousness during activities such as driving. Other causes may be intrinsically dangerous and can lead to cerebral ischemia or death.

Clinical and Laboratory Evaluation

History

More ominous causes of syncope are often associated with a history of congenital or acquired cardiac disease or other systemic illnesses. A history of Kawasaki disease may be present in patients with syncope due to coronary artery disease. A family history of sudden death or congenital deafness may be found in patients with the long QT syndrome.

When **prodromal** symptoms such as dizziness, pallor, nausea, or hyperventilation occur, **vasovagal syncope** (the common faint) is more likely (see Syncope, Differential Diagnosis). There may also be a history of an **inciting event** such as fright or stress, although these can be a trigger for arrhythmia in patients with long QT syndrome. In contrast, if there is no prior warning, or if palpitations or chest pain occur, a cardiac etiology is more likely. Syncope occurring after exercise is often a sign of a left heart obstructive lesion (e.g., aortic stenosis). The **duration of unconsciousness** is important, but may be difficult to assess; nonprofessional observers may exaggerate the length of the event. Vasovagal faints are usually brief (less than 1 min), whereas longer periods of unconsciousness are potentially more ominous. A history of **multiple episodes** is another indication for concern. Inquiries concerning whether there was any associated tonic–clonic activity, abnormal eye movements, or incontinence that could indicate a seizure disorder are appropriate.

Physical Examination

Careful measurements of heart rate and blood pressure, both in the supine and standing positions, are appropriate. Repeat measurements after the patient has remained standing for 10 to 15 minutes are necessary. Physical examination findings are especially useful in determining a cardiac etiology; patients with congenital heart disease have diagnostic murmurs such as the systolic ejection murmur of aortic stenosis (see Tables 13-1 and 13-2). Other cardiac findings such as the midsystolic click of mitral valve prolapse may be subtle, and cardiac disease may even be silent (e.g., in coronary artery anomalies). The presence of a midline or thoracotomy scar makes it likely that a patient has undergone an intracardiac surgical repair. In this circumstance, suspicion of an arrhythmogenic cause (either bradycardia or tachycardia) is heightened.

Laboratory Evaluation

The history and physical examination findings should guide the initial laboratory evaluation. If a simple vasovagal faint is suspected, minimal evaluation is necessary. Initial evaluation should include an ECG and measurement of serum glucose, calcium, and electrolytes. If a seizure disorder is suspected, a complete neurologic examination and electroencephalography are indicated, and possibly a head CT scan or MRI.

Evaluation of patients with a suspected cardiac or arrhythmogenic etiology may include 24-hour Holter or transtelephonic ECG (cardiobeeper) recording, echocardiogram, treadmill exercise test, tilt table testing, and cardiac catheterization with electrophysiologic study.

Differential Diagnosis (Table 13-16)

Vasovagal syncope (common faint) is the result of the interruption of normal central vasomotor tone, leading to arteriolar vasodilation, hypotension, and decreased cerebral perfusion pressure. It is often associated with stimuli such as anxiety, fright, or surprise, and it may be more common after a period of fasting.

Cardiac syncope is most commonly associated with heart lesions that cause obstruction to left-sided blood flow (mitral or aortic stenosis, hypertrophic cardiomyopathy). Syncope may develop in association with severe hypercyanotic spells in patients with right-sided obstructive lesions (e.g., tetralogy of Fallot) (see Congenital Heart Disease). Dizziness or syncope may also occur in patients with low cardiac output due to primary cardiomyopathies. Rarer causes of cardiac syncope in children include intracardiac tumors and coronary artery abnormalities.

TABLE 13-16

Differential Diagnosis of Syncope in Children

Etiology	*Provocation*	*Prodrome*	*Duration*	*Associated Illnesses*	*Recurrence Risk*
Vasovagal	Stress, fright	Dizziness, nausea, sweating	Brief (<1 min)	None	Rare
Cardiac	Exercise	None, palpitations, chest pain	Several minutes	Congenital heart disease	Yes
Arrhythmogenic	None except sometimes fright or surprise in long QT syndrome (LQTS)	None, palpitations	Several minutes	None, congenital heart disease after repair, congenital deafness (LQTS)	Yes
Orthostatic	Getting up from bed	None	Brief	Fluid or blood loss, pregnancy	Yes
Seizure disorders	None	None, aura	Variable	None, neurologic disorder	Frequent
Hypoglycemia	Fasting	Weakness, dizziness	Variable (may be prolonged if untreated)	Diabetes	Yes
Vagovagal	Intubation, nasogastric tube, instrumentation	None, dizziness	Brief	None	Occasional
Hysterical	In front of other people, absence of injury	None	Variable	Psychosocial problems	Yes

Arrhythmogenic syncope may occur in the presence or absence of structural heart disease. In patients with normal hearts, congenital **long QT syndrome** is one cause. When associated with congenital deafness, it is known as the Jervell and Lange-Nielsen syndrome. Affected patients often present with a history of a sudden fright- or startle-inducing syncope, which occurs secondary to a form of ventricular tachycardia known as **torsade de pointes**. Patients with one of the **preexcitation syndromes** (e.g., Wolff-Parkinson-White syndrome) may have syncope associated with episodes of rapid SVT with one-to-one AV conduction.

In patients with abnormal hearts, mitral valve prolapse, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia are associated with ventricular tachycardia. Ebstein anomaly and corrected transposition are associated with SVT. Patients who have undergone intracardiac repair of congenital heart lesions may be predisposed to the development of heart block (VSD, AV septal defect), ventricular tachyarrhythmias (tetralogy of Fallot), or sick sinus syndrome (atrial repair of transposition of the great vessels).

Orthostatic syncope develops secondary to failure of one of the vascular compensatory responses to postural change, resulting in a decrease in blood pressure and in cerebral perfusion. This form of syncope occurs in conditions that decrease blood volume (dehydration, blood loss), in association with peripheral neuropathies, after prolonged bed rest, and during pregnancy. Antihypertensive medications are another cause of orthostatic syncope.

Vagovagal syncope occurs when vagal stimulation causes severe bradycardia. The excessive vagal tone may be related to tracheal intubation, placement of a nasogastric tube or other instrumentation, or may be secondary to distension of a viscera. When associated with urination, particularly in adolescent males, it is called **micturition syncope**. When severe enough to be disabling, the syndrome is known as **vagotonia**.

Noncardiac causes of syncope include seizure disorders, migraine headaches, hypoglycemia, hypoxemia (especially due to **breath-holding spells** in younger children), and hyperventilation. **Hysterical syncope,** which may occur in older children and adolescents, is remarkable for absence of alterations in heart rate and blood pressure. It is very rare for patients with hysterical syncope to injure themselves during an attack. Drug abuse, especially with crack cocaine, may lead to syncope secondary to cardiac arrhythmias.

Management

Patients with vasovagal syncope rarely require medical intervention. In severe cases, increasing intravascular volume by increasing salt and water intake can be helpful. In patients with cardiac syncope, repair of the primary cardiac lesion, if possible, is usually curative. In arrhythmogenic syncope due to tachyarrhythmias, treatment consists of antiarrhythmic medications, an implantable cardioverter defibrillator (ICD), or catheter ablation if an accessory pathway is the inciting mechanism. In syncope due to bradycardia or heart block, treatment may require insertion of a pacemaker. If syncope is drug-induced, reduction in the dose or switching to another medication may be curative. Patients with severe vagotonia may require placement of a pacemaker, salt and water loading, and antivagal medications such as atropine.

Endocrinology and Disorders of Growth

Graeme R. Frank

The endocrine and nervous systems are responsible for regulating the body's metabolic activities. These two systems, which interact on several levels, combine to form a well-regulated unit that maintains and controls the endocrine function. The three anatomic divisions of the endocrine system that are dealt with in this chapter are the **hypothalamus, pituitary gland,** and **cells of target organs**.

Two further divisions of the pituitary gland are the **posterior pituitary** and the **anterior pituitary**. The posterior pituitary **(neurohypophysis)** contains two primary hormones: **vasopressin** (antidiuretic hormone [ADH]) and **oxytocin**. Increased vasopressin secretion is regulated by high plasma osmolality and low circulating blood volume, resulting in water retention. Oxytocin plays a role in uterine contractions and ejection of milk.

The anterior pituitary contains **growth hormone** (GH); **adrenocorticotropic hormone** (ACTH); **thyroid-stimulating hormone** (TSH); **prolactin;** and the gonadotropic hormones, **luteinizing hormone** (LH) and **follicle-stimulating hormone** (FSH). These hormones act on other endocrine glands or directly on specific target cells in the body, affecting growth and maintenance of body functions. Most anterior pituitary hormones are under negative feedback control from their target organs. Negative feedback begins with the secretion of a releasing hormone by the hypothalamus, which signals the pituitary gland to secrete its stimulatory hormone. The stimulatory hormone causes subsequent release by the target organ of the final hormone, which then exhibits negative feedback control on the hypothalamus, diminishing release of the relevant releasing hormone.

The thyroid system is an example of this mechanism (Figure 14-1). The hypothalamus releases thyrotropin-releasing hormone (TRH), which causes release of TSH and subsequent stimulation of the thyroid gland to secrete thyroxine. Thyroxine exerts negative feedback on the hypothalamus and inhibits TRH release.

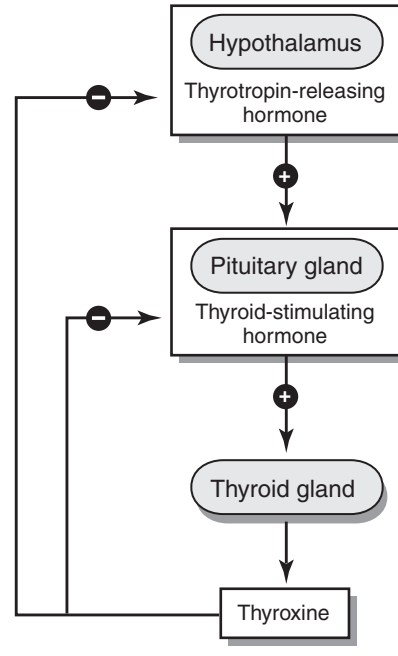

FIGURE 14-1. Thyroid hormone release as an example of positive and negative feedback loops.

SHORT STATURE

Short stature is the most common cause of referral to the pediatric endocrinologist. Several intricate processes involving genetic potential, environmental influences, and the hormonal milieu to which the skeletal system is exposed determine growth and, therefore, final adult height. The major mechanism by which linear growth occurs is the lengthening of the skeletal system; insulin-like growth factor I (IGF-I), a small polypeptide secreted by the liver and other tissues, mediates this process. In turn, this peptide is under the control of GH released by

the anterior pituitary gland. A thin plate of cartilage, the epiphyseal plate, is juxtaposed between the epiphysis and metaphysis of the long bones, and as long as it remains cartilaginous and not ossified, growth continues. Although IGF-I mediates growth, insulin, thyroid hormone, GH, proper nutritional intake, and appropriate psychosocial environment are all essential for proper growth.

Devices that can accurately and reproducibly measure recumbent length in infants and erect height in older children should be available to physicians who are evaluating children for growth. The midparental target height (TH) is a useful calculation to determine the genetic influence on growth. Because there is a 13 cm (5 in) difference in height between men and women, prior to averaging the parental heights, an adjustment must be made, namely adding 13 cm to the mother's height in the case of a boy, or subtracting 13 cm from the father's height in the case of a girl. The formula, therefore, to calculate the midparental TH for males is

$$\frac{[FH + (MH + 13)]}{2} \pm 5 \text{ cm (1 SD)}$$

For females, the formula for TH is

$$\frac{[(FH - 13) + MH]}{2} \pm 5 \text{ cm (1 SD)}$$

In both equations, FH is the father's height in centimeters and MH is the mother's height in centimeters.

Determination of the midparental height as part of the initial evaluation of a child with short stature allows for an approximate prediction of expected adult height. Any growth pattern that significantly deviates from midparental height warrants close monitoring; it may indicate pathology.

Growth rates are equally important in assessing children's growth. Standardized growth charts are readily available for both sexes and are invaluable in making this assessment (see Figures 2-3 to 2-7). Normal linear growth is approximately 16 to 17 cm in the first 6 months of life and 8 cm in the next 6 months of life. Children usually grow at least 10 cm in the second year of life and at least 5 to 6 cm per year between the fourth and tenth years of life. The presence of any chronic systemic illness may interfere with normal growth.

Pediatric Pearl: Short parents generally have short children. It is always appropriate to evaluate midparental heights before embarking on costly evaluations.

It is important to recognize that there are times when apparent growth failure (crossing percentiles) may be normal.

First 3 Years of Life

The size of an infant at birth is largely determined by placental sufficiency and less by the size of the parents. Therefore, one may have an average size baby (50th percentile for weight and length) born to a mother who is 5 ft and whose father is 5 ft 6 in. Such a child will typically decrease his or her height percentile over the first 18 months of life, a process that is sometimes referred to as physiological "catch-down" growth. In fact, the height percentile of two-thirds of normal infants shift during the first 18 months of life, with an equal number moving upward as downward.

A child who is destined to have delayed puberty (constitutional delay) will have subnormal growth during the first 3 years of life such that by 3 years their height percentile is significantly lower than it was at birth. During this period of "abnormal growth," the epiphyseal growth plate maturation is slowed with the result that by 3 to 4 years, the child is relatively short with a delayed bone age. Beyond 3 to 4 years the linear growth remains relatively normal such that the height percentile remains constant. Pubertal changes and the adolescent growth spurt are delayed, and these children grow for longer than their peers with the result that their ultimate heights are normal.

Peripubertal Period

Growth failure (crossing percentiles) is expected in any adolescent who has delayed puberty and continues to grow at a slow, prepubertal growth rate, at a time when his or her peers are experiencing their pubertal growth spurts. Because the average age of onset of puberty is 10 years in females and 12 years in males, one expects that an individual with delayed puberty will begin crossing percentiles at these ages. Although the majority

of such individuals will enter puberty spontaneously at a later time, patients with isolated hypogonadism may present the same way.

Clinical and Laboratory Evaluation

History

When evaluating children for short stature, it is essential to obtain a careful prenatal and perinatal history. The clinician should pay particular attention to birth weight, length, and mode of delivery. Perinatal asphyxia or hypoxia may explain the later development of short stature, resulting from infarction of part or all of the pituitary gland. The presence of neonatal hypoglycemia or persistent jaundice may provide an additional clue to the presence of hypopituitarism, which may present as either isolated GH deficiency or multiple pituitary hormone deficiency. It is necessary to rule out chronic illness or a history of neoplasm by a careful review of systems (e.g., the presence of headache in patients with central nervous system [CNS] disorders).

Obtaining a careful family medical history is of equal importance. Parental and sibling heights and the timing of onset of secondary sexual characteristics in parents and siblings help the physician understand the contribution that genetic makeup may have. Often, parents note that affected children are not growing as well as their siblings or classmates; therefore, sibling heights and growth patterns are crucial in the evaluative process.

Physical Examination

A careful physical examination is necessary. Accurate measurement of height, weight, and head circumference (in infants) is essential. If the parents are available, measurement of their heights is also necessary. It is important to obtain vital signs, and the clinician should pay particular attention to blood pressure and pulse rate.

In addition, dysmorphic features are worthy of note; short stature may be part of a syndrome. A careful systematic physical examination is warranted to rule out chronic illness. Palpation of the thyroid gland is necessary to rule out goiter or the presence of nodules and associated hypothyroidism or hyperthyroidism. Examination of the genitalia is a crucial part of the examination, and Tanner staging to evaluate sexual maturity is appropriate in all patients (see Figures 3-1 to 3-3). Congenital conditions involving the axial skeleton can cause short stature, and a measurement of arm span, sitting height, and body proportions is helpful in that diagnosis. For example, a normal arm span for age with a markedly abnormal height is expected in skeletal dysplasias involving the axial skeleton only. Similarly, it is necessary to obtain an upper:lower body ratio to rule out bony dysplasias of the skeleton that cause dwarfism associated with a short trunk. Plotting the weight for height in infants and body mass index in children over 2 years also provide clues regarding the etiology of growth failure. In genetic causes of growth failure (i.e., syndromes), patients usually have a normal weight for height, whereas in conditions such as malnutrition, systemic illness, and failure to thrive, patients often have "fallen off" their weight curve prior to evidencing linear growth deceleration.

Laboratory Evaluation

Laboratory evaluation should begin only after performance of a complete physical examination and recording of all abnormal findings. As a general rule, only those children who have demonstrated deceleration of growth or growth rates that are abnormal for their peer group or are more than two standard deviations below the mean for height warrant further investigation. The laboratory workup (Table 14-1) should fit the physical findings and pertinent details of the review of systems. The evaluation of bone age is an index of skeletal maturation. In addition, the evaluation of any girl with unexplained short stature should include a chromosomal analysis to rule out Turner syndrome or Turner mosaicism; in the latter condition, many of the physical stigmata may be absent.

Differential Diagnosis (Table 14-2)

There are several "occult" illnesses such as hypothyroidism, Crohn disease and celiac disease that may present with short stature and/or growth failure in the absence of other signs or symptoms. If screening tests for these conditions are negative and the IGF-I and insulin-like growth factor–binding protein-3 (IGFBP-3) are low, then investigation for the possibility of GH deficiency is warranted. **Constitutional delay of growth and puberty** is an essential consideration with short stature, a strong parental history of delayed puberty, delayed dentition, and delayed bone age accompanied by a normal growth rate. This condition represents a normal variation, and

TABLE 14-1

Karyotype (in females)

the clinician should reassure families that once puberty ensues, the child will undergo catch-up growth. A careful history and physical examination, a period of observation, plus a bone age determination are usually sufficient for diagnosis.

IGF-I and IGFBP-3, despite being sensitive indicators of GH deficiency, may not be entirely specific. Random serum GH levels are unreliable in diagnosing GH deficiency because GH is normally released in a pulsatile fashion. Therefore, a number of tests have been designed to diagnose GH deficiency by either measuring serum GH during exercise or utilizing known pharmacologic provocative agents for the release of GH (Table 14-3). The diagnosis of GH deficiency requires a peak GH value of less than 10 ng/mL in response to 2 GH stimulating agents. There are, however, several problems with GH stimulation testing (Table 14-4). Before initiation of treatment with GH in children with GH deficiency, a magnetic resonance imaging (MRI) scan of the brain is warranted to ensure that an intracranial mass involving the pituitary gland, most commonly a craniopharyngioma, is not missed.

Management

A pediatric endocrinologist skilled in teaching patients and their families how to inject and care for the medication usually initiates GH therapy using recombinant DNA-derived human GH. The initial dose varies from 0.18 to 0.3 mg/kg/week, and is given as a daily subcutaneous injection. Currently, the cost of GH therapy is approximately $30,000 per year.

Some potential risks are associated with GH therapy. Local reactions to the injection, such as pain and bruising at the injection site, are generally minor. Slipped capital femoral epiphysis, a condition seen in children during periods of rapid growth, has been attributed in some cases to GH treatment, but it may also occur in untreated GH and thyroid deficiency. Benign intracranial hypertension may occur during GH therapy but it is reversible with temporary discontinuation. Glucose intolerance is another theoretical side effect of GH therapy. One normal physiologic effect of GH is increasing blood glucose in response to hypoglycemia. In conditions of GH excess (e.g., acromegaly), hyperglycemia may occur. Thus, it is prudent to consider iatrogenic diabetes mellitus in those treated patients who present with the typical signs and symptoms of polyuria and polydipsia. Fortunately, this has been a rare problem in GH recipients. Antibodies to GH have been detected in patients treated with GH but are generally of little clinical significance.

There is no evidence that GH therapy increases the risk of leukemia. Creutzfeldt-Jakob disease, a uniformly fatal disease caused by an abnormal prion protein, was seen in patients who were treated before 1985 with GH of cadaveric pituitary origin. However, no cases of this disease have been reported in those patients treated exclusively with recombinant DNA-derived human GH.

TABLE 14-4

Problems with Growth Hormone Provocative Testing

1. Testing does not mimic endogenous growth hormone secretion.
2. There are arbitrary definitions of subnormal response to stimuli.
3. There are variations in measured growth hormone across different laboratories.
4. There is poor reproducibility of the tests.
5. Results vary with age and sex steroid status.

Currently, there a number of Food and Drug Administration (FDA) approved indications for GH in children. These include:

- GH deficiency
- Turner syndrome
- Chronic renal failure
- Small for gestational age infants who do not show postnatal catch-up growth
- Prader-Willi syndrome
- Noonan syndrome
- Idiopathic short stature (children less than 1.2 percentile with a height prediction of less than 63 in in males and 59 in in females)

ABNORMALITIES OF PUBERTY

The timing of the events of puberty is slightly different in boys and girls, and varies widely among regions and ethnic groups. In boys, the onset of pubertal changes before 9 years of age is considered precocious and after 14 years of age, delayed. In girls, the onset of pubertal changes before 8 years of age is considered precocious and after 13 years of age is considered delayed (see Chapter 3).

Pathophysiology

Complex interactions between the hypothalamus, pituitary gland, adrenal glands, and gonads control the events of normal puberty. Inhibition of gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus begins to diminish as the prepubertal dip in growth velocity occurs. This results in an increase in both the frequency and the amplitude of GnRH secretion, sensitizing the pituitary to further GnRH release and causing increased secretion of FSH and LH. FSH and LH then stimulate the gonads to produce sex steroid hormones. Estrogen and testosterone cause an increase in somatic growth and development of secondary sexual characteristics, and provide an appropriate hormonal milieu for reproduction. The onset of adrenal androgen steroidogenesis (adrenarche) generally occurs approximately 1 to 2 years before the onset of true puberty, with true puberty defined by a rise in gonadotropins (FSH, LH) and gonadal sex steroids. The adrenal androgens dehydroepiandrosterone and dehydroepiandrosterone sulfate are responsible for the development of pubic hair, axillary hair, and adult body odor in females.

PUBERTAL DELAY

Pubertal delay is subclassified based broadly on the level of gonadotropins. Elevated gonadotropins or **hypergonadotropic hypogonadism** is due to gonadal failure, whereas low gonadotropins or **hypogonadotropic hypogonadism** is due to inadequate stimulation of the gonads. Delayed puberty is a far more common complaint in males than in females.

Clinical and Laboratory Evaluation

History and Physical Examination

Patients with **constitutional delay of puberty** often have a strong family history of delayed puberty. Usually these patients are short with a moderately delayed bone age and a history of growth deceleration in early infancy. Patients with **Kallmann syndrome** complain of hyposmia or anosmia (altered sense of smell) resulting from hypoplastic or absent olfactory nerves. Patients with a history of brain tumor and resection or radiotherapy may develop gonadotropin deficiency as an isolated phenomenon or as part of complete **hypopituitarism**. A history of visual field changes, headache, personality changes, or any sign of raised intracranial pressure may herald the discovery of a brain tumor or an infiltrative process. A careful review of systems and physical examination should exclude chronic systemic illness. **Septo-optic dysplasia** can be diagnosed by an abnormal MRI scan of the brain, and patients usually have associated midline defects such as cleft or high-arched palate, hypertelorism or visual disturbances, and midline facial hypoplasia. Boys with hypogonadism present with prepubertal testes (less than 3 mL in volume) and immature facies.

Patients with **Klinefelter syndrome** may have a history of behavioral disorders and evidence of adrenarche, although with small testicles and gynecomastia. Male patients with **gonadal dysgenesis** may have no palpable testes, but in females this presents a much greater diagnostic problem. Recent weight loss and psychologic disturbances may provide the evidence of an eating disorder such as **anorexia nervosa**, particularly in female adolescents or strenuously trained athletes. In female patients with delayed puberty and short stature, **Turner syndrome** or **Turner mosaicism** warrants consideration, even in the absence of the typical stigmata: history of neonatal lymphedema, frequent otitis media, low hairline, high-arched palate, low posteriorly rotated ears, numerous pigmented nevi, cubitus valgus, and dystrophic hyperconvex nails.

Laboratory Evaluation

Initial workup involves the evaluation of bone age, gonadotropins, electrolytes, liver and renal function tests, thyroid function tests, and celiac screen. If the gonadotropins are elevated, a karyotype is warranted to exclude Turner syndrome in females and Klinefelter syndrome in males. If there is biochemical evidence of gonadotropin deficiency, a cranial MRI scan is warranted. In girls, pelvic ultrasound can be performed to delineate the anatomy of the uterus and ovaries.

Management

The treatment of pubertal delay depends on the etiology of the delay and whether this is a temporary phenomenon, as in constitutional delay of growth and puberty, or a permanent phenomenon, as in gonadal dysgenesis.

Boys with constitutional delay of puberty should be reassured that this is a normal variation and that their final adult height will be normal. Often, however, these boys are self-conscious about their lack of secondary sexual characteristics and their relative short stature (their pubertal peers are in the midst of their growth spurts). If a constitutionally delayed male patient is older than 13½ to 14 years of age and is concerned about the lack of sexual development and short stature, the recommended treatment is a short course of low-dose testosterone therapy consisting of four to six injections of testosterone enanthate 50 to 100 mg IM at monthly intervals. This regimen is usually sufficient to promote growth acceleration and begin to induce secondary sexual characteristics without compromising final adult height. Another benefit from this regimen is the concept of "jump-starting" or priming the pituitary to begin producing pubertal levels of gonadotropins. This usually occurs within 6 months to a year after the short course of testosterone and is detected clinically by testicular enlargement. If there is a failure of induction of spontaneous puberty within a year of testosterone therapy, a second, more prolonged course of testosterone or permanent testosterone therapy should be considered. However, before reinstituting testosterone therapy, it is essential to seek an organic cause for the continued delay in pubertal development.

One of the more difficult diagnostic dilemmas is discriminating between permanent hypogonadotropic hypogonadism and constitutional delay of puberty, which resemble each other clinically, radiographically, and biochemically. Often, clinicians resign themselves to adopting a wait-and-see approach.

In boys with hypergonadotropic hypogonadism, testosterone therapy is the treatment of choice. The usual adult dose is 200 to 300 mg testosterone IM every 2 to 4 weeks. Side effects include fluid retention, mood swings, and priapism.

In girls with gonadotropin deficiency, the clinician should seek a reversible cause and provide treatment. However, if the condition is due to permanent gonadotropin deficiency or hypergonadotropic hypogonadism, as in Turner syndrome, treatment with estrogen should start between 12 and 14 years of age, depending on the patient's stature. Oral estrogen is used most commonly, although transdermal and injectable forms are also available. Low-dose estrogen is started and then gradually increased over a period of 2 years. Cyclic administration of a progestin is added after about 2 years or when breakthrough bleeding occurs. Common side effects of female sex steroids are breast swelling, nausea, bloating, and fluid retention.

PRECOCIOUS PUBERTY

As previously described, sexual precocity is defined as the onset of pubertal changes in boys prior to 9 years of age and in girls prior to 8 years of age. This condition can be further subdivided into **isosexual** or **heterosexual**

precocious puberty. The development of pubertal changes consistent with the genotype of the patient is considered isosexual, and the development of pubertal changes discordant with the patient's genotype (e.g., breast enlargement in a male) is considered heterosexual. Central precocious puberty is due to stimulation of the gonads by pituitary gonadotropins. Premature production of sex steroids without evidence of pituitary gonadotropin stimulation defines peripheral precocious puberty or gonadotropin-independent precocious puberty. Precocious puberty, in contrast to constitutional delay of puberty, is far more common in females than in males.

Clinical and Laboratory Evaluation

History

Important points in the history include the recent onset of rapid growth, behavioral disturbances, body odor, and vaginal discharge or bleeding. In addition, a careful review of systems may uncover a history of CNS malformation, trauma, tumor, or poorly treated congenital adrenal hyperplasia (CAH). In adolescent males, inquiry about the use of androgens, estrogens, or marijuana, which may help explain gynecomastia, is warranted. Family history of a similar problem may point to the diagnosis of **familial precocious puberty**. Careful analysis of growth rates may indicate the presence of a growth spurt consistent with true precocious puberty.

Physical Examination

When examining children with precocious puberty, it is important to distinguish between **"true precocious puberty"** and that due to peripheral causes, also known as **"precocious pseudopuberty."** Several clinical characteristics help distinguish among the causes of early puberty in females (Table 14-7).

Visual field and careful neurologic examinations are necessary to rule out the presence of an intracranial process. Palpation of the testicles may reveal enlargement, indicating trophic effects from pituitary gonadotropins, or asymmetry, indicating the presence of a tumor. If both testes are prepubertal in size in a boy with precocious onset of secondary sexual characteristics, the diagnostic evaluation should be directed toward an adrenal etiology. A thorough examination of the skin is warranted, looking for the presence of **café au lait spots,** as would be seen in cases of **McCune-Albright syndrome or neurofibromatosis,** as well as in cases of acne or hirsutism. Careful Tanner staging (see Figures 3-1 to 3-3) is necessary as part of the initial physical examination and as a useful adjunct in following patients with precocious puberty.

Laboratory Evaluation

Measurement of random serum LH using an ultrasensitive third-generation assay may confirm the diagnosis of central, gonadotropins-dependent precocious puberty. In general, an LH of greater than 0.2 suggests central precocious puberty. If the result is equivocal, a stimulation test using the GnRH analog

TABLE 14-7

LH	Prepubertal	Suppressed	Pubertal or adult

LH, luteinizing hormone.

leuprolide is employed. A significant rise in the LH in response to leuprolide is diagnostic of central precocious puberty while the absence of a rise in LH and FSH suggests precocious pseudopuberty. In true (or central) precocious puberty, a pelvic ultrasound may show enlargement of the uterus and adnexa. If the diagnosis of central precocious puberty is established, a cranial MRI scan is necessary to rule out any anomaly or tumor that could be responsible. However, if there is no biochemical evidence of central precocious puberty, then a more careful search for peripheral causes of precocious puberty is warranted. The presence of ovarian cysts on pelvic ultrasound combined with an elevated serum estradiol may indicate estradiol-producing ovarian cysts. Production of estradiol from these cysts may fluctuate, leading to waxing and waning of symptoms.

Serum testosterone and adrenal androgens, if elevated, may suggest precocious adrenarche or a tumor in the adrenal gland or testes as the cause of precocious puberty. An ACTH stimulation test can rule out late-onset CAH. Hypothyroidism or hyperthyroidism may cause either delayed or accelerated puberty; thus, a serum TSH and thyroxine (T_4) are necessary.

Management

Irrespective of the cause, true precocious puberty causes advanced somatic growth and skeletal maturation. Thus, patients tend to be tall initially but stop growing earlier than their peers, paradoxically ending up as shorter adults. A compromised final adult height, combined with the psychological impact of early puberty and menarche years before a patient's peer group, justify treatment.

By far the most common cause of central precocious puberty, especially in girls, is idiopathic. The mainstay of treatment of true precocious puberty is monthly administration of a depot GnRH agonist, which effectively binds all the receptors at the level of the pituitary in such a way as to inhibit gonadotropin secretion. A popular alternative is a histrelin acetate subcutaneous implant (Supprelin LA) that provides effective suppression of puberty for 1 year. The implant can be replaced every 12 months until the suppression of puberty is no longer desired.

In cases in which the cause of precocious puberty is peripheral, determining the underlying cause and its treatment is necessary. It is noteworthy that in cases of androgen excess, such as poorly treated 21-hydroxylase

deficiency, central precocious puberty may eventually develop after years of peripheral precocious puberty as a result of chronically elevated serum androgens. Therefore, good control with glucocorticoids is necessary to suppress the formation of excess adrenal androgens.

Patients with benign conditions such as **idiopathic premature thelarche and adrenarche** usually require only reassurance and close follow-up.

McCune-Albright syndrome, a G protein abnormality of intracellular signaling, and **testotoxicosis (familial male precocious puberty),** a condition in which there is an activating mutation in the LH receptor and hence testosterone production independent of stimulation from the gonadotropins, are prototypes for gonadotropin-independent precocious puberty. Patients with gonadotropin-independent isosexual precocious puberty are best treated with pharmacologic agents that inhibit sex steroid formation or those that bind to receptors, thus blocking hormonal action.

An important adjunct to therapy is psychological counseling for the patient and family.

ADRENAL DISORDERS

CONGENITAL ADRENAL HYPERPLASIA

CAH comprises a group of autosomal recessive disorders that are characterized by a deficiency of an enzyme necessary for cortisol biosynthesis. Elevated ACTH leads to hyperfunction and hyperplasia of the adrenal glands.

Pathophysiology

The adrenal gland is comprised of the cortex, which produces adrenal steroids, and the medulla, which secretes catecholamines. The cortex is divided into three layers. The **zona glomerulosa,** the outermost layer, secretes **mineralocorticoids,** the **zona fasciculata** secretes **glucocorticoids, and the zona reticularis** secretes **androgens.**

The production of glucocorticoids is under the control of the pituitary and hypothalamus, with negative feedback control. The hypothalamus secretes **corticotropin-releasing factor,** which stimulates release of **ACTH** from the anterior pituitary gland. This, in turn, stimulates the adrenal cortex to produce and secrete cortisol. Cortisol exerts a negative feedback on the hypothalamus, causing a decrease in corticotropin-releasing factor release.

In contrast to the glucocorticoids, the secretion of the mineralocorticoids is not governed by ACTH. Instead, the **renin–angiotensin system,** along with serum sodium and potassium, governs the release of the mineralocorticoids (Figure 14-2).

Three pathways in the adrenal gland interact to form cortisol, aldosterone, and testosterone as their final products (Figure 14-3). The initial substrate is cholesterol. At each step, an enzyme is necessary for the production of the next product. When enzyme activity is reduced or absent, there is accumulation of precursors proximal to the block, leading to varying hormonal effects that are manifest as both metabolic disturbances and genital abnormalities. Each enzyme deficiency has classical clinical features (Table 14-9).

The most common enzyme deficiency is **21-hydroxylase deficiency,** which accounts for approximately 95% of cases of CAH. Of those individuals affected, 50% to 75% have salt-wasting of varying degrees as a result of

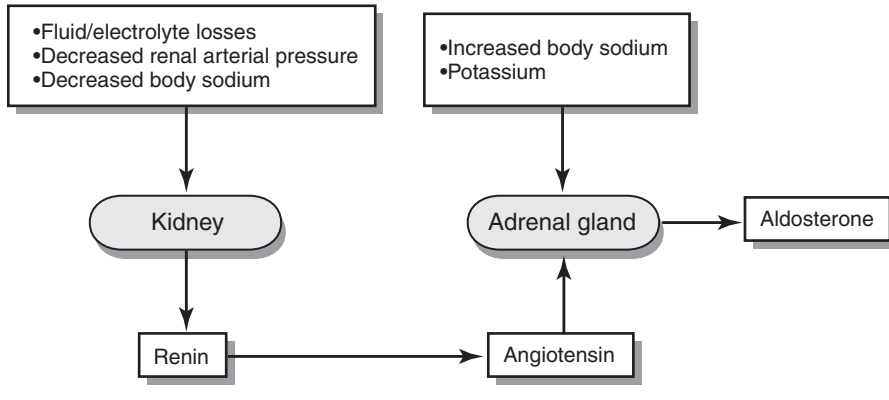

FIGURE 14-2. Regulation of mineralocorticoid secretion.

insufficient production of aldosterone. Because the enzyme deficiency leads to altered production of cortisol, negative feedback to the hypothalamus is removed, and ACTH production increases. This results in accumulation of precursors proximal to the block that are shunted to the androgen pathway, resulting in virilization of female infants.

In male infants, the disorder is usually not diagnosed until a few weeks after birth, when patients present with evidence of salt-wasting, including vomiting and dehydration. In female infants, the disorder may be diagnosed shortly after birth because of the presence of ambiguous genitalia. However, in female newborns with complete virilization, the diagnosis may be missed at birth if infants are mistakenly believed to be cryptorchid males. In the non–salt-losing variety of 21-hydroxylase deficiency, diagnosis may be delayed for several years, depending on the severity of the defect.

Clinical and Laboratory Evaluation

History

In male infants, diagnosis of the salt-losing variety of 21-hydroxylase deficiency typically occurs within the first few weeks of life. Often, infants may have a history of vomiting, diarrhea, failure to gain weight, and lethargy. The diagnosis of pyloric stenosis frequently has been entertained in these patients before the diagnosis of CAH is made. In female infants, virilization of the genitalia typically leads to the diagnosis of CAH in the neonatal period.

The presentation of other adrenal enzyme deficiencies varies with the specific enzyme defect (see Table 14-9). In contrast, in the non–salt-wasting variety of 21-hydroxylase deficiency, the diagnosis may not be made for several years. Typically, male patients present with tall stature and premature adrenarche (penile enlargement and pubic hair), but enlargement of the testicles is noticeably absent, suggesting adrenal origin of the increased levels of androgens. Female patients may present with tall stature, clitoral enlargement, premature adrenarche (pubic or axillary hair), acne, hirsutism, and menstrual abnormalities.

Physical Examination

The genital examination may be normal in male patients with 21-hydroxylase deficiency, although hyperpigmentation of the scrotum and nipples may be present. The genitalia of female patients may be only mildly virilized with enlargement of the clitoris or may be completely virilized with scrotal rugae and penile urethra. Of notable importance in these masculinized females is the absence of testicles.

If the diagnosis is delayed, patients may present with salt-losing crisis. When salt-losing crisis occurs, hypotension, tachycardia, dehydration, and shock are usually present.

Pediatric Pearl: In evaluation of children with ambiguous genitalia, it is important to remember that the presence of palpable gonads in the labial folds almost always indicates a chromosomal male child.

Laboratory Evaluation

In infants with ambiguous genitalia caused by 21-hydroxylase deficiency, chromosomal analysis is necessary. A pelvic ultrasound, urethrogram, and a vaginogram may be necessary to determine the presence of female internal genitalia and the location of the urethra. Serum 17-hydroxyprogesterone and renin levels are elevated (10× to 1000× is normal). Hyponatremia (less than 130 mEq/L), hyperkalemia (greater than 5.5 mEq/L), and metabolic acidosis are also present. Signs of metabolic acidosis, which typically are noted by 2 to 6 weeks of age, may be severe.

In other forms of CAH, laboratory data vary with the specific enzyme deficiency. Levels of the precursor steroid immediately proximal to the enzyme deficiency are typically elevated, whereas levels of products after the block are very low. Standards for adrenal hormone ratios are available and are invaluable in confirming the diagnosis. At times, laboratory data may be ambiguous, and an ACTH (Cortrosyn) stimulation test may be of use in delineating the defect.

Differential Diagnosis

On initial presentation, the diagnosis of an adrenal disorder may be confused with septic shock, pyloric stenosis, or severe dehydration. However, after serum electrolytes are obtained and reveal the presence of hyponatremia and hyperkalemia, the diagnosis typically is straightforward. The process of differentiating among the various types of CAH, congenital adrenal hypoplasia, and Addison disease then involves analyzing the results of the adrenal steroid profiles and ACTH levels.

Pediatric Pearl: Male infants who present with failure to thrive, hypotension, vomiting, and dehydration between birth and 8 weeks of age warrant evaluation for CAH.

Management

Initial management involves restoring intravascular volume with normal saline. After blood has been drawn for diagnostic studies, replacement medications should begin. With suspected CAH, clinicians should not delay treatment while they await the results of adrenal hormone studies. Mineralocorticoid replacement therapy consists of fludrocortisone (Florinef) 0.1 to 0.3 mg/day PO. In an emergency, hydrocortisone should be given at a dose of 50 to 100 mg/m^2 IV or IM, with subsequent doses of 50 to 100 mg/m^2/day divided into four doses given until the patient recovers. After serum electrolytes stabilize, the steroid doses may be reduced.

Other steps are appropriate in the medical management of adrenal hyperplasia after initial stabilization (Table 14-10). The family should receive an emergency kit containing injectable hydrocortisone to administer to the patient in the case of severe stress, trauma, or inability to take oral hydrocortisone.

TABLE 14-10

Medical Management of Congenital Adrenal Hyperplasia

1. Hydrocortisone 10–15 mg/m^2/day in three doses
2. Fludrocortisone 0.1–0.4 mg/day in one to two doses
3. Monitoring of serum 17-hydroxyprogesterone and plasma renin activity every 3–4 months
4. Close monitoring of growth rate and pubertal status
5. With illness (e.g., fever, otitis media) triple glucocorticoids
6. With surgery, trauma, or severe stress, increase glucocorticoids to 100 mg/m^2/day
7. Medic-Alert bracelet

The presence of hypertension implies overtreatment with fludrocortisone. Close monitoring of growth velocity is appropriate. In the absence of adequate treatment, growth velocity increases, and rapid skeletal maturation occurs. If chronic undertreatment occurs, final adult height may be impaired as a result of premature fusion of the epiphyses. Conversely, if overtreatment occurs, growth velocity declines and skeletal age does not progress at a normal rate.

Replacement therapy of mineralocorticoids and glucocorticoids should be continued throughout adult life. This is particularly important in females, in whom fertility may be impaired if CAH is not properly controlled. In addition, control during pregnancy is crucial in preventing virilization of a female fetus.

Surgery often plays a role in the treatment of females with CAH. Those patients with severely virilized external genitalia may need clitoral reduction, relocation of the urethra, and vaginoplasty. Timing of surgery should be individualized. Males generally require no surgical intervention unless inadequate virilization has occurred.

Through the use of amniocentesis or chorionic villus sampling, prenatal diagnosis of 21-hydroxylase deficiency is now possible when an index case has been diagnosed in a family. Prenatal treatment with dexamethasone (to suppress fetal ACTH secretion) appears to be successful in preventing the virilization in affected female fetuses. However, in order to be effective, dexamethasone treatment of the mother must be started as soon as she becomes pregnant. At 8 to 12 weeks, if chorionic villus sampling indicates that the fetus is male or genetic analysis indicates that the female fetus is unaffected, dexamethasone treatment is discontinued. It should be noted that the risk of having an affected female infant is 1 in 8 (1 in 4 chance of being affected by this autosomal recessive condition, and 1 in 2 chance of having a female). It follows, therefore, that 7 out of 8 fetuses will be treated with dexamethasone for 8 to 12 weeks unnecessarily. Prenatal treatment is currently not "standard of care" and long-term follow-up studies are ongoing to determine whether dexamethasone therapy in early pregnancy may have any long-term adverse effects in the offspring.

ADRENAL INSUFFICIENCY

Pathophysiology

Adrenal insufficiency is characterized by decreased production of glucocorticoids and mineralocorticoids. This disorder, which is rare in children, has several causes (Table 14-11). The most common cause is autoimmune adrenalitis or idiopathic adrenal insufficiency, representing approximately 80% of cases of adrenal insufficiency. In the past, tuberculosis was a common cause of adrenal insufficiency, but this is rare today.

Clinical and Laboratory Evaluation

History

Children with chronic adrenal insufficiency present with symptoms of weakness, fatigue, anorexia, abdominal pain, weight loss, nausea, vomiting, diarrhea, dehydration, and increased skin pigmentation (resulting from

TABLE 14-11

Causes of Adrenal Insufficiency

ACTH deficiency
Adrenoleukodystrophy
Congenital adrenal hypoplasia
Infiltrative (fungal infection, malignancy, hemorrhage, hemochromatosis)

ACTH, adrenocorticotropic hormone.

elevated ACTH levels). In cases of polyglandular autoimmune syndrome, other symptoms such as mucocutaneous candidiasis may also occur. In cases of congenital adrenal hypoplasia, infants present with vomiting, diarrhea, dehydration, and shock.

Physical Examination

Physical examination reveals abnormal pigmentation of the skin, particularly in the palmar, axillary, and groin creases, as well as in the buccal mucosa, nipples, and areas that have formed scars as a result of trauma since the onset of ACTH excess. Blood pressure may vary, depending on the stage of the disease. In addition, signs of dehydration are typically present. Height and weight are usually below average.

Pediatric Pearl: A tan all over without a tan line may indicate high ACTH levels associated with primary adrenal insufficiency.

Laboratory Evaluation

Initial laboratory tests reveal the following:

- Hyponatremia
- Hyperkalemia
- Hypoglycemia
- Elevated blood urea nitrogen (BUN)/creatinine
- CBC: eosinophilia, lymphocytosis
- Elevated serum ACTH (except in secondary adrenal insufficiency)
- Low cortisol level (less than 5 mg/dL)
- Blunted cortisol response to synthetic ACTH (Cortrosyn) stimulation test (cortisol less than 18 mg/dL)

Adrenal antibodies may be present along with other signs of autoimmunity (thyroid, parathyroid, islet cell antibodies). Elevated levels of serum very long-chain fatty acid are found in adrenoleukodystrophy. A computed tomography (CT) scan may show enlargement of the adrenals in the case of tuberculosis or hemorrhage. Adrenal calcifications may be seen when adrenal hemorrhage has occurred in the past.

Differential Diagnosis

In most cases of adrenal insufficiency, the diagnosis is obvious, particularly when children present with shock, hyperpigmentation, hyponatremia, and hyperkalemia. However, in some cases, the differential diagnosis includes gastrointestinal (GI) disorders, sepsis, and drug or toxin ingestion. The **polyglandular autoimmune syndromes** occur in both familial and sporadic forms. Type I disease usually occurs early in life and consists of mucocutaneous candidiasis, hypoparathyroidism, and primary adrenal insufficiency (presenting in that order). Type 2 disease, also known as Schmidt syndrome, usually presents in adulthood and consists of Addison's disease with insulin-dependent DM and/or thyroid deficiency.

ACTH unresponsiveness is a familial form of adrenal insufficiency characterized by a defect of the ACTH receptor on the adrenal gland. Glucocorticoid production is low or absent, whereas mineralocorticoid secretion is preserved.

ACTH deficiency may be an isolated hormonal deficiency or may be seen with evidence of panhypopituitarism.

Adrenoleukodystrophy is an X-linked recessive disorder that manifests as adrenal insufficiency and progressive CNS demyelination, resulting in blindness, deafness, dementia, quadriparesis, and death. Initial symptoms usually occur in the second half of the first decade of life.

Congenital adrenal hypoplasia causes severe salt-wasting in the neonatal period. It may be differentiated from CAH by the absence of increased virilization and a low serum 17-hydroxyprogesterone. This form of adrenal insufficiency occurs in an X-linked form or as an autosomal recessive disorder. In addition, associated CNS defects may also occur.

Infiltrative causes of adrenal insufficiency include hemorrhage, which may be associated with birth trauma and meningococcemia (Waterhouse-Friderichsen syndrome).

TABLE 14-12

Medical Management of Adrenal Insufficiency

1. Hydrocortisone 7–9 mg/m^2/day
2. Fludrocortisone .05–0.3 mg/day
3. Close monitoring of growth rate and pubertal status
4. With illness (e.g., fever, otitis media) triple glucocorticoids
5. With surgery, trauma, severe stress increase glucocorticoids to 100 mg/m^2/day
6. Medic-Alert bracelet

Management

Treatment of adrenal insufficiency includes replacement of glucocorticoids and mineralocorticoids (Table 14-12). Adequacy of glucocorticoid treatment is monitored by normal growth, reduced hyperpigmentation, normalization of vital signs and normal glucose. The adequacy of mineralocorticoid replacement is monitored by normalization of electrolytes and plasma renin levels.

Patients should wear a Medic-Alert bracelet at all times, stating their dependence on glucocorticoids. In addition, the family should receive an emergency kit containing injectable hydrocortisone.

AMBIGUOUS GENITALIA

Rapid evaluation of neonates with ambiguous genitalia is necessary to determine the appropriate sex for rearing.

Pathophysiology

Sex differentiation in the male is a hormone-dependent process (Figure 14-4). In the *normal male*, the presence of SRY (sex-determining region Y gene) on the Y chromosome causes the primitive gonad to differentiate into

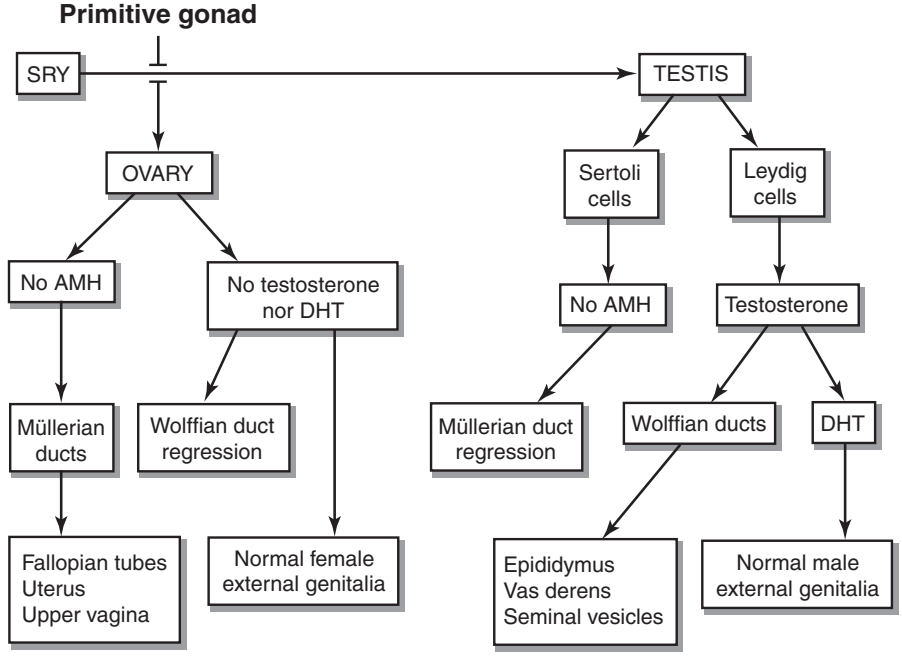

FIGURE 14-4. Normal sexual differentiation. *SRY,* sex-determining region Y gene; *AMH,* anti-Müllerian hormone; *DHT,* dihydrotestosterone.

the testicle. The testicle has two major cell types, the Leydig cell and the Sertoli cell. The Leydig cells produce testosterone under the influence of placental chorionic gonadotropins. Local testosterone causes differentiation of the Wolffian structures (epididymis, vas deferens, and seminal vesicles). Conversion of testosterone to dihydrotestosterone by the enzyme 5α-reductase is necessary for the development of the normal male external genitalia. The Sertoli cells produce anti-Müllerian hormone (AMH) causes regression of the Müllerian ducts. Defects at any of these steps can lead to ambiguous genitalia

In the **normal female,** the absence of SRY results in the primitive gonad differentiating into the ovary. The absence of AMH allows the Müllerian ducts to differentiate into the uterus, fallopian tubes, and upper vagina. The absence of local testosterone causes Wolffian duct regression, and in the absence of DHT, the external genitalia develop into the normal female anatomy. In utero exposure to androgen (CAH, exogenous, luteoma of pregnancy) may cause virilization of the external genitalia and lead to ambiguous genitalia.

Clinical and Laboratory Evaluation

History

Ambiguous genitalia is a birth defect in which the external genitalia of the newborn infant does not have the typical appearance of either a normal male or normal female. A detailed history should include:

- A history of maternal drug ingestion (e.g., progestins, Danazol)
- Unexplained death in infancy suggesting unrecognized CAH
- Virilization of the mother during pregnancy (luteoma of pregnancy, placental aromatase deficiency)

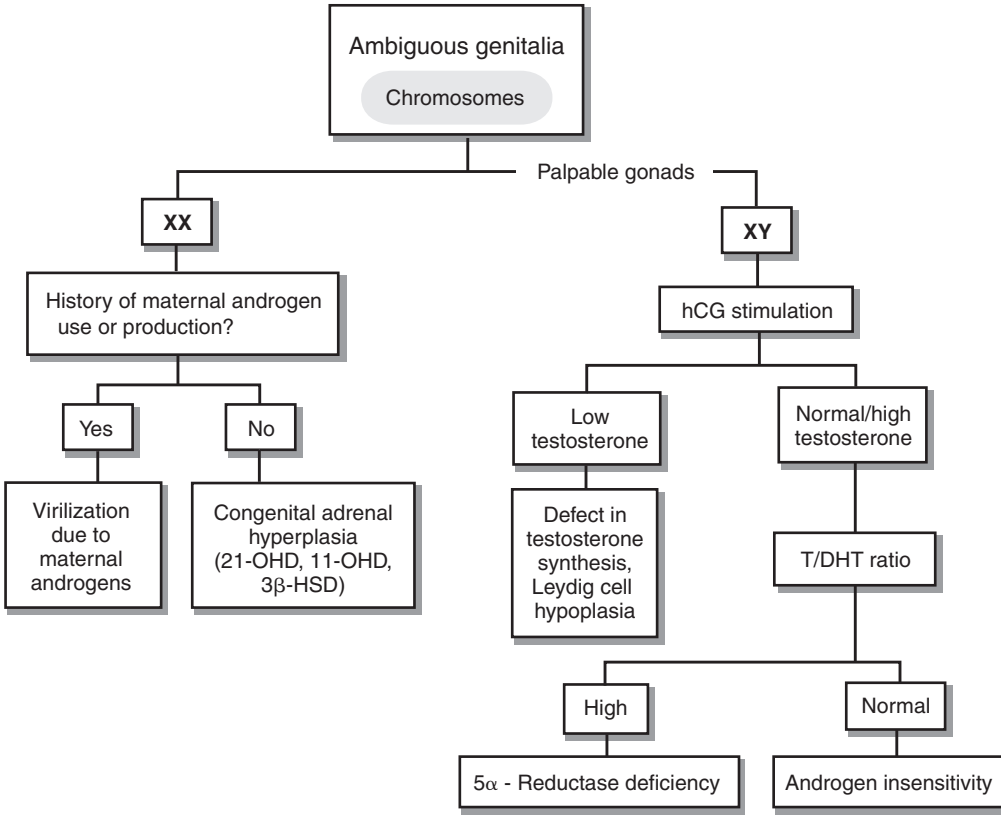

FIGURE 14-5. Laboratory evaluation of ambiguous genitalia. *hCG,* human chorionic gonadotropin; *3β-HSD,* 3β-hydroxysteroid dehydrogenase defect; *21-OHD,* 21-hydroxylase deficiency; *T/DHT,* ratio of testosterone to dihydrotestosterone.

Physical Examination

Virilization of a *genetic female* generally results in clitoral enlargement and varying degrees of labial fusion with or without a urogenital sinus. It is important to appreciate that in extreme cases there may be complete virilization of the external genitalia with no apparent genital ambiguity. Therefore, one cannot make a sex assignment unless at one can identify at least one testicle.

The common clinical features in an undermasculinized male include a micropenis (stretched penile length less than 2.5 cm) with either hypospadias or varying degrees of labioscrotal fusion.

Laboratory Evaluation

To determine the etiology of ambiguous genitalia, the first step is to determine whether the infant is a virilized female or an undermasculinzed male. This is most expeditiously done by ultrasound or MRI. This will direct the workup to identify either the cause of virilization of the female infant or undermasculinization of the male.

Useful studies include:

- Ultrasound analysis or MRI to look for Müllerian structures (uterus) and gonads
- Chromosomal analysis (Figure 14-5)
- Adrenal steroid levels
- Electrolyte analysis
- Dye contrast studies to determine the location and structure of the urogenital sinus and other internal structures

Differential Diagnosis

The differential diagnosis of ambiguous genitalia may be broken down into three separate categories (Table 14-13). In **ovotesticular disorders of sexual development (DSD),** both male and female gonadal tissue is present but may or may not be functional; the karyotype is XX in 80% of patients and XY in 10%. In **46,XX DSD,** female gonads are present and the karyotype is XX. In **46,XY DSD,** testicular tissue is present and the karyotype is XY.

TABLE 14-13

17β-Hydroxysteroid deficiency
Leydig cell hypoplasia
5-α-reductase deficiency
Androgen insensitivity syndrome, incomplete or complete
Ovotesticular DSD (previously termed true hermaphrodite)
46, XX testicular DSD (previously XX male)
46, XY sex reversal (previously 46,XY complete gonadal dysgenesis)

3β-HSD, 3β-hydroxysteroid dehydrogenase; *17-OHD,* 17-hydroxylase deficiency.

Management

Psychosocial support, along with medical management, is crucial in helping families deal with ambiguous genitalia and related issues. In 46,XX DSD with CAH, management consists of replacement of glucocorticoids and mineralocorticoids if indicated by adrenal testing. In addition, surgical reconstruction of the clitoris and vagina is usually recommended. In those patients with maternal androgen exposure and severe virilization, no treatment other than surgical reconstruction may be required. However, several clinicians in the field of intersex disorders are currently reexamining and challenging these recommendations. Experts have suggested that the affected children themselves be allowed to participate in the decision-making process.

In males with a testosterone biosynthetic defect, a short course of testosterone injections in the neonatal period is indicated to enlarge the size of the penis. Glucocorticoid and mineralocorticoid replacement are also indicated in the presence of CAH.

In cases of complete androgen insensitivity (phenotype: normal female), patients should be raised as females, and the gonads should be removed. In partial androgen insensitivity (with sexual ambiguity), testosterone injections can be used to assess the response in the neonatal period. In general, these individuals should be reared as males as there is a high likelihood of declaring male sexual identity when reared as female.

Male children with 5α-reductase deficiency may present with completely feminized genitalia (in which case they may be raised as females with removal of the gonads) or partially masculinized genitalia. During puberty and adulthood, the production and the secretion of testosterone increase significantly and allow for masculinization of the genitalia despite a persistence of 5α-reductase deficiency.

CUSHING SYNDROME

Cushing syndrome refers to a state of increased cortisol secretion. In children, iatrogenic administration of cortisol is the most common cause of this condition. Cushing syndrome occurs more commonly in females than in males, regardless of age.

Pathophysiology

Hypercortisolism is rare in children; when it occurs before 7 years of age, it typically implies the presence of an adrenal tumor. In contrast, after 7 years of age, most cases are due to increased ACTH secretion. In some cases, an ACTH-secreting pituitary tumor may be found; rarely, a nonendocrine tumor may secrete ACTH or an ACTH-like substance that causes adrenal hyperplasia.

Clinical and Laboratory Evaluation

History

Patients with excessive cortisol secretion typically present with one or more of the following characteristics: obesity, short stature, delayed puberty, hyperpigmentation, hirsutism, easy bruisability, and muscular weakness. Rarely, children may present with polyuria, polydipsia (resulting from glucocorticoid excess causing hyperglycemia), or personality changes.

Physical Examination

Obesity with a centripetal fat distribution is present, with accumulation in the face, neck, trunk, and abdomen, together with a wasted appearance of the extremities. The typical facial appearance is "moon facies," with chubby cheeks and double chin. In addition, a "buffalo hump" resulting from an increased fat pad in the supraclavicular and dorsocervical region may be evident. Short stature and delayed puberty may also occur; short stature may be the only presenting symptom in some children. Hyperpigmentation may occur with ACTH excess. Excessive hair growth is also commonly seen in children with Cushing syndrome. If the adrenal tumor is producing androgens as well as glucocorticoids, virilization may be apparent.

Laboratory Evaluation

Laboratory studies may indicate:

- Fasting hyperglycemia
- Normal sodium and normal or low potassium

- Hypercalciuria with normal serum calcium and phosphorous
- Hyperinsulinemia
- Elevation of plasma lipoproteins
- CBC: leukocytosis and lymphopenia
- ACTH level: high with primary pituitary pathology, low with primary adrenal pathology

A 24-hour urine collection for free cortisol and creatinine reveals elevated cortisol level (normal: 7 to 25 μg/g creatinine for prepubertal children). An overnight dexamethasone suppression test (20 μg/kg up to a maximum of 1 mg) at 11:00 PM with serum cortisol obtained at 8:00 AM (normal suppressed cortisol less than 5 μg/dL).

If these tests reveal increased secretion of cortisol, a prolonged dexamethasone suppression test is warranted. A CT or MRI scan to assess the presence of a pituitary or adrenal tumor is necessary, based on the results of the previous tests and with the patient's age taken into account (less than 7 years means the tumor is more likely to be of adrenal origin).

Differential Diagnosis

The differential diagnosis for the constellation of symptoms seen with cortisol excess includes exogenous glucocorticoid ingestion and exogenous obesity. Obtaining a complete history usually rules out exogenous steroids; however, ACTH stimulation may be necessary to confirm suppression of the adrenal glands in the presence of physical signs of glucocorticoid excess.

Patients with exogenous obesity typically have normal cortisol values and a history of increased nutritional intake or decreased activity level. In addition, patients with exogenous obesity typically have normal or tall stature.

Pediatric Pearl: Overweight children with short stature warrant careful evaluation for the presence of endocrine dysfunction (e.g., hypothyroidism, Cushing syndrome, GH deficiency). Overweight children with tall stature do not have Cushing syndrome.

Management

In the case of excessive pituitary ACTH release, management includes transsphenoidal microsurgery, with a remission rate of 85% to 95%. Irradiation of the pituitary gland has also been successful in 80% of patients. However, the risk of hypopituitarism is high after irradiation. During and after surgery, glucocorticoid replacement is essential. Postoperatively, hypoadrenalism may continue for several years, requiring replacement. Treatment of adrenal gland tumors consists of surgical removal with replacement of glucocorticoids until the remaining adrenal gland is functioning normally.

DISORDERS OF WATER BALANCE

Water balance is governed by the action of **ADH**, which is regulated by changes in serum osmolality and intravascular volume (Figure 14-6). Alterations in serum osmolality are detected by osmoreceptors that reside in the supraoptic and paraventricular nuclei of the hypothalamus. The osmoreceptors respond to changes in osmolality as small as 2% and cause alterations in the secretion of ADH and **angiotensin II**. In addition, baroreceptors located in the atria and carotid bodies respond to changes in intravascular volume with subsequent alterations in ADH secretion and thirst. Negative feedback mechanisms include the oropharyngeal reflex, which inhibits further thirst as well as ADH release. **Atrial natriuretic factor** also plays a role in negative feedback. ADH exerts its effect in the kidney at the level of the collecting duct. In the presence of ADH, the collecting duct becomes more permeable and allows an increase in intravascular volume, with subsequent decline in urine volume.

The disorders of water metabolism can be broken down into **hyponatremic** and **hypernatremic** states (Table 14-14).

DIABETES INSIPIDUS

Pathophysiology

Diabetes insipidus, the traditional name for the condition in which individuals pass large volumes of tasteless (nonsweet) urine, is the inability to concentrate the urine. The etiology may be lack of ADH secretion

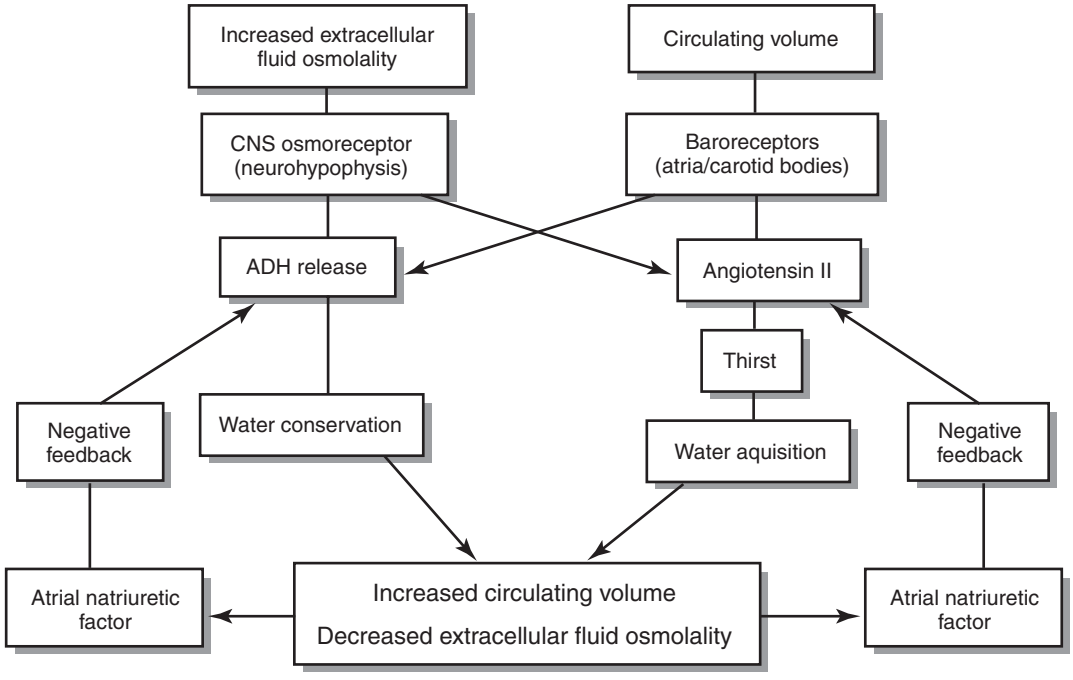

FIGURE 14-6. Regulation of antidiuretic hormone (ADH) secretion. *CNS,* central nervous system.

(central diabetes insipidus) or decreased responsiveness of the collecting duct to ADH **(nephrogenic diabetes insipidus).**

Clinical and Laboratory Evaluation

History

Symptoms of diabetes insipidus in children include polyuria, nocturia, and enuresis in a previously toilet-trained child; clear urine (including first morning urine); poor weight gain; thirst with preference for iced water; and

TABLE 14-14

Disorders of Water Metabolism

Causes of Hypernatremia	*Causes of Hyponatremia*
Hypervolemic (excess of body Na)	Hypervolemic (edema)
Iatrogenic (error in infant formula preparation)	Congestive heart failure
Salt poisoning	Nephrotic syndrome
Hypovolemic (total body water deficiency)	Cirrhosis
Insufficient intake	Hypovolemic (total body Na decreased)
Excessive loss	Hemorrhage
Renal (diabetes insipidus)	Diarrhea
Gastrointestinal (diarrhea/vomiting)	Diuretics
Burns	Adrenal insufficiency
	Euvolemic (syndrome of inappropriate secretion of antidiuretic hormone)

irritability when fluids are withheld. If the diabetes insipidus is due to the presence of a hypothalamic or pituitary tumor, strabismus, double vision, poor growth, precocious puberty, headache, and vomiting may be present. The severity of symptoms varies, depending on the etiology of the diabetes insipidus as well as on the preservation of thirst, diet, extent of ADH deficiency, and kidney function.

In **familial vasopressin-sensitive diabetes insipidus,** a family history reveals other members with symptoms of polyuria and polydipsia. Typically, symptoms do not occur until after infancy. MRI or CT scans of affected individuals have not shown any abnormalities in the hypothalamic or pituitary area. In addition, studies have shown that affected individuals are capable of vasopressin secretion, leading to the theory of an inherited defect in osmoreceptors. Autosomal dominant inheritance and X-linked inheritance have been described.

Nephrogenic diabetes insipidus is transmitted as an X-linked disorder. Symptoms usually develop within the first 3 weeks of life, although typically the diagnosis is delayed. A history of failure to thrive, vomiting, irritability, constipation, and intermittent fevers is commonly obtained. However, by the time of diagnosis, children are usually severely dehydrated and malnourished.

Physical Examination

In infants, hyperthermia, rapid weight loss, and vascular collapse may be seen. In addition, vomiting, constipation, and growth failure may be present. In older children, weight loss, mild dehydration, and distention of the bladder occur. In the presence of a tumor, signs of increased intracranial pressure may be present, as well as visual field deficits, blindness, and optic atrophy.

Laboratory Evaluation

Laboratory studies reveal:

- Serum sodium that are usually greater than 145 mEq/L.
- Urine osmolality inappropriately dilute in the presence of serum hypertonicity (serum osmolality greater than 290 mOsm/kg). A water deprivation test reveals the excretion of dilute urine with osmolality less than plasma osmolality, a rise in the serum sodium of more than 145 mEq/L, a serum osmolality of more than 290 mOsm/kg, and a weight loss of 3% to 5%.

Administration of ADH, or its analog, DDAVP, results in increased urine osmolality. MRI of the pituitary or hypothalamus is warranted to evaluate for the presence of tumor, Langerhans cell histiocytosis, or empty sella syndrome. In addition, other laboratory studies to evaluate function of other pituitary hormones (e.g., thyroid hormone, IGF-I) are appropriate.

Patients with nephrogenic diabetes insipidus present with hypernatremia, serum hypertonicity, elevated uric acid concentrations, and dilute urine despite the presence of high intrinsic ADH levels. After exogenous vasopressin administration, a dilute urine and serum hypertonicity continue to be present.

Differential Diagnosis (Table 14-15)

A careful history, including family history of failure to thrive, polyuria, and polydipsia, and the previously described laboratory tests, usually reveal the specific etiology. Patients with neurologic changes or evidence of other hormonal deficiency or excess should be evaluated for the presence of a pituitary tumor. In addition, patients who present with diabetes insipidus, otorrhea, or bone pain should raise suspicions of Langerhans cell histiocytosis.

Management

The goal of treatment of diabetes insipidus is the achievement of normal growth and weight gain and the avoidance of hypertonic dehydration. The management of central diabetes insipidus involves hormonal replacement with DDAVP, a synthetic analog of arginine vasopressin. The usual dose for children is 2.5 to 10 μg intranasally once or twice daily. Subcutaneous or intravenous administration at one-tenth the intranasal dose is also possible. In patients with an intact thirst mechanism, the clinician may adjust the dosage as needed to maintain normal serum osmolality and sodium. In patients lacking an intact thirst mechanism, specific fluid requirements must be met in addition to the vasopressin replacement.

Treatment for nephrogenic diabetes insipidus requires high water intake with frequent feedings. Restriction of sodium and salt intake is warranted to prevent enhancement of water loss. Studies have shown that the diuretic chlorothiazide is effective in maintaining serum sodium between 132 and 137 mEq/L, as long as dietary intake of sodium is restricted. Side effects of this therapy include increased serum uric acid and hypokalemia.

TABLE 14-15

Differential Diagnosis of Diabetes Insipidus

Central diabetes insipidus
Vasopressin deficiency
Physiologic suppression of vasopressin secretion
Psychogenic polydipsia
Organic polydipsia (hypothalamic disease)
Drug-induced polydipsia
Reduced renal responsiveness to vasopressin

Indomethacin also has proven effective in the treatment of nephrogenic diabetes insipidus; this agent enhances proximal tubular reabsorption of the glomerular filtrate.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

Pathophysiology

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is characterized by excessive secretion of vasopressin despite the presence of hyponatremia and the absence of osmotic or nonosmotic stimuli. It occurs in several diseases, usually of the brain or lung, and during therapy with several drugs (Table 14-16).

Clinical and Laboratory Evaluation

History

Patients with SIADH may present with weight gain, weakness, anorexia, nausea and vomiting, personality changes, or lethargy. In severe cases, convulsions and coma may occur as a result of hypotonicity of the serum. In addition, symptoms of an underlying disease (e.g., pneumonia, intracranial process, malignancy) may be present.

The clinician should elicit a complete medication history to rule out drug-induced SIADH. Medications known to stimulate ADH release include clofibrate, chlorpropamide, thiazides, carbamazepine, phenothiazines, vincristine, and cyclophosphamide.

Physical Examination

In cases of mild hyponatremia, the physical examination may be completely normal; however, in severe cases patients may be lethargic, comatose, or convulsing. It is worth noting the presence or absence of hypotension,

tachycardia, and pitting edema. In the presence of these signs, SIADH is unlikely, and it is necessary to consider a more extensive differential diagnosis.

Laboratory Evaluation

Laboratory studies reveal:

- Serum sodium levels less than 135 mEq/L
- Serum osmolality less than 270 mOsm/kg
- Urine sodium usually increased [fractional excretion of sodium (FE_{Na}) greater than 1%], with FE_{Na} calculated by the following formula:

$$FE_{Na} = \frac{[\text{Urine Na/serum Na}]}{[\text{Urine Cr/serum Cr}]}$$

- Urine osmolality greater than 100 mOsm/kg
- Normal serum BUN/creatinine and uric acid levels
- Elevated serum arginine vasopressin

The use of other laboratory tests depends on the clinician's suspicions of possible underlying etiologies of SIADH (i.e., tumor, meningitis).

Adapted from Wilson JD, Foster D: *Williams Textbook of Endocrinology*, 8th ed. Philadelphia, WB Saunders, 1992.

Differential Diagnosis

The differential diagnosis of hypotonic hyponatremia involves either excessive water ingestion or decreased water excretion (Table 14-17). First it is necessary to confirm the presence of hypotonicity because falsely lowered sodium values may occur in the presence of hyperglycemia, hyperlipidemia, and other agents that cause an artifactually low serum sodium. In these instances, the serum osmolality is normal or high, whereas in hyponatremia associated with SIADH, it is low (generally less than 270 mOsm/kg). Exclusion of disorders other than SIADH is possible based on the history and physical examination. Other laboratory data may be necessary to rule out hypothyroidism or cortisol deficiency.

Management

The management of SIADH should include treatment of the underlying disorder if present. Therapy then is directed at slowly raising the serum sodium level (0.5 to 1.0 mEq/L/h) to prevent the neurologic complication of central pontine myelinolysis. Fluid restriction causes a steady rise in serum sodium and osmolality, as well as weight loss. Generally, fluid restriction to 50% to 75% of maintenance requirements is effective. If hyponatremic seizures occur, it is necessary to give 3% saline (5 mL/kg) slowly until the seizures stop.

Drug therapy to induce vasopressin resistance has been effective in adults but should not be used in children. Medical personnel should be alert to the underlying disorders known to cause SIADH so that earlier diagnosis and treatment may occur (see Table 14-16).

DIABETES MELLITUS

DM is a group of diseases characterized by elevated levels of blood glucose secondary to decreased insulin production, impaired insulin action, or both. Diagnostic criteria for the diagnosis of DM are shown in Table 14-18 and classification of DM is shown in Table 14-19. DM can lead to by long-term sequelae involving the heart,

TABLE 14-18

Diagnostic Criteria for the Diagnosis of Diabetes Mellitus

	Fasting Plasma Glucose (FPG)	*Casual Plasma Glucose*	*Oral Glucose Tolerance Test*
Diabetes	FPG ≥126 mg/dL	Casual plasma glucose ≥200 mg/dL plus symptoms	Two-hour plasma glucose (2-PG) ≥200 mg/dL
Impaired glucose homeostasis	Impaired fasting glucose (IGF) = FPG ≥ 100 and <126 mg/dL		Impaired glucose tolerance (IGT) = 2-PG ≥140 and <200 mg/dL
Normal	FPG <100 mg/dL		2-PG <140 mg/dL

eyes, kidneys, and the nervous system. As is true with many of the chronic diseases seen in the pediatric population, psychosocial issues complicate the disease process even further.

Type 1 DM

Type 1 DM (previously called insulin-dependent diabetes mellitus or juvenile-onset diabetes), the most common form of diabetes in the pediatric population, affects approximately 2 children per 1,000. In type 1 DM there is autoimmune destruction of the pancreatic beta cells resulting in **insulin deficiency.** While type 1 DM usually presents in children and young adults, it may occur at any age.

Pathophysiology

Proinsulin, the precursor to insulin, is synthesized in the beta cells of the pancreas as a single coiled protein consisting of two chains: A and B, which are connected by a connecting or C peptide and held together by disulfide bonds (Figure 14-7). When insulin is released systemically, the 31–amino acid C peptide is cleaved from the molecule to form active insulin. The amount of insulin released is dependent on input from the autonomic nervous system, level of caloric intake, exercise, and hormonal influences. GH, glucagon, glucocorticoids, and estrogens all stimulate insulin release; however, they also antagonize the effect of insulin in peripheral tissues.

TABLE 14-19

Classification of Diabetes Mellitus

Type 1: β-cell destruction
- Type 1 a—autoimmune
- Type 1 b—idiopathic

Type 2: Insulin resistance with secretory defect

Gestational Diabetes Mellitus

Other specific types
- Genetic defects of β-cell function
- Genetic defects of insulin action
- Defects of exocrine pancreas (e.g., cystic fibrosis)
- Endocrinopathies (e.g., Cushing syndrome)
- Other genetic syndromes (e.g., Prader Willi)
- Drug- and chemical-induced diabetes
- Caused by infection (e.g., congenital rubella)

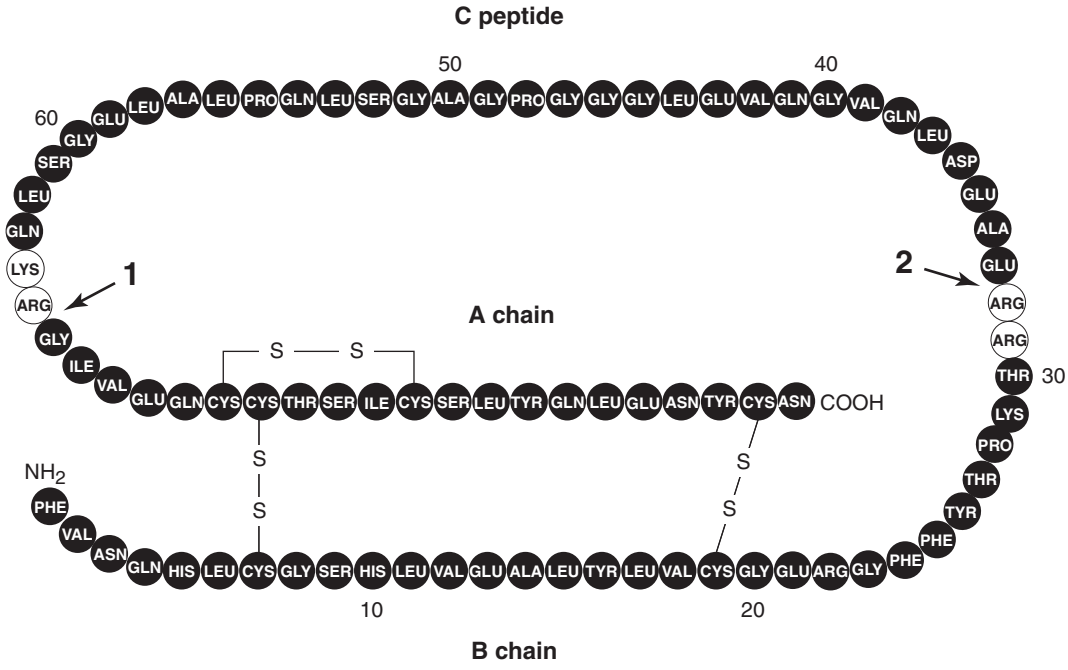

FIGURE 14-7. Proinsulin. Arrows 1 and 2 indicate the two sites of cleavage that yield insulin and C peptide. From Sperling MA: Diabetes mellitus. In *Clinical Pediatric Endocrinology*, 2nd ed. Edited by Kaplan SA. Philadelphia, WB Saunders, 1990, p 128.

Insulin acts primarily to drive glucose rapidly into the cell to provide fuel for cellular metabolism in almost all cells in the body, but especially in the liver, muscles, and fat. Insulin inhibits gluconeogenesis and promotes the conversion of liver glucose into fatty acids.

Type 1 DM results from cell-mediated autoimmune destruction of the β cells of the pancreas. Ninety percent of these patients are positive for either the DR3 or DR4 human leukocyte antigen (HLA), but the HLA type is insufficient to account for all the new cases of DM. It is theorized that a combination of a genetic predisposition *and* antigenemia provoke an autoimmune response that attacks **and** destroys the β-cells and results in insulinopenia ("double hit" theory). Markers of the autoimmune destruction of the β cells include islet cell autoantibodies and autoantibodies to both insulin and glutamic acid decarboxylase. After loss of approximately 80% of the β-cell mass, blood glucose becomes elevated as a result of decreased glucose uptake (Figure 14-8). In addition, an increase in counterregulatory hormone production results in both proteolysis and lipolysis, providing amino acids and glycerol for gluconeogenesis. Finally, in the liver, insulin deficiency results in glycogenolysis and enhanced gluconeogenesis.

Clinical and Laboratory Evaluation

History

Once the glucose level in the blood exceeds the renal threshold (approximately 180 mg/dL), glycosuria develops. Water is drawn into the renal tubules by the osmotic properties of glucose and results in polyuria. Polyuria and polydipsia are the most common and classical symptoms of diabetes. With long-standing polyuria with glycosuria, weight loss occurs because of caloric loss in the urine. Polyphagia then ensues in an attempt to overcome the caloric loss.

Physical examination

Early on in the course of diabetes, the physical examination is frequently normal. As the glucose level rises, the osmotic diuresis increases and the patient may have signs of mild-to-moderate dehydration. The longer type 1 DM goes unrecognized, the more likely the patient will present in diabetic ketoacidosis (DKA) (see Diabetic Ketoacidosis, which follows).

Laboratory Evaluation

The findings of an elevated blood glucose and glycosuria in an otherwise healthy child with new symptoms of polyuria and polydipsia confirm the diagnosis of diabetes. An elevated hemoglobin A1c confirms that the blood

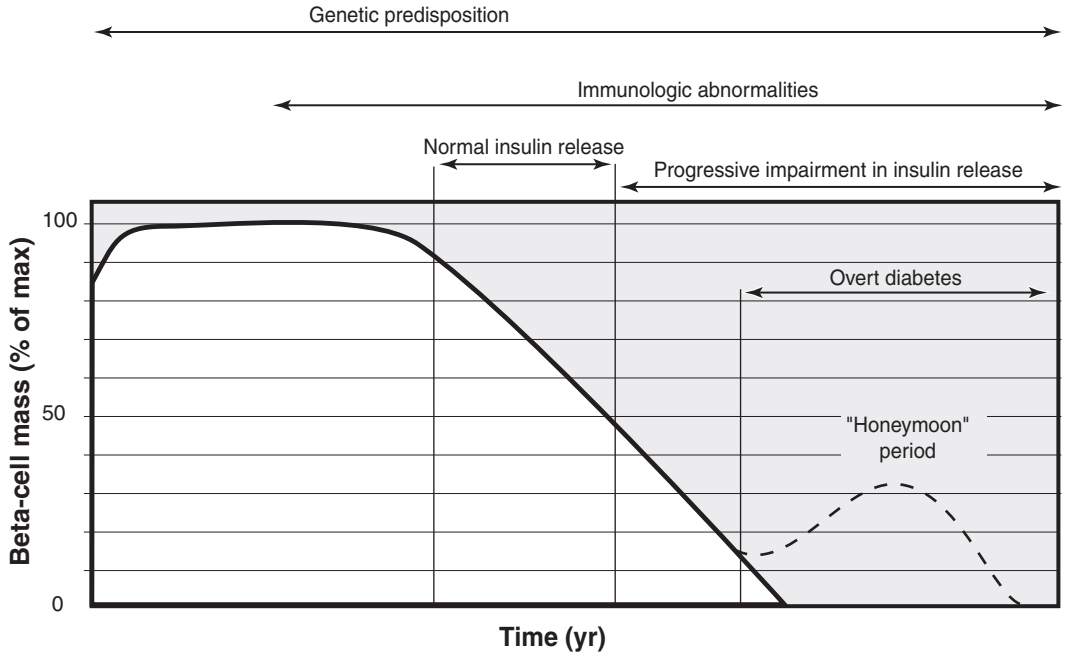

FIGURE 14-8. Proposed scheme of natural history of β-cell defect in diabetes. Overt diabetes becomes manifest only after destruction of 80% to 90% of cell reserve.

glucose has been elevated for some time. In approximately 90% of patients presenting with type 1 DM, anti-islet cell, anti-insulin, and/or anti-GAD antibodies will be positive.

Differential diagnosis

Almost all patients who present with polyuria, polydipsia, polyphagia, and weight loss will be found to have diabetes. Hyperthyroidism can present with the same symptoms. The polyuria and polydipsia in hyperthyroidism are the result of the hyperdynamic state with increased blood flow to the kidneys.

Management

The rationale behind treating type 1 DM is to normalize glucose metabolism and avoid or delay the long-term complications associated with insulin deficiency. Neuropathy, nephropathy, retinopathy, and cardiomyopathy are just a few of the known complications of DM. Clearly, prevention is the most cost-effective way of dealing with these conditions. Recent studies have suggested that better glucose control is strongly associated with a more favorable prognosis; thus, optimizing insulin therapy is of major importance.

Several insulin preparations are available (Table 14-20). Therapy is geared to maintain blood glucose close to the normal range of 80 to 150 mg/dL, with the occurrence of as few hypoglycemic episodes as possible.

Conventional insulin therapy consists of a combination of rapid- or short-acting insulin mixed with an intermediate acting insulin preparation given twice a day, before breakfast and before dinner. The usual total daily dose is approximately 0.5 to 1.0 units/kg, divided into two-thirds at breakfast and one-third at dinner. The morning dose consists of approximately two-thirds intermediate-acting and one-third short- or rapid-acting preparations. The predinner dose is usually half intermediate-acting and half short- or rapid-acting insulin. These recommendations are only an approximate guide; each patient's therapy is individualized. It is expected that patients will monitor both their blood glucose levels four times per day, premeals and at bedtime, using the fingerstick method. On this regimen, the patient is required to eat consistent amounts of carbohydrates at each meal and snack.

Intensive insulin therapy (basal bolus therapy) consists of a basal insulin supplemented by boluses of insulin.

Basal insulin: Basal insulin provides adequate insulin coverage in the nonfeeding state. It may be provided as either as a long acting insulin analogue given by subcutaneous injection, or as a continuous subcutaneous infusion of a rapid acting analog insulin provided by an insulin pump.

TABLE 14-20

Insulin Preparations

Insulin	*Onset of Action*	*Time to Peak Effect*	*Duration*
Rapid-acting analogs			
Insulin aspart – *Novolog* (Novo Nordisk)	5–15 minutes	45–75 minutes	2–4 hours
Insulin lispro – *Humalog* (Lilly)	5–15 minutes	45–75 minutes	2–4 hours
Insulin glulisine – *Apidra* (Sanofi-aventis)	5–15 minutes	45–75 minutes	2–4 hours
Short-acting (regular insulin)			
Humulin R (Lilly)	30 minutes	2–4 hours	5–8 hours
Novolin R (Novo Nordisk)	30 minutes	2–4 hours	5–8 hours
Intermediate-acting insulin (NPH)			
Humulin N (Lilly)	2 hours	6–10 hours	14–18 hours
Novolin N (Novo Nordisk)	2 hours	6–10 hours	14–18 hours
Long-acting analog			
Insulin glargine *Lantus* (Sanofi-aventis)	2 hours	No peak	20–24 hours
Insulin Detemir *Levemir* (Novo Nordisk)	2 hours	No peak	~20 hours

NPH, neutral protamine Hagedorn insulin.

Bolus insulin: Bolus insulin provides insulin coverage for the carbohydrates eaten and/or insulin to correct hyperglycemia. The bolus insulin, therefore, has two components:

(i) Insulin:carbohydrate ratio; that is, the amount of insulin required per gram of carbohydrate consumed
(ii) Correction factor; that is, the amount of insulin required to lower the glucose by a given amount

Example: A patient has an insulin:carbohydrate ratio of 1:10 (i.e., 1 unit for every 10 grams of carbohydrates), a correction factor of 1:50 (i.e., 1 unit will result in a 50 mg/dL decline in the blood glucose), and a target range for blood glucose is 80 to 150 mg/dL. He is about to eat 50 gram of carbohydrates and his blood glucose is 250 mg/dL. His insulin bolus just prior to that meal would be:

5 units for the 50 grams, plus
2 units (to correct his blood glucose to 150 mg/dL)
Total: 7 units

Basal bolus therapy allows maximal flexibility in both the timing of meals and the dietary consumption of carbohydrates.

Fingerstick blood glucose monitoring is generally performed premeals and at bedtime. Follow-up every 3 to 4 months, to monitor growth and development and adjust the insulin regimen, is recommended. Because glucose nonenzymatically glycosylates many proteins in the body, including the hemoglobin molecule, measurement of HbA1c represents a time-honored method of determining control over the previous 3 months, as opposed to the instant in time represented by a random blood glucose sample. Target HbA1c levels are between 7.5% to 8.5% in toddlers and preschool children (age 0 to 6 years), less than 8% in school-age children 6 to 12 years, and less than 7.5% in adolescents and young adults.

Patients with type 1 DM have a high incidence of autoimmune thyroid disease, and thyroid function tests are necessary on a yearly basis. Beginning 3 to 5 years after diagnosis, an ophthalmology examination and a urinalysis are recommended on a yearly basis to screen for retinopathy and nephropathy, respectively. Patients with proteinuria (greater than 150 μg/min) are at significant risk for the development of nephrosclerosis and progressive renal failure.

Pediatric Pearl: It is important to note that seeking too tight control may place patients at risk for significant life-threatening hypoglycemia.

Type 2 DM

Type 2 DM (previously called noninsulin dependent diabetes mellitus [NIDDM] or adult-onset diabetes) results from the combination of insulin resistance and relative insulin deficiency.

Pathophysiology

There has been a steady increase in the number of adolescent patients diagnosed with type 2 DM since the early 1990s, and data from diabetes referral centers indicate that currently approximately 40% of newly diagnosed cases of DM between ages 10 and 19 years have type 2 DM. Although approximately two-thirds of adolescents with type 2 DM are African American or Mexican American, type 2 DM has been seen in all ethnic groups. There is a family history of type 2 DM in a first-degree relative in more than 60% of cases.

Obesity is the most important risk factor for the development of type 2 DM. Obesity is associated with insulin resistance, and as long as the pancreas can overcome the insulin resistance by increasing insulin secretion, normal glucose homeostasis will be maintained. Once the pancreatic insulin secretion becomes inadequate to overcome the insulin resistance, glucose homeostasis become abnormal.

Clinical and Laboratory Evaluation

History

Although adolescents with type 2 DM may present with the classic symptoms of polydipsia, polyuria, and polyphagia, in many instances the diagnosis is found incidentally upon urinalysis.

Physical examination

Besides morbid obesity, a number of clinical signs should alert the physician to the possibility of type 2 DM. These include:

- Acanthosis nigricans—a cutaneous marker of insulin resistance
- Hypertension—may occur in 20% to 30% of adolescents with type 2 DM
- Polycystic ovary syndrome
- Vaginal candida infection

Laboratory Evaluation

While the diagnosis of type 2 DM is frequently easy to establish, there are times when it may be difficult to distinguish between type 1 and type 2 DM.

- Insulin and C peptide are usually high in type 2 DM, reflecting underlying insulin resistance. However, chronic hyperglycemia can cause transient insulin deficiency (glucose "toxicity").
- Negative autoantibodies to the islet cell suggest type 2 DM, whereas positive islet cell autoantibodies (positive in 90% of patients with type 1 DM) suggest type 1 DM.

Management

The major focus should be directed at the cause of the disorder, namely obesity, poor diet, and sedentary lifestyle. Patients who are symptomatic or fail conservative therapy may require medical therapy. Metformin improves

insulin sensitivity at the liver (decreases hepatic glucose production) and muscle (increases muscle glucose uptake). Patients who present with severe hyperglycemia or ketosis require insulin therapy in addition to metformin.

Diabetic Ketoacidosis

Pathophysiology

Approximately 20% to 40 % of children with new onset of type 1 DM present initially in **DKA**. This situation is most commonly seen in children younger than 5 years of age. DKA occurs when there is a decrease in insulin action, as well as an increase in the production of counterregulatory hormones such as epinephrine, norepinephrine, glucagon, cortisol, and, GH, all of which have effects opposite to those of insulin.

In the absence of insulin, the body mobilizes fat as a source of energy. Ketone bodies acetoacetic acid and β-hydroxybutyrate are produced in the liver as a by-product of fatty acid breakdown and can be used by the brain as a source of energy. Excess production of the ketone bodies cause severe metabolic acidosis and even death.

In children previously diagnosed with type 1 DM, the inciting factor may be infection or vomiting. When children are ill, the cellular glucose requirement increases, and consequently the need for insulin also rises. In part, this increased insulin requirement is due to the increased production of counterregulatory hormones associated with illness. Although baseline insulin production in these children may be just barely adequate, there may be a relative lack of insulin action under these conditions of increased glucose needs. Glucose cannot be utilized by cells, and energy production from other substrates must ensue (Figure 14-9).

In addition to the hyperglycemia and ketosis in DKA, electrolyte disturbances, dehydration, and metabolic acidosis are usually present. When the blood glucose exceeds the renal threshold for reabsorption, glycosuria occurs. The osmotic diuresis that results from glycosuria causes fluid and electrolyte losses, leading to low levels of serum sodium, potassium, and phosphate. Other mechanisms of fluid loss in DKA include vomiting and the hyperventilation that is a response to the acidosis. Patients with DKA can rapidly lose as much as 7% to 10% of their body weight through these mechanisms.

Clinical and Laboratory Evaluation

History

Most patients previously diagnosed with type 1 DM who present with DKA have a history of poor diabetes control and insulin omission. In well-controlled patients, an intercurrent illness will be the stress that results in DKA. There may be a history of polyuria, polydipsia and weight loss, and sometimes decreased urine output

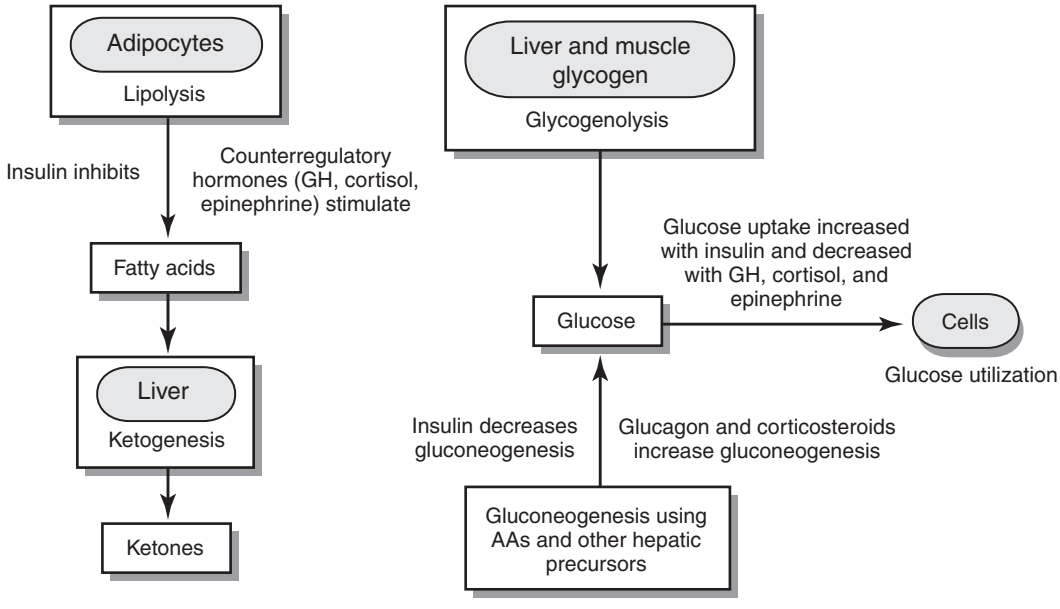

FIGURE 14-9. Pathways in diabetic ketoacidosis. *AA,* amino acid; *GH,* growth hormone. From Sperling MA: *Physician's Guide to Insulin-Dependent (type 1) Diabetes. Diagnosis and Treatment*. Arlington, VA, American Diabetes Assocation, 1988.

from decreased renal perfusion. Patients frequently complain of nausea, vomiting, and abdominal pain. In addition, altered respiratory patterns, air hunger, and a history of an acetone smell to the breath may be elicited.

Physical Examination

The physical examination of patients with DKA may reveal all or some of the following features:

- Head, ears, eyes, nose, throat (**HEENT**)**:** Dry mucous membranes (primarily from the osmotic diuresis and aggravated by vomiting and hyperventilation), sign of infection (e.g., injected oropharynx), and acetone breath.
- **Cardiovascular:** Orthostatic hypotension, thready pulses, and tachycardia. In the presence of increased intracranial pressure, Cushing triad (altered respiratory pattern, bradycardia, and hypertension) may be present.
- **Pulmonary:** Kussmaul breathing (deep, sighing).
- **Abdomen:** Abdominal pain, decreased bowel sounds.
- **Skin:** Decreased turgor.
- **Neurologic:** Altered mental status (obtundation, combativeness, coma), from decreased cerebral perfusion. Signs of increased intracranial pressure (papilledema, dilated, unresponsive pupils) suggest cerebral edema, a dreaded complication that generally occurs during therapy.

Laboratory Evaluation

- **Acidosis:** Acidosis (bicarbonate less than 15 mEq/L and pH less than 7.30) with an increased anion gap is primarily the result of excessive ketone body production and may be aggravated by lactic acidosis from tissue hypoperfusion.
  anion gap $= [Na^+] - ([Cl^-] + [HCO3^-])$: normal 12 ± 2
- **Hyperosmolality:** This is primarily due to hyperglycemia, but may be aggravated by hypernatremia. Osmolality is calculated by the formula:

$$[Na \times 2] + \frac{\text{blood glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$$

- **Hyperlipidemia:** This is due to increased lipolysis caused by the combination of insulinopenia and increased counterregulatory hormone production
- **Electrolyte disturbance:** Although there is generally a sodium deficit of approximately 10 mmol/kg body weight, the measured sodium is spuriously low as a result of the osmolar dilution induced by hyperglycemia and the sodium-free lipid fraction.
  - Potassium deficit is estimated at 5 mmol/kg from obligatory urine losses. In the presence of metabolic acidosis, however, the potassium may be spuriously normal.
  - Increased BUN.
  - Normal or elevated creatinine.
  - Increased white blood cell count with shift to the left.
  - Decreased phosphorus.

Differential Diagnosis

The diagnosis of DKA, once it is considered, is relatively easy to make. The differential diagnosis of metabolic acidosis in children is relatively limited (Table 14-21). Patients with normal or high urine output despite signs of dehydration, recurrent vomiting, and abdominal pain warrant evaluation for the presence of diabetes.

Management

The management of DKA includes very close monitoring of the patient, usually in a pediatric intensive care unit. Monitoring of the patient should include constant observation, at least until the anion gap normalizes, arterial pH is greater than 7.25, and serum bicarbonate has begun to rise. Use of a cardiorespiratory monitor is warranted until the patient's metabolic status has normalized.

Fluid and Electrolyte Therapy

In order to restore tissue perfusion, volume expansion with 20 mL/kg of an isotonic solution (0.9% saline or Ringer lactate) should be given in the first hour and repeated if necessary. Subsequent fluid management should

TABLE 14-21

Differential Diagnosis of Metabolic Acidosis in Children

Lactic acidosis (ischemia, sepsis)
Diabetic ketoacidosis (DKA)
Severe diarrhea
Renal failure and uremia
Organic acidurias
Ingestions (methanol, ethylene glycol, acetone)
Salicylate poisoning (late)
Nonketotic hyperosmolar coma

be with a solution greater than or equal to 0.45% saline and given at a rate of 1.5 to 2 times the usually daily requirement based on age, weight, or body surface area (maintenance = 1,500 mL/m^2/day). Generally, the rate of fluid administration should not exceed 4,000 mL/m^2. If the patient is hyperosmolar, 0.45% saline should be used after the initial bolus of fluid.

Potassium should be provided in the fluid at a concentration of 40 meq/L once the serum potassium is less than 5 mmol/L and urine flow is established. Potassium should be given as half KCl and half KPO_4 (to replenish low phosphate level), or as half KPO_4 and half K acetate (which is converted to bicarbonate to help correct the acidosis).

Bicarbonate is rarely needed as ketone bodies will ultimately become a source of bicarbonate. Arguments against bicarbonate therapy include:

(a) Paradoxical CNS acidosis. While the brain is well protected against the acid–base changes in DKA, CO_2 liberated during bicarbonate therapy readily crosses the blood–brain barrier and lowers the CNS pH.
(b) Theoretical impairment of tissue oxygen delivery as a result of shifting the oxygen dissociation curve to the left.
(c) Rapid correction of acidosis may result in intracellular movement of potassium and hypokalemia.

Accepted indications for bicarbonate therapy include cardiovascular instability (myocardial performance and response to catecholamines are improved at pH greater than 7.0) and severe hyperkalemia requiring medical treatment. If indicated, 1 to 2 mmol/kg can be infused over 1 hour.

Insulin Therapy

Insulin should be started once the fluid expansion is complete. A continuous insulin infusion rate of 0.1 unit/kg/h regular insulin is recommended. When the serum glucose approaches 250 to 300 mg/dL, dextrose should be added to the IV fluid. The insulin infusion rate should not be lowered until the acidosis is resolving and the patient is receiving at least 10% dextrose in the electrolyte solution.

Monitoring

The patient should be monitored in a unit in which neurological status, vital signs, and blood work can be measured hourly. A flow sheet is highly recommended so that trends can be readily identified. Bedside glucose determination should be made hourly, and electrolytes should initially be performed hourly, and thereafter the interval can be increased to 2 to 4 hourly, depending on the values.

One should expect the following:

1. Initial rapid fall in blood glucose with the initial fluid bolus. This is caused by the "dumping" of glucose in the urine once renal perfusion is restored by volume expansion. After this unavoidable fall in the serum glucose, the glucose should not be allowed to fall more rapidly than 100 mg/dL per hour. This can be achieved by adding dextrose to the IV fluids as necessary.

2. Initial worsening of acid–base status (fall in pH and HCO_3^-) during the first 1 to 2 hours of therapy. This is caused by the reperfusion of previously underperfused capillary beds and consequent liberation of lactic acid.
3. A rise in the serum sodium associated with the lowering of the serum glucose. The effective osmolality in DKA is determined primarily by the serum glucose and sodium. When the glucose concentration is greatly elevated, there is an osmotic efflux of water from the intracellular space, and this has a dilutional effect on the serum sodium (i.e., the measured sodium is lower as a result of the dilutional effect). The efflux of water from the cell results in cell shrinkage. The brain, however, generates "idiogenic osmoles" to reduce the osmotic gradient and hence protect the brain cells from water efflux. If the high osmolality is lowered too rapidly during fluid and insulin therapy, the plasma compartment becomes hypo-osmolar relative to the brain fluid compartment, and places the child at risk for cerebral edema.

During the correction of the hyperglycemia, the sodium should rise (as the osmotic gradient is less). Failure to observe a rise in serum sodium as the glucose level declines (or observing a fall in the serum sodium while the glucose remains constant) indicates that there is a physiological excess of free water (excess of water over sodium) and should be avoided during DKA therapy (see the following).

Cerebral Edema

Cerebral edema is the most serious complication of ketoacidosis. A number of risk factors associated with the development of cerebral edema have been identified and include pretreatment factors such as lower initial partial pressure of carbon dioxide, higher initial serum urea nitrogen, as well as treatment related factors such as failure of serum sodium to rise during therapy, excessive rate of fluid administration, and bicarbonate therapy.

DISORDERS OF THE THYROID GLAND

Pathophysiology

One of the major actions of the thyroid gland is to concentrate exogenous iodide in the body and to convert it into a hormonally active form that is then released to exert its effect on peripheral tissues. Biosynthesis of the active hormone occurs through a number of steps (Figure 14-10). Active transport of iodide into the thyroid gland leads to oxidation of the iodide and iodination of the tyrosyl residues within the thyroglobulin, followed by coupling of the iodotyrosines to form the active compounds thyroxine (T_4) and triiodothyronine (T_3).

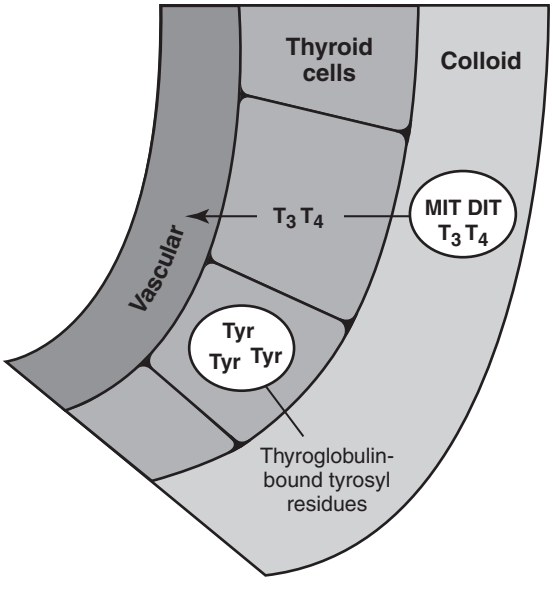

FIGURE 14-10. Biosynthesis of thyroid hormone. Oxidized iodide combines with thyroglobulin-bound tyrosyl (Tyr) residues to form monoiodotyrosine (MIT), diiodotyrosine (DIT), triiodothyronine (T_3), and thyroxine (T_4). Endocytosis, followed by proteolysis of the thyroglobulin molecule by lysosomes, releases T_3, T_4, DIT, and MIT. MIT and DIT are then deiodinated, and the iodide is reutilized, while T_4 and T_3 are released into the systemic circulation.

The active transport of iodide allows sufficient concentration of iodide in the gland despite meager dietary intake. Through this mechanism, thyroid hormone is coupled to its specific binding protein, thyroglobulin, which forms the bulk of the colloid found within the thyroid follicle. Endocytosis of the iodinated thyroglobulin from the stores of colloid and subsequent pinocytosis into the thyroid follicular cell are the first steps in the release of thyroid hormone into the periphery. Hydrolysis of the thyroglobulin molecule occurs with subsequent release of free T_4 and free T_3 into the peripheral circulation.

Regulation of the release of thyroid hormone into the periphery takes place by a complex system of feedback loops (Figure 14-11). TSH from the pituitary binds to its specific receptor on the surface of the thyroid follicular cell, stimulating an increase in 3′,5′-cyclic adenosine monophosphate. This causes the gland to enlarge and initiates a number of processes within the thyroid hormone biosynthetic pathway, ultimately causing an increase in thyroid hormone release. Thyroid-releasing hormone (TRH), a tripeptide produced in the hypothalamus, is transported to cells in the anterior pituitary that produce TSH via the pituitary portal vascular system. TRH synthesis, which increases in response to decreasing body temperature and decreased serum levels of T_4 and T_3, diminishes via negative feedback resulting from increased levels of T_3. TSH increases in response to increasing concentrations of TRH and low levels of T_4 and T_3. Production of T_4 occurs only in the thyroid gland, whereas manufacture of T_3 takes place not only in the thyroid gland but also in many cells in the periphery by monodeiodination of T_4. T_3 has approximately four times the biologic potency and ten times the affinity for nuclear thyroid receptors of T_4.

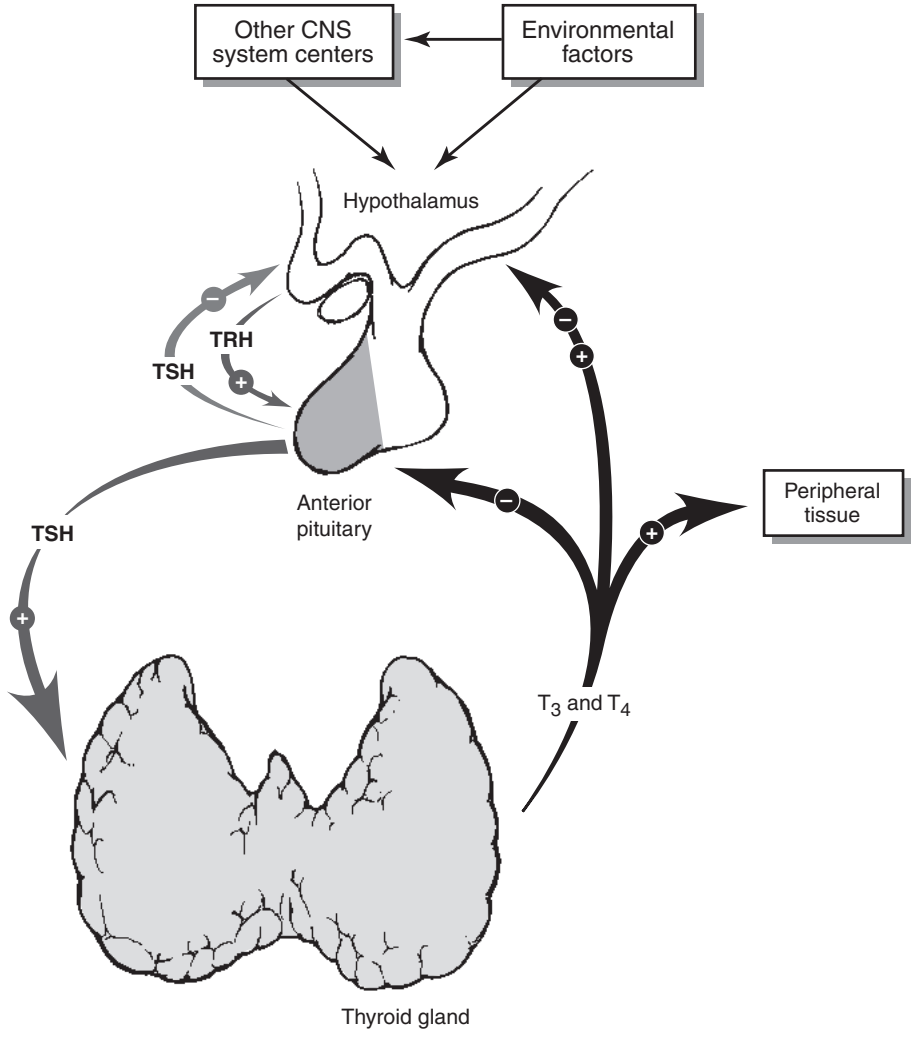

FIGURE 14-11. Feedback loops involved in regulation of thyroid hormone release. *CNS,* central nervous system; *T_3,* triiodothyronine; *T_4,* thyroxine; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone. From Bacon GE, Spencer ML, Hopwood NJ, et al: *A Practical Approach to Pediatric Endocrinology*, 3rd ed. Chicago, Year Book Medical Publishers, 1990, p 124.

The more important biologic actions of thyroid hormone, which are many, include increased amino acid turnover, calorigenesis, thermogenesis, augmentation of the β-adrenergic system, and increased growth. Thyroid hormone is also essential for neonatal brain growth, as evidenced by the development of mental retardation in untreated patients with primary congenital hypothyroidism.

Hypothyroidism

Hypothyroidism can be divided into two large categories, **congenital** and **acquired**. The congenital form can be further subdivided into **primary** (aplasia or hypoplasia of the thyroid gland; common), **secondary** (TSH deficiency; rare), and **tertiary** (TRH deficiency; rarest).

The incidence of primary congenital hypothyroidism is approximately 1 in 4,000 live births. The signs and symptoms of congenital hypothyroidism are insidious. The seriousness of the long-term effects of the condition, if left undetected (mental retardation), has resulted in the development of sensitive neonatal screening programs to avoid preventable retardation. Since the inception of these programs in the late 1970s, the incidence of complications from untreated primary congenital hypothyroidism has decreased significantly.

In the acquired form of hypothyroidism, an autoimmune phenomenon with lymphocytic infiltration of the thyroid gland is most common. However, any process that leads to destruction of the thyroid gland ultimately leads to hypothyroidism.

Hyperthyroidism

Hyperthyroidism may be due to either local or diffuse overproduction of thyroid hormone. In children, hyperthyroidism is almost always due to **Graves disease**. In this condition, the thyroid gland autonomously produces large amounts of T_4 and T_3. Graves disease generally results from an autoimmune phenomenon in which antibodies directed at the TSH receptor on the surface of the follicular cells bind and stimulate production of thyroid hormone.

It is now believed that both autoimmune lymphocytic infiltration of the thyroid gland with subsequent hypothyroidism **(Hashimoto thyroiditis)** and **Graves disease** may both be part of a continuum of autoimmune thyroid diseases. Indeed, it is not uncommon to find patients with one form of autoimmune thyroid disease who have a strong family history of the other type of autoimmune thyroid disease.

Clinical and Laboratory Evaluation

History

Patients with classic untreated **congenital hypothyroidism** often present 6 to 12 weeks after birth with a typical appearance, characterized by a thickened, protuberant tongue; hoarse cry; muscle hypotonia; umbilical hernia; constipation; bradycardia; and prolonged indirect hyperbilirubinemia. These signs are often subtle and easily missed. Although screening for congenital hypothyroidism is now almost universal in the United States, certain methodologic flaws with the testing, which are beyond the scope of this chapter, do exist. Thus, when encountering children with suspicious signs or symptoms, the physician must always keep this diagnosis in mind.

Older infants and children with **acquired hypothyroidism** may present with growth failure, bone age retardation, and delayed or precocious puberty. Other signs of **hypothyroidism** include decreased appetite, lethargy, constipation, dry skin and hair, and prolonged tendon reflex relaxation time. Acquired hypothyroidism is often difficult to diagnose on clinical grounds because the signs and symptoms are often insidious.

Patients with **hyperthyroidism** may complain of heat intolerance, nervousness, palpitations, increased appetite, proximal muscle weakness, difficulty sleeping, inattention, and emotional lability. Physical signs may include weight loss, tremor, shortened deep tendon reflex relaxation time, and a hyperdynamic precordium. The classic ophthalmopathy of Graves disease is less frequently seen in the pediatric age group, in contrast to adults. However, it is not uncommon to see lid lag and an unusual stare, which are due to the effect of excessive thyroid hormone on the sympathetic nervous system.

Physical Examination

When inspecting the thyroid gland, the physician should look for any asymmetry. The space between the sternocleidomastoid muscle and trachea should be symmetrical. The clinician should stand behind the patient, extend the neck slightly while palpating the thyroid gland, and note the size, texture, presence of nodules, and presence of pain. It is necessary to ask the patient to swallow and feel the gland as it rises with swallowing. In addition, it is appropriate to feel the cricoid cartilage; the isthmus of the thyroid should be directly beneath this. Documentation of the presence of a bruit in an enlarged gland is also warranted.

Laboratory Evaluation

The cornerstone of laboratory diagnosis of disorders of the thyroid gland relies on the use of sensitive serum TSH assays and T_4 levels. Today, almost all neonates born in the United States are screened for a variety of diseases, including phenylketonuria and hypothyroidism, before discharge from the hospital. Blood, most often obtained by a heel stick, is subsequently blotted on filter paper. In New York, for example, T_4 is initially assayed, and the lowest 10% of T_4 serum samples are then assayed for elevated TSH values. Providing there is an intact hypothalamic–pituitary axis, elevation in TSH represents a state of inadequate thyroid hormone production. Conversely, the suppression of TSH represents a state of thyroid hormone excess, either endogenous or exogenous. In some cases, patients who have clinical signs of hyperthyroidism but who have normal levels of TSH and T4 may have isolated elevations of T_3, so-called T_3 toxicosis.

Growth failure may be the only manifestation of hypothyroidism. Therefore, it may be necessary to obtain thyroid function tests on all patients referred for short stature or disorders of sexual maturation.

It is necessary to obtain antithyroglobulin and antimicrosomal antibodies in patients with a goiter as part of the evaluation of autoimmune thyroiditis. Ultrasonography may be necessary when there is a question as to the presence of nodules. Fine needle aspiration is an extremely useful technique in evaluating solitary nodules for the presence of malignancy, a rare phenomenon in children.

Pediatric Pearl: Usually a TSH and total T_4 are sufficient to make a diagnosis of hyper- or hypothyroidism.

Differential Diagnosis

The differential diagnosis of abnormal thyroid function involves a number of conditions (Table 14-22). Most children with acquired hypothyroidism have autoantibodies directed at the thyroid gland; the presence of an enlarged thyroid gland (goiter) is variable.

TABLE 14-22

Differential Diagnosis of Abnormal Thyroid Function Tests

Hypothyroidism
Congenital
Primary
Secondary
Tertiary
Acquired
Autoimmune thyroiditis
Endemic goiter
Postradiation (iatrogenic)
Hyperthyroidism
Focal
Thyroid carcinoma
Acute suppurative thyroiditis
Diffuse
Graves disease
Hashitoxicosis
Multinodular goiter

Approximately 10% of patients with DM have evidence of elevated TSH, indicating primary hypothyroidism. This increase in TSH is strongly correlated with the presence of autoantibodies directed against the thyroid gland. For this reason, children with type 1 DM are usually screened annually by obtaining T4 and TSH levels.

Endemic goiter, a condition rarely seen in the United States, is primarily due to iodide deficiency. However, this condition is the most common cause of thyroid disease worldwide. The goiter results from low serum T_4 levels, which stimulate increased TSH secretion, causing an increase in iodide trapping and colloid formation.

As the survival rates of childhood brain tumors improve, **postirradiation (iatrogenic)** destruction of the thyroid gland, or of the pituitary production of TSH, or hypothalamic production of TRH is becoming more frequent. In this setting, the incidence of hypothyroidism is 35% to 45%. Clearly, there is a relationship between the incidence of hypothyroidism, dose of radiation, age of the patient at the time of irradiation, and time elapsed since irradiation.

Hyperthyroidism caused by an overproduction of thyroid hormone may be due to a focal area within the thyroid gland or a process involving the entire gland. On physical examination, the detection of a discrete nodule or a diffusely enlarged gland would help to discriminate between the two entities.

Hashimoto thyroiditis, also known as lymphocytic infiltration of the thyroid gland, is more common in girls than in boys. A strong family history of thyroid disease is usually present. **Hashitoxicosis,** a term that describes the hyperthyroid phase of Hashimoto thyroiditis, results from either increased synthesis of thyroid hormone by the gland or destruction of the gland with subsequent release of thyroid hormone into the periphery. Ultimately, however, affected patients end up with a "burned-out" gland that underproduces thyroid hormone.

Management

Hypothyroidism

All cases of hypothyroidism involve replacement therapy with T_4, regardless of cause. With the widespread availability of oral thyroxine, replacement therapy is fairly straightforward. The starting dose of thyroxine is highest in the newborn (10 to 15 μg/kg/day) and declines throughout childhood to a dose of approximately 2 μg/kg/day by 12 years and older. Children should be monitored every 3 to 4 months to ensure normal growth and development, and to measure the TSH and T_4, or free T_4. In primary hypothyroidism, the dose of thyroxine should be adjusted to keep the TSH in the normal range. In central hypothyroidism, the level of free T_4 should be in the upper half of the normal range.

Hyperthyroidism

There are three options of therapy for Graves disease.

1. Antithyroid medication. Methimazole of 0.4 mg/kg/day, given once daily or divided two or three times daily. This agent, in the thioamide class of drugs, prevents the formation of T_4 and T_3. The aim is to render the patient hypothyroid and then replace thyroxine to normalize the TSH. The advantage of methimazole is that there is a 25% chance of remission for every 2 years of therapy. However, side effects may occur in approximately 5% of patients and may be minor and transient (rashes and arthralgias), or serious (hepatitis, lupus-like reaction, and agranulocytosis). Methimazole should be discontinued in the event of severe reactions and an alternate therapy chosen.
2. Radioactive iodine (RAI). The advantage is that RAI is safe and effective, and is not associated with increased cancer risk or risk to future offspring. The disadvantage is that RAI therapy generally results in permanent hypothyroidism that requires lifelong thyroxine replacement therapy. However, this latter therapy is cheap and easy and free from side effects.
3. Surgery by an experienced thyroid surgeon is an alternative therapy. The disadvantage is the risk of anesthesia, potential risk related to the surgery (damage to the parathyroid glands, recurrent laryngeal nerve), and the likely need for lifelong thyroxine replacement therapy.

A β-adrenergic receptor blocker may be used to control the symptoms of sympathetic hyperactivity such as tachycardia and nervousness as an interim measure. Complications of β-blockers include bradycardia and exacerbation of reactive airway disease.

Gastroenterology

Original by Harvey W. Aiges, Revised by Kenneth L. Cox and Claire M. Wilson

Gastrointestinal (GI) complaints are a significant part of ambulatory pediatrics. Abdominal pain, diarrhea, constipation, emesis, and GI bleeding are seen frequently. The pediatrician must determine whether a child's symptoms are normal in the particular age group, are caused by an abnormality of the GI tract, or are related to a systemic disease. For example, emesis can be normal in young infants, diarrhea may be due to a urinary tract infection, and abdominal pain may be caused by pneumonia. The clinician must use a meticulous history and physical examination along with various clues such as the child's age and clinical appearance to determine the cause of the symptoms and to create a therapeutic plan.

EVALUATION OF ABDOMINAL PAIN

Abdominal pain is one of the most frequent GI complaints that bring children and adolescents to the clinician. The child's complaints may be vague or quite specific.

Pathophysiology

The nature and site of the pain may aid in making a diagnosis. The pain may be **visceral** (from an abdominal viscera), **somatic** (parietal; from underlying peritoneal inflammation), or **referred** (from a more distal site). In general, visceral pain results from (1) a distension of the wall of a hollow organ or a stretching of the capsule of a solid organ, (2) inflammation, or (3) ischemia.

Clinical and Laboratory Evaluation

History

A complete history is essential in the evaluation of abdominal pain in children and is the main source of information that will be used to construct a differential diagnosis. As usual, initial questions should be open-ended, but it is helpful to organize aspects of the history in one's own mind so as not to omit important items. In considering the pain itself, one wants to know the duration of the problem, the frequency and duration of the individual episodes, and whether the pain wakes the child from sleep. The location of the pain and whether it radiates can be elicited, but many pediatric patients are unable to describe pain quality. Visceral pain tends to be poorly localized. The site of pain in hepatobiliary, pancreatic, and gastroduodenal disease tends to be the epigastrium, and small and large bowel disease tends to cause periumbilical symptoms. Abnormalities in the rectosigmoid colon, urinary tract, and pelvic organs generally result in suprapubic manifestations. Peritoneal pain is usually more sharp and constant, and is localized to the area of the involved viscera. In asking about factors that relieve or exacerbate the pain, it is important to specifically include whether eating affects it, if stooling relieves it, and in an older girl, whether it is associated with the menstrual cycle. One can then move on to asking about other GI symptoms such as vomiting, heartburn, diarrhea, constipation, melena, and hematochezia. There are also symptoms that are systemic or relate to other body areas that are relevant, such as the presence of fever, weight loss or poor growth, dysuria, jaundice, and joint pain. Inquiring about a past history of other GI problems when younger, any past abdominal trauma or surgery, and intake of potentially problematic medications or foods often adds significantly to the picture.

Physical Examination

In the evaluation of abdominal pain, the most relevant vital sign is usually the temperature; tachypnea may suggest pneumonia. Percentiles for the child's weight for age, height/length for age, and body mass index (BMI) should be noted (in those under 2 to 3 years of age, weight for length is substituted for BMI). Important aspects of the child's general appearance include any lethargy or distress, a visual assessment of nutritional status; as well as hydration status if vomiting, diarrhea, or poor fluid intake has been revealed by the history. Examples of signs observed with specific diseases follow. Jaundice and icteric sclerae may be seen in acute hepatitis. Purpuric skin lesions, usually on the lower extremities, suggest Henoch-Schönlein purpura. Oral ulcers can be seen in Crohn disease. Lung examination may reveal signs of pneumonia. Abdominal examination begins with inspection for distension or discoloration. Auscultation detects absent, hypoactive, or hyperactive bowel sounds. Palpation revealing voluntary guarding and involuntary rigidity of the overlying abdominal musculature, with or without rebound pain, suggests peritonitis. An abdominal mass in the right mid-abdomen can sometimes be appreciated in intussusception, and right lower quadrant tenderness and fullness is a recognized sign of ileocolic inflammation due to Crohn disease. Right upper quadrant tenderness, especially when acute with inspiration, suggests gallbladder inflammation. A sausage-shaped mass in the left lower quadrant can be due to retained stool in the sigmoid colon. Depending on the presentation, valuable information may also be obtained from external anal examination and digital examination of the rectum.

Differential Diagnosis

Acute abdominal pain in children is more frequently organic in nature, in contrast to chronic or recurrent abdominal pain, which is often functional. Although viral gastroenteritis is one of the most common causes of acute abdominal pain in children, it is most important for the clinician to work through the differential diagnosis carefully (Table 15-1). Several other GI problems cause acute abdominal pain. Nonintestinal causes (e.g., urinary tract disease, pharyngitis, diabetic ketoacidosis) may be extremely difficult to diagnose unless they are under specific consideration.

Chronic abdominal pain occurs in 10% to 15% of children between 5 and 15 years of age. Episodes of abdominal pain occurring at least once a week for a period of 2 months or more are termed chronic. The differential diagnosis list is long (Table 15-2).

Pediatric Pearl: Children with chronic or recurrent abdominal pain who are growing well and have no "warning signs" almost always have functional pain, even though the pain is severe.

The most common cause of chronic abdominal pain in otherwise healthy children is functional abdominal pain. In children with acute abdominal pain, appendicitis must always be considered.

Appendicitis

Acute appendicitis is the most common childhood disease that requires emergency surgery. The diagnosis, which may be easy in a classic textbook case, is often unclear in children and may account for the significant number of cases that progress to perforation (see Chapter 25).

Functional Abdominal Pain

Functional abdominal pain is only partially understood, but is felt to be a disorder in which the brain perceives increased stimuli from the motility of the GI tract. Certain individuals may be inherently susceptible to this condition, and then experience an event such as a GI infection or significant stress, which acts as a trigger. Subsequently they feel increased sensations from the normally functioning digestive system, experienced as pain. Due to what is termed the brain–gut axis, the arousal from the pain has the potential to cause GI dysmotility, further increasing symptoms. Functional abdominal pain is divided into categories based on symptom characteristics: functional dyspepsia involves the upper abdomen, irritable bowel syndrome (IBS) is associated with stool abnormalities, and functional abdominal pain without features of either of the other categories is the most common type seen. Functional abdominal pain is a major cause of school absences.

TABLE 15-1

Causes of Acute Abdominal Pain

Common
Appendicitis
Dietary indiscretion
Food poisoning
Gastroenteritis
Mesenteric lymphadenitis
Pharyngitis
Urinary tract infection
Less Common
Incarcerated hernia
Gallbladder disease
Diabetes mellitus
Hepatitis
Intussusception
Meckel diverticulum
Pelvic inflammatory disease
Peritonitis
Pneumonia (especially lower lobes)
Trauma
Pregnancy (ectopic)
Henoch-Schönlein purpura
Obstruction (adhesions)
Acute rheumatic fever
Renal stones
Pancreatitis
Testicular torsion
Vasculitis
Obstructive nephropathy
Vascular insufficiency
Malignancy
Volvulus
Mittelschmerz
Sickle cell disease

TABLE 15-2

Causes of Chronic or Recurrent Abdominal Pain

Common
Functional (including irritable bowel syndrome, functional dyspepsia, abdominal migraine)
Constipation
Lactose intolerance
Less Common
Acid-peptic disease
Recurrent pancreatitis
Gallbladder disease
Endometriosis
Parasitic infestation
Collagen vascular disease
Mittelschmerz
Sickle cell disease
Acute intermittent porphyria
Mesenteric cyst
Inflammatory bowel disease
Dysmenorrhea
Helicobacter pylori infection
Urinary tract infection
Hematocolpos
Cystic fibrosis (distal intestinal obstruction syndrome)
Enteric cyst (duplication)
Familial Mediterranean fever
Heavy metal poisoning
Abdominal mass/malignancy
Congestive heart failure

Diagnosis depends on a careful history and a normal physical examination. Routine blood studies (complete blood cell count [CBC], erythrocyte sedimentation rate [ESR], and comprehensive chemistry panel) should be normal, as should stool and urine evaluations. A lactose breath hydrogen test after a lactose challenge may be helpful in those beyond toddler age who consume normal or above-normal amounts of milk, but more invasive studies are not indicated if the history, physical examination, and routine studies are consistent with functional abdominal pain. Symptom-based criteria (Rome criteria) have been created to aid in the diagnosis of functional GI conditions.

Laboratory and Imaging Evaluation

There are no specific laboratory studies for abdominal pain, and deciding what tests to order, and in what sequence, depends on the prioritized differential diagnosis formulated after taking the history and performing the physical examination. In many cases, a CBC and urinalysis are done.

Management

Management of acute and chronic abdominal pain depends on the underlying cause. The treatment for early acute appendicitis is emergency appendectomy. If the appendix has perforated prior to surgery, it is essential to correct fluid and electrolyte disturbances and begin aggressive antibiotic therapy.

Treatment of functional abdominal pain involves the identification and explanation of the condition, and reassurance that although the pain is real, this is a "safe" rather than dangerous diagnosis. Patients who do not know what is wrong with them and remain afraid of what their symptoms may mean, are less likely to improve. The older child and adolescent may be asked to keep a diary of symptoms, oral intake, stool output, and stressors to identify their own triggers, which can then be specifically addressed. Normalizing activities, especially school attendance, is an essential part of management. Medications may be useful in specific situations. If patients cannot adapt to this functional problem and fail to participate in the normal "functions of daily living," psychologic intervention may be necessary.

DIARRHEA

Diarrhea is most commonly defined as an increase in the frequency of stools or an increase in the fluid content of the fecal material. Almost everyone has diarrhea at some time during childhood. Because there is considerable variation in stool frequency, volume, and consistency among individuals or even in the same child, the definition of diarrhea is imprecise. It is noteworthy that many infants and toddlers are said to have diarrhea by their parents but in fact do not. Infants may have as many as 10 to 12 bowel movements each day and not have diarrhea, as long as there is no watery margin around the stool mass. Some healthy toddlers, probably as a result of rapid intestinal transit time, have normal volume but unformed stools for many years. Occasionally, the clinician will hear that the child has diarrhea when the problem is actually constipation, with loose material leaking around firm stool retained in the rectum (encopresis). Understanding these aspects can be extremely helpful in avoiding certain counterproductive dietary restrictions and inappropriate medical workups.

Pathophysiology

Diarrhea may be due to abnormalities of the small intestine, colon, or both. In the small intestine, infection/inflammation or malabsorption can lead to diarrhea; whereas in the colon, rapid motility or inflammation may be the cause. Diarrhea has also been subdivided into osmotic and secretory types, where secretory diarrhea continues while the patient has oral intake and osmotic does not. However, overlap exists.

ACUTE DIARRHEA

In most cases, the cause of acute diarrhea is enteric infection. Most commonly, the infectious agents are viral. The cause of acute, self-limited, bloody diarrhea is usually bacterial.

Clinical and Laboratory Evaluation

History

The duration of acute diarrhea is short, usually less than 2 weeks. It is helpful to determine the frequency of bowel movements, as well as the consistency of the stool (a measure of the amount of water loss) and the presence of gross blood in the stool. By itself, the presence of mucus in the stool is not helpful diagnostically. The color of the stool within the brown/yellow/green spectrum is more suggestive of transit time and diet rather than any particular cause of diarrhea. Asking about decreased urine output aids in the assessment of hydration status, provided that urine can be differentiated from stool.

Physical Examination

The clinician must evaluate the patient's state of hydration by evaluating the anterior fontanelle (if open), the mucous membranes, the turgor of the skin, the pulses, and the capillary refill time. Evaluation of the stool for the presence of blood is most useful in determining whether antibiotic therapy may be indicated.

Laboratory Evaluation

Stool analysis for blood, culture and sensitivity, and Wright stain (for white blood cells [WBC]) is necessary. Serum electrolytes may be helpful. In infants, urinalysis and urine culture may be considered, as urinary tract infection can cause diarrhea in this group.

Differential Diagnosis (Table 15-3)

Acute diarrhea may result from infection with one or more of several agents.

Rotavirus

Rotavirus, the most important cause of acute diarrheal disease during the winter months, may lead to particularly severe symptoms in younger infants. Vomiting at the onset of disease is quite common, and significant dehydration is frequently seen. The diagnosis may be confirmed on rotavirus antigen testing of the stool. The initiation of routine rotavirus vaccination in the United States in 2006 has decreased the duration and severity of annual outbreaks.

Other Viral Causes of Acute Diarrhea

The Norwalk-like virus is associated with both diarrhea epidemics and food poisoning, and was the agent found in outbreaks on cruise ships. Vomiting usually accompanies the diarrhea. Enteric adenovirus, astrovirus, and mini-respiratory enteric orphan virus infections are also associated with childhood diarrhea. Viral agents do not produce blood or WBCs in the stool (except in children who have HIV and are infected with cytomegalovirus or herpes simplex). Therefore, stools that are positive for occult blood or have a positive Wright stain should prompt the clinician to consider a bacterial etiology in acute diarrhea, and inflammatory bowel disease (IBD) in chronic diarrhea.

Escherichia coli

Enteroinvasive *E. coli* may produce bloody diarrhea with fecal leukocytes. **Enterohemorrhagic *E. coli*** type 0157:H7 can cause a bloody diarrhea that may produce hemolytic-uremic syndrome, a combination of renal failure, hemolytic anemia, and thrombocytopenia. Hemolytic-uremic syndrome apparently occurs in about 10% of such infections and can be fatal. **Enterotoxigenic *E. coli*** is a leading cause of traveler's diarrhea.

Campylobacter jejuni

C. jejuni is the most common cause of bacterial enterocolitis in the United States. Children have a predilection for infection during the first decade of life. Abdominal pain, fever, nausea, and vomiting frequently accompany the diarrhea and occasionally precede it. The illness usually lasts for 4 to 5 days, but abdominal pain may persist for several weeks after the diarrhea subsides. Fecal blood and leukocytes are common.

Salmonella

Salmonella typhi infections are associated with typhoid fever (enteric fever). This serious infection, which is less common than the enterocolitis forms, arises from contaminated water or food. High, spiking fevers are the rule; if untreated, the fever may remain for 2 to 3 weeks. Nausea, vomiting, and splenomegaly are common. Diarrhea may occur, but constipation is often seen. Rose spots (a cutaneous vasculitis) are seen transiently over the abdomen, chest, and extensor surfaces. Intestinal perforation and hemorrhage, the most serious complications, occur in 1% to 3% of patients, particularly in the second and third week of illness. Other complications include pneumonia, hepatitis, myocarditis, and meningoencephalitis.

TABLE 15-3

Causes of Acute Diarrhea

Infection
Viral gastroenteritis
Bacterial enterocolitis
Overfeeding (infant)
Food poisoning
Systemic infection (e.g., urinary tract infection)
Antibiotics
Hyperthyroidism

Salmonella species other than *S. typhi* produce an enterocolitis that is usually associated with contaminated food and drink. The onset of symptoms is usually abrupt with headaches, chills, and abdominal pain followed by fever, vomiting, and diarrhea. The stools may be bloody. The course usually lasts 1 to 7 days but may be prolonged.

Shigella

Strains of *Shigella* can cause major damage to the distal colon and rectum. The clinical spectrum varies from mild, chronic diarrhea to an abrupt massive toxic process with a high mortality. The most common presentation involves abdominal cramps, fever, and vomiting. Diarrhea follows, often frequent with small volumes but mixed with blood and pus, associated with urgency and tenesmus. Meningismus and seizures often develop as a result of the presence of the neurotoxin produced by some strains of *Shigella*, and the organism can also be the cause of arthritis and the hemolytic-uremic syndrome. A high peripheral band count often accompanies this infection.

Yersinia enterocolitica

Y. enterocolitica causes diarrhea in infants and young children; most older children develop a right lower quadrant mass or tenderness from acute ileitis or mesenteric lymphadenitis, which can mimic appendicitis or Crohn disease.

Clostridium difficile

C. difficile (antibiotic-induced) colitis occurs when a patient's enteric flora is altered by antibiotics, but can be seen in the absence of antibiotic use as well. Virtually all antibiotics are implicated, although the highest risk occurs with use of ampicillin, cephalosporins, and clindamycin. The colitis, which may be associated with the formation of a pseudomembrane, can be quite severe. Marked protein-losing enteropathy and grave toxicity (often with a very high WBC count) may be seen. *C. difficile* is found with greater frequency in those with chronic IBD, and is a recognized nosocomial infection. Standard testing is based on detection of the toxin produced, rather than culture of the organism itself.

Management

The management of acute diarrhea should involve replacing fluid and electrolyte losses. Oral rehydration has fewer complications than does intravenous rehydration, and is preferred for mild and moderate dehydration. As a rule, feeding should resume once rehydration has been accomplished. Specific guidelines for oral rehydration and refeeding have been published (http://www.cdc.gov/mmwr; *Recommendations and Reports* 52(RR16):1–16, 2003). Most cases resolve without complications, and the use of peristalsis-reducing agents is contraindicated. The use of specific antibiotic treatments must be individualized, based on the identity of the organism and the underlying health of the individual. The major concerns with antibiotic treatment are (1) the emergence of resistant organisms that can worsen mild cases or (2) prolongation of the shedding state (a serious problem in nurseries and day-care centers).

C. jejuni infection is self-limited, so in most cases, no treatment is necessary. In severely affected patients, oral erythromycin diminishes fecal excretion of the organisms with a decrease in duration of symptoms. *Salmonella* enteritis is self-limited, and antibiotic therapy should be reserved for patients who are younger than 3 months of age, have bacteremia, or have salmonellosis while suffering from chronic illness or immunocompromise. However, all patients with *S. typhi* (typhoid fever) should receive appropriate antibiotics. Shigellosis is self-limited, but antibiotic treatment can be provided, as guided by organism susceptibility or concurrent recommendations of the Center for Disease Control and Prevention (CDC) . A minority suggest restricting antibiotics to only the most severe cases. Although recent evidence indicates that the risk of hemolytic uremic syndrome is not increased by administration of antibiotics for *E. coli* O157:H7, there is also no benefit from antibiotics in infection with this organism. In antibiotic-induced *C. difficile* colitis, antibiotic therapy (as well as discontinuation of the offending agent) is usually necessary. At the time of this writing, metronidazole (intravenous or oral) is the drug of choice for severe infections or those that do not respond to discontinuation of the offending antibiotic, with oral vancomycin used for treatment failures. As with all bacterial gastroenteritides, the reader is advised to review the most recent antibiotic recommendations published by the CDC and the American Academy of Pediatrics (AAP).

CHRONIC DIARRHEA AND MALABSORPTION

Chronic diarrhea is defined as diarrhea lasting longer than 2 weeks. Chronic diarrhea may or may not be linked with nutrient malabsorption.

Pathophysiology

Chronic diarrhea may be the result of disorders of the colon, small intestine, or both. Colonic dysmotility with normal small intestinal absorption of nutrients (as in irritable bowel syndrome [IBS]) causes nonbloody diarrhea in an otherwise healthy individual. Chronic infection (as in giardiasis) and celiac disease cause malabsorptive diarrhea. Severe intestinal mucosal damage from a variety of insults, such as allergic proctocolitis in infants or inflammatory bowel disease (IBD) also results in this symptom. If the small intestinal mucosa is compromised, nutrient malabsorption and diminished growth can be expected.

Clinical and Laboratory Evaluation

History

Again, it is important to determine the frequency and consistency of the stool. In addition, it is essential to look at the child's growth curve. Chronic diarrhea that affects growth must be evaluated fully. Impaired weight gain may be the result of nutrient malabsorption, or restriction of oral nutritive intake in an attempt by caregivers to treat the diarrhea.

Pediatric Pearl: Chronic diarrhea in toddlers with normal weight and length growth velocity is unlikely to have a serious organic cause.

Physical Examination

The physical examination is unlikely to help the clinician select a specific organic cause, and is most useful to assess for signs of malnutrition. A protuberant abdomen associated with loss of subcutaneous fat (in the buttocks and thighs) suggests malabsorption, and this can be best assessed by viewing the child from the side in a standing posture. There is an interesting variety of clinical findings associated with various mineral and vitamin deficiencies, involving the skin, bones, and peripheral nervous system. Plotting weight for age and weight for length (BMI in those over 2 to 3 years old) is an additional way to determine underweight. These can be falsely reassuring if edema exists, and should always be evaluated in context of the general nutritional appearance of the patient.

Laboratory Evaluation

The main infectious causes of chronic diarrhea are *Giardia* and *C. difficile*, the detection of these is discussed below. Immunosuppressed patients require expanded infectious evaluation. Patients with colitis usually have frank or occult blood and WBC in the stool. If adequate intake of calories has been assured, all children with chronic diarrhea and poor weight gain receive a workup to rule out a malabsorption syndrome. The testing strategy should be individualized based on the prioritized differential diagnosis, formulated from the history and physical examination; one does not need to do every test in every patient with a malabsorptive condition. An acidic stool pH and the presence of reducing substances in the stool suggest carbohydrate malabsorption. A hydrogen breath test can measure lactose and sucrose malabsorption. A Sudan stain of the stool for fat is a screen for fat malabsorption; a more accurate picture can be obtained by a 72-hour fecal fat measurement combined with a concurrent diet record, allowing calculation of percent absorption of ingested fat. Abnormalities of fat-soluble vitamins A, D, E, and protime to assess vitamin K status also suggest the possibility of fat malabsorption. Serologic screening tests for celiac disease are available (see the following). Many workups lead to biopsy of the small intestine, which is of most help in diagnosing celiac disease, lymphangiectasia, abetalipoproteinemia, and intestinal infections such as giardiasis.

Differential Diagnosis (Table 15-4)

A frequent cause of bloody diarrhea in infants as well as of intractable diarrhea is **cow's milk and soy protein intolerance.** Intolerant infants may develop enterocolitis, which manifests itself during the first 3 months of life with vomiting, irritability, poor feeding, and diarrhea with blood-streaked stools. Often diarrhea with streaks of blood is the only manifestation, usually beginning between 2 days and 2 months of life. Symptoms usually resolve when the formula is removed. There is a large percentage of cross-reactivity between cow's milk and soy protein formula, so the use of a casein hydrolysate formula is advised. Cow's milk intolerance may also be seen

TABLE 15-4

Causes of Chronic Diarrhea

Common
Dietary Overfeeding (infants) Cow's milk and soy protein intolerance (infants) Excessive juice intake (toddlers)

Abetalipoproteinemia
Intestinal pseudo-obstruction
Intestinal tumors
Anatomical causes Blind loop Short bowel syndrome Hirschsprung disease
Pancreatic insufficiency (exocrine)
Eosinophilic gastroenteritis

in breastfed infants, due to the presence of cow's milk in the maternal diet. Other items in the mother's diet that can produce this problem are eggs and soy.

In small infants, a cause of chronic diarrhea is a disorder known as **intractable diarrhea of infancy.** The term signifies diarrhea in infants younger than 6 months of age that is associated with diffuse mucosal injury lasting longer than 2 weeks; the condition is often accompanied by malabsorption and malnutrition. Intractable diarrhea of infancy is most often the end result of several different disease entities, including infectious enteritis potentiating cow's milk and soy protein intolerance. Less often seen are Hirschsprung enterocolitis, microvillus inclusion disease, autoimmune enteropathy, congenital transport defects (e.g., congenital chloridorrhea), and congenital carbohydrate malabsorption. Treatment of intractable diarrhea, regardless of the initial cause, is based on aggressive nutritional therapy, preferably via an enteral route. This usually involves the use of a peptide- or amino acid–based formula, which in severe cases can be administered by continuous drip via nasogastric tube to optimize nutrient absorption.

The most common cause of chronic diarrhea in children between 6 months and 3 years of age is IBS ("toddler's diarrhea"). Because this is caused by more rapid colonic motility rather than small intestinal disease or inflammation, these children feel well, and grow well as long as their diets are not calorically restricted. Some may pass intact pieces of vegetable matter such as carrots, corn, and peas in the stool; incomplete chewing combined with rapid transit accounts for this.

Many parents recall the danger of dehydration in infantile infectious diarrhea, and provide these children with excessive clear sweetened liquids, which tends to exacerbate the diarrhea on an osmotic basis. Infection with the protozoan *Giardia lamblia* warrants consideration in young children. Transmission occurs through person-to-person contact or through ingestion of contaminated food and water. *Giardia* adheres to the microvilli of the proximal small bowel and may lead to a variable clinical picture. Affected children may range from asymptomatic; to those with low-grade diarrhea and abdominal distension; to those with profound anorexia, weight loss, and malabsorption. Stool examination for ova and parasites may be normal in as many as 50% of patients, but testing for *Giardia* antigen in the stool is more sensitive. *C. difficile* should be considered in children who have recently received antibiotics or who have IBD, and standard testing is for toxin produced by the organism, rather than culture of the organism itself.

Chronic diarrhea in toddlers may also represent the initial symptoms of primary malabsorption diseases. The overwhelming majority of children with malabsorptive disorders have cystic fibrosis, giardiasis, or **celiac disease**. In Celiac disease there is an immune-mediated pathologic response to gluten exposure. The α-gliadin fraction of gluten appears to induce an inflammatory reaction in the small intestine of genetically predisposed patients. This process results in a flattening of the villi and a deepening of the crypts. After gluten has been introduced into the diet (usually after 6 months), patients present with anorexia, irritability, weight loss, and failure to thrive. Diarrhea usually develops after significant growth failure. In some cases, diarrhea is not present, and children may manifest symptoms of constipation or protein-losing enteropathy. With newer screening modalities for celiac disease, it is now known that many affected individuals have none of the classic symptoms. Celiac disease is also found with greater frequency in children with type 1 diabetes, trisomy 21, and immediate family members of an individual with the disorder.

Although suspicion is raised by a positive screening blood test, duodenal biopsies are necessary to establish the diagnosis. The currently recommended screening test is the tissue transglutaminase (tTG) IgA, which, if elevated, leads to duodenal biopsy. Many practitioners also order a total IgA level as well, as if the individual is total-IgA deficient, a normal tTG IgA is not definitive. In that case, other screening tests or duodenal biopsies will be the next step. Treatment of celiac disease is total gluten avoidance for life. This includes oats, which are often processed on the same machinery used to process gluten-containing grains. Patients should confer with a registered dietician to be sure they are avoiding the hidden sources of gluten in a wide variety of products.

Management

Management of the various causes of chronic diarrhea and malabsorption are disease-specific. Where the cause is a food or food component, elimination is the first step in successful management. Treatment frequently leads to a cessation of the diarrhea and a marked improvement in weight gain and acceleration in linear growth.

VOMITING AND GASTROESOPHAGEAL REFLUX

All children have gastroesophageal reflux (GER), especially as infants, and infantile reflux is often very apparent as "spitting up." Differentiating reflux (GER) from gastroesophageal reflux disease (GERD) is based on determination of whether the symptoms are compatible with the child's age, whether the symptoms are following the normal course for infants, and whether complications are present. Complications of GERD in infants include failure to thrive, esophagitis, respiratory disease, and (rarely) apnea. Guidelines for the evaluation and management of pediatric GER have been developed by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) (http://www.naspghan.org).

Pathophysiology

Vomiting is the **forceful, effortful** ejection of gastric contents. It is important to remember that vomiting is controlled by the medullary emesis center in the floor of the fourth ventricle, which may be affected by GI or non-GI stimuli. **GER**, on the other hand, is the **effortless** regurgitation of gastric contents. However, it

TABLE 15-5

Complications of Gastroesophageal Reflux

Failure to thrive
Esophagitis
Chest pain, heartburn pain
Bleeding and anemia
Strictures
Barrett esophagus (premalignant)
Respiratory diseases
Chronic cough
Asthma exacerbation
Aspiration pneumonia
Nocturnal cough
Apnea (infants)

may be projectile. Transient relaxations of the lower esophageal sphincter unrelated to swallowing appear to cause GER. Other implicated factors are diminished lower esophageal tone, large hiatal hernias, and delayed gastric emptying. Many infants have some degree of GER, but only a small percentage has complications (Table 15-5).

Clinical and Laboratory Evaluation

History

It is critical to differentiate between vomiting (effortful) and GER (effortless) on the basis of history. The vast majority of infants with GER do well with time or conservative management. Vomiting, on the other hand, deserves serious evaluation if it is atypical, intractable, or contains blood or bile. When reflux is suspected as the cause of emesis, the next step is to ask questions which will reveal the presence of the complications mentioned above. In infants we want to know whether growth has been normal, whether there has been chronic lung disease or apnea, whether the infant is in pain or arching, and whether blood has been seen in the emesis. Most normal infants spit up at their highest frequency between the ages of 4 and 6 months; after that the regurgitation gradually declines, resolving by the age of 1½ years. If this is not the pattern, a workup is indicated, even in the absence of complications. In older children, typical symptoms of heartburn may be reported.

Physical Examination

Growth parameters, especially weight for age and weight for length, must be assessed. Abdominal distension suggests obstruction as a cause of vomiting, although absence of distension can be seen when the level of obstruction is high. Palpation of an "olive" in the epigastrium or just to its right suggests hypertrophic pyloric stenosis. A good neurologic examination may be of help in guiding the physician to a central nervous system (CNS) cause for chronic vomiting, and in infants, the fontanelle should be assessed. Erosion of dental enamel can be due to GERD.

Laboratory Evaluation

In the infant with the typical presentation of GER and no evidence of complications, no laboratory investigation is necessary. Parents may be reassured and the infant should be followed clinically. If "warning signs" such as poor growth, chronic lung disease, or hematemesis are seen, further testing must be done. At all ages, vomiting (and the concomitant failure to eat) can be caused by metabolic acidosis. If a child with vomiting has a metabolic alkalosis (often with hypochloremia), it is essential to consider gastric outlet obstruction (e.g., hypertrophic pyloric stenosis). Electrolyte studies should be normal in GER.

In infants with emesis and a reflux complication, a barium upper GI series will assess for the presence of anatomic abnormalities. The barium study is not an accurate test for reflux, however, being both insensitive and nonspecific. Esophageal pH monitoring evaluates the degree of esophageal acid exposure and shows any

association in time between symptoms (such as respiratory ones or heartburn) and reflux events. Esophageal impedance monitoring detects both acid and nonacid reflux, and at the time of this writing is most useful for correlating symptoms with reflux events. Both these modalities usually cover a 24-hour period. Technetium-99m (99mTc) scan of gastric emptying may be rarely be useful to detect delayed gastric emptying, but is not recommended for routine GERD evaluation. In cases of blood loss, anemia, chest pain, and dysphagia, endoscopy and esophageal biopsy is usually indicated. Before deciding on a test, it is important for the clinician to know whether the test being considered is capable of answering the questions relevant to the patient's particular presentation.

Differential Diagnosis

In neonates, clinicians should view vomiting (especially if bile stained) with alarm; it suggests a congenital malformation causing obstruction or sepsis (see Congenital Gastrointestinal Anomalies and Intestinal Obstruction). In infants, vomiting most frequently results from infectious gastroenteritis, but overfeeding, systemic infections, and pyloric stenosis (2 to 6 weeks of age) warrant consideration. In addition, vomiting may be the first manifestation of inborn errors of metabolism and the adrenogenital syndrome. In children and adolescents, gastroenteritis most commonly causes vomiting, but toxic ingestions and systemic infections are possible.

In individuals of all ages, vomiting, especially if chronic or recurrent, may be nonintestinal in etiology. It is critical to consider increased intracranial pressure as a cause of vomiting. Brain tumors, hydrocephalus, and CNS bleeding, as well as seizures and migraine headaches may manifest as vomiting. Metabolic derangements, especially metabolic acidosis, may cause vomiting, as in salicylate poisoning and diabetic ketoacidosis. Vomiting may also result from psychogenic causes, including bulimia. Of course, chronic vomiting may have a GI origin, such as achalasia, peptic ulcer disease, IBD, and late-onset intestinal obstructions (such as from adhesions). Cyclic vomiting syndrome causes episodes of intense nausea and vomiting lasting hours to days, followed by completely symptom-free periods between these stereotypic episodes.

Emesis accompanied by esophageal-level dysphagia (the feeling of food getting "stuck") raises the possibility of eosinophilic esophagitis. In younger children, the dysphagia may not be apparent. Although upper GI series is usually done first to look for obstruction, this diagnosis is made by the presence of excessive eosinophils in esophageal biopsies.

Management

Treatment of vomiting involves treatment of the underlying problem. In most cases of acute vomiting caused by gastroenteritis, no therapy is necessary beyond management of fluid and electrolyte imbalances.

Treatment of infant GER must be individualized. In those of the appropriate age who have no complications, no treatment is necessary. Thickening of formula with dry cereal has not proved to decrease reflux, but may decrease emesis and consequent caloric losses. In formula-fed infants, a 2-week trial of a hypoallergenic formula may identify those for whom allergy is causing or exacerbating symptoms. Most clinicians suggest the use of position therapy, consisting of a 30-degree prone upright stance immediately after feedings, but infants should be positioned on their "back to sleep" to avoid increasing the risk of sudden infant death syndrome. Older children should avoid going to bed within 2 to 3 hours of eating, and should avoid large high-fat meals in the evening. In this age group, sleeping left-side-down or prone may be helpful. Medical therapy with prokinetic agents has limited efficacy, and these agents have significant side effects. Acid-reducing medications, especially the PPIs, are highly effective in the treatment of esophagitis. In the older child or adolescent presenting with typical heartburn, an empiric 2- to 4-week trial of acid suppression is warranted. However, it is important to know that in a recent study of proton pump inhibitor (PPI) therapy in uninvestigated irritable infants, no difference in response was seen compared to placebo. Therefore, any empiric trial in this age group should be carefully considered; and if undertaken should be limited to 2 weeks.

Antireflux surgery, usually via a Nissen fundoplication, is reserved for patients with GER who have failed optimal medical therapy, are dependent on medical therapy over a long period, are significantly nonadherent to medical therapy, or have life-threatening complications of reflux. As complications of Nissen fundoplication are not uncommon, it is essential to exclude other non-GERD causes of the patient's symptoms, and to educate the family about postsurgical expectations. For example, many adult patients continue to take acid-reduction medication postoperatively. Patients with severe neurologic disabilities, GER, and respiratory compromise stand to benefit from antireflux surgery, but these patients are also more subject to complications. Another option in this group is slow gastrostomy drip feedings combined with acid-suppression medication.

CONSTIPATION AND ENCOPRESIS

Constipation is common in infants and children. It involves the infrequent passage of hard stools, which can require straining, produce anal pain, and cause bleeding from anal tearing. In talking with parents, it is important to determine specifically what they mean when using the word "constipation." For example, a normal breast-fed infant may pass a stool only once a week, but if it is soft and the child exhibits no other signs of disease, this is not considered pathologic. Healthy infants, a few months old, may for several weeks strain for 10 to 20 minutes before passing a normal-looking stool; this pattern is termed "infant dyschezia" and is believed to represent learning of the sensory and motor process of defecation, rather than constipation. **Encopresis** refers to fecal incontinence or soiling of the underwear with formed or semiformed stool by children older than 4 years of age. Fecal incontinence may occur with or without constipation. When it accompanies constipation, it is due to leakage around a mass of retained stool in the rectum. When it does not accompany constipation (a far less common situation), it is referred to as nonretentive fecal soiling, which usually has a psychologic or behavioral problem as the underlying cause. Some children exhibit a combination of the two phenomena. Criteria for childhood constipation, infant dyschezia, and nonretentive fecal soiling are part of the Rome criteria for functional GI disorders (http://www.romecriteria.org).

Pathophysiology

Beyond the neonatal period, the vast majority of children with constipation have simple constipation as a result of a functional dysmotility or from voluntary withholding. Sometimes the withholding may become more severe as a result of problems with toilet training, or fear of defecation secondary to prior painful stool passage. If the stool retention remains untreated for a prolonged period, the rectal wall stretches, the rectal vault enlarges, and the normal sensation of the urge to stool is impaired. Children with this condition usually claim that they have not experienced the urge to defecate, which is true. Nonambulatory neurologically impaired children are commonly constipated, presumably due to colonic dysmotility.

Clinical and Laboratory Evaluation

History

Evaluation of children with constipation must take into account the fact that most children have simple constipation as an isolated problem. A good history, including a family history of constipation and IBS, aids in the diagnosis. Associated urinary symptoms may indicate urinary tract infection (for which chronic constipation is a risk factor), a behavioral or developmental element to the picture, or rarely a spinal cord abnormality.

Physical Examination

A physical examination noting muscle tone, rectal tone, abdominal contents, and rectal contents is important. A large rectal vault suggests chronic constipation. An anal fissure explains both pain with defecation and blood streaking of large firm stools. An anteriorally displaced anus with a posterior rectal shelf may make defecation difficult. The older child with untreated Hirschsprung disease often appears malnourished.

Laboratory Evaluation

In routine cases of constipation, laboratory investigation is rarely necessary. In severe or long-standing cases, screening for secondary urinary tract infection is prudent. In atypical constipation or in those in which Hirschsprung disease is under consideration, a workup is necessary.

Differential Diagnosis (Table 15-6)

The exclusion of **Hirschsprung disease** in the differential diagnosis of chronic constipation is important. Hirschsprung disease, or congenital aganglionic megacolon, is due to a congenital absence of ganglia in both the submucosal (Meissner) and myenteric (Auerbach) plexuses. It occurs in about 1 in 5,000 live births and can be associated with Down syndrome or other congenital anomalies. There is a 4:1 male preponderance, but in long-segment disease the ratio is diminished.

In Hirschsprung disease, the aganglionic segment is restricted to the rectum and sigmoid colon in the large majority (75%) of cases. Any length of bowel may be affected, however, ranging from the ultrashort segment (less than 1% of cases) to that of the entire colon, with or without small bowel involvement (8% of cases).

TABLE 15-6

Differential Diagnosis of Constipation

Functional constipation
Stool withholding, toilet phobia
Dietary Breastfeeding (infrequent stools, not true constipation) Low fiber Dehydration Starvation Excessive whole-fat cow's milk
Painful defecation (fissure, trauma)
Sexual abuse
Celiac disease
Intestinal nerve and muscle disorders Hirschsprung disease Intestinal pseudo-obstruction
Anal atresia/stenosis/anterior displacement
Drugs (e.g., narcotics)
Neuromuscular causes Hypotonia Spinal cord lesions Developmental delay with nonambulatory status Myotonias
Metabolic causes Cystic fibrosis Hypothyroidism Hypokalemia Hypocalcemia/hypercalcemia
Infections (botulism, typhoid fever)

Functionally, there is sympathetic hyperactivity in the affected segment, leading to tonic contraction. The more proximal intestine is normally innervated and dilates in response to distal obstruction.

In 50% to 75% of cases, a diagnosis is made in newborns by the failure to pass meconium in the first 48 hours of life, followed by abdominal distension and bilious vomiting. This condition accounts for 25% to 50% of all cases of neonatal intestinal obstruction. Dilation of the empty rectum by the first examiner results in explosive expulsion of retained fecal material and decompression of the proximal bowel. However, symptoms of obstruction return without repeated irrigation of the colon. Diarrhea secondary to enterocolitis develops in 25% of untreated cases, and can be life-threatening. Hirschsprung disease enterocolitis can also occur after surgical treatment.

In cases where the involved segment is shorter, early obstruction is not seen. These patients may resemble those with severe functional constipation, especially if unresponsive to consistent use of usually effective medication regimens.

In the differentiation of simple constipation from Hirschsprung disease, it is wise to remember that the urge to defecate or straining rarely occurs in Hirschsprung disease because stools are retained proximal to the anorectum. Children with Hirschsprung disease rarely soil, and they pass small, ribbon-like stools (because they must pass the hypertonic, constricted aganglionic zone) unlike the very large stools often found in children with functional constipation. In addition, the rectum is tight and narrow and almost always free of stool in children with Hirschsprung disease. In contrast, children with constipation or retention have a large rectal vault full of stool.

The diagnosis of Hirschsprung disease is based on rectal suction biopsy that demonstrates both an absence of ganglion cells in the plexus and hyperplastic sympathetic nerve fibers. An increase in acetylcholinesterase

activity by histochemical staining helps confirm the diagnosis. Anorectal manometry (failure of internal sphincter relaxation with rectal distension) and barium enema (evidence of a transition zone, delayed emptying) may be used as screening tests. Treatment is surgical.

Management

Medical treatment is indicated in functional constipation and stool withholding. Failure to treat may lead to an increase in problems and often results in further stool withholding and encopresis. In infants, a malt extract or lactulose added to the formula may be effective in the management of functional constipation. In toddlers, reduction of any excessive whole milk intake can improve motility. In older children, increasing fiber, by either dietary or supplemental means, helps in milder cases; if necessary, laxatives such as polyethylene glycol 3350, mineral oil, and magnesium hydroxide are used. Polyethylene glycol 3350 is frequently used due to its ease of administration. All of these medications work best if given on a daily basis, with dose adjustments to produce at least one soft normal-sized stool daily, and gradually tapered after two or more problem-free months. Stimulants such as senna may be added to the regimen if necessary. In some cases when there is a large amount of retained stool in the rectal vault, large doses of polyethylene glycol 3350, enemas, or oral cathartics may be needed initially. When these outpatient "clean-out" modalities are unsuccessful, polyethylene glycol administration via nasogastric drip over several hours may be indicated.

In those old enough to toilet, a toileting schedule is created whereby the child sits either at their own optimal time of day or after each meal (to take advantage of the gastrocolic reflex). Feet should be braced on a small stool if feet do not naturally reach the floor. A reward system can be created; for example, the child gets one star on the calendar for sitting and trying to stool and a second one if a stool is produced. Stars can add up to a privilege, and the calendar also serves as a record when brought to follow up medical visits. In toddlers who were in the process of toilet training when the problem began, or for whom the toilet has become associated with defecatory pain, it is better to wait until stooling has become easy and painless to reintroduce it.

Treatment failures of functional constipation are due to lack of initial removal of impaction, inadequate medication dosage, inconsistent medication administration, inappropriate medication discontinuation, lack of a toileting schedule, unaddressed psychologic factors, or inaccurate diagnosis.

ACID-PEPTIC DISEASE AND *HELICOBACTER PYLORI* INFECTION

Historically, acid-peptic disease referred to a variety of entities, including dyspepsia, gastritis, duodenitis, and ulcers of the proximal GI tract related to excess acid secretion. We now understand that inflammation and disruption of upper GI tract mucosa can be due to a variety of specific causes, often creating endoscopically distinct lesions. The discovery of *H. pylori* and its role in ulcer disease had a dramatic effect on management of this particular condition, but raised a variety of questions about the significance of *Helicobacter* in the absence of ulcer disease.

Pathophysiology

Upper GI ulceration takes place when there is an imbalance between protective and assault forces on the mucosa. The known causes of ulcer disease are similar in children and adults: *H. pylori* infection and use of nonsteroidal anti-inflammatory drugs (NSAIDs). In many cases, however, neither of these conditions exists, although given the number of over-the-counter combination drugs, some taking NSAIDs are unaware of it. Patient in intensive care units with trauma, burns, sepsis, and organ failure are at risk for "stress ulcers," which are often gastric. Crohn disease can be seen as ulcerations in the stomach, duodenum, and occasionally in the esophagus. High acidity conditions such as Zollinger-Ellison syndrome are extremely rare in children, as are ulcers associated with GI malignancy.

Clinical and Laboratory Evaluation

History

"Dyspeptic" abdominal pain is located in the upper abdomen (usually epigastrium), is made better or worse by eating, and can be accompanied by nausea, burping, regurgitation, and poor appetite. This presentation can be due to a functional disorder (described previously) or due to ulcer disease, and often the distinction cannot be made without endoscopy. However, when the picture includes waking at night due to pain, GI bleeding, or poor growth, an ulcer or gastritis is suspected, as these are not features of a functional disorder. Ulcer disease may also be asymptomatic in children until unexpected bleeding (hematemesis, melena, or both) is

seen. The history of medication intake, specifically NSAIDs and over-the-counter combination remedies must be included. Family history of ulcer disease is important, due to genetic factors as well as the potential for household spread of *H. pylori*.

Physical Examination

If the patient presents with bleeding, heart rate, capillary refill, blood pressure, and any pallor should be noted (see the following). In general, patients with ulcer disease may have tenderness on palpation of the epigastric region, or the abdominal examination may be normal. A rectal examination allows testing of stool for occult blood.

Laboratory Evaluation

Currently, the best way to evaluate upper intestinal inflammation is via upper endoscopy with biopsies. This examination is simple and safe and allows for the diagnosis of all types of mucosal abnormality as well as biopsy identification of *Helicobacter*. "Noninvasive" tests for *H. pylori* such as the stool antigen test and breath test do not allow this, and are not currently recommended as initial workup by NASPGHAN. This is because *Helicobacter* gastritis alone is associated with different management and prognosis than is *Helicobacter* gastritis accompanied by ulceration. The serological tests for *Helicobacter* are unreliable.

Differential Diagnosis

When a patient presents with dyspeptic pain, the differential diagnosis includes gastritis (generalized or antral gastric inflammation), ulcer disease (either duodenal or gastric), reflux esophagitis, pancreatitis, biliary tract disease, Crohn disease, some parasites, and functional dyspepsia. Obviously some of these conditions have the potential to be seen with bleeding and some do not. As previously mentioned, functional dyspepsia is not accompanied by weight-gain failure, bleeding, or night waking. Pancreatitis is essentially ruled out by normal lipase and amylase. Biliary tract disease is suggested by right upper quadrant pain and tenderness, and can be investigated with blood tests and imaging directed at the liver and gallbladder.

Recurrent ulcer disease may be idiopathic. However, when ulcer recurrence is documented on endoscopy, one should investigate for persistent/recurrent *Helicobacter* gastritis, unidentified NSAID intake, and hyperacidity states due to a high gastrin level.

Management

Upper GI diseases related to gastric acid respond well to H_2 blockade or PPIs; ulcers are generally treated for 6 to 8 weeks, although ulcer size and other factors influence this decision. When NSAID use is associated with ulcer disease, they should be discontinued and an alternative drug used if necessary. There is no question that *Helicobacter* should be eradicated when it is found in a patient with ulcer disease. Current initial treatment regimens include two antibiotics and a high-dose PPI inhibitor. Treatment of isolated *Helicobacter* gastritis (without ulcer) is problematic. In many of these patients, *Helicobacter* is not the cause of their symptoms, and eradication does not lead to improvement. Treatment may be associated with medication side effects (often GI), and significant emergence of resistant organisms is well documented. The decision of whether to treat in these cases should include a discussion with the child's parents about possible outcomes. When there is a family history of gastric cancer, one might be more motivated to treat. As treatment of nonulcer *Helicobacter* is an area where recommendations are in flux and where pediatric guidelines have differed from those for adults, the reader is encouraged to review the current literature for updates.

CONGENITAL GASTROINTESTINAL ANOMALIES AND INTESTINAL OBSTRUCTION

Neonates with GI anomalies often manifest signs and symptoms within hours or days of birth. Intestinal obstruction is the most frequent and the earliest clinical presentation of many of these entities. Accurate and early diagnosis is critical to avoid many of the long-term complications of these problems.

Pathophysiology

Congenital anomalies of the GI tract and the abdominal wall are the result of developmental abnormalities or intrauterine insults. The physician should be aware of possible GI congenital anomalies and their relationship to other congenital problems.

Clinical and Laboratory Evaluation

History

Immediately after birth, clinical clues about congenital anomalies resulting in intestinal obstruction can be gained by a history of polyhydramnios, a single umbilical artery, or meconium staining. Although intestinal obstruction is most frequently seen in association with congenital anomalies in the first few hours/days of life, it may occasionally present later in childhood.

Pediatric Pearl: There is a great urgency to investigate any possibility of intestinal obstruction (bilious vomiting, abdominal distension) in neonates because obstruction may be associated with impaired blood flow to the affected segment of gut.

The resulting ischemic changes may lead to catastrophic problems, with a loss of large areas of bowel and overwhelming sepsis.

Physical Examination

In the delivery room, several congenital problems such as omphalocele, gastroschisis, and imperforate anus are apparent on simple inspection. In addition, intestinal obstruction may be associated with other conditions such as cleft palate, skeletal deformities, and trisomy 21.

Laboratory Evaluation

Fetal sonography may reveal GI anomalies. When neonates present with obstruction, contrast radiographs can be used to identify the site, but this will be better delineated when the child undergoes surgery.

Differential Diagnosis

Intestinal obstruction may result from one or more conditions.

Omphalocele and Gastroschisis

An **omphalocele** is a congenital hernia involving the umbilicus, which is usually covered by a sac composed of the fused layers of amnion and peritoneum. Although there is a central defect in the skin and linea alba, the remainder of the abdominal wall is intact, including the surrounding musculature. A variable amount of viscera may herniate into this sac. Of affected patients, 35% have other GI defects, including malrotations; 20% have congenital heart disease; and 10% have Beckwith-Wiedemann syndrome (gigantism, visceromegaly, macroglossia, hypoglycemia, omphalocele). In addition, extrophy of the bladder, vesicoenteric fistulae, or other renal abnormalities may be present. It is possible to miss a small occult omphalocele; therefore, the cord tie on the umbilicus should leave enough room to avoid damage to the viscera.

A **gastroschisis** is a full-thickness, complete abdominal wall defect, usually to the right of a normal umbilicus, and a sac never covers the extruded viscera. An omphalocele with a ruptured sac may be difficult to distinguish from a gastroschisis. Of affected infants, 14% have an associated jejunoileal malformation (often an atresia), often with an abnormally short nonrotated midgut, but only 4% have an extraintestinal anomaly. Between 50% and 60% are premature.

The surgical management of an omphalocele and a gastroschisis and the associated prognosis depends on the size of the hernia, the presence or absence of a covering sac, and the severity of any associated anomalies. It is easy to repair a small omphalocele in the base of the umbilical cord with an intact membrane in a single-stage procedure. In cases in which the defect is large or there is no intact membrane, the surgeon must use many creative techniques to achieve reduction of the extruded abdominal contents into the peritoneal cavity without compromising the viscera.

Umbilical Hernia

An umbilical hernia results from the incomplete closure of the fascia of the umbilical ring. If the defect is less than 0.5 cm, it is predicted that healing will occur spontaneously by 2 years of age. If the ring is between 0.5 and 1.5 cm, healing is usually complete by 4 years of age. Surgical correction warrants consideration if the defect is larger than 1.5 cm at 2 years of age or if incarceration of viscera has occurred. Reducing the hernia by strapping a device (such as a coin) over the ring does not help the healing process.

Meckel Diverticulum

The most common anomaly of the GI tract, **Meckel diverticulum** is a blind omphalomesenteric duct that results from persistence of the duct communication between the bowel and the yolk sac. The "rule of two" applies to this lesion. It is described as an antimesenteric outpouching of the ileum; about 2 feet (60 cm) from the ileocecal valve and is present in about 2% of the population with a male predominance at 2:1. In the vast majority of cases, Meckel diverticulum causes no symptoms, but about 2% of cases are associated with complications, most occurring in children younger than 2 years of age. Ectopic GI and pancreatic tissue is seen in nearly 50% of cases, with 85% of the tissue being gastric.

Painless rectal bleeding (85%), intestinal obstruction (intussusception or volvulus, 10%) and pain mimicking appendicitis (5%) are the most common problems encountered. The rectal bleeding is secondary to ulceration of the ileal mucosa adjacent to the ectopic gastric mucosa of the diverticulum. The bleeding can manifest as recurrent occult blood to sudden, massive, wine-colored hemorrhage with shock.

The diagnosis of Meckel diverticulum is often made clinically by excluding other causes of painless rectal bleeding. Radionuclide imaging with 99mTc pertechnetate after enhancement with cimetidine or ranitidine may be helpful in identifying gastric mucosa in the diverticulum in as many as 85% of cases. A surgical wedge resection of the diverticulum is curative.

Diaphragmatic Hernia

A **diaphragmatic hernia** results from incomplete closure of the membranous pleuroperitoneal folds that normally form the lateral and posterior aspects of the diaphragm. The last portions of the diaphragm to close are the posterolateral triangular canals, the foramen of Bochdalek, through which the great majority of hernias occur. Between 80% and 90% of these are left-sided hernias, and 2% are bilateral. When the diaphragm is forming, the midgut is rapidly elongating and returning from its extracoelomic position in the yolk sac. Therefore, if there is a defect in the diaphragm, the gut takes the path of least resistance and enters the thorax. About 2% of diaphragmatic hernias are associated with a retrosternal defect, the foramen of Morgagni. These hernias are usually less severe because the retrosternal space is smaller, so less abdominal viscera can enter.

The majority of infants with diaphragmatic hernia manifest symptoms of respiratory distress in the delivery room or shortly after birth as the herniated bowel fills with air. However, some patients may present later in life with symptoms of chronic cough or congestion. Survival correlates with the presence of other anomalies, liver herniation, and degree of pulmonary space compromise.

Esophageal Atresia and Tracheoesophageal Fistula

In the embryonic process, **esophageal atresia** and **tracheoesophageal fistula** occur when the septation between the ventral tube of the foregut and the dorsal esophagus develops abnormally. The clinical clues to the diagnosis are polyhydramnios and excessive oral secretions. If these are present, a radiograph with a radiopaque nasogastric tube inserted may be very helpful by showing the tube coiled or otherwise arrested in the blind esophageal pouch.

Between 35% and 40% of patients with tracheoesophageal fistula have significant associated anomalies, and in more than 50% of cases, there are more than two malformations. The VACTERL association consists of vertebral, anal, cardiac, tracheoesophageal, renal, and radial limb abnormalities. Most deaths in patients with tracheoesophageal fistula are related to other severe abnormalities rather than to the tracheoesophageal fistula itself.

Many subtypes of esophageal atresia and tracheoesophageal fistula have been described. The most common variety of esophageal atresia (85% to 90%) is a blind proximal esophageal pouch with a distal tracheoesophageal fistula. The next most common form (8%) is a proximal esophageal pouch without a tracheoesophageal fistula. In both of these forms, coiling of the nasogastric tube occurs. Infants with tracheoesophageal fistula without an esophageal atresia, the so-called H-type tracheoesophageal fistula (4%), often present with chronic cough or choking while feeding.

Treatment of esophageal atresia and tracheoesophageal fistula is surgical division of the fistula and primary anastomosis of the esophagus. The survival rate in term infants without other abnormalities is greater than 90%. However, complications are common. Postoperative leaks occur in as many as 10% of all cases. Stricturing at the surgical anastomotic site often requires repeated dilatation. Most patients with esophageal atresia also have abnormal esophageal motility and are at risk for significant GER, with complications of chronic esophagitis. This can be associated with increased stricturing at the surgical anastomotic site and/or recurrent pneumonia.

Hypertrophic Pyloric Stenosis

The obstruction of the pylorus is the result of marked hypertrophy of the circular musculature of the pylorus. Hypertrophic pyloric stenosis occurs once in every 500 births, with a 4:1 ratio in favor of males. It appears to have both genetic and environmental causes, and to involve abnormalities of nitric oxide metabolism. Exposure to macrolide antibiotics, specifically erythromycin, in the first 2 weeks of life is suspected as a potentiating factor. Familial cases occur in 5% of siblings and as many as 25% of children if the mother was affected.

The clinical manifestations of hypertrophic pyloric stenosis are projectile, nonbilious vomiting beginning at 2 to 6 weeks of life. It occurs only rarely after 4 months of age. The frequency of the vomiting is variable at first and may be lessened by frequent feeding of small volumes, especially of clear liquids. The vomiting becomes more severe and projectile as the gastric outlet becomes more obstructed. Palpation of the pyloric mass or "olive" is diagnostic. The mass is palpable to the right of the umbilicus; it is best felt during a feeding, just after vomiting, or with the child held prone. A visible upper abdominal peristaltic wave can sometimes be observed.

Laboratory results are often normal early in the course of disease, but in severe or protracted cases, a characteristic hypokalemic, hypochloremic metabolic alkalosis (due to the composition of gastric fluid lost in emesis) occurs, associated with malnutrition and dehydration. If clinical or laboratory results are inconclusive, abdominal ultrasound or an upper GI series are helpful; the former is preferred as it avoids radiation exposure.

Pediatric Pearl: Hypertrophic pyloric stenosis is occasionally associated with mild, unconjugated hyperbilirubinemia.

Treatment of hypertrophic pyloric stenosis consists of nasogastric decompression and correction of fluid and electrolyte abnormalities. Pyloromyotomy is curative and associated with a very low mortality, and recovery is usually rapid.

Anomalies of the Small Intestine

DUODENAL ANOMALIES. Duodenal obstruction, which results from atresia (40% to 60%), stenosis (35% to 40%), or a web (5% to 15%), manifests as a high intestinal blockage. The vast majority of atresias and webs are near or just distal to the ampulla of Vater. Atresia and web anomalies result from failure of the lumen to recanalize during the 8th to 10th week of gestation. **Duodenal atresia** is associated with trisomy 21 (30% of cases), prematurity (25%), and other anomalies (30%). **Duodenal stenosis** is most often due to extrinsic duodenal obstruction such as annular pancreas, peritoneal bands, or ectopic pancreatic tissue.

Clinically, affected infants present with bilious vomiting on the first day of life, without abdominal distension. High-grade duodenal obstruction is very clearly seen on an abdominal radiograph as a typical "double bubble" sign, which is actually distension of the stomach and duodenum. Treatment is a surgical bypass of the obstruction, except for webs (the "wind sock" deformity), which involves surgical resection.

JEJUNOILEAL ANOMALIES. Jejunoileal atresia, which is more common than duodenal atresia (2:1), most often results from an impaired vascular supply. Ileal atresia occurs much more often than jejunal atresia. Atresias are 15 times more common than stenoses. About 50% of cases have an associated major malformation, including malrotation, Down syndrome, or cystic fibrosis.

Infants with small bowel atresia distal to the duodenum have bilious or fecal vomiting and abdominal distension. An abdominal radiograph shows dilated loops of bowel, often with air-fluid levels. A barium enema may reveal an unused, small colon (microcolon), particularly with very distal small bowel obstructions. An oral barium small bowel study is contraindicated in the presence of a complete obstruction.

Meconium ileus is a common cause of neonatal intestinal obstruction. This defect is the earliest manifestation of cystic fibrosis, occurring in 10% to 15% of patients with the disease. Patients with the defect almost certainly have cystic fibrosis, although there have been reports of meconium ileus without cystic fibrosis. Meconium ileus should not be confused with **meconium plug syndrome,** a relatively mild condition associated with inspissated rubbery meconium that plugs the distal colon and rectum. Most patients have no further problems, but it is necessary to rule out Hirschsprung disease, cystic fibrosis, and hypothyroidism.

MALROTATION AND MIDGUT VOLVULUS. Malrotation and other disorders of intestinal fixation ranks as the second most common cause of neonatal intestinal obstructions, just behind intestinal atresias. **Malrotation of the small bowel** is due to abnormal movement or rotational arrest of the intestine around the superior mesenteric artery when the midgut returns to the coelomic cavity via a 270-degree counterclockwise rotation. The result is an abnormal mesenteric fixation of the small intestine and cecum, with obstructive bands.

Nonrotation of the midgut is often a finding in omphalocele, gastroschisis, and diaphragmatic hernias. Malrotation or incomplete rotation may produce duodenal obstruction, volvulus, and internal hernias. Less acute presentations usually occur after 1 month of age and may manifest as chronic intermittent obstruction, malabsorption, protein-losing enteropathy, or recurrent pain and vomiting. However, more than 50% of cases present as high intestinal obstruction (a midgut volvulus) in the first week of life, with bilious vomiting, distension, and some bleeding. Cases presenting later with bilious vomiting run the risk of being confused with acute gastroenteritis, with the disastrous consequence of large-scale small intestinal necrosis.

It is possible to make the diagnosis by a barium enema that shows the cecum in the right upper quadrant, or by an upper GI series that reveals an abnormal duodenal sweep with the ligament of Treitz absent or in an abnormal position.

Pediatric Pearl: Midgut volvulus is an **absolute surgical emergency,** and all haste should be extended to make the diagnosis in order to avoid bowel ischemia and intestinal perforation. Any undue delay in making the diagnosis frequently results in massive bowel resection and "short gut" syndrome.

ENTERIC DUPLICATIONS. Enteric duplications occur throughout the GI tract. Their etiology is unclear. Ileal duplications are the most common, and gastric duplications are the rarest. Small bowel duplications often contain gastric mucosa, and a technetium radio imaging study may be useful in making the diagnosis. The lesions may be asymptomatic, but most seem to cause problems eventually. Complications can be bleeding from the ectopic gastric mucosa, bacterial overgrowth and malabsorption from a communicating duplication (a blind loop), and obstruction from a noncommunicating duplication cyst. Treatment is surgical resection.

ANORECTAL ANOMALIES/IMPERFORATE ANUS. Anorectal anomalies arise from incomplete division of the cloaca by the urorectal septum or incomplete convergence of the anal tubercles around the end of the hindgut. These malformations, which occur in 1:4,000 to 1:5,000 births, mostly affect full-term, appropriate-for-gestational age infants; there is a slight male preponderance. In two-thirds of the cases, these malformations are associated with other anomalies. The other systems most commonly affected are the vertebral column, the CNS, and the genitourinary system.

Inspection of the perineum is helpful in most cases. The **imperforate anus** should be obvious to the naked eye. Meconium may be seen emerging from the vagina, urethra, or from a pinpoint anal opening. In infants with an anal membrane, no meconium is passed, but a greenish bulging membrane may be seen.

There are multiple subtypes of anorectal anomalies in essentially two major groups: the **supralevator (high) imperforate anus** and **the translevator (low) imperforate anus**. This classification is based on the location of the blind pouch. That is, high pouches, which are more common (75%), are at or above the puborectalis sling (supralevator), and low pouches are below the sling (translevator). In both groups, the rectal pouch may end blindly or communicate by a fistula with a nearby viscus or the perineal skin. The vast majority of fistulas are present only in cases of high imperforate anus, and involve the urinary tract in males and the genital tract in females. Infants with a low pouch may exhibit a perineal bulge when crying or have a perineal fistulous aperture.

Contrast radiographs of the fistula or instillation of contrast into the rectum should allow delineation of the defect. Sonography and CT may also help define the blind pouch. Treatment is surgical except in anal stenosis, in which simple dilation is adequate. Fecal continence is achieved in more than 90% of children with low pouches, but in only 30% to 70% of those with high pouches.

INGUINAL HERNIA. The incidence of inguinal hernia is highest in the first year of life with a peak in the first month of life. They are more common in premature infants, and boys are affected more often than girls. The majority of inguinal hernias occur on the right side, with bilateral hernias frequently seen.

Inguinal hernia occurs when a patent processus vaginalis contains some portion of the abdominal viscera. During development, a peritoneal sac precedes the testicle as it descends from the genital ridge into the scrotum. The lower portion of this sac (processus vaginalis) eventually envelops the testes and forms the tunica vaginalis and the rest of the sac regresses. In almost 50% of children, the processus vaginalis remains patent, and in some, abdominal contents become trapped.

The symptoms of an incarcerated hernia are abdominal pain, irritability, and vomiting. If there are ischemic changes, pain increases and the vomiting may become bilious, which indicates that there is intestinal obstruction. Inguinal hernia presents as a bulge in the groin that often extends into the scrotum. If a child is relaxed and not crying, usually the hernia reduces either on its own or with manual manipulation by the clinician.

Initially, nonoperative management of an incarcerated inguinal hernia without strangulation is appropriate. After hernia reduction, which occurs in the vast majority of children, elective surgical repair should take place within 48 hours. However, if an inguinal hernia does not reduce spontaneously, repair is essential because of the high risk of irreducible incarceration and strangulation, especially in the first few months of life. If strangulation occurs, infarction of the contents of the sac results, and an abdominal catastrophe ensues.

GASTROINTESTINAL BLEEDING

Bleeding can occur at any location in the GI tract, and the diagnosis depends to a large extent on the patient's age, whether the blood is vomited or passed per rectum, the magnitude of the bleeding, and the color of the blood. Because GI hemorrhage can be so frightening to the child and the family, a calm and logical approach to the diagnosis and treatment of the bleed is warranted. In large-scale bleeding, stabilization must take place prior to diagnostic testing. In the great majority of cases, bleeding in children is of a smaller scale, is easy to control or stops spontaneously, and a cause is determined.

Pathophysiology

Hematemesis is the vomiting of blood. The blood is either bright red or "coffee ground" in appearance if it has been altered by gastric acid. Hematemesis implies that the site of bleeding is proximal to the ligament of Treitz, but may also reflect swallowed blood from the nose or mouth. More voluminous bleeding from the upper GI tract, appears per rectum as black or "tarry" stool (i.e., **melena**). The melenotic stool is coal-black, shiny, sticky, and frequently foul smelling. **Hematochezia** is the passage of bright red or maroon-colored blood in or on the stool. The site of this bleeding is usually in the distal small intestine or colon, but profuse upper GI bleeding can cause hematochezia due to rapid transit. **Occult** GI bleeding suggests significant, continuing blood loss in the absence of a visible change in the color of the stools.

Clinical and Laboratory Evaluation

The physician approaching a child with a presumed GI bleed must first be sure that blood is actually present. Drinks such as Kool-Aid, gelatins, beets, tomato sauces, and certain antibiotics mimic hematochezia, and bismuth compounds, iron supplements, charcoal, and spinach simulate melena.

History

Parents tend to overestimate the severity of the blood loss for two reasons: (1) they are anxious and (2) small amounts of blood mixed with toilet water may appear copious. The character of blood loss is important. Because hematemesis implies that the bleeding is proximal to the ligament of Treitz, a history of epistaxis, hemoptysis, or oropharyngeal trauma may preclude the need for a GI workup. Bright red blood, which appears only on the toilet paper, in the toilet water or on the surface of the stool suggests anorectal pathology (e.g., anal fissure, distal polyp, proctitis). The differential diagnosis of bloody diarrhea is quite different from that of hematochezia accompanied by formed or firm stool. Anal pain is more frequently reported when a fissure is present. Tenesmus (the uncomfortable urge to defecate what turns out to be small amounts of loose stool) suggests proctitis. Abdominal pain accompanies some causes of hematochezia (e.g., intussusception, IBD) and is less common in others (colonic polyps, Meckel diverticulum). Some causes of GI bleeding are associated with larger, destabilizing bleeds; and other conditions characteristically produce only small amounts of bleeding. The light-headed patient is more likely to have bled significantly. True melena usually produces a strong, foul odor.

Past medical history may also be contributory. Evidence of fever (enterocolitis); family pathology (polyps, bleeding diathesis, family polyp syndromes or IBD); ingestions of drugs, dyes, undercooked meat, or foreign bodies; systemic illnesses (liver disease, collagen vascular disease, IBD, GER); or prior symptoms of trauma, colicky pain, weight loss, or constipation with defecation can be extremely helpful.

Physical Examination

In cases of large-scale bleeding one must assess the degree of hemodynamic stability, and initially stabilize the patient if necessary, before pursuing the specific diagnosis. Heart rate, capillary refill, blood pressure, and observation for pallor are basic tools for this. Evaluation of the skin and mucous membranes for signs of Peutz–Jeghers syndrome, oral ulcerations, angiomata, jaundice, or evidence of bleeding disorders is warranted. Careful examination of the abdomen is important. Hepatosplenomegaly may indicate portal hypertension

(and variceal bleeding) or sepsis, whereas an abdominal mass may suggest intestinal duplication or intussusception. Anal examination may reveal a fissure or evidence of Crohn disease. The rectal examination allows both visual inspection of the stool and testing for occult blood.

Laboratory Evaluation

A Hemoccult test is essential, and if positive, it is appropriate to eliminate extraintestinal sources of bleeding such as nose, mouth, pharynx, and vagina. If significant lower GI bleeding is present, insertion of a nasogastric tube and aspiration of fluid may reveal an upper source and have a major impact on the diagnostic approach. If the nasogastric tube aspirate is positive, the bleeding is almost surely proximal to the ligament of Treitz.

If the nasogastric aspirate is positive or the child has hematemesis, an upper endoscopy is the procedure of choice; this establishes the source in more than 90% of cases. Exceptions to this plan would be cases in which an obvious source of swallowed blood is found, or when small amounts of blood are vomited after repeated retching/vomiting, such that a Mallory-Weiss tear is suspected. Ordering a CBC, primarily for the hemoglobin and hematocrit, will establish a baseline in cases of significant bleeding, but it is important to remember that subsequent hemodilution occurs when intravenous fluids are administered. If a bleeding disorder is suspected, one also wants to know the platelet count and results of coagulation studies; in addition, with large-scale bleeds an acquired coagulopathy can develop due to loss of clotting factors. A type and cross-match should be sent unless the amount of bleeding is minor. Endoscopy is necessary in children with active bleeding and known esophageal varices because lesions other than varices may be the source of the bleeding and because varices can be treated endoscopically.

The specific testing strategy when blood loss is via the rectum depends on construction of a prioritized differential diagnosis list, based on information obtained from history and physical examination. For example, with small amounts of painless bright red blood per rectum unaccompanied by diarrhea or anal fissure, the first test may be a colonoscopy; while in the appropriate-aged child with larger amounts of maroon blood and no pain, a Meckel scan might be chosen first. Barium studies are rarely helpful in the diagnosis of GI bleeding, and may interfere with the more productive endoscopic procedures. An exception is in intussusception, in which a barium enema is also usually curative (See Intussusception which follows). If a chosen test is negative, one should reprioritize the differential diagnosis to decide on the next move. Other tests that are useful in specific situations are capsule endoscopy, tagged RBC nuclear scan, angiography, and laparoscopy.

If the blood is admixed with the stool and associated with abdominal pain or diarrhea, consideration of IBD, infectious or allergic colitis, or vasculitis is warranted. Appropriate blood (e.g., CBC, ESR, CRP) and stool studies (WBC, culture, *C. difficile* toxin) are selected prior to endoscopy.

In a totally asymptomatic child who presents with occult blood in the stool and anemia, a thorough workup may be indicated. A Meckel scan is often done initially, followed by upper and lower endoscopy, and capsule endoscopy if feasible. If the entire workup is negative and significant rectal bleeding persists or recurs, an exploratory laparotomy may be indicated. A laparotomy in this situation most often reveals a Meckel diverticulum. Other possible diagnoses include intussusception, small bowel tumors, duplications, and vascular lesions of the bowel.

Differential Diagnosis: Etiology by Age (Table 15-7)

Newborns (Birth to 1 Month)

GI bleeding in neonates differs from that in older children. Several causes are very specific to this age group. Considerable hematemesis in the first 1 to 2 days of life can result from **hemorrhagic gastritis or stress ulcers**, caused by a perinatal insult such as hypoxia, sepsis, or a CNS lesion that renders the gastric mucosa vulnerable to the effects of the relatively high gastric acidity in newborns. Other frequently recognized causes of neonatal bleeding are **hemorrhagic disease of the newborn** and **anal fissures**. Another source of GI bleeding in neonates is **swallowed maternal blood,** which may appear as hematemesis or even massive dark rectal bleeding. The **Apt test** readily provides a diagnosis. This test differentiates fetal from maternal blood by adding sodium hydroxide to a supernatant of the blood. Fetal blood remains pink due to the alkaline resistance of fetal hemoglobin, whereas adult hemoglobin changes to a brown color.

Necrotizing enterocolitis in preterm or stressed infants and enterocolitis secondary to **Hirschsprung disease** may result in occult-to-moderate rectal bleeding (see Congenital Gastrointestinal Anomalies and Intestinal Obstruction, Differential Diagnosis). **Midgut volvulus** associated with malrotation of the bowel is a grave emergency that can produce melena or hematochezia. All three of these entities are life-threatening, and require rapid diagnosis and aggressive intervention with fluid replacement, antibiotics, bowel decompression, or surgery.

Cow's milk protein allergy may also manifest as occult or significant rectal bleeding (see Gastrointestinal Bleeding). Affected infants may also have diarrhea, vomiting, wheezing, atopic dermatitis, or rhinitis;

TABLE 15-7

Differential Diagnosis of Gastrointestinal Bleeding

Upper Gastrointestinal Tract Bleeding
Conditions specific to neonates Swallowed maternal blood Hemorrhagic disease of the newborn Hemorrhagic gastritic/stress ulcer
Acid related Esophagitis Gastritis/duodenitis Peptic ulcers
Esophageal/gastric varices
Mallory-Weiss tear
Hematobilia
Swallowed blood (nasal/oral/pharyngeal)
Lower Gastrointestinal Tract Bleeding
Anal fissure
Enterocolitis Necrotizing enterocolitis (premature infants) Infection Bacterial Parasitic Viral (immunocompromised)
Allergic Cow's milk protein/soy protein intolerance (infants) Eosinophilic gastroenteropathy
Inflammatory bowel disease
Antibiotic-induced colitis (*Clostridium difficile*)
Hirschsprung disease enterocolitis
Juvenile polyps and tumors
Intussusception
Meckel diverticulum
Henoch-Schönlein purpura
Midgut volvulus
Hemolytic-uremic syndrome
Nodular lymphoid hyperplasia
Vascular malformations
Duplication (enteric cysts)
Autoimmune vasculitis
Trauma
Foreign body
Ischemia

but the usual picture is that of a healthy looking, well-nourished infant with small streaks of bright red blood in a somewhat mucousy loose stool. Symptoms usually resolve with cessation of the cow's milk formula, or removal of cow's milk from the maternal diet in a breast-fed infant. If the child is refed with the offending protein, symptoms may recur within hours and can be associated with a peripheral leukocytosis with or without an eosinophilia. Cow's milk–induced colitis can be diagnosed with even limited colonoscopy; biopsies show an inflammatory reaction with a predominance of eosinophils. However, after excluding an active anal fissure and ruling out bacterial colitis with a negative stool culture, many parents and practitioners choose a 2- to 3-week empiric diet change. If the bleeding persists a colonoscopy is performed. In formula-fed infants treatment involves changing to a casein hydrolysate formula (soy-based formulas often cross-react with cow's milk protein when hematochezia is the manifestation of allergy and should not be used). Infants whose only symptom was hematochezia can usually be transitioned to cow's milk at 1 year of age without difficulty.

Children

ANAL FISSURES. **Anal fissures** are the most common cause of nonmassive, bright red anal bleeding in children. Blood tends to streak the stool. Fissures usually result from the trauma of passing a large, hard stool, but they may occur in children who pass softer stools accompanied by frequently straining. These fissures are usually present in the midline. Rectal prolapse may also cause bright red rectal bleeding. This lesion is most often the result of constipation and straining, but it is necessary to rule out cystic fibrosis and parasitic infestation.

MALLORY-WEISS TEARS. Mallory-Weiss tears consist of a laceration at the gastroesophageal junction that may extend through the muscularis mucosae. The tears, which are more often on the gastric side, follow forceful emesis or repeated retching. Although blood loss is usually negligible, they may cause massive upper GI bleeding, and are often difficult to diagnose without careful upper endoscopy. Clinicians have reported the existence of Mallory-Weiss tears in children as young as 16 weeks of age. Bleeding usually stops spontaneously.

GASTRITIS/STRESS LESIONS. Erosions of the intestinal mucosa may occur acutely following major trauma, burns, shock, or severe sepsis. These lesions are superficial, multiple, and occur mostly in the fundus of the stomach. The pathogenesis of these lesions appears to involve a decrease in gastric mucosal protective factors combined with an increase in luminal irritants such as acid and bile.

ACID-PEPTIC DISEASE (SEE Acid-Peptic Disease AND *Helicobacter Pylori* Infection). Peptic ulcers may present as hematemesis, melena, or both. About 25% of children with peptic ulcers present with GI bleeding.

PORTAL HYPERTENSION AND VARICES. Obstruction to portal venous flow leads to **portal hypertension,** with subsequent **esophageal or gastric varices** and splenomegaly with hypersplenism. Prehepatic portal vein obstruction usually follows neonatal events such as omphalitis or catheterization of the umbilical vein with subsequent thrombus formation. Intrahepatic causes are usually secondary to cirrhosis, such as in cystic fibrosis or biliary atresia.

The risk of bleeding is more likely related to increased portal vein pressure and the diameter of the varices, augmented by coagulopathy/thrombocytopenia if present. Excessive transfusion of these patients can promote continued bleeding. If bleeding does not cease spontaneously, intravenous octreotide is given. Banding or injection sclerotherapy is extremely effective in controlling variceal bleeding, but it is preferable to perform these procedures on an elective, rather than on an emergent basis. Balloon tamponade should only be performed when experienced personnel are present, due to high incidence of adverse outcomes otherwise. Emergency surgical interventions for acute bleeding such as vascular shunting or esophageal transection with devascularization are associated with a high morbidity; it is essential to avoid them, if at all possible. However, elective surgical shunts are often considered when repeat bleeding occurs in a child whose underlying disorder will not be better addressed by liver transplantation.

INTUSSUSCEPTION. Intussusception is the invagination or telescoping of one portion of the intestine into itself. The majority of cases occur in children younger than 2 years of age. Clinically, intussusception produces intermittent, colicky abdominal pain interspersed with intervals in which the patient appears perfectly well. After several episodes of such pain, vomiting and blood per rectum may be seen, but it is important to note that intussusception may present in atypical fashion. Apathy and altered states of consciousness may be the only signs. This presentation makes diagnosis difficult unless the clinician has a high index of suspicion.

Pathologically, the mesentery of the invaginated bowel becomes entrapped, causing venous compression and edema. This process continues until the tissue pressure exceeds arterial inflow pressure, with resultant cessation of arterial circulation and ischemia.

Early in the progression of the intussusception, there may be few significant findings. Later, a mass, which is often sausage-shaped, may be palpable. The majority of intussusceptions involve the ileocecal junction.

In children older than the usual age range, one considers a "pathological lead point" which may be a polyp, Meckel diverticulum, enteric duplication, or (rarely) lymphoma. In the usual child from the common age group, no identifiable lead point pathology is apparent, but a variety of viral infections causing enlarged Peyer patches have been implicated. In Henoch-Schönlein purpura small bowel to small bowel intussusception can take place, probably due to the edema and hemorrhage in the intestinal wall creating a lead point.

The barium enema was the hallmark of diagnosis and treatment in the past; now the diagnosis is made with ultrasound in many centers, and reduction is done using air or saline with ultrasound guidance. If contrast is used, water-soluble contrast is preferred over barium in case perforation occurs. Hydrostatic reduction is successful in about 85% of cases. Surgical intervention is necessary if there is evidence of peritonitis or perforation, or there is increased risk of these due to prolonged intussusception; if nonoperative reduction is incomplete; or a pathologic lead point is suspected on imaging. Recurrent intussusception following hydrostatic reduction occurs in about 5% to 10% of patients. Multiple recurrences can occur in the same patient, and in each occurrence the appropriate therapy is still enema reduction.

OTHER CAUSES OF BLEEDING. Important causes of GI bleeding such as Meckel diverticulum and enteric duplications are described in previous section. In addition, many systemic diseases associated with vasculitis and microangiopathy may have GI bleeding as one of their manifestations. **Henoch-Schönlein purpura,** the most common vasculitis of childhood, may have rectal bleeding or hematemesis as part of its clinical picture; but the classic features are abdominal pain, nephritis, lower extremity and buttock purpura, and arthralgia. This IgA-mediated vasculitis leads to edema and hemorrhage into the GI wall, causing pain and bleeding. As mentioned previously, these areas of submucosal edema and hemorrhage may become the lead point for an intussusception.

Bloody diarrhea may often be the presenting symptom of **hemolytic-uremic syndrome**. A verotoxin produced by *E. coli* 0157:H7, or the cytotoxin such as shiga produced by *Shigella dysenteriae,* may induce this microangiopathy. The GI symptoms of severe abdominal pain and bloody diarrhea may be secondary to the infection or may be related to thrombosis of intestinal blood vessels. Other features are thrombocytopenia, hemolytic anemia, and acute renal insufficiency. Other vasculitic disorders such as collagen vascular diseases can cause lower GI bleeding, as can vascular anomalies of the GI tract.

Management

Treatment is disease specific (see Differential Diagnosis). Most often, physicians in GI and pediatric surgical subspecialties are involved in diagnosing the etiology and guiding the management of individual children.

INFLAMMATORY DISEASES OF THE BOWEL

IBD, which includes ulcerative colitis and Crohn disease, is a major cause of chronic pediatric GI disease. Epidemiologic studies of IBD in children are limited. The incidence of IBD, which is highest in northwestern Europe and North America, is more common among whites than nonwhites. Males and females are equally affected. Susceptibility appears to be increased for Jews, especially those of a middle European background. Researchers have clearly shown the family aggregation of IBD. At the time of diagnosis of either ulcerative colitis or Crohn disease, the chances of finding IBD in a first-degree relative of the proband are 5% to 25%.

Pathophysiology

Despite great efforts from many research groups, the specific etiology and pathophysiology of IBD are still unclear. To date, no convincing evidence implicates a viral, chlamydial, bacterial, or mycobacterial pathogen as the causative agent. However, it is possible that any or all of these agents may trigger the disease in genetically predisposed patients, those less able to "downregulate" an inflammatory response. Defects in immunoregulation involving the gut-associated lymphoid tissue and the complex mixture of antigens and pathogens in the bowel lumen may play a major role in the development and progression of the diseases. In small subsets of patients, susceptibility genes have been identified.

Chronic **ulcerative colitis** and **Crohn disease** are the major inflammatory diseases of the intestine. Those affected frequently present as adolescents, but increasing numbers of children younger than 12 years of age have received these diagnoses, and there are several reports of patients under the age of 5 years.

Ulcerative colitis and Crohn disease have disease-specific differences but share many signs and symptoms. Ulcerative colitis is defined as a chronic inflammatory process limited to the **mucosal** layer of the large intestine.

Crohn disease, on the other hand, is a chronic **transmural** inflammatory process, involving noncaseating granuloma formation, which may involve any portion of the GI system from the mouth to the anus, frequently the ileum.

Clinical and Laboratory Evaluation

History

Abdominal pain and **diarrhea** are the most common complaints of children with IBD, both at initial diagnosis and at relapse. These symptoms may be nocturnal and awaken the patient. Decreased oral intake is a (sometimes subconscious) consequence of pain or diarrhea after a eating. The history should include questions about poor growth, hematochezia, low-grade fever, fatigue, arthralgia, and oral ulcerations, as well as family history of IBD.

Pediatric Pearl: The occurrence of nocturnal pain and diarrhea that awakens the patient helps distinguish IBD from IBS, in which symptoms tend to occur only when the patient is awake.

Physical Examination

Children and adolescents with IBD may have a normal examination or a myriad of clinical manifestations, such as poor growth, pallor, cachexia, and pubertal delay. Findings that should alert the physician include perianal lesions, oral ulcerations (although these can also be viral in etiology), and rashes such as erythema nodosum. The abdominal examination may reveal a tender, indistinct mass or "fullness" in the right lower quadrant in the child with Crohn disease.

GASTROINTESTINAL MANIFESTATIONS. The **abdominal pain** of IBD tends to be crampy, usually localized to the lower abdomen. The **diarrhea** may be of variable volume with small volume stools often being accompanied by tenesmus or urgency. These symptoms suggest active inflammation in the distal rectosigmoid. Visible **blood per rectum** is suggestive of active colonic inflammation in IBD, whereas Crohn disease of the small bowel is more frequently associated with occult blood or no blood at all. In a subgroup of patients with IBD, blood loss may be brisk, causing severe anemia, hemodynamic abnormalities with orthostatic changes, and requiring aggressive intervention.

EXTRAINTESTINAL MANIFESTATIONS. An important part of the clinical picture of IBD is the wide range of extraintestinal manifestations that can be seen in children with ulcerative colitis and Crohn disease (Table 15-8). The extraintestinal problems may present before the onset of intestinal symptoms or at any time after the diagnosis has been made.

It is important to remember that many patients with IBD, especially with small bowel Crohn disease, may present with more subtle findings and have little or no intestinal findings. The presentation may be one of poor growth and sexual retardation, fever of unknown origin, arthritis, perianal disease, or a seeming feeding disorder. **Anorexia** is common and is frequently associated with inadequate intake of micro- and macronutrients. In Crohn disease there may be early satiety with solid foods, reflecting upper GI involvement.

Perianal lesions, which are by far the most common of the extraintestinal problems, are also the most difficult to treat. These consist of fissures, large anal tags, fistulae, and abscesses. Because these lesions may precede the classic signs and symptoms of IBD, it reinforces the importance of the clinician doing an adequate perianal evaluation in all children with unexplained GI illness.

Delayed growth and sexual maturation, which is common in Crohn disease, may be the most devastating part of IBD for adolescents. In contrast, growth retardation infrequently affects patients with ulcerative colitis. Severe linear growth retardation occurs in about 30% of children with Crohn disease and the growth impairment frequently antedates the diagnosis, may precede weight loss, and may be the earliest indicator of the disease. Experts have attributed this marked growth delay to a combination of factors, including inadequate caloric intake, chronic inflammation and hypermetabolism, excessive enteric protein loss, and some degree of malabsorption.

Fever, usually low-grade, occurs in 25% to 50% of children with IBD. It often has no discernible focus of infection, and may be a diagnostic and therapeutic dilemma. **Anemia** is common and usually results from a combination of blood loss and decrease in iron absorption.

TABLE 15-8

Extraintestinal Manifestations of Inflammatory Bowel Disease

Perianal disease
Hepatobiliary disease
Mouth lesions
Cutaneous lesions
Vasculitis
Vascular thrombosis
Anemia, thrombocytosis
Arthralgias/arthritis
Ocular disorders
Myocarditis, pericarditis
Nephrolithiasis
Pancreatitis
Pulmonary fibrosis

Although **arthralgias** are common, frank arthritis occurs infrequently in children and adolescents with IBD. Joint deformities, resulting from chronic inflammation, are very rare in IBD and should suggest the possibility of another autoimmune disease such as rheumatoid arthritis or systemic lupus erythematosus. Aseptic necrosis of the hip is quite rare, even if the particular child or adolescent is undergoing chronic steroid therapy. Adolescents with IBD often complain of chronic lower back pain and tenderness. A few have sacroiliitis, but in most, diagnostic studies reveal no specific skeletal or joint abnormality, but signs and symptoms often remit with NSAIDs.

Liver involvement may take the form of **sclerosing cholangitis** in those with ulcerative colitis or mild elevation of the transaminases in Crohn disease. Confounding this picture is the fact that some IBD medications may have adverse hepatic effects.

Hypoalbuminemia, which is almost always seen with active IBD, results from protein loss due to bowel inflammation. This can be confirmed by looking for increased amounts of α1-antitrypsin in the stool. Protein malabsorption in IBD is usually not clinically significant. In addition, protein intake is usually adequate despite poor caloric intake.

Colorectal cancer is a formidable problem for patients with long-standing IBD. The two most important risk factors for developing colorectal cancer are disease duration and anatomic extent of disease. Therefore, it is recommended that all patients with colonic involvement, including those patients with Crohn colitis, should begin periodic colonoscopic surveillance after 8 to 10 years of disease. This suggestion most definitely pertains to children and adolescents with IBD, who have more years of disease ahead of them.

Laboratory Evaluation

In IBD, the ESR is often elevated, but normal values may be seen even in acute fulminant colitis. If the ESR is elevated, it points to IBD rather than IBS, in which laboratory data should be normal. Evaluation of stool cultures and analysis of stools for ova and parasites, *C. difficile* toxin, and WBC is necessary. A low serum albumin indicates protein loss from inflamed bowel mucosa, whereas low serum cholesterol often reflects loss of bile salts in the feces due to the presence of significant ileal disease. The serum immune markers antineutrophil cytoplasmic antibody (ANCA) and anti–*Saccharomyces cerevisiae* antibody (ASCA) have been used to help in differentiating IBD from other entities and to distinguish IBD types; their role in the evaluation of these patients has been a matter of some controversy. ANCAs are present in the sera of 60% to 80% of patients with ulcerative colitis, in less than 20% of patients with Crohn disease, and in about 6% of the general population. ASCAs are present in 60% to 70% of patients with Crohn disease and very infrequently in patients with ulcerative colitis or in children without IBD.

Upper and lower endoscopies, with multiple biopsies, are essential in the diagnostic evaluation of IBD. Imaging of the areas of the mid small bowel beyond the reach of the endoscopes has been achieved traditionally with a barium small bowel series, but magnetic resonance imaging is now capable of excellent intestinal delineation and is preferred in order to minimize radiation exposure in these patients, who are subject to repeated imaging during their lives. Capsule endoscopy has also been used to visualize small intestinal lesions, with some risk of the capsule lodging in a narrowed area.

It is very useful to determine growth velocity curves, Tanner staging for sexual maturation, and bone ages as a way of assessing a child's growth and development and potential for future maturation. A lactose breath hydrogen test may be helpful in determining whether milk can or cannot be used in the diet. It is also a good idea to perform a PPD skin test for tuberculosis at the time of diagnosis, in case steroid therapy or other immunosuppressant agents become necessary. Radiographs and bone scans are necessary in the child with chronic joint discomfort to determine whether the problem is related to osteonecrosis.

Differential Diagnosis

Despite these seemingly clear differences between ulcerative colitis and Crohn disease, it is often very difficult to distinguish between the two conditions when only colonic disease is found. Significant perianal disease or granulomas detected on biopsy allow the diagnosis of Crohn disease when GI inflammation is limited to the colon. Involvement of the rectum, once considered exclusive to ulcerative colitis, occurs in many children with Crohn disease. Moreover, the finding of a normal rectum through endoscopy, once thought of as inconsistent with ulcerative colitis, actually can occur with this disease. Biopsy specimens of mucosa that appears to be normal may show varying degrees of inflammation and granulomata (see Table 15-9).

TABLE 15-9

Endoscopic/Histologic Features of Inflammatory Bowel Disease (Colonic): Ulcerative Colitis Versus Crohn Colitis

Feature	*Ulcerative Colitis*	*Crohn Colitis*
Macroscopic		
Distribution	Continuous with rectum	Segmental
Rectal involvement	Usual	Usual
Terminal ileum	Normal, or "backwash ileitis" only	Often involved
Mucosa	Diffusely involved	Discrete ulcers, fissures, cobblestoning
Serosa	Usually normal	Congestion, thickening
Fistulas	Absent	Present
Pseudopolyps	Common	Common
Strictures	Uncommon	Common
Microscopic		
Inflammation	Diffuse, mucosal, submucosal	Patchy, transmural
Ulceration	Mucosal, submucosal	Deep
Crypt abscesses	Common	Common
Granulomata	Absent	Common (60%–75%)
Fibrosis (serosal)	Absent	Present
Terminal ileum	Usually normal	Often involved, stenotic, irregular
Symmetry	Usually symmetric	Often asymmetric

TABLE 15-10

Inflammatory Bowel Disease (Colonic): Differentiation by Imaging in Ulcerative Colitis Versus Crohn Colitis

Radiographic Feature	*Ulcerative Colitis*	*Crohn Colitis*
Foreshortening	Common	Common
Mucosa	Shallow ulceration, pseudopolyps	Longitudinal fissures, cobblestone appearance; pseudopolyps
Fistulas	Absent	Present
Sinus tract	Absent	Present
Strictures	Uncommon (suggests carcinoma)	Frequent

Certain imaging features may help distinguish ulcerative colitis from Crohn disease (Table 15-10). However, the distribution of the disease as shown by imaging examination (continuous versus segmental) is nonspecific; often, it does not reflect the extent of the inflammation. Barium enema studies may be normal in as many as 25% of children with inflammatory colitis that has been documented endoscopically and histologically, and are not recommended except perhaps in the specific situation when a stricture is suspected. Again, imaging modalities that can be diagnostic without radiation exposure are preferred.

The differential diagnosis of IBD is broad, and causes of chronic diarrhea, such as *C. difficile*, amebiasis, giardiasis, *Y. enterocolitica,* and *C. jejuni* must be entertained. In the appropriate setting, the diagnosis of tuberculosis, allergic enteropathies (including gluten-induced enteropathy), vasculitis, and neoplasms (especially intestinal lymphoma) must be considered.

Management

It is necessary to gear all therapeutic approaches to children and adolescents with IBD toward having the patient perform the functions of daily living as normally as possible. This means the suppression of incapacitating symptoms, promotion of normal growth and development, and control of complications. The clinician should take precautions to minimize medication side effects, and be aware of the level of nonadherence to medications that exists in populations of patients with chronic disease, especially adolescents coming to terms with their diagnosis.

Nutritional Support

Although the growth failure and sexual retardation in IBD is multifactorial, inadequate caloric intake seems to play a major role. It is necessary to provide nutritional support to provide adequate calories and the proper macro- and micronutrients orally, enterally, or parenterally.

Adolescents with IBD often require 80 to 90 kcal and 3.00 g protein per kg ideal body weight per day to achieve their height potential (healthy adolescents need 60 kcal and 2.25 g/kg/day). For children with asymptomatic or mildly symptomatic ulcerative colitis and Crohn disease but who have inadequate weight and height gain and delayed sexual maturation, the use of oral liquid supplementation is encouraged. Supplementing the usual diet with these drinks can result in adequate caloric intake and improved growth. However, many patients cannot or will not accept this approach because of the volume needed, the taste of the liquid, or the symptoms of gastric dysmotility.

Nasogastric infusions of formula also result in improved growth. The use of nocturnal nasogastric infusions after insertion of the tube by the patient at home allows for significant increases in weight and height and normal attainment of puberty. The approach, with the tube being removed in the morning, allows the patient to pursue normal activities. It permits flexibility because the feedings can be discontinued on weekends and vacations, if necessary. A gastrostomy tube may also be placed in selected situations. Substitution of a predigested formula for regular food can also be an effective primary treatment, which may appeal to those seeking to minimize medications.

High-calorie intravenous infusions through a central venous catheter during sleep also provide a source of increased calories, independent on intestinal function. The line is capped during the day, making normal activity possible. However, this approach is riskier than tube feedings because it can occasionally cause line sepsis or hepatobiliary dysfunction.

Medical Therapy

As previously mentioned, new evidence suggests that IBD is the result of defects in gut immunoregulation. Newer therapeutic modalities such as cytokine manipulation with "biologics" such as infliximab, an antitumor necrosis factor (TNF) antibody, are now in wide use in treatment of IBD. Other major modes of therapy are aminosalicylates, corticosteroids, immunosuppressive agents such as 6-mercaptopurine, and antibiotics. It is fascinating that some drugs are effective in one form of disease and not in another, giving rise to the exciting expectation that in the future deeper knowledge of a given patient's specific form of IBD will allow initial tailoring of the most effective drug regimen for that individual.

5-aminosalicylates. The mechanisms of action of the 5-aminosalicylate compounds are unclear but probably involve inhibition of cyclo-oxygenase, and, especially, lipoxygenase pathways as well as scavenging of oxygen radicals. Several oral and rectal preparations are now available. Some of the oral medications are effective in small bowel disease as well as the previously recognized colonic efficacy. In ulcerative colitis, preparations of 5-aminosalicylates are effective in newly diagnosed mild disease, active disease at relapse, and maintenance of remissions. In Crohn disease, 5-aminosalicylate preparations play a role in treatment of active colonic disease, and perhaps contribute to the treatment of active small bowel disease.

corticosteroids. Corticosteroids have long been the gold standard for treatment of moderate-to-severe ulcerative colitis and Crohn disease. As clinicians gain more experience and success with new methods of immunomodulation, long-term and recurrent steroid use is diminishing. Rectal corticosteroids, in foam or enema form, are often effective in children with mild active ulcerative colitis of Crohn colitis who have predominant symptoms of distal left-sided colitis such as tenesmus and urgency. These are often prescribed in conjunction with oral 5-aminosalicylate preparations. Although mucosal absorption of the rectal corticosteroids is small, some clinicians who are wary of any steroid effect are more frequently using rectal mesalamine in these circumstances with little loss of symptom control.

Oral or intravenous corticosteroid medication is usually effective in moderate-to-severe disease, but should not be relied upon for long-term management. After a remission is achieved, patients are slowly weaned and may begin taking a 5-aminosalicylate preparation, with the degree of colonic involvement often influencing this decision. Many gastroenterologists start immunomodulatory medication (6-mercaptopurine or azathioprine) early in Crohn disease treatment, as this maneuver is known to decrease the need for recurrent steroids. There are significant long-term complications of corticosteroid use, such as growth suppression, osteoporosis, hypertension, cataract formation, and aseptic necrosis of the bones. In addition, and most importantly in adolescents, the many disturbing cosmetic side effects from steroid use (cushingoid facies, hirsutism, striae, severe weight gain, acne) lead to poor compliance.

immunomodulator drugs. 6-Mercaptopurine is the most commonly prescribed immunosuppressive for adolescents with intractable Crohn disease. Studies have found that the drug is an effective long-term therapy. In addition, it has the important advantage of having a significant steroid-sparing effect, which is of particular benefit to growing children and adolescents. Potential side effects are neutropenia, serious infection and liver disease. Azathioprine is metabolized to 6-mercaptopurine; some practitioners are more familiar with this form, and for some patients it offers greater dosage flexibility. It is important to know that 6-mercaptopurine and azathioprine are not expected to produce benefit until 3 to 6 months after initiation, although exceptions to this have been observed. For this reason, a course of steroids with taper is often used as a "bridge" to the time the immunomodulator will exert its effect. Since metabolism of these drugs is variable in different patients making some more prone to toxicity, it is now recommended that activity level of the key drug metabolism enzyme, thioprine methytransferase (TPMT) be tested before beginning one of these drugs. An alternative is frequent CBC monitoring as treatment is started. One can also obtain levels of 6-mercaptopurine metabolites prior to deciding on dose escalation, or if toxicity (bone marrow suppression or hepatic disease) is suspected.

6-Mercaptopurine has efficacy in ulcerative colitis, but to a lesser degree than in Crohn disease. Methotrexate is also and effective steroid-sparing drug in Crohn disease, but whether it is efficacious in ulcerative colitis is unclear. Cyclosporine has been used in refractory ulcerative colitis, but has significant risk of toxicity. In treating refractory or recurrent ulcerative colitis medically, it is important to remember that surgery is curative and may be a better choice in the more difficult-to-control patient.

BIOLOGICS. Infliximab is clearly effective in Crohn disease, producing striking mucosal healing in many. It is also effective in ulcerative colitis, although apparently to a lesser extent. It is an antibody to TNF-α, and has become an alternative to repeated courses of steroids. It is given by infusion every 8 weeks, after "induction" with more frequent dosage. It is essential to rule out latent tuberculosis and to assess each patient for the possibility of latent coccidiomycosis and histoplasmosis before beginning therapy. Increased infection risk and infusion reactions are potential side effects. There are rare reports of fatal hepatic lymphoma in young patients on infliximab combined with 6-mercaptopurine or azathioprine, so many practitioners have decided to discontinue one of these drugs or the other. This is an area of controversy at present as remission appears to be prolonged when both drugs are used. Adalimubab, a humanized TNF-a preparation (infliximab contains murine elements) has also recently been used in children, mostly in those who have lost their response to infliximab over time.

ANTIBIOTICS. Metronidazole has been found to have a steroid-sparing effect on adolescents with active or steroid-dependent Crohn disease. The mechanism of action is unclear. A large number of adolescents on chronic metronidazole therapy develop paresthesias and dysesthesias, which are reversible with discontinuation of the drug. However, the frequency and severity of symptoms have limited the acceptance of this effective therapy. Other oral antibiotics such as ciprofloxacin may suppress symptoms of bacterial overgrowth in some patients with Crohn disease and are used more frequently when perianal disease is significant.

Surgery

ULCERATIVE COLITIS. Emergency surgical intervention may be necessary because of acute fulminant colitis, massive intestinal bleeding, free perforation, or toxic megacolon. Elective surgery is appropriate for dependence on growth-suppressive steroids, continuous debilitating symptoms despite medical therapy, or presence of dysplasia malignancy in surveillance biopsies. This surveillance is suggested for patients with ulcerative colitis and Crohn colitis for longer than 8 to 10 years.

Surgery in ulcerative colitis is curative and eliminates the risk of malignancy. The basic goals are to remove all the diseased mucosa while preserving stool elimination via the anus rather than by ileostomy. There are a variety of procedures, often done in two stages. Most involve creating of a "pouch" where the ileum is anastomosed to the anus, allowing less frequent stooling and greater continence. Postsurgical inflammation can occur in this area, which is referred to as "pouchitis" and is usually successfully treated with antibiotics.

CROHN DISEASE. Surgical intervention is recommended to deal with complications that are unresponsive to medical therapy, such as intestinal obstruction, perianal abscesses, and fistulae. Resection of a localized diseased segment may be preferable to chronic medications. Recurrence after surgical resection in Crohn disease is greater than 90%, so surgery should be considered after careful deliberation. Multiple small-intestinal resections may lead to a "short gut" problem. Patients with intestinal strictures leading to recurrent partial obstruction may undergo stricturoplasty, a bowel-sparing technique that creates a patent lumen.

LIVER DISEASE IN CHILDREN AND ADOLESCENTS

The understanding of the embryology and development of the fetal liver and the pathophysiology of pediatric liver disease has increased dramatically in the last two decades. Despite this increased knowledge, medical treatment of many of the hepatobiliary disorders of childhood has continued to be frustrating. However, optimism has arisen in view of the advances in gene therapy and the increased availability and improved techniques in liver transplantation.

NEONATAL CHOLESTASIS

Neonatal cholestasis is far less common than unconjugated hyperbilirubinemia. Despite its relative infrequency, neonatal cholestasis is always pathologic. Therefore, the clinician should consider the possibility of cholestasis in a jaundiced infant.

Pathophysiology

Cholestasis refers to impedance to bile acid formation or flow and is evidenced by elevated **conjugated or direct hyperbilirubinemia**. NASPGHAN has defined an elevated direct bilirubin as greater than 1.0 if the total bilirubin is less than 5.0; and greater than 20% of the total bilirubin if the total bilirubin is greater than 5.0. Unlike neonatal unconjugated (indirect) hyperbilirubinemia, which is more frequently physiologic rather than

pathologic, **conjugated hyperbilirubinemia should always be viewed as abnormal** and should not be ignored. Early recognition of cholestasis in infants and prompt diagnosis of the underlying disorder are imperative to identify those disorders that respond to specific treatment. It is therefore recommended that any jaundiced infant have total and direct bilirubins checked at 2 to 3 weeks of age. Several conditions may cause neonatal cholestasis (Table 15-11).

Clinical and Laboratory Evaluation

The key to the evaluation of infants with cholestasis is to determine which of them have conditions that are surgically correctable (biliary atresia, choledochal cyst) or amenable to treatment with diet and medication (e.g., tyrosinemia, galactosemia, hypothyroidism). Prompt diagnosis and therapy may have tremendous implications for prognosis.

TABLE 15-11

More Common Causes of Neonatal Cholestasis

Obstructive
Biliary atresia
Choledochal cyst
Gallstones/biliary sludge
Inspissated bile (due to hemolysis)
Alagille syndrome (biliary hypoplasia)

Galactosemia
Progressive familial intrahepatic cholestasis
Cystic fibrosis
Toxic
Total parenteral nutrition
Drugs

CMV, cytomegalovirus.

History and Physical Examination

Most infants with neonatal cholestasis present with jaundice, dark urine, acholic stools, and varying degrees of hepatomegaly. It is necessary to evaluate infants for evidence of congenital anomalies, splenomegaly, skin rash, and neurologic signs.

Pediatric Pearl: Note that patients with extrahepatic biliary atresia, choledochal cyst, and many of the intrahepatic causes of neonatal cholestasis look remarkably well despite the jaundice. On the other hand, infants with cholestasis who appear toxic should point the clinician toward an infectious or metabolic etiology.

Laboratory Evaluation

Urinary tract infections are an important cause of cholestasis in otherwise well-appearing infants, so urinalysis and culture should be routinely included in the initial stages of evaluation. The newborn screen results should be reviewed, with particular attention to the possibility of hypothyroidism, galactosemia, and cystic fibrosis. Urine-reducing substance (for galactosemia) and additional infant testing for thyroid function can also be considered. Knowledge of any maternal–infant blood group incompatibility is useful, as hemolysis can contribute to cholestasis via inspissated bile. CBC may provide evidence of sepsis or hemolysis. Liver enzymes ALT, AST, alkaline phosphatase, and GGT are included in the evaluation, although none is capable of diagnosing a particular condition. Protime/INR and albumin are tests of hepatic protein synthetic function. Protime/INR can also be prolonged due to cholestasis-caused vitamin K malabsorption; seeing the effect of parenteral vitamin K quickly clarifies this. α-1-antitrypsin phenotype (or level, if phenotype unavailable) is obtained, but subsequent diagnostic efforts are directed at the timely diagnosis of conditions requiring surgery (biliary atresia and choledochal cyst). Once these have been excluded, blood tests can be done looking for viral infections and more unusual metabolic/genetic disorders. At that point tests that may be done are titers for toxoplasmosis and cytomegalovirus (the latter also detectable in urine viral culture), serum ferritin, and urine organic acid screen (looking for elevated succinylacetone, found in tyrosinemia). Pregnant women are screened in the United States for several intrauterine infections (syphilis, rubella, herpes, and hepatitis B), but in selected situations titers for these may be sent from the infant as well. Detailed ophthalmologic examination may reveal findings associated with infantile cholestasis conditions: posterior embryotoxon of the anterior chamber seen in Alagille syndrome, septo-optic dysplasia associated with hypopituitarism, cataracts due to galactosemia or intrauterine viral infections, and chorioretinitis due to intrauterine viral infection.

Hepatobiliary ultrasonography can make or exclude the diagnosis of choledochal cyst, as well as suggest (but not diagnose or rule out) biliary atresia. **Hepatobiliary scintigraphy** (e.g., HIDA scan), after 3 to 5 days of premedication with phenobarbital, is used by many to exclude biliary atresia, if the test is negative (isotope passing from the liver into the intestine). However, if liver biopsy is available, HIDA scan in the evaluation of neonatal cholestasis is not recommended in current NASPGHAN guidelines, as it delays the diagnostic process and is usually not reliable enough to avoid the more definitive biopsy. Overall, a **liver biopsy** may ultimately be necessary to ascertain the diagnosis in a cholestatic infant.

Differential Diagnosis

Although the differential diagnosis of neonatal cholestasis is varied, the clinical presentation in many of these disorders is similar, reflecting a similar response to the underlying decrease in bile flow. The most common hepatic disorders causing neonatal cholestasis in full-term infants are biliary atresia, some of the idiopathic causes (paucity of intrahepatic bile ducts and idiopathic neonatal hepatitis) and α-1-antitrpsin deficiency. **Biliary atresia** appears to be related to a perinatal inflammatory process that continues postnatally, finally obliterating part of the extrahepatic tree. The process usually involves the intrahepatic structures as well but to a lesser degree. The etiology is unknown, and very likely there are a variety of possible causes, including genetic ones. Infants may present with cholestasis within days of birth, or be recognized as otherwise healthy but jaundiced babies at 1 to 2 months of age. Their overall healthy appearance underscores the wisdom of checking total and direct bilirubin values of all jaundiced infants at 2 to 3 weeks of age. Stools eventually become acholic but may fool parents and physicians, as instead of being white, they are far more often pale yellow or pale green.

Paucity of intrahepatic bile ducts is being recognized more frequently as a cause of neonatal cholestasis. The syndromic form, **Alagille syndrome** (arteriohepatic dysplasia), consists of paucity of the intrahepatic ducts, hypoplasia (but not atresia) of the extrahepatic ducts, and cardiac lesions (valvular or peripheral pulmonic stenosis), along with classic facies, butterfly vertebra, posterior embryotoxon in the eye and renal dysplasia. Growth failure and mild mental retardation is also seen. The nonsyndromic form of paucity of intrahepatic ducts is probably a morphologic endpoint to multiple different insults to the neonatal liver. It may occur frequently in sick neonates and prematures who have hypoxia, hypoperfusion, and sepsis. The prognosis for the syndromic form is usually better. Liver biopsy is key in diagnosis.

Management

If a percutaneous liver biopsy shows bile duct proliferation (a manifestation of biliary atresia), exploratory laparotomy with intraoperative cholangiogram is performed. If the procedure confirms biliary atresia, a Kasai procedure (portoenterostomy) to connect the bowel lumen with the porta hepatis is carried out. If the surgery is successful, bile drainage occurs. Success is often related to early operation. The Kasai procedure is palliative, not curative, and a liver transplant is usually necessary eventually, due to ongoing intrahepatic disease leading to cirrhosis.

ACUTE AND CHRONIC HEPATITIS

In the last few years, clinicians have learned a great deal about the viruses that cause hepatitis. There are at least five such viruses, causing hepatitis A, B, C, D, and E. These viruses are different from other viruses that cause hepatic inflammation (e.g., Epstein-Barr virus, herpes virus, cytomegalovirus) because in general they cause hepatitis itself rather than a wider clinical illness that may include hepatitis. Hepatitis D infection, which occurs only in conjunction with hepatitis B infection, is very infrequent in the United States, and hepatitis E has been found only in Americans who have traveled to endemic areas.

Hepatitis A

The incidence of infection with hepatitis A (HAV), a RNA picornavirus, has been declining steadily in the last 25 years as sanitary conditions have improved. However, the exact incidence is difficult to ascertain, because so many cases are subclinical or anicteric and therefore are not reported. The transmission of HAV is almost always by the fecal–oral route, although percutaneous transmission may occur. The incubation period is 25 days. The diagnosis is made on serologic grounds based on an IgM antibody that is first seen at the onset of clinical symptoms (about 5 weeks after exposure); it is evidence of acute infection. This antibody remains positive for 4 to 12 months. The IgG anti-HAV antibody, which develops at the end of the infection and remains positive for many years, is evidence of previous HAV infection.

Symptoms of HAV are increasingly apparent in accordance with increasing age. Eighty-five percent of children younger than 2 years of age who are infected are asymptomatic, as are 50% of those 2 to 4 years of age. Adolescents are usually symptomatic; 75% to 97% are ill, and 40% to 70% are icteric. Nausea, vomiting, malaise, anorexia, and cholestatic jaundice with pruritus (bilirubin greater than 10 mg/dL) may be severe, but almost all patients recover without evidence of fulminant hepatitis or chronic liver disease.

No therapy is indicated, but immunoglobulin given prior to exposure or during the incubation period of HAV is protective against clinical illness. Close personal contacts and household members of patients with HAV should receive immunoglobulin within 2 to 4 weeks of exposure, but treatment of casual contacts such as schoolmates is not necessary. HAV vaccination has now become a part of the routine childhood vaccine administration schedule.

Hepatitis B

Hepatitis B virus (HBV), a DNA hepadnavirus, is most often transmitted parenterally and has an incubation period of 45 to 75 days. The presence of surface antigen to the virus (HBsAg) signifies infection with HBV. In this era of routine hepatitis B vaccination and a standard protocol for pregnant women who test positive for HBsAg, the most frequently seen patients in the United States today are those who were infected at birth in another country or who failed to respond to the combination of hepatitis B immunoglobulin and vaccine given to infants born in the United States to positive mothers. These children, who are generally asymptomatic and

often have normal liver enzymes, in prior times would have been termed "carriers." Now that measurement of hepatitis B viral DNA level is possible and most of these patients are found to have high levels, they are better understood as having "chronic hepatitis B in the immune tolerant phase."

In children who are infected after infancy when the immune system is mature, antigenemia may appear early in the illness and may diminish before the symptoms have disappeared. Therefore, a second marker such as hepatitis B core antibody (anti-HBc) is usually needed to confirm the diagnosis of acute infection. Although the hepatitis B e antigen (HBeAg) is not necessary for diagnosis, it is an important marker, indicating viral infectivity. It is usually present when the disease was acquired at birth, with the corresponding antibody (HBeAb) absent.

Adolescents who acquire infection commonly have clinical evidence of fever, malaise, anorexia, nausea, and vomiting. Twenty-five percent of adolescents are icteric. In as many as 10% of cases, extrahepatic (immune complex) symptoms predominate. A common presentation is a "serum sickness-like" illness with urticaria, arthritis, angioedema, and a maculopapular rash. Other presentations include nephritis, nephrosis, myocarditis, and pancreatitis.

Hepatitis B treatment is not recommended for those with normal ALT, given limited efficacy of the currently available drugs in this situation. The patient should avoid unnecessary medications, excessive alcohol and illicit drugs, and should be vaccinated against HAV. Education on modes of infectivity should be provided. Household members should be immunized against hepatitis B unless they are already known to have the infection or natural immunity. There is no reason to inform school personnel of the child's status, because universal precautions for blood and fluid exposure should be in place. If ALT rises, consideration can be given to a liver biopsy to better evaluate the degree of damage, and treatment with either interferon or one of the long-term oral antivirals. Those with chronic hepatitis B should be screened for hepatocellular carcinoma with α-fetoprotein yearly and with a liver ultrasound approximately every 2 years.

Hepatitis C

In the United States, hepatitis C (HCV), a RNA flavivirus, causes the vast majority of cases of non-A, non-B hepatitis. Transmission is predominately parenteral. Sexual and perinatal transmission may occur (at a low frequency), and household contacts may be at risk. Antibody against HCV (anti-HCV) signals infection and probably infectivity, but not immunity. The antibody is not protective. Because there is a high false-positive anti-HCV rate with the enzyme-linked ummunoabsorbent assay (ELISA) method, all positive results should be confirmed with a recombinant immunoblot assay or polymerase chain reaction assay. Infants born to positive mothers may have antibody testing after 15 months of age (when potentially confusing maternal antibody will have cleared) and/or two determinations of hepatitis C RNA between 2 and 6 months of age. Even if found to be positive, treatment would not be considered in an infant, due to toxicity of hepatitis C medications in this age group, combined with uncertainty about the natural course of the disease.

Mortality from acute infection is less than 1%, but chronic disease occurs in approximately 50% of infected cases. This is usually manifested by a fluctuating pattern of aminotransferase elevation, which occurs in about 80% of chronic cases. Many patients with chronic disease develop chronic hepatitis, which may lead to cirrhosis and hepatocarcinoma. Again, the use of interferon-α and ribavirin in adults with chronic active HCV has been promising, and use in children can be considered on an individualized basis, depending on the genotype of the hepatitis C (some being significantly more responsive) and degree of illness. Many promising new hepatitis C medications are currently being reported in adult studies. Patients with hepatitis C should be vaccinated against HAV, as they are at risk for a more severe course.

OTHER CAUSES OF CHRONIC HEPATITIS

Other causes of chronic hepatic inflammation are steatohepatitis associated with obesity, drug hepatotoxicity, and Wilson disease; α_1-antitrypsin deficiency; and autoimmune hepatitis, hemochromatosis, cystic fibrosis, celiac disease, and IBD. The terms chronic active hepatitis and chronic persistent hepatitis are no longer used.

Fatty Liver Disease

Childhood fatty liver disease has increased at an alarming rate in the United States and has been, accompanied by the dramatic and widespread increase in obesity. Some of these children have more advanced disease, including fibrosis. Treatment is weight loss, but a more effective approach is preventing childhood obesity.

Autoimmune Hepatitis

Autoimmune hepatitis most frequently affects adolescent and young women. The clinical picture is variable. Affected patients may presents with (1) a prolonged typical attack of presumed viral hepatitis, (2) malaise with or without jaundice, or (3) hepatosplenomegaly found on a routine examination. In addition, these young women may have amenorrhea (primary or secondary), acne, erythema nodosum, arthritis, or arthralgia. Extrahepatic disorders such as thyroiditis, IBD, or nephritis may be present in many cases.

Patients with autoimmune hepatitis have elevated ALT and AST levels. In addition, they have markedly elevated serum IgG levels, usually detected on routine chemistry panels when the total protein is elevated and the albumin is normal or low. Two forms of autoimmune hepatitis are recognized, one in which antinuclear antibody and/or antismooth muscle antibody is elevated (type 1) and one more often associated with elevated liver–kidney microsomal antibody (type 2).

It is possible to diagnose autoimmune chronic active hepatitis by liver biopsy; an inflammatory reaction of plasma cells and lymphocytes extends beyond the portal area, eroding the limiting plate of the hepatocytes, causing individual (piecemeal) hepatocellular necrosis. If the cellular necrosis is more advanced, as it often is at diagnosis, areas of necrosis are replaced by fibrosis. Treatment with oral corticosteroids and 6-mercaptopurine (as a prednisone-sparing agent) is effective in many cases. Progression to cirrhosis may occur despite a good biochemical response to treatment, and may eventually lead to liver transplantation.

Wilson Disease

Wilson disease (hepatolenticular degeneration), an autosomal recessive disorder, results from excessive accumulation of copper in the liver, brain, eyes, kidneys, and bone. The abnormal gene that causes this condition is located on chromosome 13, and leads to impaired transport of copper out of the liver and into bile, where it would normally be excreted from the body. Although the accumulation of copper in tissues begins in infancy, clinical disease before age 6 years is rare. However, about 50% of patients develop symptoms by 15 years of age. Clinical manifestations include hepatosplenomegaly and jaundice in children, and in older patients. Coombs-negative hemolytic anemia, deterioration of neuropsychiatric behavior, and renal tubular acidosis. Kayser–Fleischer rings (golden discoloration in the limbic region of the cornea) are common and can be diagnosed by slit lamp examination.

No single test is diagnostic of Wilson disease, and the workup can be frustrating. However, it is necessary to explore all avenues if the disease is suspected because therapy is so effective. Low serum copper and low serum ceruloplasmin levels suggest the diagnosis, but both may be normal. Quantitation of the urinary copper level, which is usually extremely high in this disorder, is the best screening test, in association with a slit lamp examination. Once the diagnosis is established, treatment with D-penicillamine (a copper chelator) or trientine should begin. Maintenance options also include oral zinc. Prognosis depends on early diagnosis and effective removal of excess copper.

α1-Antitrypsin Deficiency

Homozygous α1-antitrypsin deficiency, an autosomal recessive disorder, is associated with neonatal cholestasis and childhood liver disease with chronic hepatitis, or early adult-onset emphysema. α1-antitrypsin, a glycoprotein produced by hepatocytes, inhibits trypsin, pancreatic elastase, and acid proteases of alveolar macrophages. Uninhibited proteolytic activity of these enzymes in the face of the disorder can cause liver, pulmonary, or pancreatic injury. The diagnosis is made by measuring levels of α1-antitrypsin or by doing a phenotype of the protease-inhibitor system. The abnormal form of A1AT found in the disease is trapped in the liver, such that excess A1AT is usually identified on liver biopsies in the face of deficiency elsewhere. There is no treatment at present, but liver transplantation is an option in cases with severe hepatic involvement.

Pancreatic Disease

Diseases of the exocrine pancreas are relatively uncommon in children. Many of the pediatric diseases that affect the pancreas are the result of inborn errors of metabolism such as cystic fibrosis and Schwachman-Diamond syndrome (pancreatic insufficiency, cyclical neutropenia, dysostosis, and growth retardation).

Pancreatitis may be secondary to duct obstruction or parenchymal inflammation, which causes release of proteases that cause more inflammation and edema. Causes include infectious agents (e.g., mumps, Epstein-Barr

virus, coxsackie B), drugs (e.g., valproic acid, L-asparaginase, prednisone, 6-mercaptopurine) trauma, gallstones, or diseases such as cystic fibrosis. Recurrent pancreatitis suggests abnormalities of triglyceride metabolism, an anatomic defect such as pancreas divisum (a failure of fusion of the dorsal and ventral embryonic pancreas) or a genetic disorder (e.g., cystic fibrosis). When pancreatitis recurs without obvious cause, magnetic resonance cholangiopancreatography is done to identify ductular strictures and other structural abnormalities, and testing is done for cystic fibrosis and other genetic causes of pancreatitis.

Patients with pancreatitis are often very toxic-appearing, with severe epigastric pain and nausea and vomiting. Laboratory findings include elevated amylase and lipase levels to at least 2 to 3 times the upper limit of normal. Abdominal ultrasonography or CT scan may be helpful. Treatment is directed at massive fluid replacement and pain control as part of general supportive care. Bowel rest and nasogastric decompression are rarely necessary. Nasojejunal tube feeding rather than total parenteral nutrition is now the preferred means of providing nutrients. Pseudocysts may form, and larger ones may require drainage or surgery.

Peritonitis

Peritonitis is defined as a chemical or infectious inflammation of the peritoneal lining of the abdominal cavity. Infectious peritonitis may be either primary or secondary. The clinical presentation includes fever, severe abdominal pain, and vomiting. However, corticosteroids may suppress the manifestations. Diagnosis is made by abdominal paracentesis that reveals organisms and many leukocytes.

Primary peritonitis, also called spontaneous or idiopathic peritonitis, is an infection of the peritoneal cavity in which the source of the infection arises outside of the abdomen and reaches it by either hematogenous or lymphatic spread. Most cases of primary peritonitis in children occur in patients with nephrotic syndrome or cirrhosis. The usual responsible bacteria in primary peritonitis are *Streptococcus pneumoniae* and gram-negative enteric organism such as *E. coli* and *Klebsiella pneumoniae*.

Secondary peritonitis is an inflammatory response to the rupture of an abdominal viscus, spillage of an abdominal abscess (e.g., with appendicitis), trauma, or a vascular accident. Enteric gram-negative organisms such as *E. coli* and anaerobic organisms such as *Bacteroides fragilis* are the most frequently found pathogens. Treatment is appropriate antibiotics.

Hematology and Oncology

Gary V. Dahl and Michael R. Jeng

HEMATOLOGY

Hematologic disorders of children may involve the cellular components (red blood cells [RBCs], white blood cells [WBCs], and platelets) or plasma components (coagulation factors) of blood. The fundamental pathophysiology underlying most hematologic disorders is based on the limited life span of marrow-derived blood cells. RBCs survive in the circulation for 120 days, platelets for approximately 5 to 10 days, and neutrophils for only 1 to 2 days. Either the senescent cells die or the reticuloendothelial system removes them from the circulation. The end-stage cells cannot replace themselves. (In contrast, lymphocytes, are generally long-lived, and travel among the blood, lymphatics, and tissues.) Because of the limited life span of RBCs, platelets, and neutrophils, the bone marrow must constantly produce new cells. Abnormalities that occur at any stage of this process result in various clinical presentations.

Hematopoiesis takes place in the bone marrow as a series of orderly, programmed steps in which mature blood cells are produced from immature progenitors. The majority of cells in the bone marrow are **committed** to one hematopoietic lineage; they have acquired characteristics of the appropriate lineage (e.g., hemoglobin for the RBCs, primary and secondary granules for the neutrophils). These **precursors**, which are recognizably differentiating into mature blood cells, progressively lose their ability to proliferate as they mature. Less mature cells in the bone marrow, the progenitors, are committed to one or more hematopoietic lineages but have not morphologically differentiated. Stem cells are the least mature progenitors and are capable of differentiating into all hematopoietic lineages (**pluripotentiality**) and can replace themselves (self-renewal).

Progenitors, which are extremely rare, represent less than 1/10,000 nucleated marrow cells. They are called **hematopoietic stem cells**. A single hematopoietic stem cell can give rise to over 1,000,000 mature blood cells.

Any sort of interference with the survival of the mature blood cells or the production of new blood cells may result in disease. Blood cell function is abnormal in some inherited diseases. These genetic conditions may result from mutations that affect the ability of the RBCs to perform gas exchange, the ability of the neutrophils to kill microorganisms, or the ability of the platelets to form primary blood clots.

The noncellular component of blood contains many essential proteins: the clotting factors required for blood coagulation, the immunoglobulins that serve as antibodies, and the complement proteins used for lysis of organisms that have been bound to antibodies. Much of pediatric hematology and immunology concerns inborn errors that result in nonfunction of these important proteins. Acquired illnesses that result in consumption of these proteins also occur.

BLOOD CELL DISORDERS

Disorders of blood cells can be classified as quantitative, qualitative, or both.

- The majority of clinical encounters in pediatric hematology are **quantitative disorders,** which are due to problems with decreased production of blood cells from the bone marrow or increased loss of blood cells from the circulation (Figure 16-1). In children, abnormally low blood counts are more common than abnormally high counts (i.e., anemia and thrombocytopenia are more common than polycythemia and thrombocytosis).

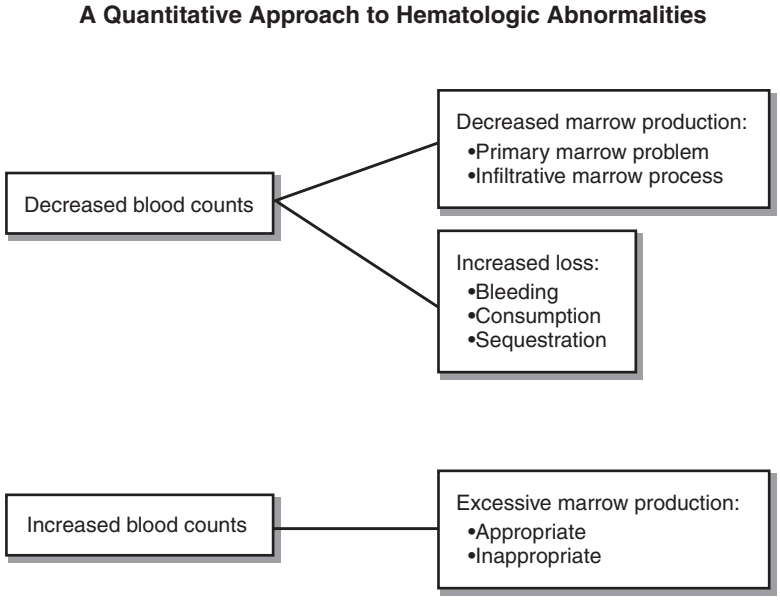

FIGURE 16-1. Significance of quantitative abnormalities in blood counts.

- **Qualitative disorders** are due to inherent abnormalities in the blood cells themselves and are less common. However, they often lead to quantitative problems as well (i.e., hemolytic anemia due to a qualitative abnormality in hemoglobin such as sickle cell anemia).

ANEMIA

Anemia is an abnormally low hemoglobin, hematocrit, or **RBC count**. It can be classified using the previously discussed production–destruction approach and a morphologic approach based on the appearance of the RBCs on a peripheral blood smear and RBC parameters such as **mean corpuscular volume (MCV)** and **mean corpuscular hemoglobin concentration (MCHC)**. Because the values of RBC parameters vary with age, the pediatrician must be aware of the normal age ranges before determining that a child has a microcytic, normocytic, or macrocytic anemia.

Clinical and Laboratory Evaluation

History

In evaluating children with anemia, a careful history is essential. It is necessary to ask about a family history of anemia, transfusion requirements of relatives, or histories suggestive of chronic hemolysis (e.g., splenectomy or gallbladder disease). A dietary history is essential for determining whether the intake of iron, folate, and vitamin B_{12} is adequate. In toddlers, a detailed history of the amount of milk intake is important, as well as specific questions regarding pica. Pica, or the habit of chewing dirt, paper, ice, or other material, is often seen with iron deficiency anemia. A history should also include assessment of possible lead exposure. Vegans (vegetarians who consume no animal food or dairy products) may develop folate deficiency. In addition, the onset of hemolysis in children with **glucose-6-phosphate dehydrogenase (G6PD) deficiency** is sometimes associated with intake of certain foods (e.g., fava beans) or exposure to naphthalene (moth balls). Questions regarding melena, hematochezia, hematemesis, or abdominal pain are appropriate; these may indicate chronic blood loss from the gastrointestinal (GI) tract. In adolescent girls, excessively heavy menstrual bleeding is noteworthy. Patients with hemolytic anemias may relate a history of dark-colored urine, icterus, or jaundice. Pallor may or may not be recognized by the family members, as this may develop very gradually. Symptoms of fatigue, shortness of breath, and increased heart rate may also be present and help in determining the cause of anemia.

Physical Examination

Physical signs of anemia include pallor of the skin, oral mucosa, conjunctivae, and nail beds. Infants with iron deficiency anemia secondary to excessive milk consumption are frequently overweight. Tachycardia may occur

as a physiologic response to anemia, and patients may also develop a systolic flow murmur. The presence of icterus or jaundice is a sign of hemolysis. The facial appearance of children with untreated thalassemia are altered by increased bone marrow production (medullary expansion). Children with Fanconi anemia often have microcephaly and an unusual bird-like facies, thumb abnormalities, café-au-lait spots , and are small for their age. Patients with Diamond-Blackfan anemia, a form of congenital anemia due to lack of production of red cells, may be small for gestational age, small for age with poor growth, have abnormalities of the thumb, and may have cleft lip and palates. Adenopathy should be carefully noted; it may indicate either infection or malignancy. Abdominal examination should focus on determining the presence of hepatosplenomegaly, adenopathy, mass, or tenderness. The extremity examination is important for diagnosing several underlying causes of anemia. Children with arthritis and a secondary anemia may have a systemic rheumatologic, oncologic, or infectious disease. Children with Fanconi anemia usually have absent or hypoplastic thumbs. Children with sickle cell disease have extremities that may show signs of acute swelling and tenderness due to sickling or osteomyelitis.

It is important to note that the signs and symptoms of anemia vary with the degree of anemia and the rapidity with which it has developed. When anemia has developed over a period, pallor, fatigue, headache, and lightheadedness are more likely. When the onset of anemia is fairly acute, cardiovascular symptoms related to reduced oxygen-carrying capacity and resultant tissue hypoxia are more common. In iron deficiency anemia, which occurs very gradually, often there is no change in heart rate or very little fatigue.

Laboratory Evaluation

A **complete blood cell count** (CBC) with red blood cell parameters (often referred to as red cell indices), peripheral blood smear, and reticulocyte count are part of the initial evaluation. The reticulocyte count and red blood cell distribution width (RDW or RCDW) may help to determine whether the anemia is due to poor production or increased destruction of red cells. To evaluate for a hemolytic anemia, a plasma-free hemoglobin, serum indirect bilirubin, and lactate dehydrogenase may be elevated while a haptoglobin will be decreased, as this is a scavenger for hemoglobin. A Coombs test may identify antibodies to the RBCs, red cell osmotic fragility for red cell membrane abnormalities, and red cell enzyme measurements may reveal an enzyme defect. Once a differential diagnosis has been generated from the clinical evaluation, CBC, and peripheral smear, other tests should be ordered judiciously. The laboratory evaluation of anemia can be expressed as an algorithm (Figure 16-2).

Differential Diagnosis

Anemias in children may be classified in terms of decreased RBC production, RBC destruction, RBC sequestration, or blood loss (Table 16-1). In addition, this group of disorders may be organized somewhat differently with the same primary categories (Table 16-2).

Management

The treatment of anemia is based on the underlying cause, the degree of anemia, and the clinical status of the patient. The approach to the management of anemia is twofold. One, the severity of the situation must be assessed for the necessity of immediate interventions such as blood transfusions or other supportive care. Two, the cause of the anemia must be determined. Most children with anemia that general pediatricians frequently encounter are not acutely ill, and a careful determination of the etiology is the first step.

Abnormalities of Erythrocyte Production

Anemias due to decreased RBC production are due to deficiencies of substances needed for the synthesis of erythrocytes (iron, B_{12}, or folate), exposure to toxins such as lead, suppression of production (such as that associated with viruses, which may be the mechanism for **transient erythroblastopenia of childhood [TEC]**), or a primary failure of erythropoiesis **(Diamond-Blackfan anemia or acquired aplastic anemia)**.

IRON DEFICIENCY ANEMIA. Classically, the cause of iron deficiency anemia in children is inadequate dietary intake of iron. The clinical scenario may be that of a toddler who is drinking large quantities of cow's milk from the bottle and eating little in the way of solid food. The lack of iron in cow's milk, combined with the exclusion of iron-rich food and chronic microscopic blood loss in the GI tract (thought to be microvillus sloughing due to inflammation associated with milk-protein exposure) leads to a **hypochromic, microcytic anemia**. The child can be quite anemic, with hemoglobin concentrations as low as 1 to 2 g/dL, and still be hemodynamically stable because of the gradual onset and the body's ability to compensate for a chronically decreased oxygen-carrying capacity.

Diagnostic Approach to Anemia

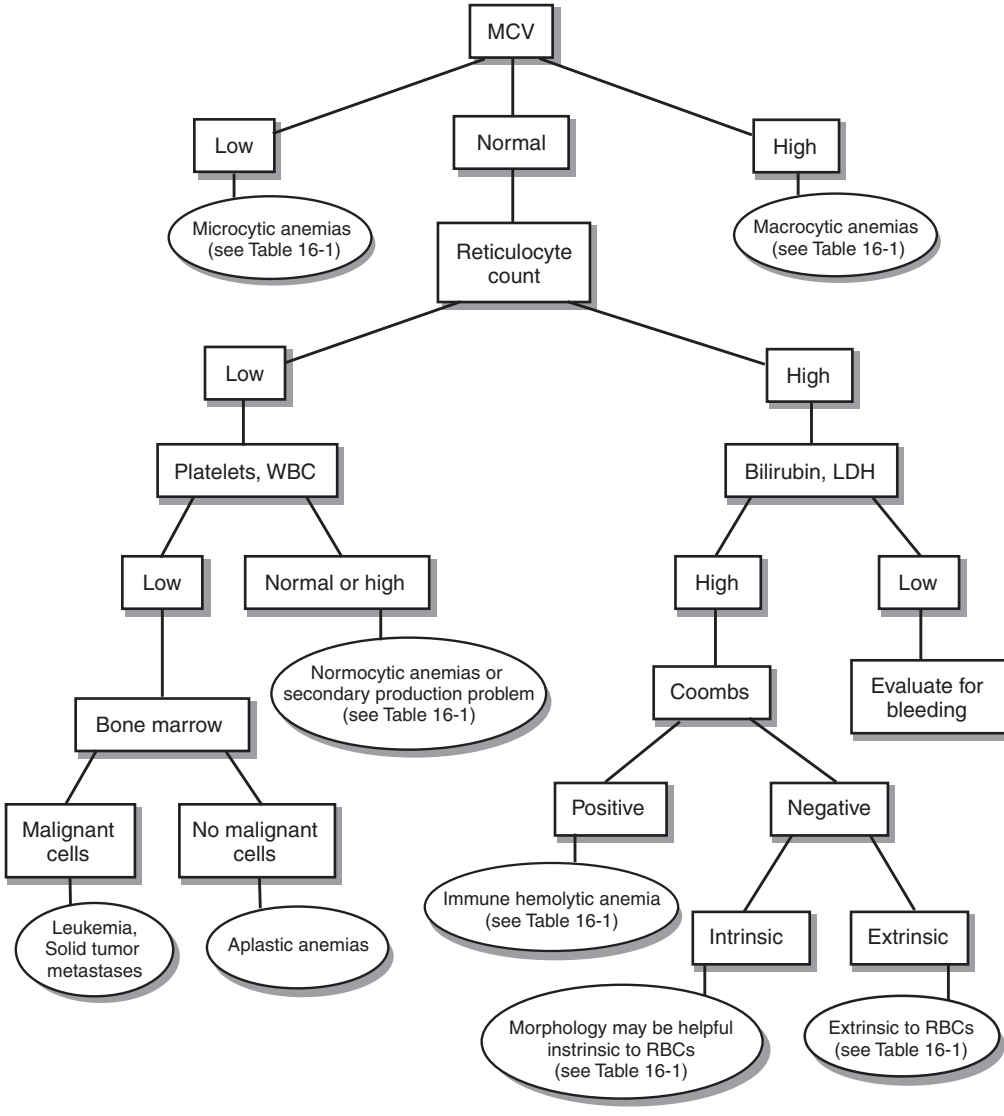

FIGURE 16-2. Diagnostic approach to anemia. Boxes represent diagnostic tests and results. Oval boxes represent diagnoses. *LDH*, lactate dehydrogenase; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC* , white blood cell.

In addition to a careful dietary history, laboratory studies to assess iron status are serum iron, ferritin (a measure of iron stores), and total iron-binding capacity (Table 16-3) may be necessary. Depending on the child's clinical state, if iron deficiency is the cause, the initiation of oral iron supplements results in a **reticulocytosis** in several days and a rise in hemoglobin. Consideration must also be given to the possibility of **lead poisoning** because iron deficiency is often seen in children who also have lead toxicity.

It is sometimes difficult to distinguish between iron deficiency and **thalassemia trait**. The **Mentzer index** can assist in the diagnosis of thalassemia trait during the assessment of microcytic anemia.

Pediatric Pearl: The Mentzer index, which is the ratio of the MCV to the RBC number, is useful as a screening test to differentiate between iron deficiency and thalassemia. If the MCV/RBC is less than 10, thalassemia is more likely; if it is greater than 14, iron deficiency is more likely. Values between 10 and 14 are considered indeterminate.

TABLE 16-1

Classification of Anemia *(Continued)*

Microangiopathic
Sepsis
Disseminated intravascular coagulation
Hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura
Prosthetic heart valve
Hypersplenism
Blood loss

[a]Thalassemia is included in both production and destruction categories.
[b]Diamond-Blackfan anemia may be macrocytic or normocytic.

Coexisting diseases (e.g., hemolysis) that alter the RBC value invalidate the Mentzer index as a diagnostic tool. Other tests that may be helpful are serum tests for iron stores and quantitation of subtypes of hemoglobin by hemoglobin electrophoresis (see Table 16-2). Once iron deficiency is excluded, the diagnosis of β-thalassemias depends on measurement of HgA_2 and HgbF levels. α-Thalassemia trait patients (two-gene deletions) will have a normal hemoglobin pattern, and the diagnosis is often one of exclusion. DNA testing now can be performed for α thalassemia trait, although it does not pick up all mutations. Thus, a history of nonresponsiveness to iron supplementation, normal iron studies, and perhaps a family history or documentation of microcytosis in a parent support this diagnosis.

VITAMIN B_{12} OR FOLATE DEFICIENCY ANEMIA. Deficiencies of vitamin B_{12} or folate, which are associated with **macrocytic (megaloblastic) anemia,** are seen less commonly than iron deficiency in pediatrics. Vitamin B_{12} deficiency may result from inadequate dietary intake (e.g., vegan diet) or inadequate intestinal absorption of vitamin B_{12} (e.g., inflammatory bowel disease, surgical resection of the terminal ileum, genetic defect in intrinsic factor, or rare parasitic infections). Folate deficiency may also result from inadequate dietary intake (intake of goat's milk instead of cow's milk) or inadequate intestinal absorption (inflammatory bowel disease). Treatment consists of administration of vitamin B_{12} or folate orally or intramuscularly. Laboratory testing of serum B_{12} levels and red cell folate levels is helpful, as is the testing of serum methylmalonic acid and homocysteine levels for B_{12} deficiency. Serum folate levels often reflect recent dietary ingestion and are less diagnostic than red cell folate levels.

TABLE 16-2

Alternative Classification of Anemias Due to Abnormalities of Production

Anemia Due to Deficiencies of Substrate
Iron deficiency anemia
Vitamin B_{12} or folate deficiency
Anemia Due to Suppression of Production
Transient or acquired
Transient erythroblastopenia of childhood
Aplastic crisis due to parvovirus B19
Congenital
Diamond-Blackfan anemia
Sideroblastic anemia
5′-Nucleotidase deficiency
Other conditions
Bone marrow infiltrative process
Anemia of chronic disease

TABLE 16-3

Laboratory Evaluation of Iron Deficiency Anemia and β-Thalassemia Trait

Feature	*Iron Deficiency Anemia*	*β-Thalassemia Trait*
MCV/RBC (Mentzer index)[a]	>14	<10
RBC morphology	Hypochromia	Target cells/hypochromia
Serum iron	Decreased	Normal
Iron-binding capacity	Increased	Normal
% Saturation	Decreased	Normal
Serum ferritin	Low	Normal
Hemoglobin A_2	Normal or Decreased	Increased
Hemoglobin F	Normal	Normal or increased

[a]indices between 10-14 are indeterminate
MCV, mean corpuscular volume; *RBC*, red blood cell.

TRANSIENT OR ACQUIRED SUPPRESSION OF ERYTHROCYTE PRODUCTION. Transient suppression of RBC production as an abnormal response to a viral infection is the suspected cause of **TEC**. Several viruses have been associated with this condition (e.g., human herpes virus 6). Children with TEC may require transfusion if they present with very low hemoglobin values without evidence of reticulocytosis. If reticulocytosis does not occur after several weeks, evaluation for other causes of hypoplastic anemia should proceed.

Pediatric Pearl: Children with chronic hemolytic anemia (e.g., sickle cell anemia, hereditary spherocytosis) who are dependent on a high reticulocyte count to maintain their hemoglobin are at risk for more severe anemia, or aplastic crisis, when reticulocytosis ceases as a result of viral infection. Classically, this is due to infection with **parvovirus B19**, which causes a brief period (usually 5 to 7 days) of reticulocytopenia. TEC is typically not due to parvovirus B19.

CONGENITAL SUPPRESSION OF ERYTHROCYTE PRODUCTION. Congenital anemias are rare, with **Diamond-Blackfan anemia** (DBA) being the most common. DBA manifests as either a normocytic or macrocytic anemia, and usually presents in the first year of life. Associated physical abnormalities occur in approximately 25% of cases (most commonly, radial and thumb abnormalities; sometimes abnormalities of the face and head). Recent studies have shown an abnormality in a ribosomal protein encoded on chromosome 19 in a subset of patients with DBA while other studies have shown linkage to chromosome 8. Bone marrow aspiration or biopsy, which may be warranted if DBA is suspected, shows marked reduction of RBC precursors. In addition, red cell adenosine deaminase levels are often elevated in DBA, aiding in the diagnosis. Treatment for patients with this condition includes corticosteroid therapy, chronic transfusion, and allogeneic bone marrow transplantation (BMT). Other congenital anemias due to lack of erythrocyte production include sideroblastic anemia and 5′ nucleotidase deficiency, which are even more rarely encountered.

SECONDARY CAUSES OF SUPPRESSION OF ERYTHROCYTE PRODUCTION. Infiltration of the bone marrow space can interfere with RBC production. Usually, this is also associated with leukopenia and thrombocytopenia. Diseases such as leukemia, solid tumor metastases, or rare stromal bone marrow disease (e.g., osteopetrosis) can be diagnosed with bone marrow studies.

Anemia of chronic disease, which is usually normocytic, should only be a diagnosis of exclusion in chronically ill patients when there is no other explanation for anemia. Although iron stores are normal, serum ferritin is often increased because of inflammation caused by the underlying condition. The inflammatory process does not allow utilization of iron stores, and thus a reticulocytopenia develops.

Abnormalities Due to Increased Erythrocyte Destruction

Hemolysis, or erythrocyte destruction, may result from a variety of causes. The hemolytic anemias are marked by RBCs with a shortened life span. Normally, RBCs survive in the circulation for 120 days. When the senescent

cells are removed by the reticuloendothelial system, the iron contained in the hemoglobin is recycled. The normal **reticulocyte count** of 0.8% to 1% reflects the need to replace approximately 1/120 of the RBC volume each day. If the production capacity of the bone marrow is normal, hemolytic anemias result in increased reticulocyte levels. Diseases that shorten the RBC life span can be **intrinsic** or **extrinsic** to the RBC. Intrinsic factors leading to hemolysis include mutations of the hemoglobin chains causing quantitative abnormalities of specific globin chains (thalassemia syndromes) or qualitative globin chain abnormalities (sickling syndromes), membrane abnormalities (hereditary spherocytosis and elliptocytosis), and red cell enzyme abnormalities (G6PD and pyruvate kinase deficiencies). Extrinisic factors leading to hemolysis include antibody-mediated hemolysis (autoimmune hemolytic anemia), an enlarged spleen leading to RBC sequestration, causes of microangiopathic hemolysis such as disseminated intravascular coagulation (DIC) or thrombotic thrombocytopenic purpura (TTP)/hemolytic-uremic syndrome (HUS), and prosthetic heart valves.

THALASSEMIAS. The thalassemias are the most common single gene disease in humans. They are a heterogeneous group of disorders of hemoglobin synthesis characterized by the absence or reduced output of either the α or β globin chains. If production of the α and β proteins is not balanced, then an abnormal hemoglobin results from the aggregation of the excess chains. The abnormal hemoglobin produced in the developing RBCs may be unstable, and thus die prematurely in the bone marrow (referred to as ineffective erythropoiesis). The resulting anemia leads to an increased stimulus for RBC production and increased RBC precursors in the bone marrow, and also the spleen and liver (extramedullary hematopoiesis). The unstable hemoglobin also leads to chronic hemolysis as evidenced by signs of increased bilirubin (icterus or jaundice).

Thalassemias are classified on the basis of whether production of the α-or β-globin chains is defective. The degree of clinical disease depends on the number of normal genes present. Humans normally have four α globin genes (chromosome 16) and two β-globin genes (chromosome 11). **α-Thalassemia** patients may have a deletion of one or more of the four α-globin genes. Patients with one deletion are referred to as **silent carriers** and have no hematologic abnormalies, whereas patients with two gene deletions have **α-thalassemia trait** and generally exhibit a mild anemia with microcytosis. Those patients with three deletions have a more severe microcytic anemia and are referred to as having α-thalassemia, or hemoglobin H disease because of the presence of hemoglobin H (tetramer of four β-globin chains). Deletion of all four genes usually results in fetal demise due to hydrops fetalis (**hemoglobin Bart hydrops fetalis syndrome**). Hemoglobin Bart is a homotetramer consisting of four gamma chains, which forms because no alpha chains are produced.

At birth the major hemoglobin is fetal hemoglobin, which is composed of two α- and two γ-globin chains. In contrast to the α-globin gene, β-globin is not expressed until after birth, when production of γ globin decreases. Levels of adult hemoglobin, composed of two α and two β-globin chains, are low at birth and increase gradually over the first few months of life. Thus, symptoms of β-**thalassemia** are usually not evident until after 6 months of age. Similar to α-thalassemia, the severity is related to the number of genes deleted; however, there are only two β-globin genes. To complicate matters further, some defective β-globin genes produce no β-globin at all (β^0 thalassemia), whereas others produce intermediate levels of β-globin (β+ thalassemia). Patients who are heterozygous for a β-globin deletion have β-**thalassemia minor** with a mild or moderate microcytic anemia that usually does not require transfusion. Patients who are homozygotes have β-**thalassemia major (Cooley anemia)** and suffer from severe anemia and hepatosplenomegaly that develops within the first year of life. If patients are not treated with regular red blood cell transfusions, then expansion of the bone marrow space and spleen (**extramedullary hematopoiesis**) results in characteristic abnormal facies and pathologic fractures of long bones, as well as splenomegaly.

The form of thalassemia most often encountered by general pediatricians is that of **thalassemia trait**, either alpha or beta. Because of genetic differences in populations, the more severe thalassemia syndromes occur more commonly outside of the United States. β-Thalassemia major is encountered in the Mediterranean, Asian, and African populations, and the α-thalassemia syndromes are encountered in the Asian and African populations. Typically, severe α-thalassemia is not seen in Africans because they tend not to have two gene deletions on the same chromosome (trans configuration).

Asymptomatic children with thalassemia trait usually present with **microcytic anemia** on routine screening for anemia. The primary considerations for initial management consist of excluding iron deficiency anemia or lead toxicity. Mild thalassemia syndromes usually require no specific treatment. Patients with β-thalassemia are treated with hypertransfusion regimens designed to maintain hemoglobin levels between 10 and 14 g/dL. Because of the repeated transfusions and the body's inability to excrete iron, these patients may develop the deleterious effects resulting from chronic iron overload, such as diabetes, growth hormone and gonadal failure, liver failure, and cardiac arrythmias and heart failure. Thus, it is imperative that these patients receive iron chelation therapy. For decades, subcutaneous or intravenous deferoxamine was the only available agent for iron chelation.

More recently, oral agents, such as deferasirox and deferiprone, have become available. Stem cell transplantation with a compatible sibling donor is the only cure for this disorder and has now become a major therapeutic option for patients with β-thalassemia major.

Genetic counseling at an appropriate age should be provided because individuals with the thalassemia trait can pass on the affected gene to their children, potentially resulting in one of the more severe thalassemia syndromes. Parents of newly identified patients should receive counseling regarding future pregnancies.

SICKLE CELL DISEASE. Sickle cell disease is a chronic hemolytic anemia caused by a point mutation in the β-globin gene, which results in the substitution of valine for glutamic acid in the sixth amino acid position of the β-globin chain. This abnormal hemoglobin polymerizes and condenses when it is in the deoxygenated state, leading to distortion of the RBC membrane and the characteristic sickle morphology. Sickle cells cause occlusion of vessels through their interactions with the vascular endothelium as well as cytokine release by activated WBCs and adhesive plasma proteins. The abnormal behavior of the sickle RBCs in the capillaries results in the characteristic painful crises and end-organ damage of sickle cell disease. Cells that leave the capillary bed become reoxygenated on entering the arterial circulation, reform to normal shape, but then enter the capillaries again. The chronically damaged RBCs have a shortened half-life (approximately 20 days), leading to hemolysis and anemia.

Patients suffering from sickle cell anemia (homozygous hemoglobin SS) typically have a hemoglobin level around 7 g/dL, an elevated WBC count, and a reticulocyte count of 10% to 25%. Characteristic sickle morphology is evident as well as target cells and poikilocytes. Hemoglobin electrophoresis shows the presence of hemoglobins S and F.

Homozygous hemoglobin S (sickle hemoglobin) is the most common sickling syndrome. Other sickling syndromes, which may be clinically indistinguishable from homozygous hemoglobin S, are the double heterozygote conditions of hemoglobin SC (hemoglobin C is another mutation in the β chain) and hemoglobin S-β thalassemia.

The clinical complications of sickle cell disease become apparent when affected children are at least 6 months old. Before that time, most of the hemoglobin is fetal hemoglobin, or hemoglobin F, which consists of two α chains and two γ chains. However, by 6 months of age, most of the hemoglobin is hemoglobin S, consisting of two α chains and two β^S chains (superscript S denotes the sickle mutation in the β chain).

The clinical result of hemoglobin S is vaso-occlusion and resultant tissue infarction. Acutely, the infarction produces pain that is often termed **pain crisis** or **vaso-occlusive crisis** due to small vessel occlusion and infarction of bone and bone marrow. In infants, vaso-occlusion usually presents in the hands and feet with soft tissue swelling and pain, called **dactylitis**. It is sometimes difficult to distinguish the bony pain and swelling of vaso-occlusive crises from osteomyelitis. In older children and adults, vaso-occlusive crises usually occur in the larger long bones, the back, and abdomen. The latter condition is easily confused with an acute abdomen due to infection. Sickling may also occur in the central nervous system (CNS) vasculature, resulting in strokes and infarction. Penile vaso-occlusion can produce painful priapism. Repeated vaso-occlusion over many years, whether symptomatic or asymptomatic, leads to chronic organ damage. Virtually every organ can be affected (Table 16-4). Of particular importance is the risk of complications due to chronic hemolysis (increased bilirubin causing gallstones and a shortened RBC life span leading to aplastic crisis).

The management of sickle cell disease begins at birth, with affected children most commonly identified by the nationwide newborn screening program. In addition to the well-child evaluations and anticipatory guidance that all children receive, children with sickle cell disease should be followed in a parallel manner by a pediatric hematologist (Table 16-5). Most important is the implementation of penicillin prophylaxis for children during infancy, which dramatically decreases the incidence of sepsis in these patients.

The management of the complications of sickle cell disease depends on their severity. Pain crises are treated with hydration and analgesia (nonsteroidal anti-inflammatory drugs such as ibuprofen or ketorolac or narcotics such as morphine). Infectious complications are treated with appropriate antibiotics. The management of other complications can be found in Table 16-4.

The only currently available definitive cure for sickle cell disease is a stem cell/bone marrow transplant (SCT). Because of the potential morbidity and mortality of SCT, this therapy is considered only if patients have had severe complications, such as a stroke, recurrent priapism, recurrent acute chest or pain crises. The main treatment for prevention of vaso-oclussion in sickle cell disease is hydroxyurea. Hydroxyurea is effective at increasing fetal hemoglobin concentration, and it appears to be well tolerated with mild, reversible myelosuppression. Patients who receive hydroxyurea have fewer painful and other acute vasoocclusive events.

OTHER HEMOLYTIC ANEMIAS. In children with hemolytic anemia, the history is frequently helpful in narrowing the diagnostic workup. However, laboratory tests are usually required for definitive diagnosis.

TABLE 16-4

Clinical Complications of Sickle Cell Disease

Organ/System	*Complication*	*Symptoms*	*Management*	*Other*
Bone	Infarction	Pain, tenderness, swelling	Hydration, analgesia	Dactylitis in infants
	Osteomyelitis	Fever, pain, tenderness, swelling	Antibiotics	Risk for encapsulated organisms such as *Streptococcus pneumoniae* and *Salmonella*
	Avascular necrosis of the femoral or humeral head	Hip or shoulder pain	Bedrest, Orthopedic interventions such as hip replacement	
Lungs	Acute chest syndrome	Chest pain, hypoxia, infiltrate on chest X-ray	RBC transfusion, oxygen, antibiotics	
	Chronic lung disease	Symptoms of pulmonary hypertension		
Central nervous system	Stroke	Paresis	Exchange transfusion, chronic transfusion therapy, BMT if sibling is an HLA-match	Transcranial Doppler studies to identify patients with high risk of stroke
Spleen	Sequestration	Splenomegaly, anemia, thrombocytopenia	Transfusion (simple or RBC)	Splenectomy after second sequestration
Immune system	Sepsis, infection functional asplenia	Fever and other symptoms, depending on site	Antibiotics, immunization,[a] penicillin prophylaxis	Risk for encapsulated organisms
Hematopoietic system	Accelerated hemolytic crisis	Symptoms of anemia, jaundice	Transfusion if needed, hydration	
	Aplastic crisis	Symptoms of anemia	Transfusion	Due to parvovirus B19
Skin	Ulceration of lower extremities			
Genitourinary system	Priapism	painful erection	Hydration, transfusion (simple or exchange)	
	Hyposthenuria	bedwetting		
Gastrointestinal system	Cholecystitis	Abdominal pain	Cholecystectomy	
Eyes	Retinopathy	vision changes	laser therapy	

TABLE 16-4

Clinical Complications of Sickle Cell Disease *(Continued)*

Cardiac system	Cardiomyopathy
Endocrine system	Growth and pubertal delay

[a] Particularly against encapsulated organisms such as Streptococcus pneumoniae and Haemophilus influenzae.
BMT, bone marrow transplantation, *HLA*, human leukocyte antigen.

A family history of hemolytic anemia suggests a genetic cause. Patients with hereditary spherocytosis are frequently treated with splenectomy; a family history of splenectomy is suggestive. Similarly, relatives may have a history of gallstones, which are common in chronic hemolytic anemias. Using the history to establish a pattern of hemolysis is sometimes helpful. Patients with chronic hemolysis from energy production defects such as pyruvate kinase deficiency or membrane defects may have long-standing histories of hemolysis, iron-unresponsive anemia, and jaundice going back to the neonatal period. Patients with G6PD deficiency or autoimmune hemolytic anemia are more likely to have a sudden onset of pallor, jaundice, and dark urine. G6PD deficiency is X-linked, and thus primarily affects males. Patients with G6PD deficiency may also have a history of drug ingestion, especially sulfa drugs, quinines, or nitrofurans, or eating of foods such as fava beans. Patients with autoimmune hemolytic anemia frequently have a history of antecedent infection.

The physical examination should focus on looking for signs of hemolysis and assessing the severity of anemia. Patients with severe hemolysis, especially of sudden onset, may have signs of high-output congestive heart failure. Jaundice is always present in patients with severe hemolysis. Splenomegaly is common in older children with RBC membrane defects.

Except in patients with an aplastic crisis caused by viral infection, the **reticulocyte count** is generally elevated in hemolytic anemias. Supportive evidence for the presence of hemolysis includes measurement of the serum bilirubin level lactose dehydrogenase (LDH) and the presence of urinary urobilinogen. The peripheral blood smear frequently indicates the diagnosis in patients with hereditary spherocytosis, elliptocytosis, or stomatocytosis, who have changes in RBC morphology typical of each disease. Additional laboratory tests required for specific diagnoses are described for each individual condition.

HEMOLYSIS DUE TO MEMBRANE ABNORMALITIES. Inherited disorders of the RBC membrane are due to abnormal proteins or abnormal protein interactions in the lipid bilayer. The result is decreased deformability and increased fragility of the RBC, which hemolyzes in the splenic microcirculation.

Hereditary spherocytosis may be **either** autosomal dominant or autosomal recessive, and is due to defects in the cell surface–associated proteins spectrin, ankyrin, or band 3. On peripheral blood smear, the cells appear to be spheres rather than the characteristic biconcave disk (absence of the normal central pallor). The diagnosis is confirmed by incubating the RBCs in a progressively hypotonic solution and measuring the percentage of RBCs that undergo hemolysis at decreasing concentrations of NaCl (**osmotic fragility test**). Patients with RBC membrane defects will typically have an increased hemolysis. An MCHC at or above the upper limit of normal on an automated CBC should prompt suspicion of hereditary spherocytosis.

Hereditary elliptocytosis is inherited in an autosomal dominant fashion. The pathophysiology involves several potential sites of defects in cell surface–associated proteins. Penetrance may vary; most individuals have greater than 60% elliptocytes on peripheral blood smear, but some may have less than 10%. Hemolysis may be mild, but patients with homozygous elliptocytosis may have pyropoikilocytosis due to a compound heterozygosity for elliptocytosis and a separate "silent carrier" protein defect. Pyropoikilocytosis is characterized by very abnormal RBCs of aberrant shapes and a high degree of hemolysis. Both hereditary spherocytosis and hereditary elliptocytosis can be treated with splenectomy to remove the site of hemolysis. However, the RBC defect remains and is visible on the blood smear.

HEMOLYSIS DUE TO ENZYME DEFECTS. G6PD deficiency, the most common RBC enzymopathy, is an X-linked defect in which both males and females may be symptomatic. Frequency is highest in Mediterranean, African, and Asian countries. The dehydrogenase enzyme is part of the hexose monophosphate shunt that replenishes the supply of reduced glutathione in RBCs to reduce oxidants produced during stress. Without an adequate supply of reduced glutathione, the unbuffered oxidants damage the RBC membrane, resulting in hemolysis. There are different variants of G6PD deficiency, which can be grouped according to the ethnic background of the individual.

TABLE 16-5

Routine Hematologic Care of the Child with Sickle Cell Disease

Time of Visit	*Intervention*
Initial visit	Review hemoglobin analysis results Initiate penicillin prophylaxis Initiate parent education regarding potential complications (continue at every visit) Ensure patient receives pneumococcal vaccines along with routine immunizations of childhood Refer to hematologist when hemoglobin electrophoresis results are obtained, usually at 2–3 months of age
6 months	Reinforce parent education
12 months	Start folic acid if reticulocyte count >3%
18 months	Reinforce parent education
2 years	Initiate transcranial Doppler studies and repeat every 6 months–1 year until 10 years of age to identify children at risk for stroke
Annual visits	Provide ongoing education regarding potential complications Perform regular eye examinations and renal function tests

To make the diagnosis of G6PD deficiency, RBC enzyme levels are measured. However, this measurement may be inaccurate immediately following an acute episode of hemolysis because the deficient cells have hemolyzed, leaving only new reticulocytes with increased levels of enzyme. The oxidant stresses that precipitate acute hemolysis in individuals with G6PD are infection, drugs, chemicals (e.g., naphthalene), and, in the Mediterranean variant, fava beans. Avoidance of known precipitants and supportive care are important aspects of the management of the disease.

Pyruvate kinase deficiency, a rare deficiency, is inherited in an autosomal recessive pattern. It is the most common enzyme deficiency in the glycolytic pathway. The decreased ATP production in the cell caused by the deficiency is thought to result in accelerated aging and subsequent hemolysis of RBCs.

EXTRINSIC CAUSES OF HEMOLYSIS. Immune-mediated hemolysis is an acquired process and may be autoimmune or alloimmune. Autoimmune hemolysis can be idiopathic or secondary to infection, exposure to certain drugs, or associated with a systemic process such as systemic lupus erythematosus (SLE). Alloimmune antibodies to antigens on RBCs can cause hemolysis as the antibody-coated cells are destroyed by the spleen. Alloimmune hemolysis is most classically seen in the neonatal period with ABO or Rh incompatibility in which the mother is antigen (A, B, or Rh)-negative, and the fetus is antigen-positive. The mother makes antibodies to the RBC antigens on the fetal RBCs, which are then destroyed. Transfusion of incompatible blood products can also result in an alloimmune-mediated hemolysis that can be life-threatening.

Pediatric Pearl: A Coombs test is used to identify antibodies that bind antigens on RBCs and indicates an immune-mediated hemolytic anemia.

In **nonimmune hemolysis,** hemolysis can occur in the spleen as a result of hypersplenism or inappropriate removal of normal RBCs from the circulation. **Microangiopathic hemolysis** can occur outside the spleen in diseases such as DIC, HUS, and TTP, as well as secondary to mechanical shearing forces such as with prosthetic heart valves. This type of anemia is due to shearing of the red cells across fibrin strands. This can be seen on peripheral blood smears.

WHITE BLOOD CELL DISORDERS

WBCs consist of two major cell types: myeloid cells (neutrophils, monocytes, basophils, eosinophils) and lymphocytes. **Myeloid cell disorders,** which are presented as follows, can be grouped into quantitative and qualitative abnormalities. For **lymphoid cell disorders,** see the discussion of the evaluation of lymphadenopathy in the oncology section of this chapter as well as Chapter in 18.

Pathophysiology

Defects of neutrophil number or function can result in susceptibility to infections. Because neutrophils are important for killing bacteria and fungi, infection with these organisms are most commonly observed in neutropenic patients. Infection with viruses is generally not problematic in patients with neutrophil disorders. Patients frequently develop cutaneous infections or infections at mucosal surfaces such as the mouth, lungs, or GI tract. In patients with severe neutropenia, occult infection may occur with minimal signs on physical examination.

Developmental changes in neutrophil number occur, just as they do for RBC. Newborns normally have neutrophils representing 60% of the total WBC count. This number declines with age, and lymphocytes become predominant until the age of 4 to 5 years, when neutrophil predominance recurs. The number of neutrophils is best quantified as the **absolute neutrophil count (ANC),** which is calculated as the percent of neutrophils and bands × 100 × WBC/mm^3. Normally, the ANC of infants older than 2 weeks of age to 1 year of age is over 1,000/mm^3, and the ANC of older infants and children is greater than 1,500/mm^3. In general, the risk of infection increases with the degree of neutropenia.

Pediatric Pearl: Children with **ANCs** less than 500/mm^3 are at highest risk for developing overwhelming infection.

Clinical and Laboratory Evaluation

History

Evaluation of the medical history of children with suspected disorders of neutrophil function or number should primarily focus on infections. It is necessary to evaluate for a family history of severe, recurrent, or fatal bacterial infections. The history of the particular child, especially with regard to growth, infections of the skin, periodontal tissues (gingivitis, oral ulcers), sinuses, and lower respiratory tract, is important. Other specific historical events that should be considered include delayed separation of the umbilical cord (leukocyte adhesion deficiency [LAD]) and widespread granuloma formation (chronic granulomatous disease [CGD]).

Physical Examination

The level of acuity should be assessed first. Children in shock are probably septic and require prompt attention to potential bacterial or fungal infections. Neutropenic children who are febrile, even though they are not in shock, also require immediate diagnosis and treatment for presumed infection. Many children with neutrophil disorders appear to be chronically ill with abnormal weight and height, diminished muscle mass, and listlessness. The examination of neutropenic children must take into account the fact that most of the physical findings of infection (e.g., redness, swelling) require neutrophilic infiltration to become manifest and thus may be absent in these patients. Thus, only local tenderness may mark an area of infection. Careful palpation of potentially infected areas is therefore essential to determine whether infection is present. A perianal examination is particularly important. The condition of the teeth and mouth is noteworthy; neutrophilic disorders frequently result in chronic oral infections. Children with Chédiak-Higashi syndrome have abnormal pigmentation with very pale skin and silver hair.

Laboratory Evaluation

The laboratory examination begins with a CBC to determine whether neutropenia is present. The morphology of the neutrophils may also provide a clue. In LAD, the WBC count becomes very elevated (more than 30,000 mm^3). In suspected CGD, the nitroblue tetrazolium test, which is based on the ability of the neutrophil respiratory burst to alter the color of an oxidized compound, is warranted. Specialized tests of neutrophil function are necessary to diagnose other disorders such as LAD, actin deficiency, or Chédiak-Higashi syndrome.

Differential Diagnosis

Quantitative Myeloid Cell Disorders

Neutropenia is used to describe a decreased number of neutrophils. Neutropenia can be congenital or acquired, and etiologies are listed in Table 16-6.

TABLE 16-6

Causes of Neutropenia in Childhood

Congenital
Kostmann syndrome
Severe chronic neutropenia
Shwachman-Diamond syndrome
Congenital benign neutropenia
Cyclic neutropenia
Acquired
Drug-induced
Toxins
Infection (suppression and destruction)
Immune-mediated
Alloimmune
Autoimmune
Hypersplenism

CONGENITAL NEUTROPENIAS. **Kostmann syndrome,** or **congenital agranulocytosis,** results from maturational arrest of myeloid precursors in the bone marrow. Life-threatening bacterial infections develop soon after birth. Affected patients have an increased incidence of leukemia and myelodysplastic syndrome. Treatment may involve granulocyte colony-stimulating factor (G-CSF), although often these patients may not respond to this cytokine. Mutations in the *HAX-1* gene have been identified in a subset of these patients. Stem cell transplantation is recommended for these patients.

Shwachman-Diamond syndrome is a syndrome of short stature, exocrine pancreatic dysfunction, and neutropenia. Aplastic anemia develops in as many as 25% of patients, and leukemia in at least 5%. Inheritance is autosomal recessive. Patients may also be small, have poor growth, and have a bony abnormality (metaphyseal dysplasia).

Severe Chronic Neutropenia (SCN) is a disease also resulting from mutations in the *ELA-2* gene, although usually in different exons than those mutations leading to cyclic neutropenia.

Cyclic neutropenia leads to periods of normal WBC counts that alternate with periods of neutropenia (mean oscillatory period, about 21 days). The disease, which may also be familial, is autosomal dominant in 10% of cases. Recurrent fever, gingivitis, mouth ulcers, and lymphadenopathy may develop during periods of neutropenia. This disorder is due to a mutation in the neutrophil elastase gene (*ELA-2*).

Congenital benign neutropenia, as the name implies, is not associated with increased risk of infection. The condition may be familial. Patients often mount a neutrophil response during infections.

ACQUIRED NEUTROPENIAS. **Decreased marrow production** leading to neutropenia may be associated with drugs such as chemotherapeutic agents, anticonvulsants, immunosuppressive agents, and other medications. Toxins such as benzene may also have a similar effect. Viral or bacterial infections and leukemia or metastatic solid tumors in which malignant cells infiltrate the bone marrow may also suppress bone marrow function and cause neutropenia.

Increased peripheral destruction or consumption may be a result of overwhelming infection if the rate of consumption of neutrophils at the site of infection exceeds the rate of production in the bone marrow. Immune-mediated neutropenia can be alloimmune, which is seen in neonates with maternally generated antibodies, or autoimmune, such as with lupus. In **hypersplenism,** WBC trapping in the spleen can lead to neutropenia.

NEUTROPHILIA. An increased neutrophil count is most often seen with infection. A **leukemoid reaction** is a markedly increased WBC count in which the differential consists of immature myeloid precursors not usually seen in the periphery. Leukemoid reactions are common in infants with infection and, in particular, those with Down syndrome.

Acute myeloid leukemia (AML) may be associated with a high WBC count, but most often the cells seen on the peripheral blood smear are very immature myeloid cells known as **blasts,** as opposed to the mature neutrophils, band forms, and myelocytes seen with a leukemoid reaction (see Acute Myeloid Leukemia). Often a bone marrow aspirate is needed to differentiate leukemia from a leukemoid reaction.

Qualitative Myeloid Cell Disorders

Neutrophil dysfunction may be due to rare genetic mutations that can occur at various sites in the pathway of normal neutrophil function (see Chapter 18). Inheritance may be X-linked or autosomal recessive.

CGD results from the inability of WBCs to form the bactericidal product hydrogen peroxide due to mutations in the neutrophil oxidase system. Children with CGD have lymphadenopathy and recurrent abscesses that require drainage.

LAD is due to an inherited deficiency of adherence glycoproteins (CD11, CD18) that normally allow the WBCs to adhere to endothelium and migrate to sites of infection. Affected children have poor wound healing, with recurrent infections of the skin and mucosal surfaces.

Defects in opsonization include deficiencies in the complement system. Patients with absent or dysfunctional spleens, such as patients with sickle cell disease, can also have defective opsonization.

Chédiak-Higashi disease is an autosomal recessive disorder in which there is abnormal fusion of the neutrophil granules resulting in the formation of giant granules that interfere with bacterial killing. The disorder is associated with partial oculocutaneous albinism, photophobia, and rotary nystagmus.

Management

The treatment of neutropenia includes the immediate management of infection as well as long-term efforts to either minimize infection or treat the underlying disorder. It is assumed that children with neutropenia and fever are infected, and they usually receive broad-spectrum antibiotics. The precise combination of antibiotics largely depends on institutional experience and patterns of antibiotic resistance in the community. Patients with localizing signs of infection (e.g., staphylococcal skin abscess) can be treated with a more specific antibiotic regimen.

Treatment of the underlying cause of the neutropenia is dependent on the precise etiology. Congenital agranulocytosis has been cured by histocompatible BMT. Patients have also been successfully treated with chronic administration of recombinant G-CSF, a hormone that regulates the differentiation of myeloid cells. Autoimmune neutropenia is treated with immunosuppressive therapy. If a drug is suspected of causing neutropenia as an idiosyncratic reaction, every effort must be made to withdraw the offending drug. Neutropenia from chemotherapeutic drugs may require modification of subsequent doses. Patients with benign congenital neutropenia and cyclic neutropenia benefit from careful oral and skin hygiene and the cautious use of antibiotics.

The management of defects of neutrophil function must focus both on the immediate treatment of existing infections and on long-term management. The presenting infections for children with either LAD or CGD are frequently serious, requiring intensive antibiotic therapy. Leukocyte transfusions have been used as an adjunct to the treatment of LAD-associated infections. The optimal treatment for LAD is histocompatible BMT from a sibling donor, which can be curative. Unfortunately, most patients do not have access to a donor and receive only supportive therapy with antibiotics. CGD is also responsive to BMT, but because of the infrequency of matched donors and the relatively high risk associated with BMT, most patients are currently receiving alternative treatment. Treatment with interferon-γ decreases the risk of infections in patients with CGD, although the beneficial effect is probably not due to enhanced activity of the oxidative burst. Supportive care also includes use of prophylactic antibiotics, especially trimethoprim-sulfamethoxazole.

PLATELET DISORDERS (SEE DISORDERS OF HEMOSTASIS AND THROMBOSIS)

SYNDROMES OF BONE MARROW FAILURE

When bone marrow fails to function, a loss of effective production of mature RBCs, myeloid cells, and platelets occurs. This loss of production is due either to a decreased number of hematopoietic precursors or to reduced function of the precursors. Only one or two cell lines may be affected. **The congenital bone marrow failure syndromes,** which are characterized by cytopenias, eventual aplastic anemia, myelodysplastic syndrome, or leukemias are often accompanied by congenital anomalies. These disorders include **Fanconi anemia, thrombocytopenia absent radii,** and **dyskeratosis congenita**. Acquired bone marrow failure syndromes include **aplastic anemia** and **paroxysmal nocturnal hemoglobinuria**. Except for thrombocytopenia absent radii, in which the hematologic abnormality

usually resolves after the first year of life, BMT may be required and can be curative; however, the potential morbidity associated with the procedure may be significant. Patients with Fanconi anemia and dyskeratosis congenita are at increased risk for the development of AML and require frequent and careful monitoring.

DISORDERS OF HEMOSTASIS AND THROMBOSIS

Trauma to blood vessels constantly occurs in day-to-day activities, and a complex system for the regulation of blood clotting has evolved to protect the body from serious bleeding. Bleeding disorders may involve defects of the **platelet system,** which forms the initial platelet plug at the site of vessel injury, or the **coagulation system,** which forms the clot that stabilizes the vessel until tissue repair occurs. These two components also interact in complex ways. Platelets are fragments of megakaryocytes, precursor cells that reside in the bone marrow. Production of megakaryocytes is under the control of a secreted protein called thrombopoietin, much as RBC production is controlled by erythropoietin.

Pathophysiology

The first step in blood clotting occurs when endothelial cells are damaged (e.g., by trauma). Platelets do not normally stick to the endothelium, but after injury, they attach to the endothelial cells through several mechanisms. Damaged endothelial cells bind a circulating protein, **von Willebrand factor (vWF),** which in turn binds to the platelets and mediates the association of platelets with the endothelium. Exposed collagen also leads to the binding of platelets to damaged tissue. After one platelet adheres to the endothelium or tissue, it becomes activated, releases mediators of clotting and inflammation, and aggregates with other platelets. The aggregated platelets congeal to form a platelet plug, which usually stops bleeding from the damaged blood vessel within minutes. This is often referred to as primary hemostasis.

In addition to the platelet plug, blood clotting involves a series of enzymatic reactions that result in the transformation of a plasma protein, fibrinogen, into polymerized fibrin strands. The fibrin acts as a cement that stabilizes the platelet plug. The generation of fibrin is the culmination of two different pathways, one initiated by proteins extrinsic to the plasma, and the other started by proteins present in the plasma (Figure 16-3). The clotting cascade contains proteins with protease activity, which results in partial cleavage and activation of the next protein in the pathway.

Clinical and Laboratory Evaluation

History

Evaluation of children for bleeding disorders usually occurs for two reasons: (1) history of unusual bleeding or (2) an abnormal result on a routine screening test, often obtained prior to an elective surgical procedure. If bleeding is present, a careful description of the bleeding episode is helpful in determining the cause.

Pediatric Pearl: Mucocutaneous bleeding and petechiae are more typical of platelet or collagen vascular disorders (wet bleeding is more typical of primary hemostasis disorders), whereas joint or soft tissue bleeding is more characteristic of clotting factor deficiencies.

Serious bleeding episodes may be seen in children with preexisting bleeding disorders who are suffering from an acute exacerbation or undergoing surgery as well as in patients with bleeding diatheses acquired as the result of other illness. Patients with severe bleeding usually carry the diagnosis of a bleeding disorder and have a preexisting history, but they may have a newly acquired disorder with no previous history. Occasionally, detection of inherited bleeding disorders occurs after the onset of severe bleeding that requires hospitalization.

The history should focus on sites of previous bleeding. Petechiae (nonblanching lesions less than 2 mm in size) usually indicate a platelet disorder, rather than a clotting protein disorder. Bleeding from the nose, purpuric bleeding in the skin, intracranial hemorrhage, GI tract bleeding, or genitourinary tract bleeding can occur with either condition. Children with a history of fat malabsorption are susceptible to vitamin K deficiency. Children with liver disease may develop a coagulopathy due to lack of production of a number of clotting proteins. Children with known platelet or coagulation disorders who complain of headaches must be carefully evaluated and presumptively treated for CNS hemorrhage. When evaluating children with suspected coagulation disorders, a careful family history is warranted. Factor VIII and factor IX deficiencies, the most common forms, are both X-linked and affect only males.

Physical Examination

The physical examination should include a thorough evaluation for sites of bleeding. In children with suspected platelet disorders, it is necessary to search for petechiae. In addition, a careful examination for signs of SLE is useful;

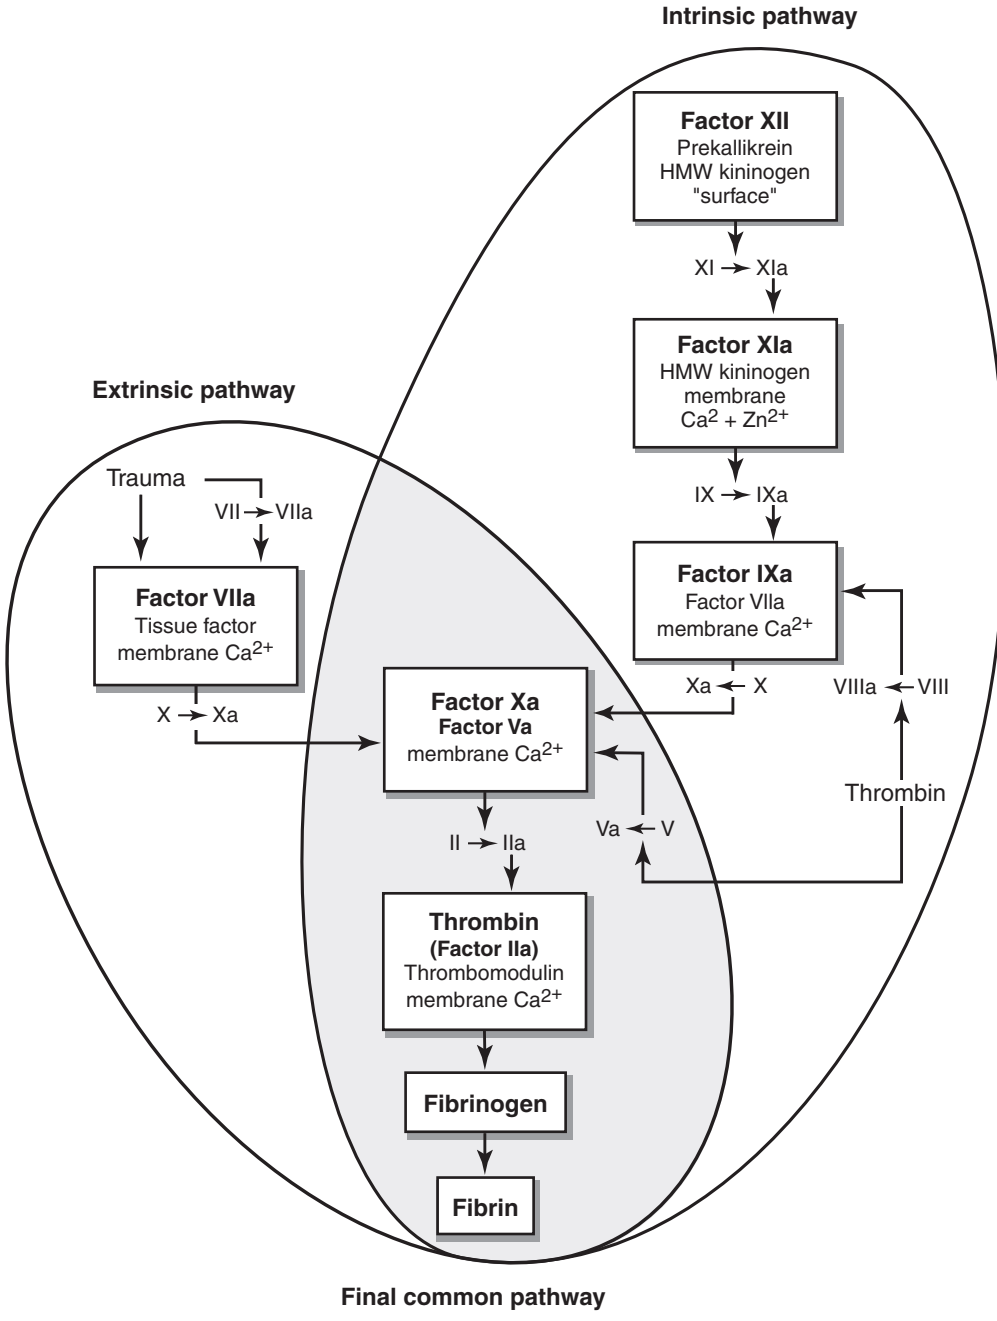

FIGURE 16-3. The coagulation cascade involves enzyme complexes comprised of serine proteases, cofactors, divalent cations, and a tissue surface. The intrinsic and extrinsic pathways converge to a shared final common pathway. The prothrombin time measures the intrinsic pathway; the activated partial thromboplastin time measures the extrinsic pathway. *HMW*, high molecular weight.

immune thrombocytopenia purpura (ITP) may be associated with SLE, especially in older children. Children with suspected thrombocytopenia with significant adenopathy, organomegaly, or bone pain are more likely to have leukemia or a malignancy other than ITP. Signs of chronic hepatic disease such as varices may be present. Deep hematomas are usually the result of a clotting protein abnormality. Patients with iliopsoas hemorrhages may present with abdominal pain that mimics appendicitis as well as neurologic signs due to compression of the lumbar plexus and numbness over the medial thigh. Patients with known clotting abnormalities who have major trauma warrant careful examination for sites of bleeding in soft tissues, the mouth, abdomen, and brain.

TABLE 16-7

Laboratory Abnormalities in Coagulopathies

Type of Coagulopathy	*PT*	*PTT*	*Platelets*	*Factor Levels*
Factor VIII deficiency (hemophilia A)	Normal	Prolonged	Normal	VIII decreased
Factor IX deficiency (hemophilia B)	Normal	Prolonged	Normal	IX decreased
Factor VII deficiency	Prolonged	Normal	Normal	VII decreased
Vitamin K deficiency	Prolonged	Prolonged	Normal	II, VII, IX, X decreased
Liver disease	Prolonged	Prolonged	Normal	Decreased[a] (except factor VIII)
Disseminated intravascular coagulation	Prolonged	Prolonged	Decreased	Decreased (including factor VIII)
vWD	Normal	Normal or prolonged	Normal, decreased in type IIB vWD	VIII decreased in type I and III vWD
Thrombocytopenia	Normal	Normal	Decreased	Normal

[a] Factor VIII is made in endothelial cells and levels are not decreased in liver disease.
PT, prothrombin time; *PTT*, partial thromboplastin time, *vWD*, von Willebrand disease.

Laboratory Evaluation

The major coagulopathies encountered in children are characterized by certain laboratory abnormalities (Table 16-7). Initially, the pediatrician should be able to distinguish platelet from coagulation protein disorders. The platelet count helps in evaluation for quantitative disorders. The platelet function screen (PFA-100) and the bleeding time detect numerical and functional defects of platelets. The PFA-100 is a recently developed test that uses whole blood and a variety of platelet stimulants to determine a closure time, or a time to develop a clot. This test is often used as a screening tool and has replaced the bleeding time. The bleeding time is performed by using a special template to create a 1-cm long, 1-mm deep incision, repeatedly blotting the wound, and measuring the time required for bleeding to stop. (Because the results of a bleeding time can be influenced by the technique of the person performing the test [e.g., site of incision, amount of pressure with which the template is held against the skin to make the incision], the results have the potential to be misleading.) Both the PFA-100 and the bleeding time are abnormal in both numerical and qualitative disorders of the platelets. The prothrombin time (PT) detects defects of the extrinsic and common pathways, whereas the partial thromboplastin time (PTT) evaluates the intrinsic and common pathways. Special platelet coagulation studies are now available to evaluate platelet function; these tests should be considered instead of bleeding time.

In children with abnormal screening tests but with no significant bleeding history, the laboratory evaluation can be more focused (Figure 16-4). Specific tests of factor levels are necessary to further define inherited deficiencies.

PLATELET DISORDERS

Quantitative Disorders of Platelets

Platelets arise from megakaryocytes in the bone marrow. As the platelet count decreases, the risk of bleeding increases. A platelet count below normal (150,000/mm^3) is termed **thrombocytopenia,** which may be due to decreased production in the bone marrow or increased destruction peripherally.

Causes of decreased bone marrow production of platelets include infection; an infiltrative bone marrow process such as leukemia; and congenital abnormalities in platelet production such as **congenital megakaryocytic**

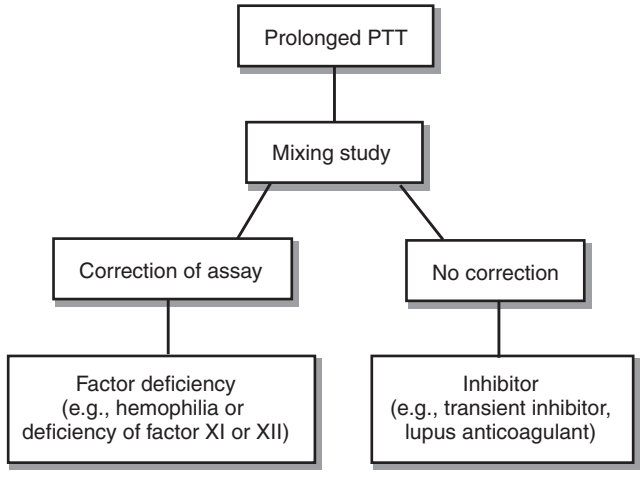

FIGURE 16-4. Approach to the evaluation of prolonged partial thromboplastin time (PTT).

hypoplasia, thrombocytopenia absent radii, aplastic anemia, or **Wiskott-Aldrich syndrome**. An X-linked disease, Wiskott-Aldrich syndrome causes variable degrees of thrombocytopenia and both cell-mediated and humoral immune deficiency leading to autoimmune processes like ITP. Affected boys, who have frequent infections with encapsulated organisms, may have eczema. The disease is allelic with isolated X-linked thrombocytopenia, both being due to mutations of a gene called *WASP*.

Increased destruction of platelets in children is most commonly due to **ITP**. Children usually have a history of antecedent viral infection. Patients most often present with extensive bruising, and platelet counts can be quite low (less than 10,000/mm^3). Associated bleeding may occur, and intracranial hemorrhage occurs in less than 1% of patients. Treatment includes intravenous immunoglobulin, anti-D antibody in Rh+ patients only, and steroids. Rarely, platelet transfusions are used in emergent situations. For patients with chronic ITP (lasting longer than 6 to 12 months), splenectomy or rituximab (anti-CD20 antibodies) may be considered.

Immune-mediated platelet destruction can also be encountered in autoimmune disorders such as SLE. Thrombocytopenia due to peripheral destruction or consumption can be due to **DIC** associated with infection, or the **Kasabach-Merritt syndrome,** which is the occurrence in infants of localized DIC within a giant congenital hemangioma.

Thrombocytosis is an abnormally high platelet count, defined as greater than 450,000/mm^3. Because platelets are an acute phase reactant, thrombocytosis may often be seen in the setting of infection or other stress; this condition is a common finding in patients with Kawasaki disease (see Chapter 14). Thrombocytosis can also be seen in iron deficiency or in states of increased production of another cell line such as in patients with chronic hemolytic anemia or in patients lacking a spleen (e.g., patients with sickle cell disease often have elevated platelet counts). Thrombocytosis is also associated with neuroblastoma. Thrombocytosis may also be seen with certain types of myelodysplastic syndrome. This condition is much more common in adults. In extremely high platelet counts (usually over 1.5 million/dL) that persist over time, the diagnosis of essential thrombocytosis, which is a myeloproliferative disorder due to a JAK-2 or MPL (thrombopoietin receptor) mutation, should be considered.

Qualitative Disorders of Platelets

The most common inherited bleeding disorder is **von Willebrand disease (vWD),** due to decreased, absent, or abnormal vWF protein. The role of vWF is twofold: (1) it is necessary for platelet adhesion to the vascular endothelium and (2) it stabilizes the clotting factor VIII. Affected children may have mucosal bleeding (epistaxis, bleeding with tooth eruption, heavy menstrual bleeding); the extent varies depending on the type of disorder. Type I disease (all multimers present) is due to a mild quantitative decrease in vWF, type II disease (large multimers absent) is due to qualitative abnormalities of vWF, and type III disease (all multimers absent) is the most severe with essentially no detectable vWF. Laboratory evaluation includes vWF levels; vWF multimeric

analysis; factor VIII levels; and ristocetin cofactor assay, which is an indirect measure of platelet aggregation. Formal platelet aggregation studies are usually not necessary.

Treatment for patients with mild disease consists of desmopressin (1-desamino-8-D-arginine vasopressin), which promotes endothelial release of vWF. Many subtypes of type II disease do not respond to desmopressin, which is contraindicated in some (patients with the IIB subtype) because it causes thrombocytopenia. In patients who are not candidates for desmopressin, concentrates of plasma-derived vWF and factor VIII such as antihemolytic factor/vWF complex (human) are available. Antifibrinolytic agents such as ε-aminocaproic acid are used to stabilize clots in patients with mucosal bleeding.

CONGENITAL COAGULATION DISORDERS (HEMOPHILIAS)

The two most common inherited deficiencies of coagulation proteins are due to mutations in the genes for factor VIII (**hemophilia A**) and factor IX (**hemophilia B or Christmas Disease**). Factor VIII deficiency accounts for approximately 80% of cases. Both diseases are X-linked. The family history is positive in about half of patients. These two disorders affect all ethnic groups equally, with a frequency of approximately 1/5,000 male births (1/10,000 births). The clinical severity depends on the level of coagulation protein activity in the plasma, which can vary considerably; however, severity tends to be similar among affected family members. Affected boys may present in infancy with excessive bleeding after circumcision or hematoma formation after intramuscular injection. As they become older, easy bruising and severe bleeding into soft tissues or joints after minimal trauma occurs. Most patients have experienced severe bleeding by the end of the first year of life. Diagnosis is confirmed by abnormalities of the PTT and by specific assays for factors VIII or IX. Treatment consists of infusion of appropriate recombinant factor concentrates.

Other less common factor deficiencies include those of factors VII, XI, and XII. Factor VII deficiency will have an isolated elevation in the PT. Factors VII and XI deficiencies exhibit variable bleeding, and are initially detected by an isolated increased PTT (similar to factors VIII and IX deficiencies). Factor XII deficiency is not associated with clinical bleeding, although the PTT is slightly prolonged. Deficiencies of factors V, X, prothrombin will exhibit prolonged PT and PTT. Factor XIII deficiency is not detected by PT or PTT, however, and can be severe. This disorder has a history of delayed bleeding (4 to 5 days) after surgery or injury. A specific assay for factor XIII is needed for diagnosis.

ACQUIRED COAGULATION DISORDERS

Vitamin K Deficiency

Deficiency of vitamin K, a fat-soluble vitamin, results in the inability to carboxylate the vitamin K–dependent clotting factors (II, VII, IX, and X). Carboxylation is necessary for the formation of coagulation complexes between the clotting factors and the phospholipid membranes of platelets and endothelium. PT and PTT are both prolonged.

In neonates, **hemorrhagic disease of the newborn** occurs as a result of poor transfer of vitamin K across the placenta, relative deficiency of clotting factors in the neonate, and the low concentration of vitamin K in breast milk. An early form of this disease occurs in mothers treated with certain medications (e.g., anticonvulsants, warfarin) while pregnant. A routine intramuscular injection of vitamin K at birth prevents classic hemorrhagic disease of the newborn, which occurs at 2 to 7 days of age.

In older children, vitamin K deficiency is seen in the setting of malabsorption (e.g. crohn disease, celiac disease, cystic fibrosis), prolonged antibiotic therapy, or warfarin (rat poison) ingestion. Treatment with vitamin K intramuscularly corrects the PT in 4 to 8 hours. If immediate correction is indicated, fresh frozen plasma or prothrombin complex concentrates can be administered to supply carboxylated clotting factors.

Other Acquired Coagulation Disorders

DIC or consumption coagulopathy may occur in the presence of diseases, particularly sepsis, that cause hypoxia, acidosis, shock, or tissue necrosis. Widespread intravascular deposition of fibrin leads to further tissue ischemia, generalized hemorrhage, and a microangiopathic hemolytic anemia. Bleeding may begin around the sites of intravenous lines or surgical incisions. Infarcts may occur of both internal organs and areas of the skin.

The vast majority of patients with **liver disease** have some form of coagulation defect as determined by laboratory testing, although clinically significant bleeding develops in a much smaller group of patients. The abnormality results from a decrease in the synthesis of all the clotting factors except factor VIII, which is typically elevated in liver failure. The severity is related to the degree of hepatic damage.

THROMBOPHILIA (HYPERCOAGULABILITY)

Just as coagulation factors are needed to form a clot, factors are needed to prevent extension of the clot beyond what is necessary. Clinically, venous or arterial thromboses and pulmonary emboli are potential signs of hereditary hypercoagulable states. The evaluation of children with thromboembolism should be directed toward identifying whether there is an underlying hereditary or acquired abnormality leading to thromboses involving veins, arteries, or the microvasculature. The list of factors that play a role in regulating the extent of thrombus formation is growing as research in the field identifies new factors and new genetic mutations.

Several environmental factors can increase the risk of thrombosis, including postoperative immobility, infection, smoking, dehydration, an indwelling venous catheter, and certain medications (e.g., oral contraceptives, L-asparaginase). Evaluation for inherited predisposition is indicated to determine whether long-term anticoagulation is necessary. In many situations, once the environmental factor is removed, there is no need for long-term anticoagulation.

Evaluation of patients with a suspected inherited predisposition to thrombophilia includes assays for deficiencies of **protein C, protein S,** and **antithrombin III** (measured by levels of protein activity); genetic analyses for the **factor V Leiden** mutation, which confers resistance to activated protein C, **prothrombin mutation,** and **methylene tetrahydrofolate reductase mutation;** and serum tests for **lupus anticoagulant** and **anticardiolipin antibody** (associated with the **antiphospholipid syndrome**).

EXCESSIVE BLEEDING IN SURGICAL PATIENTS

Pediatricians are often asked to evaluate surgical patients for hematologic problems both pre- and postoperatively. The usual reasons for consultation are concern about either anemia or bleeding. Accordingly, clinicians should seek a past medical history of anemia or bleeding. The reason for surgery should be considered in determining whether a hematologic problem exists. For example, a child undergoing abdominal surgery for GI bleeding (e.g., Meckel diverticulum) might have iron deficiency anemia. The physical examination should also focus on signs of either anemia or bleeding.

Preoperative Evaluation

The most important screening preoperatively is the family history and the patient's own bleeding history. Medication history is also important. However, screening laboratory tests are frequently ordered. In general, for moderate- to high-risk surgery (e.g., orthopedic, intra-abdominal, cardiac, neurologic), a CBC with platelet count, PT, and PTT, and PFA-100 are often obtained. For low-risk surgery (e.g., herniorrhaphy), a hematocrit is usually adequate if the history and physical examination are normal. Elective surgery can usually be performed when the hemoglobin level is 10 g/dL, the platelet count is normal, and the PT and PTT are normal. If the hematologic tests are abnormal in a child scheduled for elective surgery, it is better to postpone the surgery until the cause of the abnormality is determined. If surgery is urgent, then correction of the abnormality may be necessary. Management of the anemic child might include packed RBCs to achieve hemoglobin of 10 g/dL. In patients with thrombocytopenia, transfusion to a platelet count of greater than 50,000/mm^3 is adequate, but additional intraoperative platelet transfusions may be necessary. Correction of clotting abnormalities might include infusions of fresh frozen plasma or cryoprecipitate, with administration of vitamin K to correct the defect.

Postoperative Bleeding

A careful examination of the patient is essential. Children with bleeding only at the site of surgery are likely to have a surgical problem, rather than a bleeding diathesis, especially if the preoperative history, physical examination, and screening tests are normal. The pediatrician should look for other sites of bleeding (e.g., endotracheal tube, mucous membranes, skin, sites of intravenous or intra-arterial line).

Diffuse bleeding may be due to **DIC** or a previously undiagnosed bleeding diathesis. Surgical patients who have undergone open-heart surgery, neurosurgery, trauma, or sepsis are at particular risk for DIC. Laboratory tests for the patient with excessive postoperative bleeding should include a CBC with platelet count, PT, PTT, **fibrin split products,** and **fibrinogen levels**. Patients with DIC have a low platelet count, prolonged PT and PTT, elevated fibrin split products, and decreased fibrinogen levels. The blood smear may also show microangiopathic changes in RBC morphology. Patients exhibiting a drop in platelets who have been on heparin may have heparin-induced thrombocytopenia and a work-up should ensue.

ONCOLOGY

LYMPHADENOPATHY

Hematologists–oncologists and infectious disease specialists are frequently asked to examine children with lymphadenopathy, which usually occurs as a result of infection or infiltration with inflammatory or malignant cells. Lymphoid tissue grows at a very rapid rate during childhood. Because children are constantly being exposed to new infectious agents, lymphadenopathy is a frequent occurrence, and palpable lymph nodes in the cervical, axillary, and inguinal areas are common. Lymph nodes more than 2.5 cm in diameter or located in other areas are more likely to indicate the presence of a disease process.

Localized lymphadenopathy is more frequently associated with a bacterial or fungal infection in the region drained by that particular group of lymph nodes. Thus, a basic knowledge of patterns of regional lymph node drainage is useful in the assessment of lymphadenopathy. For example, a child with isolated submental or submandibular lymphadenopathy may have a dental or gingival infection but is unlikely to have a scalp infection. Diffuse adenopathy is more suggestive of viral infection, storage disease, leukemia, or chronic autoimmune disease. Popliteal and inguinal lymphadenopathy may be due to a lower extremity infection. When a lymph node is enlarged as a result of infection, resolution of the infection is associated with shrinkage of the lymph node back to normal size. When a lymph node has been enlarged for a prolonged period, usually more than 1 month, the lymphadenopathy is considered chronic. Administration of appropriate antibiotic treatment leads to the resolution of most infection-related adenopathy within 2 weeks. Persisting significant adenopathy or nodes increasing in size in the face of antibiotic therapy need further investigation.

CLINICAL AND LABORATORY EVALUATION

History

The history should focus on the duration of lymphadenopathy and antecedent history. A history of trauma or infection to distal areas drained by the node is particularly important. Exposure to bacteria via a cat scratch, tick bite, rodent or other animal bite, or distal wound warrants careful exploration. Generalized symptoms such as fever, anorexia, weight loss, joint or bone pains, and diarrhea may indicate a systemic illness.

Physical Examination

Experience with palpation of lymph nodes is invaluable in the assessment of lymphadenopathy. Lymph nodes should be characterized by location, number, size, consistency, mobility, and attachment to skin and soft tissues. Infected lymph nodes may be fluctuant, tender, and matted together, and have overlying superficial erythema. A sinus tract, with or without drainage, is relatively common in **tuberculosis,** but can also be seen in **aspergillosis** or **actinomycosis**. Lymph nodes that are enlarged as part of the systemic response to infection tend to be diffuse and not fluctuant, but may be tender. Lymph nodes that are enlarged because of malignancy tend to be rubbery and firm and can be matted down, especially if the malignancy is a solid tumor. Supraclavicular lymph nodes on the left side may be derived from an intra-abdominal malignancy spreading through the thoracic duct, such as Hodgkin or non-Hodgkin lymphoma (NHL). Right-sided supraclavicular lymphadenopathy is more often associated with intrathoracic or pulmonary diseases.

Other noteworthy physical features include hepatosplenomegaly, jaundice, wasting, bruising, petechiae, or pallor. A detailed examination to look for evidence of local infection in the areas drained by regional lymph nodes is necessary (e.g., throat in the presence of cervical lymphadenopathy).

Laboratory Evaluation

Children with lymphadenopathy should have a CBC with differential, a tuberculin skin test, and culture of relevant primary sites of infection (e.g., throat with cervical adenitis). A chest radiograph is necessary if no localized site of infection can be identified to account for the lymphadenopathy. In children with diffuse adenopathy, appropriate serologic tests include those for Epstein-Barr virus, cytomegalovirus, and *Toxoplasma gondii*. If localized adenopathy persists despite an appropriate course of antibiotics, usually of 2 weeks' duration, an excisional lymph node biopsy may be indicated.

If leukemia is suspected, a bone marrow aspirate should be obtained prior to referral to a surgeon because a leukemic marrow would make a surgical node biopsy unnecessary. The biopsy material should be stained for histopathology and for evidence of infection, including Gram stain, acid-fast bacteria, and fungal stains.

It should be sent for culture for these organisms. In the event that the lymph node demonstrates malignancy, the pathology laboratory should be prepared to perform a careful analysis for lymphoma or leukemia with monoclonal antibody staining by flow cytometry and cytogenetics. It is important to consider florescence in situ hybridization should the sample of marrow be positive for malignancy. It is essential that the pediatrician, surgeon, and pathologist coordinate the tests to be done in advance of the biopsy.

Differential Diagnosis

The differential diagnosis of lymphadenopathy is quite extensive, including infections, noninfectious inflammatory diseases, malignancies, and storage diseases. It may help to distinguish localized from generalized lymphadenopathy according to its common causes (Table 16-8). Not all swellings are due to lymphadenopathy. Congenital malformations such as thyroglossal duct cysts, branchial cleft cysts, cystic hygromas, or tumors such as neuroblastoma and rhabdomyosarcoma can cause neck masses that may be mistaken for lymphadenopathy.

Management

The management of children with localized lymphadenopathy depends on the suspected etiology. In children with infections of the oropharynx such as streptococcal pharyngitis, treatment with a β-lactam antibiotic (e.g., amoxicillin, amoxicillin–clavulanic acid, cefuroxime) is adequate. When *Staphylococcus aureus* is suspected, a β-lactamase-resistant antibiotic is required. Parenteral administration may be necessary if swallowing difficulties or severe emesis is present.

For children with infections of the extremities causing regional lymphadenopathy, coverage for both streptococcus and staphylococcus is recommended. For these bacterial infections, parenteral antibiotics are usually warranted. Diffuse lymphadenopathy due to viral infection is usually managed by observation after obtaining a CBC and appropriate viral titers or cultures. In such viral infections, resolution of lymphadenopathy usually occurs within 1 month. Children with suspected malignancy should be referred to a pediatric hematologist–oncologist; the care of such children is relatively urgent.

CANCER

The diagnosis of a malignancy in children or adolescents is most definitely a life-changing event, although the long-term outcome for these young patients has dramatically improved over the past 40 years. By implementing randomized clinical trials and providing multidisciplinary care, effective therapies have been identified, and the outlook for children with malignancy continues to improve. The remainder of this chapter will review the clinical presentation, differential diagnosis, management, and outcome for both common and uncommon malignant diseases seen in the pediatric age group.

Every year cancer develops in 15 of every 100,000 children between birth and 21 years of age, resulting in approximately 12,000 new cases of cancer in this age group in the United States. The incidence of disease varies among racial groups. Cancer is more prevalent in the Caucasian population than in African Americans and Hispanic Americans. Although pediatric malignancies are curable in over 70% of cases, cancer is still the most common cause of death from disease in the U.S. population between the ages of 1 and 15 years. The Surveillance, Epidemiology, and End Results Program of the National Cancer Institute presents the most recent data concerning the incidence of different types of cancer in children, adolescents, and young adults (Table 16-9).

Pediatric Pearl: As more children with cancer are cured, long-term side effects of therapy such as infertility and secondary malignancy have become more common.

Pathophysiology

Cancer is the result of uncontrollable cellular proliferation (hyperplasia). By the time of diagnosis, one transformed neoplastic cell can multiply and become over 10 billion cells. Cancer cells may be either localized or disseminated throughout the body. The disease is frequently identified by the presence of a mass that can be palpated or imaged.

TABLE 16-8

Common Causes of Lymphadenopathy

Generalized Lymphadenopathy	*Localized Lymphadenopathy*
Bacterial infections	Occipital/posterior auricular region
Pyogenic bacterial infection	Local scalp infection (e.g., impetigo)
Tuberculosis	Ringworm
Brucellosis	Pediculosis
Typhoid fever	Roseola (HHV-6 infection)
Syphilis	Preauricular
Fungal infections	Chlamydia
Histoplasmosis	Catscratch disease
Coccidioidomycosis	Trachoma
Viral infections	Tularemia
Epstein-Barr virus (infectious mononucleosis)	Sarcoidosis
Cytomegalovirus	Submaxillary/submental region
HIV	Dental caries and abscesses
Measles	Bacterial gingivitis
Rubella	Herpes simplex stomatitis
Parasitic infections	Cervical region
Toxoplasmosis	Viral infections
Malaria	Respiratory viruses
Inflammatory diseases (noninfectious)	Epstein-Barr virus
Systemic lupus erythematosus	Cytomegalovirus
Juvenile rheumatoid arthritis	Bacterial
Serum sickness Sarcoidosis	Upper respiratory tract infection (e.g., group A hemolytic streptococcus)
Neutrophil disorders	*Staphylococcus aureus* infection
Chronic granulomatous disease	Head and neck impetigo
Leukocyte adhesion deficiency	Tuberculosis and atypical *Mycobacterium*
Storage disease	Parasitic: *Toxoplasma gondii*
Gaucher disease	Other
Niemann-Pick disease	Kawasaki disease
Malignancies	Sarcoidosis
ALL	Malignancy
Acute myeloid leukemia	Hodgkin disease
Hodgkin lymphoma	Non-Hodgkin lymphoma

TABLE 16-8

Common Causes of Lymphadenopathy *(Continued)*

Neuroblastoma	Histiocytosis X

Other sarcomas	1.6
All other tumors	9.1
Total	100.0

ALL, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CNS*, central nervous system.

Solid tumors may interfere with organ function, often causing pain. When the bone marrow is replaced by leukemia or metastatic tumors, loss of marrow function can occur. One or more of the following findings may indicate this loss: anemia, leukocytosis, leukopenia, or thrombocytopenia. In children, solid tumors are usually derived from mesenchymal tissues and called sarcomas, whereas in adults, the majority of solid tumors are derived from epithelial tissues and called carcinomas. In children, the percentage of cases classified as carcinomas and other malignant epithelial neoplasms is approximately 14%; in adults, the percentage is over 90%.

Just what initiates clonal expansion is unknown in most childhood cancers. Epidemiologic studies indicate that as few as 5% of cancers in children are linked to known genetic abnormalities (Table 16-10). Germline and somatic mutations of tumor-suppressor genes are associated with a variety of inherited cancer-susceptibility syndromes and sporadic neoplasia, respectively. Experts once believed that alterations in the structural DNA sequence alone could account for the etiology and pathogenesis of most cancers, but a growing body of evidence currently supports the hypothesis that **epigenetic** events may play a prominent role, particularly in leukemia. Epigenetic inheritance is defined as the acquisition of heritable change in gene expression

TABLE 16-10

Inherited Syndromes Associated with Childhood Cancer

Brain Tumors

Neurofibromatosis type I (NF I) [TS]: neurofibroma, sarcoma, pilocytic astrocytoma
Neurofibromatosis type II (NF II) [TS]: acoustic neuroma, meningioma
Tuberous sclerosis TSC1 and TSC2 (TS): subependymal giant cell astrocytoma
Gorlin syndrome: medulloblastoma, basal cell carcinoma
Turcot syndrome: colon carcinoma, medulloblastoma
Von Hippel-Lindau syndrome, hemangioblastoma, renal cell carcinoma, pheochromocytoma

Leukemia (as many as 5% of cases associated with inherited genetic syndromes)

Down syndrome (10–20-fold increase in ALL and AML)
Bloom syndrome
Neurofibromatosis
Shwachman syndrome
Ataxia-telangiectasia (*ATM* [DNA repair gene])
Fanconi anemia
Kostmann syndrome

Solid Tumors

Multiple endocrine neoplasia (MEN type II A and B) [OG]: thyroid/parathyroid cancer, pheochromocytoma
Li-Fraumeni syndrome (p53) [TS]: sarcoma, breast cancer, brain tumor, leukemia
Adenomatous polyposis coli (APC) [TS]: intestinal polyposis colorectal cancer, hepatoblastoma
Hereditary retinoblastoma (RB1) [TS] retinoblastoma and secondary cancer

ALL, acute lymphocytic/lymphoblastic leukemia; *AML*, acute myeloid leukemia, *OG*, oncogene; *TS*, tumor suppressor gene.

that occurs without a change in DNA sequence. Examples of epigenetic events that appear to be involved in the process of cancer cell transformation are DNA methylation, histone deacetylation, and changes in chromatin organization. Little evidence suggests that exposure to environmental carcinogens plays a major role in pediatric cancer.

HEMATOPOIETIC MALIGNANCIES, LEUKEMIAS, AND LYMPHOMAS

Eighty percent of the cases of acute leukemia that present in childhood are **acute lymphoblastic leukemia (ALL)**. On the basis of immunophenotype, 84% are B-cell subtype, 14% are T-cell subtype, and 2% are mature B-cell subtype (Burkitt) leukemia. Approximately 20% of leukemias are **acute myelocytic leukemia (AML). Chronic myelocytic leukemia (CML)** and **juvenile myelomonocytic leukemia (JMML)** together make up only 1% to 2% of cases. Children with CML present most commonly with leukocytosis and splenomegaly. Their leukemia cells contain the pathognomonic chromosomal translocation t(9:22) known as the **Philadelphia chromosome**. Leukemia cells from approximately 3% of children with ALL share the same chromosomal translocation. JMML usually presents in children younger than 5 year of age with leukocytosis of less than 100,000 cells/mm^3, monocytosis, abnormally elevated hemoglobin F, and hepatosplenomegaly. **JMML** is not associated with the Philadelphia chromosome.

Clinical and Laboratory Evaluation

The diagnostic evaluation of children with suspected leukemia begins with a careful review of the medical history, family history, a thorough physical examination, and laboratory studies (Table 16-11).

History and Physical Examination

It is important to pay attention to the family history, medication history, and any indication of exposure to ill individuals or report of recent international or other travel. Children may exhibit pallor and give a history of persistent fever, weight loss, fatigue, and bone or joint pain. Involvement of the bone marrow with an expanding

TABLE 16-11

Diagnostic Evaluation of Leukemia

Medical history and physical examination
Review of blood smear
CBC (hemoglobin, WBC differential, platelets)
Uric acid, BUN, total bilirubin, LDH, calcium, phosphorus, electrolytes, glucose, amylase, ALT (to identify hepatic, renal or metabolic abnormalities)
Urinalysis: infection, uric acid crystals, specific gravity
PT, PTT, and fibrinogen: DIC
Immunoglobulins, varicella titer
Imaging: chest radiograph (posteroanterior and lateral) [mediastinal mass]; radiography of kidneys or renal ultrasound (if abnormal renal function)
Bone marrow aspirate for cell morphology with cytochemical stains, immunophenotype, cytogenetics and storage for future studies
Lumbar puncture (to identify presence of CNS leukemic involvement)
Blood culture (if febrile and neutropenic)

ALT, alanine aminotransferase; *BUN*, blood urea nitrogen; *CBC*, complete blood count; *CNS*, central nervous system; *DIC*, disseminated intravascular coagulopathy; *LDH*, lactate dehydrogenase; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *WBC*, white blood count.

population of cells may also lead to petechiae, ecchymoses, epistaxis, and a multitude of other signs and symptoms (Table 16-12). The clinical findings are a result of marrow replacement and extent of spread. Often the history of illness is days to weeks in acute leukemia or months in chronic leukemia.

As Table 16-12 indicates, children with ALL present most commonly with fever, fatigue, bone or joint pain, and evidence of bleeding. Complaints of pain in the legs and joints and difficulty walking often indicate periosteal infiltration, elevation, and bone necrosis secondary to leukemia. On physical examination, lymphadenopathy is frequent, and hepatosplenomegaly occurs in over 50% of patients. Rarely, skin infiltration (leukemia cutis) and ocular involvement may be evident. An anterior mediastinal mass with or without adenopathy may be present in T-cell ALL, making it necessary to perform a careful initial history and examination that pays particular attention to respiratory symptoms such as cough or orthopnea. Superior vena cava syndrome and tracheal compression may be a presenting feature of ALL, particularly in adolescents.

Although the presenting features of children with AML and ALL are similar, gingival hypertrophy and subcutaneous or periosteal tumor infiltrates (**chloromas**) are found only in AML.

Pediatric Pearl: Chloromas are masses of myeloid leukemia cells found only in patients with AML and may be present with or without involvement of the bone marrow.

Rarely, subcutaneous masses, but not chloromas, can be found in patients with pre–B-cell ALL. Children with Down syndrome, who are at increased risk for leukemia, are more likely to have AML if younger than 4 years of age. Children with leukemia who have skin infiltrates (leukemia cutis) are more likely to have AML, except those younger than 1 year of age, when leukemia cutis can be seen with either ALL or AML.

Laboratory Evaluation

Children with leukemia most commonly present with increased numbers of WBCs or immature or primitive cells (blasts) circulating in the blood, so it is necessary to scrutinize the blood smear carefully for circulating blasts. In addition, coexisting anemia or thrombocytopenia is often present. A new patient who has

TABLE 16-12

Presenting Clinical and Laboratory Features in Newly Diagnosed Childhood Cases of Acute Lymphoblastic Leukemia

Clinical Feature	*Percent of Children Affected (%)*
Symptoms	
Fever	53
Fatigue	50
Bone or joint pain	40
Bleeding	38
Anorexia	19
Abdominal pain	10
Signs

Anterior mediastinal mass	10
Laboratory findings	
Leukemic cells in spinal fluid	5
Leukocyte count	
$<10 \times 10^9$ cells/L	24
$>50 \times 10^9$ cells/L	23
Hemoglobin	
<8 g/dL	52
>10 g/dL	22
Platelet count	
$>100 \times 10^9$ cells/L	32
$>10 \times 10^9$ cells/L	9

abnormal values of any two of the three blood cell lines (i.e., RBCs, WBCs, platelets) should undergo a bone marrow aspirate. The bone marrow study determines whether the marrow has been replaced with undifferentiated cells (leukemia), has been infiltrated with clumps of tumor cells (solid tumors metastatic to the marrow), or demonstrates evidence of abnormal marrow function (myelodysplasia or aplasia).

Lymphoma should be suspected when enlarged lymph nodes or any tumor mass is found. To make a diagnosis, samples of the tumor are taken in addition to a bone marrow aspirate to check for marrow involvement. Sometimes the diagnosis can be made by identifying malignant cells in pleural fluid removed by thoracentesis. By arbitrary convention, if the bone marrow contains 25% or more blast forms, the patient is considered to have leukemia, and if less than 25% blast forms, the diagnosis is considered to be lymphoma with marrow involvement.

Differential Diagnosis

After a thorough review of the medical history, a physical examination, and laboratory studies, including a CBC, the clinician should consider the many possible differential diagnoses before concluding that leukemia is present (Table 16-13).

TABLE 16-13

Differential Diagnosis of Acute Leukemia

Differential Diagnosis	*Specific Disease*
Decrease in two or more cell lines	
Infection	CMV, EBV, leishmaniasis, severe overwhelming infection, hepatitis, HIV
Bone marrow failure	Aplastic anemia, Fanconi anemia, Shwachman-Diamond syndrome
Marrow replacement or infiltration	Neuroblastoma, Ewing sarcoma, rhabdomyosarcoma
Hemophagocytic syndrome	Familial hemophagocytic lymphohistiocytosis, possibly associated with viral disease or leukemia, medulloblastoma
Decrease in single cell line	
Anemia	Transient erythroblastopenia of childhood, hemolytic anemia, Diamond-Blackfan anemia, dyserythropoietic anemia (congenital)
Thrombocytopenia	ITP, thrombocytopenia absent radii, Wiskott-Aldrich syndrome, DIC, HUS, Kasabach-Merritt syndrome
Neutropenia	Familial neutropenia (Kostmann syndrome), chronic idiopathic neutropenia, splenic trapping
Liver/spleen enlargement	Infections, liver disease, lymphoma, Gaucher disease (other storage diseases), myeloproliferative disease, polycystic disease with liver fibrosis, Langerhans histiocytosis

CMV, cytomegalovirus; *DIC*, disseminated intravascular coagulation; *EBV*, Epstein-Barr virus; *HUS*, hemolytic-uremic syndrome; *ITP*, idiopathic thrombocytopenic purpura.

Acute Lymphoblastic Leukemia

Since the advent of chemotherapy in 1948, the outlook for children with ALL has improved greatly; the cure rate is now approximately 90%. The improved survival seen over the past 40 years has been generated by advances in the design of clinical trials, the addition of tumor molecular markers to the standard classification of acute leukemia, the development of new chemotherapeutic agents, new and improved uses of antibiotics for infectious complications, avoiding excessive toxicity, safer supportive care with blood products, and SCT.

The availability of genetic and molecular information from the leukemic cells of each patient allows for a biologic subtyping of leukemia. Different cure rates are noted for patients with certain cellular biologic differences. Current laboratory research is helping investigators design treatments that are selectively targeted at different subtypes of leukemia. Treatment is then based on the clinical and biological characteristics of each patient at the time of diagnosis. Criteria used to classify and risk-stratify leukemia include age at diagnosis, initial WBC, CNS involvement, leukemia cell immunophenotype, leukemia cell karyotype, molecular abnormalities, and global gene expression patterns.

The **Children's Oncology Group** is a worldwide organization of institutions and physicians, nurses, and allied health professionals from the United States, Canada, Europe, and Australia who are committed to the development of new therapies for malignant disease in adolescence and childhood. Investigators from this group and others have developed specific trial protocols for children based on leukemia classification. These treatment

protocols, which take into account differences in risk of relapse and long-term drug toxicities among patients, are used by member institutions. Patients are monitored for expected and unexpected effects of treatment to provide state-of-the-art care and a source of ideas for improvement of future therapy.

At the present time, the protocols for different categories of lymphoid leukemia are based on presenting features. For patients with B-precursor ALL, there are four levels of treatment regimens depending on clinical and biologic prognostic factors. Separate regimens exist for those children with infant leukemia (under 12 months of age at presentation), mature B-cell ALL and T-cell ALL. Aside from the important clinical features of initial WBC, age, sex, and CNS involvement, the biologic features of immunophenotype, molecular abnormalities, classical cytogenetics, and DNA index are used to qualify and stratify children for treatment regimens. Certain nonrandom chromosomal and molecular abnormalities have independent prognostic importance. Four subsets of children with ALL have a very poor prognosis despite intensive chemotherapy: Ph+ ALL, hypodiploid (less than 44 chromosomes), infants with t(4;11) and those who fail their initial induction therapy. An additional prognostic factor is the measurement of **MRD (minimal residual disease),** which is now used to stratify patients for postinduction therapy.

CHEMOTHERAPY. There are three phases of chemotherapy for ALL: induction, intensification/consolidation, and maintenance. In each phase, multiple drug combinations are used. The total duration of therapy is usually 2 ½ to 3 years. Studies have shown that treatment for a longer period does not improve prognosis, and treatment for a shorter period leads to more frequent relapses.

Leukemia may involve the brain and meninges at the time of diagnosis, and treatment of the CNS is part of therapy. During induction, patients receive intrathecal administration of chemotherapy. To prevent CNS involvement, all patients receive high doses of systemic chemotherapy, which crosses the blood–brain barrier.

In general, children with ALL achieve remission after a 4- to 6-week period of **induction therapy**. The chemotherapeutic agents used during this phase usually include a steroid (prednisone or dexamethasone), vincristine, and asparaginase with or without daunomycin.

After completion of the induction phase, 98% to 99% of children are in **remission,** which is defined as less than 5% blasts when the bone marrow has returned to normal (no leukemia cells can be seen in the marrow). To be in remission, the blood count should have recovered to more than 1,000 neutrophils/mm^3 and more than 100,000 platelets/mm^3. In addition, no infection should be evident.

Once remission is achieved, the **intensification/consolidation therapy** that follows is designed to destroy leukemia cells that cannot be seen with the microscope. In some patients in remission, small numbers of leukemia cells (1 in 1,000 to 1 in 100,000 nucleated marrow cells), which remain undetected morphologically, can be detected by using sensitive MRD immunologic or molecular biologic techniques. The prognostic importance of identifying small numbers of leukemia cells in the marrow in children in early remission is an important topic that is currently undergoing study in clinical trials. It is estimated that as many as 10^8 leukemia cells can remain following induction therapy.

Currently, the duration of the intensification/consolidation phase is 6 to 8 months. Often, patients are admitted to the hospital for administration of chemotherapy or treatment of fever and neutropenia. The chemotherapeutic drugs involved are usually high-dose methotrexate and standard-dose methotrexate, 6-mercaptopurine, cyclophosphamide, cytarabine, and the agents used during induction. The intensity of this phase varies depending on the risk group of the individual patient.

The final phase of treatment is called **maintenance therapy**. The duration of this phase is 1 to 2 years, depending on the duration of the consolidation phase. During maintenance therapy, chemotherapy is less intensive, usually with daily 6-mercaptopurine and weekly methotrexate with periodic vincristine and steroid pulses. The maintenance phase is commonly outpatient-based and well tolerated.

Following completion of therapy, patients are examined regularly to monitor for relapse and identify any late effects of the therapy. If patients are still in initial complete remission 5 years after the end of therapy or 7 ½ years after diagnosis, they are considered cured and free of leukemia. Particular areas of concern to clinicians following children after they have completed chemotherapy include growth and development, cognitive ability, fertility, cardiac and hepatic function, and surveillance for second malignancies.

SUPPORTIVE CARE. To ensure that children pass through therapy without significant morbidity, issues relating to supportive care are of paramount importance. During induction, children need aggressive fluid management as successful therapy can result in rapid tumor cell lysis. The breakdown of leukemia cells releases intracellular contents into the systemic circulation, which are excreted through the kidneys. To prevent complications of **tumor lysis syndrome,** high volumes of fluid (often more than 2 L/m^2), alkalinization of the urine, and allopurinol (a xanthine oxidase inhibitor) are necessary. In patients with poor renal function, rasburicase, a recombinant urate oxidase enzyme, may be utilized to treat tumor lysis syndrome.

Frequently, infectious complications may develop during therapy due to neutropenia- or therapy-induced immunosuppression. Both bacterial and systemic fungal infections may occur. *Pneumocystis carinii (*now also called *Pneumocystis jiroveci)* is a pathogen of particular importance; infection can be prevented by administration of a combination of trimethoprim and sulfamethoxazole, given daily for three consecutive days each week. This prophylactic regimen is given throughout the duration of therapy and continued several months after therapy has been completed. Patients on therapy are followed closely with weekly monitoring of CBCs. Those who develop a temperature above 38°C and have an ANC less than 500/mm^3 are admitted to the hospital for therapy with appropriate broad-spectrum antibiotics.

STEM CELL TRANSPLANT. Chemotherapy alone results in long-term disease-free survival (**DFS**) in over 80% of children with ALL, so BMT is considered early during the first remission only for children who are likely to have a very poor prognosis—a **DFS** of less than 40%. (The DFS is the period from the achievement of complete remission to the time of relapse.) Patients with Ph+ ALL, hypodiploid ALL, infants less than 12 months of age with t(4;11), day 29 MRD greater than 1% and those who have failed initial induction therapy are considered to have a DFS of less than 40%. Children with these characteristics should be considered for an allogeneic marrow transplant during first remission because current reports indicate that following BMT, these high-risk patients have a DFS of 67% to 80%. Otherwise, BMT is used only when patients have suffered a relapse and are in second remission.

Acute Myelocytic Leukemia

A heterogeneous disease, AML is classified based on the morphology of the blasts and by the presence or absence of specific cytogenetic abnormalities. The WHO classification of AML and the French–American–British (FAB) classification are frequently used to subtype the leukemia. The outlook for children with AML has gradually improved and now almost 60% are cured, although the rate of improvement in prognosis is slower than for ALL.

CHEMOTHERAPY. Following one or two courses of an intensive induction regimen using aggressive combinations of several agents (usually high-dose cytosine arabinoside, daunorubicin [or idarubicin, mitoxantrone], etoposide, 6-thioguanine, dexamethasone), over 90% of children are in remission.

However, the morbidity and mortality of this myelosuppressive induction are quite high. Approximately 5% of children are resistant to induction therapy, and 10% die during induction from infectious or toxic causes. Although as many as 90% of children achieve remission, some 60% are cured of their disease with chemotherapy alone. The risk of severe toxicity and death associated with the therapy is significant.

Once children achieve remission, the next phase of therapy comprises three or four aggressive courses of consolidation chemotherapy or SCT. Identifying the most effective chemotherapy regimens for children once they achieve complete remission is still under active investigation. Currently, repeated courses of intensive myelosuppressive chemotherapy are given over 4 to 6 months. This treatment is associated with frequent hospitalization because children are at great risk for bacterial and fungal infections. Less toxic postinduction therapy is not effective.

SCT may also be useful. The 15% to 20% of patients with a **human leukocyte antigen** (HLA) identical sibling donor may be transplanted soon after achieving complete remission and have a 65% 4-year **event-free survival** (EFS), which is from the time of diagnosis until failure of remission, death in remission, or relapse of any kind. HLA identical sibling donor SCT in patients in remission is superior to chemotherapy or autologous SCT in large randomized treatment protocols. At the present time, children with Down syndrome AML or "good prognosis AML" (CBF phenotype or acute promyelocytic leukemia [APL] [see the following]) should avoid SCT because the prognosis is best with chemotherapy alone. For children with high-risk AML or those in first relapse or failing induction, SCT can be performed as soon as remission is obtained, although whether it is better than chemotherapy alone is still a therapeutic question. In all other AML cases if a patient has an HLA match the decision to undergo a SCT is a clinical research question. Studies have not shown that autologous SCT is better than chemotherapy alone in patients in first remission; however, it warrants consideration in second remission if the first remission occurred over 12 months previously.

UNIQUE AML SUBTYPES. In pediatric AML, certain morphologic and karyotypic abnormalities have prognostic importance. The morphology and karyotype of the myeloid leukemia cell at the time of diagnosis can be used to identify children whose leukemia cells contain specific chromosomal translocations that have therapeutic and prognostic importance. Using the FAB system, pediatric AML can be generally subtyped from MO (undifferentiated AML) to M7 (megakaryocytic AML).

Information at diagnosis helps plan therapy for three particularly important AML subtypes. One is **APL,** which is designated as M3 AML by the FAB system. The APL leukemia cells frequently contain numerous granules and Auer rods (pathognomonic of AML). Clinically, patients with APL (about 10% of AML in children) present with low WBCs, and not infrequently DIC occurs when therapy is initiated. The diagnosis

of this subtype of myeloid leukemia is associated with a specific chromosomal translocation, t(15;17). Most importantly, children with APL can be successfully treated and achieve remission with all–*trans* retinoic acid (ATRA) therapy, a vitamin A analog. At the present time, the best outcome is found when chemotherapy is used in combination with ATRA. A new strategy adding arsenic trioxide (As_2O_3) to this combination of ATRA combined with chemotherapy for induction and maintenance is an attempt to improve on the current 70% to 80% EFS.

The second subtype is AML in children with **Down syndrome,** who are at increased risk for acute leukemia. Approximately 1 in 150 children with Down syndrome develops leukemia, and when a child with Down syndrome under the age of 4 years is diagnosed with leukemia, it is usually AML, frequently the M7 type. Newborns with Down syndrome may manifest a self-limited **transient myeloproliferative disorder (TMD)**. This "pseudoleukemia" presents with circulating blasts, leukocytosis, and organomegaly and usually resolves with only supportive care within 6 weeks to 3 months. Some 20% of the TMD patients may succumb before the TMD resolves and may need some minimal therapy. It is estimated that 25% to 30% of infants with Down syndrome whose TMD has resolved will subsequently develop AML 1 to 3 years following resolution of the TMD. Children with Down syndrome exhibit a relatively low tolerance for high-dose chemotherapy. Due to the frequent association with other defects associated with Down syndrome, aggressive therapy should be given very carefully. With current chemotherapy regimens utilizing anthracyclines and cytosine arabinoside for induction, AML-affected children with Down syndrome have a better EFS and a decreased relapse rate compared to children without Down syndrome. In recent studies, EFS, for children with Down syndrome and AML is over 80%.

The third subtype of AML involves children with monosomy 7, who may present with AML in a subacute myelodysplastic phase or de novo AML. Monosomy 7 and partial deletion of the long arm (7q–) is seen in myeloproliferative disease, **myelodysplastic syndrome,** and AML. This cytogenetic finding usually is a sign of poor response to chemotherapy and a rapidly progressive course. Although initial chemotherapy is essential for achievement of remission, children with monosomy 7 have a better EFS when treated with early SCT.

SCT

In Down syndrome–affected children, BMT should be avoided because the prognosis is best with chemotherapy alone. For patients in first relapse or failing induction therapy, a matched unrelated SCT should be considered. Studies have not shown that autologous BMT is better than chemotherapy alone in patients in first remission; however, it warrants consideration in second remission if the first remission occurred over 12 months previously.

Non-Hodgkin Lymphoma and Hodgkin Disease

Lymphomas, a heterogeneous group of diseases arising from B- or T-lymphocytes, are the most common cancer seen in older adolescents—in the 15- to 19-year age group. **NHL** predominates in younger children, and **Hodgkin disease** predominates in adolescents. The risk of lymphoma is increased in children with congenital and acquired immune deficiencies. Currently, most children with lymphoma are curable; the 5-year overall survival rates for NHL and Hodgkin disease are 72% and 92%, respectively.

Lymphoma should be suspected in children with any significantly enlarged lymph node or mass lesion. The diagnostic evaluation always includes a bone marrow aspirate to rule out leukemia and identify whether the marrow is involved. Imaging studies are performed to identify the extent of disease. Both NHL and Hodgkin disease are pathologically classified, once adequate diagnostic material has been obtained and then staged (a determination of the extent of disease) so that appropriate therapy may be given. Patients who have extensive disease require more intensive therapy than children with less extensive disease.

Lymphomas in children are particularly sensitive to chemotherapy. All patients with NHL receive chemotherapy alone, while patients with Hodgkin disease are treated with radiation therapy to the area where tumor masses were present at the time of diagnosis in addition to three to five cycles of chemotherapy.

SOLID TUMORS

Clinical and Laboratory Evaluation

History

A solid tumor in a child is by definition a mass lesion. Most frequently, parents note an abdominal mass or a lump on the trunk or extremity in a young child during a bath; the mass continues to enlarge and may cause

pain. Severe back pain, extremity weakness, and ataxia are symptoms that need immediate evaluation by a health care provider. A thorough review of the clinical history, with signs and symptoms, is mandatory. A detailed family history can be quite helpful for those diseases frequently linked to known genetic abnormalities (see Table 16-8). With solid tumors, the history of illness is usually longer than with hematologic malignancies. A history of signs and symptoms for 3 to 9 months is not unusual. Occasionally hemorrhage into a tumor (e.g., Wilms tumor) may lead to an earlier diagnosis. There appears to be no relationship between time to diagnosis and extent of disease.

Physical Examination

The tumor can often be identified directly by palpation (e.g., Wilms tumor, soft tissue sarcoma, Ewing sarcoma, osteosarcoma) or indirectly because the tumor interferes with normal functioning (e.g., CNS tumors, germ cell tumors). Occasionally, solid tumors (e.g., neuroblastoma, rhabdomyosarcoma, Ewing sarcoma) may partially infiltrate bone marrow and cause signs not unlike leukemia (i.e., anemia, neutropenia, thrombocytopenia).

Laboratory Evaluation

A chronic limp or extremity pain that does not resolve after a few days may be an indication for a radiograph to rule out tumor as a cause. Several laboratory studies are necessary in the diagnostic evaluation of children with suspected solid tumors (Table 16-14).

Differential Diagnosis

The presenting signs and symptoms associated with solid tumors in children can also be seen with several benign conditions and tumors (Table 16-15).

Brain Tumors

Brain tumors, which are the most common category of solid tumor in children in the United States, occur at a rate of 2.5 to 3.6/100,000 children 15 years of age and younger. In general, boys are affected more often (ratio 1.2:1), and the median age at time of diagnosis is 6 ½ years. About one half of all CNS tumors in children are located in the cerebellum (25%) or brainstem (23%). **Astrocytomas,** which account for about 50% of childhood brain tumors, are the common solid tumor seen in individuals less than 20 years of age. Other tumors

TABLE 16-14

Diagnostic Evaluation of Solid Tumors

Clinical history and physical examination
CBC (hemoglobin, differential, platelets)
BUN, LDH, ALT, total bilirubin, creatinine, calcium
PT, PTT, fibrinogen (prior to biopsy, identify DIC)
Varicella titer (may need periodic varicella-zoster immune globulin or acyclovir)
Imaging studies (plain radiographs, CT scans, MRI, ultrasounds) of the primary tumor (to look for distant spread and appropriate staging)
Bone marrow aspirate and biopsy (to look for tumor involvement, particularly in Ewing sarcoma, primitive neuroectodermal tumor, rhabdomyosarcoma, neuroblastoma)
Tumor markers, such as α-fetoprotein (hepatoblastoma, germ cell tumor) and β-human chorionic gonadotropin (germ cell tumor)

ALT, alanine aminotransferase; *BUN*, blood urea nitrogen; *CBC*, complete blood count; *CT*, computed tomography; *DIC*, disseminated intravascular coagulation; *LDH*, lactate dehydrogenase; MRI, magnetic resonance imaging; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *WBC*, white blood count.

TABLE 16-15

Differential Diagnosis of Solid Tumors

Sign or Symptom	*Benign Condition*	*Tumor*
Abdominal mass	Polycystic liver or kidneys, constipation, hydronephrosis, hepatomegaly, splenomegaly, nephroblastomatosis	Wilms tumor, neuroblastoma, lymphoma, germ cell tumor, PNET, soft tissue sarcoma, hepatoblastoma, intra-abdominal desmoplastic round cell tumor of the abdomen
Thoracic mass		
Anterior mediastinum	Thymoma, thymic cyst, dermoid	Lymphoma (NHL), germ cell tumor, thyroid carcinoma
Middle mediastinum	Sarcoidosis, tuberculosis, aspergillosis, vascular anomaly	Lymphoma (Hodgkin disease), metastatic disease
Posterior mediastinum	Esophageal duplication, ganglioneuroma, neurofibroma	Neuroblastoma, Ewing sarcoma/PNET,
Chest wall	Osteoma, Langerhans histiocytosis, scoliosis	Ewing sarcoma/PNET, osteosarcoma
Head and neck mass	Infectious adenitis, hemangioma, cystic hygroma	Lymphoma, rhabdomyosarcoma, nasopharyngeal carcinoma, neuroblastoma
Extremity mass	Fracture, trauma, eosinophilic granuloma, osteoid osteoma, enchondroma	Lymphoma, Ewing sarcoma/PNET, osteosarcoma, rhabdomyosarcoma
Pelvic area mass	Bladder distension, constipation	Rhabdomyosarcoma, neuroblastoma, Ewing sarcoma/ PNET, osteosarcoma
Intracranial mass	Dysplastic tissue, abscess, hemorrhage	Medulloblastoma/PNET, low- and high-grade astrocytoma, brainstem glioma, craniopharyngioma, germ cell tumors, ependymoma

NHL, Non-Hodgkin lymphoma; *PNET*, primitive neuroectodermal tumor.

include **primitive neuroectodermal tumors** (e.g., **medulloblastomas** and other embryonal tumors) (20%), ependymomas (9%), and craniopharyngiomas (less than 5%). As many as 80% of brain tumors in children require surgical intervention, either for diagnosis or as primary treatment; 60% require radiation therapy; and 40% need chemotherapy.

Neuroblastomas

Neuroblastomas, the most frequent extracranial solid tumor in children, account for approximately 8% of all malignancies in patients younger than 15 years of age. These tumors are the most frequent malignancy diagnosed in infants, and over 80% of cases occur in patients younger than 4 years.

Neuroblastomas may originate anywhere along the sympathetic nervous system chain from the organ of Zuckerkandl to the stellate ganglion. Over 65% of primary tumors arise in the abdomen. Adrenal tumors are more common in children, whereas thoracic and cervical primary tumors are more common in infants. Unlike other solid tumors in children, neuroblastomas are associated with metastatic disease at the time of diagnosis in 60% to 70% of patients.

Pediatric Pearl: Common sites of metastasis of neuroblastoma are the bone marrow, bone, liver, and skin.

At the time of diagnosis, children older than 1 year of age are more likely than infants to have disseminated disease. The presenting signs and symptoms of neuroblastoma relate to the primary and metastatic sites involved, as with all solid tumors. For example, abdominal distension and hepatomegaly may occur in an abdominal primary tumor with liver metastases, whereas ptosis or eye swelling may indicate a metastatic or primary neuroblastoma of the head or neck. Several paraneoplastic syndromes are associated with neuroblastoma: (1) opsoclonus-myoclonus, consisting of myoclonic jerking and conjugate, shooting eye movements, and (2) intractable secretory diarrhea, hypokalemia, and dehydration.

During initial evaluation, patients with suspected neuroblastoma should undergo bilateral bone marrow aspiration and biopsy, tumor mass biopsy, and collection of urine for catecholamines to confirm the diagnosis. Imaging studies, including computed tomography and magnetic resonance imaging, iodine-131-meta-iodobenzylguanidine scan are used for staging, along with other biologic, radiographic, and pathologic information prior to initiating therapy. Therapy involves surgery to confirm the diagnosis and usually to remove residual disease following aggressive chemotherapy. In selected high-risk patients, autologous BMT in addition to surgery, and chemotherapy has improved survival. Studies of the effectiveness of autologous BMT for all high-risk patients are as yet incomplete.

Among children with neuroblastoma, a unique category of disease called **stage IV-S neuroblastoma** may affect children younger than 1 year of age. These children present with a limited primary tumor (stage I or II) and have evidence of distant spread to the liver, skin, or bone marrow (but not actual bone involvement). These patients, who have an exceptionally good prognosis, most often require only observation. It is important to obtain adequate tissue for biological studies in these children because a few manifest poor prognostic features such as N-*myc* amplification and require chemotherapy.

Wilms Tumors

Wilms tumors, which are only slightly less common than neuroblastomas, account for 7% of childhood malignancies. They are almost exclusively a tumor of young children, with 80% of cases occurring before the age of 5 years. Exclusive to the kidney, Wilms tumors arise out of persisting immature renal tissue termed nephrogenic rests, which are considered tumor precursor lesions. The classic presentation is a silent abdominal mass; however, as many as one-third of patients complain of pain. Parents usually discover the mass accidentally during bathing or pediatricians identify it incidentally during a physical examination performed for other reasons. The mass is usually limited to one side of the abdomen. Occasionally, acute hemorrhage into the tumor occurs, which is manifested as anemia and an acutely enlarging abdominal mass. Hematuria and hypertension are found in more than 20% of patients.

Histologic variants in Wilms tumor differ based on the presence of anaplasia, and these variants have prognostic importance. The two histologic variants that are associated with the kidney but are no longer called Wilms tumor are now distinct tumor types: (1) clear cell sarcoma and (2) rhabdoid tumor. They have much poorer prognoses than Wilms tumor and require a different chemotherapeutic regimen.

Wilms tumor occurs in hereditary and nonhereditary forms. It is frequently associated with the following congenital anomalies: WAGR syndrome (**W**ilms tumor, **a**niridia, **g**enitourinary abnormalities, mental **r**etardation), with a 30% likelihood of developing Wilms tumor; Beckwith-Wiedemann syndrome (gigantism, macroglossia), with a 5% incidence of Wilms tumor; sporadic aniridia; and hemihypertrophy. When children have one of these anomalies, they should undergo routine surveillance (approximately every 3 months) with renal ultrasound until either Wilms tumor develops or they reach the age of 8 years, at which time the risk of Wilms tumor decreases significantly.

Over many years, children with Wilms tumor have been treated by a succession of clinical protocols developed by the National Wilms Tumor Study Group. At the present time, over 90% of children with Wilms tumor are cured with a combination of surgery, less than 6 months of chemotherapy using vincristine, actinomycin D with or without doxorubicin, and radiation therapy for patients with more advanced disease.

Bone Tumors, Osteosarcomas, and Ewing Sarcomas

Approximately 5% of all childhood cancers are malignant bone tumors. Almost two-thirds are **osteosarcomas**, and one-third are Ewing sarcomas. Each tumor type is more frequent in adolescent patients; the peak occurrence coincides with the adolescent growth spurt. The incidence of osteosarcoma is slightly higher in African American children; the occurrence of Ewing sarcoma in African American children is very rare. A few cases of osteosarcoma have been associated with ionizing radiation and the Li-Fraumeni syndrome. Ewing sarcoma is not associated with any such predisposing conditions.

Although **osteosarcomas** may develop in any bone, they are most often seen in the metaphysis of long bones. Fifty percent of cases involve the distal femur or proximal tibia. Parents usually seek medical attention

because of pain, a mass, or swelling around a joint. Radiographs demonstrate a lytic or sclerotic lesion associated with a soft tissue mass. Staging studies indicate that approximately 25% of patients have metastatic disease. The most frequent site of metastases is the lungs. Therapy involves aggressive chemotherapy and resection of the primary tumor, with limb salvage therapy if possible. Radiation therapy is not used as primary therapy; osteosarcoma is resistant to radiation. With current therapy, as many as 75% of patients with nonmetastatic disease may be cured; in contrast, about 30% of those with metastatic disease at diagnosis may be long-term survivors.

As with osteosarcoma, **Ewing sarcoma,** a **primitive neuroectodermal tumor,** frequently occurs as pain or swelling around a bone or joint in a child or young adult. On presentation, the primary tumor is as likely to be in a long as a flat bone. With long bone involvement, the diaphysis is more likely to be affected, with bony destruction, a soft tissue mass, and an "onion skin" appearance. The pelvis and the femur are the most frequently involved bones. Approximately 20% of patients have pulmonary or bony metastatic lesions at diagnosis. Therapy initially involves intensive chemotherapy and is followed by surgery, radiation, or both for local tumor control. A recent clinical trial found that patients with no metastasis at diagnosis had an EFS of 80%, and those who had metastatic disease at diagnosis had an EFS of 25%.

Soft Tissue Sarcomas and Rhabdomyosarcomas

Of the soft tissue sarcomas, rhabdomyosarcomas are identified in slightly more than 3% of children with cancer; they are the most common soft tissue sarcomas, representing over 50% of cases. Fibrosarcomas and embryonal sarcomas, which are examples of other soft tissue sarcomas, occur much less frequently, and are much less sensitive to chemotherapy. Rhabdomyosarcomas may occur anywhere in the body, either as a clearly visible mass lesion or as an occult mass interfering with a body function (e.g., bowel or bladder control, vision or hearing loss). A few cases occur in patients with Li-Fraumeni syndrome. On histology, there are alveolar and embryonal varieties. In general, the alveolar type of rhabdomyosarcomas occurs in the extremities of older children or adolescents and has a worse prognosis, while the embryonal type develops in the genitourinary or head and neck region of younger children and has a good prognosis.

The tumor may be primarily resected in 35% of cases, with metastatic lesions found approximately 15% of the time. Metastatic disease may occur as enlarged lymph nodes and pulmonary or bone lesions, and bone marrow infiltration is not uncommon. The site, presence of metastasis, and initial resectability of the tumor, in addition to histology, have significant prognostic import, and form the basis for a risk-group stratification. With up to 1 year of aggressive therapy, long survival and cure is likely for more than 90% of patients with low-risk disease, 70% to 80% of those with intermediate-risk disease, and 20% of those with high-risk disease.

Germ Cell Tumors

Approximately 900 children, adolescents, and young adults are diagnosed with germ cell tumors yearly in the United States. One half of pediatric germ cell tumors occur in adolescents from the ages of 15 to 19 years. This group of tumors can be separated into three general categories: benign teratomas (55%), immature teratomas (10%), and malignant tumors (35%). The malignant germ cell tumors are yolk sac tumors (known as endodermal sinus tumors), choriocarcinomas, embryonal carcinomas, and germinomas (seminoma, dysgerminoma).

Clinically, these tumors are usually very large when diagnosed and present as palpable or visible masses usually in the sacrococcygeal, testicular, or head and neck region. Germ cell tumors can cause constipation, urinary obstruction, respiratory difficulty, or neurologic dysfunction. Metastases from non-CNS primary tumors are usually pulmonary or nodal. Typically, ovarian tumors occur in children older than 4 years of age, whereas testicular tumors develop in infancy or adolescence. Tumor markers in the serum are useful for diagnosis and for following patients during and after completion of therapy. Serum α-fetoprotein is elevated in yolk sac tumors, and human chorionic gonadotropin is elevated in choriocarcinoma and embryonal carcinoma.

The management of germ cell tumors depends on site and initial resectability. Benign teratomas require surgical resection only. For control of sacrococcygeal tumors, coccygectomy is warranted to prevent malignant degeneration at a later date. Follow-up involves imaging of the tumor area and monitoring of tumor markers for a 3-year period. Using this follow-up, more than 90% of patients with benign teratomas show no tumor recurrence. Surgery is usually effective for stage I germ cell tumors, while platinum-based adjuvant chemotherapy with etoposide and bleomycin is notably effective for higher stage testicular disease and for all ovarian primary tumors and patients with extragonadal tumors. Complete surgical resection of the tumor should be attempted whenever feasible. At present, the EFS for those with germ cell tumors requiring chemotherapy is greater than 80%.

Allergy and Immunology

Lynda C. Schneider, Elizabeth C. TePas, and Dale T. Umetsu

ALLERGIC DISORDERS

Allergies are caused by untoward, inappropriate immunologic responses to "foreign" substances. Although any individual can have an allergic reaction, **atopic** individuals have a propensity to develop specific types of allergic reactions. Atopic individuals are not allergic to all foreign substances, but tend to develop four specific diseases: **allergic rhinitis, asthma** (see Chapter 18), **atopic dermatitis** (eczema; see Chapter 22), and **food allergy**. Anaphylactic reactions, which are also discussed in this chapter, can occur in both atopic and nonatopic individuals.

Pathophysiology

"Immediate" or type 1 hypersensitivity responses are triggered by antigen binding to allergen specific immunoglobulin E (IgE) molecules on the surface of mast cells, resulting in mast cell degranulation and the release of mediators such as histamine and leukotrienes. These mediators can cause urticaria, sneezing, and wheezing (due to increased vascular permeability and bronchial smooth muscle contraction). Persistence of symptoms occurs as a result of the later production of mast cell mediators such as leukotrienes, prostaglandins, platelet-activating factor (PAF), and cytokines (tumor necrosis factor-α [TNF-α], interleukin-4 and -5 [IL-4, IL-5]). In addition, persistent allergic symptoms may be due to the development of an **allergic inflammatory** response resulting from the influx of basophils, eosinophils, monocytes, lymphocytes, and neutrophils. These cell types interact extensively and amplify the allergic response by producing factors that increase synthesis of allergen-specific IgE (e.g., IL-4, IL-13) and factors that increase the influx and growth of eosinophils, basophils, and mast cells (e.g., granulocyte-macrophage colony-stimulating factor, IL-3, IL-5, IL-9, IL-10, regulated on activation, normal T expressed and secreted [RANTES]). The infiltration of such cells characterizes the allergic inflammatory response associated with **late-phase responses** and bronchial or nasal **hyperreactivity**.

Children of parents with atopic disease are at higher risk for the development of allergies due to the involvement of multiple susceptibility genes. Early exposure to allergens is thought to enhance the development of atopic disease, whereas breastfeeding for 6 months or more may prevent or delay the development of allergies in such infants. Because antigens from foods ingested by the mother can be excreted into breast milk, breastfeeding decreases but does not eliminate exposure of the infant to food allergens. Protection occurs only if the quantity of allergenic foods (e.g., cow's milk, eggs, fish) has been reduced in the maternal diet during lactation. If breast-feeding is not possible, infants at risk may be fed hydrolyzed milk-based formulas (e.g., Alimentum, Pregestimil, Nutramigen). Patients with severe food allergies may require amino acid–based formulas (e.g., Neocate, EleCare).

ALLERGIC RHINITIS

Allergic rhinitis (hay fever) is a very common disorder, affecting as many as 30% to 40% of children. Unless it is associated with asthma, allergic rhinitis is generally not a life-threatening disorder. However, it remains a significant problem in terms of morbidity and health care costs.

Pathophysiology

Allergic rhinitis is caused by allergic reactions to environmental allergens. Reaction to wind-borne pollens of grasses, trees, and weeds leads to **seasonal allergic rhinitis**, and reaction to house dust mite allergen, pet dander, or mold spores results in **perennial allergic rhinitis**.

Clinical and Laboratory Evaluation

History

A careful history regarding the nature, frequency, seasonality, duration, location (e.g., indoors or outdoors, home or school), and intensity of the symptoms is required to assess the problem. Exposure to nonspecific irritants (e.g., perfumes, smoke, air pollution, solvents) may also result in significant symptoms in patients with hyperreactive nasal mucosa.

Symptoms of allergic rhinitis include chronic recurrent sneezing, nasal congestion, clear rhinorrhea, and pruritus of the nose, eyes, ears, and soft palate. Patients frequently rub their nose with the palm of their hands (**allergic salute**) or rub the soft palate with their tongue, producing clucking sounds. Usually, allergic symptoms immediately follow (within 20 minutes) exposure to the offending allergen. In addition, severe reactions with nasal congestion, sneezing, and rhinorrhea may reoccur 6 to 12 hours after exposure (**late-phase reactions**). Perennial allergic rhinitis, with chronic rather than intermittent exposure to allergen, results in significant chronic nasal congestion, sniffing, and snoring but less sneezing than in seasonal rhinitis (which occurs mainly in the morning on awakening). Associations between exposure and onset of symptoms are often less clear in perennial allergic rhinitis. In severe cases, an "allergic facies" with mouth breathing and dental malocclusion or overbite is observed.

Family history may be important. Often, patients with allergic rhinitis have a personal or family history of asthma or atopic dermatitis. An evaluation of clinical responses to medications and an environmental history, recording the place and type of residence, type of indoor heating, and the presence of pets and of cigarette smokers, is also warranted.

Physical Examination

The physical examination is often remarkable for the presence of **clear nasal discharge** and for **enlarged, often pale turbinates**. A transverse nasal crease may be present, secondary to the chronic practice of the allergic salute. Nasal polyps (gray, glistening membranous tissue, often with fine blood vessels) are very uncommon and are seen mainly in older children, adults, and in patients with cystic fibrosis. The sclera may be injected and, rarely, edematous; the lower eyelids may be darkened (**allergic shiners**) from venous stasis and creased (**Dennie-Morgan lines**) from intermittent edema. When **vernal conjunctivitis** is present, the palpebral conjunctiva has a cobblestone appearance. A **geographic tongue** is also common in atopic patients. The middle ear may contain fluid or evidence of infection, and examination of the chest may reveal wheezing, rales, or rhonchi. Signs of asthma and atopic dermatitis may be present. Digital clubbing, which occurs in patients with severe chronic lung diseases (CLDs) (e.g., cystic fibrosis), does not generally occur in patients with an allergy.

Laboratory Evaluation

Specific allergens to which patients are allergic can be identified by (immediate) skin tests or by in vitro measurement of serum allergen-specific IgE. For inhalant allergens, skin testing is more sensitive, is less costly, and gives results in minutes rather than days, compared with in vitro measurement of specific IgE. Identification of specific offending allergens is critical if specific environmental control measures are to be implemented or if immunotherapy is contemplated (see Allergen Immunotherapy).

Other relevant laboratory studies include nasal cytology, which may show eosinophils (instead of neutrophils as in sinusitis). A complete blood cell count (CBC) with differential may show eosinophilia. Elevated serum IgE suggests the presence of allergic disease. Because there is considerable overlap between the values of normal and allergic individuals, however, the total IgE test has low sensitivity and low specificity and is useful mainly as a screening test when the presence of allergic disease is not clear. Total IgE is also elevated in parasitic infections, infectious mononucleosis, allergic bronchopulmonary aspergillosis, and various immunodeficiencies and neoplastic diseases.

Differential Diagnosis

Several conditions may be confused with allergic rhinitis (Table 17-1). Upper respiratory viral infections and chronic sinusitis are often very difficult to distinguish from allergic rhinitis, which is generally associated with sneezing and pruritus of the nose and eyes.

Management

The treatment for allergic rhinitis must be individualized. Disease severity varies greatly, and the clinician must assess its impact on patients before embarking on therapy, especially because some children (and adults) with

TABLE 17-1

Differential Diagnosis of Rhinitis

Diagnosis	*Character of Nasal Discharge*	*Comments*
Allergic rhinitis		Both seasonal and perennial rhinitis are associated with nasal pruritus, sneezing, and allergic conjunctivitis
Seasonal rhinitis	Clear	Symptoms are more acute than in perennial rhinitis
Perennial rhinitis	Clear	Chronic nasal congestion and allergic shiners are prominent
Viral URI	Clear	Symptoms last only 7–10 days, may be associated with sore throat, fever, poor appetite, and exposure to others with URI
Sinusitis	Purulent or clear	Symptoms, often lasting >10 days, are associated with cough, headache, halitosis, and abnormal sinus radiographs or CT scans
NARES	Clear	Skin tests are negative but eosinophils are present on nasal smear
Vasomotor rhinitis	Clear	Perfuse nasal discharge is triggered by exercise, heat, cold, and strong smells
Hormonal rhinitis		
Other	Clear	Nasal congestion can result from hypothyroidism or pregnancy
Nasal polyps	Purulent or clear	Nasal polyps are associated with cystic fibrosis, aspirin triad (asthma, aspirin sensitivity, nasal polyps with chronic sinusitis), or symptoms of chronic rhinitis
Foreign body	Purulent	Condition primarily occurs in children <2 years of age
Tumors	Purulent or clear	Condition is rare in children

CT, computed tomography; *NARES*, nonallergic rhinitis with eosinophilia syndrome; *URI*, upper respiratory infection.

severe allergic rhinitis often refuse prescribed medical therapy. Treatment modalities include avoidance of allergens, pharmacologic therapy (systemic and topical therapy), and allergen immunotherapy. Environmental controls may be sufficient for treatment of less severe disease, but a combination of therapeutic measures is necessary for more severe disease.

Environmental Control and Avoidance of Allergens

Environmental measures play a very important role in the treatment of allergic rhinitis and are often overlooked (Table 17-2).

Pharmacologic Therapy

Antihistamines (H1 antagonists), which are safe and effective medications for the treatment and prevention of allergic reactions, are particularly useful in controlling the symptoms of sneezing, nasal pruritus, and rhinorrhea. A large number of different antihistamines are available, but for simplicity, the physician should become familiar with only a few. Although diphenhydramine (Benadryl) and hydroxyzine (Atarax) are extremely effective in relieving acute allergic reactions, these should be avoided in patients with allergic rhinitis because they are especially sedating. Second-generation antihistamines include loratadine (Claritin) and fexofenadine (Allegra), which are nonsedating, and cetirizine (Zyrtec), which has a low rate of sedation (5% to 10%). Loratadine and cetirizine are available in pill and liquid forms without a prescription, and all are available in combination with a decongestant, although only in dose formulations suitable for older children and adults. Other antihistamines including fexofenadine (Allegra), desloratadine (Clarinex), and levocetirizine (Xyzal) are also effective and have few side effects, but they are expensive and still require a prescription in the United States. Topical antihistamine

TABLE 17-2

Environmental Control Measures

1. Prohibit smokers from entering house.
2. Do not keep pets indoors if patient is allergic to cats or dogs.
3. Avoid using paints, solvent-based glues, or insect sprays while patient is home.
4. Use dust mite control measures, including covering pillows, mattresses, and box springs with special encasements. Keep humidity relatively low, as mites thrive in humid environments. Wash bedding weekly. Keep stuffed animals off bed and to a minimum. Discourage use of upholstered furniture.
5. Discourage use of carpets as floor coverings, because they greatly increase the level of dust mite antigen compared with hardwood floors.
6. Use air conditioners, which are beneficial in hot summer weather because windows can be kept closed to exclude airborne pollen allergens and humidity can be controlled. (This is true not only for houses but also for automobiles.)
7. Use air cleaners with high-efficiency particle arresting (HEPA) filters, which are able to remove 99.97% of particulate matter and are beneficial in bedrooms (effective for pollen, mold spores, and animal dander but not dust mite allergens).

nasal sprays, olopatadine (Patanase), and azelastine (Astelin, Astepro, Astepro 0.15%) are prescription drugs with good efficacy, although bitter taste, and somnolence may reduce compliance.

For patients who have infrequent symptoms, first-generation antihistamines such as chlorpheniramine and brompheniramine, alone or in combination with decongestants (e.g., phenylephrine or pseudoephedrine), may be options for the treatment of allergic rhinitis (and upper respiratory infections). Although the older antihistamines can be sedating and may cause problems during the daytime in school-age children, they are often preferred by parents for use in young children at night.

Systemic adrenergic drugs (decongestants) are effective treatment for nasal congestion, but they do have significant potential side effects and so should be used judiciously. Topical preparations such as oxymetazoline hydrochloride (Afrin) or xylometazoline hydrochloride (Otrivin) should not be used for the treatment of allergic rhinitis because after prolonged use (more than 3 to 5 days), they can cause severe rebound edema (**rhinitis medicamentosa**).

Cromolyn (Nasalcrom), which is available as a nasal spray without prescription, is a weak anti-inflammatory agent. It inhibits mast cell degranulation, but has other antiallergic effects and is effective at relieving symptoms of allergic rhinitis. Because it has virtually no side effects, it is safe for use in children, although it must be used 2 to 6 times/day to be effective.

Topical nasal steroids (mometasone [Nasonex], fluticasone [Flonase], budesonide [Rhinocort], beclomethasone [Beconase], and ciclesonide [Omnaris]) are the most effective pharmacologic agents for the treatment of allergic rhinitis. They provide the greatest benefit for the broadest range of symptoms and are especially useful in patients who have prominent symptoms of nasal congestion. In general, patients receive only minute doses. However, at higher doses systemic effects may occur in some patients, possibly affecting growth and bone mineralization. Therefore, topical nasal steroids should be used with some caution. There is no indication for the use of systemic corticosteroids in the treatment of allergic rhinitis.

Allergen Immunotherapy

Allergen immunotherapy, which involves the subcutaneous administration of increasing doses of allergen, is highly effective and safe in patients with allergic rhinitis in whom specific allergens (inhalant allergens and bee venom) are identified. Immunotherapy alters the underlying immune response to allergens by decreasing the production of allergen-specific IgE and of allergen-induced T_H2 cytokines such as IL-4. It is the only treatment currently available that alters the natural course of, and potentially cures, allergic disease. Because of the cost in terms of time and pain, allergen immunotherapy is generally reserved for patients older than 5 to 6 years of age with moderate-to-severe allergic rhinitis. However, immunotherapy prevents polysensitization and also prevents the progression from allergen sensitization toward allergic asthma, suggesting that a more liberal use particularly

in young children should be considered. The administration of allergen immunotherapy must take place in a physician's office where treatment for systemic reactions is readily available because of a small but real risk of anaphylaxis, particularly in patients with asthma.

ATOPIC DERMATITIS

Atopic dermatitis, or eczema, is a very common childhood skin disorder that affects about 10% to 15% of children. The prognosis in most affected patients is extremely good, with a tendency for remission at 3 to 5 years of age and with approximately 75% of patients outgrowing the problem by adolescence.

Clinical Evaluation

There is no pathognomonic feature or laboratory marker of atopic dermatitis, and therefore the diagnosis is a clinical one. The condition is characterized by the following essential features:

- Pruritis
- Dry, scaly, and often erythematous skin lesions
- Skin lesions that have a typical distribution
- A chronic relapsing course

The most useful clue in making the diagnosis of atopic dermatitis is the distribution of the lesions, which is very typical but varies with age. In the infantile form, the face, extensor surface of the arms, and the chest are affected; the diaper area is spared. In any age, the lesions appear in the antecubital and popliteal fossae, and on the wrists and dorsal surface of the hands. In the adult form, the dorsal surfaces of the hands and feet are affected. Important features that are observed in most cases include early age of onset, personal or family history of atopy, elevated total and specific IgE, and xerosis.

Differential Diagnosis

Any "eczematoid" lesion may have the appearance of atopic dermatitis, and these conditions must be distinguished from atopic dermatitis (Table 17-3). Because the term "eczematoid" is often used to describe the response of the skin to a sensitizing agent, it is important that the specific sensitizing agent be identified (where possible) for proper management. If a specific offending agent is identified (contact antigen or chemical), then part of the preventive approach obviously is avoidance of the particular agent or agents.

Management

As with other atopic diseases, patients with atopic dermatitis often experience a chronic relapsing course, which can be frustrating to both parents and children. The focus of treatment should be on assessing the severity of the problem, which will vary with time, and on providing measures appropriate for the disease severity to control the symptoms. Excellent control can almost always be achieved.

General measures in the treatment of atopic dermatitis include avoidance of irritants such as soap, detergents, solvents, chemicals, and wool or acrylic clothing. The patient should dress with loose-fitting cotton clothing and should avoid overheating. Fingernails should be trimmed often.

Pediatric Pearl: Because pruritus is a significant feature of the disease and injury to the skin from scratching aggravates the condition, it is important to provide measures that reduce pruritus.

Skin hydration is a major part of the treatment plan because it greatly reduces pruritus. Frequent baths with water can result in drying of the skin due to water evaporation, and this has led some physicians to recommend limitations on bathing. However, improved skin hydration can be achieved by using the "soak and seal" technique. With this method short baths or showers in lukewarm water are followed immediately by the application of lubricants to trap moisture in the skin. Depending on the severity of the problem, fragrance-free creams, hydrated petrolatum, or petroleum jelly (Vaseline) can be used. A more severe disease requires greater occlusion, using wet wraps or zinc oxide wraps, which are applied after emollients and topical steroids.

TABLE 17-3

Differential Diagnosis of Atopic Dermatitis

Disorder	*Comments*
Seborrheic dermatitis	Usually begins on scalp (cradle cap) and sides of nose, with greasy, scaly lesions
Diaper dermatitis	Sparing of diaper area with atopic dermatitis
Contact dermatitis	Generally not chronic and recurring; does not occur with typical distribution but rather on exposed sites
Tinea	Usually found in skin folds (neck, diaper area) rather than with typical distribution of atopic dermatitis
Histiocytosis X	Generally hemorrhagic (petechia)
Psoriasis	Raised plaques with sharply demarcated, irregular borders and silvery scales, occurring mainly on scalp, knees, elbows, and genitalia
Pyoderma	Generally pustular
Scabies	Usually in intertriginous areas; can have generalized rash with Id reaction; often several family members affected
Other conditions Immunodeficiency disorders (Wiskott-Aldrich, SCID, hyper-IgE syndrome, IPEX syndrome)	Unusual presentation; poor response to steroids
Metabolic disorders	
Phenylketonuria, histidinemia	
Acrodermatitis enteropathica	
Ectodermal dysplasia	

IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; *SCID,* severe combined immunodeficiency disease.

Treatment of atopic dermatitis involves the use of topical steroids on affected skin (generally only on erythematous areas). Topical steroids decrease pruritus, reduce inflammation, and cause vasoconstriction. Topical steroids are available in different strengths and with different vehicles (Table 17-4). Ointments and gels provide better penetration, and therefore increased potency, compared with creams or lotions. Only low-potency steroids should be used on the face to avoid skin atrophy. High-potency steroids should be avoided except for limited periods and in restricted areas because systemic side effects may occur with treatment of large areas of the body. Generally, systemic steroids are not necessary for the treatment of atopic dermatitis.

Oral antihistamines, which are effective in decreasing pruritus, are another component in the treatment of atopic dermatitis. Antihistamines such as hydroxyzine (Atarax or Vistaril), diphenhydramine (Benadryl), and cetirizine (Zyrtec) are often used. Nighttime doses are particularly important because pruritus and scratching are often worse at night.

Because topical corticosteroids, especially high-potency formulations used for long periods, have potential local and systemic side effects, alternative treatments are promoted. Topical tacrolimus (Protopic) ointment and pimecrolimus (Elidel) are important second-line therapies. These agents have a broad range of antiinflammatory activities and are highly effective at treating atopic dermatitis. They do not cause skin atrophy because they do not affect collagen synthesis. In addition, at prescribed doses, they do not appear to have any systemic side effects.

Most patients with atopic dermatitis respond to treatment with good skin care, topical steroids, and antihistamines, but in those who are resistant to such care, food allergies must be considered. Recent studies

TABLE 17-4

Some Topical Steroid Preparations

Low-potency agents
Hydrocortisone 1%
Moderate-potency agents

Mometasone furoate 0.1% (Elocon)
High-potency agents
Fluocinonide 0.05% (Lidex)
Halcinonide 0.1% (Halog)

indicate that as many as 30% to 50% of young children with severe atopic dermatitis have food allergies. The diagnosis and the management of patients allergic to food are described in the next section.

Disease severity in atopic dermatitis tends to wax and wane. Acute exacerbations, caused by increased scratching, stress, heat, or infection, are characterized by increased pruritus and development of new skin lesions and should be treated with more aggressive skin care, including more frequent baths followed by emollients. When lesions become crusted, weepy, or vesicular, infection with *Staphylococcus aureus* or herpes simplex (**eczema herpeticum**) should be suspected. Discontinuation of steroid medications and emollients is necessary at the involved sites, and cool, wet compresses to the skin are appropriate. Staphylococcal infections warrant topical or systemic antimicrobiol/antibiotic therapy, whereas herpes simplex infections need topical or systemic acyclovir.

Pediatric Pearl: Patients with atopic dermatitis are also prone to superficial fungal skin infections. Therefore, scaly erythematous lesions without the usual distribution of atopic dermatitis that are unresponsive to the usual therapy for eczema should be scraped and examined for hyphae and treated with antifungal medications.

FOOD ALLERGY

Adverse reactions to foods are relatively common in both children and adults. Because of the confusion regarding adverse reactions to food, as many as one-third of adults believe they have food "allergies," although the true incidence is estimated to be less than 3% to 6% of the general population. In this discussion, the term "food allergy" refers to an abnormal response to a food that is triggered by an **IgE-mediated immunologic reaction**.

Pathophysiology (IgE-Mediated Food Allergy)

When severe reactions such as **anaphylaxis** occur immediately after ingestion, it is usually not difficult to identify the offending food. When symptoms are more vague (e.g., headache, fatigue, increased irritability, behavior disorders, colic, diarrhea, vomiting) and do not occur immediately after ingestion of the food, identification of the cause and mechanism can be extremely difficult. Much of this difficulty is due to the fact that reactions to foods can occur via several mechanisms (Table 17-5), some of which are poorly understood.

Clinical Evaluation

The symptoms of food allergy vary considerably and range from rash (often urticaria or hives, or exacerbation of atopic dermatitis) to nausea, vomiting, abdominal pain, and diarrhea to wheezing, nasal congestion, and sneezing. Anaphylaxis, with respiratory and cardiovascular collapse, is the most severe reaction following ingestion (see Anaphylaxis). In young children, other reactions such as colitis may occur, in which case the mechanism may include T cells or immune complexes rather than IgE. In infants, food allergies may cause colic, vomiting,

TABLE 17-5

Mechanisms for Developing Adverse Reactions to Food

Mechanism	*Example*
IgE-mediated allergy	Anaphylaxis, urticaria (e.g., peanuts), oral allergy syndrome
IgE and/or Immune (non–IgE-mediated)	Atopic dermatitis, eosinophilic esophagitis
Immune (non–IgE-mediated)	Celiac disease, eosinophilic gastro-enteropathy, FPIES, cow's milk protocolitis
Food poisoning	Botulism, *Staphylococcus* enterotoxins
Infected food	Reaction to viruses or bacteria (e.g., *Salmonella, Shigella, Escherichia coli*)
Pharmacologic effect	Reaction to caffeine, alcohol, tyramine, histamine
Gastrointestinal disorders	Peptic ulcer disease, lactose deficiency, cholelithiasis, inflammatory bowel disease
Reactions to additives	Headaches (sodium nitrate), headache/flushing (monosodium glutamate), diarrhea (sorbitol), acute airway obstruction (metabisulfite)

FPIES, food protein-induced enterocoloitis.

feeding problems, or growth failure. Most food allergies in young children resolve with time, although allergies to peanuts, which can be particularly severe, often remain for life.

Food protein–induced proctocolitis and enterocolitis are non-IgE-mediated food reactions that primarily affect infants, commonly caused by sensitivity to cow's milk protein. Proctocolitis is characterized by bloody stools in formula-fed or breast-fed infants. Food protein-induced enterocolitis syndrome is characterized by severe emesis, diarrhrea, and, at times, dehydration and hypotension up to 2 hours after ingestion of milk, as well as failure to thrive. The neutrophil count is elevated and at times this condition is confused with sepsis. The most common cause is cow's milk, but other foods (e.g., soy, egg) are also associated with these problems. Both proctocolitis and enterocolitis symptoms resolve on withdrawal of milk protein and introduction of hydrolyzed or amino acid–based formulas, and generally fully resolve after 1 to 2 years of age.

Eosinophilic esophagitis is a disorder of mixed IgE- and cell-mediated immunopathology. Patients have dysphagia, vomiting, and abdominal pain, often caused by sensitivity to various food proteins. The diagnosis is made by endoscopy and esophageal biopsy showing large numbers of eosinophils in the mucosa, even after treatment with proton pump inhibitors for 1 to 2 months. Symptoms improve with swallowed corticosteroid aerosols, and avoidance of the offending foods, although occasionally a broad-based elimination diet and elemental diets are required.

Diagnostic Studies

Food reactions are difficult to diagnose because reliable tests are not widely available, except perhaps for IgE-mediated reactions. The diagnosis of food allergy is based on a careful history with regard to the reproducibility of the reaction, timing of the reaction (reactions occurring soon after ingestion are more likely to be confirmed), response to treatment (antihistamines should relieve urticaria), and response to elimination of the food from the diet. Adverse reactions resulting from food poisoning, pharmacologic effects, and gastrointestinal (GI) disorders (see Table 17-5) must be ruled out. A positive family history of food allergy or atopic dermatitis is common, and IgA deficiency may be present.

Skin tests for foods or in vitro measurement of food-specific IgE (RAST) can be performed to confirm IgE-mediated food allergies. Food skin testing or RAST have a relatively **low specificity**, in that positive tests may occur in patients not experiencing allergic reactions to the particular food. However, the tests have a relatively **good sensitivity**; a negative test makes the presence of IgE-mediated allergy unlikely. Skin tests or RAST are of limited value for diagnosing food protein–induced proctocolitis and enterocolitis. A more

definitive, although more time-consuming, test for food allergies and food intolerance is the double-blind placebo-controlled food challenge in which the patient is given increasing oral doses of the suspected food in a blinded fashion. The most common foods causing IgE-mediated reactions are milk, eggs, peanuts, tree nuts, shellfish, soy, and wheat. It is important to identify the specific problematic food(s) so that specific dietary recommendations can be made.

Management

Once food allergies have been identified, the treatment is dietary avoidance of the offending food or foods. Some foods, such as celery, are easily eliminated from the diet. Avoidance of other foods such as milk or wheat, which are added to several products such as bread, cakes, and cookies, requires careful dietary planning. Patients or their parents must read food product labels carefully and communicate closely with restaurants and schools in order to avoid the offending foods. Overzealous restriction of the diet frequently causes malnutrition and failure to thrive. Therefore, substitute foods must be recommended. In infants, allergy to cow's milk or soy products (estimated frequency in 2% to 5% of all infants) is often blamed for vomiting and feeding problems, prompting multiple formula changes over short periods. In such instances, diagnostic testing is useful, as is the switch to hypoallergenic formulas such as Pregestimil, Nutramigen, Alimentum, Neocate, or Elecare. Once the feeding problem is under control and the offending food or foods have been identified, substitution of a less costly (and more palatable) formula can be attempted.

Because accidental ingestion of offending foods still may occur in spite of precautions, antihistamines and bronchodilators for mild reactions and epinephrine for more severe reactions (see Anaphylaxis) should be available for administration. Patients with a history of food-induced anaphylaxis should be taught how to self-administer epinephrine using self-injectable epinephrine (Epipen or Twinject), and should wear a Medic-Alert bracelet.

ANAPHYLAXIS

Anaphylaxis is an acute, severe, life-endangering situation caused by an immunologic reaction. Risk factors for fatal anaphylaxis include asthma and other respiratory diseases, cardiovascular disease, and mastocytosis. Peanuts and tree nuts are the foods most likely to cause severe anaphylaxis. Use of β-blockers and angiotensin-converting enzyme inhibitors make anaphylaxis more difficult to treat.

Pathophysiology

Most anaphylactic reactions are IgE- and mast cell–initiated processes and can occur in atopic as well as nonatopic individuals. Virtually any foreign substance, including foods or latex-associated proteins, can induce IgE synthesis, and therefore induce an anaphylactic reaction (Table 17-6). As in other IgE-mediated reactions, mast cells are activated and release the contents of their granules, including histamine; tryptase; TNF; IL-1, IL-4, IL-6, and IL-33; and lipid mediators such as prostaglandin D2, leukotriene C4, and PAF. Histamine, TNF, and PAF cause the production of nitric oxide, resulting in vascular dilation and leakage. Depending on the allergen, mast cells can release some mediators but not others, resulting in clinical variants of anaphylaxis.

Pediatric Pearl: In treating allergic reactions that occur on accidental food ingestion in allergic individuals, delayed administration of epinephrine is associated with a fatal outcome. Allergic reactions should be treated promptly with epinephrine, particularly reactions involving the respiratory tract (e.g., symptoms of wheezing, stridor, cough, or voice change), and the patient should be close monitored to determine whether a second dose of epinephrine is required.

Clinical Evaluation

The symptoms of anaphylaxis include generalized urticaria, stridor, laryngeal edema, difficulty swallowing, wheezing, nasal congestion, abdominal cramps, diarrhea, hypotension (decreased systemic vascular resistance, increased vascular permeability), and vascular collapse. Sneezing, pruritus (especially of hands and soles),

TABLE 17-6

Causes of Anaphylaxis

IgE-Mediated
Drugs and medications Penicillin, cephalosporins Chymopapain, L-asparaginase Blood products
Foods Peanuts, tree nuts, seafood, eggs, milk, wheat, soy
Stinging insects (*Hymenoptera*) Honey bee Wasp, vespid Fire ant
Allergen immunotherapy (allergy shots)
Latex (especially in patients with meningomyelocele)
Immunologic Non-IgE-Mediated
IgG-antigen immune complexes
Aspirin
Preservatives (e.g., metabisulfite)
Anesthetic agents
Radiocontrast media
Direct mast cell degranulation Opiates Vancomycin Ciprofloxacin Complement components C5a, C3a
Nonimmunologic
Idiopathic exercise induced
Cold induced (air or water)

a feeling of impending doom, or hoarseness in the throat and dysphonia may initiate the episode. Some clinicians have classified the degree of severity of anaphylaxis in the following manner:

- 1-Mild: Involving skin and subcutaneous tissues only (generalized urticaria, periorbital edema, angioedema)
- 2-Moderate: Features suggesting respiratory, cardiovascular, or GI involvement
- 3-Severe: Hypoxia, hyptension, or neurologic compromise

It is now recognized that although anaphylaxis (like other allergic reactions) is an acute problem caused by an explosive release of mediators, in many cases anaphylaxis can be protracted or biphasic, due to the development of late-phase responses. Therefore, patients with anaphylaxis who symptomatically improve rapidly with treatment must be observed closely for recurrence for at least an additional 4 to 12 hours after the initial episode. Concurrent illness, underlying asthma, or use of α-adrenergic blockers (propranolol [Inderal]) can also predispose to a more severe episode of anaphylaxis.

Differential Diagnosis

Vasovagal reactions, hypoglycemic reactions to insulin, and cardiac arrests can mimic anaphylaxis. These types of episodes are not associated with skin manifestations (except diaphoresis).

Angioedema without urticaria can be caused by **C1 esterase inhibitor deficiency or hereditary angioedema (HAE)**, an autosomal dominant disorder. Patients have attacks of swelling (angioedema) that can involve any part of the body, including the airway, extremities, and GI tract. Minor trauma may trigger an attack. The disorder, which is not associated with urticaria or pruritis, is diagnosed by low serum level of C4, even when a patient is asymptomatic, and the C1 esterase inhibitor level will also be low or its function abnormal. Traditional treatments for anaphylaxis, such as epinephrine and antihistamines, are not effective. C1 esterase inhibitor replacement therapy for acute episodes and for prophylaxis is an effective although expensive therapy for HAE. Treatment with androgen derivatives such as danazol and stanozolol is effective in preventing symptoms. However, these drugs can have unwanted side effects, especially in children and females.

Management

Successful treatment requires the prompt recognition of anaphylaxis and the institution of appropriate therapy as soon as possible. The causative agent should be identified and discontinued (e.g., intravenous antibiotics). The treatment of choice is epinephrine 0.01 mL/kg (up to 0.3 to 0.5 mL) intramuscular (IM). If anaphylaxis is due to an insect sting or allergy shot, another dose of epinephrine is indicated at the site of the sting or allergy shot, and a tourniquet should be placed around the involved extremity. Supplemental oxygen should be administered if necessary, and an airway should be established and maintained. Intubation or tracheotomy may be required. If the blood pressure is reduced, intravenous fluids (10 to 20 mL/kg of normal saline) should be administered (see Chapters 4 and 24). In addition, diphenhydramine, 1 to 2 mg/kg IM, intravenous (IV), or by mouth (PO), should be given. Cimetidine or ranitidine (H2 receptor antagonists) may also help. Corticosteroids (methylprednisolone/Solu-Medrol 1 to 2 mg/kg IV, or prednisone 1 to 2 mg/kg PO), when given early, may help limit late-phase or prolonged responses. Inhaled bronchodilator therapy (albuterol sulfate) or aminophylline may also benefit patients with wheezing. For prevention, patients with a history of severe bee sting anaphylaxis benefit from immunotherapy with bee venom and from appropriate measures to avoid insects. Patients with a history of food, bee sting, or latex allergy and anaphylaxis should also be taught how to self-administer epinephrine using an EpiPen Twinject and should wear a Medic-Alert bracelet.

IMMUNOLOGIC DISORDERS: RECURRENT INFECTION

Most children have frequent minor infections, including an average of 8 to 10 upper respiratory infections per year and at least one, if not many, episodes of otitis media in the first years of life. Thus, a high proportion of visits to pediatricians are for the evaluation and treatment of infection.

Pathophysiology

Several mechanisms are involved in host defense against infection. These mechanisms may be divided into three groups (Table 17-7). The anatomic-mucociliary compartment is an important part of host defenses and is frequently overlooked in the evaluation of recurrent infection. Innate immunity is the first line of defense against pathogens, occurs relatively rapidly (minutes to hours), and is antigen-nonspecific. However, innate immunity can influence the subsequent development of adaptive immune responses. In contrast, adaptive immunity involves antigen-specific memory and is more versatile, but slower in response (5 to 14 days) than innate immunity, especially with the first exposure to a particular antigen. All of these compartments interact with each other,

TABLE 17-7

Mechanisms Involved in Host Defense

Anatomic-mucociliary barrier mechanisms
Innate immunity Cellular components: phagocytes, dendritic cells, and natural killer cells Soluble factors: complement, acute-phase proteins, and cytokines
Adaptive immunity B-cell compartment: humoral immunity T-cell compartment: cell-mediated immunity

and defects can occur in one or more of them. In young children, all of these compartments are less well developed than in adults, and this immaturity can result in increased susceptibility to infection. In primary immunodeficiency, gene mutations or deletions result in frequent or unusually severe infections, with microorganisms that are either common or unusual. Autoimmune disorders and malignancies may also occur in these patients.

Anatomic-Mucociliary Defenses

The body interfaces with its environment via the skin and the mucous membranes of the respiratory tract. Breaks in the integument or obstruction of normal drainage at these sites can lead to recurrent infection. Several defects in the anatomic-mucociliary system may lead to recurrent infection (Table 17-8).

Innate Immunity

CELLULAR COMPONENTS. Phagocytic cells engulf and digest foreign antigens and microorganisms. **Polymorphonuclear neutrophils** are the predominant phagocytic cells in the blood. Their major function is to ingest pyogenic bacteria and some fungi, particularly *Aspergillus* spores. Neutrophils have cell surface receptors for the Fc portion of immunoglobulin (Ig) and complement, which enhance recognition and phagocytosis of foreign material. Phagocytosis triggers the nicotinamide adenine dinucleotide phosphate oxidase system that generates superoxide and hydrogen peroxide, which aid in the killing of ingested organisms.

Macrophages are long-lived phagocytic cells that develop from monocytes in the blood and are particularly effective in killing facultative intracellular organisms (e.g., *Mycobacteria*, *Toxoplasmosis gondii, Legionella pneumophila*). Macrophages present antigen to T cells and secrete cytokines such as IL-1, IL-6, and IL-12.

Natural killer (NK) cells mediate cytotoxic activity against virally infected cells and tumor cells. NK cells, identified by expression of CD56 and CD16, but not CD3, recognize antibody-coated cells (through CD16, FcγRIII) and kill them by antibody-dependent cellular cytotoxicity. In addition, NK cells recognize their targets through killer-activating and killer-inhibitory receptors. The activating receptors recognize several ubiquitous cell surface molecules, and the inhibitory receptors recognize major histocompatibility complex (MHC) class I. Normally both molecules are present on the target cell surface and the kill order is overridden. However, when MHC class I expression is suppressed (e.g., by viral infection), limited inhibitory signaling is generated and the target cell is lysed.

TABLE 17-8

Anatomic-Mucociliary Defects that Result in Recurrent Infection

Anatomic defects in upper airways
Aspiration syndromes (gastroesophageal reflux, poor gag reflex, ineffective cough)
Cleft palate, eustachian tube dysfunction
Adenoidal hypertrophy
Nasal polyps
Obstruction of paranasal sinus drainage (osteomeatal complex disease)
Encephaloceles, sinus tracts
Anatomic defects in tracheobronchial tree
Tracheoesophageal fistula
Pulmonary sequestration, bronchogenic cysts, vascular ring
Tumor, foreign body, or enlarged nodes
Physiologic defects in upper and lower airways
Primary ciliary dyskinesia syndromes, Young syndrome
Cystic fibrosis
Allergic rhinitis (causing congestion, obstruction, and abnormal secretions)
Chronic smoke exposure (resulting in congestion, obstruction, and abnormal secretions)
Other defects
Chronic atopic dermatitis
Ureteral obstruction/reflux
Poor vascular perfusion
Central venous lines, artificial heart valves

Bacteria, fungi, and viruses contain conserved molecular motifs called pathogen-associated molecular patterns (PAMPs), which are recognized by pattern recognition receptors on cells of the innate immune system. There are three different types of pattern-recognition receptors: endocytic, signaling, and secreted. The first type of receptor (e.g., mannose receptor and macrophage scavenger receptor, which recognize microbial carbohydrates) enhances phagocytosis. The second type of receptor leads to increased production of cytokines and costimulatory molecules. These receptors include Toll-like receptors, on the cell surface or in endosomes, which recognize endotoxin, flagellin, bacterial/viral RNA or DNA, and inflammasome receptors (NLRs), which recognize PAMPs in the intracellular compartment. Binding of PAMPs to these receptors leads to enhanced antigen presentation and T-cell activation. A third type of pattern recognition receptor, a soluble factor (e.g., mannan-binding lectin), binds to microbial cell walls, flagging them for recognition by complement and phagocytes.

SOLUBLE FACTORS. The major soluble factors in the immune system are part of **complement,** a system consisting of about 30 plasma and cell membrane proteins that act in a sequential cascade to amplify immunologic stimuli in an antigen-nonspecific manner. The alternative and lectin pathways are antibody-independent, whereas the classic pathway is antibody-dependent. Activated complement components have potent opsonizing; chemotactic, vasoactive, and lytic activity; and can activate neutrophil respiratory burst activity.

Several other soluble factors are important in innate immunity. Acute-phase proteins have both pro- and anti-inflammatory activity. They are involved in recognition of damaged cells and pathogens, activation of complement, induction of cytokine production, and promotion of wound healing. Chemokines are produced by antigen-presenting cells, endothelial cells, and B and T cells. They are involved in recruitment and activation of inflammatory cells. Cytokines serve as the messengers of the immune system and are also produced by inflammatory cells as well as epithelial and endothelial cells.

Adaptive Immunity

The adaptive immune system is composed of B cells and T cells, which generate extremely diverse yet specific receptors against pathogens and proteins.

B CELLS. **Antibodies** or **immunoglobulins** are serum proteins produced by B cells that bind specifically to **antigens** (e.g., glycoproteins, carbohydrates, or toxins). This interaction results in the inactivation or **agglutination** of the antigen, in **opsonization** of the antigen for **phagocytosis**, or in the binding and activation of **complement,** leading to **cytolysis** of the pathogen. Ig molecules can be divided into five major isotypes based on differences in their heavy-chain components: IgG, IgM, IgA, IgD, and IgE. Infants produce only small amounts of Ig before 4 to 6 months of age and receive virtually all of their Ig transplacentally from their mothers. Normal levels of serum Ig reach a nadir at around 4 to 6 months of age and then increase slowly over the next several years (Figure 17-1). Because the immune system matures over a period of several years, the ability to respond to bacterial polysaccharide antigens is not consistently acquired until after approximately 2 years of age. Adult levels of IgG are not present until about 5 to 7 years of age, whereas adult levels of IgA are not acquired until 10 to 14 years of age.

IgG, the major Ig in serum, is the major Ig produced in **secondary immune responses**. It diffuses well into tissues and crosses the placenta. IgG can be subdivided into four subclasses based on differences in the heavy chain: IgG1, IgG2, IgG3, and IgG4. In general, the IgG2 subclass accounts for antibody responses to polysaccharide antigens, whereas the IgG1 and IgG3 subclasses account for responses to protein antigens.

IgM in the first antibody produced after primary antigenic stimulation. It is involved in complement activation and opsonization. Secretory IgA is the primary Ig of the mucosa. IgD serves as an antigen receptor on B cells. IgE is the principal mediator of immediate hypersensitivity reactions.

T CELLS. T lymphocytes are involved in many immune mechanisms, including the cytolysis of virus-infected cells; stimulation of B-cell activation and differentiation; and recruitment of macrophages, neutrophils, eosinophils, basophils, and mast cells. T cells are the major cell type responsible for immunity to intracellular organisms (viruses, *Mycobacteria*, *Toxoplasma gondii, Legionella, Brucella*), fungal organisms (e.g., *Candida*), and protozoa; for immune surveillance for cancer cells; and for causing **graft-versus-host disease** in patients after bone marrow transplantation.

T cells can be divided into two major subsets: CD4+ and CD8+. **CD4+ T cells** produce **cytokines** and play a central role in helping and regulating immune responses. CD4+ helper T (T_H) cells can be further subdivided into T_H1 cells, which secrete cytokines such as interferon-α and IL-2; T_H2 cells, which secrete cytokines such as IL-4, IL-5, and IL-13; T_H17 cells, which secrete IL-17 and IL-22; and T_{Reg} cells, which express the transcription factor Foxp3. T_H1 cells are important in activating macrophages and in cell-mediated immunity, and T_H2 cells are critical for the activation and differentiation of B cells (humoral immunity) and in downregulating immune responses. T_H17 cells are involved in protection against bacteria and fungi, and increased T_H17 cell activity is associated with autoimmunity, including inflammatory bowel disease. Development of

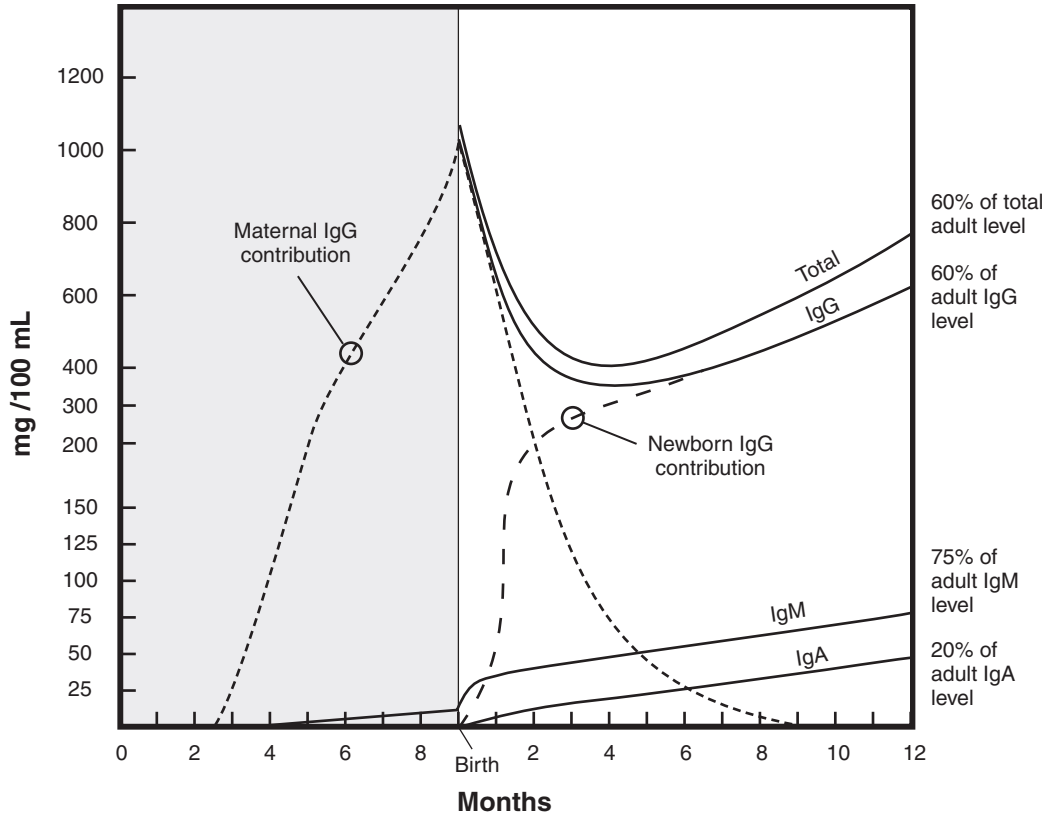

FIGURE 17-1. Immunoglobulin (IgG, IgM, IgA) levels in the fetus and infant in the first year of life. The IgG of the fetus and newborn infant is solely of maternal origin. Maternal IgG disappears by 9 months of age, by which time endogenous synthesis of IgG is well established. IgM and IgA in the neonate are entirely endogenously synthesized because maternal IgM and IgA do not cross the placenta.

T_H cells expressing inappropriate cytokine profiles can exacerbate infection and cause allergy (T_H2), autoimmunity (T_H1), and graft-versus-host disease. Reduced numbers or activity of T_{Reg} cells is also associated with allergy and autoimmunity, and patients with mutations in Foxp3 (immune dysregulation, polyendocrinopathy, enteropathy, X-lined [IPEX] syndrome) develop severe food allergy, eczema, and autoimmune disease. **CD8+ T cells** are involved in killing virus-infected cells or tumor cells and possibly in suppressing or limiting immune responses.

Clinical and Laboratory Evaluation

History

A careful history of the frequency, type, location, and severity of infections is required to assess the severity of the problem and determine the extent of the immunologic workup that is necessary. Appropriate clinical judgment is essential so that the immunologically normal child is not burdened with unnecessary tests but the rare child with a true immunodeficiency is not missed. Determining the number of infections is an important part of the assessment. Separate episodes must be differentiated from recurrence of single episodes, which often occurs when episodes of otitis media or sinusitis are inadequately treated. **With upper respiratory infection or otitis media, individuals who have more than 6 to 10 episodes per year may require investigation.** However, there is wide variation in the number of such infections occurring in immunologically normal children, and the frequency can increase with increased exposure, as in day-care centers or schools, and during the winter months. **With more severe infections such as meningitis or sepsis, individuals with two or more such infections may warrant investigation.**

The site(s) of infections must also be determined. Patients with antibody deficiency disorders or with ciliary dyskinesis develop infections at multiple sites (e.g., ears, sinuses, lungs). Individuals with T-cell deficiencies or neutrophil disorders such as chronic granulomatous disease (CGD) develop infections at multiple mucous membrane sites (skin, nails, mouth, and groin). In contrast, individuals with anatomic problems (e.g., sequestered pulmonary lobe or ureteral reflux) develop infections confined to a single anatomic site (e.g., a single pulmonary lobe or the urinary tract).

The history must also include determination of the type(s) of infections that have occurred. Infection with encapsulated bacteria suggests antibody, complement, or neutrophil deficiency disorders. Multiple infections with fungi suggest T-cell deficiency. Invasive pulmonary infection with *Aspergillus fumigatus* suggests **CGD**. Infections with *Neisseria* suggest a complement disorder. Severe infection after administration of live viral vaccines indicates severe immunodeficiency (e.g., reaction to oral polio vaccine suggests the diagnosis of **X-linked agammaglobulinemia**). Finally, development of opportunistic infections caused by uncommon organisms such as *Pneumocystis carinii* or *Pseudomonas aeruginosa* suggests severe impairment of the immune system.

Another important aspect of the history is the assessment of the severity and consequences of the infections. Clearly, recurrent life-threatening infections such as meningitis or sepsis are worrisome and require extensive investigation. However, recurrent otitis media or sinusitis may occur in immunologically normal children and require only limited studies. In such cases, full recovery is achieved after each infection without the accrual of morbidity. In contrast, recurrent infection in immunologically deficient children is associated with incomplete recovery at the sites of infection (e.g., tympanic membranes, skin, lung), resulting in scarring, abnormal hearing, persistent drainage, CLD, failure to thrive, or anemia of chronic disease. In these cases, the accrual of substantial morbidity from repeated infections (including minor infections) suggests the presence of significant immunologic deficiency.

Other important aspects of the history include (1) family history of infants dying from infection, and (2) HIV risk factors such as history of blood transfusions, intravenous drug use, or family history of HIV infection. A history of the particular conditions suggests certain immunodeficiency disorders. Infection associated with persistent atypical rashes indicates graft-versus-host disease in severe combined immunodeficiency; persistent eczema, history of thrombocytopenia, and Wiskott-Aldrich syndrome; presence of petechiae or telangiectasia and ataxia telangiectasia; neonatal tetany, cardiac disease, ormicrognathia, DiGeorge syndrome; delay in umbilical cord detachment and leukocyte adhesion deficiency; chronic atypical diarrhea and malabsorption, graft-versus-host disease; and chronic viral GI infection, a possible specific immunologic diagnosis. Finally, because **primary immunodeficiency** is rare (see the following), a history of diseases causing **secondary immunodeficiency** should be sought (Table 17-9).

Physical Examination

The physical examination should focus on the extent to which recurrent infection has disturbed normal growth and development and on the presence of features specific for certain immunodeficiency syndromes. The clinician should search for evidence of persistent infection (e.g., evidence of thrush in the mouth, purulent nasal or otitic discharge,

TABLE 17-10

Screening Laboratory Examinations[a]

General
Complete blood count, including hemoglobin, WBC count with differential and morphology, and platelet count
Radiographs to document infection in chest, sinus, mastoids, long bones, if indicated by clinical history culture, if appropriate
Erythrocyte sedimentation rate, CRP
Antibody-Mediated Immunity
Quantitative immunoglobulin levels: IgA, IgG, IgM, IgE
Isohemagglutinin titers (anti-A, anti-B): measures IgM function
Preexisting antibody levels: **diphtheria, tetanus,** polio, rubella, *Haemophilus influenzae, Streptococcus Apneumoniae* (check pre- and post-titers if applicable)
Cell-Mediated Immunity
Lymphocyte count and morphology
Delayed hypersensitivity skin tests (*Candida,* tetanus toxoid, tuberculin, mumps): measures T-cell and macrophage function
T- and B-cell subset enumeration by FACS analysis
T-lymphocyte function analyses: measures proliferation to mitogens and antigens
Phagocytosis
Neutrophil cell count and morphology
Dihydrorhodamine oxidative burst assay (by FACS)
Staphylococcal killing, chemotaxis assay
Myeloperoxidase stain
Complement
Total hemolytic complement (CH_{50}): measures complement activity
C3, C4 levels: measure important pathway components

[a]Initial screening tests for less severe disease are in **boldface** type.
CRP, C-reactive protein; *FACS,* fluorescence-activated cell sorter; *WBC*, white blood cell.

From Berhman R, Kliegman RM: *Nelson's Essentials of Pediatrics*, 4th ed. St. Louis, WB Saunders, 2002.

or persistent rales). It is essential to check the tympanic membranes for scarring and the skin for scarring or rashes. It is also important to examine lymphoid tissue such as the tonsils and lymph nodes. Absence of tonsils suggests **SCID** or **X-linked agammaglobulinemia,** whereas increased size of lymphoid tissue suggests **common variable immunodeficiency (CVID)** or **HIV infection.** Examination of the extremities may show clubbing or cyanosis.

Laboratory Evaluation

Initiation of laboratory tests for recurrent infection is appropriate if the history and physical examination indicate an immunologic diagnosis. The history and physical examination may also suggest which of the five host defense compartments is defective, and the laboratory evaluation should be approached accordingly. The extent of the evaluation also depends on the assessment of the severity of the problem. If the severity of the problem is relatively low, screening tests alone may be necessary; more severe disease requires more sophisticated testing to search for a specific diagnosis (Table 17-10).

Pediatric Pearl: Children with recurrent mycobacterial infections should be evaluated for deficiencies of IFN- production, IL-12 production, and reduced IL-12 receptor function.

Management

Several measures are appropriate in the management of immunocompromised children (Table 17-11). Immediate culture and aggressive antibiotic therapy is necessary for fever or other manifestations of infection because infection may rapidly disseminate and become life-threatening. Continuous prophylaxis with antibacterial, antiviral, or antifungal agents may also be warranted in certain instances in which infection is difficult to control. Children with immunodeficiency contract infections with uncommonly encountered organisms. Therefore, poor response to commonly used antibiotics suggests the presence of a resistant or atypical pathogen, which must be specifically identified by culture or biopsy and antibiotic sensitivities determined.

When examination and laboratory tests show children with recurrent infections to be immunologically normal, the goals of management are to eradicate infection already present and to reduce the frequency of reinfection. The use of **prophylactic antibiotics** is often helpful in children with **recurrent otitis media or sinusitis.** In children who have recurrent otitis media or sinusitis resistant to a long course (6 to 8 weeks) of antibiotics, other treatment methods are necessary (e.g., placement of pressure equalization tubes, adenoidectomy, or endoscopic sinus surgery to improve sinus drainage). **Recurrent streptococcal pharyngitis** is generally not associated with immunodeficiency. Recurrence may be secondary to poor compliance with antibiotic regimens, presence of streptococcal strains resistant to penicillin, or exposure to family members who are carriers.

Pediatric Pearl: Tonsillectomy may be indicated after the failure of effective prophylactic antibiotics and after seven or more episodes of streptococcal pharyngitis in 1 year.

IMMUNOLOGIC DISORDERS: PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiencies may be classified into four categories; B-cell defects, T-cell defects, phagocytic defects, and complement defects. Specific disorders are considered in the following sections.

B-CELL DEFECTS

Deficiencies of antibody production are the most common primary immunodeficiency disorders (50%) (Tables 17-12 and 17-13). These defects result in recurrent sinopulmonary infections (otitis media, sinusitis,

TABLE 17-11

General Management of Patients with Immunodeficiency

Avoid transfusions with blood products unless they are irradiated and cytomegalovirus-negative.
Avoid live virus vaccines, especially in patients with severe T-cell deficiencies or severe agammaglobulinemia and in household members.
Follow pulmonary function in patients with recurrent pneumonia.
Use chest physiotherapy and postural drainage in patients with recurrent pneumonia.
Use prophylactic antibiotics because minor infections can quickly disseminate.
Examine diarrhea stools for *Giardia* and *Clostridium difficile.*
Avoid unnecessary exposure to individuals with infection.
Use intravenous immunoglobulin for severe antibody deficiency states at a dose of 400–500 mg/kg every 3–4 weeks.

TABLE 17-12

Predominant Antibody Defects (B-Cell Defects): Pathophysiologic Aspects

Disorder	*Genetics*	*Onset*	*Pathogenesis*
Bruton agammaglobulinemia	X-linked (Xq22) Btk deficiency	Infancy (6–9 months; 20% of cases present at >12 months, up to 3–5 yr)	Arrest in B-cell differentiation (pre-B level)
CVID	AR, AD (ICOS, CD19, TACI, BAFF)	>2 years of age usually second to third decade)	Arrest in B cell to plasma cell differentiation
Transient hypogammaglobulinemia	Unknown	Infancy (3–7 months)	Delayed development of plasma cell maturation
IgA deficiency	X-linked, AR, ? (6p21.3)	Variable	Failure of IgA expressing B-cell differentiation
IgG subclass deficiency	AR (2p11, 14q32.3)	Variable	Defect in isotype IgG production
IgM deficiency	AR (m heavy chain mutation)	First year	Defective B-cell differentiation
Immunodeficiency with increased IgM (hyper-IgM syndrome)	X-linked (CD40L deficiency)	2–3 years	Defect in IgG and IgA synthesis due to CD40 ligand (CD154) deficiency
	AR (CD40, AID, UNG deficiency)	2–3 years	Defective B-cell differentiation and macrophage activation

AD, autosomal dominant; *AR,* autosomal recessive; *Btk,* Bruton tyrosine kinase; *CVID*, common variable immunodeficiency; *Ig,* immunoglobulin.

pneumonia, and bacteremia) with encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae,* and Staphylococci. Infections with fungal or viral pathogens (except enterovirus) do not generally pose problems. Classically, antibody deficiency states do not become manifest until after 6 months of age, when transplacentally acquired maternal antibody has been depleted. Deficiency of IgG synthesis can be observed in the first year of life (e.g., **X-linked agammaglobulinemia**) or may develop later in childhood or adulthood (e.g., **CVID). Isolated deficiency of IgA** is associated with recurrent infection, although many individuals with low IgA levels are asymptomatic. Similarly, isolated IgG2 subclass deficiency is usually associated with a propensity to develop recurrent sinopulmonary infection.

A classic example of a B-cell deficiency is X-linked agammaglobulinemia, which is a congenital immunodeficiency in males. The characteristic profound deficiency of B cells results in severe hypogammaglobulinemia and absence of lymphoid tissue. The defect is limited to the B-cell linkage and is caused by mutations of the Bruton tyrosine kinase (Btk) gene on chromosome Xq22. Other B-cell deficiencies are listed in Tables 17-12 and 17-13.

Laboratory Evaluation

Patients with B-cell disease have decreased serum Ig levels, which must be interpreted in the context of the patient's age (see Table 17-12). An association of low albumin with low Ig levels suggests a low synthetic rate (due to poor nutrition) or an increased loss of proteins (e.g., from protein-losing enteropathy or through skin disease). High levels of Ig suggest intact B-cell immunity (e.g., in CGD, immotile cilia syndrome, or cystic fibrosis).

TABLE 17-13

Predominant Antibody Defects (B-Cell Defects): Clinical Aspects

Disorder	*Manifestations*	*Associated Features*	*Laboratory Evaluation*	*Treatment*
Bruton agammaglobulinemia	Recurrent high-grade infections (sinusitis, pneumonia, meningitis) with *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus,* and *Pseudomonas aeruginosa;* poliomyelitis with polio vaccine	Lymphoid hypoplasia (no tonsils)	Decreased CD19 or $CD20^+$ B cells, Btk mutation or absent mRNA or protein, agammaglobulinemia, absent isohemagglutinins	IVIG, antibiotics
CVID or common variable agammaglobulinemia	Sinusitis, bronchitis, pneumonia, chronic diarrhea	Autoimmune disease (RA, SLE, Graves disease, ITP), malignancy	Decreased IgG and IgA, absent isohemagglutinins	IVIG, antibiotics
Transient hypogammaglobulinemia	Recurrent viral and pyogenic infections	Frequently in families with immunodeficiencies	Decreased immunoglobulins, often have normal titers to tetanus and diphtheria toxoids and normal isohemagglutinins	Antibiotics (no IVIG)
IgA deficiency	Sinopulmonary and GI infections; may be normal	IgG subclass deficiency, common variable immunodeficiency, autoimmune disease	Serum IgA <7 mg/dL with normal IgG and IgM, normal response to immunizations	Antibiotics
IgG subclass deficiency	Variable (normal to recurrent infections) sinopulmonary and GI	IgA deficiency, ataxia telangiectasia	IgG subclass deficiency (IgG 1, 2, 3, or 4); whether patient responds to protein, polysaccharide and viral antigens is more relevant	Antibiotics (IVIG if has antibody deficiency to many antigens)
μ heavy chain deficiency	Recurrent septicemia, pneumococcus, *H. influenzae*		All isotypes decreased	Antibiotics, IVIG
Immunodeficiency with increased IgM (hyper-IgM syndrome)	Recurrent pyogenic infections (otitis media, sinusitis, tonsillitis, pneumonia), *Pneumocystis carinii* pneumonia, chronic diarrhea	Hematologic autoimmune disease	CD40L mutation, decreased IgG and IgA and normal to increased IgM, normal numbers of B cells but no antigen-specific antibodies	IVIG

Btk, Bruton tyrosine kinase; *CVID*, common variable immunodeficiency; *GI,* gastrointestinal; *Ig*, immunoglobulin; *ITP,* idiopathic thrombocytopenia purpura; *IVIG,* intravenous immunoglobulin; *RA*, rheumatoid arthritis; *SLE,* systemic lupus erythematosus.

Pediatric Pearl: Very high levels of immunoglobulin suggest HIV infection.

Because the level of total Ig may sometimes be within the normal range even in the face of abnormal B-cell function, it is also important to determine whether antibodies to specific antigens are present. Titers may be examined for specific antigens to which the patient has been exposed through routine immunizations (e.g., tetanus). If titers are low, the patient can be reimmunized, and the titers can be reexamined 2 to 4 weeks later. Inadequate responses to polysaccharide antigens such as *S. pneumoniae* generally occur before 2 years of age. Older patients with reduced responses associated with IgA deficiency and IgG subclass deficiency may over time evolve into generalized hypogammaglobulinemia and CVID. Patients with X-linked agammaglobulinemia do not have circulating B cells, which can be confirmed by B-cell enumeration on flow cytometry.

Management

The treatment for such B-cell disorders as X-linked agammaglobulinemia and CVID is intravenous immunoglobulin (IVIG) and prophylactic courses of antibiotics with a low threshold for use (see Table 17-13). Patients with other antibody deficiency disorders benefit from prophylactic antibiotics, but IVIG should be used only if prophylactic antibiotics fail or if B-cell function (responsiveness on antigen challenge) is impaired. Replacement immunoglobulin is most commonly given intravenously every 3 to 4 weeks, but can be also given subcutaneously once a week.

T-CELL DEFECTS

Patients with disorders of T-cell immunity (30% of primary immunodeficiencies) develop infections with fungi or intracellular pathogens (e.g., viruses, mycobacteria, *T. gondii, Leishmania*) that proliferate in somatic cells and macrophages (Tables 17-14 and 17-15). Such patients may lack cytotoxic $CD8^+$ cells and $CD4^+$ helper T cells that activate macrophages. In severe T-cell deficiency, B-cell function may also be impaired because B-cell function requires the assistance of T cells.

A classic example of T-cell deficiency is **DiGeorge syndrome**. The severity of this immunodeficiency syndrome varies markedly from severe T-cell deficiency to normal immune function. In the complete absence of T-cell function, B-cell function fails, resulting in SCID. Other diseases with abnormal T-cell function are listed in Tables 17-14 and 17-15.

Laboratory Evaluation

Immunologic findings in T-cell disorders include lymphopenia and the absence of delayed-type hypersensitivity reactions (e.g., to tetanus, diphtheria, or *Candida albicans*) (see Table 17-14). Negative delayed-type hypersensitivity reactions may be apparent in 10% to 20% of normal individuals. Therefore, patients with a negative test should receive a booster of tetanus or diphtheria toxoids and have repeat skin tests 2 to 4 weeks later. Analysis of T- (and B-) cell subsets may enumerate total numbers of $CD4^+$ and $CD8^+$ cells, NK cells, and monocytes. In addition, functional T-cell studies such as in vitro proliferation of T cells to mitogens (phytohemagglutinin, concanavalin A, or pokeweed mitogen) or to antigens (tetanus toxoid or *Candida*) are also appropriate. In certain states, neonatal screening for SCID has been established by evaluating for T-cell receptor recombination excision circles (TRECs) in spotted blood. TRECs are formed in developing T cells, and are absent when thymocyte development is abnormal.

Management

The treatment for severe T-cell disorders is bone marrow or stem cell transplantation (see Table 17-15). Intravenous immune (γ-globulin) replacement is also useful. In other forms of SCID, transfer of the normal gene into the patient's stem cells (gene therapy) is currently being studied and may soon be a common therapeutic modality for these diseases.

PHAGOCYTIC DEFECTS

Disorders of the phagocytic defenses can be divided into those of deficient cell numbers and those of insufficient function (Tables 17-16 and 17-17). These disorders are characterized by mucous membrane infections

TABLE 17-14

Predominant Defects of Cell-Mediated Immunity (T-Cell Defects): Pathophysiologic Aspects

Disorder	*Genetics*	*Onset*	*Pathogenesis*
DiGeorge anomaly (velocardiofacial syndrome or CATCH 22 syndrome)	AD (22q11.2, 10p13)	Early infancy	Hypoplasia of third and fourth pharyngeal pouch (thymic hypoplasia)
Wiskott-Aldrich syndrome	X-linked (Xp11.22)	Early infancy	53-kD protein (WASP) defect (impaired response to polysaccharide antigens)
AT	AR (11q22.3)	2–5 years	AT gene mutation (PI3 kinase) (involved in chromosomal repair)
Nijmegen breakage syndrome	AR (8q21)	Infancy	Defect in Nibrin protein (involved in chromosomal repair)
Cartilage-hair hypoplasia (short-limbed dwarf)	AR (9p13–21)	Birth	Unknown
SCID			
Common α-chain deficiency; Jak-3 kinase deficiency	X-linked (Xq13.1-q21.1) AR	1–3 months	Common α chain (αc) mutation or Jak3 dysfunction → IL-2R dysfunction→ severe T-cell depletion; B cells present, decreased NK cells
IL-7R⟨ chain	AR	1–3 months	Decreased T-cell differentiation, normal B cell and NK cell numbers
ADA deficiency	AR (20q13.11)	1–12 months	ADA deficiency results in dATP-induced lymphocyte toxicity, decreased T, B, and NK cells
PNP deficiency	AR (14q13.1)	1–3 months	PNP deficiency results in dGTP-induced T-cell toxicity
Reticular dysgenesis	AR	1–3 months	Defective maturation of common stem cell affecting myeloid and lymphoid cells
ZAP70 deficiency	AR	1–6 months	Decreased CD8 cells, normal CD4 numbers
Omenn syndrome	AR (11p13)	1–3 months	Mutations of recombinase activating genes (*RAG-1* and *RAG-2*), decreased T and B cells, normal NK cell number
NEMO syndrome	AR (hypomorphic mutations of *IKBKG*)	First year of life	Anhidrotic ectodermal dysplasia, mycobacterial infection, decreased antibody production due to NF-κB dysfunction
Bare lymphocyte syndrome			
MHC class I	AR (6p21.3)	First decade	TAP1 and TAP2 mutations (transporters associated with antigen processing)

TABLE 17-14

Predominant Defects of Cell-Mediated Immunity (T-Cell Defects): Pathophysiologic Aspects *(Continued)*

Disorder	*Genetics*	*Onset*	*Pathogenesis*
MHC class II	AR (1q, 13q, 16p13)	Early infancy	Mutations in RFX-5, RFXAP, CIITA, and RFX-B (DNA-binding factors)
Chronic mucocutaneous candidiasis (APECED, autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy)	AR (*AIRE* deficiency)	3–5 years	Reduced self-tolerance resulting in parathyroid, adrenal and other endocrine autoimmune disease, with candidiasis
Chronic mucocutaneous candidiasis	AR, Dectin-1/*CARD9* deficiency	Childhood	Reduced innate immunity to fungi; no associated autoimmune disease
Lymphoproliferative syndrome XLP1 (Duncan syndrome)	X-linked (Xq24–26);	Variable	SAP defect (SH2D1A). Severe EBV infection, hypogam, decreased NKT cells
Lymphoproliferative syndrome XLP2	XIAP deficiency	Variable	Severe EBV infection, hypogam, decreased NKT cells

AD, autosomal dominant; *ADA*, adenosine deaminase; *AR*, autosomal recessive; *CATCH 22*, cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia with 22q11.2 deletion; *Ig*, immunoglobulin; *IL*, interleukin; *MHC*, major histocompatability complex; *NK*, natural killer; *PNP*, purine nucleosidase; *SAP*, SLAM-associated protein; SCID, severe combined immunodeficiency; *SLAM*, signaling lymphocytic activation molecule; *WASP*, Wiskott-Aldrich syndrome protein.

(e.g., gingivitis, abscesses in the skin and viscera), lymphadenitis, poor wound healing, delayed umbilical cord separation, and absence of pus (in disorders of cell numbers or of leukocyte movement). Microorganisms involved in these infections include *S. aureus,* fungi, and gram-negative bacteria.

Laboratory Evaluation

Evaluation for neutrophil disorders begins with a CBC and the examination of neutrophil number and morphology (see Table 17-16). Further studies are more complex and not always available, including the dihydrorhodamine respiratory oxidative burst assay for CGD and in vitro tests for neutrophil phagocytosis, chemotaxis, and bacterial killing. In addition, tests for expression of CD18 and CD11 antigens (leukocyte adhesion deficiencies) and for myeloperoxidase activity by flow cytometry can be performed.

Management

Frequent courses of antibiotics are required for the treatment of neutrophil disorders (see Table 17-17). The frequency of infection in CGD is also decreased by treatment with subcutaneous recombinant interferon. Recombinant granulocyte-macrophage colony-stimulating factor also appears to be effective in the treatment of some forms of neutropenia.

COMPLEMENT DEFECTS

Deficiency of some components results in recurrent pyogenic infection, whereas deficiency of other components results in lupus-like disease or vasculitis (Table 17-18).

TABLE 17-15

Predominant Defects of Cell-Mediated Immunity (T-Cell Defects): Clinical Aspects

Disorder	*Manifestations*	*Associated Features*	*Laboratory Evaluation*	*Treatment*
DiGeorge anomaly (velocardiofacial syndrome or CATCH 22 syndrome)	Variable	Hypoparathyroidism → hypocalcemia, cardiac anomalies (truncus arteriosus, interrupted aortic arch type B, transposition, atrial septal defect), dysmorphic features (micrognathia, hypertelorism, low-set ears, bifid uvula, short philtrum), esophageal atresia	Decreased CD3 T cells (<500/mm^3 in severe cases), chromosome 22q11.2 deletion in some patients	No treatment needed for partial form, BMT or thymic epithelial explant for severe form
Wiskott-Aldrich syndrome	Recurrent otitis media, pneumonia, meningitis with encapsulated organisms; infection with *Pneumocystis carinii* and herpesviruses	Atopic dermatitis (also asthma and allergies), platelet dysfunction, thrombocytopenia, autoimmune cytopenias and vasculitis, malignancy	<70,000/mm^3 platelets, mutation in WASP or absent mRNA or protein	BMT, splenectomy
AT	Sinopulmonary infections	Neurologic and endocrine dysfunction, malignancy, telangiectasia, sensitive to radiation, decreased IgA	Increased radiation-induced chromosomal breakage in cultured cells, mutation in *ATM*	Antibiotics, IVIG
Nijmegen breakage syndrome	Sinopulmonary, urinary tract, and gastrointestinal infections; bronchiectasis	Sensitivity to ionizing radiation, microcephaly with mild neurologic impairment, malignancy	Increased radiation-induced chromosomal breakage in cultured cells, mutation in Nibrin gene	Antibiotics
Cartilage-hair hypoplasia (short-limbed dwarf)	Variable	Metaphyseal or spondyloepiphyseal dysplasia → short extremities, short stature, fine sparse hair, short fingernails, redundant skin folds	Decreased numbers of T cells and decreased proliferation to antigens, with *RMRP* deficiency	BMT for severe forms

Continued

TABLE 17-15

Predominant Defects of Cell-Mediated Immunity (T-Cell Defects): Clinical Aspects *(Continued)*

Disorder	*Manifestations*	*Associated Features*	*Laboratory Evaluation*	*Treatment*
SCID				
Common γ chain	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Severe graft-versus-host disease from maternal fetal transfusions, failure to thrive	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm^3, and detected gene mutation or decreased enzyme activity (depending on defect)	BMT or stem cell transplant
ZAP-70, Jak-3 kinase, or IL-7R chain	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Severe graft-versus-host disease from maternal fetal transfusions, failure to thrive	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm^3, and detected gene mutation or decreased enzyme activity (depending on defect); absence of CD8 cells in ZAP-70 patients	BMT or stem cell transplant
ADA deficiency	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Multiple skeletal abnormalities, chondro-osseous dysplasia	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm^3, and detected	BMT or stem cell transplant, polyethylene glycol-modified bovine ADA (PEG-ADA) if transplant not an option
PNP deficiency	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Neurologic disorders, severe graft-versus-host disease from transfusions	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm^3, and detected	BMT or stem cell transplant
SCID (reticular dysgenesis)	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Agammaglobulinemia, alymphocytosis, agranulocytosis	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm^3, and detected	BMT or stem cell transplant
Omenn syndrome	Candidiasis, all types of infections (bacterial, viral, fungal, protozoal)	Exfoliative erythroderma, eosinophilia, elevated IgE, lymphadenopathy, hepatosplenomegaly	<20% $CD3^+$ T cells, absolute lymphocyte count <3,000/mm3, and detected	BMT or stem cell transplant

TABLE 17-15

Predominant Defects of Cell-Mediated Immunity (T-Cell Defects): Clinical Aspects *(Continued)*

Disorder	*Manifestations*	*Associated Features*	*Laboratory Evaluation*	*Treatment*
Bare lymphocyte syndrome				
MHC class I	Sinopulmonary infections	Chronic lung inflammation	$CD8^+$ T-cell deficiency, no MHC class I antigens, TAP mutation	Variable
MHC class II	Respiratory tract infections, chronic diarrhea, CNS viral infections (polio, enterovirus, herpes)	Autoimmune disease, failure to thrive, sclerosing cholangitis	$CD4^+$ T-cell deficiency, no MHC class II antigens on B cells and monocytes, decreased immunoglobulins, normal lymphocyte proliferation to mitogens but not to antigens	Variable
NEMO deficiency	Reduced antibody responses, mycobacterial infection	Ectodermal dysplasia	Variable changes in immune parameters	BMT or stem cell transplant, IVIG, antibiotics.
Chronic mucocutaneous candidiasis (APECED)	Candidal infections of mucous membranes, skin, and nails	Autoimmune endocrinopathies	No delayed type hypersensitivity or lymphocyte proliferation to *Candida* auto antibody against IL=17	Systemic antifungal therapy
Lymphoproliferative syndrome (XLP1, XLP2)	Variable decrease in T-, B-, and natural killer cell function and hypogammaglobulinemia following EBV infection	Life-threatening EBV infection, lymphoma or Hodgkin disease, aplastic anemia, lymphohistiocytic disorders	SAP or IL-2R mutation, decreased antibody titers to EBV nuclear antigen (EBNA)	BMT

ADA, adenosine deaminase; *AR*, autosomal recessive; *AT*, ataxia telangiectasia; *BMT*, bone marrow transplant; *CATCH 22*, cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia with 22q11.2 deletion; *CNS*, central nervous system; *EBV*, Epstein-Barr virus; *Ig*, immunoglobulin; *IL*, interleukin; *IVIG*, intravenous immunoglobulin; *MHC*, major histocompatability complex; *PNP*, purine nucleosidase; *SCID*, severe combined immunodeficiency; *WASP*, Wiskott-Aldrich syndrome protein.

TABLE 17-16

Phagocytic Defects: Pathophysiologic Aspects

Disorder	*Genetics*	*Onset*	*Pathogenesis*
CGD	X-linked (66%) (Xp21.1), AR (33%) (1q25, 16q24)	First year of life for X-linked, later for AR	$gp91^{phox}$ deficiency (X-linked) $gp22^{phox}$, $gp47^{phox}$, and $gp67^{phox}$ deficiencies (AR)
Chédiak-Higashi syndrome	AR (1q42–43)	Infancy	Defect in vesicle membrane component → defective bactericidal function and chemotaxis, also poor natural killer and cytotoxic T-cell function
Hyper-IgE (Job syndrome)	AD (*STAT3* deficiency)	Infancy	Decreased cell-mediated immunity and humoral immune responses to specific antigens with near-normal IgG, IgA, and IgM levels, and markedly elevated IgE, impaired chemotaxis, and opsonization, decreased Th17 cell development
Hyper-IgE (Job syndrome)	AR (S*TAT1*, DOCK8, *TYK2* deficiency, decreased IFN-γsignaling	Infancy	Rare forms of hyper-IgE syndrome
Myeloperoxidase deficiency	AR	Variable	Impaired bactericidal and fungicidal activity
Glucose-6 G6PD deficiency	X-linked (highly polymorphic)	Variable (depends on level of enzyme activity)	Impaired bactericidal activity
Leukocyte adhesion deficiency	AR (21q22.3)	Infancy	Mutations in CD18 (β_2 integrin), a α-chain shared by three α-chains (LFA-1, Mac-1, and CR3) on chromosome 16; all four molecules are not expressed; defects in adherence, chemotaxis, and phagocytosis; reduced lymphocyte cytotoxicity
IFN-γ axis deficiency	AR or AD; mutations in *IFNGR1, IFNGR2,* or IL-12B, *IL-12RB1, STAT1*.	Childhood	Reduced IFN-γ secretion, resulting in susceptibility to *Mycobacteria* and *Salmonella*
HSE	AR, mutation in *UNC93B1*	Neonatal period	Reduced TLR3, 7 and 9 function, reduction in IFN production, and susceptibility to HSE

AD, autosomal dominant; *AR*, autosomal recessive; *CGD*, chronic granulomatous disease; *G6PD*, glucose-6-phosphate dehydrogenase; *gp*, glycoprotein; *HSE*, herpes simplex encephalitis; *IFN*, interferon; *Ig*, immunoglobulin.

TABLE 17-17

Phagocytic Defects: Clinical Aspects

Disorder	*Manifestations*	*Associated Features*	*Laboratory Evaluation*	*Treatment*
CGD	Osteomyelitis, adenitis, and abscesses caused by *Staphylococcus aureus, Burkholderia cepacia,* and *Aspergillus fumigatus*	Granulomas (respiratory, gastrointestinal, and genitourinary tracts), failure to thrive, hepatosplenomegaly, lymphadenopathy)	Dihydrorhodamine oxidative burst assay, gene mutation or absent mRNA	Antimicrobial therapy (with granulocyte transfusion for fungal infections), IFN-γ, BMT
Chédiak-Higashi syndrome	Recurrent respiratory tract and other types of infections	Oculocutaneous albinism, neuropathy, giant neutrophilic cytoplasmic inclusions, malignancy	Gene mutation, giant lysosomal granules in neutrophils, neutropenia, abnormal chemotaxis assay with control serum	BMT
Hyper-IgE (Job syndrome)	Staphylococcal abscesses of the skin, lungs, joints, and viscera; infections with *Haemophilus influenzae, Candida,* and *Aspergillus*	Eczema, eosinophilia, coarse facial features, osteopenia, giant pneumatoceles, red hair, malignancy	Increased IgE and IgD; normal IgG, IgA, and IgM; eosinophilia; decreased T-cell proliferation to antigens; low antibody titers	Antistaphylococcal drugs
Myeloperoxidase deficiency	Mild immune dysfunction with increased susceptibility to infection with *Candida* (especially with coexisting disease such as diabetes)	Persistent candidiasis in diabetics	Decreased myeloperoxidase in leukocytes, decreased granulocyte count (when automated counter identifies granulocytes by myeloperoxidase content)	Antifungal therapy
G6PD deficiency	Phenotypically similar to CGD	Hemolytic anemia	Abbreviated H_2O_2 production on superoxide assay, decreased G6PD	Antimicrobial therapy
Leukocyte adhesion deficiency	Staphylococcal, gram-negative enteric bacterial and fungal infections (periodontitis, omphalitis, gingivitis, recurrent skin infections, repeated otitis media, pneumonia, septicemia, ileocolitis, peritonitis, perianal abscesses)	Delayed separation of the umbilical cord, impaired wound healing, leukocytosis (WBC count $>25{,}000/mm^3$) neutrophilia, absence of pus	Flow cytometry for CD18 or CD11a, CD11b, or CD11c (absent); abnormal chemotaxis assay with control serum	BMT for severe form

BMT, bone marrow transplant; *CGD*, chronic granulomatous disease; *G6PD*, glucose-6-phosphate dehydrogenase *gp*, glycoprotein; *IFN*, interferon; *Ig*, immunoglobulin; *WBC*, white blood cell.

TABLE 17-18

Deficiency of Complement and Associated Disease

Deficient Protein	*Associated Disease*
C1q, C1r	SLE, glomerulonephritis
C2	SLE, arthritis, JRA, recurrent infections in some patients
C3	Recurrent infections, glomerulonephritis
C4	SLE-like disease
C5	Recurrent *Neisseria* infections
C6	Recurrent *Neisseria* infections
C7	Recurrent *Neisseria* infections, Raynaud phenomenon
C8	Recurrent *Neisseria* infections
C9	Autoimmune disease in some patients
Properdin C1 inhibitor	Recurrent infections, meningococcemia
Factor D	Hereditary angioedema
Factor H	Glomerulonephritis
Factor I	Recurrent infections
C4-binding protein	Collagen-vascular disease
C5a inhibitor	Familial Mediterranean fever
C3b receptor	SLE
C1 inhibitor	Hereditary angioedema

JRA, juvenile rheumatoid arthritis; *SLE*, systemic lupus erythematosus.

Laboratory Evaluation

The total hemolytic activity of serum (CH_{50}) is a widely available test that is dependent on the presence of normal levels of the major components of complement. If the CH_{50} is abnormal, individual complement components must be analyzed in specialized laboratories.

Management

Specific therapy with component replacement is not available, and frequent and long courses of antibiotics are the current treatment of choice for complement deficiencies. Immunization of patients and their close contacts with pneumococcal and meningococcal vaccines may be useful.

Pulmonology

Carol Conrad

Respiratory failure, the most frequent cause of life-threatening cardiorespiratory illness in children, indicates that there is a failure of gas exchange. Among the many causes of respiratory failure are infection, structural airway abnormality, aspiration into the airway and lungs, pulmonary embolus, exposure to noxious substances (e.g., smoke inhalation), and cardiac failure with pulmonary edema.

Maintenance of normal carbon dioxide homeostasis requires normal lung mechanics, circulation, and ventilatory drive. The principal causes of respiratory failure in children are **pulmonary disease** (pneumonia, acute respiratory distress syndrome, pulmonary edema), **airway disease** (mucous plugs, foreign bodies, anatomic abnormalities, compressions), **restrictive disease** (chest deformity, flail chest, abdominal ascites), and **neuromuscular disease** (myasthenia, botulism, tetanus, intoxication, head injury).

GENERAL PRINCIPLES OF PULMONARY DISEASE IN CHILDREN

Alveoli are few in number at birth at full-term, and maturation of the gas exchange area as well as the supporting cartilaginous structures affects the results of illness much differently in premature infants than in term infants. In turn, respiratory disease in toddlers is different than in older children or adults.

BASIC CONCEPTS IN PULMONARY PHYSIOLOGY

The basic function of the respiratory system is to supply oxygen to the body and to remove excess carbon dioxide from the body. The basic steps involved in this process are as follows:

1. **Ventilation**, which is the exchange of gas between the atmosphere and the alveoli
2. **Diffusion** of gases across the alveolar–capillary membranes
3. **Transport** of gases in the blood
4. **Diffusion** of oxygen from the capillaries of the systemic circulation to the cells of the body
5. **Internal respiration**, which is the use of oxygen and production of carbon dioxide within the cells

These processes cannot occur efficiently if there is a mismatch of airflow (ventilation) and blood flow (perfusion) to the alveoli. This is termed as ventilation–perfusion defect, or a V/Q mismatch.

Various disorders of the pulmonary system affect the first three steps. Decreased ventilation may be due to an absence or occlusion of a conductive airway. If the airways are obstructed physically (e.g., due to a congenital defect such as stenosis or severe malacia [softness of the cartilage] of the airways), this can affect ventilation of the alveolar units. Similarly, obstruction of the bronchi and bronchioles occurs in diseases such as asthma and cystic fibrosis (CF) that are characterized by increased mucous production.

Abnormalities in perfusion can occur in instances of hypoxic or hypercarbic vasoconstriction of the arterioles and capillaries of the alveoli. The presence of an abnormal vascular pathway through the lungs (**arteriovenous malformation**) as well as pulmonary hypertension can also alter V/Q. Conditions that can inflame the alveolar epithelium (alveolitis) or cause fibrosis and thickening eventually create a decreased diffusion of gases across the alveolar wall. Acute inflammation affects gas diffusion more than blood perfusion, but progressive fibrosis affects perfusion eventually.

Gas transport in the blood takes place in two primary ways: by dissolving in plasma or by combining with hemoglobin. Approximately 98% of oxygen transport in the blood occurs by an oxygen–hemoglobin interaction.

The binding of hemoglobin to oxygen is not a linear process; the avidity of hemoglobin for oxygen changes as the heme molecule becomes more "loaded" with oxygen. This relationship is the basis of the sigmoidal shape of the oxyhemoglobin dissociation curve.

Conformational changes in the hemoglobin molecule are essential within muscles and organs to allow for the release of oxygen and the uptake of carbon dioxide. Normal physiologic changes in the blood pH such as acidosis allow for the release of oxygen from the hemoglobin molecule to the tissues, which is essential for proper homeostasis during times of stress, including exercise and disease states such as sepsis. Another example involves fetal hemoglobin, which binds oxygen more avidly than adult type hemoglobin; this gives a growing fetus the ability to extract oxygen from the mother's blood cells.

Certain disease states confer an abnormally high or low affinity of the hemoglobin molecule for oxygen. With sickle cell disease, the hemoglobin molecule has low oxygen-binding affinity, and this worsens as the hemoglobin becomes less saturated with oxygen. As sickle cell hemoglobin starts to release oxygen molecules from its binding sites, it collapses, and the cells become "sickled" in appearance. The red blood cells (RBCs) become lodged in capillaries and produce the vaso-occlusive events typical of sickle cell disease.

When interpreting the meaning of arterial oxygen saturation measurements, it is vital to understand the correlation between the **oxygen saturation (SaO_2)** and the **arterial oxygen content (PaO_2)**. The PaO_2 reading measured with an arterial blood gas determines the amount of oxygen dissolved in plasma, which is in equilibrium with the oxygen bound to hemoglobin. The SaO_2 is a measure of how many available oxygen-binding sites of the hemoglobin molecule are saturated by oxygen.

Pediatric Pearl: To remember an approximate correlation between the PaO_2 and the pulse oximetry reading, a useful memory aid is: PaO_2 readings of 40, 50, and 60 mm Hg correlate with pulse oximetry readings of 70%, 80%, and 90%, respectively. Two rules of thumb properly evaluate SaO_2 readings and blood gas measurements:

1. A PaO_2 value below 80 mm Hg, which indicates hypoxia, is abnormal.
2. An SaO_2 value of 94% or less indicates hypoxia and is abnormal.

It is important to understand that poorly perfused limbs may produce low or inaccurate transcutaneous measurements of oxygen saturation. Shock, vasopressor administration, severe edema, or peripheral edema may cause erroneous readings. Finally, pulse oximeters are not calibrated to read accurately below a saturation of 70%; therefore, reported values less than 70% are difficult to interpret.

Oxygen and Carbon Dioxide Imbalance

Hypoxemia refers to a decreased delivery of oxygen from the atmosphere to the blood, whereas **hypoxia** refers to decreased delivery of oxygen to the tissues. Arterial hypoxia may result from hypoventilation, absolute shunting, diffusion defects, or relative shunting (Table 18-1). Several conditions may lead to hypoxemia (Table 18-2).

TABLE 18-1

Types of Hypoxia

Cause	*Underlying Problem*
Hypoxemic hypoxia	Lower-than-normal PaO_2 (hypoxemia)
Anemic hypoxia	Decreased hemoglobin or RBC count Carboxyhemoglobin Hemoglobinopathy
Circulatory hypoxia Affinity hypoxia	Decreased cardiac output Decreased local perfusion Decreased release of oxygen from hemoglobin to the tissues
Histotoxic hypoxia	Cyanide poisoning

RBC, red blood cell.

TABLE 18-2

Clinical Causes of Arterial Hypoxemia

Problem	*Example*
Low PIO_2 (partial pressure of inspired oxygen)	Low FiO_2, altitude
Alveolar hypoventilation (low alveolar PO_2 with increased alveolar PCO_2)	CNS depression Pulmonary disease (pneumonia, pulmonary edema) Obstructive lung disease (cystic fibrosis, asthma) Restrictive chest wall disease (Jeune syndrome) Neuromuscular disease (muscular dystrophy)
Diffusion block	Pulmonary fibrosis (systemic lupus erythematosus, juvenile rheumatoid arthritis, vasculitides) Alveolitis Pulmonary hypoplasia (congenital lung hypoplasia syndromes) Pulmonary resection (lobectomy, pneumonectomy)
V/Q mismatch, poor distribution of ventilation	Pulmonary embolism Mucous plugging Bronchospasm
Shunt	Congenital heart disease (persistent patent ductus arteriosus, ventricular septal defect with right-to-left shunt, pulmonary arteriovenous malformation) Pneumonia Atelectasis Pulmonary hypertension

CNS, central nervous system.

Hypoventilation is a physiologic state in which the patient is neither breathing a sufficient tidal volume or an adequate number of breaths per minute (minute volume). This results in elevated levels of carbon dioxide in the blood and also in the alveolar gas. When the alveolar carbon dioxide content increases significantly (**hypercapnia**), the volume available for oxygen to diffuse through to the alveolar capillary bed is reduced and creates arterial hypoxemia (Table 18-3).

An **absolute shunt** is defined as blood passing from the right to the left side of the heart without being oxygenated. A shunt diverts blood away from oxygenated alveoli, and the blood cannot receive oxygen. An absolute shunt can occur due to an **anatomic shunt** with persistent fetal circulation through a patent ductus arteriosus (see Chapter 10), idiopathic or secondary pulmonary hypertension, arteriovenous malformation, and congenital heart defects (see Chapter 13).

A **relative shunt** may develop at the level of the alveolus if the alveolus is blocked (pneumonia), collapsed (atelectasis), or filled with fluid (pulmonary edema). Decreased diffusion of oxygen and carbon dioxide across the alveolar epithelium to the pulmonary capillary bed is characteristic of disease states in which the alveolar and bronchiolar epithelium are thickened due to inflammation or fibrosis. This phenomenon is termed a **diffusion defect** and occurs in disease states such as CF, systemic lupus erythematosus, juvenile rheumatoid arthritis, and Wegener granulomatosis.

Many conditions may result in hypercapnia (see Table 18-3). These conditions can be divided into two broad physiologic categories resulting in carbon dioxide imbalance: increased carbon dioxide production and decreased carbon dioxide clearance.

Respiratory Me ments

Blood Gas Analysis

A blood gas determination consists of four important measurements, pH, PO_2, PCO_2, and base excess, which provide information about the respiratory, circulatory, and metabolic condition of the patient.

TABLE 18-3

Causes of Hypercapnia

Problem	*Example*
Increased production	Increased body temperature Excessive muscular activity Physiologic stress Sepsis Parenteral nutrition with glucose
Decreased clearance	Tissue gas exchange Increased tissue CO_2 production Poor tissue perfusion (ischemia) Disrupted diffusion (edema) Loading Capillary shunt from peripheral vasodilation (septic shock) Transport Low hemoglobin level Low cardiac output Unloading Venous-to-arterial shunts (right-to-left cardiac shunts) Pulmonary gas exchange Decreased ventilation (asthma, cystic fibrosis, emphysema, respiratory depression, neuromuscular disorder) Increased dead space (asthma) Disruption of alveolar–capillary diffusion (alveolitis, pulmonary edema, pneumonia)

A sample of blood from arteries, veins, or capillaries may be used for blood gas determination. Arterial puncture is the one measure that most accurately reflects the level of oxygen being delivered to the tissues. A venous blood gas can be used instead of an arterial blood gas but tends to reflect local tissue oxygenation and carbon dioxide clearance. However, a venous blood gas is a reasonable estimate of arterial acid–base status in a patient who is well hydrated and well perfused.

Pediatric Pearl: When perfusion of the circulatory system is adequate, the venous pH is 0.04 units lower than the arterial pH because the venous PCO_2 is 5 to 7 mm Hg higher than the arterial PCO_2.

Carbon dioxide is transported more readily than oxygen in the blood because it is highly lipid soluble. Due to the higher solubility and diffusivity of carbon dioxide, V/Q mismatches lead more frequently to measured abnormalities of the PaO_2.

Respiratory acidosis develops from an imbalance between metabolic carbon dioxide production and pulmonary carbon dioxide excretion. This most often arises from decreased efficiency of carbon dioxide elimination in the lung—**alveolar hypoventilation**. Alveolar hypoventilation results in carbon dioxide retention and **hypercapnia**. A new balance between carbon dioxide production and removal may be corrected by short-term chemical buffering and more long-term renal adaptations. Hypoxemia usually accompanies respiratory acidosis.

Blood pH changes in response to acute respiratory events in expected ways (Tables 18-4 and 18-5). The tables are a guide to determine the direction in which the pH, PCO_2, and the HCO_3^- should vary in different clinical circumstances.

Pediatric Pearl: A tip for rapid analysis of blood gas values: for every 10-mm Hg change in carbon dioxide, the pH changes by 0.08 units in the opposite direction.

TABLE 18-4

Rules of Acute Respiratory Compensation

Change	*Rule*	*Example*
↑ PCO_2	For every increase of 10 mm Hg, pH decreases by 0.08	PCO_2: 40 → 60 mm Hg; pH: 7.40 → 7.24
↓ PCO_2	For every decrease of 10 mm Hg, pH increases by 0.07	PCO_2: 40 → 20 mm Hg; pH: 7.40 → 7.54

Estimating Oxygenation

The PaO_2, the partial pressure of oxygen dissolved in serum, is used as a measure of the adequacy of oxygenation (assuming that there is an adequate amount of hemoglobin present to bind the oxygen, and that the hemoglobin binds oxygen normally). The **alveolar gas equation**, which is the amount of oxygen that should be present in the alveoli (PaO_2) based on a known temperature and FiO_2 (fraction of inspired oxygen), reflects the efficiency of gas exchange.

$$PaO_2 = PiO_2 - PaCO_2[FiO_2 + \{1 - FiO_2/R\}]$$

where PaO_2 = partial pressure of oxygen at the alveolar level, PiO_2 = partial pressure of inspired oxygen, $PaCO_2$ = partial pressure of carbon dioxide in arterial blood as measured by arterial blood gas, FiO_2 = fraction of inspired oxygen, and R = respiratory quotient (0.8). For most clinical applications, the alveolar gas equation can be closely estimated with the following modified formula and thus stated more simply:

$$PaO_2 = [760 \text{ mm Hg} - 47 \text{ mm Hg}] \times FiO_2 - PaCO_2\,(1.25)$$

where 760 mm Hg = barometric pressure at sea level and 47 mm Hg = vapor pressure in airway. $PaCO_2$ is measured from arterial blood gas, which can be used to approximate the alveolar carbon dioxide.

TABLE 18-5

Acid–Base Disturbances as Measured by Arterial Blood Gas

TABLE 18-6

Predicted Effect of Fraction of Inspired Oxygen (FiO_2) on Blood Oxygen Content

FiO_2	*Predicted Arterial PO_2 (mm Hg)*
0.30	150
0.40	200
0.50	250
0.80	400
1.00	500

Subtracting the PaO_2 measured on arterial blood gas from the calculated PaO_2 gives the measure of the **alveolar–arterial oxygen gradient**. Calculation of the alveolar–arterial oxygen gradient while a patient is breathing room air and compared to that obtained while the patient is treated with supplemental oxygen can differentiate hypoventilation from shunting.

Arterial oxygen values can be altered by the fraction of inspired oxygen (FiO_2), the condition of the alveolar air–blood barrier, and the amount of pulmonary blood flow. At sea level, an arterial PO_2 of 97 mm Hg (range, 80 to 105) is normal for a patient breathing "room air." A patient with normal lungs receiving supplemental oxygen should have an arterial PO_2 approximately five times the FiO_2 (Table 18-6).

CLINICAL APPROACH TO THE CHILD WITH PULMONARY DISEASE

When a pediatrician is faced with a child with acute or chronic respiratory illness and worried parents, it is essential to obtain a complete history and perform a comprehensive physical examination.

History

In general, the pulmonary history should include questions that establish the age of onset of the problem and factors that appear to initiate cough, breathlessness, or "noisy" breathing. It is necessary to inquire about the duration of symptoms and whether the problem has persisted despite medical interventions. The vast majority of referrals to pediatric pulmonologists are for recurrent or chronic cough, and the second most frequent reason for referral is for noisy breathing. A significant proportion of children referred with a chronic cough receives the diagnosis of asthma. Other conditions are possible; the history may provide specific clues to the diagnosis of cough (Table 18-7).

Pediatric Pearl: It is important to remember that history taking primarily involves the ability to listen carefully. However, some caution is indicated. Parents may use words that have an entirely different meaning to them than to the health professional. "Bronchitis," "wheeze," and "croup" are some of the most frequently misused words in the pediatric lexicon.

It is essential to determine the nature of the child's problem. For example, is a cough dry or wet? Has the child's primary care physician heard the child wheeze? The child may have associated symptoms or signs with the cough (e.g., pale, boggy mucosa that indicate allergic rhinitis with postnasal drip). Other important factors to consider include the timing of the symptoms, which can lead to rapid diagnosis (e.g., nighttime cough in patients with gastroesophageal reflux disease, which worsens when patients are sleeping or supine); knowledge of response to previous medication regimens, which can help determine the nature of the disease; and any occurrences of allergies to medicines or foods, which could account for the child's current problem or may affect treatment.

The history should also include details of the antenatal and perinatal periods. Decreased fetal motion may indicate a neuromuscular disorder that leads to alveolar hypoventilation and restrictive chest wall disease. **Oligohydramnios** may indicate the presence of pulmonary hypoplasia because much of the amniotic fluid produced by the fetus is

TABLE 18-7

Clues to Diagnosis in Children with Chronic Cough

History	*Disease*
Cough starts when child is supine	Gastroesophageal reflux, postnasal drip
Paroxysmal cough	Pertussis, chlamydia, foreign body
Recurrent cough with wheeze	Asthma, foreign body, mediastinal tumor, cystic fibrosis
Cough associated with swallowing	Gastroesophageal reflux, aspiration due to dysfunctional swallow, tracheoesophageal reflux
Cough with aphonia	Foreign body in larynx, papillomatosis, croup, or psychoneurosis
Ringing, brassy cough	Tracheitis
Barking cough	Croup or subglottic disease
Cough in early A.M.	Asthma
Cough with exercise	Exercise-induced bronchospasm

generated from lung epithelium. Oligohydramnios may also be a sign of a renal anomaly and the presence of other congenital anomalies. Knowledge of any perinatal resuscitation efforts, including the reason for their use, is helpful. It is crucial to know the gestational age at birth and if intubation and mechanical ventilation or supplemental oxygen was necessary to determine whether **respiratory distress syndrome** occurred. Any history of cyanosis in the absence of cardiac anomalies should lead to an investigation of possible tracheal or bronchial stenosis or malacia, decreased alveolar volume (pulmonary hypoplasia), and pulmonary vascular malformations (see Chapter 10).

When evaluating respiratory difficulties, family history is important. A family history of asthma is significant. The family history is also helpful in determining the likelihood of other disorders such as CF; however, the majority of children diagnosed with CF have no family history of the disease. A history of multiple unusual infections that include the sinopulmonary tract or the skin as well as recurrent candidiasis or delayed umbilical cord disconnection could lead to a suspicion of chronic granulomatous disease, immunoglobulin G (IgG) deficiency, or other lymphocytic disorders that predispose children to recurrent infection (see Chapter 17).

Pediatric Pearl: All details of the past medical history are important to elicit. A history of multiple admissions to the hospital or repeated trips to the emergency department can provide information about the adequacy of the regimen of medications children are receiving.

Physical Examination

Before beginning the physical examination, it is necessary to scrutinize the vital signs and anthropometrics. As a general rule, children with chronic illness such as CF or immunodeficiency syndromes present with growth failure. In contrast, children with asthma rarely have problems maintaining their weight.

Examination of the head and neck is an essential part of the pulmonary examination and can guide the differential diagnosis. The structures of the upper respiratory tract warrant careful inspection for signs of sinusitis (edematous, erythematous nasal mucosa; purulent or clear nasal discharge); nasal polyps (present in CF and asthma); allergic shiners (darkness under the eyes); cobble stoning of posterior pharynx (subcutaneous lymphoid nodules that form due to post nasal drip); allergic rhinitis (pale, edematous mucosa); and a nasal crease (or a history of the "salute sign" in which the patient rubs the nose with the palm of the hand). It is also important to look for signs consistent with **obstructive sleep apnea syndrome** when evaluating a history of snoring or gasping during sleep. Children with large tonsils and adenoids are often mouth breathers who snore loudly while asleep. Enlarged tonsils and signs of enlarged adenoids (poor palatal elevation with phonation) are regions of possible airflow obstruction.

TABLE 18-8

Sounds Produced by Lower Airways

Sound (ATS)	*Frequently Used Synonym*	*Acoustic Characteristics*
Crackle		Usually inspiratory sound
Coarse	Rhonchi	Loud, low in pitch
Fine	Rale	Softer and shorter in duration, higher in pitch
Wheeze		Usually expiratory sound
High-pitched		Long, musical
Low-pitched		Loud, long, sonorous

ATS, American Thoracic Society.

Examination of the chest involves observation of the breathing pattern and assessment of the respiratory effort initially. A normal inspiratory-to-expiratory ratio (I:E) is 1:2. Children with **obstructive** types of illness (e.g., CF, asthma) breathe with a prolonged expiratory phase, and the I:E increases to 1:3 or 1:4. In addition, they may have a hyperinflated thorax. Patients with **restrictive** breathing patterns breathe rapidly and shallowly. Inspection of the chest wall for symmetry, pectus deformity, and the size of the thorax is warranted. Retractions can be more difficult to appreciate in infants than in older children; they are not seen in the intercostal spaces. More often, the lower part of the rib cage is actually pulled inward as the diaphragm contracts when the infant inspires due to the high compliance of the chest wall. "Head-bobbing," a result of the use of the suprasternal accessory muscles of respiration, is a sign of increased resistance of the small airways in infants. It is important to evaluate how much effort the patient expends to achieve sufficient airflow. Percussion of the thorax can reveal either hyperresonance due to localized air trapping or dullness to percussion if consolidation of a lobe or segment is present.

When auscultating breath sounds, it is necessary to listen for crackles, wheezing, and stridor. Crackles and wheezes originate from lower airway disease (Table 18-8). Do these sounds occur during inspiration or expiration? The resistance to airflow caused by obstructing lesions depends on the location of the obstruction (intra- or extrathoracic) and on the phase of respiration. Noise that occurs on both inspiration and expiration suggests a **fixed stenosis** of the airway (i.e., a lesion in which the internal diameter, and hence the airway resistance, does not change with the phase of respiration). Such a lesion could be either intrathoracic or extrathoracic in origin.

It is also important to determine the distribution, pitch, and quality of sounds to differentiate between upper (extrathoracic) and lower (intrathoracic) airway pathology (Table 18-9). Airways are distended or compressed during the phases of respiration. The occurrence of an expiratory wheeze in the absence of inspiratory stridor (or vice versa) indicates a **variable stenosis**. When a variable obstruction is **intrathoracic**, it is primarily appreciated on **expiration** because the lesion is dilated on **inspiration** by the negative intrathoracic pressure surrounding the airway at that point. When a variable obstruction is **extrathoracic**, obstruction worsens on **inspiration** and improves during expiration because the positive intraluminal pressures distend this portion of the airway.

Other signs to note on physical examination include heart murmurs; a loud snapping P2 (the portion of the second heart sound that indicates closure of the pulmonic valve, which when loud indicates pulmonary hypertension); digital clubbing (present in CF, cyanotic heart disease, bronchiectasis, inflammatory bowel disease); signs of atopy (eczema, Dennie lines, pale nasal mucosa, edema of mucosa); and enlargement of the abdominal organs.

TABLE 18-9

Sounds Produced by Upper Airway Obstruction

Type of Obstruction	*Type of Pathology*	
	Intrathoracic	*Extrathoracic*
Fixed	Noise on both inspiration and expiration	
Variable	Expiration: Wheeze predominates	Inspiration: Stridor dominates

Laboratory Evaluation

Pulmonary Function Tests

Pulmonary function tests are well characterized in young infants and toddlers as well as in older children. Clinicians have traditionally performed spirometry and lung volume measurements on patients who can accomplish a coordinated, forced expiratory maneuver (i.e., children over 5 years of age). More recently, techniques have been developed in which these maneuvers can be performed with sedated infants, but standard values are still being collected and the technique refined. Results are more readily obtainable in children older than 5 years of age. Uses for pulmonary function tests include (1) differentiating between restrictive and obstructive lung pathology, and (2) answering questions about respiratory function. Clinicians most commonly perform these pulmonary tests to assess the response to bronchodilator treatment and to determine whether a disease is improving or progressing in response to therapy. It is useful to obtain results both before and after bronchodilator use to determine reversibility of obstruction.

Two basic methods are useful for the determination of lung volume and function. **Spirometry** measures "active" lung volumes (i.e., air volumes that a patient actively blows into the spirometer). A pneumotachometer simultaneously measures the rate of airflow. Use of these values allows the clinician to characterize the type of lung disease that affects a particular child. **Plethysmography** measures the actual volumes of air contained within the thorax. The patient sits in the plethysmograph and performs breathing maneuvers that result in measurable pressure changes inside the device. Using the ideal gas law, it is possible to calculate the volume at which the maneuver began. By convention, the maneuver begins when the patient has exhaled to the **functional residual capacity (FRC)**. Once this volume is known, the calculation of all other lung volumes is possible.

The use of spirometry and plethysmography is reliable in children of all ages. However, the technique used for infants and toddlers is different from that used for more cooperative older children, who can consistently follow instructions and perform repeated and prolonged exhalation maneuvers.

ABSOLUTE LUNG VOLUMES. **Total lung capacity (TLC), FRC,** and **residual volume (RV)** are determined using plethysmography (Figure 18-1). A lung capacity is simply the addition of two or more lung volumes; a lung

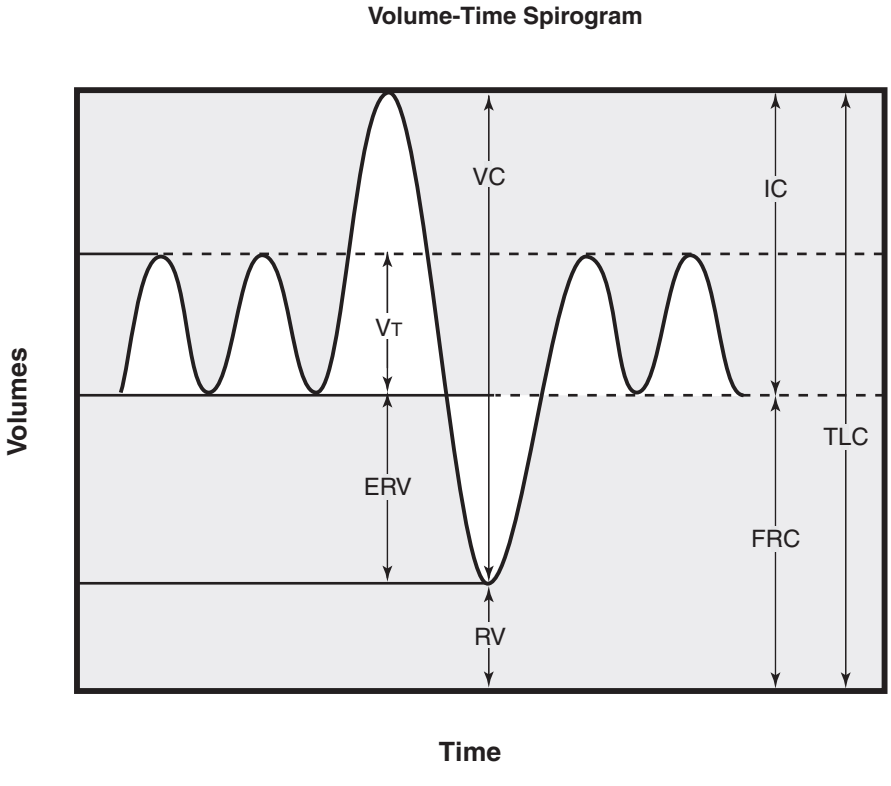

FIGURE 18-1. Volume–time spirogram. *ERV*, expiratory reserve volume; *FRC*, functional reserve capacity; *IC*, inspiratory capacity; *TLC*, total lung capacity; *RV*, residual volume; *VC*, vital capacity; *Vt*, tidal volume.

TABLE 18-10

Definitions of Lung Volumes and Measures Used in Spirometry and Plethysmography

Term	*Acronym*	*Definition*
Forced expiratory flow rate	FEF	Rate at which exhaled air flows; by convention, FEF is measured at 25%, 50%, and 75% of FVC
Forced expiratory volume in 1 second	FEV1	Amount of air released after 1 second during a maximal exhalation
Functional residual capacity	FRC	Usual point at which exhalation ends; reflects balance of forces between expansile nature of chest wall and contractile nature of lung parenchyma
Residual volume	RV	Least volume of air remaining in lung after maximal expiratory maneuver (after SVC or FVC)
Tidal volume	VT	Amount of air inhaled during breath
Total lung capacity	TLC	Total amount of air that can be contained within thorax after maximal inspiratory maneuverç
		Sum of RV and VC
Vital capacity (slow and forced)	SVC, FVC	Amount of air released when exhaling from TLC to RV

volume is defined as the smallest unit measure of the additive volumes within the thorax (Table 18-10). TLC, FRC, and RV are useful for following the course of chronic lung disease such as CF or restrictive lung disease.

SPIROMETRY. The most basic maneuver in spirometry is the slow **vital capacity** maneuver. To obtain a volume–time spirogram (see Figure 18-1), a child should first breathe quietly into the spirometer. After two or three tidal breaths are recorded, the child slowly inspires to **TLC**, then blows out calmly and smoothly to **RV**. When the same maneuver is repeated, but with a forced exhalation (a forced vital capacity [FVC]), the rate of airflow rises quickly to its maximum value immediately after exhalation is initiated. As the lung volume decreases, the intrathoracic airways narrow, airway resistance increases, and the rate of airflow progressively falls. The standard time for exhalation is 6 seconds. Shorter exhalation times may be insufficient for detection of lung dysfunction and lead to underestimation of abnormalities. The volume exhaled in 1 second **[forced expiratory volume in 1 second (FEV_1)]** is obtained during this maneuver.

It is essential to obtain maximal efforts to differentiate restrictive and obstructive lung disease. The two types of lung disease produce different spirometric patterns (Table 18-11).

Pediatric Pearl: The relation of the FEV_1 to the FVC is the key to differentiating obstructive lung disease from restrictive lung disease.

Obstructive lung disease (e.g., asthma, CF) is characterized by a reduction in airflow and trapping of air inside the thorax behind tight, plugged airways. This physiologic abnormality lowers the FEV_1. Because the FEV_1 is more reduced than the FVC, obstruction results in a low FEV_1/FVC ratio (FEV_1 [%]). On the flow-volume curve, the exhalation limb has a scalloped shape.

Restrictive lung disease is characterized by a low FEV_1 and a proportionate reduction in the FVC. Thus, the FEV_1/FVC ratio is unchanged from normal (greater than 80%). Children with pulmonary fibrosis (secondary to chemotherapy for cancer, systemic lupus erythematosus, or Wegener granulomatosis) typically have spirometric abnormalities of this type.

DIFFUSING CAPACITY (DLCO). V/Q relationships within the lung and the function of the pulmonary capillary bed primarily affect gas transfer in the lungs, which is measured as the diffusing capacity for CO (DLCO). Any factor that affects the alveolus or the hemoglobin molecule alters the uptake of CO. Anemia and the lung volume at

TABLE 18-11

Plethysmographic and Spirometric Patterns of Obstructive and Restrictive Lung Disease

which it is measured affect the measurement of the DLCO. Decreased DLCO is most commonly seen in interstitial lung disease, sickle cell disease, and pulmonary vascular disease (pulmonary hypertension). DLCO is useful for monitoring the effects of chemotherapeutic agents and radiation on the lung parenchyma in children.

Measurement of DLCO is usually performed as a single breath maneuver. The patient inhales a low concentration of CO mixed with a tracer gas such as helium. Any reduction in the concentration of the CO as it is exhaled and measured by the detecting sensor relates to its diffusion throughout the alveolar membrane and into RBCs as they circulate through the pulmonary capillaries.

Additional modalities for assessing pulmonary function, including **arterial blood gas measurement** and **oxygen saturation measurement,** are discussed in the section on respiratory physiology (see Blood Gas Analysis and Estimating Oxygenation).

Radiologic Procedures

The reasons for obtaining plain chest films in children are numerous. All children with chronic coughs should have a recent chest radiograph (Figure 18-2). Sudden chest pain is an indication for radiography (Figure 18-3). Children with suspected pulmonary infections are obvious candidates for radiography. It is necessary to read films carefully and systematically (Table 18-12).

Computed tomography (CT) is a noninvasive procedure, which offers many advantages. CT scans of the sinuses are more sensitive and specific than plain radiographs, and such sinus films may be appropriate in patients with chronic purulent nasal secretions. In addition, a CT scan allows for the assessment of the fine detail of the pulmonary parenchyma. Several patterns of CT abnormalities correspond with specific histologic diseases (Table 18-13).

A high-resolution CT (HRCT) scan, which combines the technique of obtaining frequent "slices" of images through the chest with high-frequency resolution, can provide the detail of structures as small as 0.5 mm. With HRCT, it is possible to stage disease severity and more readily follow a response to therapy. Situations in which HRCT provides new or important information include airspace disease, complicated infections, empyema, evaluation of loculated effusions, immunocompromise, tuberculosis, pulmonary hemorrhage, pulmonary edema, interstitial disease, bronchopulmonary dysplasia, histiocytosis, sarcoid disease, bronchiectasis, CF (Figure 18-4), bronchiolitis obliterans, and bronchial obstruction. HRCT is also used as a guide for percutaneous biopsy or for open lung biopsy.

Barium studies (contrast esophagrams) may be warranted in infants who have cough associated with feeding or frequent large emesis after feedings. These procedures, which detect **vascular rings** or mediastinal lesions that impinge on the trachea and **tracheoesophageal fistulae**, are useful in the evaluation of swallowing dysfunction, esophageal anatomy, and intestinal obstructive defects.

Noncontrast use of fluoroscopy is helpful in assessing diaphragmatic excursion and upper airway and pharyngeal anatomy. Diagnosis of infants with stridor due to **laryngomalacia** or infants with wheezing and **tracheobronchomalacia** may involve fluoroscopy.

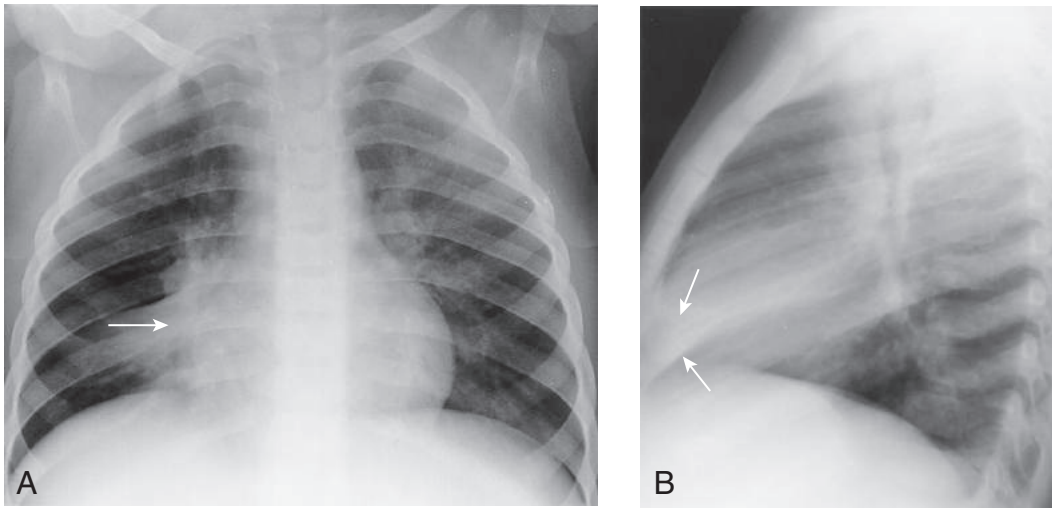

FIGURE 18-2. Chest radiograph of a child with asthma who was evaluated for ongoing cough and recurrent "pneumonia." **(A)** This anteroposterior view clearly shows an area of atelectasis of the medial segment in the right middle lobe. This film demonstrates the classic "silhouette" sign, in which consolidation of the medial segment of the right middle lobe obscures the normal silhouette of the heart on the right border. **(B)** This lateral view demonstrates the classic wedge-shaped opacity of right middle lobe atelectasis.

Tests for Specific Situations

Immunology studies (total IgG, IgM, and IgA titers, IgG subclass titers, antibody titers to previous vaccinations) warrant consideration in the evaluation of children with recurrent otitis, bronchiectasis, or productive cough unresponsive to antibiotics. Serum IgE levels and radioallergosorbent or skin testing are necessary for evaluation of atopic disease (see Chapter 17).

Ciliary function studies may be warranted in patients with purulent otitis unresponsive to antibiotics or patients with an association of sinusitis, otitis, pneumonia, bronchiectasis, with or without situs inversus anomaly. Diagnosis of immotile cilia syndrome (ICS) relies on a combination of clinical evaluation and electron microscopic analysis of ciliary structure. Supplemental tests involve nuclear scans, which use technetium-99–labeled inhalant and real-time imaging to evaluate mucociliary clearance time, and measurement of the nasal nitric oxide levels. The genetics of ICS are not yet fully elucidated, due to the extensive genetic heterogeneity and the large size of the disease-causing

FIGURE 18-3. Chest radiograph showing a right-sided pneumothorax. This 11-year-old girl with severe lung disease due to cystic fibrosis complained of a sudden onset of chest pain. The right side of the chest film demonstrates a sickle-shaped area of a dark lucency at the apex of the thorax indicative of a pneumothorax.

TABLE 18-12

Approach to the Chest Film: ABCS

Nodular pattern	Cystic fibrosis Histiocytosis X Hypersensitivity pneumonitis Sarcoidosis Fungal infection
Ground glass pattern	Alveolar proteinosis Eosinophilic pneumonia Bronchiolitis obliterans with organizing pneumonia

FIGURE 18-4. High-resolution computed tomography (HRCT) scan from the same girl described in Figure 18-3. Note that the definition of airway disease and areas of consolidation are more readily apparent, and the disease process is much more advanced than appears on the chest film. The airway walls are thickened, both the central and peripheral airways exhibit bronchiectatic changes, and opacifications are present where mucous plugs and lung consolidation exist.

genes. To date, six genes have been linked with PCD, two dynein genes, encoding the outer dynein arm (ODA), intermediate chain (DNAI1), and heavy chain (DNAH5), have been found approximately 30-38% of the families evaluated. Mutations in other ODA genes (TXNDC3 and DNAI2) have been noted in a small fraction (~2%) of all PCD patients and have not been included in the clinical genetic panel available yet. Recently, mutations have been described in ktu (encodes cytoplasmic protein that is required for ODA assembly) in approximately 12% of PCD patients with defects in both the ODA and IDA. Diagnosis of PCD is very difficult in patients who present with the compatible clinical phenotype, but normal ultrastructure findings. Very recently, DNAH11 was shown to be mutated in a PCD family, but at this juncture, studies to define large-scale mutation profiling in a variety of PCD patients are needed to determine the importance of this mutation in PCD. Sweat chloride iontophoresis is used to diagnose CF. This test is indicated in all patients with an abnormal chest radiograph, failure to thrive, steatorrhea or constipation, a cough unresponsive to bronchodilator use and routine antibiotic courses, and sputum cultures previously positive for *Haemophilus influenzae, Staphylococcus aureus,* and *Pseudomonas aeruginosa*.

Pediatric Bronchoscopy

The direct visual examination of children's airways is an important diagnostic tool. Airway structure and anatomy can be directly visualized while the child is spontaneously breathing; the appearance of the airway mucosa can provide information about certain pathologic processes. Sampling tissues with biopsy or brushing or lavage of airway secretions can help establish specific diagnoses. Determination of the dynamic changes occurring in the airways may lead to diagnoses of laryngo-, tracheo-, or bronchomalacia. There are several indications for bronchoscopic evaluation, which have a variety of causes (Table 18-14). A pulmonologist may often perform a bronchoscopy to remove airway obstructions such as foreign bodies, inspissated secretions, or tissue masses. A bronchoscope may also be useful in the delivery of therapeutic agents to the lower airways.

Two types of bronchoscopes exist. The original bronchoscopes were rigid metal tubes passed through the mouth. Over the last 15 years, flexible fiberoptic instruments more suitable for use in very small infants and children have been developed. In general, rigid bronchoscopy is the procedure of choice for the removal of foreign bodies, some dynamic studies of the airways, and for other therapeutic purposes. Flexible bronchoscopy is the preferred modality for cases that require diagnosis and lower airway (alveolar) sampling, and transbronchial and mucosal biopsy specimens may be obtained, which may provide information that allows for adequate diagnosis, and obviates the need for a more invasive procedure, such as open lung biopsy. The major advantage of using a rigid bronchoscope lies in the fact that the inner diameter of the scope is usually large enough for the passage of instruments. In addition, it doubles as an endotracheal tube during the procedure, thus establishing and maintaining control of the airway and facilitating the delivery of oxygen and anesthetic gases. The primary drawback is that the bronchoscope must be passed through the patient's mouth to reach the trachea; the bronchoscopist must be able to open the mouth and extend the neck to provide a straight pathway. Certain congenital defects of the head and neck may obviate this method. General anesthesia is always required for rigid bronchoscopy.

SPECIFIC PULMONARY DISORDERS

STRIDOR

Stridor, a form of a wheeze, is frequently loud and harsh in quality. It is primarily described as an inspiratory sound. Children who exhibit difficulty breathing in the form of stridor are described as being **stridulous**.

Pathophysiology

The stridulous sound is generated by increased turbulent airflow from obstruction at the level of the larynx, the subglottic region of the larynx, and/or the extrathoracic trachea. The pitch is related to the degree of obstruction as well as to the velocity of airflow through the obstructed area. As a rule, the higher the pitch, the more severe the obstruction.

Clinical and Laboratory Evaluation

The previous discussion of the components of the history and physical examination allows the clinician to differentiate between intrathoracic and extrathoracic obstruction lesions of the airway (see Clinical Approach to the Child with Pulmonary Disease).

TABLE 18-14

Indications for Bronchoscopy

Symptom	*Cause*
Stridor (recurrent or chronic)	Congenital laryngomalacia Cricoid ring Complete tracheal rings Mass lesion compressing trachea
Persistent wheezing	Tracheomalacia Bronchial or tracheal compression Foreign body aspiration
Pneumonia (acute) Pneumonia (chronic or recurrent)	Bacterial, fungal, or viral pathogen Tracheoesophageal fistula Recurrent aspiration Congenital airway anomaly Foreign body Pulmonary hemorrhage Alveolar proteinosis
Persistent cough	Anatomic abnormalities (tracheoesophageal fistula, tracheal bronchus) Foreign body aspiration Tracheomalacia Bronchomalacia Chronic infection (immune deficiency, cystic fibrosis)
Atelectasis	Mucous plugging unresponsive to medical therapy Foreign body Anatomic abnormality
Radiographic abnormalities Hemoptysis Tracheostomy	Localized hyperinflation (congenital lobar emphysema, bronchial stenosis, foreign body) Acute pulmonary hemorrhage Routine endoscopic evaluation of airway Evaluation of development of granulation tissue Bleeding, acute Evaluation of resolution of tracheo- or bronchomalacia
Vocal cord dysfunction	Vocal cord paralysis Vocal cord tethering Paradoxical vocal cord movement
Aid in endotracheal intubation	Congenital deformities of the airway

Laboratory Evaluation

Many diagnostic tools are available to evaluate the upper and lower airway for causes of stridor (Table 18-15). The test with the highest yield is **flexible fiberoptic bronchoscopy**. However, this procedure is invasive and not without risk (see Pediatric Bronchoscopy). **Fluoroscopy** of the airways, which is quicker and less invasive, can provide good dynamic visualization of the airway. However, this method may "miss" certain pathologies such as subglottic stenosis or intraluminal hemangioma, so if doubt still exists, bronchoscopy should be undertaken.

Differential Di agnosis

The differential diagnosis of stridor varies with the age at presentation, the type of noise, and the acuity of the presentation (see Table 18-15).

TABLE 18-15

Diagnostic Evaluation of Stridor

Condition	*Infants*	*Older Children/ Adolescents*	*Diagnostic Studies*
Acute Onset			
Viral croup (laryngotracheobronchitis)	X	X	Anteroposterior neck radiograph
Spasmodic croup		X	History
Foreign body aspiration	X	X	Inspiratory and expiratory films, right and left lateral decubitus films, fluoroscopy, barium esophagram, rigid bronchoscopy
Epiglottitis		X	Lateral neck or direct visualization in operating room with qualified surgeon
Abscess: retropharyngeal, peritonsillar		X	Lateral neck radiograph
Allergic reaction		X	History
Trauma		X	History
Angioneurotic edema (C1 esterase deficiency)		X	History, C1 esterase level
Chronic Onset			
Laryngomalacia	X		History, fluoroscopy, flexible bronchoscopy
Vocal cord dysfunction	X	X	Flexible bronchoscopy, history
Subglottic stenosis	X	X	History, pulmonary function test, flexible bronchoscopy
Laryngeal cyst, hemangioma, web, papilloma	X	X	Flexible bronchoscopy
Epiglottic cyst	X		Flexible bronchoscopy
Laryngotracheoesophageal cleft	X		Suspension laryngoscopy
Retained foreign body		X	Flexible bronchoscopy, rigid bronchoscopy

Management

Most causes of stridor require some form of medical or surgical intervention. The only type of stridor that might not require treatment is **congenital laryngomalacia**. Most infants are born with some degree of softness of the cartilage of the larynx; as they mature, this cartilage becomes stiffer. If the laryngomalacia is severe, the infant may suffer growth failure, develop a pectus excavatum deformity, or suffer chronic aspiration if the pressure generated during a vigorous gasp causes gastroesophageal reflux. These extreme and rare cases may require treatment with uvulopalatoplasty or with tracheostomy until the child is older.

ASTHMA

Asthma is defined as a disease of the bronchial airways characterized by hyperresponsiveness to inhaled allergen. The application of smooth muscle relaxants reverses the resulting bronchoconstrictive response. A heterogeneous disease, asthma has different clinical pictures and different pathogenic mechanisms.

Asthma occurs in about 4% to 9% of the population, but urban areas have far higher reported rates, estimated at 20% in some areas. The incidence is highest during the first 3 to 4 years of life, with more than 80% of cases starting before 4 years of age. During these early years, both the immune system and the respiratory system undergo growth and maturation, which subsequently determine the pattern of future response of these systems to environmental exposure. Asthma is a developmental disease with a strong genetic component. The basic abnormality consists of an altered development of the patterns of immune and airway response to external stimuli; this abnormality probably persists for life.

Males are more likely than females to have asthma, and the disease clusters in certain regions of the United States such as the south and the west. However, the most striking clusters are in urban areas, where air pollutants may play a role. The incidence is also higher in the African American population.

Pathophysiology

Various clinical conditions can be associated with lower airway obstruction during childhood, depending on age, gender, genetic background, and environmental exposure. Which of these conditions leads to the chronic asthmatic condition is poorly understood. The most important environmental factors in the development of asthma are the intensity, timing, and mode of exposure to aeroallergens that stimulate the production of IgE. Atopy and an increased predisposition to form IgE antibodies on exposure to common environmental antigens are present in the majority of patients with asthma (see Chapter 17). Exposure to high levels of inhaled allergens, especially dust mites, at an early age is an important determinant in the development of asthma. Additional environmental determinants are concurrent exposure to cofactors such as cigarette smoke. The role of food allergens in the pathogenesis of asthma is controversial. In general, pulmonary reactions to ingested foods are rare, and the correlation of hyperreactivity to food allergens with radioallergosorbent testing and abnormal IgE levels is low.

Two phases represent the pathophysiology of the inflammatory response in asthma: the early and late asthmatic reactions (Figure 18-5). In the **early asthmatic reaction**, rapid bronchoconstriction usually occurs after bronchial provocation with an allergen to which the subject is sensitized; this lasts for about 1 hour. The cause of the acute inflammation of the airways is the release of mediators from a variety of effector cells such as mast cells and eosinophils. Mast cell degranulation leads to release of mediators including prostaglandins, leukotrienes, and other mediators, which lead to signs of the late asthmatic reaction and result in increased vascular permeability, mucus hypersecretion, and smooth muscle contraction.

The **late asthmatic reaction**, a more prolonged phase of airway narrowing that follows the early asthmatic reaction, starts 2 to 3 hours after exposure, reaches a maximal airway response by 4 to 8 hours, and resolves in 12 to 24 hours. An overall increase in hyperresponsiveness marks this late asthmatic reaction; this increase may persist for days after the late asthmatic reaction appears to have resolved. Pathologic examination of asthmatic airways has shown a highly cellular infiltration into the bronchial epithelium of neutrophils, eosinophils, and lymphocytes. These cellular infiltrations are associated with destruction of bronchial epithelium, the expansion and activation of fibroblasts, and hypertrophy and hyperplasia of the smooth muscle. In fact, after airway inflammation has been established, airway hyperresponsiveness and symptoms can persist despite the removal of the responsible allergens because structural and functional alterations remain.

Clinical and Laboratory Evaluation

Establishing the diagnosis of asthma in children may be challenging due to the extreme difficulty of testing airway reactivity to inhaled allergens. This procedure is usually not performed because of safety issues, especially in infants and small children. The nature of asthma is episodic. A thorough history and physical examination, as well as knowledge of the child's response to bronchodilators and anti-inflammatory medications, may suffice until the child is old enough to cooperate with spirometric testing procedures.

History

Knowledge of precipitating factors is valuable. Do the symptoms have a recurrent nature, suggesting environmental or seasonal factors? In older children, the most common triggers of asthma are dust or other aeroallergens, whereas in younger children, viral respiratory infections usually trigger asthma. Many families live in older homes that drain poorly during the winter and rainy seasons. This situation can lead to growth of molds in the home, which may lead to development of allergic bronchopulmonary aspergillosis or mold hypersensitivity. For many children with a chronic cough, eliciting a history of a sudden appearance of cough, wheezing, or stridor may guide the diagnosis toward foreign body aspiration, especially in toddlers. Travel history and any recent history of

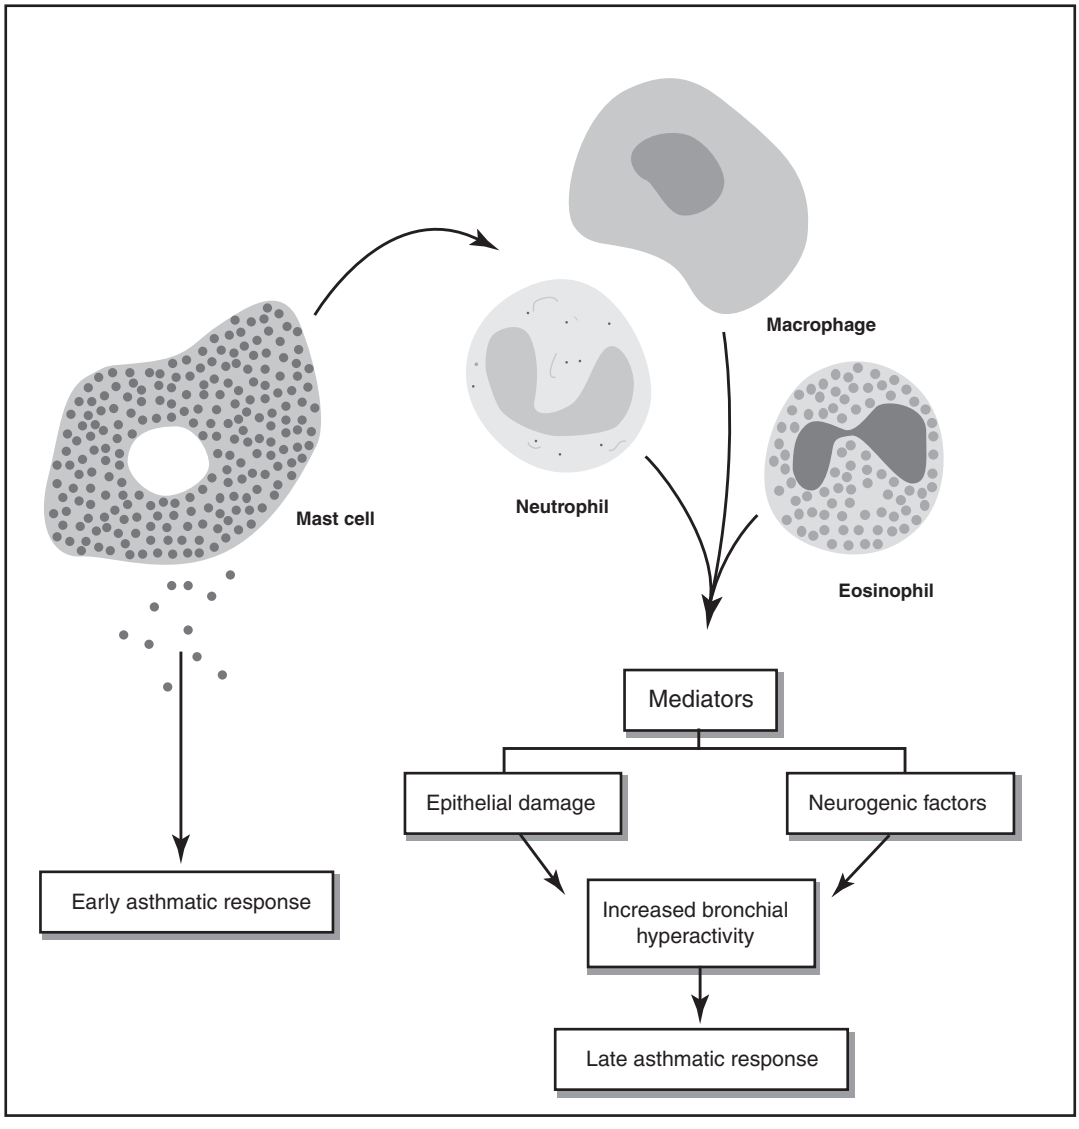

FIGURE 18-5. Asthma inflammatory cascade.

immigration is important too. Tuberculosis is endemic in several countries. Therefore, it is necessary to determine a family's country of origin and whether a tuberculosis skin test was administered on entry to the United States.

Other key questions that the pediatrician should ask during history taking have been mentioned previously (see Clinical Approach to the Child with Pulmonary Disease, History). If a sibling has previously been diagnosed with asthma, the child in question is seven times more likely of being diagnosed with asthma. After elucidating the character of the disease, the physician should attempt to classify the asthma into one of four types (Table 18-16). Is it mild, mild persistent, moderate persistent, or severe? Because asthma can present in many different subtypes, this classification is somewhat arbitrary.

Physical Examination

Most children with asthma present with recurrent episodes of wheezing and dyspnea. Several different clinical syndromes may be apparent (Table 18-17).

Laboratory Evaluation

Pulmonary function testing before and after bronchodilator therapy is the most specific means of evaluation. These tests can be reliably performed in most clinics that treat children 5 years of age or older (see Pulmonary Function Tests).

TABLE 18-16

Classification of Asthma Subtypes

	Asthma Subtype		
Characteristics	*Mild Persistent*	*Moderate Persistent*	*Severe*
Frequency of exacerbations	1–2 times/wk	2 times/wk <3 ED visits/yr	Daily wheezing; sudden, severe exacerbations >3 ED visits/yr >2 hospitalizations/yr
Frequency of symptoms	Few between exacerbations	Cough/low-grade wheeze frequent	Continuous low-grade cough; wheezing always present
Exercise tolerance	Good	Diminished	Very poor; limited activity
Nocturnal asthma	1–2 times/month	2–3 times/wk	>3 times/wk
School attendance	Good	Occasional absence	Frequently absent
Pulmonary function			
• Peak expiratory flow rate	80% predicted; variability <20% A.M. to P.M.	60%–80% of predicted; variability ≤30%	<60% predicted; variability >30% colair challenge
• Spirometry	Minimal obstruction; >15% response to bronchodilator	Obstruction at low lung volumes; >15% response to bronchodilator	Scalloped flow–volume loop ≤35% predicted flow in small airways
• Methacholine sensitivity[a]	PC_{20} > 20 mg/mL	PC_{20} = 2–20 mg/mL	PC_{20} <2 mg/mL

[a]Sensitivity to methacholine is measured by the PC_{20}, of the dose of methacholine inhalation challenge that results in a decrease in the FEV1 by 20% from baseline.
ED, emergency department.

Management

Convincing evidence suggests that untreated asthma results in chronic inflammation that may induce structural changes in the asthmatic airway, leading to irreversible abnormalities in lung function. This knowledge has led to significant changes in both the short- and long-term management of the disease.

As previously described, recurrent bouts of asthma may lead to cellular infiltration into the airways, and fibrotic remodeling of the airways develops in severe asthma. While it is not currently known whether these pathophysiologic changes eventually occur in patients with all levels of severity of asthma, the currently available medications have been refined and proven safe for long-term use in children.

A written treatment plan may also help patients with asthma. The **Asthma Action Plan**, commonly used by physicians, is a method for asthma management and monitoring that patients take home and use to help modify their medication regimen based on changes in their clinical status (e.g., shortness of breath, cough, chest tightness).

Medical Treatment

In general, any child with persistent asthma should receive preventive daily treatment with an anti-inflammatory therapy (Table 18-18). The purpose of anti-inflammatory treatment is to decrease the number of exacerbations experienced by a particular child. It is hoped that this will lead to a more normal lifestyle as well as greater participation in usual childhood activities. Additional therapy may be necessary depending on the type of asthma the child has (Table 18-19).

TABLE 18-17

Clinical Appearance of Asthma

Clinical Syndrome	*Symptoms/Signs*
Classical episodic asthma	Episodes of coughing and/or wheezing that occur intermittently
Between episodes, no overt symptomatology	
Persistent asthma	Daily symptoms Acute, severe exacerbations
Cough-variant asthma	Cough only
Hypersecretory asthma (common in infants and children, especially after viral infections)	Recurrent cough with bronchitis
Recurrent "pneumonia"	Similar to pneumonia in radiologic appearance with excessive, tenacious mucous secretions blocking larger airways, causing atelectasis of segments and subsegments
Exercise-induced asthma	Severe bouts of bronchospasm triggered only by exercise and/or cold air Seemingly well between episodes
Severe episodic asthma	Life-threatening attacks Symptom-free and quite well between episodes
Persistent wheezing (infants known as the "fat, happy wheezers")	Usually without much respiratory distress Often due to chronic aspiration from gastro esophageal reflux

Children with only seasonal symptomatology may require daily use of anti-inflammatory medications, starting several weeks before the expected antigen exposure. For patients with exercise-induced asthma, albuterol or formoterol (a long-acting β-agonist [LABA] that has rapid onset of action), taken 5 to 10 minutes before exercise, may offer effective prophylaxis against bronchospasm.

Children with asthma who experience more frequent symptoms should receive daily prophylaxis with anti-inflammatory therapy. LABAs can be used in conjunction, based on the determined level of severity of asthma and whether control is gained with the use of inhaled corticosteroid (ICS) alone. The medication most commonly prescribed to achieve effective anti-inflammatory treatment is generally ICS such as beclomethasone, fluticasone, or budesonide. Asthma ICS fluticasone has the highest topical-to-systemic ratio of drug absorption, is rapidly metabolized by the liver, and is very potent compared to other ICSs. Therefore, it is often the ICS drug of first choice. If this is not helpful, and breakthrough episodes of wheezing still occur frequently, then the addition of a short-acting β-agonist or black box LABA is indicated. Some premixed combination medications are available for prescription, though not in all forms (liquid for nebulization, metered-dose inhaler, or dry powder inhaler), and thus are not available for all age groups. ICSs may require several weeks of daily use before the beneficial effects are realized. There are several advantages to using LABAs. When used in combination with a corticosteroid, a synergistic effect in improving control of asthma has been confirmed in multiple studies. LABAs bind more tightly to the β-adrenergic receptor and have a duration of action of up to 12 hours.

Pediatric Pearl: Glucocorticoids in combination with LABAs are the most efficacious treatment currently available for the long-term management of moderate persistent asthma.

TABLE 18-18

Medications Used for Treatment of Asthma

Medication	*Mild Intermittent*	*Mild Persistent*	*Moderate Persistent*	*Severe*
β-agonist				
Short-acting	As needed	As needed	As needed	As needed
Long-acting	No	No	Daily	Daily
Inhaled corticosteroid (ICS and LABA)	No	Yes	Yes	Yes
Leukotriene receptor Antagonist or synthesis Inhibitor	No	Yes, but not as monotherapy	Yes	Yes
Anticholinergic	No	Consider	Yes	Yes
Theophylline	No	No	Consider	Yes

The anti-inflammatory effects of corticosteroids are likely to be via directly inhibiting the binding of certain transcription factors to cellular DNA that are activated by signals from inflammatory cells. Corticosteroids also upregulate the number of β-adrenergic receptors on bronchial smooth muscle. Within the respiratory epithelium, corticosteroids decrease the numbers of inflammatory cells such as eosinophils, basophils, and polymorphonuclear cells. However, it may take as long as 6 months to reverse the acute inflammation seen in the pathohistologic changes present in asthma-affected airways. It has not been demonstrated that fibrotic airways remodeling is either preventable or reversible in long-term studies in asthmatic children.

Children with severe, uncontrollable asthma, which is diagnosed in less than 10% of cases, require a medication regimen that "brings out the big guns" quickly and effectively. The use of two or three types of bronchodilators may be necessary, along with large doses of inhaled steroids.

Leukotriene receptor antagonists and leukotriene-synthesis inhibitors provide new mediator-specific therapy for asthma. These agents block the inflammatory airway response to an inhaled aeroallergen challenge. In chronic asthma, they lead to improved lung function, reduced symptoms, and they frequently can allow for reduced doses of ICSs. Because several studies reported that these medications are less effective than steroids, it is not recommended that they be used as monotherapy.

In addition, the use of LABAs such as salmeterol is often indicated. These drugs bind more tightly to the β-adrenergic receptor and have a duration of action of up to 12 hours. Of note, studies suggest an increased incidence of hospitalization and sudden death in association with LABAs as monotherapy. However, the available preparations that combine a LABA with a corticosteroid (e.g., fluticasone/salmeterol and budesonide/formoterol) appear to be safe and are approved for use in children. The FDA has issued a black box warning regarding the long-term safety for the use of combined LABA/corticosteroid drug formulations. Thus, the most recent guidelines for use of these medications recommends that LABA/ICS formulations be utilized only until disease control and stability are attained. It is then suggested that the medication regimen be de-escalated to ICS alone, if possible. Oral β-agonists are effective, along with sustained-release theophylline preparations. However, systemic side effects such as jitteriness, hyperactivity, headache, and emesis are frequent when serum levels exceed the therapeutic range (for theophylline and other xanthine derivatives). Additionally, theophylline and similar agents often have interactions with other medications, either resulting in an increase or a decrease in blood serum levels, and can lead to toxicity if other medication dosages are not altered.

Unfortunately, children with asthma are often undertreated, based on the perception by both parents and physicians that long-term treatment with ICSs is deleterious. Much investigation has taken place concerning the possible association of long-term use of ICSs and bone growth delay as well as other side effects such as adrenal suppression, behavioral changes, blood glucose elevation, and cataracts. Side effects are rare with ICSs, but can occur, primarily when high doses are used. It is necessary to regularly monitor children who receive long-term

TABLE 18-19

Medications Used in Asthma

Medication	*Action*	*Dose*	*Side Effects*
Albuterol salbutamol	β-agonists bronchodilator	MDI (90 μg/puff): 2 puffs per dose q4–6 hour; can be used q1 hour in monitored setting Neb solution (0.5%): 0.25–0.5 mL in 2 mL diluent Neb solution premix (0.083%): 1 vial q4–6 hour	Tachycardia, jitteriness, hyperactivity
Fluticasone/salmeterol	β-agonist, bronchodilator, long acting	HFA (45/21 mcg/puff):1 puff bid HFA (115/21 mcg/puff):1 puff bid HFA (230/21 mcg/puff):1 puff bid Diskus (100/50 mcg/puff): 1 click bid Diskus (250/50 mcg/puff): 1 click bid Diskus (500/50 mcg/puff): 1 click bid	Tachycardia, jitteriness, hyperactivity
Ipratropium bromide	Anticholinergic, inhibits bronchospasm	MDI (18 μg/puff): 2 puffs q4 hour prn	Dry mouth or respiratory secretions
Beclomethasone dipropionate	ICS, preventive, anti-inflammatory	MDI (42 μg/puff): 2 puffs bid DPI (100 μg/puff): 1 puff bid	Thrush, adrenocortical suppression (very high doses)
Fluticasone	ICS	MDI (44, 110, 220 μg/puff): 1–2 puffs bid DPI (50, 100, 250 mcg/puff): 1 click bid	Thrush, adrenocortical suppression (very high doses)
Flunisolide	ICS	MDI (250 μg/puff): 1–2 puffs bid	Thrush, adrenocortical suppression (very high doses)
Budesonide	ICS	DPI (100, 200 μg/puff): 2 ml nebulized qd–bid solution premix (250, 500 μg/ml): 0.5–1 mL qd–bid Flexhaler (90, 180 mcg/click): bid	Thrush, adrenocortical suppression (very high doses)
Montelukast	Leukotriene receptor antagonist	4 mg chewable tablet qhs for children 2–4 years of age 5 mg chewable tablet qhs for children 5–11 years of ge 10 mg tablet qhs for children ≥12 years of age	Headache, gastritis

DPI, dry-powder inhaler; *ICS,* inhaled corticosteroid; *MDI*, metered-dose inhaler; *neb*, nebulizer; *q*, every; *bid*, twice a day; *PO*, by mouth; *prn*, as needed; *qhs*, every night before sleep.

treatment with ICSs for elevation in blood pressure, serum blood sugar, lag in growth, and cataract development (i.e., yearly ophthalmologic examinations). However, recent growth and ICS studies have shown only a 1-cm difference in height between moderate asthmatics treated with 400 μg/day of budesonide and their healthy cohorts, with no occurrence of side effects consistent with adrenal suppression or corticosteroid excess. In addition, ICSs have been associated with dysphonia and thrush, but it is possible to avert these conditions by using spacer devices and by "swishing and spitting" or drinking immediately after the medication is administered.

Methods of Drug Delivery

In asthma therapy, inhalation tends to be the preferred mode of drug delivery. Not only does it allow for more rapid onset of action and lower dosage requirements, but it also eliminates systemic side effects of drugs that are also available in ingestible form. Three inhalation systems are currently available for the delivery of aerosolized medications: metered-dose inhalers, dry-powder inhalers, and nebulizers used with liquid preparations.

Metered-dose inhalers have the advantage of being portable, lightweight, and less expensive than the liquid nebulizer forms of medications. The disadvantage of using a metered-dose inhaler is the high speed of delivery; when the inhaler is actuated, the medication is dispensed from the canister at a speed approximating 400 miles/hour. This leads to impaction of nearly 99% of the medication on the oropharynx; only 1% of the medication reaches the lungs. This problem has been ameliorated with the development of hydrofluoroalkanes (HFA) as the transport vehicle for medications delivered by a metered-dose inhaler (MDI). Because of environmental concerns, the availability of MDIs that utilize chlorofluorocarbons (CFC) to propel the medication from the inhaler were completely eliminated from the market by the end of 2010. CFCs, when released into the environment, deplete the ozone layer. In the United States and many other countries, MDIs now dispense small particles propelled by HFAs. HFA MDIs dispense the dose as a slower moving fine mist that can be inhaled easily without the use of a spacer device, but the HFA-MDI device can be utilized in combination with a spacer device. Spacers can be used in infants; they are available with masks that fit around the nose and mouth for a tight seal. Older children can use spacers fitted with a mouthpiece. It is necessary to inhale one puff of medication at a time. The medication can be inhaled either through the mouth as a single breath or with panting tidal maneuvers with equal effect.

Dry-powder inhalers are breath-actuated devices designed to eliminate the use of fluorocarbons (i.e., the propellant used in metered-dose inhalers) and to obviate the need for spacer devices. Dry-powder inhalers, like metered-dose inhalers, are also portable, lightweight, and less expensive than the liquid nebulizer preparations. However, not all medications are yet available in dry-powder or HFA inhalant form.

Nebulizers are used for two reasons: (1) they are effective, and (2) even the most cooperative child may not receive adequate amounts of medication by metered-dose inhalers or dry-powder inhalers. In addition, the breathing patterns of infants or children have a great effect on intrapulmonary deposition of medication. Nebulizers may thus be more effective in children with tachypnea and cough in the setting of an acute asthma attack.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is a chronic, multisystem, and lethal recessive disorder that results from defective epithelial chloride transport with major manifestations affecting the respiratory, gastrointestinal (GI), and reproductive systems. The primary morbidity results from progressive obstructive lung disease. In addition, a very large percentage of patients with CF have pancreatic insufficiency, which manifests as malabsorption and insulin deficiency. Nearly 100% of affected patients also have chronic sinusitis and nasal polyposis. Male infertility results from congenital bilateral absence or eventual obstruction and scarring of the vas deferens. Other less common problems encountered in patients with CF include cirrhosis of the liver, cholelithiasis, recurrent pancreatitis, gastroesophageal reflux, and GI hypomotility.

In the past, the prognosis in patients with CF was quite grave, and most infants and children did not survive past the age of 5 years. Due to the advent of supplemental enzymes to aid in food digestion and absorption, refined methods of chest physiotherapy, and improved antibiotics, the median survival age for individuals with CF in the United States is now approximately 38 years. Associated symptoms and the rate of decline in pulmonary function vary widely in severity, and many patients are now living into their 40s and 50s. It is difficult to predict the life expectancy of a child born in 2010 with CF because of the time delay of the impact of changes in therapy on life expectancy.

Pathophysiology

CF is inherited in an autosomal recessive pattern; both parents are usually asymptomatic carriers of the gene mutation. The most common lethal genetic disease affecting Caucasians, CF has an incidence of approximately 1 in 3000 live births, with a corresponding carrier frequency of 1 in 40. In Mexican Americans, the incidence

is approximately 1 in 9,000 live births. In African Americans, the incidence is approximately 1 in 15,000. CF is rarer (1 in 45,000 live births) in persons of Native African or Asian descent.

Mutations in the CF transmembrane conductance regulator (CFTR), located on chromosome 7, are responsible for CF. The gene, which was cloned in 1989, is quite large, containing over 250,000 base pairs; it encodes a chloride channel protein of 1,480 amino acids. To date, scientists have identified over 1,500 mutations and over 200 polymorphisms. The ΔF508 mutation is a three-base pair deletion that results in deletion of a phenylalanine at position 508 of the protein. This mutation, which most commonly occurs in persons of Anglo-Saxon descent, is found in approximately 75% of patients with CF. The large number of mutations described so far limits the usefulness of DNA analysis as a screening test for CF.

Some CFTR mutations are associated with more severe disease expression than others, and ΔF508 is one of the mutations most commonly associated with the "severe" phenotype. Conversely, patients with mutations correlated with normal pancreatic function tend to have a "milder" CF phenotype. Although there is a correlation between genotype and pancreatic status, there is no correlation between specific mutations and pulmonary phenotype, implying the presence of modifier genes that impact on the expression of the disease.

In CF, the characteristic defect involves a reduced ability of epithelial cells in the airways and pancreas to secrete chloride in response to cAMP-mediated agonists. The decrease in chloride secretion into the airway leads to decreased fluid in the airways, which is thought to lead to relatively dehydrated respiratory (and intestinal) secretions, abnormal mucociliary clearance, and eventually, lung disease. The exact pathophysiologic mechanism of altered ion and water transport across the epithelia of these organs is not completely known, and the understanding of how CFTR dysfunction leads to organ dysfunction is a matter of much debate. Whatever the mechanism is, it is clear that the CFTR defect eventually leads to inflammation and chronic obstruction of the lungs (Figure 18-6).

Colonization with certain strains of bacteria, usually *Staphylococcus aureus, Haemophilus influenzae,* and *Pseudomonas aeruginosa* eventually occurs in CF. Scientists believe that bacterial colonization is due to increased adherence of these organisms to the airway epithelia. Colonization with *S. aureus and H. influenzae* is common in infants and younger children with CF. *P. aeruginosa* colonizes approximately 75% of children by 10 years of age. After colonization with *P. aeruginosa*, lung function deteriorates more rapidly.

Another classic pathologic feature of the CF airway is the infiltration of inflammatory cells into the airways, even in early lung disease and in patients who are not yet colonized by bacteria. Neutrophil elastase appears to be a major player in the pathogenesis of cystic and bronchiectatic changes.

Clinical and Laboratory Evaluation

History

CF has many clinical manifestations (Table 18-20). Meconium ileus of the newborn is the most common manifestation in infants. Respiratory symptomatology becomes the more common presenting sign in older infants, toddlers, and children with CF.

Intestinal obstruction is common in patients with CF. Meconium ileus is a presenting sign in about 20% of infants with CF immediately after birth and may lead to intestinal perforation. In older patients, a meconium ileus "equivalent" syndrome results in distal intestinal obstruction due to the bulkiness of the stools. Episodes of rectal prolapse occur because of this condition and should serve as a "red flag" for the practitioner. The incidence of intussusception is high for this reason as well. Children with a history of slow growth or failure to thrive, even in the absence of respiratory problems, should also be evaluated for CF.

Physical Examination

Some of the many findings discovered by the physical examination in CF are "classic," and their presence may be a strong indication for CF testing. Children with CF are frequently at the 25th percentile on growth charts. However, it is important to note that 20% of children with CF have normal pancreatic function for the first 5 years of life, and therefore, may not present initially with failure to thrive.

Physical examination in children with CF should begin with the head—the nose in particular. Virtually all patients with the disease have inflamed erythematous nasal mucosa. One of the most classic findings is nasal polyps, which are often growing from the epithelium of the nasal turbinates. These opaque-white structures are composed of mucus-secreting epithelium and glisten in the light of the otoscope. They are similar to a small bunch of grapes in appearance.

Although sinusitis and rhinitis are universal, signs such as pain to palpation or frequent headaches are most often absent. In addition, the maxillary sinuses of affected patients are small, and the frontal sinuses often are hypoplastic or completely absent. If this is evident on a sinus CT, it is nearly always an indication of CF.

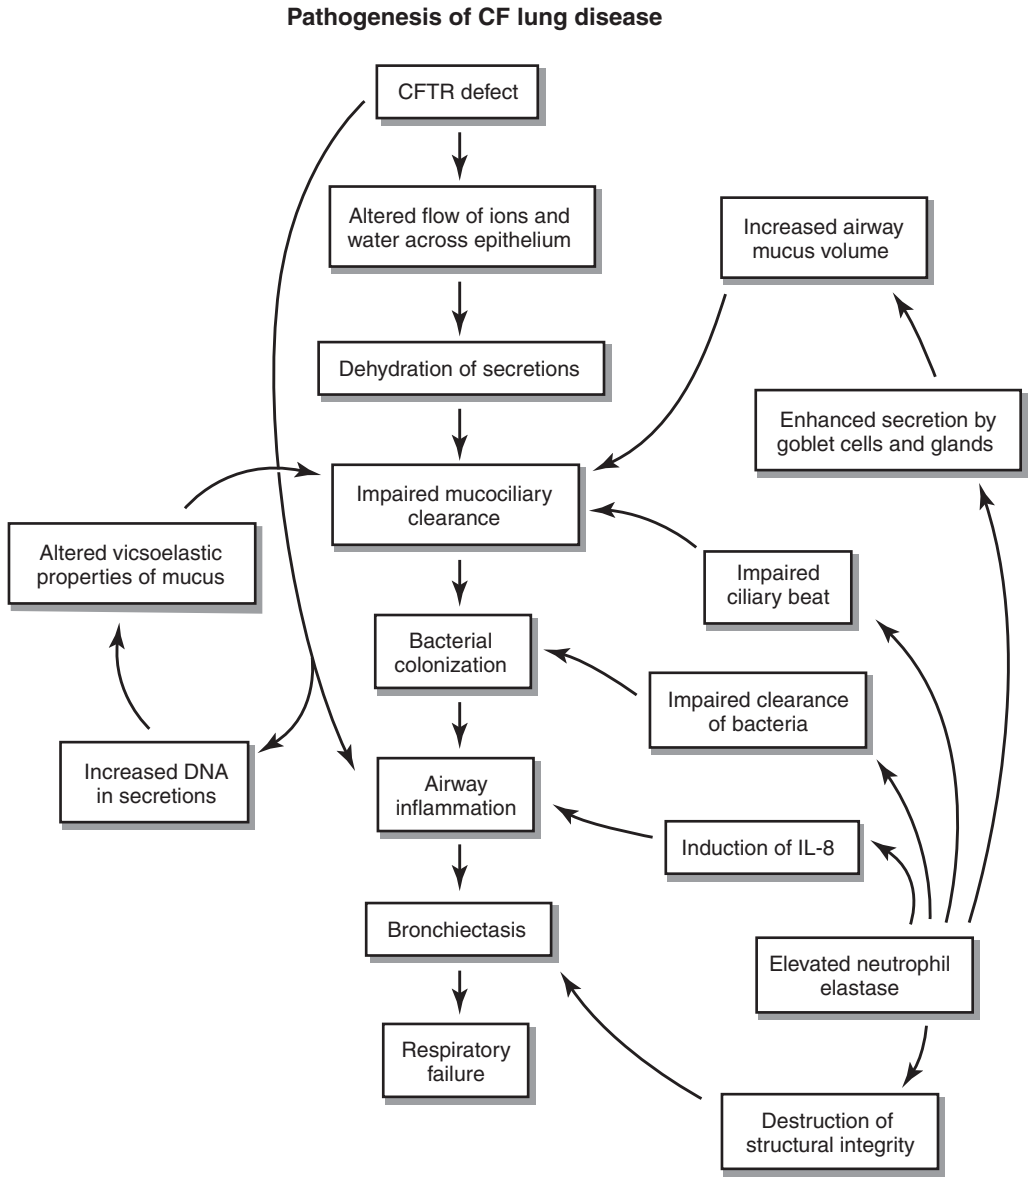

FIGURE 18-6. Pathogenesis of lung disease in cystic fibrosis. Airway secretions, being dehydrated and viscous, obstruct the airway. Pathologic changes include inflammatory cell infiltration of the airways, goblet cell hyperplasia, and submucosal gland hypertrophy. Bacterial colonization may occur. Chronic infection and inflammation leads to bronchiectasis and peribronchial fibrosis. Mucociliary clearance is also greatly impaired. *CFTR*, cystic fibrosis transmembrane conductance regulator; *IL-8*, interleukin 8. From Taussig L, Laundau L, LeSouef P, et al (eds): *Pediatric Respiratory Medicine*, St. Louis, Mosby, 1999.

The examination of the chest in patients with moderate or severe disease may reveal signs of air trapping, including the use of the suprasternal accessory muscles of respiration, some bowing of the sternum, or kyphosis of the superior thoracic spine, which all cause an evident increase from the normal anterior–posterior dimension of the chest. Crackles and wheezes are not unusual, but in infants, the most common finding is only wheezing or a slightly prolonged expiratory phase.

Examination of the abdomen may reveal the presence of firm but ill-defined stool masses in the colon. Hepatomegaly is rare, but splenomegaly may be present in patients with significant biliary cirrhosis. Palpation of the spermatic cord in boys may reveal the absence of the vas deferens.

The fingers and toes show changes associated with clubbing early in the disease process. There are four grades of clubbing (Table 18-21). Signs such as cardiac abnormalities consistent with cor pulmonale are rare.

TABLE 18-20

Clinical Manifestations and Treatment of Cystic Fibrosis

Symptom	*Treatment*
Upper Respiratory Tract	
Nasal polyposis	Nasal saline rinses, topical corticosteroid, polypectomy
Sinusitis	Maxillary antrostomy and ethmoidectomy, antibiotic flushes
Pulmonary	
Bronchiolitis, bronchiectasis	ICS, high-dose ibuprofen, chest physiotherapy, oral corticosteroids, antibiotic
Atelectasis	Chest physiotherapy, ICS, antibiotic, oral corticosteroids
Bronchitis	Chest physiotherapy, antibiotic, ICS, oral corticosteroids, mucolytics
Hemoptysis	Arterial embolization, transfusion
Pneumothorax	Chest tube, fibrin glue, surgical stapling, pleurodesis
Pneumonia	Intravenous, inhaled, or oral antibiotic, chest physiotherapy
Reactive airway disease	ICS, oral corticosteroids, β-agonist, anticholinergic agents
Respiratory failure	Oxygen, noninvasive mechanical ventilation, endotracheal intubation with mechanical ventilation, lung transplant
Gastrointestinal	
Gastroesophageal reflux	Antacid, intestinal prokinetic agent, fundoplication
Intussusception	N-acetylcysteine enema, Gastrografin, or hypaque enema, surgery
Meconium ileus	N-acetylcysteine by nasogastric tube, lactulose, surgery
Meconium ileus equivalent (distal intestinal obstruction syndrome)	N-acetylcysteine by nasogastric tube, lactulose, laxative, hypaque enema
Pancreatic exocrine deficiency	Pancreatic enzyme replacement, antacid, gastrointestinal promotility agents
Pancreatitis	NPO, fluid, low-fat diet, surgery
Peptic ulcer disease	Antacid
Rectal prolapse	Enhanced nutrition and optimized pancreatic enzyme replacement, surgical treatment rarely necessary
Hepatobiliary	
Cholecystitis	Antibiotic therapy
Cholelithiasis	Ursodeoxycholic acid, cholecystectomy
Cholestasis	Ursodeoxycholic acid, pancreatic enzyme, gastrointestinal prokinetic agent
Cirrhosis/portal hypertension	Liver transplant, lactulose, ursodeoxycholic acid, splenectomy
Nutritional/Metabolic	
Diabetes mellitus	Insulin, oral hypoglycemics
Hypoprothrombinemia	Vitamin K
Iron deficiency anemia	Iron

TABLE 18-20

Clinical Manifestations and Treatment of Cystic Fibrosis *(Continued)*

Symptom	*Treatment*
Salt depletion syndrome	High-salt diet, liquid intake
Protein-calorie malnutrition	High-calorie, high-protein diet with pancreatic enzyme replacement therapy
Vitamin A deficiency	5,000–10,000 IU/wk supplement
Vitamin E deficiency	400–800 IU/day supplement
Failure to thrive	Nutritional support, pancreatic enzyme, intravenous lipids
Malnutrition	Nutritional support, pancreatic enzyme
Growth retardation	Nutritional support, pancreatic enzyme
Osteoporosis	Calcium replacement, pamidronate, high-dose vitamin D replacement
Miscellaneous	
Arthritis/arthropathy	Analgesics, pamidronate
Clubbing of the digits	
Absence of the vas deferens	
Decreased female fertility	
Delayed puberty	
Erythema nodosum	Oral corticosteroid therapy

ICS, inhaled corticosteroid; *NPO*, nothing by mouth.

Laboratory Evaluation

Newborn Screening. Screening for CF at the time of birth has led to early identification of CF with a resultant positive impact on the nutritional status of young children with CF. Beginning in August of 2007, the California legislature mandated the addition of testing for CF with the measurement of serum immunoreactive trypsinogen (IRT) to the newborn screening panel. By 2010, all 50 states will have implemented newborn screening programs for early detection of CF. Most states utilize the following four-step screening algorithm to potentially identify CF in newborn infants. All newborn blood spots are tested for IRT at the regional Neonatal and Prenatal Screening laboratory (step one). Newborns with values in the top 2.2% of the IRT distribution (*n* about 11,844 per year) will have their blood spots tested at a designated core facility for genetic testing.

TABLE 18-21

Stages of Clubbing

Stage	*Description*
0	Normal
1+	Obliteration of notch at fingernail cuticle
2+	Slight rounding of base of nail
3+	Involvement of soft tissues of finger pad
4+	Most extreme amount of clubbing, described as a “parrot’s beak”

In California, 38 different CFTR mutations are tested. These include the four most common mutations detected in the Hispanic population (step two). Newborns with low IRT values or zero mutations are deemed to be screen negative for CF (n ~ 539,882). Those with one mutation found (*n* about 876 per year) will have one of their existing filter paper blood spots sent to Ambry Genetics for more sophisticated testing using DNA sequencing methods capable of detecting over 98% of all CFTR mutations (step three). Newborns with two or more mutations identified are screened positive for CF (*n* about 104 per year), and in conjunction with the newborn's primary care provider, will be referred to a Cystic Fibrosis Special Care Center for a diagnostic work up and sweat chloride test (step four).

By this algorithm and the cut-off for elevated IRT, it is calculated that of the 78 new CF cases are expected to occur each year, based on population demographics, and that 75 will be correctly identified, giving a 96% sensitivity to the screen.

Serum for CF DNA. As stated previously, in general, this is a less sensitive test than the sweat test in many populations, due to the fact that the panel of mutations that are routinely checked at the Stanford Clinical laboratory includes 24 of the most common mutations known for the Caucasian population and adds 5 more thought to be more common in the Hispanic population. This takes about 7 days to return.

Many more mutations exist, and it is not uncommon to receive a result that identifies only one CF mutation. This DOES NOT exclude CF from the differential. More extensive genetic analysis can be obtained from Ambry Genetics, a laboratory that sequences nearly the entire CF genome of samples. This may be requested as the initial DNA analysis for patients with different ethnic backgrounds than Northern European Caucasians. This takes about 14 to 21 days to return.

Stool Elastase Quantification. A small amount of stool may be obtained and sent for elastase quantification. The lower limit of normal that is selected to be the most sensitive and specific for true pancreatic exocrine insufficiency is 200 mcg/gm stool.

Sweat Test. The gold standard for diagnosis of CF is the sweat test or pilocarpine iontophoresis test. Because CF affects the sweat glands, affected patients are less able to reabsorb chloride from sweat than normal individuals. This leads to a very high level of chloride in the sweat and a reliable method of diagnosis. Premature infants lack fully developed, mature sweat glands, but usually by the time a term infant is 9 weeks of age, the test can be performed successfully.

Pediatric Pearl: False-positive sweat tests do occur. Causes include adrenal insufficiency, ectodermal dysplasia, nephrogenic diabetes insipidus, glycogen storage disease type 1, anorexia nervosa, hypoparathyroidism, familial cholestatic syndromes, malnutrition, hypothyroidism, mucopolysaccharidoses, and fucosidosis.

Management

The management of patients with CF can be very complicated because of the multisystem involvement and a high frequency of complications. For these reasons, a comprehensive and intensive therapeutic program is essential. A physician experienced in CF and its manifestations should follow all affected patients at intervals of 2 to 3 months. A team approach, including nursing, nutrition, physical therapy, respiratory therapy, and counseling personnel, is most beneficial. A variety of therapeutic measures are useful (see Table 18-20).

Treatment of Pulmonary Problems

Treatment of pulmonary complications of CF, which occurs on a daily basis, focuses on clearance of excess mucus from the tracheobronchial tree. There are several modes of clearance: flutter device, positive expiratory pressure device, manual chest physiotherapy, intrapulmonary percussive ventilation, percussion vest, active cycle of breathing, and autogenic drainage. With the exception of autogenic drainage, these are forms of airway clearance that achieve airway clearance maneuvers with the use of mechanical devices. No studies have found that one particular method provides more optimal clearance than the others, and individual patients have different experiences with each of the different modes. Clinicians should educate patients about the importance of daily clearance of mucus and expect them to perform twice-daily airway clearance sessions once a mode of treatment has been selected.

It is necessary to use aggressive antibiotic therapy when patients begin to experience signs and symptoms of a pulmonary exacerbation—a characteristic slow deterioration of pulmonary function that usually presents as an increase

in baseline cough, sputum production, wheezing, crackles, and weight loss. When available, the patient's most recent sputum or throat culture guides antibiotic therapy. A recent addition to the routine regimen for patients colonized with *P. aeruginosa* has been twice-daily dosing with inhaled tobramycin, given for 28-day cycles every other month.

If hospitalization for CF-associated pneumonia is necessary, double antibiotic therapy is used in the treatment of a gram-negative bacillus such as *P. aeruginosa* to achieve a synergistic bactericidal effect. The most common antibiotic regimens use an aminoglycoside, such as tobramycin, combined with a third-generation semisynthetic penicillin or a cephalosporin that has adequate antipseudomonal activity (ceftazidime or cefepime).

No clinical trials have found that corticosteroids are effective in slowing the rate of pulmonary deterioration in CF. These agents do not diminish chronic airway inflammation. However, nonsteroidal anti-inflammatory drugs (NSAIDs) appear to slow the progression of lung disease significantly. Some patients with CF who are older than 5 years of age have received high-dose ibuprofen as an addition to their daily drug regimen. Doses are 20 to 30 mg/kg/dose twice daily.

Azithromycin is recommended as therapy for CF patients with chronic *Pseudomonas aeruginosa* infection. In a randomized, controlled trial with CF patients over 6 months, the results demonstrated that the azithromycin group had a significant increase in FEV_1. In addition, the subjects in the azithromycin group had less risk of experiencing an exacerbation than participants in the placebo group and weighed an average of 0.7 kg more at the end of the study than participants receiving placebo. These findings have led to the routine treatment with azithromycin for patients with CF who are 6 years or older and chronically infected with *P. aeruginosa*. In a multicenter, randomized, double-blind placebo-controlled trial was conducted in the United States and Canada with 260 patients ages 6 to 18 years and negative respiratory tract cultures for *P. aeruginosa* for at least 1 year. The primary outcome was a change in FEV_1. Exploratory outcomes included additional pulmonary function end points, pulmonary exacerbations, changes in weight and height, new use of antibiotics, and hospitalizations. Changes in lung function and microbiology as well as adverse events were monitored. None of the exploratory pulmonary function end points were significantly improved statistically. But, the incidence of pulmonary exacerbations was significantly lower in the azithromycin group compared to the placebo group. Additionally, participants in the azithromycin group had an increase in body weight of 0.58 kg compared with placebo participants. Participants in the azithromycin group had less of a cough and a less productive cough compared with placebo participants.

Because of the high concentration of DNA released from dead leukocytes, the sputum of patients with CF is more abundant and has increased viscosity. Recombinant human DNAse (rhDNAse) is effective at decreasing sputum viscosity, increasing expectorated quantity, and minimizing the number of pulmonary exacerbations.

In most patients with CF who have severe, end-stage lung disease, lung transplantation is an option. Since 1985, more than 750 patients with CF in the United States have undergone lung transplantation. The 2-year survival rate is approximately 65%. The survival rate of CF patients after transplant is no different than for non-CF patients who undergo heart–lung or double-lung transplantation.

Treatment of Gastrointestinal Problems

GI symptomatology is typical in patients with CF. However, treatment with oral pancreatic enzyme replacement therapy is often all that is needed to improve and maintain adequate nutritional status and minimize malabsorption, steatorrhea, constipation, and diarrhea. Pancreatic enzymes are available in many forms (e.g., powder, capsule, gel). Most patients are maintained on lipase 500 to 5,000 U/kg/meal. Infants often require the powdered form added to their formula. The capsules contain small microencapsulated enzymes, which are protected from acid digestion in the stomach, and are most active in the duodenum and ileum, where the pH is alkaline. Because patients with CF tend to be pancreatic insufficient, they may require concomitant doses of antacid to maximize the activity of the pancreatic enzyme in the small intestine.

Treatment of Complications

HEMOPTYSIS. Patients often experience blood streaking of their sputum, which is probably due to rupture of surface capillaries secondary to vigorous coughing. A larger danger exists if bleeding occurs due to erosion of a bronchus into a bronchial artery; this most often occurs in association with a pulmonary exacerbation. Massive hemoptysis, a serious complication in patients with advanced disease, results in significant mortality. Although the condition occurs in less than 10% of adults and rarely in children, an estimated 1% of all patients with CF die from massive hemoptysis. The majority of patients who experience this complication and survive will suffer a recurrence.

For significant bleeding, a procedure known as arterial embolization is used to control the rupture. It involves a procedure similar to cardiac catheterization, in which the femoral artery is entered and the catheter is passed up the aorta to the point of branching of the bronchial arteries. Abnormal arterialization to the lung from

the aorta, the internal thoracic artery, and the thyroid artery are most often the culprits; they can be embolized with fibrin beads or springs placed in the blood vessel.

PNEUMOTHORAX. Pneumothorax, which occurs in 8% to 23% of older patients with CF, may affect children with severe disease. The mortality rate is about 4%, and the recurrence rate is 50% to 70%. Rupture of subpleural blebs is the progenitor of pneumothorax in most patients.

Treatment for pneumothorax varies. If the area is small and the patient is stable, treatment with 100% oxygen by mask is preferred. However, a bronchopleural fistula may persist, and treatment with fibrin glue to obliterate the pleural space may be necessary. Partial pleurectomy has the highest success rate, but if the patient is a lung transplant candidate, intercostal drainage, chemical pleurodesis, ligation of bullae, or limited surgical pleurodesis should be performed in preference to pleurectomy.

RESPIRATORY FAILURE AND COR PULMONALE. Hypertrophy of the right ventricle is common in adults with severe CF. However, progression to overt cardiac failure is not, and once it develops, survival time is short. Before cor pulmonale develops, oxygen therapy may begin, initially for nocturnal use.

Intubation and mechanical ventilation are considered futile in most patients with severe lung dysfunction unless there is an acute reversible problem (e.g., hemoptysis, pneumothorax); after its resolution, removal of the mechanical ventilation may occur. However, nasal mechanical ventilation with bilevel positive airway pressure supports many patients nocturnally or as a bridge to eventual lung transplantation.

BRONCHOPULMONARY DYSPLASIA/CHRONIC LUNG DISEASE

Previous clinical observations and investigations suggest that **bronchopulmonary dysplasia (BPD)** is the chronic phase of neonatal lung damage caused by oxidant injury and barotrauma in susceptible premature infants. Over 30 years ago, BPD was described as a progression of characteristic radiographic findings that correlate with pathologic changes of acute and chronic inflammation, fibrosis, and bronchial smooth muscle hypertrophy in premature respiratory-dependent infants. Despite the improved survival of extremely low birth weight infants (less than 1,000 g) since the introduction of exogenous surfactant, BPD remains a major cause of morbidity in neonatal intensive care units (NICUs).

The "classic" BPD described by Northway in 1967 has now been replaced by less severe forms of "new" BPD, which are infrequently found in patients >30 weeks of gestation and birth weights >1200 grams. In a recent study, where BPD was defined as oxygen need at 36 weeks post menstrual age, the incidence was 52% in infants with birth weights of 50l to 750g, 34% in infants with birth weights of 751 to 1000g, 15% in infants with birth weights of 100l to 1200g, and 7% in infants with birth weights of 1201 to 1500g.

The pathology of the BPD lung from the pre-surfactant era was characterized by the presence of severe airway injury, inflammation and parenchymal fibrosis and marked heterogeneity in lung pathology with severe alveolar septal fibrosis in some areas and presence of normally inflated and/or hyperinfiated lung in the adjacent lobules. Pathological findings of the "new" BPD lung reveal more uniform inflation and less marked fibrosis and absence airway epithelial metaplasia, smooth muscle hypertrophy and fibrosis, as compared to lungs of infants with "classic" BPD. New BPD is characterized by arrest of acinar development, resulting in decrease in alveolar number and a decrease in the arterial count with normal alveolar/arterial ratio regardless of whether the patients are treated with surfactant (Table 18-22).

TABLE 18-22

Diagnostic Criteria for BPD

	MILD *Supplemental 02 (for 28 days) and*	*MODERATE* *Supplemental 02 (for 28 days) and*	*SEVERE* *Supplemental 02 (for 28 days) and*
< 32 weeks GA at birth	RA at 36 weeks corrected GA or at discharge	<0.3 Fi02 at 36 weeks corrected GA or at discharge	≥0.3 Fi02 +/− positive pressure support at 36 weeks corrected GA or at discharge
≥ 32 weeks GA at birth	RA by postnatal day 56 or at discharge	<0.3 Fi02 by postnatal day 56 or at discharge	≥0.3 Fi02 +/− positive pressure discharge 56 or at discharge

Diagnosis

The term **chronic lung disease (CLD)** refers to the complex interaction of antenatal and postnatal factors that lead to ongoing symptomatology and the need for treatment for respiratory problems in infants. CLD describes a wide variety of disorders that affect the upper and lower respiratory tract, including BPD.

CLD is frequently accompanied by other disorders, such as cardiovascular problems, gastroesophageal reflux, congenital anomalies, growth impairment and nutritional difficulty, and sensory and neurodevelopmental handicaps. The pediatrician must follow these conditions closely. It is important to realize that many affected infants will require ongoing respiratory treatment for the first 2 years of life, if not longer.

A large proportion of children with CLD have concomitant reactive airways disease. Bronchodilators improve gas exchange and decrease the resistance of the airways such that the work of breathing is reduced after bronchodilator administration. Anti-inflammatory agents such as inhaled corticosteroids (see Asthma) are also commonly used as a means to decrease airway reactivity and also to hasten the resolution of inflammatory status of the airway epithelium and to avoid fibrotic remodeling of the airways. No controlled trials have demonstrated that long-term use of corticosteroids leads to an improvement in pulmonary function in older children or adults.

In CLD, there is evidence of a disturbance in water balance and chronic peribronchiolar edema. Diuretics are frequently used to decrease interstitial fluid, increase pulmonary compliance, and minimize small airway obstruction. However, there is no convincing evidence that this medication is effective for long periods of time, and infants are often allowed to "outgrow" their disease after they are discharged from the NICU.

Management

Adequate oxygenation is the cornerstone of CLD management. However, controversy exists about how low oxygen levels should be before infants are considered hypoxic, and thus, what PaO_2 level to attain once supplemental oxygen is prescribed. Chronically hypoxemic children exhibit growth failure, and developmental delays, and they may have pulmonary hypertension. Too much oxygen promotes the formation of oxygen radicals in airways where an inflammatory process is occurring, which leads to poor lung function in the long run.

APNEA AND THE CONTROL OF BREATHING

The problem of infantile apnea is difficult for pediatricians; it is impossible to establish an underlying cause in many cases. Parents want to be reassured that their child is not at risk for **sudden infant death syndrome (SIDS; crib death)**. Unfortunately, no predictive tools are available to assess the risk of SIDS in any individual infant. In this section, SIDS will be discussed, and the approach to the conditions of **apnea of infancy** and **apparent life-threatening event (ALTE)** will also be addressed. Each of these terms has a particular meaning for pediatricians (Table 18-23).

SUDDEN INFANT DEATH SYNDROME

SIDS is the sudden death of an infant younger than 1 year of age that remains unexplained after completion of a postmortem investigation, including an autopsy, examination of the scene of death, and review of the clinical history. In 1998, SIDS was the third leading cause of infant mortality (8.9%) in the United States after congenital anomalies (22%) and short gestation/low birth weight (14%).

Deaths from SIDS follow a recognizable epidemiologic pattern. They are most likely to occur in the colder months and in the second to fourth months of life. The risk for SIDS in siblings of SIDS victims is approximately four times greater than in the general population. The rates of SIDS in the United States are higher for African American infants than for Caucasian, Hispanic, and Asian infants.

In California, SIDS-related public health measures were initiated during the early 1990s. To help standardize the diagnosis of SIDS, autopsy and death scene protocols, including medical history, were developed by an expert committee and implemented after legislative mandate.

Pathophysiology

No single mechanism for SIDS has been established. It is likely that several distinct pathophysiologic mechanisms may contribute to SIDS. A brainstem abnormality related to neuroregulation of cardiorespiratory or other autonomic functions is a compelling hypothesis that is currently being investigated. Autopsy studies indicating preexisting, chronic, low-grade hypoxemia attributed to sleep-related hypoventilation support this hypothesis. Environmental factors associated with an increased risk for SIDS include prone positioning for sleep, exposure to cigarette smoke during gestation or after birth, overheating, and not breast-feeding.

TABLE 18-23

Disorders of Control of Breathing

Condition	*Definition*
Apnea	Cessation of airflow Central (no respiratory effort) or obstructive May be normal at all ages (short [<15 seconds])
Periodic breathing	Three or more respiratory pauses of >3 seconds with <20 seconds of respiration between pauses May be normal
ALTE	Episode that is frightening to observer; characterized by some combination of apnea, color change, marked change in muscle tone, choking, or gagging In some cases, fear the infant has died
Apnea in infancy	Unexplained episode of apnea (>20 seconds) or shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia Infants in whom no specific cause for an ALTE can be identified
SIDS	Sudden death that is unexplained by history; thorough postmortem evaluation fails to demonstrate adequate cause of death

ALTE, apparent life-threatening event; *SIDS*, sudden infant death syndrome.

From Consensus Statement: National Institute of Health Consensus Development Conference on Infantile Apnea and Home Monitoring, Sept. 29–Oct. 1, 1986. *Pediatrics*, 79:292, 1987.

Clinical Evaluation

No autopsy finding is pathognomonic for SIDS, and no finding is required for the diagnosis. However, some features are common to many victims. Petechial hemorrhages are found in more than 70% to 90% of cases. Pulmonary edema is often found, and it may be substantial. Some unexpected deaths may be "misdiagnosed" as pneumonia or other natural conditions based on minimal findings at autopsy that are insufficient to explain sudden death; this relates to the lack of uniform criteria among pathologists.

Management

The American Academy of Pediatrics (AAP) Task Force on Infant Positioning and SIDS issued its first recommendation on the nonprone positioning of infants in June 1992, the "Back to Sleep" program. Public education campaigns focused on reduction of environmental risk factors for SIDS such as prone positioning and exposure to cigarette smoke. Changes in the rate and epidemiologic patterns of SIDS in California from 1990 to 1995 demonstrated drastic changes in the patterns of SIDS. The SIDS postneonatal mortality rate declined 38.9% from 118 deaths/100,000 live births in 1991 to 72/100,000 in 1996 ($P < .001$), thus indicating the impact of ongoing strategies to reduce SIDS mortality.

APPARENT LIFE-THREATENING EVENTS

ALTE, a term used to describe the clinical presentation of infants who have a seemingly life-threatening event, is not a diagnosis. The etiology is known in 49% to 62% of cases (Table 18-24). Having an ALTE is a risk factor for SIDS. However, less than 7% of SIDS victims have a prior history of ALTE. Infants who have experienced ALTE are at particular risk for SIDS, including those who have had repeated episodes requiring mouth-to-mouth resuscitation, especially if they are siblings of SIDS victims or have a seizure disorder. Although the reported recurrence rate for ALTE based on parental observation is 41% to 63%, recent data based on the occurrence of actual events suggest that these values are overestimated. This lack of agreement between parental observation and recorded events underscores the difficulty in defining groups at risk for SIDS.

Pathophysiology

During active sleep, the tone of upper airway and intercostal muscles decreases, possibly leading to upper airway narrowing or closure. Increased resistance to airflow and hypoventilation may result. Reduction in tone of upper

TABLE 18-24

Differential Diagnosis of Apparent Life-Threatening Event (ALTE)

CNS, central nervous system; *RSV*, respiratory syncytial virus; *TB*, tuberculosis.

airway and intercostal muscles may lead to severe reductions in FRC, providing a lower reserve of oxygen and putting the infant at risk for rapid development of hypoxemia during apnea.

Clinical and Laboratory Evaluation

History

The clinician must decide if an ALTE truly occurred and if an underlying condition caused the episode. The history obtained from the parents or caregiver is the most important part of the evaluation of an

infant who presents with ALTE. The infant's state of consciousness (i.e., asleep or awake) at the time of the event should be ascertained. Awake events are atypical for apnea of infancy and suggest other causes. The timing of feeding in relation to the event is important. Any evidence of prior sleep disturbance, noisy breathing, or feeding difficulties is noteworthy. Vomiting or choking suggests **gastroesophageal reflux** or **aspiration**. Noisy respirations suggest **upper airway obstruction**. Abnormal movement or rigidity suggests the occurrence of a **seizure**. A seizure may be the cause of the ALTE, or it may be secondary to prolonged hypoxemia. The duration of the episode and any change in skin color (e.g., pallor, cyanosis) or muscle tone are important.

A history of recent illness suggests infection as the cause of the event. The type of intervention (stimulation versus resuscitation) and the time to recovery give clues as to the severity of the event. Repeat events always in the presence of the same witness may suggest a diagnosis of **Munchausen syndrome by proxy**. A perinatal history of asphyxia or sepsis is frequently seen in ALTE of neurologic origin. Any medications given to the infant should be noted. A family history of unexplained deaths or syncopal episodes warrants consideration of rare metabolic disorders (especially if occurring outside the normal age range for SIDS), seizure disorders, cardiac rhythm disturbances, or child abuse.

Physical Examination

It is important to note the temperature, cardiac and respiratory rate, and rhythm. The pediatrician should look for features that might indicate increased risk for upper airway obstruction such as micrognathia, Pierre Robin syndrome, midface hypoplasia, and large tonsils and adenoids. The rate and depth of breathing, retractions, or unusual pauses are noteworthy. Signs of upper and lower respiratory tract infection should be noted. Respiratory syncytial virus (RSV) is frequently a cause of apnea in infants. A careful cardiac, neurologic, and developmental assessment is mandatory.

Laboratory Evaluation

For patients whose history does not suggest a significant event, a limited diagnostic evaluation is warranted (Table 18-25). A bicarbonate level should be obtained as soon as possible after the event; a low value suggests a significant insult. The clinician may obtain additional studies according to the index of suspicion (Table 18-26).

TABLE 18-25

Laboratory Evaluation of Apparent Life-Threatening Event (ALTE)

Test	*Comments*
CBC, hematocrit	Low hematocrit (anemia), high WBC count (infection)
Bicarbonate	Low: significant event High: chronic hypoventilation
Electrolytes	Low yield
Calcium	Low yield
Glucose	Low yield
Cultures (blood, urine, CSF)	Positive culture: infection
Chest radiograph	Infection, aspiration, cardiomegaly
ECG	Dysrhythmia, prolonged QT interval
EEG (for seizure)	Spike-wave pattern
pH probe (for gastroesophageal reflux)	Abnormal values, which differ depending on the age of infant
Nasopharyngeal swab for DVE	Rapid detection of RSV, influenza A and B, parainfluenza

CBC, complete blood count; *CSF*, cerebrospinal fluid; *DVE*, direct viral examination; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *RSV*, respiratory syncytial virus; *WBC*, white blood cell.

TABLE 18-26

Other Tests to Consider in Evaluating an Apparent Life-Threatening Event (ALTE)

Test	*Comments*
Airway films	Adenoidal and tonsillar hypertrophy, subglottic stenosis
CT (head)	Concussion, areas of bleeding, brainstem compression
Polysomnography	Hypoventilation, abnormal periods of apnea, bradycardia
Metabolic workup	Urine organic acids, serum long-chain fatty acids
Barium swallow	Assessment for aspiration or tracheoesophageal fistula
ECG	Right ventricular hypertrophy, arrhythmias
Cranial ultrasound	Bleeding, periventricular leukomalacia
Bronchoscopy	Hemorrhage, culture of lavage fluid, foreign body aspiration

CT, computed tomography; *ECG*, echocardiography.

Management

Infants who present after having a significant ALTE should be hospitalized for at least 48 hours for diagnostic evaluation and cardiorespiratory monitoring. After testing is complete (see Laboratory Evaluation), it is necessary to decide whether home monitoring or pharmacologic therapy is appropriate. Specific causes of ALTE require treatment. However, it should not be assumed that identification of a cause eliminates future risk. Pneumograms should not be used as a screening tool to determine future risk as normal pneumograms do not imply the absence of risk for SIDS. The National Institutes of Health recommends monitoring for the following groups of patients: (1) infants who have had one or more severe ALTEs requiring mouth-to-mouth resuscitation or vigorous stimulation, (2) siblings of two or more SIDS victims, and (3) infants with central hypoventilation. Monitoring may be considered on an individual basis for siblings of one SIDS victim and infants with less severe ALTE episodes.

Because of the low incidence of SIDS and the low incidence of ALTE in infants who subsequently die of SIDS, it is difficult to demonstrate the effectiveness of monitoring in preventing SIDS. The decision to monitor an infant at home requires multiple support systems to be in place, including nursing and physician support, psychosocial support, and periodic visits from the supplier to inspect the equipment. Patients are not discharged from the hospital until all caretakers can effectively perform cardiopulmonary resuscitation. Parents must understand that home monitoring is not a guarantee against SIDS. Criteria for discontinuing monitoring include: (1) no event requiring vigorous stimulation or resuscitation in 2 to 3 months, (2) no observed prolonged apnea or bradycardia for 2 months, (3) no alarms with stress (i.e., upper respiratory infection, immunization), and (4) normal event recording.

Neurology

Henry Hasson, Akila Venkataraman, Alfred J. Spiro, Barbara L. Trommer, and Steven G. Pavlakis

Infants, children, and adolescents often present to pediatricians with neurologic complaints. Here we discuss some of the more common neurologic conditions that might be encountered by the pediatrician.

THE FLOPPY INFANT

Hypotonia is a diminished resistance to passive movement around a joint. Floppiness and the degree of hypotonia is a subjective determination. Hypotonia is an indication of low muscle tone, not strength. If there is associated weakness, this aids in the differential diagnosis.

Pathophysiology

The condition may result from varied lesions of the central nervous system (CNS) or peripheral nervous system (PNS). The CNS consists of brain and spine, and the PNS consists primarily of the motor unit, which includes the anterior horn cell, peripheral nerve, neuromuscular junction, and the muscle.

Hypotonia may be benign and familial with the infant ultimately developing normally. Benign familial hypotonia occurs in otherwise normal infants with a family history of hypotonia and is typically associated with late walkers.

Infants with hypotonia secondary to lesions of the motor unit have reduced strength, in addition to hypotonia. An example of this includes infants with myopathy. Children with CNS-related hypotonia, in contrast, may just have low tone usually without weakness. An example of this includes Down syndrome. Hypotonia may also be found in infants with systemic disease such as sepsis and hyperbilirubinemia.

History

Hypotonia may be present from birth or may be acquired, may be static or progressive, and may affect only the legs, only the arms, or all limbs. The presence of asymmetries and weakness may be important. As an example, hypotonia that affects the legs more than the arms may be the result of a spinal cord lesion such as a neuroblastoma. Finally, symptoms of systemic illness or of a genetic syndrome need to be excluded. In the hypotonic infant, details of the pregnancy, including the mother's perception of fetal movements, and information concerning delivery, birth weight, and the presence of hyperbilirubinemia or neonatal seizures are important.

Family history with special emphasis on neuromuscular disorders is important. For example, most of the motor unit disorders in which floppiness or weakness are prominent are genetically determined. Benign familial hypotonia often has a family history consistent with the condition.

Physical Examination

The examination is helpful in localizing the cause of the floppiness. The first step, before touching the child, is to simply look at the child from a distance. The first item to be noted is the appearance of dysmorphic features. This can help determine whether there is an underlying syndrome. At this point one can assess for spontaneous movements and asymmetries that may point to generalized or focal weakness.

The head circumference of an infant needs to be plotted on an appropriate graph. If it exceeds the 95th percentile, the head circumference of both parents should be measured. If the head is very large or if there has

been an acceleration of head size, brain imaging needs to be considered. In contrast, if the child is microcephalic this too points to a hypotonia of CNS origin. For example, autism and neurofibromatosis are two static conditions both of which are associated with relative macrocephaly. Large heads can also be associated with certain progressive conditions such as Canavan and Alexander disease.

The degree of hypotonia is subjective. If infants are weak as well as hypotonic, decreased spontaneous movements or inability to move an extremity against gravity may be observed. Strength can be tested by determining whether an infant can hold the head erect or pull the neck up in the traction response, roll over, sit up, crawl, or stand with support or independently at the appropriate time. If there is weakness in addition to hypotonia, this suggests a neurologic condition affecting the motor unit. Weakness associated with the CNS may occur but is often associated with abnormal reflexes or asymmetries.

Developmental assessment may be a source of information about the normalcy of gross and fine motor, language, and social-adaptive milestones. In hypotonia due to cerebral lesions, a delay in cognitive development often occurs, although motor system abnormalities may be the most obvious. Examination of the cranial nerves should focus on the extraocular muscles because certain disorders of the myoneural junction and rare myopathies can cause abnormalities in eye movements, in addition to weakness. In infantile progressive spinal muscular atrophy (SMA), the tongue (with the baby not crying) will have fasciculations (abnormal firing of muscle groups at rest).

Generally, deep tendon reflexes are maintained or are hyperactive in hypotonia of cerebral origin and reduced or absent in most motor unit disorders.

Diagnostic Evaluation

In infants with dysmorphic features and hypotonia such as observed in **Down syndrome,** chromosomal studies might be diagnostic. If **hypothyroidism** is suspected, thyroid function studies are appropriate. In addition, one may consider lactate, pyruvate, ammonia, organic acids, and amino acids, if there is suspicion of a metabolic disorder or progressive disease. Genetic studies (DNA testing to document a specific deletion on chromosome 5) to confirm a diagnosis of anterior horn cell disease in infants and children (SMA of varying types) are available in specialized laboratories.

If the history and physical examination are suggestive of a cerebral lesion, an imaging study such as magnetic resonance imaging (MRI) of the brain might be indicated.

Electrodiagnostic studies (e.g., EMG and nerve conduction) and muscle biopsy are useful procedures in selected instances when noninvasive testing is not confirmatory. Nerve conduction velocity determinations can usually document peripheral nerve disorders.

An edrophonium (Tensilon) test and specialized electrodiagnostic tests can be useful in a suspected myoneural junction disorder such as myasthenia gravis. Muscle biopsy, using specialized analytical techniques, may be diagnostic when myopathy is suspected; serum muscle enzyme levels are often elevated in myopathies, especially in the dystrophies. Generalized hypotonia is often seen in other conditions with genetic testing such as Prader-Willi syndrome (chromosome 15). In fact, most genetic conditions with associated hypotonia have a predisposition to cognitive abnormalities.

Differential Diagnosis

First, one should consider a primary lesion outside of the nervous system.

Down syndrome infants are mildly to moderately floppy. In addition, they will have other stigmata (see Chapter 11) characteristic of these babies. Infants with **Prader–Willi syndrome** are severely floppy and obtunded early in infancy. Developmental retardation is noted in both conditions. Hypotonia due to **hypothyroidism** is associated with other signs of thyroid dysfunction. Previous magnesium sulfate therapy for toxemia in the mother may relate to hypermagnesemia in newborns by blocking neuromuscular transmission. The hypotonia, muscle weakness, and decreased reflexes in this situation are transient.

Hypoxic-ischemic encephalopathy and intraventricular hemorrhage are frequently associated with hypotonia and, often, weakness. These infants might develop features of cerebral palsy with spasticity or other neurologic manifestations later in infancy or early childhood.

In **infantile SMA, type I (Werdnig-Hoffmann disease),** infants are bright and alert as well as weak and floppy. Onset occurs in the first 6 months of life, with areflexia, normal central recognition of pain, relatively preserved diaphragmatic function versus chest wall weakness (paradoxical respirations), and fasciculations of the tongue. Inheritance is autosomal recessive. There are more benign phenotypes of SMA with onset of symptoms sometimes occurring in childhood or even later. In all types of the disorder, cognition is normal. The disorder is now better defined with a mutation in chromosome 5 with associated mutations, which modify disease severity. Clinical trials are now underway, but there is as yet no proven therapy.

Pediatric Pearl: In a floppy infant with normal cognition, absent deep tendon reflexes, and fasciculations of the tongue, SMA is the most likely diagnosis.

Most peripheral neuropathies are hereditary sensorimotor neuropathies. Clinical manifestations are very rare in newborns but appear in childhood or later. Rare CNS disease such as the **leukodystrophies** (e.g., metachromatic leukodystrophy) are characterized by peripheral nerve involvement but are associated with dementia and generally present in later childhood. **Transient infantile myasthenia gravis** is an autoimmune disorder that may occur in newborns of mothers with myasthenia gravis. Recovery from this disorder occurs within the first few weeks, but some infants require therapy for only a few days. Often all that is required is supportive treatment. Actively acquired **autoimmune myasthenia gravis** is very rare in infants but can be seen in older children. Nonautoimmune myasthenic syndromes (**congenital myasthenia gravis syndromes**), in contrast to transient myasthenia gravis and botulism, are also rare.

Involvement of muscle (uncommon in infancy) or the nervous system is variable in **mitochondrial encephalomyelopathies**. Lactic acidemia is frequent, and the test for elevated serum lactate is useful for screening. MRI may show specific patterns of basal ganglia abnormalities in infantile disorders such as Leigh disease. Mitochondrial or nuclear DNA studies performed on blood samples can be useful in the diagnosis. Specialized studies on muscle mitochondria obtained from a skeletal muscle biopsy may also provide a specific diagnosis in selected cases, although are utilized less frequently because of advances in genetic testing.

Management

Specific therapy depends on diagnosis, but in general, it is essential to provide respiratory and nutritional requirements and supportive therapy. Some neonates or infants require temporary ventilatory support and gavage feedings or a feeding gastrostomy. Many disorders with hypotonia as a prominent feature are genetically determined, which makes a diagnosis imperative, even if no therapy is available. In many instances, careful observation is the only necessary treatment because many children have no underlying cause and others have a benign course.

In cerebral disorders, physical, occupational, and language therapy may be appropriate. In infantile SMA, treatment is supportive. No specific medical therapy is available although some are under study. Genetic counseling is warranted because prenatal diagnosis is readily available if the parents desire. Neonates with symptomatic transient myasthenia gravis may receive treatment with pyridostigmine (Mestinon). After several days the dose can be reduced or stopped and, if necessary, restarted. Prognosis is good and most patients do not require ongoing medication.

Most infants with myotonic dystrophy are developmentally delayed in all spheres. Supportive therapy, such as tube feeding and respiratory support, may be necessary. Genetic counseling is warranted because prenatal diagnosis is available if the parents desire it. Orthopedic surgeons should treat clubfoot. There are no known treatments.

With congenital myopathies, genetic counseling is appropriate because many myopathies are hereditary, although prenatal diagnosis is not yet available for most. Supportive therapy may be necessary, depending on the severity of respiratory and swallowing problems. Therapy is needed for congestive heart failure in infants with glycogen storage disease due to acid maltase deficiency. There was recently approved an enzyme replacement for acid maltase deficiency, but treatment in the infant is not promising once the disease has progressed.

MYOPATHIES

The next category one must consider are the myopathies. In **myotonic dystrophy**, hypotonia may be severe at birth, with obtundation, difficulty with sucking and respirations in the neonatal period, areflexia, clubfoot, and weakness of facial muscles. These infants have a profound distal myopathy. The mother should be examined for myotonia (autosomal dominant disorder); DNA studies can confirm the diagnosis. Myotonia is an abnormal sustained contracture of muscles after percussion. Interestingly, infants do not have myotonia until they become older. Myotonic dystrophy is a trinucleotide repeat disorder and, as such, shows phenotypic anticipation. These babies are profoundly impaired, whereas the mother may not even know she has the disease.

Congenital muscular dystrophy and myopathies with characteristic morphology (e.g., nemaline myopathy, central core disease, fiber-type disproportion, glycogen storage disease due to acid maltase deficiency) are hereditary disorders, with varying degrees of floppiness, weakness, and respiratory and sucking problems that surface early in life. Infants with glycogen storage disease due to acid maltase deficiency **(Pompe disease**) have

enlarged hearts on radiography. Diagnosis is made by muscle biopsy in many of these conditions. In addition, some infants present with congenital muscular dystrophies and elevated serum creatine phosphokinase (CPK). These disorders are genetically determined, and effects on the CNS are variable, with some patients having profound CNS involvement. These conditions are generally related to deficiencies of large muscle proteins.

Myopathies constitute a group of diverse disorders in which skeletal muscle is the organ system primarily involved. Three types of myopathies—dystrophic, myotonic, and inflammatory—are considered, and all these are usually associated with elevated blood CPK. Dystrophic myopathies (the several types of muscular dystrophies) and myotonic myopathies are genetically determined disorders, whereas inflammatory myopathies (polymyositis and dermatomyositis) are autoimmune-related entities (Tables 19-1 and 19-2).

Pathophysiology

Skeletal muscle biopsy specimens from patients with myopathies reveal characteristic pathologic abnormalities. These include abnormal variability in fiber size, increased amount of endomysial connective tissue and fat, architectural changes in scattered fibers, and internally positioned nuclei. Inflammatory cells and vascular abnormalities are evident in inflammatory myopathies. Serum muscle enzymes, the most important of which is creatine kinase (CK), are generally elevated in the myopathies.

TABLE 19-2

Muscular Dystrophies

Disorder	*Inheritance*	*Onset*	*Course*	*Muscles Involved*	*Other Findings*
Duchenne muscular dystrophy	X-linked recessive	<5 years	Progressive	Pelvic and shoulder girdles; large calves	Mental retardation; cardiac involvement; absent dystrophin
Facioscapulohumeral dystrophy	Autosomal dominant	Early to late	Slow	Facial muscles; shoulder girdle	Cognition normal
Limb-girdle muscular dystrophy	Recessive and dominant	Variable	Slow	Shoulder and pelvic girdles	Cognition normal

History

Depending on severity, myopthies result in weakness manifesting in difficulty climbing or descending stairs; trouble or awkwardness in running (waddling like a duck); or other gait abnormalities, such as walking up on the toes or difficulty getting up from a sitting position or getting up from the floor, raising the arms over the head, or carrying packages. The examiner should ask about these functional problems, and if present, about the duration of symptoms, whether there has been any worsening or improvement, and the presence or absence of pain and muscle tenderness. Other questions to ask include: Is weakness accompanied by any signs or symptoms of systemic involvement such as a rash or fever, as seen in dermatomyositis? Has there been stiffness or weakness in the hands or difficulty in letting go of objects after holding them in the hand (myotonia)? Has there been any problem with swallowing or chewing, which would be present if pharyngeal muscles or muscles of mastication are weak? Are there any problems with the facial muscles, which would affect the child's ability to blow up a balloon, whistle with pursed lips, or close the eyelids completely during sleep?

Because dystrophic and myotonic myopathies are genetically determined, a careful family history with special emphasis on muscular and related problems is mandatory.

Physical Examination

A complete general and neurologic examination is necessary. Functional testing may be helpful because the major complaint will most likely be **weakness**. The clinician should observe children walking, not in the confines of a small room, but in a corridor and up and down stairs, to see whether there is a waddle, indicating weakness. It is necessary to see whether any muscle wasting (atrophy) or enlargement is present, especially large calves. The clinician should check whether children can walk on their toes to document normalcy of the gastrocnemius-soleus group, and on their heels, to test function of the anterior tibialis muscles. It is necessary to check muscles supplied by the cranial nerves, with special emphasis on the extraocular, facial, palatal, lingual, sternocleidomastoid, and trapezius muscles.

Manual muscle testing (i.e., testing strength of individual muscles) takes a great deal of practice, but a few large muscles, such as deltoids, biceps, and quadriceps, are relatively easy to test, as is hand grasp strength. In place of testing neck flexor muscle strength, which also takes much practice, the examiner may ask the child to raise his or her head while in the supine position. Tendon reflexes are normal or diminished.

In addition, observation of children's skin for a subtle rash, particularly the skin over the eyelids, the interphalangeal joints and knuckles, and the extensor surfaces of the elbow and knee areas, is necessary. Skin involvement is evident in **dermatomyositis.**

Myotonia is the inability to relax after a voluntary contraction. The clinician may ask the child to close his hands forcibly. If he has action (or reflex) myotonia, the child will only be able to open his hands very slowly and may have to flex the wrists to perform this function. A sharp tap with a reflex hammer on the thenar mass may elicit myotonia, but this requires practice or demonstration by an experienced examiner.

Diagnostic Evaluation

Genetic studies (DNA analyses) are currently available in many commercial laboratories for selected muscular disorders such as Duchenne or Becker muscular dystrophy and myotonic dystrophy. Serum muscle enzyme determinations (CK) usually reveal abnormal values in myopathies. **In Duchenne and Becker muscular dystrophy, the CK values are almost always markedly elevated**. However, with some of these disorders, abnormalities, if present, may be very modest.

Pediatric Pearl: Any boy with a gait abnormality, muscle weakness, or toe walking should have a CK level evaluated.

Electromyography **(EMG)** and muscle biopsy may be useful, but for genetic myopathies, they are becoming less important.

Differential Diagnosis

Dystrophic Myopathies

The different types of myopathies (muscular dystrophies) each have characteristic patterns of inheritance, onset, clinical course, muscular involvement, and laboratory findings.

Duchenne muscular dystrophy affects only boys, with very rare exceptions, because it is an X-linked disease. Toe-walking is frequently seen after the child learns to walk; attempts at running may be awkward and waddling may become prominent by 5 years of age. Calf muscles appear large by that time. Because of slowly increasing weakness, children experience difficulty with stairs as they grow older. Weakness is relentlessly progressive, and all boys with Duchenne muscular dystrophy are wheelchair-bound by 12 years of age. Cardiorespiratory compromise leads to death in their 20s. All boys with Duchenne muscular dystrophy have markedly elevated serum CK levels even before developing overt muscle weakness. About two-thirds have a deletion on DNA testing; in the one-third who have no demonstrable deletion, a muscle biopsy specimen indicates characteristic pathologic findings without the muscle protein dystrophin. In a milder form of X-linked muscular dystrophy **(Becker type),** the onset is generally later, and the course is much more slowly progressive. Dystrophin is present in muscle biopsies, although in diminished amounts.

Limb-girdle (LG) and **facioscapulohumeral (FSH) muscular dystrophies** are much more variable in their time of presentation of weakness and in their course. Genetic testing (DNA) is available when FSH muscular dystrophy is suspected. Serum CK elevation may be modest or absent. Similarly, muscle biopsies are much less specific than those in Duchenne muscular dystrophy; dystrophin content is normal. To distinguish the several forms of LG dystrophy, specialized testing of muscle biopsy specimens is necessary.

Myotonic Dystrophy

This autosomal dominant disorder exhibits marked variability in age of onset and progression. In addition to myotonia, which is most readily demonstrable by the inability to relax the hand after squeezing it shut tightly, children may complain of weakness of the hand muscles, may be mentally retarded or have learning difficulties in school, and may have hypernasal speech. Adolescent boys often have early onset of frontal baldness, and cataracts (seen with a slit lamp examination) are very common. An infantile form may be manifest with severe floppiness and clubfoot at birth; in this form, the mother, not the father, always has myotonic dystrophy, although signs and symptoms are so mild that neither she nor her physician is usually aware of the presence of the disease. Myotonic dystrophy is usually a clinical diagnosis, but in older children, the results of EMG are characteristic. Muscle enzymes are usually only minimally elevated, and muscle biopsies are unnecessary. Myotonic dystrophy can also affect heart muscle, and some children can develop endocrinological abnormalities. DNA testing is now available. Infantile myotonic dystrophy is discussed in the Hypotonic Infant section.

Pediatric Pearl: If an infant has floppiness and/or clubfoot, myotonic dystrophy should be suspected. The mother can easily be tested for myotonia even in the absence of any clinical history.

INFLAMMATORY MUSCLE DISORDERS

Weakness (more in the legs than in the arms), which can be documented on functional testing, is usually the presenting symptom in children. The onset of weakness is generally not as insidious as it is with dystrophy, although it is still most commonly subacute. The child or parents can usually date the onset of weakness, often a matter of weeks or a few months. Muscle, joint pain, or both sometimes accompany the weakness. In **dermatomyositis,** an inflammatory muscle disease of children that is more common than polymyositis, a violaceous rash may be present on the eyelids, and erythema may be present on the knuckle areas and extensor surfaces of the knees and elbows. Inflammatory myopathies are not genetically determined. Serum muscle enzymes are generally elevated, and EMG studies, although not specific, are helpful. A muscle biopsy specimen provides a tissue diagnosis in a large percentage of children.

Management

No specific medication to cure the dystrophin myopathies or myotonic dystrophy is available. Prednisone 0.75 mg/kg/day can slow the relentless progression of Duchenne muscular dystrophy. Gene replacement therapy, which may be a possibility, is not yet available. Physical therapy is indicated in most children with muscular dystrophy, and bracing and adaptive devices can be provided when necessary. It is essential to observe children for joint contractures, and treatment for scoliosis is necessary. The multidisciplinary approach available in Muscular Dystrophy Association–supported clinics is the best therapy for most children. Genetic counseling for families is indicated in most instances.

Prednisone or immunosuppressive agents such as azathioprine or methotrexate in appropriate doses, with the usual cautions regarding side effects, are also useful in inflammatory myopathies because these conditions are immunologically mediated disorders with an inflammatory component. Physical therapy is also helpful.

CEREBROVASCULAR ACCIDENT OR STROKE

Stroke in children affects about 3/100,000 children a year. This is as common as brain tumors in children. Children have brain infarctions more often than hemorrhages. Strokes can arise from arteries (infarction with arteriopathy, hemorrhage of an aneurysm or arteriovenous malformation [AVM], or vein cerebral venous thrombosis [CVT]).

Pathophysiology

Arterial ischemic strokes (AIS) are the most common strokes and more commonly involve the middle cerebral artery distribution. There is an arteriopathy on magnetic resonance angiography (MRA) in 10% to 40% of patients. There may be an association with infections such as varicella. There is an increased association with clotting abnormalities and congenital cardiac disease, but often there is no underlying risk factor. Trauma can also result in dissection. Hemorrhage can occur after a rupture of an arterial aneurysm or arterial venous malformation (AVM). In total, the most common cause of brain hemorrhage in the child and infant is trauma. CVT occurs with occlusion of a deep vein and results in venous infarction and hemorrhage.

History

For AIS, the history and examination is usually that of an acute onset of focal neurologic deficit or seizure. A family history for clotting abnormalities is important, and trauma and infection should be excluded by history. For brain hemorrhage, the onset is usually that of an acute headache, often without focal neurologic findings, but these may be present, along with seizures, at onset. A stiff neck may also be present secondary to blood clotting. As for CVT, this also typically presents with an acute onset of headache, but focal neurologic signs and seizure are common. A seizure is a more common presenting sign of a stroke in children compared to adults with a stroke.

Physical Examination

The physical examination must extensively evaluate the entire CNS. By determining which deficits are present, one can localize the lesion and better predict the cause.

Diagnostic Evaluation

Routine laboratory tests should be performed including a workup for bleeding disorders. In AIS, an MRI shows an acute infarct in an arterial distribution. Brain computed tomography (CT) will show a hemorrhage and a brain MRI is the best for all other strokes. Imaging of blood vessels can be accomplished by MRA, magnetic resonance venography, or CT angiogram. In the face of a hemorrhage that might be an aneurysm, emergency angiography is performed but often a CT angiogram can be obtained first to exclude an aneurysm.

Differential Diagnosis

An acute focal neurologic deficit in a child is most likely secondary to a migraine, is possibly secondary to a focal seizure, and is lastly secondary to a **cerebrovascular accident**.

Management

For AIS, an MRI with MRA and a cardiac evaluation and workup for systemic disease and clotting diathesis is indicated. Because there is an about 30% risk of second stroke (especially if there is evidence of arteriopathy), most neurologists place patients on aspirin. Some clinicians treat with heparin first for a period of time especially if there is a question of dissection.

For a hemorrhage, an emergency craniotomy and evacuation of the clot is indicated if the patient has impending herniation. For AVMs in which a patient is stable, serial vascular imaging ultimately with angiography is electively done with an aim at surgical or intervascular intervention. As for aneurysms, these should be

treated urgently with either surgery or intravascularly by an interventional radiologist, but AVMs are less likely to rebleed immediately after the first hemorrhage. In aneurysms, there is a 50% chance of rebleed and this often occurs within days of the first event. As such, aneurysmic hemorrhage is a neurologic emergency.

For CVT, a watchful waiting approach is all that is often needed, although there is more data arising suggesting that heparin treatment may ameliorate the disease course. Workup for clotting problems is indicated. There are now two clinical recommendations both advocating heparin acutely for CVT, but this is still controversial because of the risk of hemorrhage.

FEBRILE SEIZURES

Febrile seizures are the most common form of seizure, occurring in 2% to 5% of children in the United States. A febrile seizure is defined as a seizure occurring in childhood after 1 month of age associated with a febrile illness not caused by an infection of the CNS, without previous neonatal seizures or a previous unprovoked seizure, and not meeting the criteria for other acute symptomatic seizures. Febrile seizures occur in infants and children from 6 months to 5 years of age but peak at about 20 months of age.

There are two types of seizures:

- Simple febrile seizures which are generalized, last less than 15 minutes, and do not recur within 24 hours
- Complex febrile seizures which are prolonged, recur more than once in 24 hour, or are focal

Pathophysiology

Febrile seizures may occur sporadically or may be familial. Specific mutations in ion channels (e.g., SCN1A) cause channelopathies, which present in families as a predilection toward febrile and afebrile seizures. Animal studies have shown that an increase in temperature could enhance the rate, magnitude, or synchrony of neuronal firing, and thus epileptiform activity, leading to seizures.

Hyperthermia also induces hyperventilation and alkalosis, and this environment may lead to neuronal excitability, predisposing to seizures. In addition to the temperature increase, fever involves the release of cytokines, such as interleukin (IL)-1β, and other inflammatory mediators in the body and within the brain itself, which enhances neuronal excitability and the generation of febrile seizures. Although febrile seizures must not have a direct infectious cause, there is an association with the human herpes virus 6.

History

The type of seizure, whether generalized or focal, and its duration should be elicited. History and duration of fever and potential exposures to illness must be obtained. It is important to try and determine the cause of the fever. A history of seizures, neurologic problems, developmental delay, or other potential causes of seizure (e.g., trauma, ingestion) should be excluded. Family history of seizures, febrile or afebrile, is important as well.

Physical Examination

After termination of the seizure, serial evaluations of the patient's neurologic status including examination are essential. Acute neurologic conditions, which may precipitate seizures must be considered with assessment of the anterior fontanelle (in an infant) and assessment for meningismus (neck stiffness) to evaluate for meningitis. Funduscopy is necessary to exclude papilledema, which would be suggestive of increased intracranial pressure (ICP). Hints of paralysis or weakness on one side of the body, for example, may be present transiently (Todd paralysis), and may be found by noting differences in tone or strength between the right and left arms and legs. Similarly, differences in reflexes and toe (Babinski) responses may also suggest focality. Any such abnormalities are inconsistent with febrile seizure.

A careful physical examination often reveals a source for the fever such as an otitis media, pharyngitis, or exanthem. Once the child is stable, the clinician should note any dysmorphic features and plot the head circumference, as in every examination. It is essential to check the skin for evidence of a neurocutaneous disorder.

Diagnostic Evaluation

When attempting to ascertain the cause of the fever, a complete blood cell count, appropriate cultures, and a urinalysis are appropriate. **In young children with a first febrile seizure, lumbar puncture is only required if**

there is clinical suspicion of meningitis or encephalitis. In 1996, the American Academy of Pediatrics (AAP) recommended that a lumbar puncture be **strongly considered** in patients younger than 12 months presenting with fever and seizure. The AAP also recommended that a lumbar puncture **be considered** in patients ages 12 to 18 months. A lumber puncture is not routinely necessary in patients older than 18 months. But with recent studies showing that the risk of bacterial meningitis presenting as first simple febrile seizure at ages 6 to 18 months is very low, these recommendations may have to be revised. An electroencephalogram (EEG) usually is not necessary in the routine evaluation of a child with a first simple febrile seizure. Imaging studies are unnecessary following a simple febrile seizure, but if there is any evidence of focality or prolonged seizure, an MRI may be considered.

Differential Diagnosis

The single most important practical consideration in the differential diagnosis of febrile seizures is bacterial meningitis or any other forms of meningitis. Other neurologic infections such as encephalitis and epidural and subdural infections must also be considered.

Management

The first step in managing any seizure is to ensure proper **airway, breathing, and circulation**. Once stable, the next step is to safely terminate the seizure if it is not self-limited. Most seizures cease within 1 to 2 minutes, but some seizures may be prolonged and may require intervention. Acute treatment such as with rectal diazepam is effective and can be given at home for a seizure lasting longer than 5 minutes. Upon arrival to the emergency department, if a child is having a prolonged seizure that is not stopping spontaneously, intravenous lorazepam may be required. Careful observation for respiratory problems and the possible need for assisted ventilation are essential. The likelihood of the need for ventilatory assistance rises sharply in proportion to the duration of the seizure. If the seizure does not abort, then emergency management of status epilepticus must be initiated.

In addition, it is necessary to lower the body temperature and treat the acute infection that resulted in the temperature elevation, if possible. Reduction of body temperature generally involves evaporative cooling and administration of antipyretics in appropriate dose. Antibiotics to treat the source of the fever may be considered.

Any seizure can be a terribly frightening experience for a child's parents and family. When a child recovers quickly to baseline after a brief febrile seizure, parental reassurance is generally easy to provide; in these circumstances, the benign nature of the condition is clearly evident. Prophylactic use of antipyretics, sedatives, or anticonvulsants for febrile seizure has not been shown to be effective. The AAP guideline released in 2008 does not recommend prophylactic use of diazepam, as the risk outweighs the benefits.

Prognosis

In general, simple febrile seizures are benign, with little in the way of detrimental long-term effects on cognition, academic performance, behavior, and overall development. Children with febrile seizures and other risk factors have a slightly higher incidence of epilepsy compared with the general population (2% versus 1%), but it should be stressed to parents that this is still a very low likelihood of developing epilepsy. Risk factors for epilepsy later in life include complex febrile seizure, family history of epilepsy or neurologic abnormality, and developmental delay or impairment.

Pediatric Pearl: Febrile seizures are relatively benign. Long-term treatment is usually not required.

EPILEPSY

Epilepsy is a disorder characterized by the occurrence of at least two unprovoked seizures.

Pathophysiology

Seizures are paroxysmal manifestations of the electrical properties of the cerebral cortex. A seizure results when a sudden imbalance occurs between the excitatory and inhibitory forces within the network of cortical neurons in favor of a sudden-onset net excitation. Seizures or epilepsy may be of idiopathic/cryptogenic/genetic etiology,

wherein an external insult to the brain is not discerned. Identification of genes/chromosomes (e.g., Chr 20, Chr 6) and mutations causing channelopathies (e.g., SCN1A, KCN) have strengthened the understanding of the genetic basis of epilepsy. Alternatively, seizures may occur secondary to some acute or remote insult to the brain and is termed symptomatic epilepsy.

Classification

The clinical signs or symptoms of seizures depend on the location of the epileptic discharges in the cortex and the extent and pattern of the propagation of the epileptic discharge in the brain. In 1981, the International League Against Epilepsy (ILAE) developed an international classification of epileptic seizures that divides seizures into two major classes: partial-onset seizures and generalized-onset seizures. Generalized-onset seizures have an onset recorded simultaneously in both cerebral hemispheres, whereas partial-onset seizures begin in a focal area of the cerebral cortex. Some seizures are difficult to fit into a single class, and they are considered unclassified seizures.

Generalized-Onset Seizure Types

Generalized-onset seizures are classified into six categories: **(1) absence seizures, (2) myoclonic seizures, (3) clonic seizures, (4) tonic seizures, (5) primary generalized tonic–clonic seizures, and (6) atonic seizures** (Table 19-3).

Absence seizures are brief episodes of impaired consciousness with no aura or postictal confusion. They typically last less than 20 seconds and are accompanied by few or no automatisms. If there are automatisms, they are usually facial, and repetitive blinking is the most common facial automatism. Hyperventilation or photic stimulation often precipitates these seizures, which typically begin during childhood or adolescence. The classic EEG correlate of absence seizures consists of 3.5-Hz generalized spike-and-slow wave complexes. Absence seizures are common in several different epilepsy syndromes including, but not exclusive to, childhood absence epilepsy.

Myoclonic seizures are brief, arrhythmic, jerking, motor movements that last less than a second. Myoclonic seizures often cluster within a few minutes. Myoclonus is not always epileptic in origin.

Clonic seizures are rhythmic, jerking motor movements with or without impairment of consciousness. Primary generalized clonic seizures simultaneously involve the upper and lower extremities. The EEG correlate consists of generalized rhythmic epileptiform discharges. Clonic seizures that begin focally and secondarily generalize are not considered primary generalized seizures and will be discussed in the next section.

Tonic seizures are sudden-onset tonic extension or flexion of the head, trunk, and/or extremities for several seconds. The correlate of tonic seizures in the EEG includes an electrodecremental response. An electrodecremental response is a sudden generalized drop in amplitude of the EEG. This pattern may evolve into slow spike-and-wave complexes or diffuse polyspikes. Tonic–clonic seizures consist of several motor behaviors, including generalized tonic extension of the extremities lasting for few seconds followed by clonic rhythmic movements and prolonged postictal confusion. The EEG correlate of generalized tonic–clonic seizures consists of generalized complexes of spikes or polyspike and slow waves.

Atonic seizures consist of brief loss of postural tone, often resulting in falls and injuries. The EEG correlate is similar to abnormalities observed in tonic seizures.

Partial-Onset Seizures

Partial-onset seizures are classified as simple partial seizures and complex partial seizures. A simple partial seizure is a focal seizure with preserved consciousness. Simple partial seizures include sensory, motor, autonomic, and psychic types. Complex partial seizures cause impaired consciousness and arise from a single brain region. Impaired consciousness implies decreased responsiveness and awareness of self and surroundings. During a complex partial seizure, the patient may not communicate, respond to commands, or remember events that occurred. Consciousness may be diminished without complete impairment.

Epilepsy Syndromes

It is helpful to classify patients by a particular epilepsy syndrome as certain epilepsy syndromes have better prognoses than others. Syndromes may be age dependent such as benign neonatal convulsions, West syndrome, benign rolandic epilepsy, and juvenile myoclonic epilepsy. In addition, the etiology of the seizures can aid in classification as well as those caused by cerebral malformations, infections, metabolic disturbances, enzyme disturbances, and strokes. Many are genetically determined, and ongoing research is identifying new genes constantly. Several of the common pediatric epilepsy syndromes should be familiar to the practicing pediatrician.

TABLE 19-3

Childhood Epilepsies

Seizure Disorder	*Associated Characteristics*
Generalized tonic–clonic convulsions	Involve all extremities Tonic and clonic components Loss of consciousness Postictal phase common
Absence or petit mal seizures	Last a few seconds No aura Body movement unusual Child unaware of occurrence
Juvenile myoclonic epilepsy	Genetically determined Generalized seizures with myoclonic jerking in morning
Complex partial seizures	Blunted consciousness Aura Strange behavior and speech (chewing and lip-smacking)
Simple partial seizures	Localized motor or sensory symptoms No impairment of consciousness May become generalized
Infantile spasms	Brief sudden muscular contractions Begin at 3–9 months of age Associated with retardation

Benign rolandic epilepsy is usually associated with a good prognosis, is self-remitting, and no neurologic abnormality is noted. It usually occurs around ages 4 to 15, with a male predominance. The seizures typically occur out of sleep and may involve the mouth or speech. The EEG is typical with a pattern of centrotemporal sharp waves. **Juvenile myoclonic epilepsy** is an autosomal dominant generalized epilepsy syndrome with multiple types of seizures, including generalized tonic–clonic, absence, and myoclonic seizures, usually occurring upon awakening. This syndrome is responsive to anticonvulsants, but may require lifelong treatment.

Infantile myoclonic spasms consist of attacks, which frequently begin between 3 and 9 months of age; consist of one or more brief, sudden muscular contractions in which the head is flexed (head nodding), the arms are extended, and the legs drawn up; usually occur in clusters. Episodes are very brief and may be confused with colic or an exaggerated Moro response. Very often, parents do not recognize the attacks as abnormal or as seizures until they occur in large numbers and are accompanied by retarded development, an extremely common feature in infantile spasms. In most children, the EEG is abnormal, and consists of a disorganized background with high-voltage slow waves and multiple spike wave discharges, a pattern called hypsarrhythmia.

Lennox-Gastaut syndrome is an intractable epilepsy syndrome, associated with multiple seizure types, typically resistant to most anticonvulsant therapy and associated with global developmental impairment. Infantile spasms with hypsarrhythmia can progress to Lennox-Gastaut syndrome as the child matures.

History

One key feature of epileptic seizures is their often stereotypic nature. It is crucial to identify how the seizure began as this can assist in understanding whether the seizures are primarily generalized or are focal in onset. If there is focality, it is important to document the location of the convulsion. Sometimes an aura or warning can point to a focal onset. At times there will also be associated signs or symptoms that should be identified. One of the most important factors to determine is the approximate length of the seizure. The majority of seizures cease within 1 or 2 minutes. If the seizure lasts longer than that, there is a greater risk of future prolonged seizures as well, which may require medical attention. Objective measures of the duration of seizure is important. Comparing the mother's phone call record with the ambulance response sheet may be helpful. One must determine how

often the seizures are occurring and whether the pattern is becoming more frequent. Family history of seizures is always important as it may indicate a particular syndrome and is very helpful in prognosis. The child's medical history, including any past trauma or injury and possible medications used, should be documented.

Physical Examination

The clinical diagnosis of seizures is based on the history obtained from the patient and, most importantly, from the observers. Once the seizure has stopped and the child is stabilized, it is possible to perform a general examination, with special emphasis on assessing any features of focality. Postictal paralysis (Todd paralysis), although rare, can last for several hours or more. Deep tendon reflex asymmetry and frank hemiparesis may provide a clue to focality. The clinician should be sure to assess mental status and cranial nerve function, with particular emphasis on funduscopy and on asymmetries of extraocular and facial muscular function.

In addition, it is important to examine the skin carefully, looking for evidence of a neurocutaneous disorder (e.g., neurofibromatosis, tuberous sclerosis), which may be associated with seizures. Careful assessment for evidence of trauma should also occur, and if the history is suspicious, the clinician should consider the possibility of child abuse.

Diagnostic Evaluation

Routine blood studies are generally not helpful in establishing a particular metabolic cause for seizures in most children unless the history suggests one. The exception is in neonates with seizures in whom routine measurements of glucose, calcium, and electrolytes are suggested.

The EEG is often helpful in confirming the diagnosis, although it is not always required. The electrical activity of active nerve cells in the brain produces currents spreading through the head. These currents also reach the scalp surface, and resulting voltage differences on the scalp can be recorded as the EEG. A normal EEG in the interictal period does not exclude the diagnosis of a seizure disorder, as the routine EEG is brief and may miss epileptiform abnormalities. Repeating the EEG may provide a better yield. A routine EEG is a recording of less than 1 hour of brain activity. Activation procedures can be used to document an abnormality not seen in a routine study; activation procedures include sleep, sleep deprivation, photic stimulation at various frequencies, and hyperventilation. In specialized situations, the EEG may be recorded over a prolonged period of time (e.g., for several days, if necessary), often with simultaneous closed circuit TV (Video-EEG) monitoring of the patient. Video-EEG monitoring is also used to characterize the type of seizure and epileptic syndrome to optimize pharmacologic treatment and for presurgical workup.

Clinicians must always assess EEG recordings with the history and physical examination in mind; an EEG request should, therefore, include a clinical summary and list any anticonvulsants or other medications the child is taking because these may affect the tracing. The EEG can be very helpful in distinguishing partial from generalized seizures and in diagnosing seizures that begin focally and become generalized secondarily. In some instances, the pattern of EEG abnormality may raise the possibility of the presence of an underlying structural lesion. The EEG interpretation takes into account the level and type of sleep and the maturity of the brain.

Pediatric Pearl: A normal EEG does not exclude the possibility of the patient having experienced an epileptic seizure.

Neuroimaging studies, namely MRI or CT scanning, are indicated when the seizures are focal, the EEG interpretation suggests an underlying focality in the presence of abnormal neurologic findings on examination, or the seizures accompany a neurocutaneous disorder. Imaging studies are unlikely to be positive in children with primary generalized seizures.

Differential Diagnosis

Epileptic seizures can sometimes be mistaken for psychogenic or nonepileptic seizures. One of the most characteristic features of psychogenic seizures is the maintenance of consciousness during a generalized tonic or tonic–clonic attack and the usual lack of a postictal phase. Similarly, in psychogenic seizures, the EEG fails to show epileptic discharges during an attack. Other episodic disorders that can mimic seizures include breath-holding spells, syncope, night terrors, jitteriness, head banging, Sandifer syndrome, tics, panic attacks, and transient ischemic attacks (TIAs) (Table 19-4).

TABLE 19-4

Nonepileptic Paroxysmal Events (in Contrast to Epilepsy)

Psychogenic seizures	Consciousness not lost Normal EEG during attack No postictal behavior Frequently combative during attack Can occur in patients with seizures
Breath-holding spells	Mainly between 1 and 2 years of age Precipitating event before attack Breath holding after crying Pallor or cyanosis, then limpness
Syncope	Usually follows emotional episode May have orthostatic hypotension EEG is normal
Night terrors	Paroxysmal sleep disturbance EEG normal during attacks

EEG, electroencephalogram.

Management

The goal of treatment is to achieve a seizure-free status without adverse effects. However, many children have adverse effects, and some have seizures that are refractory to medical therapy. Monotherapy is important because it decreases the likelihood of adverse events and avoids drug interactions. Sometimes a rational polytherapy approach may need to be considered. Although it is commonly believed that one should push a single medication to toxicity before adding a second drug, recent studies have been challenging that assertion. The mainstay of therapy for people with recurrent unprovoked seizures is an anticonvulsant. If a patient has had more than one seizure, administration of an anticonvulsant is usually recommended. If the patient has only one seizure and no risk factors, the risk of recurrence often does not warrant immediate treatment. The risk of recurrence in the 2 years after a first unprovoked seizure is 15% to 70% depending on several factors, mainly an abnormal brain MRI, an abnormal sleep-deprived EEG, a partial-onset seizure, and family history. The type of seizure and the specific epileptic syndrome play a role in the selection of anticonvulsants, probably because of the different pathophysiologic mechanisms.

Anticonvulsants can be divided based on their mechanisms: blockers of repetitive activation of sodium channel (e.g., phenytoin, carbamazepine, oxcarbazepine, lamotrigine, topiramate); GABA-A receptor enhancers (e.g., phenobarbital, benzodiazepines); glutamate modulators (e.g., topiramate, lamotrigine, felbamate); T-calcium channel blockers (e.g., ethosuximide, valproate); N- and L-calcium channel blockers (e.g., lamotrigine, topiramate, zonisamide, valproate); H-current modulators (e.g., gabapentin, lamotrigine, pregabalin); blockers of unique binding sites (e.g., gabapentin, levetiracetam); and carbonic anhydrase inhibitors (e.g., topiramate, zonisamide). Many anticonvulsants have more than one mechanism of action and some are unknown.

Pediatric Pearl: In the treatment of epilepsy, the goal should be to use the lowest effective dose of the least toxic anticonvulsant for the briefest period of time.

Nonpharmacologic treatments

There are several nonpharacologic treatments that have been shown to be effective in treating epilepsy. The ketogenic diet has a role in helping children with severe epilepsy. This is a low-carbohydrate, high-fat diet. The classical (4:1 ratio) ketogenic diet, MCT (medium chain triglyceride) diet, and modified MCT diet are variations. Increased cerebral energetics supplied by the ketogenic diet may provide increased resistance to seizures; the ketogenic diet also elevates GABA levels locally. Complications of the diet include constipation, renal

stones, anorexia, hypercholesterolemia, and vitamin deficiencies. Some syndromes such as Leigh syndrome, Landau-Kleffner syndrome, Rett syndrome, and glucose transporter type I defect are typically treated with a ketogenic diet.

The vagal nerve stimulator (VNS) is a palliative device similar to a pacemaker with an efficacy similar to an antiepileptic drug. The lead is laid on left cervical vagus nerve, and the generator is implanted in the left upper chest; the patient has programmable pacemaker and magnet. Acute interruption of the seizure relies on activation of the inhibitory pathways; the chronic antiepileptic effect of VNS may be due to persistent changes to neurotransmitters or changes in cortical and subcortical synaptic activity. Side effects may include hoarseness, tingling, dyspnea, and throat pain.

For children with intractable focal epilepsy, surgery should be considered without delay. Surgeries may be palliative or curative. A common palliative surgery is anterior callosotomy. This surgery has been indicated for patients with intractable atonic seizures. Several curative surgeries are possible, including lobectomy and lesionectomy (of tumors and gliosis). Focal cortical resection, hemispherectomy, and multiple subpial transection are other surgical procedures considered in specific epilepsy patients.

Activity Limitations

The major problem for patients with seizures is the unpredictability of the next seizure. Seizure precautions should be discussed with patients and their caregivers. Safety must be balanced with the risk of seizures. Recommendations regarding driving motorized vehicles vary depending on state law. Patients with seizures should not swim alone, and these patients should be particularly aware of being in the presence of an adult lifeguard who is aware of their disorder and who is well trained to pull them out of the water if needed. Showers are recommended in favor to baths, as taking a bath possesses an added risk of drowning if not directly supervised. Patients who might have a seizure, for example, while waiting for the water to warm up, may incur hot-water burns.

Patients with seizures might experience a seizure during activities in the gym or during another activity at considerable height from the floor and caution is therefore advised. Contact sports are allowed, but sports such as American tackle football that may have considerable contact on the head should be discouraged. Certain video games and televised programs may provoke seizures, particularly in photosensitive epilepsy. It should be noted, that video games are only contraindicated in children with photosensitive epilepsy, which is rare. The following suggestions, adapted from ways of reducing the risk of seizures in photosensitive children while they watch television, may be helpful with regard to video games: Play in a well-lit room to reduce the contrast between the lighted screen and the surrounding area. Reducing the brightness of the screen may also be helpful; keep as far back from the screen as possible; use smaller screens in which it is more difficult to see the horizontal scan lines; avoid playing for long periods and take regular breaks; and look away from the screen every once in a while.

HEADACHE

Headaches in children are common. Furthermore, when children have psychosomatic complaints, the common regions they complain about are their heads and abdomens. The vast majority of headaches are benign, and many are related to systemic infection with fever, such as "flu" or a sore throat, especially a streptococcal pharyngitis. However, it is important to be able to differentiate between the common benign headache and the less frequent but potentially serious headache.

Pathophysiology

Headaches result from a variety of causes. The most common cause of headache in children is migraine. Migraines are defined as a headache, which is often familial, lasting form 0.5 hours to 5 days. Migraine headaches are often associated with phonophobia, photophobia, nausea, vomiting, dizziness, and vertigo. Chronic daily headaches are defined as headaches that persist for at least 15 days per month. Often these headaches were migraines that evolved into chronic daily headaches.

Some headaches are related to head trauma, either acutely or subacutely. Others may be due to disorders of other structures in the head, such as paranasal sinuses and the temporomandibular joint. Some headaches are purely psychogenic in origin, as those associated with depression, anxiety, or stress. Increased ICP may be caused by a brain tumor, intracranial hemorrhage, or infection, but may also be idiopathic. Increased ICP presents with headaches that are typically worse on lying down and may be associated with nocturnal headaches and vomiting. Infections such as meningitis, with or without increased pressure, can also result in headaches.

Pediatric Pearl: The most common cause of chronic headaches in young children is migraine.

Brain parenchyma is insensitive to pain. However, other intracranial structures such as the large arteries, the venous sinuses, and the dura at the base of the skull are sensitive to pain. Pain may result from various vascular changes and several abnormalities relating to the metabolism of serotonin and its metabolites. In migraines, serotonin metabolism is systemically abnormal both during and between attacks. Serotonin may lead to vasodilation or vasoconstriction of the intracranial vasculature; this forms the basis for some of the old and many of the new drugs used in patients with migraines because many of these drugs affect serotonin metabolism.

History

In most children with headaches, a good history yields the diagnosis without the need for unnecessary testing. Migraine headache, for example, is a diagnosis based on the history a description of the headaches in a child with a normal neurologic examination. The frequency of the headaches, the duration, dates of origin, character, frequency, and severity is necessary. Character and severity are subjective; occasionally, the examiner may obtain an assessment of severity by asking children to rate the severity on a scale of 1 to 10 or if the headache interferes with activities or necessitates absence from school or cessation of play. The examiner should ask about associated symptoms such as aura; is there a warning before a headache begins or do the parents perceive something different about a child's appearance or behavior? Other associated manifestations include photophobia; annoyance or being bothered by loud noises; visual abnormalities such as changes in visual perception; nausea, vomiting, or associated abdominal pain; or vertigo.

The history should include precipitating factors such as stress, poor sleep hygiene, and dehydration, as well as food triggers. Factors that improve symptoms in children include lying down and sleeping. If the headache worsens on lying down, increased ICP needs to be excluded. If the headache is aggravated on leaning forward, sinusitis should be suspected. A migraine headache is less likely to wake a child from sleep. Questions should include concurrent illness, fever, family history of headaches, and association with eating a particular type of food. Information concerning any prior self-medication attempts and the dosage and length of use of prescribed medications are important to obtain. Some children overuse analgesics such as aspirin, acetaminophen, or nonsteroidal anti-inflammatory drugs (NSAIDs), resulting in rebound headaches.

Physical Examination

Tests for meningismus, increased ICP, and associated illnesses, such as sinusitis, that might explain the headache are necessary. A careful funduscopic examination is important to check for papilledema, which may be a sign of increased ICP. Abnormalities in the extraocular movements, diplopia, and visual field testing are important, because abnormalities may be due to increased ICP as well. Dysmetria or ataxia may be signs of a cerebellar mass. Reassurance is an important modality of treatment in headaches.

Diagnostic Evaluation

In children with chronic or recurrent headaches, when good current and past histories are coupled with normal physical and neurologic examinations, a diagnosis is generally possible with no laboratory work. Here, an MRI is not necessary.

Pediatric Pearl: If focal neurologic findings, papilledema, or history consistent with increased ICP are present, a brain MRI is necessary. Most children with headaches do not need imaging.

The clinician should order other laboratory tests judiciously. For example, Lyme disease studies are done in the event of exposure or if a rash is present. If systemic findings suggestive of rheumatological disease are present, then an appropriate workup is indicated.

Differential Diagnosis

When a patient presents with headaches, it is important to determine whether this is a primary headache such as migraine or a secondary headache due to another cause. The most common causes of secondary headache are concurrent illness or minor head trauma. Other causes of secondary headache must be excluded. Brain tumors will usually develop other symptoms in addition to a headache.

Vascular malformations-induced headaches are an acute-onset headache and are typically severe. In **pseudotumor cerebri**, patients show papilledema on exam and the MRI is normal. If the MRI is normal, the LP will be normal and show increased ICP. Although mild-to-moderate levels of hypertension do not commonly cause headaches, **extreme hypertension** in the setting of renal disease may cause a hypertensive encephalopathy and headaches as a manifestation of posterior reversible encephalopathy syndrome (PRES). Rarely, metabolic disorders such as heterozygous **ornithine transcarbamylase deficiency** can present with headaches and abdominal discomfort as can mitochondrial disorders such as **mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS).**

As headaches are paroxysmal events, seizures may also present as episodic headaches. Finally, other rheumatologic and inflammatory disorders may present with headaches, and an appropriate use of a laboratory examination and a referral to an appropriate specialist may be helpful.

Management

For most migraines, determining the triggers and reassurance improves the headaches. Improving sleep and hydration are often important. Avoiding stressors if possible may be necessary as well. If a patient is overusing analgesic medications, discontinuation often improves symptoms. Changes in diet may also be helpful, but diet is not usually the primary trigger.

For children who have infrequent attacks of common migraines, the use of NSAIDs, taken when the headache begins, is a reasonable option if acetaminophen does not help. NSAIDs should be taken with food, which may be difficult when nausea or vomiting accompany a headache. In older children who experience infrequent attacks of migraines, drugs known as triptans have made an important addition to migraine therapy in older children. These are formulated for oral, intranasal, and subcutaneous administration in individuals free of cardiac disorders.

For children with debilitating and frequent migraine attacks, prophylaxis should be a topic of physician–child–family discussion. Several classes of drugs may be used for migraine prophylaxis, including β-blocking agents (e.g., propranolol [contraindicated in asthmatics]), antidepressant agents (e.g., amitriptyline), calcium channel blocking agents, topiramate, levetiracetam, and divalproex sodium. There are no class I or II data showing that these medications (e.g., amitriptyline and propranolol) work in children but there are some data that show they may be helpful. Other therapies include riboflavin, which may work in a subset of patients. If one of these drugs is successful over a substantial period of time, an attempt at lowering the dosage or stopping the medication should be considered because spontaneous remission may occur in children with chronic headaches. The long-term prognosis is generally favorable in childhood migraines.

AUTISM SPECTRUM DISORDERS

Autism spectrum disorders (ASDs) represent three of the pervasive developmental disorders defined in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV): autistic disorder, Asperger syndrome, and pervasive developmental disorder not otherwise specified (PDD-NOS). The three core features of ASDs are qualitative impairments in social interaction, qualitative impairments in verbal and/or nonverbal communication, and the presence of restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. Although unification of the three ASDs as one diagnosis is under consideration for the next edition of the DSM, we have found it practical to utilize "autistic disorder" when all features are present in full form, "Asperger syndrome" when social impairments and restricted and stereotyped behaviors are present but early language and cognitive development are normal, and "PDD-NOS" when symptoms are relatively mild or atypical. We are indebted throughout this section to Chris Plauché Johnson, Scott M. Myers, and the Council on Children with Disabilities for their guidelines published in *Pediatrics* (see Suggested Readings).

Clinical Manifestations

Social Deficits

Because there is no pathognomonic feature, but there is a wide heterogeneity of features in individual children, the diagnosis of ASDs may be challenging. One fairly reliable marker seems to be delayed or absent "joint attention." Joint attention refers to the enjoyment in sharing an object or event with another person. It is manifest in infancy as smiling in recognition of a parent's vocalizations, following parental gaze or pointing, and later, by initiating bids for attention and social interactions with multiple emotional expressions, sounds, words, and gestures. Children with ASDs may fail to orient to social stimuli, be less likely to develop age appropriate peer relationships than would be predicted for their age and language abilities, have few friends, and have difficulty understanding the perspective of others, known as lack of Theory of Mind skills.

Communication Deficits

Speech delay is an extremely common presentation for toddlers who ultimately receive the diagnosis of autistic disorder or PDD-NOS. It must be distinguished from deafness, global mental deficiency, and isolated language deficit. When language is present, it is often echolalic or scripted (e.g., from television programs or videos). Regression of language, often accompanied by regression of gestural communication and social skills, occurs in 25% to 30% of children with ASDs, usually between 15 and 24 months of age.

Restricted, Repetitive Behavior, Interests, and Activities

The play of children with ASDs often lacks creativity and may include spinning the wheels or lining up cars instead of "driving" them, arranging crayons in order instead of coloring with them, or choosing common objects (e.g., string, sticks, rocks, pens) over commercial toys. Children with ASDs may manifest compulsions, self-injurious behaviors (e.g., head banging, skin picking, eye poking, hand biting), and stereotypies (repetitive, nonfunctional, atypical behaviors such as hand flapping, finger movements, rocking, or twirling). Sometimes a topic of interest (e.g., dinosaurs) may be typical for any child but the degree of interest, the detailed knowledge, and the preoccupation to the exclusion of all else is exceptional (Johnson et al., 2007).

Associated Findings

Mental retardation occurs in approximately 70% of children with ASDs, and seizures occur in about 30%. "Splinter skills" and, more rarely, highly developed talents or "savant" skills may occur. Simultaneous hypo- and hypersensitivities may be present within the same sensory modality, for example, intolerance to certain environmental noises, but a lack of response to a human voice (Johnson et al., 2007). Many children are hyperactive and actually meet the criteria for comorbid attention deficit hyperactivity disorder (ADHD). Blindness, deafness, and long-tract signs are notably absent in almost all cases.

Pathophysiology

ASDs are considered to be highly heritable but without a single genetic cause. Indeed there may be hundreds of distinct causes, each likely to be significant in a small subset of patients—a multigenic model rather than the older polygenic model that postulates groups of synergistically acting genes to produce the phenotype. Recurrence risk in families with one older sibling with an idiopathic ASD ranges from 2% to 8%, and is higher when two children are already affected. Identifiable syndromes account for less than 10% of cases of ASDs. Among these, the most common, Fragile X syndrome, accounts for approximately 3% to 4% of cases, although the incidence of ASDs in Fragile X is as high as 30% to 50%. Other examples of neurogenetic syndromes associated with ASDs include neurocutaneous syndromes (tuberous sclerosis, neurofibromatosis), fetal alcohol syndrome, Angelman syndrome, and Down syndrome (Johnson et al., 2007). The prevalence of ASDs has grown strikingly in the last 20 years and is now estimated to approach 1%. How this increase relates to improved detection, reclassification, and the complex interaction of environmental and genetic factors is an area of intense study.

The coincidence of autistic regression with the toddler vaccine schedule has contributed to the controversial speculation that certain vaccines are causal in autism. A more compelling hypothesis is that regression is a hallmark of "mitochondrial autism," characterized biochemically by increased blood lactate and pyruvate levels, elevated plasma alanine level, and increased urinary levels of Krebs cycle intermediates or 3-methylglutaconate. Clinically, mitochondrial autism is more likely than idiopathic autism to be accompanied by hypotonia, significant gross motor delay and regressions that may be repeated or have late onset (after age 3 years), and include loss of motor skills. In this context, vaccinations may indeed precipitate apparent autistic symptoms in susceptible

children, although the contribution would not be specific to the vaccine but rather would resemble the inflammatory or catabolic stress of common childhood diseases that are known precipitants of mitochondrial regression

Autism is increasingly regarded as a disorder of connectivity, with evidence ranging from clinical and pathologic studies of affected humans to the synaptic level in experimental models. The clinical connectivity hypotheses is based on studies of high functioning patients with ASDs in which the acquisition of basic information is spared, but complex information processing and integration is impaired. It was thus proposed that local circuitry is preserved or overdeveloped, whereas connections within and between cortical systems (association cortex) are underdeveloped. Evidence in support of this hypothesis includes structural MRI demonstration of increased volume of the outer radiate white matter (consistent with the overgrowth of short range intrahemispheric corticocortical connections); increased number of minicolumns (radial cortical units) in gray matter on pathological examination; and the fMRI demonstration of diminished mirror neuron (pars opercularis of the inferior frontal gyrus) activity in response to observation or imitation of emotional facial expressions—as if the existing neural systems did not permit feelings to be connected to information. Children with ASDs were found to have deficient sensory encoding of pitch, as tested with passively evoked brainstem responses to speech syllables, suggesting that subcortical connectivity is also impaired, thus providing a candidate mechanism for deficient prosody.

Animal models are frequently used in the study of ASDs. For example, fragile X syndrome has a corresponding feature in knockout mouse which lacks the same critical protein as affected patients (FMRP) and has behavioral features of autism. In this mouse, the metabotropic glutamate receptor is upregulated, leading to long-term depression and the weakening of synaptic connections (Bear et al., 2004). Long-term potentiation (synaptic strengthening) is impaired in the dentate gyrus, a region that is crucial for the rapid formation of distinct representations of temporal and spatial relationships (Yun et al., 2009). Such information, gleaned from a known genetic cause of ASDs, is likely to be help elucidate the cellular basis of ASDs in general.

History

As of October 2007, the AAP recommends that all children be screened for autism at age 18 months and again at age 2 years, even in the absence of signs of developmental delay. An extensive body of screening tools is available for this purpose. The absolute indications for immediate evaluation as established by the Quality Standards Subcommittee of the American Academy of Neurology and the Child Neurology Society are as follows: No babbling, pointing, or other communication gestures by 12 months of age; no single words by age 16 months; no two-word spontaneous phrases by 24 months; and loss of language or social skills at any age.

Physical Examination

Evaluation of the child with suspected ASD should include a comprehensive medical and family history and a physical examination that includes a search for dysmorphic features and neurologic abnormalities. A developmental or neuropsychologic assessment to determine a child's level of functioning is crucial. The use of a standardized diagnostic tool (e.g., the Autism Diagnostic Observation Schedule [ADOS], Lord et al.) is highly desirable, particularly when the diagnosis is subtle or in question. Laboratory testing is controversial and probably more likely to yield a specific etiology if global developmental delay or intellectual disability is present. Referral to neurologists, developmental pediatricians, and geneticists may be helpful to direct the extent of evaluation in individual patients; diagnosis may be important for counseling purposes if not necessarily for treatment.

Diagnostic Evaluation

Because the ASD spectrum is so broad clinically, it is difficult to prescribe a universal diagnostic evaluation. That said, it is clear that all children with language delay or impairment should undergo hearing testing. Most neurologists will order a fragile X DNA analysis, particularly if the child has any of the physical stigmata of this syndrome because that is the single gene abnormality most commonly associated with ASD. Localizing signs on neurologic examination are rare and should always prompt brain imaging studies. Electroencephalography may be helpful if there is clinical suspicion of seizures or if there is language regression. More complicated regressions (e.g., later onset, motoric involvement) should prompt an evaluation for metabolic disorders/mitochondrial autism. The threshold should be low for referral to a geneticist, particularly if more than one child in a family is affected. There are a number of international databases (such as the IAN project) that accept both clinician and patient members and are involved in ongoing genetic as well as clinical diagnostic and research programs. In general, the more global the impairment, the higher the yield of diagnostic studies.

Differential Diagnosis

In our experience, the most difficult differential diagnosis occurs when trying to distinguish a toddler with an isolated language delay from one with an ASD. This often requires the use of a standardized tool such as the ADOS. The distinction is important both prognostically and therapeutically. Many features characteristic of ASDs may be seen transiently during normal development. These include echolalia, and, at times, stereotypies such as hand flapping when excited. It is important to keep in mind that ASD or ASD-like symptoms may form part of known genetic syndromes (e.g., Down syndrome, neurocutaneous syndromes, Angelman syndrome) that should be considered when hallmark stigmata are present.

Management

Educational and play-based interventions remain the cornerstone of treatment for children with ASDs. Intervention should be introduced even in the absence of a firm diagnosis whenever the diagnosis is seriously considered. Applied behavior analysis is one well-studied approach that relies largely on discrete trial learning to improve attention, compliance, imitation, and discrimination learning. Functional behavioral analysis is a systematic means of identifying and eliminating those settings and behaviors that impede learning while encouraging desirable and adaptive behaviors. Several reports have documented progress in children who have received Treatment and Education of Autistic and Related Communications Handicapped Children (TEACCH) services ("structured teaching") which emphasizes organization of the physical environment, predictable sequences of activities, visual schedules, and other approaches designed to both improve the skills of patients with ASDs and modify the environment to accommodate their deficits. Speech and language therapy, including augmentative and alternative communication modalities as warranted, is critical. Social skills instruction and occupational therapy may be desirable depending on the needs of the child and the focus of the therapy.

There is no specific medication management for ASDs. However, symptomatic treatment is often indicated. It is important to remember that medical factors such as otitis, pharyngitis, sinusitis, dental abscess, constipation, urinary tract infection, fracture, headache, gastritis, and rhinitis may all exacerbate so called challenging behaviors, and might, if properly diagnosed and treated, eliminate the quest for a symptomatic pharmacologic agent. Because of the high prevalence of epilepsy in this population, EEGs should be obtained with low clinical thresholds and antiepilepsy treatment should be initiated as appropriate. Sleep disturbance is common and sometimes responds dramatically to melatonin. Other agents that are used to improve sleep in children with ASDs include antihistamines, α_2-agonists, benzodiazepines, chloral hydrate, trazaodone, and the newer nonbenzodizepine hypnotics such as zolpidem and zalepon. Symptomatic treatment is also indicated for maladaptive behaviors such as aggression, self-injury, obsessions and compulsions, irritability, inattention, hyperactivity, and irritability. Rational polypharmacy is often the regimen of choice, with stimulants or atomoxetine used to address inattentive and hyperactive behavior, and selective serotonin reuptake inhibitors, atypical neuroleptics, and α_2-adrenergic antihypertensives most commonly used to treat repetitive or aggressive behaviors or irritability. The use of complementary and alternative medicines is beyond the scope of this chapter, but parents should be questioned about their use because it is so common and should be informed that the National Institutes of Health maintains a National Center for Complementary and Alternative Medicine that may be accessed at http://nccam.nih.gov/.

BRAIN TUMORS

Approximately 20% of all malignancies in childhood are brain tumors. About two-thirds of these brain tumors are infratentorial (below the dural partition that separates the cerebrum from the cerebellum); the remainder are supratentorial. The most common tumors derive from astrocytic elements.

Pathophysiology

Any intracranial mass, including a brain tumor, results in compression of the parenchyma and may result in obstruction of the normal CSF pathways, causing ventricular dilation. Because of very limited compressibility, ICP rises, with further compression on draining venous sinuses. In addition, the tumor itself may cause focal abnormalities related to the tumor location. For example, infiltrative tumors in the brainstem will produce cranial nerve abnormalities by local encroachment on their nuclei.

History

Because brain tumors may lead to increased ICP, questions should primarily elicit information regarding symptoms associated with increased pressure, which include vomiting, positional headache, and visual dysfunction. Vomiting is a very common feature in the presence of increased pressure, and nausea may also be present. Both nausea and vomiting are most prominent in the morning or at night. Headache, which is more pronounced in the morning, is virtually a constant accompanying feature in children with increased ICP. Of note, some migraineurs have morning headaches. The distinction arises in that migraineurs improve with sleep, but patients with brain tumors improve by arising and walking around. It is important to ask about headache duration. When increased ICP is initially present, headaches may last for just a short time in the morning, and children may be better the rest of the day. As the pressure increases with time, the headaches may become more severe and of longer duration. The examiner should direct questions to elicit a history of diplopia (double vision), which may result from involvement of the cranial nerves, most commonly of the sixth (or abducens) nerve. At times, children may compensate and develop a head tilt. However, it should be emphasized that papilledema resulting from increased ICP produces no visual symptoms early on.

Personality changes, drowsiness, irritability, or changes in level of consciousness may occur, any or all of which may be associated with increased ICP or lesions encroaching on the brainstem and other regions of the brain such as the hypothalamus. Other questions should include those designed to obtain information about problems with motor dysfunction such as gait disturbances, loss of balance, or loss of normal function of the hands.

Physical Examination

It is important to check the skin for evidence of a neurocutaneous disorder. For example, if numerous café au lait spots or axillary freckles are present, the observer should consider **neurofibromatosis type 1–related tumors**. The presence of irregular depigmented areas on the skin should prompt the examiner to consider **tuberous sclerosis–related intracranial lesions**.

Detailed assessment of mental status is necessary because somnolence and irritability may accompany increased ICP. Checking for papilledema is an integral part of the assessment. In papilledema, the disk margins are blurred or obliterated, and the loss of spontaneous venous pulsations is present. The veins may be tortuous, and frank hemorrhages may be seen in the retina.

Examination of the motor system is also important. Gait abnormalities, for example, may provide clues to the localization of a tumor. Ataxia, which is assessed by asking children to walk in tandem forward and backward, is observed in infratentorial tumors. Unilateral weakness, evaluated by watching for drift of the outstretched arms, limping, or strength asymmetries and checked either functionally by observation or with manual muscle testing, may provide a clue to hemispheric or long tract involvement. Similarly, asymmetries in tone or deep tendon reflexes, presence of dysmetria (past-pointing), presence or absence of extensor plantar responses, and sensory abnormalities may provide clues to the localization of a tumor.

Diagnostic Evaluation

In children with suspected brain tumors, an MRI can be used to visualize the lesion. Contrast enhancement is important to assess tumor size as well as the potential for malignancy. Other MRI techniques may also be helpful such as MR spectroscopy, which sometimes shows elevated choline peaks in a fast growing malignancy.

Differential Diagnosis

Not all children with increased ICP have underlying brain tumors. For example, brain abscesses may occur in young children, especially in those with cyanotic congenital heart disease; an MRI can be used to substantiate the diagnoses. In pseudotumor cerebri or so-called benign increases in ICP, neuroimaging studies are normal and document the absence of a structural lesion. Hydrocephalus may also lead to increased ICP, although hydrocephalus without a tumor usually is not associated with papilledema.

If the history, physical examination, and laboratory evaluation indicates a probable brain tumor, several types are possible. Three of the common brain tumors in children—**medulloblastomas, astrocytomas, and ependymomas**—often arise in or near the cerebellum. Although these tumors arise from different structures, their clinical manifestations may be similar. In all tumors involving the cerebellum, the ventricular system may

become obstructed, leading to increasing ICP. Vomiting, headache, and unsteadiness of gait (ataxia) are the most common manifestations and are generally present for several weeks before the diagnosis is established. Unsteadiness of gait results in children holding their feet far apart in an attempt to steady themselves while walking. They may fall and use objects or the wall for support. Hemispheric cerebellar lesions such as **astrocytomas** may also lead to dysmetria. An MRI generally substantiates the diagnosis. **Medulloblastoma** is typically seen in the midline cerebellum and results in trunkal ataxia, whereas the **ependymomas** are most commonly found within the fourth ventricle resulting in hydrocephalus without abnormalities in neurologic examination.

Tumors of the brainstem are usually malignant not only because of their biology but also because of their location. These tumors arise most commonly from the pons (pontine glioma) and result in gross enlargement of the brainstem, commonly caused by infiltration. Some tumors in this area result in signs and symptoms caused by torsion or pressure on the brainstem.

In brainstem tumors (most are astrocytomas), cranial nerve palsies are very common. In early stages, signs and symptoms of increased ICP may be absent. Facial muscle weakness, strabismus, and swallowing difficulties may be accompanied by gait disturbances, vomiting, or gradual onset of hemiparesis. Children may have a head tilt and evidence of extensor plantar responses. Involvement of one or more cranial nerves, especially when findings suggest long tract (corticospinal) involvement, should prompt the examiner to localize the lesion to the brainstem. The progression of symptoms and signs is often relentless, and children may experience involvement of several cranial nerves, increasing paralysis, and impaired consciousness.

The most common midline tumor is the **craniopharyngioma**. Other midline tumors include optic nerve gliomas and pineal region tumors. Craniopharyngiomas are generally slow-growing tumors located in the suprasellar region; if they expand forward, they can press against the optic chiasm. With further expansion to other regions, they may compress the pituitary gland and the third ventricle. Because of the proximity to the optic chiasm, impaired vision or defects in the peripheral fields of vision such as unilateral or bitemporal field cuts are common. Routine school examination may lead to the discovery of diminished vision, frequently in one eye, in otherwise apparently asymptomatic children. Other signs and symptoms include growth failure, endocrine abnormalities, and, later on, obstructive hydrocephalus as the tumor grows backward and obstructs the ventricle.

Optic nerve gliomas are one of the most common intracranial tumors in neurofibromatosis type 1. Diminished vision in one eye (of which children may not be aware) is the most common finding; other findings are exophthalmos, strabismus, nystagmus, and optic atrophy. A clinician who may suspect a tumor in a child with cutaneous signs of neurofibromatosis type 1 can readily make the diagnosis with neuroimaging studies.

Hemispheric tumors account for approximately one-third of brain tumors in children. These are mostly astrocytomas and oligodendrogliomas. Many are benign but some are malignant. Because of their location in the cerebral hemispheres, seizures, either generalized or with a focal component, are a common presenting feature.

Management

Treatment of brain tumors in children, which depends on the biology and location of the particular tumor, usually involves a multidisciplinary team approach. In some tumors (e.g., unilateral confined optic glioma), careful observation and follow-up may be prudent. For most, surgery is indicated. In the event of a malignancy, concurrent radiation and/or chemotherapy is sometimes indicated. For most tumors, clinical trials are available at many centers. See Suggested Readings for a further discussion of treatment effects.

NEPHROLOGY

Hridya Suman, Frederick J. Kaskel, and Juan C. Kupferman

EVALUATION OF KIDNEY FUNCTION

By convention, kidney function is usually interpreted as the degree of glomerular filtration. However, the kidneys have many other functions that may be assessed by both laboratory and imaging studies (Table 20-1).

Assessment of Renal Status and Evaluation of Parenchymal Damage

The first study in the evaluation of children with suspected renal disease is complete **urinalysis,** which yields information about the overall function of the urinary tract. The presence of **proteinuria** may be indicative of renal parenchymal damage. **Hematuria,** either macroscopic or microscopic, is an important manifestation of renal disease, although other urinary tract and systemic entities may present with hematuria. Furthermore, a urine dipstick that is positive for blood may reflect the presence of not only red blood cells (RBCs) but also hemoglobin and myoglobin. Analysis of the urine sediment confirms the presence of RBCs (hematuria) or white blood cells (WBCs), different types of casts, crystals, and bacterias (see hematuria).

Assessment of Glomerular Filtration

The **glomerular filtration rate** (GFR) provides a broad reflection of the functioning nephron mass. In common clinical practice, GFR can be evaluated by measuring serum creatinine (SCr), blood urea nitrogen (BUN), and creatinine clearance, or by performing a renal radionuclide scan.

Serum Creatinine

Creatinine is synthesized predominantly in the skeletal muscle and is excreted exclusively through the kidneys. In general, the rate of creatinine synthesis remains constant, and its serum concentration reflects the rate of renal elimination. Therefore, **an elevated SCr concentration denotes a diminished renal clearance of creatinine and a decline in GFR.** It is important to remember that **SCr is lower in children** than in adults. After the first days of life (with SCr higher, close to maternal levels), the normal SCr in infants is about 0.3 to 0.4 mg/ dL and increases slowly up to 0.9 to 1.0 mg/dL in adolescents.

Blood Urea Nitrogen

BUN is the final product in the metabolism of proteins and is excreted by the kidneys. Urea is freely filtered by the glomerulus, but is also reabsorbed in the renal tubules, **making the BUN a less reliable indicator of the GFR.** Furthermore, extrarenal factors may increase (e.g., gastrointestinal [GI] bleeding, dehydration, increased protein intake, or catabolism) or decrease (e.g., decreased protein intake, malnutrition, liver disease) the concentration of BUN, independent of renal function.

Creatinine Clearance

Creatinine clearance is a relatively accurate test to assess GFR in pediatric patients. One disadvantage of this method is the need for a 24-hour urine collection, which may be difficult to obtain in young children. The following formula is used:

$$\text{CCr (mL/min/1.73m}^2\text{)} = \frac{\text{UCr(mg/dl)} \times \text{UV(mL/day)} \times 1.73(\text{m}^2)}{\text{SCr(mg/dL)} \times 1440\ (\text{min}) \times \text{BSA}\ (\text{m}^2)}$$

TABLE 20-1

Laboratory and Imaging Studies Used to Evaluate Renal Status

Laboratory Studies

Blood

- Serum sodium, potassium, chloride, bicarbonate, pH, PCO_2, anion gap
- SCr, BUN, CCr (Schwartz formula for estimation of CCr)
- Calcium, phosphorus, alkaline phosphatase, magnesium, uric acid
- Hematocrit/hemoglobin, reticulocyte count, iron studies
- Hormone or enzyme serum levels: renin, aldosterone, vasopressin, parathyroid hormone, erythropoietin, vitamin D_3

Urine

- Urinalysis: specific gravity, pH, dipstick, protein, blood, urine sediment
- Urine electrolytes, fractional excretion of electrolytes, urinary anion gap
- Urine osmolality
- Calcium:creatinine ratio, protein:creatinine ratio
- Microalbuminuria
- Urine culture

Kidney

- Renal biopsy: histology, immunofluorescence, electron microscopy

Imaging Studies

- Renal and bladder ultrasound
- Doppler ultrasound
- Radionuclide renal scan
- VCUG, nuclear cystogram
- Intravenous pyelogram
- Computed tomography
- MRI, magnetic resonance arteriography
- Arteriography

BUN, blood urea nitrogen; *CCr*, creatinine clearance; *MRI*, magnetic resonance imaging; *SCr*, serum creatinine; *VCUG*, contrast voiding cystourethrogram.

where CCr equals creatinine clearance, UCr equals urine creatinine concentration, UV equals urine volume, 1440 is the time of collection in minutes (24 hours), and BSA is the patient's body surface area. It is important to note that creatinine clearance is expressed in relation to BSA and that the normal range has been standardized to a BSA of 1.73 m^2. GFR is low at birth (20 mL/min/1.73 m^2), increases to 60 mL/min/1.73 m^2 by the first month of life, and reaches normal adult levels by the second year of life.

CASE 20-1

A 4-year-old boy has a SCr of 0.5 mg/dL, a UCr of 30 mg/dL, a UV of 1000 mL/day, and a BSA of 0.7 m^2. By using the formula for creatinine clearance, his GFR (by creatinine clearance) is:

$$\frac{30\ (\text{mg/dL}) \times 1{,}000\ \text{mL} \times 1.73\text{m}^2}{0.5\ (\text{mg/dL}) \times 1{,}440\ \text{min} \times 0.7\text{m}^2} = 103\ \text{mL/min/1.73m}^2$$

The adequacy of the 24-hour collection can be determined by total creatinine content. An adequate 24-hour urine collection should have at least a total creatinine content of 15 mg/kg in a female or 20 mg/kg in a male.

Schwartz Formula

It is easier to estimate the GFR using a mathematical (Schwartz) formula without the need of a 24-hour urine collection. It requires only the patientís height and SCr, as follows:

$$\text{GFR} = \frac{\text{k} \times \text{height (cm)}}{\text{SCr(mg/dL)}}$$

where k (constant) equals 0.33 for low birth weight infants, 0.45 for term average for gestational age (AGA) infants, 0.55 in children and adolescent females, and 0.7 in adolescent males. The result is expressed directly for 1.73 m^2 of BSA.

CASE 20-2

A 5-year-old boy has a height of 110 cm and a SCr of 0.5 mg/dL. By using the Schwartz formula, his estimated GFR is:

$$\frac{0.55 \times 110}{0.5} = 121 \text{ mL/min/1.73m}^2$$

Modified Schwartz Formula

The Schwartz formula overestimates the GFR when compared to the plasma clearance of iohexol, which is currently used as the standard method in studies. Hence, modifications to the Schwartz formula have been devised, based on height, SCr, cystatin C, BUN, and gender through the Chronic Kidney Disease in Children cohort. The other tests used for renal function include the Cockcroft-Gault and modification of diet in renal disease formulas that are SCr-based equations, and the Cystatin C formula, based on Cystatin C, which is a small protein expressed throughout the body, freely filtered, and completely reabsorbed and catabolized by tubular cells. It is useful in detecting changes in GFR between 60 and 90 mL/min/1.73 m^2.

Radionuclide Scan

In specific situations, it is necessary to evaluate each kidney GFR separately by radionuclide studies. Quantitative estimation of the GFR during renal imaging studies is used for assessing renal function. Technetium-99m–labeled diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) or 51-chromium-EDTA (Cr-EDTA) clearance, may be used to measure GFR (see Assessment of Renal Structure).

Functional MRI

Functional magnetic resonance imaging (fMRI) techniques have been developed over the last few years for the evaluation of perfusion, renal excretory function, and intrarenal oxygenation using MRI. Renal perfusion, redistribution of intrarenal blood flow and GFR estimation have been studied using contrast agents such as gadolinium. Blood oxygenation level-dependent MRIs have been used to study renal ischemic injury and hypertension. These techniques are still evolving and require further studies.

Assessment of Renal Concentration and Dilution Capacity

The **renal concentration capacity** is commonly assessed by measuring the urine **specific gravity** and the urine **osmolality**. Urine specific gravity reflects the ratio between the weight of an amount of urine and the weight of the same amount of distilled water. Because the weight of urine is determined by the number of solutes dissolved, specific gravity indirectly reflects the urine concentration of the solutes. However, specific gravity has limitations; any solute in the urine (e.g., protein, glucose) may increase the urine weight and, therefore, be reflected in the specific gravity evaluation. The urine specific gravity may vary between 1.000 and 1.030, depending on the hydration status. **Urine osmolality is a more accurate method of assessing the renal concentration capacity** because it measures the number of osmotically active solutes present in a solution. If a renal concentration defect is suspected, a water deprivation test may be necessary for confirmation and for diagnosing either a renal or an extrarenal cause.

Assessment of Renal Acidification

To evaluate a renal acidification defect, the excretion of NH_4^+ should be assessed by the **urine net charge (or urinary anion gap)** (see Renal Tubular Acidosis). The appropriate renal response in metabolic acidosis should

be the excretion of an acid urine. The **urine pH** is another tool to assess the renal acidification process. If the urine pH is high in a child with acidosis, it suggests a renal acidification defect. A complete evaluation may include other studies, such as fractional excretion of bicarbonate ($\mathbf{HCO_3^-}$) and urinary PCO_2.

Assessment of Renal Handling of Electrolytes

The kidneys are important regulators of fluid and electrolyte balance, although other factors, such as hormones (e.g., antidiuretic hormone, aldosterone, parathyroid hormone, vitamin D3, insulin) also participate in the complex regulation of sodium, potassium, chloride, bicarbonate, calcium, phosphorus, and magnesium. The serum electrolytes may reflect the consequence of the interaction between extrarenal and renal factors. It is important to note that **the level of a particular electrolyte does not necessarily reflect the content of that electrolyte in the body.**

Urine electrolytes may be measured in a 24-hour urine collection or in a random urine sample. The fractional excretion of an electrolyte expresses the amount excreted related to the amount filtered, as a percentage. The **fractional excretion of sodium** (FE_{Na}), a useful parameter in the evaluation of oliguria, can help differentiate between prerenal and renal causes of acute renal failure (ARF). The FE_{Na} is calculated as follows:

$$FE_{Na} = \frac{\text{Urine Na (mEq/L)} / \text{Serum Na (mEq/L)}}{\text{Urine Cr (mg/dL)} / \text{Serum Cr (mg/dL)}} \times 100$$

In prerenal oliguria, the FE_{Na} is less than 1%. In acute tubular necrosis, the FE_{Na} is greater than 2%.

CASE 20-3

A 1-year-old girl presents with decreased urine output. She has a history of vomiting and diarrhea. Serum Na is 136 mEq/L, SCr is 1.0 mg/dL, urine Na is 6 mEq/L, and urine Cr is 20 mg/dL. Her FE_{Na} is $6/136 \div 20/1.0 \times 100 = 0.22\%$, consistent with a prerenal cause of oliguria (dehydration secondary to vomiting and diarrhea).

Assessment of Hormone Production

The kidneys also have important endocrine functions. Many different substances are produced or metabolized by the kidney. **Erythropoietin** production is impaired in children with renal failure, leading to chronic anemia. **Vitamin D3** (1,25-dihydroxycholecalciferol) is also decreased in renal failure secondary to a decrease in the 1-hydroxylation of 25-hydroxyvitamin D3, which normally occurs in the kidneys. **Renin** is produced by the kidneys and is elevated in some forms of hypertension. The plasma renin activity level can be measured during the evaluation of hypertensive disease. The kidneys are also the target organs for substances produced elsewhere in the body (e.g., **aldosterone** and **antidiuretic hormone),** which may be measured in plasma.

Assessment of Renal Structure

Urinary tract (kidneys and bladder) ultrasonography is usually the first imaging study in the evaluation of a child with possible kidney disease. It provides excellent information about renal size, parenchymal texture, size of the collecting system, and anatomy of the bladder. It allows for the detection of hydronephrosis, cysts, calculi, duplicated kidneys, and ureterocele, although it cannot detect vesicoureteral reflux (VUR) and does not provide any information about renal function. Doppler ultrasonography is used to assess blood velocity in the renal vessels to provide information about the patency and flow, to calculate resistive indices (RI), and to detect significant arterial stenosis. It is limited in sensitivity and by the position of the vessels and hence is used as a screening tool.

A contrast **voiding cystourethrogram** (VCUG) is a fluoroscopic study in which the contrast media is injected into the bladder via an indwelling catheter. Appearance of the dye above the level of the bladder indicates the presence of VUR. VCUG may not only confirm the presence of VUR but may also give information about bladder and urethral anatomy, including the presence of posterior urethral valves in males.

Radionuclide renal imaging is useful for assessing the glomerular filtration and the relative contribution of each kidney to overall renal function, and for evaluating urinary obstruction. Radionuclide renal imaging is also used for evaluating renal parenchyma and VUR. ^{99m}Tc-DTPA is one of the agents most frequently used because

it is excreted only by glomerular filtration. Technetium 99m–labeled mercaptoacetyltriglycine (^{99m}Tc-MAG-3) is another commonly used agent. Differential kidney function measurements are useful when renal function is asymmetric, such as in unilateral renal hypoplasia, scarring, or renal vascular lesions. Technetium 99m–labeled dimercaptosuccinic acid, which binds to cortical tubular cells, is the agent of choice for the evaluation of renal scarring and acute inflammation. Radionuclide voiding cystography (RVC) involves introducing a technetium 99m–labeled radiopharmaceutical in the bladder through a urethral catheter and filling the bladder to capacity with sterile normal saline. A gamma camera behind the patient provides continuous computer recording of bladder filling and voiding to detect VUR. Advantages of RVC are a lower radiation dose than with VCUG and continuous monitoring for reflux during the study. The major disadvantage of RVC is that it provides less anatomic information than VCUG. RVC does not provide any anatomic evaluation of the urethra, which is necessary to exclude posterior urethral valves in males. It is used in follow-up studies for VUR.

The **intravenous pyelogram** was previously used to evaluate the anatomy of the kidney and collecting system, but has now been replaced by less invasive and safer studies. Computed tomography (CT), magnetic resonance imaging (MRI), or angiography may be used in such cases.

Assessment of Renal Histology

A renal biopsy is sometimes necessary to establish a specific diagnosis in children with renal disease. It is a safe procedure, which can be done either percutaneously or by open surgery. The percutaneous technique is the most commonly used and can be guided by ultrasound or CT. The sample is evaluated by histologic and immunologic staining methods and by electron microscopy.

PROTEINURIA AND NEPHROTIC SYNDROME

The occurrence of **proteinuria** in a single urine specimen in children and adolescents is relatively common. About 5% to 15% of children have a random urine specimen showing proteinuria by urine dipstick. However, proteinuria may indicate the presence of renal injury, progression of renal disease, and is an independent risk factor for cardiovascular disease.

The **nephrotic syndrome** is characterized by massive proteinuria, hypoalbuminemia, edema, and hyperlipidemia; the most common presenting symptom is edema. The primary renal abnormality is an increased glomerular permeability due to alterations in the glomerular filtration barrier; that is, the fenestrated endothelium, glomerular basement membrane, podocytes, and slit diaphragm. Mutations of the slit diaphragm or podocytes have been discovered in several forms of congenital nephrotic syndrome (Table 20-2). An immunologically mediated decrease in the anionic charge on the glomerular filtration barrier also results in proteinuria. The urinary protein loss generally exceeds 40 mg/h/m^2 and is composed primarily of albumin (albuminuria).

TABLE 20-2

Genetic Forms of Nephrotic Syndrome

Gene/Protein	*Location*	*Phenotype*	*Inheritance*
NPHS/nephrin	Slit diaphragm	CNF	AR
NPHS2/podocin	Slit diaphragm	FSGS	AR
CD2AP/CD2AP	Near slit diaphragm	FSGS	
TRPC6/TRPC6	Podocyte	FSGS	AD
WT1	Podocyte	FSGS	AR
ACTIN4	Foot process	FSGS	AD
$tRNA^{Leu}$	Podocyte	FSGS	
COQ2	Podocyte	FSGS	

AD, autosomal dominant; *AR*, autosomal recessive; *CNF*, congenital nephrotic syndrome.

Pathophysiology

The normal rate of protein excretion in the urine is less than 4 mg/m^2/h throughout childhood. Approximately 50% of this small amount of protein consists of Tamm-Horsfall protein, a glycoprotein secreted by the renal tubules. Another 50% are plasma proteins filtered by the glomeruli, including albumin, β_2-microglobulin, and transferrin. Albumin comprises less than 30% of the total urinary protein excretion in normal individuals. The modest proteinuria that is normally present is usually not detected on routine dipstick testing. The low excretion rate of protein occurs because large serum proteins (e.g., albumin, immunoglobulins) are not filtered by the glomeruli and because the proximal tubules reabsorb most of the filtered low-molecular-weight proteins (e.g., insulin, β_2-microglobulin). Excess urinary protein losses may be caused by increased permeability of the glomeruli to the passage of proteins (glomerular proteinuria) or by decreased reabsorption of low-molecular-weight proteins by the renal tubules (tubular proteinuria).

Increasing levels of proteinuria are known to be predictors of progressive renal damage in children with proteinuric renal disease. Persistent proteinuria seems to be both a marker of renal disease and a cause of progressive renal injury. Severe persistent proteinuria is a long-term risk factor for atherosclerosis in children. It is associated with a variety of metabolic disturbances that contribute to cardiovascular disease, including hypercholesterolemia, hypertriglyceridemia, and hypercoagulability.

Clinical edema usually appears when the serum albumin level falls below 2.5 g/dL. The current understanding for the mechanisms for the development of edema include an intrinsic renal abnormality leading to increased renal tubular reabsorption of sodium and water. Transudation of fluid from the intravascular space into the interstitium secondary to hypoalbuminemia, decreased oncotic pressure, and activation of the renin-angiotensin-aldosterone system leading to salt and water retention has not been fully borne out by studies. Hyperlipidemia is secondary to both an increase in lipoprotein synthesis by the liver due to low albumin and oncotic pressure, and a decrease in lipid catabolism resulting from reduced activity of the enzyme lipoprotein lipase and lecithin cholesterol acetyltransferase. Hepatic uptake of low-density lipoprotein also decreases.

Clinical and Laboratory Evaluation

Children with nephrotic syndrome may present with a history of mild puffiness around the eyes, especially in the morning. This sign is often confused with manifestations of allergy. The edema can progress further, resulting in ascites, pleural effusion, and scrotal or labial edema. When fever is present, it may reflect sepsis, pneumonia, or peritonitis.

History

The search for the significant underlying renal disease begins with a careful history. Impairment in growth and development, unexplained polydipsia or polyuria, hearing loss, or visual problems increase the suspicion of a significant underlying renal disease. The medical history should include perinatal events such as oligohydramnios; a history of previous infections such as upper respiratory tract infection; symptoms of bladder dysfunction such as frequency or dysuria; and systemic symptoms such as headache, edema, and joint pain. A thorough inquiry into the patient's medication history is necessary. Family history of renal diseases or renal failure is important. Assessment of any changes in urine output warrant evaluation.

Physical Examination

In patients with proteinuria, the physical examination is usually unremarkable. The patient's height and weight should be plotted on a growth chart to assess the nutrition and growth status. In patients with established nephrotic syndrome, a careful physical examination is essential to assess the severity of disease and to determine whether the child needs to be hospitalized. Examination findings help to distinguish nonrenal causes of edema such as cardiac, hepatic, or nutritional factors and to exclude the possible involvement of systemic diseases. The first step should be an assessment of the vital signs and of hemodynamic stability. Orthostatic changes in blood pressure along with decreased peripheral perfusion may indicate a decrease in the intravascular volume. Edema may appear in the extremities, in the abdomen, in the pleural space, in the scrotum or labia majora, or around the eyes. Auscultation of the lungs is important to evaluate for a pleural effusion or signs of consolidation. Palpation of the abdomen is necessary for the evaluation of ascites and to rule out peritonitis in patients with fever and abdominal pain.

Laboratory Evaluation

TESTING FOR PROTEINURIA. The urinary dipstick test, the most commonly used screening test for proteinuria, primarily detects urinary albumin. False-negative results may occur with very dilute urine. False-positive results

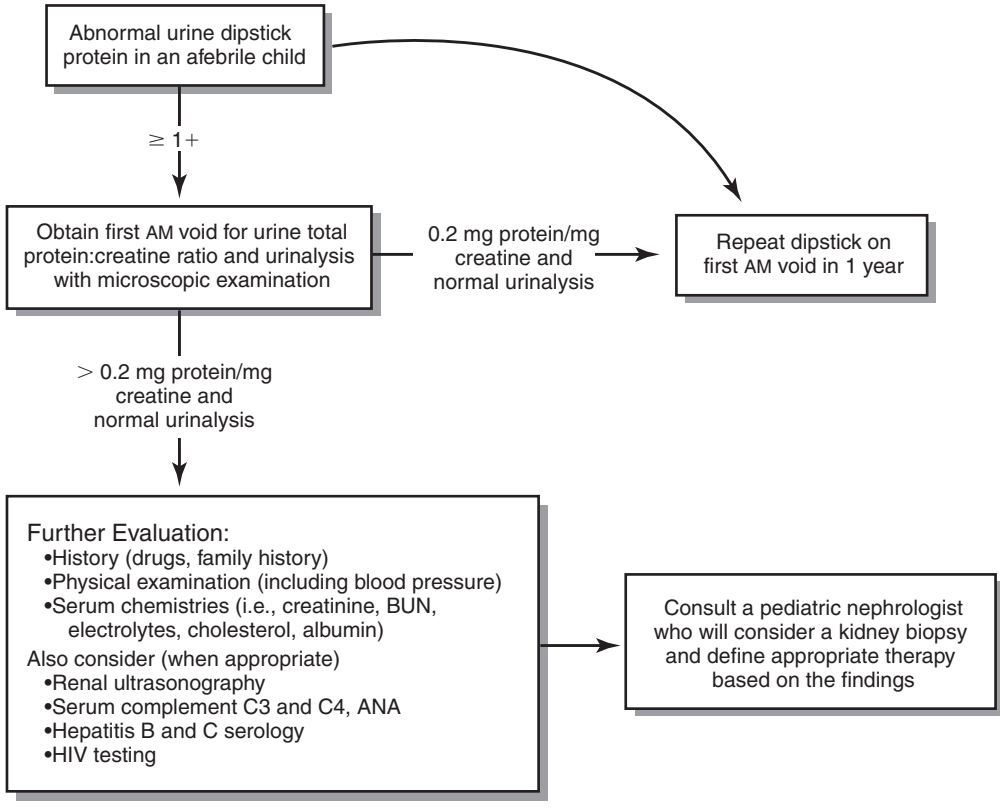

FIGURE 20-1. Evaluation of asymptomatic persistent proteinuria in children and adolescents. If the urinalysis is normal and the protein:creatinine ratio is less than 0.2, no additional studies are necessary. However, if the urinalysis shows other abnormalities or the first-morning urine protein:creatinine ratio is greater than 0.2, the blood level of albumin, cholesterol, creatinine, and electrolytes should be determined. A low serum albumin along with an increase in serum lipid levels confirms the diagnosis of nephrotic syndrome. Additional laboratory studies are indicated to rule out secondary causes. Antistreptolysin O and streptozyme levels may be useful to rule out previous streptococcal infection. Serum complement levels C3 and C4 and antinuclear antibodies (ANAs) assist in the diagnosis of systemic lupus erythematosus (SLE). Serologic studies for hepatitis B and C, and *HIV* should also be considered. *BUN*, blood urea nitrogen. From Hogg RJ et al: Evaluation and management of proteinuria. *Pediatrics* 105:1244, 2000.

may occur with concentrated or very alkaline urine (pH >8), gram-negative bacteria, detergents, or skin cleansers containing ammonium salts.

Evaluation of children with persistent proteinuria is complex (Figure 20-1). Several methods to test for proteinuria are available (Table 20-3). The most accurate method is the 24-hour urine collection. However, it is inconvenient and difficult to obtain in children. Therefore, a spot urine test for protein and creatinine has become the most common method to quantify proteinuria in children. It should be obtained preferably in a first-morning urine specimen, as urine protein concentration can vary widely during the day. Studies have indicated that the urine protein:creatinine ratio accurately reflects 24-hour urine protein excretion. In addition, a renal sonogram should be obtained in children with persistent proteinuria.

In most children with nephrotic syndrome, a renal biopsy is not required for initial diagnosis because the majority have minimal change disease. If nephrotic syndrome develops during the first year of life or during adolescence, or if a child presents with features that make the possibility of minimal change disease less likely (e.g., a decrease in renal function, hypertension, gross hematuria, or hypocomplementemia), a biopsy should be considered before treatment. Children with nephrotic syndrome have a urine protein:creatinine ratio greater than 2.0 or a 24-hour urine protein excretion of more than 40 mg/m^2/h (or more than 50 mg/kg/day, more than 10 times the normal range).

TESTING FOR ALBUMINURIA. Specific measurement of albumin in the urine (microalbuminuria) is a more accurate measurement than a routine urinalysis dipstick in assessing the degree of albuminuria. Increased urine albumin excretion appears before other measurable changes in renal function. **Levels of urine albumin excretion below the sensitivity of the dipstick have been referred to as microalbuminuria, which is defined as urine**

TABLE 20-3

Laboratory Testing for Proteinuria

Method	*Normal Range*
Dipstick	Negative
Protein:creatinine ratio	<0.5 (mg protein/mg creatinine) in children 6–24 months of age <0.2 (mg protein/mg creatinine) in children >2 years of age
24-hour urine for protein	<4 (mg protein/m^2/h) or <5 (mg protein/kg/day)
Microalbuminuria	<30 (mg albumin/g Cr)

albumin excretion between 30 and 300 mg per 24 hours. To simplify testing, a first-voided urine can be analyzed for its albumin (milligram) to creatinine (gram) ratio. A ratio (albumin:creatinine) greater than 30 is considered abnormal.

Pediatric Pearl: It is important to note that children with microalbuminuria may have a normal urinalysis.

Studies have shown that the presence of microalbuminuria is a sensitive indicator of kidney disease in diabetes mellitus. Testing for microalbuminuria is indicated in children with diabetes to check for early kidney involvement.

Differential Diagnosis

When proteinuria is detected, it is important to determine whether it is transient, orthostatic, or persistent. **Transient proteinuria** (e.g., associated with fever, dehydration, stress, exercise) is not considered to be indicative of underlying renal disease. **Orthostatic proteinuria,** which rarely exceeds 1 g/m^2/day, is defined as an elevated protein excretion in the upright position, but is normal during recumbency. It occurs in school-age children. Long-term follow-up studies have documented the benign nature of orthostatic proteinuria. However, there have been a few reports of renal disease identified later in life in children who were initially found to have orthostatic proteinuria. **Persistent proteinuria** is defined as proteinuria over 1+ by dipstick on multiple occasions and is abnormal and should be investigated.

Nephrotic syndrome can be divided into two major categories (Table 20-4). In **primary, or idiopathic nephrotic syndrome,** the etiology is unknown. The three histologic types of idiopathic nephrotic syndrome by renal biopsy are minimal change nephrotic syndrome, focal segmental glomerulosclerosis (FSGS), and membranous nephropathy (MN). Whereas the incidence of nephrotic syndrome has remained stable for decades, the distribution of histologic types apparently has changed due to an increase in the incidence of FSGS.

In **secondary nephrotic syndrome,** a renal disorder appears during the course of another systemic disease or during drug treatment. The most common form of nephrotic syndrome in childhood is **minimal change disease,** which accounts for 85% of cases.

Management

It is recommended that children with proteinuria receive the recommended daily allowance of protein for age. High dietary protein intake may worsen proteinuria and does not improve hypoalbuminemia.

Corticosteroids are the drugs of choice in childhood nephrotic syndrome (Figure 20-2). Oral prednisone or prednisolone (60 mg/m^2/day or 2 mg/kg/day; maximum: 80 mg/day) is given daily for 4 to 6 weeks. Then, the dose is tapered to 40 mg/m^2/day on alternate days for another 4 to 6 weeks to minimize side effects such as growth retardation. This form of therapy results in complete remission in more than 90% of patients. A prolonged initial treatment with prednisone (6 weeks of daily followed by 6 weeks of alternate-day administration) has been found to decrease the frequency of relapses. If the patient does not respond to steroids in 4 to 6 weeks, a renal biopsy is indicated for histologic diagnosis. Most children (60% to 80%) experience a number of relapses of nephrotic syndrome. Treatment for relapses involves a short course of daily steroids at the initial higher dose

TABLE 20-4

Etiologic Classification of Nephrotic Syndrome in Children

Primary Nephrotic Syndrome
Minimal change nephrotic syndrome
Focal and segmental glomerulosclerosis
Membranous nephropathy
Membranoproliferative glomerulonephritis
Congenital nephrotic syndrome
Secondary Nephrotic Syndrome
Infections: Hepatitis B and C, syphilis, HIV, malaria
Malignancies: Lymphoma, leukemia
Miscellaneous: Diabetes, systemic lupus erythematosus, amyloidosis, Alport syndrome, Henoch-Schönlein purpura, sickle cell disease
Drug reaction (drug-induced nephrotic syndrome): NSAIDs, gold, lithium, interferon, heroin

NSAID, nonsteroidal anti-inflammatory drug.

until the urine is free of protein for 3 days, followed by the alternate-day schedule for 4 to 6 weeks at the lower dose. The edema improves in steroid-responsive patients as soon as the proteinuria decreases, the serum albumin increases, and the driving forces for edema formation disappear.

Cytotoxic agents are indicated in steroid-dependent nephrotic syndrome, and in frequent relapsers, when steroid side effects become a problem. Cyclophosphamide or chlorambucil, given for 8 to 12 weeks, may achieve long periods of remission and reduce the need of steroids. Both drugs have significant side effects that include infection, leukemia, gonadal dysfunction, hemorrhagic cystitis, and bone marrow suppression. Levamisole, cyclosporine, and mycophenolate-mofetil also have been found to reduce the frequency of relapses. Calcineurin inhibitors such as Cyclosporine A and Tacrolimus are increasingly used in patients with steroid-resistant nephrotic syndrome. Cyclosporin has serious adverse effects (hypertension, hyperkalemia, hypertrichosis, gingival hyperplasia). Renal insufficiency, initially transitory, can become permanent due to interstitial fibrosis. Tacrolimus is reported to have a similar profile but less cosmetic side effects than cyclosporin. Often, proteinuria recurs when the treatment is discontinued. A multicenter, prospective, controlled, randomized trial, sponsored by the National Institutes of Health, is in progress for patients younger than 40 years of age who have biopsy-proven FSGS and who have been assigned to treatment with either pulse steroids plus mycophenolate-mofetil or to cyclosporine. Adjunctive therapy with angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers in patients with steroid-resistant nephrotic syndrome is now being used more frequently. It decreases the rate of protein excretion and has a protective effect on renal function.

In patients with severe edema, intravenous albumin (1 g/kg of 25% albumin) administered in conjunction with diuretics may be of help. It must be remembered that this is only a temporary therapy and carries the risk of inducing hypertension, fluid overload, and pulmonary edema. During chronic management of patients with nephrotic syndrome, fluid restriction is generally not necessary, although a low-sodium diet is indicated to counteract the alterations in sodium metabolism.

Complications in nephrotic syndrome may derive from the disease itself or from its treatment. As nephrotic children lose immunoglobulin G (IgG) in the urine, they are at increased risk for infections (e.g., cellulitis, peritonitis, pneumonia). Antibiotics with broad-spectrum coverage of both gram-positive and gram-negative organisms are appropriate until culture results are available. A serious complication is the risk of a thromboembolic event secondary to a hypercoagulability state. Avoidance of arterial punctures and of diuretics during periods of hypovolemia may be of help in preventing thrombosis. Growth retardation is one of the multiple side effects of long-term steroid therapy; however, administering steroids on alternate days may reduce this effect. Children may need treatment with calcium and vitamin D for bone mineral density. Statins are used

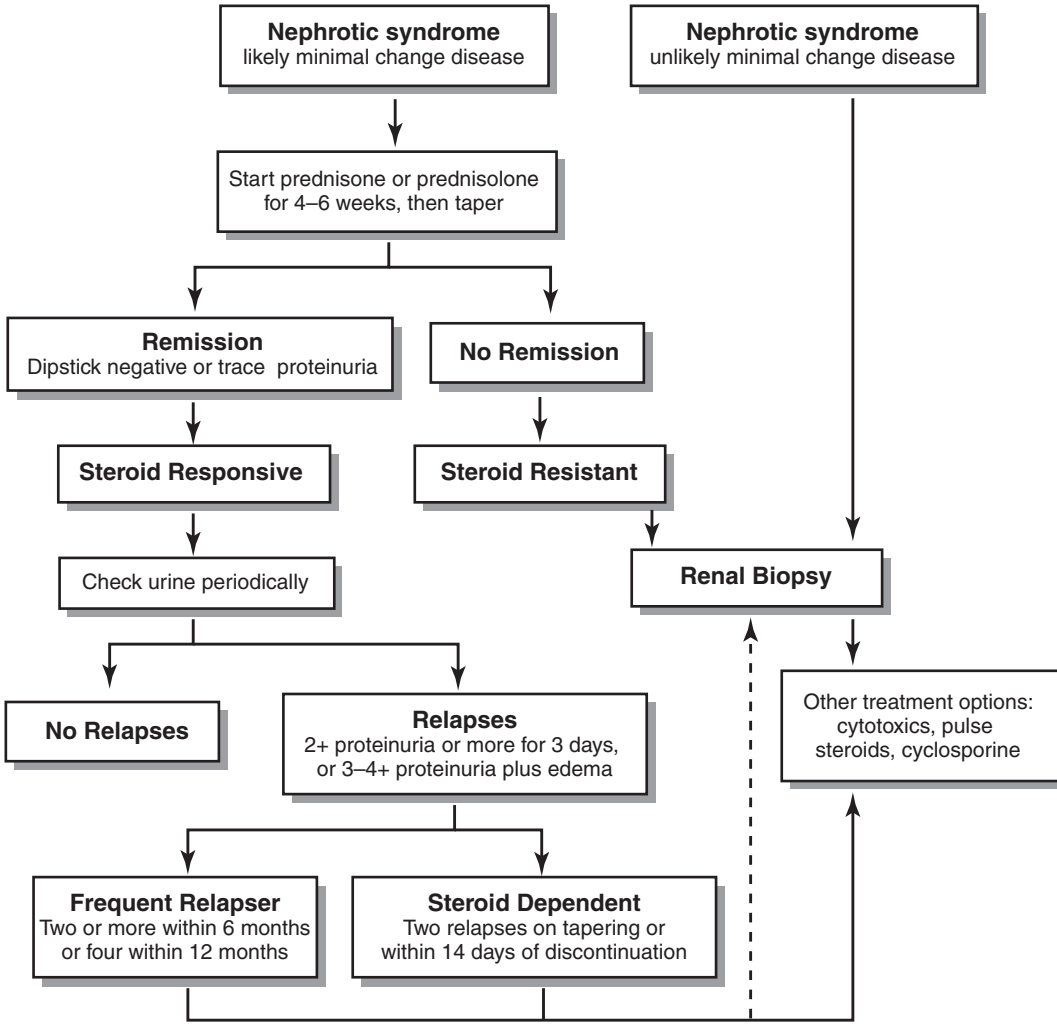

FIGURE 20-2. Management and response to treatment in children with nephrotic syndrome.

for control of hyperlipidemia and prevention of premature atherosclerosis, and may be reno-protective due to their anti-inflammatory effects.

HEMATURIA AND GLOMERULONEPHRITIS

Hematuria may be gross (macroscopic) or microscopic. By definition, gross hematuria is the presence of enough blood in the urine to change its appearance to naked eye inspection and, therefore, is easily recognized. In contrast, microscopic hematuria, an abnormal number of RBCs in the urine, should be defined more precisely to include all patients with disease and exclude patients without disease. By definition, microscopic hematuria is more than five RBCs per high power field. Macroscopic hematuria, which is tea or cola colored, is glomerular in origin, whereas red or pink urine is usually from the lower urinary tract.

Pathophysiology

Glomerulonephritis is an important cause of hematuria in children. Glomerular disease may result from immunologic abnormalities, coagulation disturbances, biochemical defects, or direct toxic insults. Immunologic abnormalities appear to be the predominant mechanism for glomerular disease in humans. Renal injury may be due to one of several immunologic processes: circulating autoantibodies to glomerular antigens, deposition of circulating antigen–antibody complexes in the glomeruli, and cell-mediated processes damaging the glomeruli. The glomerular antigen may be a normal component of the glomerulus or an antigen that has been deposited in the glomerulus.

TABLE 20-5

Personal and Family History in Children with Hematuria

History	*Possible Cause of Hematuria*
Personal	
Streptococcal pharyngitis or impetigo	Poststreptococcal glomerulonephritis
Dysuria, urinary frequency	Lower UTI
Recurrent episodes of gross hematuria with viral illnesses	IgA nephropathy
Exercise	Exercise-related hematuria
Trauma	Trauma-related hematuria
Family	
Deafness and renal insufficiency	Alport syndrome
Urolithiasis	Hypercalciuria, urolithiasis
Hematuria, isolated	Thin basement membrane disease

UTI, urinary tract infection.

Clinical and Laboratory Evaluation

History

Children with hematuria may present in one of three ways: (1) onset of gross hematuria, (2) onset of urinary or other symptoms with the incidental finding of microscopic hematuria, or (3) incidental finding of microscopic hematuria during a health evaluation. It is important to inquire about activities and symptoms that preceded or were concomitant with the hematuria as well as history of hematuria, or other renal disease in family members (Table 20-5).

Children with acute glomerulonephritis typically present with hematuria, edema, and hypertension, with or without oliguria. Gross hematuria is the presenting symptom in many patients. However, affected children may be completely asymptomatic, and the disease may be discovered when a routine urinalysis reveals microscopic hematuria. Clinical edema, typically in the periorbital area, or a decrease in urine output are other significant presenting signs. Nonspecific symptoms such as fever, anorexia, weakness, or headache may accompany the disease. Respiratory symptoms and neurologic abnormalities may indicate a severe ongoing process. The presence of extrarenal manifestations such as a purpuric skin rash, joint involvement, GI bleeding, or pleuritis may be more indicative of a systemic disease with renal involvement.

Physical Examination

A complete physical examination is important for the assessment of disease severity and for diagnosis of a secondary cause. (In children with asymptomatic microscopic hematuria, the physical examination is usually unremarkable.) Measurement of blood pressure and determination of growth pattern are the first steps. Hypertension and failure to thrive are commonly present in children with chronic renal disease. It is essential to address the presence and localization of edema. A sudden weight gain may relate to the presence of edema. Abnormal physical features may indicate a congenital syndrome with renal disease. Eye fundi should be examined to detect changes related to chronic hypertension or systemic diseases. The presence of tonsillar hypertrophy or resolving exudates may be present in a child with recent streptococcal pharyngitis. Auscultation of the chest is important to rule out cardiac failure and pulmonary edema. Hepatosplenomegaly is not an expected finding in primary glomerulonephritis, and its presence may indicate another systemic illness. The presence of an abdominal or flank mass suggests a renal tumor, obstructive uropathy, or multicystic or polycystic kidney disease. Pain and tenderness over the costovertebral angle or the suprapubic area suggest a urinary tract infection (UTI). The external genitalia should be examined for trauma, infection, or bleeding. The skin should be examined for infection or rashes.

Laboratory Evaluation

The most common test for the detection of RBCs in the urine is the urine strip test for blood (dipstick test). The chromogen in the reagent strip specifically reacts with hemoglobin (or myoglobin) to produce an oxidized

TABLE 20-6

Laboratory Testing for Hematuria

Urine Dipstick for Blood/Urinalysis	*Interpretation*
Negative (dark or red urine)	Foods, dyes, drugs, metabolites, or crystals in urine (e.g., nitrofurantoin, rifampin, beets, blackberries)
Positive	
• No/few RBCs	Hemoglobinuria or myoglobinuria
• <5 RBCs	Most likely normal; repeat periodically
• >5 RBCs	*Confirms hematuria*

product, which has a green-blue color. These very sensitive strips can detect the presence of 2 to 5 RBCs/HPF Urinalysis with a fresh spun urine sample is needed to confirm the presence of RBCs. The presence of RBC casts and dysmorphic RBCs is characteristic of glomerulonephritis (Table 20-6).

Urinalysis of family members may provide important information regarding the diagnosis and prognosis of the patient's underlying disease. A stable relative with hematuria may indicate a favorable prognosis.

Urine for calcium-to-creatinine ratio (Ca:Cr) should be obtained to identify hypercalciuria (over 0.8 in children younger than 6 months, over 0.6 in children 7 to 18 months, and over 0.2 in children 6 years and older). A 24-hour urinary calcium excretion greater than 4 mg/kg confirms the diagnosis. A urine culture should be obtained to exclude cystitis or pyelonephritis. Serum electrolytes, BUN, and SCr should be obtained to assess renal function; a complete blood cell count (CBC) should be obtained for anemia and infection; hemoglobin electrophoresis should be obtained if the sickle cell status is unknown; and prothrombin time and partial thromboplastin should be obtained time for coagulopathy.

The diagnosis of postinfectious glomerulonephritis requires the detection of both the glomerulonephritis and the cause of infection. In poststreptococcal glomerulonephritis, the success rate in obtaining a positive culture during an epidemic varies between 10% and 70%. The diagnosis usually depends on serologic criteria. An increase in titers of antistreptococcal antibodies indicates recent infection, but not all of these tests are equally useful. Antistreptolysin O (ASO) titers are less frequently elevated than anti-DNAse B titers (streptozyme). An immune-mediated process should be suspected if there is any alteration in the serum complement level or the presence of autoantibodies (Figure 20-3). In the first week of poststreptococcal glomerulonephritis, the serum C3 and the total serum hemolytic complement are decreased in more than 90% of cases. Serum complement levels should normalize after 6 to 8 weeks of onset in children with poststreptococcal glomerulonephritis.

If hypocomplementemia persists beyond 8 weeks, the possibility of another diagnosis should be considered (membranoproliferative glomerulonephritis, lupus nephritis). Antinuclear antibody (ANA) for systemic lupus erythematosus (SLE), hepatitis B titers for MN, and hepatitis B and hepatitis C for membranoproliferative glomerulonephritis should also be obtained. A formal neurosensory test for hearing loss is necessary in any child with persistent hematuria.

Imaging studies may also be indicated. Urinary tract ultrasonography, a noninvasive study, is useful for the evaluation of children with hematuria. Other imaging studies may also be necessary (VCUG, CT, radionuclide studies) in selected patients. A renal biopsy may be indicated in children with rapidly progressive glomerulonephritis for histologic diagnosis and for assessment of severity of disease.

Differential Diagnosis

The causes of gross and microscopic hematuria in children are extensive (Table 20-7).

Macroscopic hematuria can be further divided as follows:

1. Glomerular disease: Postinfectious glomerulonephritis, **immunoglobulin A** (IgA) nephropathy, Alport syndrome, thin basement membrane disease, systemic vasculitis (Henoch-Schönlein purpura, SLE), and others (membranoproliferative glomerulonephritis, membranous glomerulonephritis)

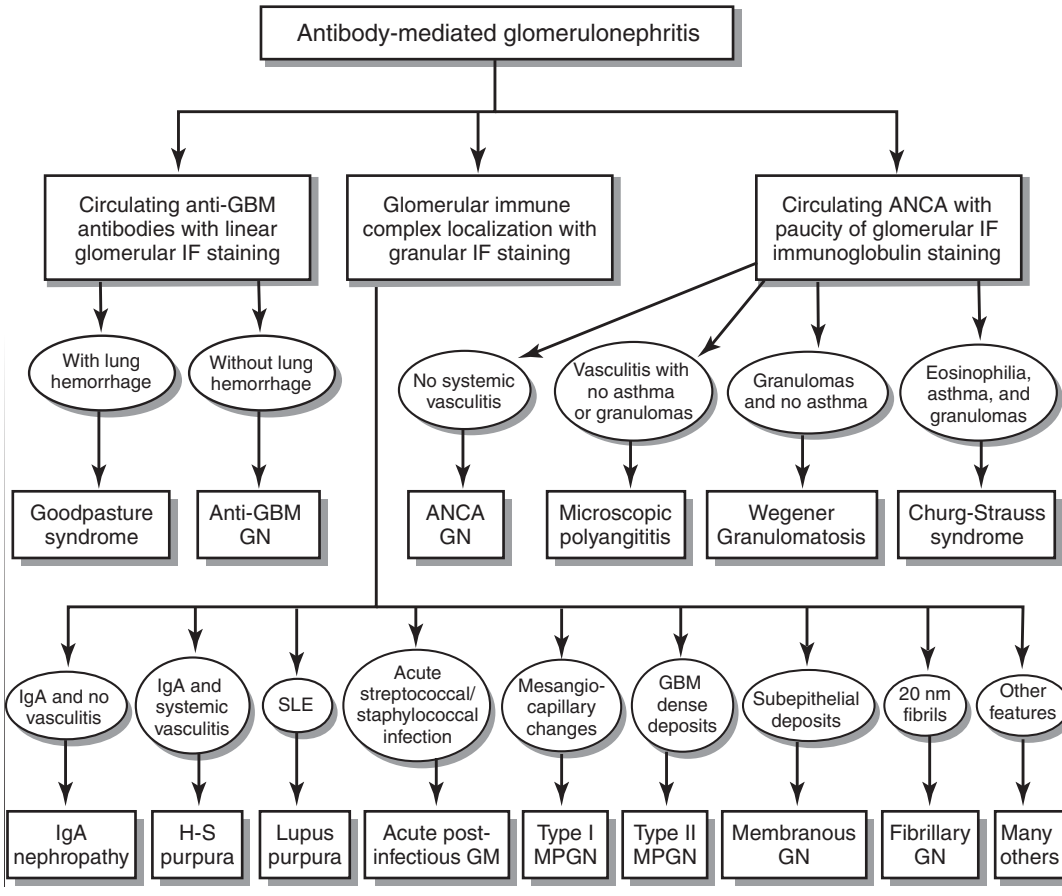

FIGURE 20-3. Features that distinguish different immunopathologic categories of antibody-mediated glomerulonephritis. *ANCA*, antineutrophil cytoplasmic autoantibodies; *AntiGBM*, anti-glomerular basement membrane; *CBC*, complete blood count; *Cr*, creatinine; *GBM*, glomerular basement membrane; *GN*, glomerulonephritis; *IF*, immunofluorescence microscopy; *H-S*, Henoch-Schönlein; *MPGN*, membranoproliferative glomerulonephritis; *SCr*, serum creatinine. From Hellerstein S: Urinary tract infections in children. *Am Fam Phys* 57:2445, 1998.

2. Interstitial or tubular disease: Pyelonehritis, interstitial nephritis, papillary necrosis (sickle cell)
3. Urinary tract or vascular disease: Infection, nephrolithiasis, trauma, polycystic kidney disease, coagulopathy, hemorrhagic cystitis, and renal vein thrombosis

Microscopic hematuria may be isolated and is asymptomatic or associated with proteinuria. The most common causes of isolated asymptomatic proteinuria are thin basement disease, IgA nephropathy, idiopathic hypercalciuria, and sickle cell disease trait.

Glomerulonephritis is considered primary when the kidney is the only involved organ and secondary when the renal involvement is part of a systemic disease. It can be acute, chronic, or rapidly progressive according to its clinical presentation and prognosis. Acute glomerulonephritis has a tendency for spontaneous resolution. Rapidly progressive glomerulonephritis refers to a marked and rapidly progressive deterioration in renal function. Chronic glomerulonephritis involves a persistent abnormal urine sediment with a slow and progressive loss of renal function over time.

Specific types of glomerulonephritis include:

- **Poststreptococcal glomerulonephritis,** the most common type of glomerulonephritis in children, results, indirectly, through an immunologic process, from group A β-hemolytic streptococcus. Reported cases of acute glomerulonephritis following infection with many other bacteria and viruses have occurred. Gross hematuria mostly occurs 2 weeks after acute infection. Hypertension, edema, and impairment of renal function may develop.

TABLE 20-7

Causes of Hematuria in Children

Anatomical abnormalities (hydronephrosis; cystic disease)
Bladder and kidney infection (UTI)
Coagulation/hematology (sickle cell trait or disease; leukemia)
Drugs
Exercise
Familial hematuria (Alport syndrome; thin basement membrane disease)
Glomerulonephritis
Hypercalciuria–hyperuricosuria–urolithiasis
Interstitial nephritis
Trauma and tumors (Wilms tumor)

UTI, urinary tract infection.

- **IgA nephropathy,** the most common variety of primary glomerulonephritis, is characterized by recurrent episodes of gross hematuria, usually 1 to 2 days after a viral respiratory or GI infection. Mesangial IgA deposition is the most prominent finding on renal biopsy specimens.
- **Alport syndrome** is a form of familial nephritis with neurosensory hearing loss and slow progression to renal insufficiency.
- **Familial benign hematuria** is defined by familial occurrence of persistent hematuria without proteinuria, progression to renal failure, or hearing defect. Thin glomerular basement membrane is commonly found on these patients.

Management

From the practical point of view, children with confirmed hematuria can be divided clinically into four groups: (1) gross hematuria, (2) microscopic hematuria with clinical symptoms, (3) asymptomatic microscopic hematuria (isolated), and (4) asymptomatic microscopic hematuria with proteinuria. The evaluation and management of children with hematuria is complex (Figure 20-4).

The general management of glomerulonephritis involves salt and water restriction. Treatment depends on the severity of the disease, degree of renal involvement, and presence of renal failure, hypertension, or other complications. A decrease in urine output, the presence of high blood pressure, or any sign of fluid overload may be an indication for hospitalization. Fluid restriction and close monitoring of electrolytes may be indicated in patients with ARF. Dialysis may be necessary in patients with fluid overload or hyperkalemia that is unresponsive to conservative therapy. When hypertension is present, it is generally related to fluid overload. Loop diuretics such as furosemide may be useful in the management of both fluid overload and hypertension.

Specific treatment of glomerulonephritis depends on the etiology or severity of the disorder. Steroids and cyclophosphamide are indicated for severe lupus nephritis in an attempt to decrease the immunologic process. The use of plasma exchange may be indicated in severe cases to decrease the amount of circulating factors (e.g., immunoglobulins) involved in kidney damage (e.g., in Goodpasture syndrome).

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura (HSP) is the most common form of **vasculitis** in children. Vasculitis is a clinicopathologic process characterized by inflammation and damage to blood vessels, resulting in compromise of the vessel lumen and ischemic changes in the tissues supplied by the involved vessels.

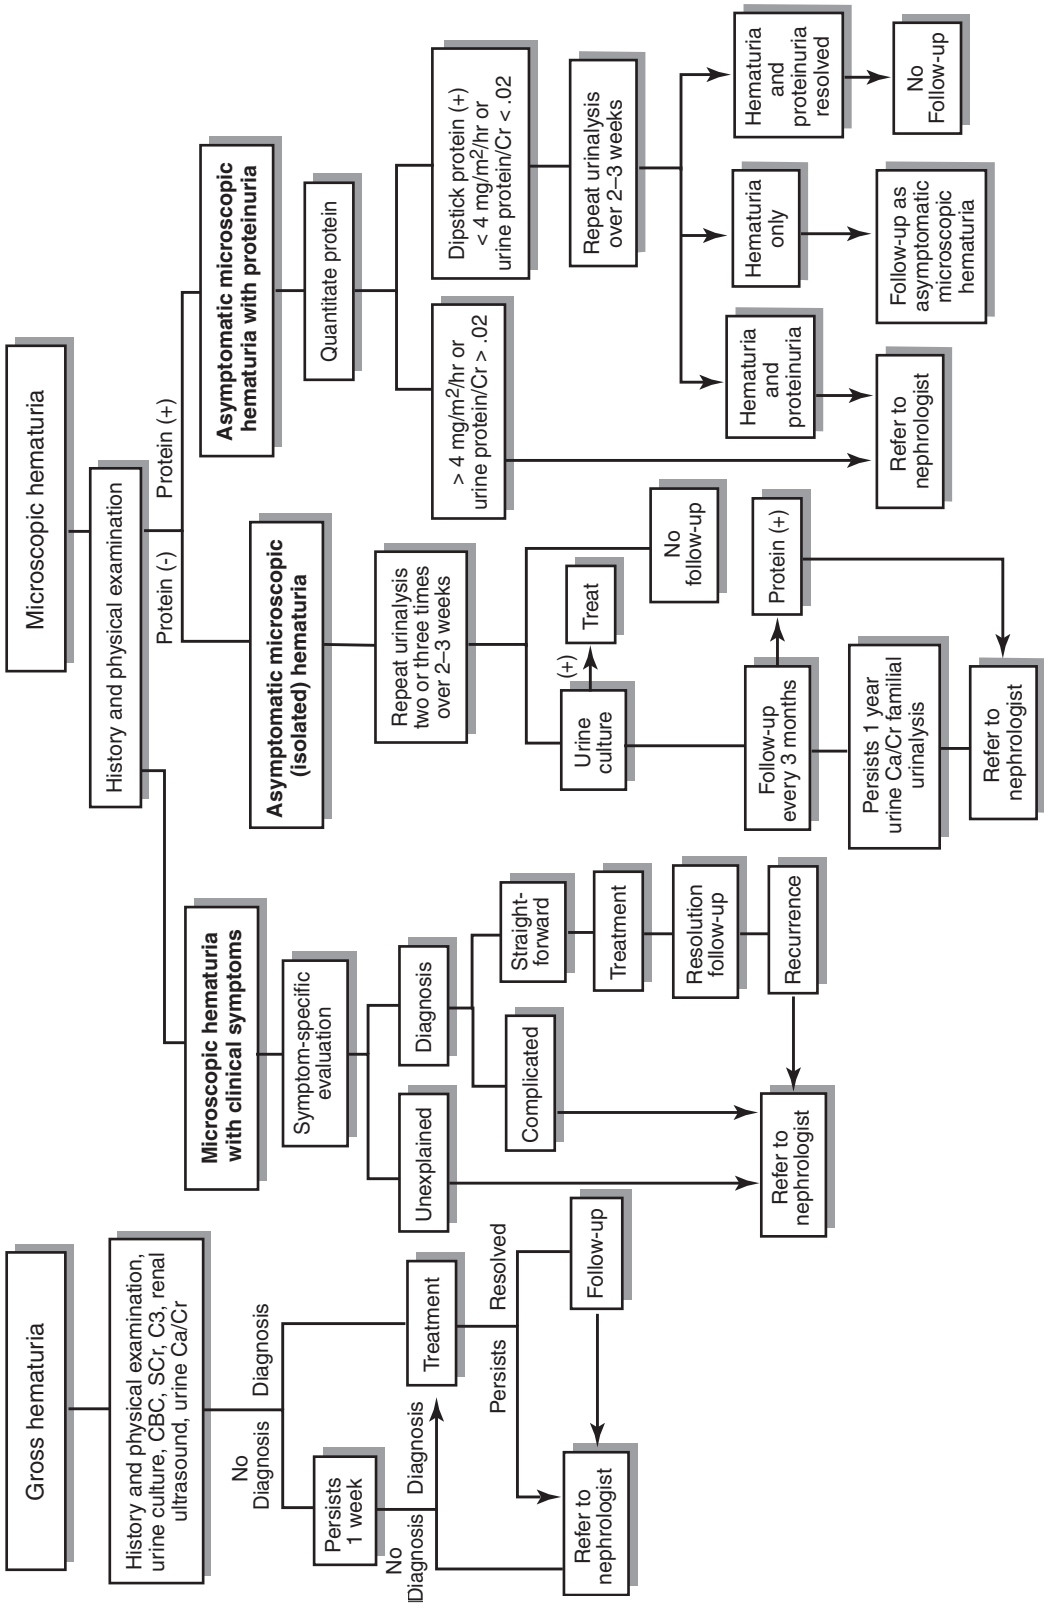

FIGURE 20-4. Algorithm for the practical evaluation and management of children with hematuria. *Dx*, diagnosis; *F/U*, follow-up; *PE*, physical examination; *UA*, urinalysis; *US*, ultrasound. From Diven SC et al: A partical primary care approach to hematuria. In *Pediatric Nephrology*, vol 14. Springer-Verlag, 2000, p 69.

The incidence of HSP is approximately 10 cases per 100,000 children per year. Seventy-five percent of all cases occur in children between 2 and 11 years of age; the disease is rare in adults and younger children. Males are affected twice as frequently as females.

Pathophysiology

HSP is an IgA-mediated vasculitis in the small vessels of involved organs. The etiology is unknown. Both bacterial (*Streptococcus, Yersinia, Mycoplasma*) and viral infections (Epstein-Barr virus, varicella, parvovirus, and adenovirus) have been reported to precede HSP. Other reported preceding stimuli include immunizations, drugs, foods, and insect bites.

Clinical and Laboratory Evaluation

A preceding event (e.g., infection, medication, immunization) may be discovered in many children. The onset of HSP may be acute with the appearance of characteristic symptoms in any order or simultaneously.

History

Purpuric rash, arthritis, abdominal pain, and nephritis are the most typical findings. **Purpura** is the most common finding, but it may not be the presenting feature. It appears typically in the lower extremities and buttocks, but may also be present in the upper extremities, trunk, and face. The rash may persist for weeks, be transient, or may recur. **Arthritis** or **arthralgias** may also be manifest in the ankles, knees, or hands. In some cases, joint involvement may be the presenting feature. Although the arthritis may be incapacitating, it is self-limited and nondeforming. **GI symptoms** result from edema of the bowel wall and hemorrhage owing to vasculitis, and generally appear after the purpura, but rarely may precede it. Abdominal pain is the most common complaint. Vomiting, hematemesis, bloody diarrhea, or melena are common and may be severe. Intussusception is the most common surgical complication.

Renal manifestations generally appear within 3 months of the onset of the rash. In a few cases, gross hematuria is the presenting finding. The frequency of renal involvement (gross or microscopic hematuria) varies between 20% and 90%. Hematuria is the clinical hallmark of HSP nephritis. Approximately 80% of patients manifest nephritis within 4 weeks and 95% within 3 months of onset of other symptoms. There is no relationship between the severity of extrarenal organ involvement and the severity of nephritis.

Other complications include central nervous system (CNS) involvement (seizures, paresis, or coma), eye and cardiac involvement, and pulmonary or intramuscular hemorrhage. Pancreatitis and orchitis have also been described.

Physical Examination

Inspection of the skin may show the typical distribution and appearance of the rash. The classic lesions consist of urticarial, maculopapular, or palpable purpuric lesions. In some cases, different appearances or localizations may complicate the diagnosis. Vesicular eruptions and erythema multiforme have been described. Vital signs, blood pressure, and urine output should be monitored in patients who present with GI bleeding. Edema may be present in the scalp, extremities, back, and eyelids. Joint involvement tends to be periarticular, and joints may be swollen, tender, and painful on motion. A complete physical examination is important to rule out involvement of the pancreas, lungs, heart, testes, and CNS.

Laboratory Evaluation

An initial urinalysis is necessary to diagnose any renal involvement. The long-term prognosis is determined by the extent of renal involvement, which varies from mild to severe rapid progressive glomerulonephritis. The most common finding is **hematuria with or without proteinuria.** If the urine is abnormal, a SCr level and BUN need to be performed to assess kidney function. A kidney biopsy should be considered in patients with severe clinical manifestations of renal disease, nephrotic syndrome, or rapid progressive glomerulonephritis. Histologically the typical finding in HSP is the presence of mesangial deposits of IgA by immunofluorescence.

Laboratory studies are indicated depending on the clinical presentation. A CBC may show **anemia** in patients with GI bleeding. ANA, antineutrophilic cytoplasmic antibody (ANCA), and rheumatoid factor are usually negative. **Stool guaiac** examinations should be done to screen for occult GI bleeding. Serum IgA levels may be elevated or normal. Radiologic studies are indicated in patients with acute abdominal pain. A head CT scan may be useful in children with neurologic involvement to rule out other causes.

Differential Diagnosis

In the presence of an atypical rash, other vasculitides should be considered. Patients with microscopic polyarteritis, Wegener granulomatosis, and SLE may all present with nephritis. The associated clinical features with the presence of ANCA or ANA can help differentiate these conditions. Cytoplasmic ANCA (c-ANCA) is more commonly associated with Wegener granulomatosis, whereas perinuclear ANCA (p-ANCA) is more often associated with microscopic polyarteritis. A purpuric rash can be caused by sepsis or thrombocytopenia. The clinical picture, distribution of the rash, and hematologic studies should identify these patients.

Management

No specific treatment is available for HSP, and the management is supportive. Most patients with renal involvement show mild urine abnormalities, but should be followed up for a prolonged period of time until the urinalysis becomes normal. Children with more severe presentations such as ARF, hypertension, or nephrotic syndrome should be hospitalized and followed very carefully **because of possible rapid progression to end-stage renal disease (ESRD).**

Many drugs, including oral corticosteroids, intravenous pulses of methylprednisolone, cytotoxic agents, anticoagulants, and plasmapheresis, have been used to treat severe renal involvement. The available data suggest that patients with severe nephritis (decreased renal function and 50% or more crescents on renal biopsy) should receive a combination of high-dose intravenous methylprednisolone plus an immunosuppressive agent, either azathioprine or cyclophosphamide. Plasmapheresis may be of benefit in a few patients with rapidly progressive HSP nephritis. Some studies have shown that oral prednisone may be effective in preventing the development of nephropathy, whereas others have shown no effect. However, prednisone is effective in alleviating the GI manifestations.

In the absence of nephropathy, recurrence of clinical manifestations may occur, but the prognosis of patients with HSP is excellent. Long-term follow-up is necessary in children with renal involvement for evidence of progression of disease. The presence of renal insufficiency or nephrotic syndrome at onset and the finding of crescentic glomerulonephritis on biopsy appear to increase the risk of progressive renal disease.

URINARY TRACT INFECTION

UTIs are common in children. UTIs are important because they cause acute morbidity and may result in long-term medical problems, including hypertension and reduced renal function.

Pathophysiology

UTIs usually occur as a consequence of colonization of the periurethral area by a virulent organism that subsequently gains access to the bladder. Only in the first 8 to 12 weeks of life, UTIs may be secondary to a hematogenous source. During the first 6 months of life, male infants are at increased risk for UTIs, but thereafter UTIs predominate in females. An important risk factor in girls is previous antibiotic therapy, which disrupts the normal periurethral flora and fosters the growth of uropathogenic bacteria. Several factors predispose one to UTIs (Table 20-8).

The most common organisms isolated from the periurethral area are members of the Enterobacteriaceae. *Escherichia coli* is the most common cause of infection. *Enterococcus* species, *Staphylococcus aureus,* and group B streptococcus are the most frequent isolated gram-positive bacteria. In adolescence, *Staphylococcus saprophyticus* becomes a frequent pathogen. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be considered for UTIs in sexually active adolescents. Adenovirus has been associated with acute hemorrhagic cystitis in school-age children. Additional organisms causing UTIs in patients with instrumented urinary tracts or urinary tract abnormalities include *Pseudomonas* species, *Candida* species, *Corynebacterium* species, coagulase-negative staphylococci, and *Candida*.

VUR, which may lead to UTIs, is considered a congenital anomaly of the ureterovesical junction in which there is a shortened submucosal tunnel with lateral placement of the ureteral orifice in the bladder. The longitudinal muscle is not able to adequately constrict the submucosal ureter, so the valve mechanism is defective and urine backflows into the ureter. VUR is graded according to degree of reflux from mild (limited to the ureter) to severe (associated with massive dilatation of calyces, pelvis, and ureter). VUR is identified in 30% to 50% of children who are evaluated after their first UTI. As they grow, the submucosal tunnel elongates and the valve mechanism becomes more effective. Therefore, the natural course of mild reflux is to resolve or improve with time. Patients with more severe reflux are less likely to have spontaneous resolution.

TABLE 20-8

Factors Predisposing to Urinary Tract Infection (UTI)

Urinary tract obstruction
Vesicoureteral reflux
Neurogenic bladder
Urolithiasis
Presence of foreskin
Voiding dysfunction
Constipation
Sexual abuse
Sexual intercourse
Uroepithelial deficiency with increased bacterialadherence
Antibiotic therapy
Poor perineal hygiene

Renal scarring, a potential consequence of UTIs, may be congenital or acquired. It has been recently shown that infants may have renal scarring at birth even without infection. In older children with UTIs, the infection itself, and not VUR, is the prerequisite for acquired renal scarring. However, there is a correlation between the degree of reflux and the severity of renal scarring. Furthermore, the risk of renal damage increases with the number of recurrences.

Clinical and Laboratory Evaluation

History

The spectrum of clinical manifestations of UTIs in children is broad. The clinical signs and symptoms specific for UTIs commonly seen in adults such as dysuria, urgency, and flank pain are not generally identified in infants, although they may occur in older children (Table 20-9). Young infants with UTIs generally present with fever.

Pediatric Pearl: The possibility of a UTI should be considered in any child younger than 2 years of age with unexplained fever.

TABLE 20-9

Signs and Symptoms of Urinary Tract Infection

Young Children	*Older Children*
Fever	Fever, chills, malaise
Crying on urination	Dysuria, urgency, pain on urination
Frequency	Frequency
Hematuria	Hematuria
Gastrointestinal symptoms	Flank pain
Poor growth	New-onset enuresis

A history of crying on urination or of foul-smelling urine increases the likelihood that a UTI is the cause of fever. An altered voiding pattern may be recognized as a symptom of UTI as early as the second year after birth in some children. Nonspecific signs and symptoms, such as irritability, vomiting, diarrhea, and failure to thrive, may reflect the presence of UTI. Hematuria when associated with dysuria or pain with urination is most likely due to lower UTI. A detailed voiding and defecation history should be obtained in any child with recurrent UTIs.

Physical Examination

A complete physical examination is essential to assess the degree of illness or toxicity and to rule out other severe infections such as sepsis or meningitis. The presence of fever is important in young children with UTIs because it has been accepted as a clinical marker of renal parenchymal involvement (pyelonephritis). It is important to record vital signs, including blood pressure. Examination of the abdomen and back for costovertebral tenderness, flank or abdominal mass or tenderness, or a palpable bladder is appropriate, and inspection of the genitalia for signs of trauma or infection is warranted. It is also important to note whether the child has been circumcised because uncircumcised boys have a higher chance of developing UTIs in the first year of life than do circumcised boys. Physical examination should also include careful inspection of the lumbosacral area for signs of underlying dysraphism.

Laboratory Evaluation

In infants or children who are unable to void on request, catheterization or suprapubic aspiration should be used to obtain a specimen for urinalysis and culture. A midstream clean-catch specimen may be obtained from children with urinary control. A bagged urine specimen that shows no growth or fewer than 10,000 colony-forming units (CFU)/mL is evidence of the absence of a UTI. If children who have not yet achieved urinary control have symptoms that require immediate treatment, and a urinalysis obtained by urine bag shows pyuria, positive nitrites, or bacteriuria, a urine culture should be obtained by either suprapubic aspiration or bladder catheterization before the initiation of antibiotics because of the high incidence of false-positive urine cultures obtained by urine bag.

The three most useful components of the urinalysis in the evaluation of a UTI are the leukocyte esterase test, the nitrite test, and urine microscopy. A positive result on a leukocyte esterase test appears to be as sensitive as microscopy, with the identification of WBCs. The nitrite test has a very high specificity and positive predictive value. Urinalysis cannot substitute for a urine culture to document the presence of a UTI, but it can be valuable in selecting patients for prompt initiation of therapy while waiting for the results of the urine culture. UTI is confirmed or excluded based on the number of CFUs that grow on the culture media. What constitutes a significant colony depends on the collection method and the clinical status of the patient; definitions of positive and negative cultures are operational and not absolute (Table 20-10).

The goals of performing imaging studies in children with UTIs are to detect urologic abnormalities (e.g., VUR, bladder dysfunction, obstructive uropathy) and to discover renal parenchymal damage. The current imaging workup consists of renal ultrasound and VCUG or RVC (Table 20-11). VCUG is recommended as baseline study in all first time UTIs, and isotope voiding cystography for follow-up studies. If significant hydronephrosis is discovered on renal ultrasound, a nuclear renal scan (with ^{99m}Tc-MAG-3 or DTPA) is used for

TABLE 20-10

Interpretation of Urine Culture for Diagnosis of Urinary Tract Infection

Method of Collection	*Quantitative Culture: Urinary Tract Infection Present*
Suprapubic aspiration	Growth of urinary pathogens in any number (exception is up to 2–3 × 10^3 CFU/mL of coagulase-negative staphylococci)
Catheterization	Febrile infants or children usually have ≥50 × 10^3 CFU/mL of single urinary pathogen, but infection may be present with counts from 10 × 10^3–50 × 10^3 CFU/mL
Midstream clean-void	Symptomatic patients usually have ≥10^5 CFU/mL of single urinary tract pathogen
	Asymptomatic patients need to have at least two specimens on different days with ≥10^5 CFU/mL of same organism

CFU/mL, colony-forming units per milliliter.

From Hellerstein S: Urinary tract infections. Old and new concepts. *Pediatr Clin North Am* 42(6):1433–1457, 1995.

TABLE 20-11

Indications of Imaging Studies in Children With Urinary Tract Infections (UTIs)

- RUS and VCUG or RVC in a child of any age with a febrile UTI
- RUS and VCUG or RVC in a young child with a well-documented UTI
- RUS only in an older child with symptoms of lower UTI
  - -VCUG or RVC if abnormal RUS or if recurrent UTI
  - -VCUG with history of dysfunctional voiding
- DMSA scan if RUS or voiding study are markedly abnormal, to detect renal scars, if this changes clinical management
- Radionuclide renal scan if urinary tract obstruction is considered

DMSA, dimercaptosuccinic acid; *RUS*, renal ultrasound; *RVC*, radionuclide voiding cystography; *VCUG,* voiding cystourethrogram.

evaluation of urinary tract obstruction. Renal cortical scintigraphy with ^{99m}Tc-labeled DMSA is sensitive and specific for the diagnosis of pyelonephritis in children. This renal test shows decreased uptake of radiotracer in areas of inflammation, which is secondary to decreased delivery of agent to the infected tissue (cortical ischemia) and decreased tubular function in areas of infection. CT imaging and MRIs have also been utilized for diagnosis of pyelonephritis. CT may be useful in patients with a presentation that could be caused by some other illness (e.g., intra-abdominal abscess, appendicitis). Cost and the need of sedation are the major disadvantages of an MRI.

Differential Diagnosis

The presentation of febrile infants who have positive results on urine cultures frequently poses a diagnostic question: Do the infants have true UTIs or asymptomatic bacteriuria with fever from another source? Asymptomatic bacteriuria does not appear to present a danger to the host. It is considered to be a phenomenon whereby mucosal receptors permit attachment by *E. coli,* creating a carrier-state (colonization) rather than infection. Pyuria may be a possible marker to differentiate between a UTI and asymptomatic bacteriuria. However, although the presence of pyuria increases the likelihood of a true UTI, the absence of pyuria does not preclude the possibility of a true UTI. Pyuria is particularly insensitive in neonates and very young infants. Therefore, it is prudent to consider that all young infants with significant bacteriuria and fever have a true UTI.

Management

The goals of treatment of an acute UTI are to eliminate the acute infection, prevent urosepsis, and reduce the likelihood of renal damage. Patients who are toxic-appearing, dehydrated, or unable to retain oral intake (including medications) should receive an antimicrobial parenterally. The clinical condition of most patients improves within 24 to 48 hours. Treatment can then be completed orally. For patients who do not appear toxic, options include administration of an antimicrobial parenterally on an outpatient basis, or receiving the antibiotic orally for 7 to 14 days.

Treatment of acute pyelonephritis or cystitis may be initiated based on clinical findings and urinalysis (Figure 20-5). However, the diagnosis of a UTI is not documented by urinalysis, and imaging studies of the urinary tract should not be obtained until the diagnosis of a UTI is confirmed by a positive urine culture. The usual choices for oral treatment of a UTI include cephalosporin, trimethoprim–sulfamethoxazole, or amoxicillin. However, amoxicillin appears less effective due to emerging bacterial resistance. Cephalosporins are very effective antibiotics parenterally. Other antibiotics are useful in the treatment of UTIs (Table 20-12). Agents that are excreted in the urine but do not achieve therapeutic concentrations in the bloodstream (e.g., nitrofurantoin) should not be used to treat a UTI in patients in whom renal involvement is likely.

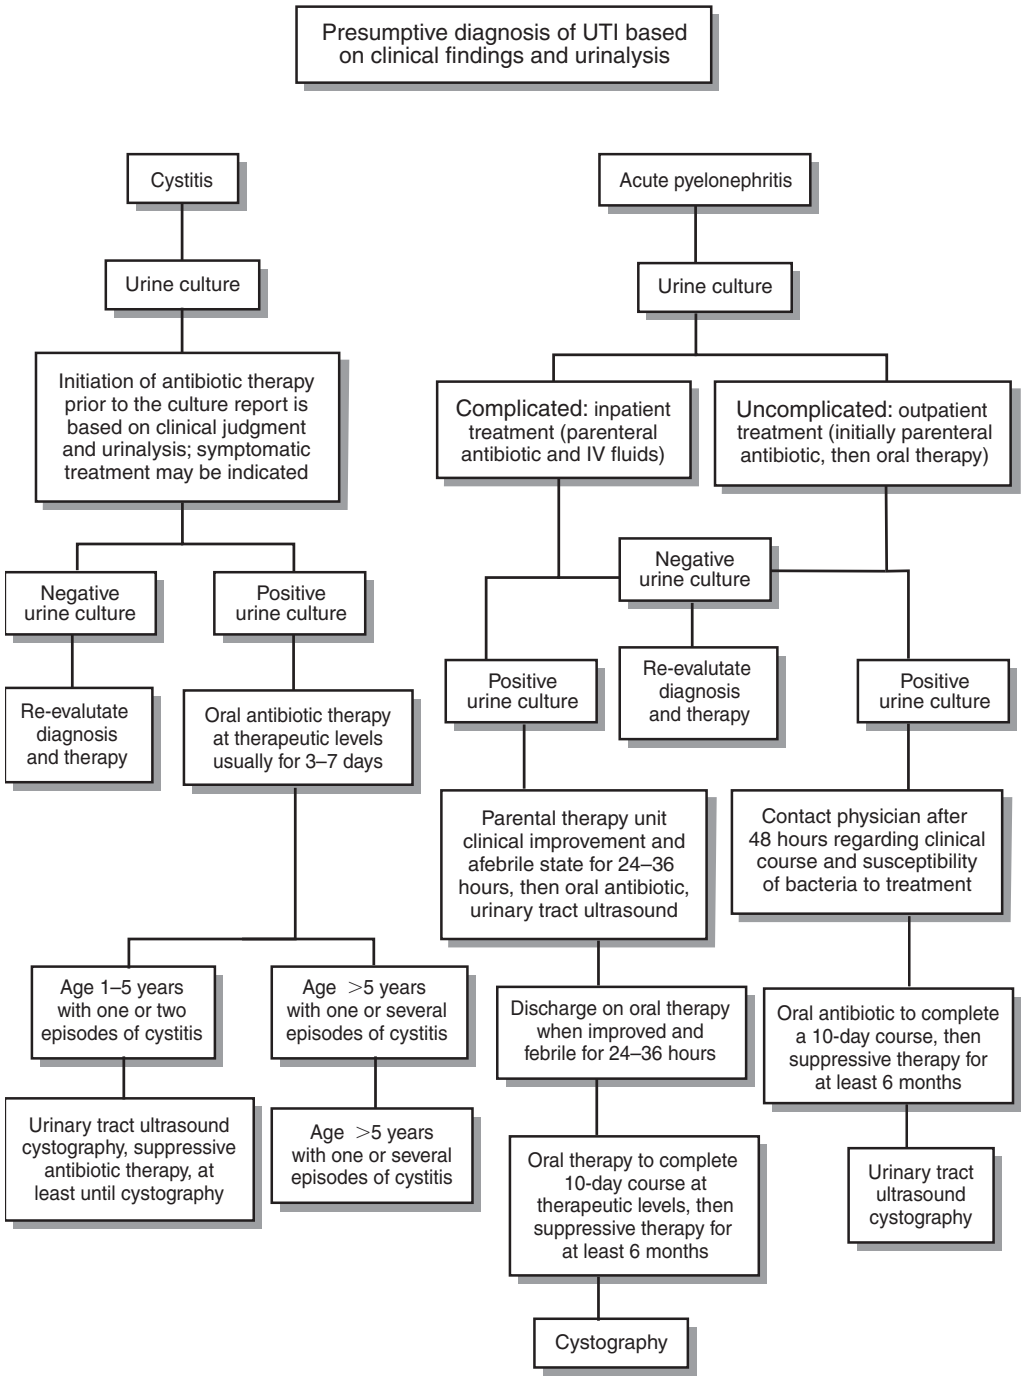

FIGURE 20-5. Algorithm for the evaluation and management of urinary tract infection in children. *IV*, intravenous. From Hellerstein S: Urinary tract infections in children. *Am Fam Phys* 57:2445, 1998.

Routine reculturing of the urine after 2 days of antimicrobial therapy is generally not necessary if the patient has had the expected clinical response and the bacteria isolated is determined to be sensitive to the antimicrobial being administered. If a patient does not improve, or the bacteria is resistant to the antimicrobial, a repeat urine culture is warranted after 48 hours of treatment. Approximately 30% of children under 12 months of age have recurrent UTIs. A majority of the recurrences occur within 6 months of the primary episode.

Antibiotic prophylaxis is indicated in children with VUR. The antibiotics of choice are cephalexin or amoxicillin in children younger than 2 months of age and trimethoprim–sulfamethoxazole or nitrofurantoin in children older than 2 months of age. All agents should be given as a single daily dose (Table 20-13). Deflux

TABLE 20-12

  - Amoxicillin
  - Trimethoprim–sulfamethoxazole

therapy, involving transurethral endoscopic submucosal injection of a biodegradable gel to decrease VUR, has shown some success. Surgical reimplantation may be needed in children with severe VUR and breakthrough infections.

HYPERTENSION

Normal blood pressure in children and adolescents is defined as systolic and diastolic blood pressure readings that are less than the 90th percentile for age, sex, and height. **Prehypertensive blood pressure** is defined as average systolic or diastolic pressure readings between the 90th and the 95th percentile for age, sex, and height. **Hypertension** is defined as average systolic or diastolic blood pressure readings, taken on at least three

TABLE 20-13

Antimicrobials for Prophylaxis of Urinary Tract Infection

Children <2 months

- Cephalexin
  10 mg/kg/day (single dose)
- Amoxicillin
  15–20 mg/kg/day (single dose)

Children >2 months

- Trimethoprim—sulfamethoxazole
  2–4 mg/kg/day of trimethoprim, 10–20 mg/kg/day of sulfamethoxazole (single dose)
- Nitrofurantoin
  1–2 mg/kg/day (single dose)

separate occasions, greater than or equal to the 95th percentile for age, sex, and height (Tables 20-14 and 20-15). **Hypertensive emergency** can be defined as an acute and severely elevated blood pressure that determines the occurrence of symptoms and signs directly attributable to high blood pressure (Table 20-16).

It is important to remember that normal blood pressure in children increases with age. For example, a blood pressure of 120/80 mm Hg is normal for an 18-year-old adolescent, but is definitely above the 95th percentile for a 5-year-old child.

Pathophysiology

Hypertension may be either primary, or essential, or secondary to another disease process. Primary hypertension is not a single disease entity, but is probably secondary to several mechanisms. A genetic component is likely; normotensive children of hypertensive parents have greater increases in blood pressure in response to stress or sodium loading than children of normotensive parents. Racial differences in these blood pressure responses are present, with exaggerated hypertensive responses more likely in black than in white children.

As children grow older, their blood pressures tends to track along a given percentile. Thus, children and adolescents with blood pressures above the 90th percentile for age are more likely to become adults with hypertension. There are other maturational differences in the pathophysiology of hypertension. For example, adolescents with primary hypertension are more likely to have elevated cardiac output and normal systemic vascular resistance, whereas adults with primary hypertension are more likely to have normal cardiac output and elevated systemic vascular resistance.

Clinical and Laboratory Evaluation

History

Most children with hypertension are asymptomatic; their condition is detected as the result of a routine examination (e.g., a preschool or precamp "physical"). Many children and adolescents with blood pressure levels at or just greater than the 95th percentile are overweight and have family histories of hypertension.

It is important to enquire about inherited renal diseases (e.g., polycystic kidney disease), early cardiovascular disease, stroke, or hypercholesterolemia in other family members. A history of hematuria, proteinuria, polyuria, or frequent UTIs may suggest underlying parenchymal renal disease. The presence of weight loss, sweating, flushing, fevers, palpitation, or weakness may suggest an underlying endocrine problem. A thorough history should include the neonatal period, with emphasis on the use of umbilical catheters, present and past history of renal or urologic disorders, and use of medications.

Initially, symptoms may include headache and blurry vision. With more severe and chronic hypertension, these may progress to seizures, stroke, coma, congestive heart failure, and renal failure. Hypertensive neonates often have feeding difficulties, respiratory distress, irritability, lethargy, or congestive heart failure.

Physical Examination

Accurate measurement of blood pressure is critical. It is important to reduce the level of patient anxiety and select a cuff of the proper size. The length of the cuff should cover at least two-thirds of the length of the upper arm, and the bladder of the pressure cuff should nearly encircle the upper arm with no overlapping of the ends.

A cuff that is too small yields an artificially elevated blood pressure. If the child's arm size seems to be between sizes of available blood pressure cuffs, the error in blood pressure measured with too large a cuff is smaller than the error in blood pressure measured with too small a cuff. Doppler and oscillometric techniques may be useful in infants and young children.

Blood pressure increases gradually with age, and reference standards must be used (see Tables 20-14 and 20-15). Blood pressure that is consistently above the 95th percentile for age on several repeated measurements over several weeks warrants further evaluation.

The physical examination should explore for evidence of secondary hypertension and end-organ damage (e.g., eyes, heart, vessels, kidneys, brain). Always measure blood pressure in all four extremities at least once to evaluate for the presence of coarctation of the aorta. Always palpate the femoral and radial pulses simultaneously when evaluating a patient with hypertension. A weak femoral pulse or a radial–femoral delay is an indication of coarctation of the aorta as the cause of the hypertension.

Other physical findings that may provide clues about secondary illnesses include abdominal bruits (**renal artery stenosis**); café au lait spots (**neurofibromatosis**); abdominal or flank masses (**renal conditions, tumors**); and striae and cushingoid features (**Cushing syndrome**).

The 90th percentile is 1.28 *SD*, the 95th percentile is 1.645 *SD*, and the 99th percentile is 2.326 *SD* over the mean.
BP, blood pressure; *DBP*, diastolic blood pressure; *SBP*, systolic blood pressure.
Adapted from the National High Blood Pressure Education Program Working Group on Hypertension Control in Children and Adolescents.

TABLE 20-16

Classification of Hypertension in Children and Adolescents, with Measurement Frequency and Therapy Recommendations

	SBP or DBP Percentile[a]	*Frequency of BP Measurement*	*Therapeutic Lifestyle Changes*	*Pharmacologic Therapy*
Normal	<90th	Recheck at next scheduled physical examination	Encourage healthy diet, sleep, and physical activity	—
Prehypertension	90th to <95th or if BP exceeds 120/80 even if <90th percentile up to <95th percentile[b]	Recheck in 6 month	Weight-management counseling if overweight; introduce physical activity and diet management[c]	None unless compelling indications such as chronic kidney disease, diabetes mellitus, heart failure, or LVH exist
Stage 1 hypertension	95th–99th percentile plus 5 mm Hg	Recheck in 1–2 week or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 mo	Weight-management counseling if overweight; introduce physical activity and diet management[c]	Initiate therapy based on indications in Table 20-6 or if compelling indications (as shown above) exist
Stage 2 hypertension	>99th percentile plus 5 mm Hg	Evaluate or refer to source of care within 1 week or immediately if the patient is symptomatic	Weight-management counseling if overweight; introduce physical activity and diet management[c]	Initiate therapy[d]

[a] For gender, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.
[b] This occurs typically at 12 years of age for *SBP* and at 16 years of age for *DBP*.
[c] Parents and children trying to modify the eating plan to the Dietary Approaches to Stop Hypertension Study eating plan could benefit from consultation with a registered or licensed nutritionist to get them started.
[d] More than one drug may be required.
BP, blood pressure; *DBP*, diastolic blood pressure; *LVH*, left ventricular hypertrophy; *SBP*, systolic blood pressure.

It must be emphasized that blood pressure is not static but varies, and a more accurate representation of blood pressure may be determined by an average of multiple blood pressure measurements. To document blood pressure changes at home and at school, 24-hour ambulatory blood pressure monitoring is used. This helps determine nocturnal and diurnal variations, including preservation of nocturnal dipping, and evaluate response to antihypertensive therapy.

Laboratory Evaluation

Severe blood pressure elevation warrants aggressive evaluation, regardless of age. In contrast, asymptomatic adolescents with mild blood pressure elevation may require only minimal studies.

Initial laboratory evaluation, including CBC, serum chemistries, BUN, SCr, and urinalysis, may suggest the presence of an identifiable cause. Children with renal parenchymal disease may have abnormal urinalysis or elevated BUN and SCr. Children with renovascular disease often have elevated plasma renin activity. If plasma renin activity is below normal, it may indicate the presence of mineralocorticoid excess. A lipid profile should be obtained, especially in overweight children and adolescents.

Imaging studies include chest radiography and renal ultrasound. Echocardiography is more sensitive than electrocardiography (ECG) for detecting left ventricular hypertrophy.

More sophisticated laboratory and imaging studies are necessary in selected patients. Captopril renal scan, magnetic resonance arteriography, or renal vein renin sampling may be useful for the evaluation of renovascular hypertension. Measurement of catecholamines in urine or plasma is indicated when pheochromocytoma is a strong clinical possibility.

Differential Diagnosis

Hypertension may be either primary (essential) or secondary to another disease process. The younger the patient, the greater the likelihood that the hypertension is secondary. Potential causes of secondary hypertension include abnormalities of renal, endocrine, cardiovascular, and neurologic systems as well as reactions to drugs or toxins (Table 20-17). Renal parenchymal disease accounts for 60% to 80% of secondary hypertension in children.

Management

For patients with primary (essential) hypertension, initial treatment is usually nonpharmacologic unless blood pressure is dangerously high or symptoms are present. Therapeutic measures include weight reduction, a decrease in dietary sodium intake, and initiation of a regular exercise program.

For patients with secondary hypertension, management is directed both at control of blood pressure and correction of the primary pathologic process, if possible. Treatment of renal artery stenosis may involve catheter angioplasty; surgical resection (e.g., for coarctation of the aorta); and appropriate pharmacologic therapy (e.g., for other primary diseases).

For those children with more severe or persistent hypertension and those with end-organ involvement (e.g., left ventricular hypertrophy, hypertensive retinopathy), the use of antihypertensive pharmacotherapy is warranted. Many different medications are now available (Table 20-18). In general, hypertension related to renal parenchymal disorders with elevated plasma renin levels respond well to angiotensin-converting enzyme (ACE) inhibitors, which decrease the formation of angiotensin II and aldosterone. Calcium channel antagonists are effective antihypertensive agents. Other useful agents include diuretics, β-adrenergic antagonists, and vasodilators. Angiotensin receptor antagonists are a new group of antihypertensive drugs that may be more commonly used in children in the near future. The fourth report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents gives recommendations for management based on the classification of hypertension (see Table 20-16).

In hypertensive emergencies, the goal of therapy is to prevent hypertension-related adverse effects by a controlled reduction of blood pressure, allowing for the preservation of target organ function and minimizing the complications of therapy. Placement on a cardiac monitor is essential, and establishment of intravenous access is appropriate. An arterial line to confirm the blood pressure cuff readings and to guide therapy may be necessary. Treatment should occur in an intensive care unit, where therapy should begin as soon as possible.

A reasonable objective in most hypertensive emergencies is to lower the blood pressure by approximately 25% to 30% over a period of several minutes to several hours, depending on the clinical situation. It is important to avoid precipitous reduction in blood pressure, and reductions to normotensive or hypotensive

TABLE 20-17

Differential Diagnosis of Secondary Hypertension

Peripheral Vascular Causes
Coarctation of the aorta
Renal artery or vein thrombosis (premature infants with umbilical catheters)
Renal artery stenosis
Fibromuscular dysplasia
Neurofibromatosis
Arteritis
Sarcoidosis
Renal Causes
Congenital lesions
Obstructive uropathies
Dysplastic or polycystic kidneys
Acquired lesions
Glomerulonephritis
Henoch-Schönlein purpura
Hemolytic-uremic syndrome
Nephrotic syndrome
Collagen vascular disease (systemic lupus erythematosus)
Alport syndrome
Vesicoureteral reflux
Drugs (cyclosporine, steroids)
Toxins (lead)
Endocrine Causes
Pheochromocytoma
Neuroblastoma
Adrenogenital syndrome
Cushing syndrome
Diabetic nephropathy
Hyperparathyroidism
Hyperaldosteronism
Hyperthyroidism

TABLE 20-17

Differential Diagnosis of Secondary Hypertension *(Continued)*

Neurologic Causes
Neurofibromatosis
Increased intracranial pressure
Intracranial hemorrhage
Encephalitis
Guillain-Barré syndrome
Riley-Day syndrome
Quadriplegia

levels should be avoided because they may provoke end-organ ischemia or infarction. Maintenance of an initial target blood pressure over several days and subsequent reduction to normotensive levels over several weeks is appropriate. Short-acting parenteral therapy is recommended for successful and safe management. Effective medications for the treatment of hypertensive emergencies in children include sodium nitroprusside, labetalol, and nicardipine. Once blood pressure is stabilized with intravenous drugs, oral antihypertensive agents should gradually be introduced.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA) is a clinical–biochemical syndrome characterized by impaired renal acidification. It involves the reabsorption of HCO_3^- or the excretion of H^+ and expression by hyperchloremic metabolic acidosis and minimal or absent renal insufficiency. There are three different types of RTA based on clinical and functional studies: (1) proximal RTA, or type 2; (2) distal RTA, or type 1; and (3) hyperkalemic RTA, or type 4.

Pathophysiology

Acidification of the urine can be viewed as a coordinated two-step process. The first step is the reabsorption of filtered HCO_3^- in the proximal tubule. The second step is excretion of fixed acids through the titration of urinary buffers and the excretion of NH_4^+ in the distal tubule.

In **proximal HCO_3^- reabsorption,** 80% to 90% of the filtered load of HCO_3^- is reabsorbed in the proximal tubule. The primary processes that occur in this segment are H^+ secretion at the luminal membrane via a specific Na^+–H^+ exchanger and HCO_3^- transport at the basolateral membrane via a Na–HCO_3^- cotransporter (Figure 20-6).

In **distal urinary acidification,** the primary processes are reclamation of the 10% to 20% of the remaining HCO_3^- that escaped proximal reabsorption, titration of divalent basic HCO_3^{2-}, which is converted to the monovalent acid form or titratable acid, and accumulation of NH_3 intraluminally, which buffers H^+ to form nondiffusible ammonium (NH_4^+) (Figure 20-7).

Proximal RTA (type 2), which is caused by an impairment of HCO_3^- reabsorption in the proximal tubule, is characterized by a decreased renal HCO_3^- threshold. Distal acidification remains intact, and when plasma HCO_3^- concentration decreases to a level below the renal threshold, patients may lower urine pH below 5.5 and excrete adequate amounts of NH_4^+

Distal RTA (type 1), which is caused by impaired distal acidification, is characterized by the inability to maximally lower urine pH (less than 5.5) under the stimulus of systemic acidemia. The impaired excretion of NH_4^+ is secondary to this defect.

Hyperkalemic RTA (type 4), which involves an acidification defect that is primarily caused by impaired renal genesis of ammonia, is characterized by a normal ability to acidify the urine after an

acid load. However, net acid excretion remains subnormal due to a very low rate of NH_4^+ excretion. The decrease in NH_3 production is largely caused by hyperkalemia. Aldosterone deficiency or resistance may also play a role.

Clinical and Laboratory Evaluation

History

A pediatrician may suspect RTA during the workup of children with failure to thrive. Children may have a history of repetitive episodes of dehydration, with vomiting, anorexia, or constipation. Others may present with clinical manifestations of electrolyte depletion such as periodic paralysis secondary to hypokalemia. In some cases, symptoms and signs of kidney stones may precede the diagnosis of RTA. Renal deposition of calcium salts (nephrocalcinosis), thought to be the result of hypercalciuria and hypocitraturia, may occur.

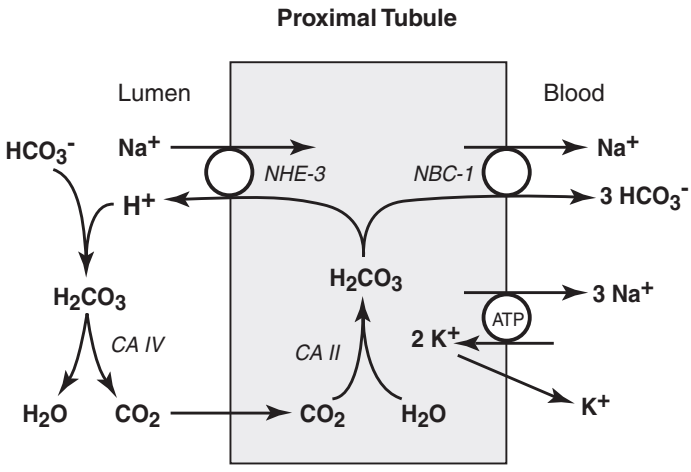

FIGURE 20-6. Schematic model of HCO_3^- reabsorption in the proximal tubule. The processes shown are H+ secretion at the luminal membrane via a specific Na^+–H+ exchanger (NHE-3) and HCO_3^- transport at the basolateral membrane via a Na^+– HCO_3^- cotransporter (NBC-1). Cytoplasmic carbonic anhydrase II (CA II) and membrane-bound carbonic anhydrase IV (CA IV) are necessary for reabsorption of HCO_3^-

Physical Examination

Physical examination may reveal only growth retardation. Other clinical findings may include signs of dehydration secondary to diarrhea or polyuria. In some cases, examination suggests a secondary cause of the RTA (e.g., cystine crystals in the cornea in patients with cystinosis, neurologic involvement in Lowe syndrome, jaundice in hepatic diseases).

Laboratory Evaluation

The first step in the evaluation of children with metabolic acidosis is calculation of the **plasma anion gap** (Figure 20-8). The plasma anion gap is calculated by the difference between the sum of the major plasma cations (Na^+ + K^+) and the major anions (Cl^- +HCO_3^-). However, because of the relatively low and stable serum concentration of K^+, it has only a minor influence on the plasma anion gap.

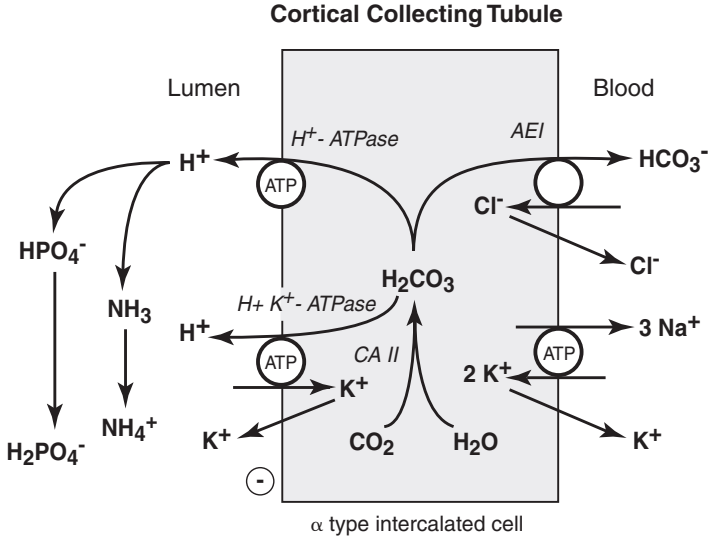

FIGURE 20-7. Schematic model of H^+ secretion in the cortical collecting tubule. The process shown is luminal H^+ secretion in the α-type intercalated cell by a H^+-ATPase (main pump) and by a H^+,K^+-ATPase. Intracellularly formed HCO_3^- leaves the cell via Cl^-- HCO_3^- exchange, facilitated by an anion exchanger (AE1). Cytoplasmic carbonic anhydrase II (CA II) is necessary for secretion of H^+.

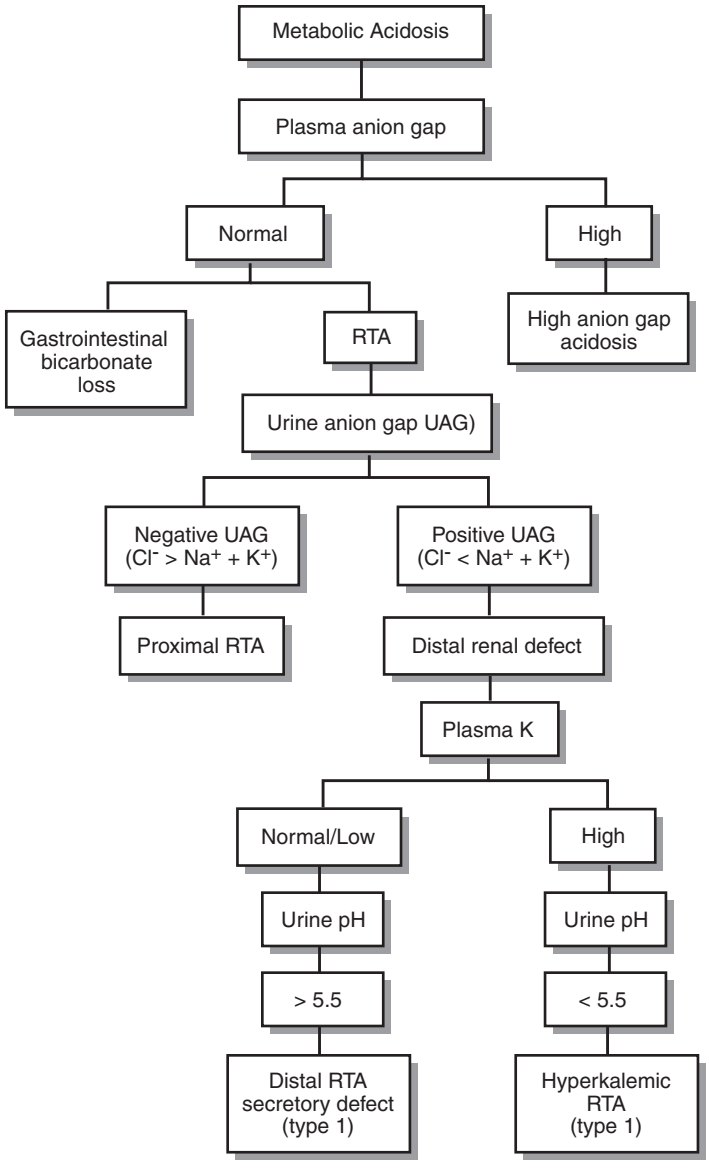

FIGURE 20-8. Algorithm representing the evaluation of children with renal tubular acidosis (RTA).

$$\text{Plasma anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

If the plasma anion gap is normal (12 ± 4 mEq/L), the possibility of GI losses of HCO_3^- or RTA should be considered.

URINARY ANION GAP. This value is an indirect index of urinary NH_4^+ excretion. It is estimated by using the measured concentration of electrolytes in the urine: Na^+, K^+, and Cl^-; NH_4^+ is not directly measured. A normal renal response to metabolic acidosis is an increase in the excretion of NH_4^+ in the urine, and NH_4^+ is usually excreted in the urine along with Cl^-. Any increase in the excretion of NH_4^+ during metabolic acidosis is accompanied by an increase in the excretion of Cl^-. Therefore, a negative urine anion gap ($[Cl^-] > [Na^+] + [K^+]$) reflects an increased excretion of NH_4^+. If urine NH_4^+ does not increase, the urine anion gap becomes positive ($[Cl^-] < [Na^+] + [K^+]$), which suggests a distal acidification defect.

Urine ph

This measurement has been used for diagnosis of distal RTA (type 1), the only type of RTA in which the urine pH cannot decrease below 5.5 to 6.0, regardless of the severity of the acidosis. A urine pH of more than 6.0 in

the setting of metabolic acidosis suggests a defect in distal acidification. However, the urine pH may be misleading. Although urine pH of less than 5.5 rules out distal RTA (type 1), it does not ensure a normal distal acidification because it does not reflect the rate of NH_4^+ excretion.

It is important to assess the **plasma potassium** for characterization of RTA. Distal RTA is characterized by hypokalemia due to an increased excretion of potassium in the collecting duct. In hyperkalemic RTA (type 4), a low rate of NH_4^+ excretion is associated with hyperkalemia.

Other Studies

In specific cases, other tests may be necessary. Examples include fractional excretion of HCO_3^- to confirm the diagnosis of proximal RTA, urine PCO_2 to confirm distal RTA, and renin and aldosterone levels for hyperkalemic RTA. In addition, a kidney ultrasonogram aids in the diagnosis of nephrocalcinosis and urolithiasis, which may develop in children with RTA.

CASE 20-4

A 5-year-old girl presents with failure to thrive. She has no history of GI losses. Serum electrolyte values are Na^+, 136 mEq/L; Cl^-, 111 mEq/L; and HCO_3^-, 13 mEq/L. Urine electrolyte values are Na^+, 30 mEq/L; Cl^-, 40 mEq/L; and K^+, 20 mEq/L. Urine pH is 6.5.

Step 1: Calculation of plasma anion gap

Plasma anion gap = $Na^+ - (Cl^- + HCO_3^-)$ 136 – 124 = 12 mEq/L
This value is consistent with normal anion gap acidosis.

Step 2: Calculation of urine anion gap

The serum electrolyte value for Cl^- (40 mEq/L) is less than the sum of the values for $Na^+ + K^+$ (50 mEq/L), which denotes a positive urinary anion gap. This is consistent with low NH_4^+ excretion and a defect in distal acidification (type 1 versus type 4).

Step 3: Evaluation of plasma K

K^+ is normal. Therefore, this rules out hyperkalemic RTA (type 4).

Step 4: Evaluation of urine pH

The urine pH is 6.5, which confirms the inability to acidify the urine during acidemia and distal RTA (type 1).

Differential Diagnosis

Proximal RTA (type 2) is most commonly observed in children with Fanconi syndrome, which is a condition of global proximal tubule dysfunction, but it may also occur as a primary or inherited disease. In children, distal RTA (type 1) is almost always observed as a primary inherited entity. Hyperkalemic RTA (type 4) is associated with low aldosterone states such as congenital adrenal hyperplasia, with aldosterone-resistant states such as pseudohypoaldosteronism, and with medications such as spironolactone and ACE inhibitors.

Management

The first goal in the treatment of both proximal and distal RTA is the correction of the metabolic acidosis with the use of daily alkali supplementation. Generally, patients with proximal RTA need a larger dose of alkali than patients with distal RTA. The correction of the acidosis improves the growth rate significantly and may reduce the risk of nephrocalcinosis. Potassium abnormalities should be corrected. Hypokalemia is treated with potassium supplementation, whereas hyperkalemia may need a potassium-restricted diet, diuretics, or potassium-binding exchange resins.

ACUTE AND CHRONIC RENAL FAILURE

ARF is defined as a rapid deterioration of renal function associated with the accumulation of nitrogenous waste products in the body and is associated with significant morbidity and mortality. The terminology has been changed from ARF to acute kidney injury (AKI) to focus attention on early recognition and treatment of renal

insult. Graded AKI classification systems like the RIFLE criteria (risk, injury, failure, loss, and ESRD) identify patients at risk for developing significant kidney insult by changes in SCr and duration of decreased urine output. However, the urine volume in AKI may vary over a wide range, from oliguric (less than 300 mL/m^2/day) and oligoanuric to nonoliguric.

Chronic renal failure (CRF) is characterized by a slow and progressive decrease in kidney function over time. CRF includes a broad spectrum of functional impairment, from a GFR of 80 mL/min/1.73 m^2 to as low as 10 mL/min/1.73 m^2. **ESRD** is present when the GFR is 10 mL/min/1.73 m^2 or below and renal replacement therapy is needed to maintain life.

Etiology

The causes of AKI in children have changed from primary kidney diseases to secondary effects of other systemic illnesses from their treatment. The most common causes are congenital heart disease, sepsis, and nephrotoxic medications.

Pathophysiology

Several hypotheses regarding the pathophysiology of AKI have been suggested. The **vascular/hemodynamic theory** states that hemodynamic events are important factors in the pathogenesis. Three events may account for the decrease in glomerular filtration: (1) a constriction of the afferent arteriole; (2) a dilatation of the efferent arteriole; and (3) a decrease in permeability of the glomerular capillaries. Different hormones may be responsible for these hemodynamic abnormalities (e.g., angiotensin II, thromboxane A_2, endothelin). The **tubular obstruction theory** states that the glomerular filtration may be decreased secondary to a tubular obstruction by cellular debris, increasing the hydrostatic pressure within the Bowman capsule. The **back leak theory** states that the glomerular filtrate (including nonreabsorbable substances) may be reabsorbed because of disruption in the integrity of the tubular epithelium. In summary, the pathogenesis of AKI appears to be multifactorial and cannot be explained completely by any one of these theories alone.

The initial damage in CRF may be due to a wide spectrum of diseases that may present abruptly (as AKI) or insidiously. Different factors may be involved in the progressive deterioration of renal function. The **hyperfiltration theory** states that the surviving glomeruli can be damaged as a result of the increased filtered load to which they are exposed.

Clinical and Laboratory Evaluation

History

The history should focus on determining the probable cause of AKI. Hospitalized patients may develop AKI after a surgical procedure, an especially complex cardiovascular surgery, or after administration of nephrotoxic medications such as aminoglycosides and radiocontrast material. Patients at risk for developing AKI in the hospital are children with severe burns, trauma, sepsis, or tumors. A history of skin or throat infection, hematuria, and edema is suggestive of a **poststreptococcal glomerulonephritis**. In neonates, the use of umbilical artery catheters may predispose the patient to **renal artery thrombosis** and AKI. Abnormal prenatal or postnatal ultrasound may suggest a **congenital urinary tract abnormality** as a predisposing factor.

A family history of genitourinary diseases is an important consideration in any kidney disease. A history of poor growth and development, polyuria, polydipsia, enuresis, hematuria, edema, and hypertension suggests an underlying chronic abnormality. A history of **recurrent UTIs** or recurrent episodes of fever diagnosed as pharyngitis/otitis and treated with antibiotics could have been undiagnosed and undertreated UTIs. Anorexia, nausea, vomiting, headaches, and neurologic abnormalities may also be present, but are nonspecific. A family history of deafness, ocular abnormalities, hypertension, or cystic kidney disease may be indicative of an inherited renal disorder.

Hemolytic–uremic syndrome (HUS), is a common cause of AKI in infants and children. It is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and AKI. Two predominant types of HUS are identified. The classic form, D+ HUS, preceded by a prodrome of bloody diarrhea, accounts for 95% of cases, and is most commonly caused by an infection by shiga-toxin producing *E. coli*, especially serotype O157:H7. Atypical, or *D*-HUS, occurring without the diarrhea, may be familial, caused by mutations in the complement system activation, or sporadic, triggered by infection, cancer, drugs, or transplantation. Atypical HUS is associated with a poor prognosis and a high rate of progression to ESRD.

Physical Examination

Assessment of the state of hydration and volume status helps distinguish AKI from prerenal azotemia and establish the severity of the process. Many children with AKI will have diminished urine output, leading to fluid retention and edema. This may be iatrogenic, from attempts to increase urine output by increasing fluid intake. A height below the third percentile may be the first indicator of a kidney problem and by itself suggests an underlying chronic disorder. Vital signs, including blood pressure and weight changes, should be monitored closely. The blood pressure should be monitored periodically, and if elevated, funduscopic examination and an echocardiogram should be performed for evaluation of involvement of target organs. The presence of edema, purpura, or pallor should be assessed. Chest auscultation may be used to evaluate cardiac arrhythmias, tachycardia, or congested lungs. Hepatomegaly, palpable renal masses, or an abdominal bruit may be discovered on abdominal examination. It is important to rule out an enlarged bladder secondary to urinary retention. Signs of rickets and bone deformities may be present secondary to renal osteodystrophy.

Laboratory Evaluation

A urinalysis with renal tubular casts, tubular cells, and cellular debris suggests AKI. The absence of cellular elements and protein is most compatible with prerenal or postrenal azotemia. **Prerenal azotemia** is caused by diminished blood flow to a well-functioning kidney. **Postrenal azotemia** is a result of events occurring after urine formation, generally secondary to an obstruction to urine flow. In prerenal azotemia, as tubular function is preserved, urinary sodium concentration is low. As the concentration capacity remains intact, urinary osmolality is high. Normal tubular reabsorption results in the normal concentration of urinary nitrogenous waste products, increasing the urine plasma creatinine ratio. On the other hand, when the tubules are damaged, as in acute tubular necrosis, the urinary sodium concentration is high and the urine:plasma creatinine ratio is low because of impaired concentration capacity.

Serum electrolytes should be monitored very closely, including calcium, phosphorus, and magnesium. Hemoglobin, hematocrit, and platelet count may be decreased, and reticulocyte and WBC counts may be increased in HUS. Uric acid may be increased as a result of **tumor lysis,** whereas lactic dehydrogenase and creatine phosphokinase may be elevated in **rhabdomyolysis** (traumatic or nontraumatic muscle destruction causing myoglobinuria and AKI). Serum complement levels may be decreased in both **SLE** and **poststreptococcal glomerulonephritis**. Elevated antinuclear antibodies are suggestive of SLE. A throat culture and ASO or streptozyme are indicated if poststreptococcal glomerulonephritis is a consideration. Blood and urine cultures are indicated if an infection is suspected. A toxicologic screening of urine may be of help in the diagnosis of AKI secondary to **nephrotoxins.** Urinary biomarkers like **n-GAL** (neutrophil gelatinase associated lipocalin) are being developed for early diagnosis and risk stratification of AKI.

A chest radiograph may reveal pulmonary congestion and increased heart size resulting from fluid overload. An ECG may show alterations related to hyperkalemia or other electrolyte abnormalities. Radiologic evaluation may include a kidney ultrasound to assess kidney size, the presence of hydronephrosis, or cystic disease. A DMSA renal scan is of help in the diagnosis of renal scarring secondary to **VUR** or **pyelonephritis.** Bone radiographs may show signs of osteodystrophy such as subperiosteal decalcification. A kidney biopsy may be necessary for the diagnosis of the primary disease in mild-to-moderate CRF, but it will show nonspecific chronic scarring, fibrosis, and atrophy in advanced disease, making it very difficult to determine the precise underlying etiology of the CRF.

Periodic follow-up for evaluation of the degree of renal function is necessary in children with CRF. Assessment of serum electrolytes and acid–base status is routine, followed by treatment for metabolic complications such as **acidosis, hyperkalemia, hyperphosphatemia, hypocalcemia,** and **hyponatremia.** It is important to monitor calcium, phosphorus, parathyroid hormone, and alkaline phosphatase to prevent or ameliorate the complications of osteodystrophy. Hematocrit, hemoglobin, reticulocyte count, serum iron, ferritin, and transferrin are necessary for evaluation of anemia.

Differential Diagnosis

The processes contributing to AKI can frequently be identified from the patient's history. Both prerenal and postrenal factors may cause alterations in renal function with retention of nitrogenous waste products. It is important to distinguish these entities for appropriate therapeutic intervention. Several conditions may cause AKI (Table 20-19).

TABLE 20-19

Causes of Acute Kidney Injury in Children

Prerenal Azotemia
• Hypovolemia: dehydration, hemorrhage
• Hypotension: sepsis, heart failure
• Hypoxia: respiratory distress syndrome
• Renal vasoconstriction: drug effect
Intrinsic Renal Failure
• Ischemic disorders: hypovolemia, hypotension
• Nephrotoxins: aminoglycosides, radiocontrast agents, myoglobin, hemoglobin
• Diseases of glomeruli or small blood vessels: glomerulonephritis, hemolytic-uremic syndrome
• Major blood vessel disease: renal artery thrombosis or embolism, renal artery stenosis
• Interstitial nephritis: medications, infection, crystals
Obstructive Renal Failure (Postrenal)
• Congenital: ureteropelvic junction obstruction, posterior urethral valves
• Acquired: stones, abdominal/retroperitoneal tumors

It is important to make a specific diagnosis in children with CRF, even if the degree of renal failure is advanced and no specific therapy is available. Appropriate genetic counseling for families with hereditary or metabolic diseases and identification of potential living related donors for renal transplantation are facilitated by identifying the cause of CRF. Several diseases may cause CRF (Table 20-20).

Management

The management of AKI consists of supportive care until the kidneys recover from the acute renal insult. Patients with AKI require hospitalization, often in an intensive care unit. A careful balance of intake and output of fluids and electrolytes is extremely important. This approach may prevent or ameliorate the development of fluid overload (in oliguric AKI), of fluid depletion (in nonoliguric AKI), and of electrolyte abnormalities such as metabolic acidosis, hyponatremia, hyperkalemia, hypocalcemia, hyperphosphatemia, and hypermagnesemia. Worsening fluid overload has been shown to be an independent risk factor for mortality. A reasonable approach to fluid management is to restrict fluids to insensible losses (35 to 45 mL/kg/day) plus replacement of any output the patient might have (urine, vomiting, diarrhea, nasogastric tube drainage). The use of diuretics such as furosemide or renal-dose dopamine, have not been shown to be useful. Fenoldopam has been used to prevent AKI in some adult populations. Monitoring of serum electrolytes should occur at least daily. It is important to maintain an appropriate caloric and protein intake. Protein restriction (1 g/kg/day) may be indicated to slow the development of azotemia.

Early and aggressive initiation of renal replacement therapy is recommended in critically ill children with AKI (Table 20-21).

Children with CRF usually do not require hospitalization except for acute complications or for the initiation of dialysis. Patients are followed periodically for the side effects of uremia. The diet should be sufficient to provide the child's nutritional needs, hence a protein-restricted diet is rarely indicated to decrease the rate of progression of CRF. Sodium restriction may be appropriate in patients with edema or hypertension, but supplements are necessary in individuals with salt-losing nephropathies. Potassium restriction should be the primary approach to the prevention of hyperkalemia. Calcium gluconate, glucose and insulin, sodium bicarbonate, or potassium-binding

TABLE 20-20

Causes of Chronic Renal Failure in Children

Congenital
Renal dysplasia or hypoplasia, cystic disease, obstructive uropathy
Hereditary
Alport syndrome, juvenile nephronophthisis, congenital nephrotic syndrome
Acquired

Renal tumor
Metabolic
Diabetes, cystinosis, oxalosis

exchange resins (e.g., Kayexalate) may be needed to treat hyperkalemia. Initial management of hypertension involves sodium restriction, weight loss, and exercise. Pharmacologic treatment of hypertension is indicated if patients are symptomatic or if end-organ damage is evident. Renal osteodystrophy can be prevented with the use of calcitriol and phosphate binders.

Use of **recombinant human erythropoietin** is used to treat anemia. Significant improvement in growth velocity in the growth-delayed child with CRF is possible with the use of **recombinant human growth hormone.** The optimal treatment for the pediatric patient with ESRD is **renal transplantation** because it offers the greatest potential for complete rehabilitation. Dialysis is an important tool to maintain life until a successful transplantation can be accomplished (see Table 20-21).

TABLE 20-21

Indications for Dialysis in Children

AKI
• Symptomatic fluid overload unresponsive to conservative management
• Serious, life-threatening, or medically uncontrollable metabolic disturbances (hyperkalemia, intractable acidosis)
• Acute tubular necrosis associated with poisoning due to dialyzable or hemofilterable compound
CRF
• Early enough to prevent the development of severe malnutrition and uremic symptoms
• Decline in creatinine clearance to about 5–10 mL/min/1.73 m^2
• Fluid overload resulting in systemic hypertension or cardiovascular instability
• Severe restriction in fluid intake so that adequate nutrition cannot be provided
• Uncontrolled hyperkalemia, hyperphosphatemia, or acidosis
• Uremic signs or symptoms (e.g., changes in mental status, pericardial effusion)

AKI, acute kidney injury; *CRF*, chronic renal failure.

Rheumatology

Christy Sandborg

Juvenile rheumatic diseases are a family of inflammatory diseases that variably involve the musculoskeletal system, connective tissue, and vascular system. **Juvenile idiopathic arthritis (JIA)** is the most common type of rheumatic disease that affects children, followed by **systemic lupus erythematosus (SLE), juvenile dermatomyositis, vasculitis,** and **scleroderma.** Experts currently believe that autoimmunity is a key pathophysiologic feature. Although the precise precipitating events for these diseases are not known, many of them appear to be complex genetic traits with 12 to 20 genes contributing up to 30% to the risk of disease. Some of these genes are in the human leukocyte antigen (HLA) region of chromosome 6; however, many non-HLA genes also appear to be contributors, including genes that regulate the immune and inflammatory responses such as cytokines, immune regulatory receptors, complement components, and immunoglobulin receptors, as well as genes that regulate cell biology, including apoptosis regulatory proteins and signaling pathways. Many of these genetic associations have led to focused therapeutic development, leading to some of the most effective treatments we have today for these diseases. Other contributing factors to disease expression play equally important roles as genetics, including age, pubertal stage, and environmental triggers (e.g., sun exposure, infectious agents). Interestingly, some genes confer susceptibility to multiple autoimmune diseases, as indicated by families affected by multiple autoimmune diseases.

JUVENILE IDIOPATHIC ARTHRITIS

JIA is the most common rheumatic disease in children in the United States, affecting approximately 140/100,000 to 180/100,000 children. Arthritis (swelling or effusion, limitation of motion, tenderness or pain on motion, or increased heat) for longer than 6 weeks in one or more joints is a key feature. The onset of JIA may occur at any time before 16 years of age.

Pathophysiology

The currently accepted criteria for JIA recognizes five main categories of JIA, based on clinical features during the first 6 months of disease. These are **oligoarticular JIA, polyarticular JIA, systemic JIA, enthesopathy-related arthritis (juvenile spondyloarthropathy), and psoriatic arthritis** (Table 21-1). It is important to classify patients into a type for prognostic reasons; some forms of disease may be relatively benign, whereas others may lead to significant functional disability or even death (Table 21-2). In addition, some therapies are more effective in some categories than others.

Clinical and Laboratory Evaluation

History

Age and developmental level are important factors to consider in the history because arthritis in children can begin at any age from 8 months through adolescence. Young children with significant joint swelling and inflammation may not complain directly of pain, so careful questioning of parents regarding the presence of morning stiffness, limp, or decreased use of an extremity may be helpful. As children grow older, their perception of pain or lack of function improves, but fear, anxiety, and denial continue to affect their expression of pain. Parental observation continues to be a key element in the history, in addition to the clinical features that are characteristic of

TABLE 21-1

Categories of Juvenile Idiopathic Arthritis

Characteristic	*Oligoarticular*	*Polyarticular (RF− or RF+)*	*Systemic*	*Spondyloarthropathy or Enthesopathy-Related Arthritis*	*Psoriatic Arthritis*
Percent of patients (%)	30–45	30–35	10–15	10–20	5–10
Number of inflamed joints	<5	≥5	Variable	Variable	Variable
Peak age of onset (years)	1–3	Variable	Variable	7–16	Variable
Female–male ratio	4–5:1	3:1	1:1	1:3–4	3:1

RF, rheumatoid factor.

each type of JIA (Table 21-3). The recent identification of anticyclic citrullinated peptide antibody as a risk factor for more severe disease in rheumatoid arthritis has been evaluated to some extent in JIA and may be important in JIA as well, especially in association with RF+ (rheumatoid factor positive) polyarticular JIA.

Physical Examination

Careful examination of the musculoskeletal system is necessary to document the presence of true **synovitis,** which is defined as either joint swelling or joint pain or tenderness with limitation of motion. References that show the normal ranges of motion for all joints and the approach to the musculoskeletal examination in children are available. The number of joints involved and the severity of involvement are important to assess for both diagnostic and management purposes (see Table 21-3).

TABLE 21-2

Prognosis in Juvenile Idiopathic Arthritis without Appropriate Treatment

Oligoarticular Onset
About 70% generally good, 30% have progressive disease with addition of more joints (oligoarticular, extended) progressing to destructive arthritis
30% of affected eyes can develop visual loss if the disease is unrecognized and untreated
Polyarticular Onset
40%–50% of patients progress to destructive arthritis; after 15 years, 50% are significantly disabled
Systemic Onset
After 15 years, 50% of patients are significantly disabled
Spondyloarthropathy or Enthesopathy-Related Arthritis
Variable; may develop into classical ankylosing spondylitis
Psoriatic Arthritis
40%–50% of patients progress to destructive arthritis; after 15 years, 50% are significantly disabled

TABLE 21-3

Clinical Features of Juvenile Idiopathic Arthritis (JIA)

	Type of JIA				
	Oligoarticular	*Polyarticular*	*Systemic*	*Spondyloarthropathy Enthesopathy-Related Arthritis*	*Psoriatic Arthritis*
Pattern of joint involvement	Large joints; asymmetrical; sparing hips May extend to polyarticular involvement in minority	Both small and large joints; symmetrical	Polyarticular or oligoarticular pattern	Large joints; lower extremity (sacroiliac, hips, knees, ankles); frequent enthesitis	Dactylitis Polyarticular or oligoarticular pattern
Other extra-articular features	Otherwise healthy	Possible low-grade constitutional symptoms; nodules if RF-positive	High, spiking fevers; evanescent, salmonpink, macular rash; hepatosplenomegaly; adenopathy; anemia; pericarditis; macrophage activation syndrome	Acute anterior uveitis; urethritis; keratoderma blennorrhagica; inflammatory bowel disease	Psoriasis; nail pits; oncholysis
Subacute anterior uveitis	20–50% (ANA+) 15% (ANA−)	15% (ANA+) 10% (ANA−)	Rare	Acute symptomatic anterior uveitis	20%–50%
ANA	60%	35%–40%	<10%	<10%	50%
RF	Negative	20%, usually in older children	Negative	Rare	Rare
Ferritin (mg/dL)	Normal	Normal	Highly elevated in macrophage activation syndrome complicating systemic JIA (levels often greater than 2500 mg/dL)	Negative	Negative
WBC count (cells/μL)	Normal	8,000–15,000	15,000–30,000	8,000–15,000	
Hgb (g/dL)	Normal	10–12	6–10	Normal	
ESR (mm/h)	5–40	20–80	50–150	5–60	
CRP (mg/dL)	Mild elevation or normal	Mild-to-moderate elevation	Moderate to marked elevation	Mild elevation or normal	Mild elevation or normal

ANA, antinuclear antibody; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *Hgb*, hemoglobin; *RF*, rheumatoid factor; *WBC*, white blood cell.

Careful general examination is required to detect evidence of nonarticular pathology in JIA. Fever and rash are characteristic of the systemic form of JIA, and the presence of these findings either by history or by physical examination should prompt careful evaluation for other associated findings such as pneumonitis, pericarditis, hepatosplenomegaly, lymphadenopathy, and coagulopathies. Tachycardia, tachypnea, and irritability may be indications of serious systemic disease.

A potentially fatal condition known as **macrophage activation syndrome** occurs in a minority of children with systemic JIA. This syndrome, also called acquired hemophagocytic lymphohistiocytosis, can be associated with severe systemic disease or triggered by drugs or intercurrent viral illnesses. It is manifested by disseminated intravascular coagulation, leukopenia, anemia, thrombocytopenia, and marked hyperferritinemia as well as hepatic, pulmonary, and central nervous system involvement. Rapid recognition of this complication facilitates prompt, aggressive treatment to prevent severe morbidity or mortality.

Ophthalmologic inflammatory changes such as **subacute anterior uveitis** may occur, but physical findings are subtle. Neither conjunctival irritation nor significant complaints of eye pain usually are present. **Synechia** (irregular pupillary margins), cloudy anterior chambers, and cataracts may be seen in advanced cases, but in mild or early involvement, ophthalmologic slit lamp examination may be the only way to detect inflammatory changes in the anterior chamber. Acute iritis, which does involve acute onset of pain and conjunctival erythema, is associated with the enthesopathy-related arthropathies.

Pediatric Pearl: The uveitis associated with JIA, which is most commonly seen with the oligoarticular type of disease, is asymptomatic. Serial slit lamp examinations, performed as many as four times per year in high-risk patients, have successfully decreased the incidence of permanent eye damage from uveitis.

Laboratory Evaluation

No specific diagnostic test for the confirmation of JIA is available. The presence of autoantibodies, especially antinuclear antibody (ANA) and RF, are not specific to any particular type of JIA, although some trends are evident (see Table 21-3). In children with systemic JIA who have very high fevers or appear toxic, presence of the coagulopathy associated with macrophage activation syndrome should be rapidly assessed.

Synovial fluid analysis is important when joint infection is being considered as a possible diagnosis, especially important when children present with a single joint. Septic arthritis and osteomyelitis occur in the same age group (1 to 4 years) as oligoarticular JIA. Typically, synovial fluid in JIA is an inflammatory exudate with a white blood cell (WBC) count of 10,000 to 50,000 cells/μL, primarily neutrophils, and few red blood cells. In contrast, septic arthritis is usually associated with higher WBC count (from 50,000 to more than 100,000 cells/μL). Because crystal arthropathies such as gout are exceedingly rare in children and adolescents, synovial fluid analysis to look for crystals is rarely necessary. Synovial biopsy, which is infrequently performed for diagnostic purposes, usually shows marked lymphocytic infiltration.

Imaging studies may be helpful in determining the severity of synovitis in JIA. Plain radiographs usually are normal in early or mild disease, but cartilage loss, periarticular osteoporosis, erosions, sclerosis, subchondral lucency, and deformity may be visible in long-standing or severe disease. Radiographic evidence of sacroiliitis with sclerosis and erosions of the sacroiliac joints is diagnostic for juvenile ankylosing spondylitis. Magnetic resonance imaging (MRI) is becoming a very useful modality to determine the extent of synovitis and cartilage involvement and to exclude other diagnoses such as trauma.

Differential Diagnosis

Three major conditions should be considered in the differential diagnosis of JIA: trauma, infection, and neoplasm. Trauma is usually excluded based on history, clinical, and laboratory findings.

It is essential to rule out a bone or joint infection in oligoarticular JIA, which often manifests initially in one joint, most frequently the knee or ankle. The high fevers, leukocytosis, and elevated acute phase reactants seen in systemic JIA should prompt a comprehensive evaluation to exclude infection. **Acute rheumatic** fever may account for a recent onset of arthritis and fever (see Chapter 13). **Lyme arthritis,** which usually presents 1 to 2 years after exposure to the tick-borne *Borrelia burgdorferi*, is generally oligoarticular (see Chapter 9). Diagnosis depends on potential exposure. Laboratory evaluation for Lyme disease includes confirmation of a positive enzyme-linked immunosorbent assay test with a western blot or similar test for multiple *B. burgdorferi* proteins.

Neoplastic disease is another important differential to be considered. Twenty percent of children with acute leukemia present with bone pain, and in many cases this is so early in the course of disease that no abnormal cells may be seen in the peripheral smear. Rarely are there large synovial swellings in leukemia, but periarticular swelling and pain or point tenderness may be evident. Lymphoma, neuroblastoma, and bone cancers can also present with features suggestive of arthropathy.

Other juvenile rheumatic diseases may present initially with arthritis, including SLE, sarcoidosis, and vasculitis. Clinical and laboratory features help distinguish these diseases from JIA (see the following sections).

Pediatric Pearl: Bone pain is a common presentation of childhood leukemia. Thus, when evaluating arthritis in children with an unusual clinical presentation (e.g., low-grade fever, weight loss, bone pain out of proportion to physical findings) and a low or low-normal total WBC count with lymphocyte predominance or atypical lymphocytes, or thrombocytopenia, bone marrow examination is necessary.

Management

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a mainstay of systemic treatment of JIA (Table 21-4) followed by low-dose methotrexate. The major complications of low-dose methotrexate therapy are hepatic toxicity, allergies, mild bone marrow suppression, and, rarely, pneumonitis. It is rare for permanent or serious complications to occur in children with methotrexate. In cases where methotrexate and NSAIDs have not achieved disease control, the newer family of biologic therapies has been highly effective. The most widely used

TABLE 21-4

Management of Juvenile Idiopathic Arthritis

Standard First-Line and Second-Line Therapy for Low–Moderate-Risk Disease Categories[a]
Start with NSAIDs.
Consider initiation of low-dose methotrexate (0.3–0.6 mg/kg/wk) if significant synovitis involving multiple joints persists for 3–6 months or radiologic evidence of destructive disease is present.
Consider intra-articular corticosteroid injection(s) if significant synovitis persists in ≤2 joints for 3–6 months.
Use sulfasalazine in spondyloarthropathy.
Lack of Response to Standard First-Line and Second-Line Therapy or High-Risk Disease Categories[b]
Consider parenteral methotrexate weekly (up to 1 mg/kg/wk).
Use TNF inhibitors (etanercept, adalimumab) approved for JIA, infliximab approved in adult RA.
Consider systemic corticosteroid therapy in appropriate cases (see Table 22-5)
Consider IL-1 or IL-6 inhibitors especially in systemic JIA (in trials, approved for adult RA)
Consider anti-CTLA Ig (abatacept, approved for JIA)
Consider anti B cell therapies (rituximab approved for adult RA)
Consider IVIG for systemic manifestations (efficacy not proven).
Consider immunosuppressive agents (azathioprine, cyclosporin A, cyclophosphamide)
Consider surgery in cases in which medical treatment has been unable to control joint damage. In severe cases of JIA, joint replacement may be performed during adolescence when growth is completed.

[a] Low-to-moderate risk: Oligoarticular, RF-, anti-CCP-polyarticular, mild systemic, spondyloarthropathy, or psoriatic arthritis.
[b] Erosive, aggressive disease or severe systemic manifestations (systemic category) or severe eye disease.
IVIG, intravenous immune globulin; *NSAID*, nonsteroidal anti-inflammatory drug; *RA*, rheumatoid arthritis.

are the tumor necrosis factor (TNF) inhibitors (Table 21-4). These agents are effective in as many as 70% of children who are resistant or intolerant to methotrexate. Other cytokine inhibitors such as inhibitors of interleukin (IL)-1 and IL-6 have been shown to be effective specifically in systemic JIA where methotrexate and TNF inhibitors are not as helpful. There are a variety of additional biologics shown in Table 21-4, which are becoming available and have been shown to be helpful in JIA and adult rheumatoid arthritis.

Systemic or local corticosteroids are used in JIA for selected indications only (Table 21-5). If systemic corticosteroids are required, every effort should be made to decrease the dose to prevent the severe side effects of this family of medications.

Nonpharmacologic interventions, including physical and occupational therapy, continue to be a mainstay of any treatment regimen in JIA. Surgical interventions, such as total joint replacements, have significantly decreased since the advent of the TNF inhibitors.

SYSTEMIC LUPUS ERYTHEMATOSUS

The childhood form of **SLE,** the second most common rheumatic disease in children, is similar in many ways to the adult form except that organ system involvement is more frequent and more severe in children. This complex, multisystem disease is rare before the age of 4 years, and females are more commonly affected than males. Prior to puberty, the female:male ratio is 3 or 4:1; after puberty, it is 7 or 8:1. The incidence increases until it peaks at the age of 20 to 30 years.

Pathophysiology

Many of the manifestations of SLE are caused by deposition of immune complexes along basement membranes of multiple tissues. Table 21-6 shows the 1997 American College of Rheumatology Criteria for the diagnosis of SLE, which is used in both adult and pediatric SLE; 4 of 11 criteria are required for diagnosis. Table 21-7 shows the common autoantibodies seen in SLE as well as those in other childhood rheumatic diseases. Without appropriate treatment, 30% of children with SLE progress to end-stage renal disease; however, with current medical management, overall survival at 15 years is estimated to be 90%.

Clinical and Laboratory Evaluation

History

The onset of SLE may be insidious or acute. Acute onset of fever in patients who are receiving treatment for SLE may indicate infection, a side effect of the commonly used corticosteroids and immunosuppressive

TABLE 21-5

Use of Corticosteroids in Juvenile Idiopathic Arthritis (JIA)

Indications for High-Dose Systemic Corticosteroid Therapy (prednisone 2 mg/kg/day or pulse methylprednisolone 30 mg/kg/day for 3 days)
Symptomatic pericarditis, pneumonitis, cerebritis, coagulopathy, macrophage activation syndrome in systemic JIA
Severe uveitis unresponsive to topical therapy
Indications for Low-Dose Systemic Corticosteroid Therapy (prednisone <0.5 mg/kg/day)
Significant anorexia
Failure to thrive
Pain, joint limitations significantly limiting quality of life
Indications for Local Corticosteroid Therapy
Uveitis (ophthalmologic corticosteroids; subtenon injections for severe disease)
Persistent synovitis in ≤3 joints (intra-articular corticosteroid injections [triamcinolone hexacetonide])

TABLE 21-6

1997 ACR Criteria for Systemic Lupus Erythematosus[a] (SLE)

1. Malar rash (rash on cheeks)
2. Discoid rash (red, scaly patches on skin that cause scarring)
3. Photosensitivity (exposure to ultraviolet light causes skin rash, or other symptoms of SLE flare-ups)
4. Oral ulcers (includes oral or nasopharyngeal ulcers).
5. Arthritis: Nonerosive arthritis of two or more peripheral joints, with tenderness, swelling, or effusion
6. Serositis: Pleuritis (inflammation of the membrane around the lungs) or pericarditis (inflammation of the membrane around the heart)
7. Renal disorder: More than 0.5 g/day protein in urine or cellular casts seen in urine under a microscope
8. Neurologic disorder: Seizures or psychosis
9. Blood, hematologic disorder, hemolytic anemia (low red blood cell count) or leukopenia (total white blood cell count $<4{,}000/mm^3$), lymphopenia ($<1{,}500/mm^3$) or thrombocytopenia ($<100{,}000/mm^3$) in the absence of offending drug
10. Immunologic disorder: Positive anti-Smith, anti-dsDNA, antiphospholipid or anticardiolipin antibodies, and/or false-positive serological test for syphilis
11. Antinuclear antibody test positive

[a] Four of 11 are required for diagnosis.

TABLE 21-7

Autoantibodies and Associated Diseases

Autoantibody	*Disease*
ANA	SLE (98% of patients), JIA, scleroderma, dermatomyositis, MCTD, Sjögren disease; positive in 10% of healthy children
Anti-dsDNA	SLE (highly specific)
Anti-Smith	SLE (highly specific)
Antiribonucleoprotein	SLE, MCTD
Anti-Ro (SSA)	SLE, neonatal lupus syndrome, Sjögren syndrome
Anti-La (SSB)	SLE, neonatal lupus syndrome, Sjögren syndrome
Antihistone	SLE, drug-induced lupus
Antiscleroderma-70	Systemic sclerosis
Anticentromere	Limited diffuse scleroderma
Antiphospholipid	SLE, antiphospholipid syndrome, MCTD, viral infections
Anticardiolipin	SLE, antiphospholipid syndrome, MCTD, viral infections
Antineutrophil cytoplasmic antibody	Vasculitis, inflammatory bowel disease
Antiplatelet, antierythrocyte, anti-WBC	SLE, antiphospholipid syndrome, MCTD
Antismooth muscle	Autoimmune hepatitis
RF	JIA, MCTD

ANA, antinuclear antibody; *JIA*, juvenile idiopathic arthritis; *MCTD*, mixed connective tissue disease; *RF*, rheumatoid factor *SLE*, systemic lupus erythematosus; *WBC*, white blood cell.

agents. Prolonged flu-like illness with or without rashes and joint pain in adolescent girls should raise suspicion for SLE.

Physical Examination

The presentation of SLE in children is diverse, and a comprehensive examination is essential. The most common signs and symptoms are rash, arthritis, fatigue, weight loss, and fever (Table 21-8).

Laboratory Evaluation

Many laboratory findings are abnormal in children with active SLE (Table 21-9). Depressed complement levels are a reflection of immune complex formation and deposition; in fact, regular checking of complement components C3 and C4 is an excellent way of monitoring disease activity. Screening for **antiphospholipid antibodies**, the most common antibodies associated with hypercoagulability in SLE, should include anticardiolipin, anti-β2 glycoprotein 1, and lupus anticoagulant or dilute Russell viper venom test.

MRI, computed tomography (CT), magnetic resonance angiography, and conventional angiography may be helpful in assessing for cerebral vascular accidents and arterial thromboses. However, MRI and CT scans may be normal in patients with generalized **cerebritis,** and spinal fluid studies may also be entirely normal in these individuals. Metabolic scans such as positron emission spectroscopy or spectamine scanning may be useful, but are often unable to distinguish between new or old disease, or mild or severe disease.

Evaluation of the extent of renal disease is often the most important diagnostic consideration in SLE because renal involvement is the most powerful predictor of morbidity. It is now possible to classify patients according to risk of renal failure, which helps guide therapy (Table 21-10).

Differential Diagnosis

The most common infections that may mimic SLE are **infectious mononucleosis** and streptococcal infections (see Chapter 9). Lymphoid neoplasms can also resemble SLE, especially B-cell lymphoma, which may have associated positive ANAs. Drug-induced lupus occurs infrequently in children on anticonvulsants, minocycline, and methylphenidate (Ritalin). In addition, other rheumatic diseases of children must be distinguished from SLE, most notably systemic JIA, dermatomyositis, scleroderma, mixed connective tissue disease, and vasculitis.

TABLE 21-8

Signs and Symptoms of Systemic Lupus Erythematosus (SLE) in Children[a]

Arthritis
Rash (malar, purpuric, vasculitic)
Alopecia
Constitutional symptoms (fever, weight loss, fatigue)
Oral and nasal ulcers
Cardiac disease (pericarditis, myocarditis)
Pulmonary disease (pneumonitis, pleural effusions, pulmonary hemorrhage, pulmonary hypertension)
Renal disease (glomerulonephritis, nephrosis, hypertension, renal insufficiency)
Hematologic abnormalities (anemia, bleeding, hypercoagulability)
Raynaud phenomenon
Central nervous system disease (cerebritis, seizures, cerebral vascular accidents, peripheral neuropathy, movement disorders)
Gastrointestinal (pancreatitis, vasculitis, microperforation, exudative ascites)

[a] Clinical manifestations listed in order of frequency of occurrence (from most common to least common).

TABLE 21-9

Laboratory Abnormalities in Systemic Lupus Erythematosus (SLE)

Laboratory Test	*Finding in SLE*
CBC	
WBC count	2,000–4,000/μL (leukopenia)
Platelet count	100,000–150,000/μL (common) <10,000/μL (infrequent)
Hgb	9–10 g/dL (common) <8 g/dL (severe hemolytic anemia; infrequent)
ESR	Elevated
Complement levels	Low
Autoantibody screening	Antiphospholipid (50% of patients), ANA, among others
ANA	High titer in ≥98% of patients
Anti-DNA	Present in ≥60% of patients
Antiphospholipid antibodies[a]	Present in 50% of patients
VDRL test for syphilis	False-positive
Circulating immune complexes	Immune complexes
Serum albumin	Hypoalbuminemia
Urinalysis	Proteinuria Presence of RBCs
Serum creatinine and BUN	Elevated in renal insufficiency

[a] Anti-phospholipid antibodies detected by assays for anticardiolipin, anti-b2 glycoprotein antibodies, lupus anticoagulant or dilute Russell viper venom test (DRVVT).
ANA, antinuclear antibody; *BUN*, blood urea nitrogen; *CBC*, complete blood count; *ESR*, erythrocyte sedimentation rate; *Hgb*, hemoglobin; *RBC*, red blood cell; *VDRL*, Venereal Disease Research Laboratory; *WBC*, white blood cell.

Management

Once the diagnosis of SLE is made, the key management principle is matching the intensity of the treatment to the severity of the disease—whether the manifestations are mild, moderate, or severe (Table 21-11). In general, corticosteroids are required to control disease in the majority of patients, but once the disease is controlled, corticosteroids should be tapered to a minimal dose. Hydroxychloroquine and very low dose corticosteroids have been shown to be effective in preventing relapses of disease. When SLE is well controlled, many of the once-abnormal laboratory values return to normal, and is in remission, almost all laboratory values are normal except perhaps for a positive ANA.

The use of intravenous cyclophosphamide has dramatically improved the outcome of severe lupus and lupus nephritis in children and adults. The major complications of cyclophosphamide are bone marrow suppression, infection, hemorrhagic cystitis, infertility, and increased future risk of neoplastic disease. Mycophenolate mofetil is increasingly being used as maintenance therapy as well as induction therapy, replacing cyclophosphamide for some types of disease. Azathioprine is usually used in cases of mycophenolate intolerance. Anti-B cell therapies such as rituximab have been shown to be helpful in cases that have failed or only partially responded to cyclophosphamide or mycophenolate. Currently, infectious complications are the major cause of significant morbidity and mortality in children with SLE. Physicians should pay meticulous attention to any signs of potential infection because even low-grade fevers may be significant in patients who take high-dose steroids and immunosuppressive agents. In addition, opportunistic infections are also found in SLE. Some experts recommend that patients who take cyclophosphamide should receive prophylaxis for *Pneumocystis carinii.*

TABLE 21-10

Lupus Nephritis (LN) in Systemic Lupus Erythematosus (SLE)

ISN/RPS[a] *Classification*	*Pathologic Description*	*Associated Laboratory Findings*	*Prognosis*
Class I	Minimal mesangial LN	Normal	No renal dysfunction
Class II	Mesangial proliferative LN	Hematuria, mild proteinuria	No renal dysfunction
Class III	Focal LN (<50% of glomeruli) • III(A): active lesions • III(A/C): active and chronic lesions • III(C): chronic lesions	Hematuria, proteinuria, hypoalbuminemia	Mild renal dysfunction
Class IV	Diffuse LN (>50% of glomeruli) Diffuse segmental (IV-S) or global (IV-G) LN • IV(A): active lesions • IV(A/C): active and chronic lesions • IV(C): chronic lesions	Hematuria, proteinuria, hypoalbuminemia, elevated serum creatinine	Significant risk of renal failure
Class V	Membranous LN	Proteinuria, hypoalbuminemia	Risk of slow progression to renal failure
Class VI	Advanced sclerosing LN (>90% globally sclerosed glomeruli without residual)	Severe azotemia and associated findings	Renal failure requiring renal replacement therapy

[a] *ISN/RPS* (International Society of Nephrology/Renal Pathology Society) has replaced previous World Health Classification in 2003.

Pediatric Pearl: Infection is common in children with rheumatic disease who are receiving corticosteroids and immunosuppressive medications. Fever should prompt obtaining blood and other cultures. When faced with potential serious infections in immunosuppressed patients, it is appropriate and safe to start broad-spectrum antibiotics before culture results become available.

JUVENILE DERMATOMYOSITIS

Juvenile dermatomyositis is characterized by inflammation of the skeletal muscles and skin. The illness, which may occur any time during childhood, is slightly more common in girls.

Pathophysiology

Although juvenile dermatomyositis is outwardly clinically similar to adult dermatomyositis, it is distinct from the adult form of disease in several important ways. The juvenile disease is primarily a **vasculitis** with small vessel and capillary involvement, with no associated neoplasms, as in adult dermatomyositis. If the inflammatory process is well controlled, most children enter a permanent remission after 2 to 5 years of therapy.

Clinical and Laboratory Evaluation

History

The onset of juvenile dermatomyositis may be acute, with rapidly progressive weakness and rash over a few weeks, or insidious, with slow progression of signs and symptoms over years. In some cases, the weakness can

TABLE 21-11

Treatment of Childhood Systemic Lupus Erythematosus (SLE) Based on Disease Severity

Severity of SLE	*Treatment*
Mild	
Rashes, arthralgias, leukopenia, anemia, arthritis, fever, fatigue	NSAIDs Low-dose prednisone (<0.5 mg/kg/day) Hydroxychloroquine Prednisone (1–2 mg/kg/day)
Moderate	
Mild disease + mild organ system involvement (mild pericarditis, pneumonitis, hemolytic anemia, thrombocytopenia, mild renal disease, mild CNS disease)	NSAIDs Hydroxychloroquine Low-dose methotrexate (0.5–1.0 mg/kg/wk) Mycophenolate mofetil, azathioprine
Severe	
Severe, life-threatening organ system involvement (CNS disease, diffuse lupus nephritis, pulmonary hemorrhage)	High-dose corticosteroids (2–3 mg/kg/day) or pulse methylprednisolone (30 mg/kg/day × 3 days) Induction therapy with intravenous monthly cyclophosphamide or high dose mycophenylate mofetil for 6-12 months Maintenance therapy with mycophenylate mofetil Anti B cell therapies (belimumab, rituximab) Intravenous cyclophosphamide (1,000 mg/m^2 every 1–3 months) mycophenylate mofetil Plasma exchange

CNS, central nervous system; *NSAID*, nonsteroidal anti-inflammatory drug.

be profound. Muscle pain is usually mild. Constitutional symptoms, such as fever, weight loss, or anorexia, may occur.

Physical Examination

Key clinical features of juvenile dermatomyositis are evident on physical examination (Table 21-12). Careful muscle strength testing is important to perform to monitor disease activity and response to treatment (Table 21-13).

Laboratory Evaluation

Abnormal muscle enzymes are detected in the vast majority of patients with juvenile dermatomyositis, including elevated creatine kinase, lactate dehydrogenase, aspartate aminotransferase, and aldolase. Diagnostic procedures such as electromyography, MRI, and muscle biopsy may be helpful in ambiguous cases.

Differential Diagnosis

The major diagnoses that should be considered in children with muscle weakness are **muscular dystrophy** and neurologic disease. Other rheumatic diseases in children may have elements of inflammatory myopathy, including **SLE** and **scleroderma**.

Management

The mainstay of therapy in juvenile dermatomyositis is corticosteroids in dosages adequate to control inflammation, usually 1 to 2 mg/kg/day of prednisone and/or pulse methylprednisolone intermittently for a period of time. Low-dose methotrexate and hydroxychloroquine are often used in moderate cases, and a variety of

TABLE 21-12

Clinical Features of Juvenile Dermatomyositis

Organ/System	*Symptoms and Signs*
Skin	Heliotrope (purplish) rash over eyelids Erythematous thickened lesions over MCP and PIP joints (Gottron papules) Erythematous thickened lesions over elbows, knees, and malleoli, with malar rash Vasculitis lesions Calcinosis, soft tissue deposition of calcium
Muscle	Proximal and symmetric weakness Poor head and trunk control Gower sign Trendelenburg sway
Gastrointestinal	Vasculitis Microperforation
Pulmonary	Recurrent pneumothoraces
Cardiac	Rare myocardial involvement

MCP, metacarpophalangeal; *PIP*, proximal interphalangeal.

other therapies have been used as well (e.g., IVIG, cyclosporine). Because of the wide variability in treatment regimens, there is currently a research effort underway to identify the best treatment approaches to juvenile dermatomyositis. Normalization of muscle enzymes with treatment is a good measure of adequate suppression of inflammation. One of the longer term complications of the disorder is subcutaneous calcification or **calcinosis**. When early inflammation is well controlled, this complication is much less frequent. If the disease continues to be active, the addition of low-dose methotrexate to the corticosteroid regimen is appropriate. In cases of severe vasculitis involving the gastrointestinal (GI) tract, cyclophosphamide or cyclosporine may be helpful. Physical and occupational therapy is essential to improve strength and prevent muscle tightening.

SCLERODERMA

Scleroderma assumes two major forms in children: **localized scleroderma,** which is limited to focal areas of skin and subcutaneous tissues and is the most common form, and **diffuse scleroderma** (also called systemic sclerosis), which is very similar to the adult disease. Diffuse scleroderma is extremely rare in children.

TABLE 21-13

Muscle Strength Testing

Grades	*% Function*	*Activity Level*
5 Normal	100	Complete range of motion against gravity with full resistance
4 Good	75	Complete range of motion against gravity with some resistance
3 Fair	50	Full range of motion against gravity
2 Poor	25	Full range of motion without gravity
1 Trace	15	Evidence of slight contractility; no effective joint motion
0 No contraction	0	No evidence of muscle contractility

TABLE 21-14

Characteristics of Diffuse and Localized Scleroderma

Type	*Subtype*	*Skin Involvement*	*Associated Findings*
Diffuse scleroderma	Systemic sclerosis	Sclerosis proximal to the metacarpophalangeal joints required for diagnosis, may progress to involve all areas	Raynaud syndrome, esophageal dysmotility, atrophy and dilatation of small and large bowel, pulmonary fibrosis, pulmonary hypertension, cor pulmonale, nephrosclerosis, myocardial fibrosis
	Subacute diffuse scleroderma	Sclerodactyly, telangiectasia	Esophageal dysmotility, Raynaud syndrome, calcinosis, milder pulmonary and renal disease compared to systemic sclerosis
Localized scleroderma	Morphea	One or more plaque-like atrophic hypopigmented lesions with lilac border	No associated organ system involvement No progression to diffuse scleroderma
	Linear scleroderma	One or more band-like sclerotic lesions extending along dermatomes, hypo- and hyperpigmentation	Local growth abnormalities underlying lesions on face, skull, and extremities Joint tightness and arthralgias No organ system involvement No progression to diffuse scleroderma
	Eosinophilic fasciitis	Thickened skin and subcutaneous tissues, "peau d'orange" appearance	Eosinophilia sometimes seen No organ system involvement

Pathophysiology

Both forms of scleroderma are characterized by progressive fibrosis of affected tissues due to immune stimulation of fibroblast activity. Each form of scleroderma has different characteristics (Table 21-14).

Clinical and Laboratory Evaluation

History

Both types of scleroderma are typically of slow onset and have a gradually progressive course (over several years). However, further progression of localized scleroderma tends to stop after 5 to 7 years. Localized disease is first noticeable as a painless, nonpruritic skin lesion anywhere on the body. Diffuse scleroderma usually begins as **sclerodactyly** and **Raynaud syndrome**.

Physical Examination

Skin changes and other associated findings are evident in scleroderma (see Table 21-14). In diffuse disease, organ system involvement is the major morbidity in diffuse scleroderma. In the linear form of localized scleroderma, sclerosis of skin and soft tissues can be associated with underlying bony involvement, impairing growth of the facial bones or involved extremity, and is seriously disfiguring. Sclerotic lesions crossing a joint may lead to decreased range of motion. Active morphea (plaque-like lesions) or linear lesions often are associated with erythematous borders.

Laboratory Evaluation

ANAs are commonly positive in both localized and diffuse scleroderma, especially antiscleroderma-70 and anticentromere antibodies. Laboratory abnormalities are rare in localized scleroderma, but may be indicative of organ system involvement in diffuse scleroderma including myositis and renal or GI involvement. Because there is little stimulation of the acute phase response, the erythrocyte sedimentation rate or C-reactive protein is unremarkable.

Imaging studies are very helpful in assessing the presence and severity of pulmonary disease. High-resolution CT of the chest may reveal alveolitis and fibrosis, which may eventually lead to severe pulmonary fibrosis, pulmonary hypertension, and cor pulmonale. Chest radiography may be normal. Pulmonary function tests, echocardiography (for pulmonary artery pressure estimates), and GI barium studies may be used to delineate the extent of disease.

Differential Diagnosis

The slow onset and progression of scleroderma in childhood makes diagnosis difficult; symptoms appear slowly. One of the earliest features in diffuse scleroderma is **Raynaud syndrome**. However, **Raynaud phenomenon** may occur in otherwise healthy individuals and usually does not lead to significant disease. Positive ANA and other autoantibodies, and changes in nail bed capillaries (dilated vessels, avascular areas with capillary dropout, tortuous or dilated loops) are subtle indications that systemic sclerosis may develop. Scleroderma-like syndromes are associated with long-standing insulin-dependent diabetes mellitus, and skin and autoimmune changes are seen with allogeneic bone marrow transplantation. The lesions of localized scleroderma, which may appear very similar to a scar, may be confused with lichen sclerosis et atrophica or fungal infections.

Management

In localized scleroderma when symptoms are mild, emollients or creams are most useful. In cases of linear scleroderma, in which patients are at risk for development of disability or significant cosmetic defect, systemic corticosteroids and low-dose methotrexate should be considered.

In diffuse scleroderma, the severity of involvement dictates the aggressiveness of treatment. Cyclophosphamide may be effective with pulmonary alveolitis and early fibrosis, and low-dose methotrexate, D-penicillamine, or low-dose corticosteroids may control milder forms of these conditions. Symptomatic treatment with proton pump inhibitors and GI motility agents may be useful for GI problems, calcium channel blockers may be helpful for Raynaud syndrome, and angiotensin-converting enzyme inhibitors or analogs are helpful for hypertension and renal disease.

Systemic sclerosis progresses slowly, and cardiopulmonary manifestations currently account for the major life-threatening morbidity associated with the disorder. Early detection is required because late stages of cardiopulmonary disease are often resistant to treatment. Regular monitoring with pulmonary function tests and echocardiograms is recommended.

VASCULITIS

Many of the major forms of chronic vasculitis that affect adults also rarely affect children. The chronic forms of childhood vasculitis are discussed in this section. Two common forms of "transient" vasculitis, **Kawasaki disease** and **Henoch-Schönlein purpura,** will not be discussed here (see Chapters 13 and 22).

Pathophysiology

The most common forms of vasculitis in children may be differentiated according to their major clinical and pathologic manifestations (Table 21-15).

Clinical and Laboratory Evaluation

History

The history obtained in vasculitis reflects the type and extent of organ system involvement. Granulomatosis with polyangiitis (formerly Wegener granulomatosis) is characterized by recurrent sinusitis and pulmonary disease. In contrast, polyarteritis may be characterized by constitutional symptoms such as fever and fatigue, as well as features of mesenteric vasculitis such as abdominal pain.

Physical Examination

The key features of the physical examination reflect the type of organ system involvement in the various types of vasculitis (see Table 21-15). Upper and lower respiratory track and eye involvement suggests granulomatosis with polyangiitis. Hypertension suggests renal involvement, as seen in polyarteritis or the antineutrophil cytoplasmic antibodies (ANCA)-positive vasculitides. Symptoms of syncopy, claudication, and altered peripheral pulses suggest large-artery involvement, as in Takayasu arteritis.

TABLE 21-15

Classification of Vasculitis in Children

Vasculitis	*Vessel Involvement*	*Associated Autoantibodies*	*Clinical Manifestations*
Leukocytoclastic vasculitis	Small vessel perivascular polymorphonuclear cell infiltration		Urticarial vasculitis, palpable purpura
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)	Small and medium vessel granulomatous vasculitis	80%+ c-ANCA, antiproteinase 3	Upper and lower respiratory tract involvement, glomerulonephritis
Crescentic (pauci-immune) glomerulonephritis	Focal or diffuse glomerulonephritis with crescents, rare immunoglobulin deposition	Frequent p- and c-ANCA	Glomerulonephritis
Churg-Strauss allergic granulomatosis	Small and medium vessel granulomatous vasculitis with eosinophils	30% p-ANCA	Pulmonary infiltrates with asthma syndrome, glomerulonephritis
Polyarteritis nodosa	Small and medium necrotizing arteritis	30% p-ANCA, especially antimyeloperoxidase	GI and renal arteritis with microaneurysms; skin, CNS, hepatic, and muscle vasculitis
Microscopic polyangiitis	Small vessel necrotizing vasculitis	80%+ p-ANCA, especially antimyeloperoxidase	Pulmonary vasculitis, glomerulonephritis
Kawasaki disease	Medium and small vessel necrotizing arteritis		Fever, rash, mucocutaneous lesions, coronary aneurysms
Behçet syndrome	Small and medium vessel vasculitis		Anterior and posterior uveitis, aphthous ulcers, genital ulcers, small and large bowel colitis, thrombotic phenomenon
Giant cell (temporal) arteritis (not seen in childhood)	Large vessel granulomatous vasculitis		Temporal and cranial vasculitis, ocular involvement
Takayasu arteritis	Granulomatous vasculitis of the aorta and major branches		Hypertension, vascular insufficiency, aneurysms, stenoses
Primary CNS vasculitis	Vasculitis involving medium sized or small vessels		Seizures, dementia, focal neurologic findings

ANCA, antineutrophil cytoplasmic antibody; *CNS*, central nervous system; *GI*, gastrointestinal.

Laboratory Evaluation

One of the most helpful tests for diagnosis and monitoring of disease activity in vasculitis is ANCA, which are associated with the major forms of vasculitis (see Table 21-15). Inflammatory changes, including leukocytosis, thrombocytosis, and elevated acute phase reactants, are seen in active disease. **Glomerulonephritis,** with active urinary sediments and decreased creatinine clearance leading to renal failure, is a major complication of granulomatosis with polyangiitis and **microscopic angiitis.**

Imaging studies are helpful in understanding the extent of vasculitis. MRI and CT of the sinuses and chest are indicated in granulomatosis with polyangiitis, and CT/MR angiography and conventional angiography are required in the evaluation of **Takayasu arteritis.** The renal or mesenteric microaneurysms in **polyarteritis nodosa** may only be visualized on conventional arterography.

Differential Diagnosis

It is essential to distinguish among the major types of vasculitis in children because the extent and type of organ system involvement characterizes distinct clinical syndromes. However, when symptoms are vague, the major nonrheumatic diseases that should be considered are infectious (e.g., infectious mononucleosis) and neoplastic (e.g., lymphoma).

Management

The approach to management depends on both the type of vasculitis and the severity of involvement. Corticosteroids are the mainstay of treatment, but in certain types of vasculitis, corticosteroids alone may not be adequate. For example, cyclophosphamide is almost always indicated in granulomatosis with polyangiitis and frequently in polyarteritis with organ system involvement. Other drugs that may be useful in milder forms of vasculitis, such as microscopic polyangiitis, include immunosuppressive agents such as mycophenolate mofetil and methotrexate.

PAIN SYNDROMES IN CHILDREN

Although rarely leading to permanent dysfunction or organ system damage, severe chronic pain may be extremely disabling unless recognized and treated. Pain syndromes in children may be frequently confused with rheumatic diseases. However, distinct features are helpful in distinguishing the major pain syndromes in children from rheumatic diseases (Table 21-16).

Pathophysiology

The etiology of pain syndromes may in part be developmental or mechanical. Familial associations are seen in benign limb pains and fibromyalgia. Psychologic causes are not associated except in conversion reactions; however, secondary depression due to chronic pain and disability is frequent.

Clinical and Laboratory Evaluation

History

The typical historical features of pain syndromes are a long onset period as well as variable intensity and frequency (see Table 21-16). Females are more commonly affected than males, and onset occurs during puberty. Patients describe the pain as intolerable and unrelenting; as described, the severity of pain is greater than it is in other diseases such as JIA. The pain causes affected children to be unable to participate in normal activities.

Physical Examination

The physical examination is usually the basis for the diagnosis, with the major symptoms and signs as noted in Table 21-16. Typically, there is no evidence of joint swelling, skin rash, or other signs of inflammatory diseases. Muscle or diffuse extremity pain and tenderness are more common than joint tenderness.

Laboratory Evaluation

No laboratory abnormalities are evident with the pain syndromes. Severe disuse in reflex sympathetic dystrophy can be associated with osteopenia and changes detected by technetium bone scan.

TABLE 21-16

Characteristics of Common Pain Syndromes in Children

Syndrome	*Age at Onset (Years)*	*F:M Ratio*	*Physical Findings*	*Description of Pain*	*Associated Features*
Benign limb pains of childhood	4–13	F >M	None	Intermittent nocturnal pain in calves, thighs, and shins	No pattern of recurrence
Patello-femoral pain	11–13	F >M	Crepitance, positive patellar apprehensive and compression tests, mild swelling	Grating, catching pain at edges of patella; instability	Increased with descending stairs, squatting, kneeling, running; inability to sit for long periods without extending knee (theater sign)
Benign hypermobility syndrome	3+ (10% of population)	F >M	Hyperextensibility of elbows >5 degree, genu recurvatum >5 degree, hyperextension of MCP joints and thumbs	Aching in joints common	Familial occurrence, dislocation of joints, mitral prolapse; Ehlers-Danlos Type III
Juvenile fibromyalgia	10 through adolescence	F >M	>13 tender areas at discrete anatomic locations	Aching, burning, pain at tender areas, palpation sometimes causing radiation; generalized, chronic, diffuse musculoskeletal pain	Fatigue, headaches, sleep disturbances, paresthesias, depression, anxiety
Reflex sympathetic dystrophy (also called complex regional pain syndrome)	8 through adolescence	F >M	Painful extremity with swelling; changes in temperature, color, perspiration pattern; occasionally >1 extremity affected	Exquisite pain to light touch; chronic pain without touch	Often disconnected effect from pain, "la belle indifference"
Psychogenic pain	7 through adolescence	F =M	None, unless induced injury	Unusual patterns of pain, unusual functional use of extremity or abnormal gait, intermittent severe pain, continuous severe pain	Possible psychologic disturbance

F, female; *M*, male; *MCP*, metacarpophalangeal.

Differential Diagnosis

The key conditions that must be distinguished from pain syndromes are trauma, other rheumatic diseases, and neoplastic and neurologic diseases. In some cases, **fibromyalgia** may be secondary to musculoskeletal disease due to SLE, JIA, and trauma. Although psychologic diseases (e.g., conversion reactions) may sometimes be confused with pain syndromes, the presenting symptoms and pain manifestations are frequently bizarre in these conditions.

Management

Accurate diagnosis is the key to management of pain syndromes. The families of many children are extremely concerned about the potential seriousness of symptoms and will continue to "doctor shop" until they find a physician whom they believe has made a reliable diagnosis. Reassurance, often the first step, is very effective in the majority of milder pain syndromes. Intensive physical therapy, sometimes requiring inpatient therapy, is helpful in severe cases of **fibromyalgia** and **reflex sympathetic dystrophy.** In addition, psychologic counseling for stress management, depression, and school dysfunction is often necessary in cases where significant disability and lack of normal functioning have occurred.

Dermatology

Latanya T. Benjamin and Alfred T. Lane

DEFINITIONS

To best understand the response of the skin to disease processes, it is first important to understand the structure of the skin. The skin can be divided into two layers, the epidermis and the dermis. The **epidermis (Figure 22-1)** is the outer layer of skin that protects the body from the outside environment and maintains internal homeostasis. The epidermis contains **keratinocytes,** which divide and undergo a process of maturation called keratinization. This process results in the formation of the **stratum corneum,** an outer skin layer that is less than 0.1 mm thick, yet provides the majority of the barrier function of the skin. The **dermis,** the deeper layer of the skin, provides flexibility and support. The main blood supply and sensory innervation for the skin is found in this layer.

It is essential to know the basic terminologies used in the field of dermatology in order to describe skin findings. Skin examination is necessary for identification of **primary lesions,** the first lesion to appear, and any secondary changes. The clinician should also note the color, arrangement, and distribution of lesions. At times, only **secondary lesions** are apparent, and the correct diagnosis depends on finding less obvious primary lesions. Atopic dermatitis is an example of a skin condition with no primary lesions. There are various types of primary and secondary lesions (Table 2-21).

DERMATOPHARMACOLOGY

Several principles of skin care are important in caring for infants and children. The epidermis, with its combination of cells surrounded by a lipid layer, provide a hydrophobic barrier that can be injured by the outside environment as well as by genetic abnormalities in production of the barrier. Recognized abnormalities in the barrier are **dry skin** and **dermatitis** (inflamed or irritated skin). Dry skin may be associated with scaling, roughened

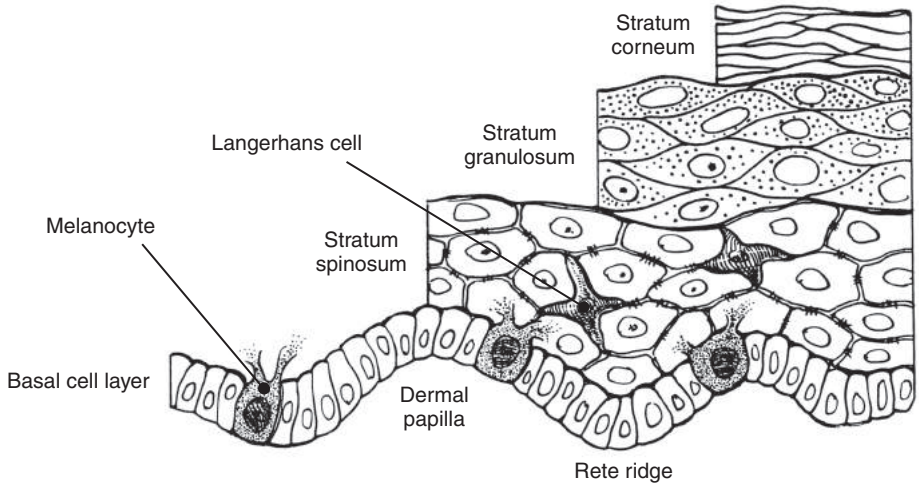

FIGURE 22-1. Cross-sectional representation of the skin. From Lookingbill DP, Mark JG: *Principles of Dermatology.* Philadelphia, WB Saunders, 1993, p 6.

TABLE 22-1

Definitions of Primary and Secondary Skin Lesions in Infants and Children

Primary Skin Lesions

- **Bulla**—A lesion larger than 1 cm in diameter, filled with clear fluid.
- **Cyst**—A raised lesion that contains a palpable sac filled with liquid or semisolid material.
- **Macule**—Color change in the skin that is flat to the surface of the skin and not palpable.
- **Nodule**—A raised, solid lesion with indistinct borders and a deep palpable portion. If the skin moves over the nodule, it is subcutaneous in location; if the skin moves with the nodule, the nodule is intradermal.
- **Papule**—A solid, raised lesion 1 cm or less in diameter.
- **Plaque**—A solid, raised, flat-topped lesion larger than 1 cm in diameter.
- **Pustule**—A raised lesion filled with purulent exudate, giving it a yellow appearance.
- **Vesicle**—A raised lesion less than 1 cm in diameter, filled with clear fluid.
- **Wheal**—An area of tense edema in the upper dermis, producing a flat-topped, slightly raised lesion.

Secondary Skin Changes

- **Atrophy**—The skin surface is depressed because of thinning or absence of the epidermis or subcutaneous fat.
- **Crusting**—Dried exudate of plasma combined with the blister roof, which sits on the surface of skin following acute dermatitis.
- **Erosions**—Moist, circumscribed, slightly depressed area representing a blister base with the roof of the blister removed.
- **Excoriations**—Oval-to-linear depressions in the skin with removal of the epidermis, exposing a broad section of red dermis. Excoriations are the result of traumatic removal of the epidermis and upper dermis.
- **Fissures**—Characterized by linear wedge-shaped cracks in the epidermis, extending down to the dermis and narrowing at the base.
- **Lichenification**—Thickened plaques with accentuated skin markings secondary to chronic rubbing of the skin.
- **Scaling**—Small flakes on the skin surface, secondary to abnormal shedding or accumulation of stratum corneum cells.

texture, and possible erythema (redness), and treatment often involves **topical creams, moisturizing lotions, or ointments** (Table 22-2). These **lubricants** smooth the skin and replace lipids in the stratum corneum. Ointments are more greasy and occlusive than creams or lotions. The higher the humidity in the environment, the less occlusive the cream or lotion should be; in a drier environment, a greasier ointment or cream may feel better.

Care should be a consideration when applying any products to the skin in children, recognizing the potential for absorption of the product and systemic toxicity. **Topical steroids** are commonly used to treat inflamed skin conditions, irrespective of the cause. The strength of topical steroids ranges in potency from low to high (Table 22-3).

Pediatric Pearl: Only low- or moderate-potency topical steroids should be used in infants and children.

Dangerous and unwanted side effects may result from the use of high-potency topical steroids in young individuals.

TABLE 22-2

Examples of Common Over-the-Counter Emollients/Moisturizers

Petroleum jelly
Aquaphor ointment
Eucerin cream
Cetaphil moisturizing cream
Purpose moisture lotion with SPF 15
CeraVe moisturizing cream or lotion
Aveeno daily moisturizing lotion
Moisturel sensitive skin, therapeutic cream or lotion

SPF, skin protection factor.

SKIN LESIONS COMMON IN THE NEONATAL PERIOD

NEONATAL PUSTULES

Term infants may suffer from several common, benign dermatologic conditions, including **erythema toxicum and transient neonatal pustular melanosis.** The lesions of erythema toxicum, which develop 1 to 14 days after birth, appear as erythematous papules or pustules associated with multiple erythematous macules (Figure 22-2).

TABLE 22-3

Topical Steroids Listed by Level of Potency[a]

Low Potency
Hydrocortisone 1% cream, 2.5% ointment
Desonide 0.05% cream or ointment
Aclovate 0.05% cream or ointment
Moderate Potency
Fluocinolone acetonide 0.025% cream or ointment
Hydrocortisone valerate 0.2% cream or ointment
Mometasone furoate 0.1% cream
Triamcinolone acetonide 0.1% cream or ointment
High Potency
Fluocinonide 0.05% cream or ointment
Desoximetasone 0.25% cream or ointment
Mometasone furoate 0.1% ointment
Clobetasol propionate 0.05% cream or ointment

[a] Only low- or moderate-potency topical steroids should be used in pediatric dermatology.

The macules may be at the site of the pustules or elsewhere on the body. Typical sites of involvement include the face, trunk, and proximal extremities. The palms and soles are spared. Bedside examination of a scraping of the pustule with Wright stain indicates that the pustule mainly contains eosinophils. Individual lesions can disappear within hours, but new lesions typically appear and resolve over several days to weeks, leaving no residua.

Infants, commonly those of African descent, born with pustules and/or collarettes of scale may have the condition called **transient neonatal pustular melanosis.** The pustules may be seen anywhere on the body but appear to be most common on the face and trunk, and occasionally, on the palms and soles. Upon resolution of these pustules, hyperpigmented brown macules remain. It can take up to several months for these residual dark macules to completely fade. Wright stain of the pustule contents usually reveals predominance of polymorphonuclear leukocytes.

Cultures of both erythema toxicum and neonatal pustular melanosis should be sterile, and Gram stains should not show bacteria. These two common conditions should be distinguished from potentially serious infections such as herpes simplex, cutaneous candidiasis, and *Staphylococcus aureus* infection. Although both lesions appear to be of no consequence, because of their appearance at birth, they may be of great parental concern.

FIGURE 22-2. This 3-day-old healthy newborn has developed multiple erythematous macules and papules on the trunk, a classic sign of erythema toxicum.

BIRTHMARKS

Vascular birthmarks are very common in children. Flat vascular lesions occur on the nape of the neck, where they are commonly referred to as "stork bites," or over the midline forehead, nose, or upper eyelid region, where they are called "salmon patches." About 0.3% of infants have **port-wine stains,** which are darker, red-violaceous, flat vascular lesions. A subset of port-wine stains with a particular facial distribution may be associated with either underlying brain or eye involvement (**Sturge-Weber syndrome**) or overgrowth of a limb when they are on an extremity (**Klippel-Trenaunay syndrome**).

Raised vascular birthmarks usually represent **hemangiomas** (Figure 22-3), which result from a proliferation of endothelial cells. Hemangiomas usually enlarge for the first 3 to 6 months of life and then start to flatten. Most of these lesions have flattened to skin level by the time the child reaches 10 years of age. Hemangiomas can cause problems when they are large and deforming, multiple, obstruct vision or airway, or break down and ulcerate. Ulcerated hemangiomas may require antibiotic therapy, as they are usually secondarily infected, most commonly with *S. aureus*. At the time of this writing, further advances for the treatment of severe infantile hemangiomas are being made. The oral use of the β-blocker propranolol is currently being investigated as a potential therapy for complicated and disfiguring hemangiomas. Preliminary results are encouraging and offer promise. Laser surgery has also made early nonscarring therapy for both flat and raised vascular lesions possible.

Another condition, **Kasabach-Merritt syndrome,** was once thought to be associated with infantile hemangiomas. It is now known that these vascular lesions actually represent other distinct rare vascular tumors (**Kaposiform hemangioendothelioma** or **tufted angioma**). This tumor may trap platelets, and affected infants present with profound thrombocytopenia and multiple areas of bruising. Although less common than infantile hemangiomas, this entity is important to recognize early, as it could represent a true medical emergency.

FIGURE 22-3. This infantile hemangioma is a proliferation of blood vessels that involute over time.

SKIN LESIONS COMMON IN INFANTS AND OLDER CHILDREN

DIAPER DERMATITIS

Pathophysiology

Irritant diaper dermatitis, a common condition seen in infants wearing diapers, is caused by a combination of skin wetness, change in pH level, and friction beneath the diaper-covered skin. Entrapped urine and prolonged skin wetness within diaper-covered areas increase the infant's susceptibility to macerated skin. Furthermore, urine elevates the pH of the environment beneath the diaper. The alkaline pH then allows for activation of fecal enzymes (lipase, protease) that may be present in the diaper. These proteolytic enzymes would further injure the skin. Therefore, it is common for prolonged diarrhea to aggravate this condition. In addition, secondary infection with *Candida albicans* may increase the severity and pain associated with diaper dermatitis (Figure 22-4). When diaper dermatitis is associated with erythematous papules at the periphery, it is suggestive of superinfection with *C. albicans.*

FIGURE 22-4. This infant has severe diaper dermatitis infected with *Candida albicans*. The periphery of the rash has multiple red papules and pustules that extend out of the area usually covered by the diaper.

Management

It is best to minimize any prolonged contact of urine and feces on the skin of young infants wearing diapers. Mild irritant diaper dermatitis is typically treated with an application of a barrier cream or ointment such as zinc oxide or petroleum jelly.

Pediatric Pearl: Superabsorbent gel disposable diapers have proved effective in preventing diaper dermatitis by absorbing wetness away from the skin and by buffering the pH back to normal.

The addition of 1% hydrocortisone may be effective in decreasing the inflammation and tenderness. Hydrocortisone treatment is usually only necessary for several days.

Infants with *C. albicans* diaper dermatitis require a topical antifungal agent such as nystatin, miconazole, or clotrimazole. Many children who have *C. albicans* may have recurrences of diaper dermatitis and may need intermittent reapplication of the antifungal medication. These infants may also require the continuous application of barrier cream or moisturizers in the diaper area with each diaper change.

ACNE

Acne vulgaris is a common skin condition that occurs in the pediatric age group. Although it may be seen in infants between 2 weeks and 6 months of age, it more commonly develops several years prior to the onset of adolescence. The lesions of acne are often apparent on areas of the face, upper chest, and the upper back. These locations correspond to areas of increased concentration of sebaceous glands.

FIGURE 22-5. Open and closed comedones, as well as inflammatory papules, are present on the forehead of an adolescent with acne vulgaris.

Pathophysiology

The early lesions of acne are called microcomedones. These subclinical clogging of pores then develops into either **open comedones (blackheads), closed comedones (whiteheads),** or both (Figure 22-5). Both lesions represent obstruction of the sebaceous follicle just beneath the follicular opening

in the neck of the follicle. The stratum corneum accumulates in this area, obstructing the orifice. Over time, with the accumulation of sebum (oils) and *Propionibacterium acnes* (bacterial overgrowth), the closed comedones may eventually become inflammatory papules and, possibly, pustules. Larger lesions may become nodules or cysts. Upon healing of individual cysts, pitted scars may result secondary to elastic tissue destruction and fibrosis in the dermis, which then pulls the overlying epidermis downward.

Pediatric Pearl: Acne is not caused by diet (such as pizza or chocolate) or dirty skin. These are common myths.

Many patients believe that acne is caused by dirty skin and aggressively scrub their skin in an effort to eliminate the acne. There are no data to support that facial scrubbing improves acne, however, it definitely increases the irritative side effects and can result in brown acne stains, particularly in darkly pigmented skin. Keeping the face clean with only water or a mild, noncomedogenic cleanser is usually adequate. Patients in occupations where their skin is exposed to large quantities of grease may require avoidance of the grease or a more effective method of skin cleansing.

Management

Treatment of acne varies depending on severity (Table 22-4). For patients who present primarily with open and closed comedones or a few inflammatory papules and pustules, benzoyl peroxide, either as a 5% to 10% over-the-counter lotion or as a 2.5% to 10% prescription gel, may be adequate. Physicians should warn patients that benzoyl peroxide might cause staining of colored clothes and bleaching of bathroom towels. Retinoic acid (tretinoin) is another excellent preparation that helps prevent the formation of comedones, the primary lesions of acne. This agent causes skin dryness and irritation; it is also a photosensitizing drug that may increase the risk of developing sunburn. Retinoic acid is available as a cream (0.025%, 0.05%, 0.1%), a gel (0.01%, 0.025%), and a micronized gel (0.04%, 0.1%). The creams tend to be less irritating and less drying than the gels, whereas the gels are more effective for patients who believe that their skin is oily and greasy despite treatment with the cream. Adapalene gel (0.1%), a new synthetic product with retinoid activity, is not photosensitizing and causes less skin irritation.

Benzoyl peroxide and retinoic acid can also be used in combination. Usually, benzoyl peroxide is applied in the morning and retinoic acid is applied at night. It is important that retinoic acid be applied to skin without any other products and to skin that has not been washed in the previous 30 minutes. Wetting the

For Many Comedones, Inflammatory Papules, Pustules, Nodules, and Cysts
Retinoic acid cream or gel
Oral antibiotics
Referral to dermatologist; patient may require systemic retinoids

skin prior to the application hydrates the skin and increases the incidence of absorption and irritation from retinoic acid.

Patients who continue to have inflammatory papules and pustules despite therapy with topical benzoyl peroxide and retinoic acid may require additional treatment with antibiotics. Effective topical antibiotics include clindamycin phosphate 1%, erythromycin 1% to 2%, or sodium sulfacetamide 5% to 10%. Oral antibiotics can be used for patients who do not respond to topical antibiotic therapy or combination products (benzoyl peroxide plus an antibiotic or retinoic acid). Tetracycline, doxycycline, or erythromycin are the most frequently prescribed oral antibiotics for acne and are usually taken in two divided doses per day. For patients for whom oral antibiotics have failed or are demonstrating scarring acne, oral isotretinoin is customarily indicated. A common side effect of this medication is dryness of the mucous membranes. Systemic isotretinoin is contraindicated in female patients who are pregnant or who are attempting to become pregnant or at risk for becoming pregnant due to the known harmful effects to the developing fetus that may result in major birth defects. Furthermore, the use of this oral agent requires monthly blood work to access for other potential toxicities such as hypercholesterolemia, hypertriglyceridemia, and elevated liver function tests. Other potential significant side effects include pseudotumor cerebri, myalgias, arthralgias, decreased night vision, pancreatitis, impaired wound healing, premature epiphyseal closure, photosensitivity, and depression or significant changes in mood.

All acne therapies require several weeks to months before a response is seen. Patient motivation is thus an important component of successful therapy. Initially, it is necessary to follow acne patients at 4- to 8-week intervals to assess use, evaluate response to therapy, modify therapy as necessary, and motivate the patient to continue therapy. It is also necessary to confirm the dosing regimen for patients for whom the application of multiple different products to the face becomes confusing.

ATOPIC DERMATITIS

Atopic dermatitis, also known as eczema, is a common skin disorder, affecting 10% to 20% of children. It has been described as the "itch that rashes," which emphasizes that the primary pathology is associated with **pruritus** (itching) and the results seen on the skin are secondary, such as **lichenification** (skin thickening) and **excoriations** (linear markings) secondary to repeated scratching. Patients typically present with a history of pruritus and areas of excoriation on their face or other body sites. In general, the extensor surfaces (knees and elbows), scalp, and cheeks of infants are the sites involved. The most common areas of involvement for older children are the antecubital and popliteal fossae (Figure 22-6). Atopic dermatitis can cause severe disability for children and their families secondary to the chronicity of daytime itching and lack of sleep, especially from the intensity of nighttime itching. For a discussion of the pathogenesis, clinical manifestations, and management of this disease, see Chapter 17, Atopic Dermatitis.

Differential Diagnosis

Two conditions that must be differentiated from atopic dermatitis are **allergic contact dermatitis** and **scabies**. Usually, patients with allergic contact dermatitis have a history of exposure to poison ivy or poison oak. Often, the lesions in allergic contact dermatitis appear initially as vesicles that then become excoriated. Occasionally, linear vesicles can be seen where the leaf or stem of the plant has come in contact with the skin. Scabies is caused by a mite and is often associated with pruritus in other family members. This condition often appears to be worse on the hands and feet of infants and children (see Scabies).

FIGURE 22-6. Atopic dermatitis is seen in this child as bilateral excoriations of the antecubital fossa with associated hypopigmentation.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is common before 6 months of age and after puberty. It occurs as an accumulation of greasy scales on a base of an erythema. When the condition involves the scalp of infants, it is known as **"cradle cap."**

Pathophysiology

Seborrheic dermatitis is thought to occur from a physiologic overproduction of sebum and colonization with

Malassezia (*Pityrosporum ovale*). In infants younger than 6 months of age, it is often difficult to distinguish this condition from atopic dermatitis involving the scalp.

Management

For infants who have a thick accumulation of scale, application of mineral oil 30 minutes prior to washing the hair may help remove the scale. Treatment may involve low-potency topical steroids such as hydrocortisone cream in infants or fluocinolone solution applied once or twice a day to the area of dermatitis. Adolescents may require topical hydrocortisone applied to the areas of dermatitis on the face and fluocinolone applied to the areas of dermatitis on the scalp.

PSORIASIS

Although psoriasis is a common condition in adults, it does occur in children. Affected children often present with **guttate lesions,** which are small discrete papules 2 to 4 mm in size that suddenly appear on the trunk with extension to the proximal and then distal extremities. Occasionally, 10 to 100 lesions may appear over several days. Classic psoriasis (as seen in adults) can also occur in children, who have 1- to 20-cm erythematous plaques with overlying fine scales or thicker, silver white scales. Often, children have genital involvement with dermatitis on the perineal area, inguinal folds, and genitalia.

Pathophysiology

Guttate psoriasis may follow a sore throat, particularly streptococcal pharyngitis, or a perianal streptococcal infection. Psoriasis is a condition associated with rapid proliferation of keratinocytes.

Management

Psoriasis can be very difficult to treat and may require variation of therapy from time to time. Therapy often includes topical steroids, a topical tar preparation, a topical vitamin D analog (calcipotriene), or possibly ultraviolet light. For patients who present with guttate lesions, evaluation for streptococcal disease may document a preceding infection. Often, therapy with antistreptococcal antibiotics may be beneficial as an adjunct to psoriasis therapy in these children.

PITYRIASIS ROSEA

Pityriasis rosea is a common condition of unclear etiology seen in children and adolescents. Children may present with erythematous papules or plaques with scales. The lesion may resemble **psoriasis** or **tinea corporis** initially. Over 1 to 30 days, multiple new lesions may appear, usually on the central trunk. These lesions are often oval, with the long axis of the oval lesions parallel to the lines of skin stress. The configuration of these lesions on the back may result in a "Christmas or pine tree" appearance (Figure 22-7). The lesions of pityriasis rosea often resolve in 6 to 10 weeks. If the lesions are symptomatic, a low-potency topical steroid or moisturizers may help relieve the pruritus.

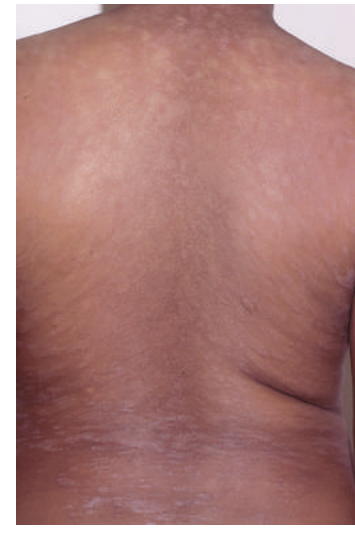

FIGURE 22-7. The distribution of lesions in pityriasis rosea follows skin tension lines and resembles a Christmas or pine tree in appearance.

URTICARIA

Urticarial lesions often present as individual lesions with a central **wheal (swelling)** and a surrounding **flare** of erythema. These lesions can be seen with insect bites **(papular urticaria)** or are associated with infection, drugs, food, cold, trauma, heat, or exercise. Often, the cause of urticaria is not identifiable, and the lesions will resolve over time. Individual lesions usually last several minutes to several hours, but episodes of recurring lesions may last for days to weeks. While investigating the cause of the urticaria, symptomatic therapy with oral antihistamines such as hydroxyzine or diphenhydramine may be useful.

FIGURE 22-8. This child's vitiligo is somewhat symmetrical. It is very disfiguring and difficult to hide.

PALPABLE PURPURA

Children who present with erythematous papules that do not totally lose their color when the overlying skin is pressed may have palpable purpura. These lesions are usually associated with bleeding from small vessels within the skin, usually caused by an inflammatory infiltrate injuring the vessels. A specific type of palpable purpura seen in children is called **Henoch-Schönlein purpura** (see Chapter 20). Purpura may also be associated with viral or bacterial infections. The presence of palpable purpura should alert the physician to the possibility of underlying severe disease and the need for more comprehensive evaluation.

VITILIGO

Occasionally, children may present with localized areas of total absence of skin pigment (Figure 22-8). In this condition the melanocytes are injured and absent from the area of the decreased pigment. Vitiligo is usually symmetrical, involving the arms, legs, or both sides of the body. Frequently, the "islands" of involved skin can be described as having a geographic pattern. Affected areas do not tan with the potential to burn easily, even in darkly pigmented patients. The diagnosis is confirmed by Wood lamp examination, which highlights the sharp demarcation between areas where the pigment is normal. This is an especially useful tool when evaluating patients of lighter skin color. Vitiligo can be extremely difficult to treat, and response to therapy is often poor. Common treatment options include aggressive use of sunscreens, potent topical steroids, calcineurin inhibitors, and ultraviolet therapy. The condition may result in major aesthetic deformity in ethnic patients with darkly pigmented skin.

ALOPECIA AREATA

Alopecia areata, or acute hair loss, is often a very distressing condition. Usually, complete hair regrowth eventually occurs, but a potential for long-term absence of hair or total body hair loss exists.

Alopecia areata is characterized by a circumscribed patch or patches devoid of hair, usually on localized areas of the scalp (Figure 22-9). However, it may progress to involve all body hairs. Often, the lesion is noticed suddenly. **"Exclamation point"** hairs are affected terminal hairs that become progressively narrowed as it approaches the scalp. These hairs are frequently found at the periphery of the patch and eventually break off and fall out. Alopecia areata must be distinguished from **tinea capitis,** which

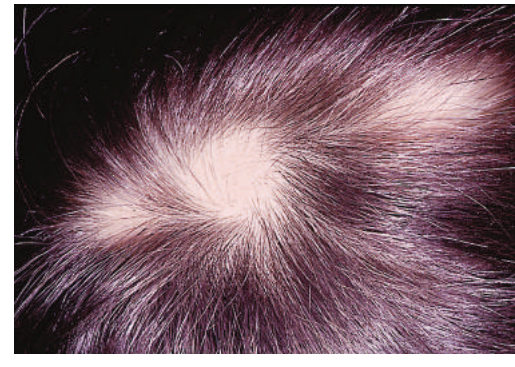

FIGURE 22-9. These three patches of alopecia without scales or erythemas are an example of alopecia areata.

usually manifests with broken-off hairs and a scaling dermatitis of the involved skin. Tinea capitis can be identified and confirmed by a positive fungal culture of the involved area.

Given time, spontaneous regrowth of hair can occur. However, some available treatment options include topical, intralesional or oral steroids, nonspecific growth promoters, and allergic contact sensitizers.

NEVI

Infants and children can be born with a nevus **(congenital melanocytic nevus)** or can develop nevi over time. A congenital nevus is identified at birth as a tan-to-dark brown macule, papule, or patch that is sharply circumscribed (Figure 22-10). The congenital nevus grows proportionately to the child as the child grows and may demonstrate surface change and **hypertrichosis** (excessive hairs) often around the time of puberty.

Ordinary nevi may develop on any surface area of the body but are most frequent on areas exposed to sunlight. The number of nevi may be greater in children who experience more sun exposure during the first 10 years of life. Recent data indicate that nevi appear to be sun induced. Although malignant change is very uncommon in infants and children, the amount of sun exposure that children receive and the number of sunburns may increase their risk of developing **melanoma** as adults. Prior to and during puberty, several new lesions may develop and old lesions may evolve to grow in elevation and width. Lesions that appear asymmetrical have borders that are irregular, change color, or rapidly enlarge is a greater concern. Although melanoma is uncommon in children, nevi that are undergoing changes may require evaluation over a period of time in order to identify the possibility of their being abnormal. Abnormal-appearing nevi should be biopsied to obtain a histologic diagnosis. If a melanoma develops, early excision of that melanoma may be curative. The longer the time and the deeper the melanoma develops, the greater its risk of metastasis. Sun protection for infants, children, and adolescents may help prevent the development of skin cancer (Table 22-5). Education of children and parents about daily solar protection and sunscreen use is essential.

Pediatric Pearl: The ABCDEs of skin cancer refer to the important clues to look for in a changing nevus: **A**symmetry (changes in shape), **B**orders (changes in edges), **C**olor (variation in color), **D**iameter (larger than 6 mm), and **E**volving/**E**levation (change in morphology over time/uneven surface).

FIGURE 22-10. This patient has a history of a congenital nevus that has grown proportionately to the child and has developed the characteristic change of superimposed hypertrichosis.

TABLE 22-5

Guidelines for Basic Sun Protection

Keep infants <6 months of age out of direct sunlight (sunscreen may be used on limited body surface areas that are not covered by clothing)
Use sunscreen with a physical blocker (titanium dioxide or zinc oxide) with a minimum SPF of 15 for infants and children >6 months of age with frequent reapplication every 2 to 4 hours
Wear protective clothing
Avoid sun exposure between the peak hours of 10 A.M. and 4 P.M.

INFECTIONS OF THE SKIN

BACTERIAL INFECTIONS

Infants and children are chronically exposed to minor cuts and injuries. Usually, these injuries heal without consequence and do not become infected. When infants do develop cutaneous infections, they are usually due to *Staphylococcus aureus* or *Streptococcus pyogenes*. Superficial infections are called **impetigo**, and deeper infections of the skin are known as **ecthyma**. These lesions may manifest as small fluid-filled pustules or vesicles that rupture easily or, more likely, as erosions, which develop a honey-colored thick crust. The erosions occur on multiple sites of the skin distant to each other (Figure 22-11). Affected children sometimes have a prior history of injury or insect bite. Treatment is usually necessary with topical mupirocin or an oral antistaphylococcal antibiotic such as dicloxacillin, a first-generation cephalosporin, or erythromycin.

FIGURE 22-11. The bullous impetigo in the diaper area in this infant results from infection by *Staphylococcus aureus*. The stratum corneum has eroded centrally but remains on the edge, giving an appearance of a white collar around the lesion.

FUNGAL INFECTIONS

Fungal infections of the body (**tinea corporis**) may appear as localized, round or annular erythematous plaques with scale (Figure 22-12). Often, there is increased scale in the periphery of the lesion. Fungal infections of the scalp (**tinea capitis**) may develop as localized areas of dermatitis, usually with hair loss and cervical lymphadenopathy. Confirmation of the differential diagnosis of fungal infection of the skin necessitates scraping the periphery of the lesion and identifying hyphae in tissue partially dissolved in 10% to 20% potassium hydroxide (KOH). Scalp infections usually require a culture to confirm the diagnosis. The best culture technique involves a Cytobrush® or moistened culture swab rubbed against the involved site multiple times before transfer to the culture media.

Topical therapy with antifungal creams such as miconazole, clotrimazole, or terbinafine is usually effective for localized tinea corporis in children. Infections involving the scalp require oral griseofulvin 10 to 20 mg/kg/day for a minimum of 6 weeks. To maximize absorption of griseofulvin, children should take it with a "fatty" meal that includes 4 to 8 ounces of fresh whole

FIGURE 22-12. Patients with tinea corporis typically present with erythematous annular plaques with scale on the body.

milk or ice cream. Family members should be discouraged from sharing common **fomites** (objects that can spread infection), such as combs, brushes, and caps while the child is undergoing treatment. It is also important to identify other siblings infected in the household in order to treat and potentially minimize the risk of reinfection. Children with scalp infections should be followed closely at 4- to 6-week intervals and treated until clinically cured and cultures are negative.

SCABIES

In infants and children, the infestation known as scabies often presents with increased irritability secondary to the severity of the pruritus. Unlike adults, the face and scalp are commonly involved in infants. Older children and adults also complain of pruritus, although excoriations are frequently seen on other sites of the body. Often, several family members have pruritus and excoriations at the same time. The infestation is caused by the eight-legged mite *Sarcoptes scabiei*. The mite lives in the epidermis, where it lays its eggs.

Diagnosis

Confirmation of the diagnosis involves scraping the skin and finding the mite, which may be difficult, because infected patients may have only 10 to 20 mites present throughout the entire body. Often, only eggs or scybala (stool) are found on scraping. It is important to check patients who have multiple family members with pruritus or individual patients who, on examination, have linear burrows for scabies (Figure 22-13). Scraping involves lightly covering the site of the burrow as well as surrounding small papules with mineral oil and then using a number 15 blade scalpel for the actual scraping. Since the mite lives in the uppermost layer of the skin, it is not necessary to scrape deeply below the epidermis. However, slight bleeding may result from effective skin scraping and clinicians should warn parents about this. Caution should be taken in the uncooperative child. The scraped material is then placed on a slide and examined

FIGURE 22-13. A scabies burrow is seen as a 2 to 10 mm linear tunnel created under the skin as the mite travels. Note the adjacent erythematous papule on the center wrist.

under magnification of 40 to 100×. Identification of the live mite, who may be moving about on the slide, or individual eggs, or feces is diagnostic.

Management

Often, it is difficult to identify the mite, stool, or egg on skin scraping, and therapy is indicated when the diagnosis is suspected and multiple family members appear to be infested. Current recommended therapy is permethrin cream 5%. Application of the cream to the entire body from the neck down is necessary. Clinicians should counsel families that the genital folds, area between the toes and fingers, and the umbilical area are well treated. Infants with involvement of their scalp and face require treatment of these areas as well. It is essential to avoid the eyes and prevent the topical therapy from entering the eyes and causing irritation. Often, therapy is applied at bedtime and washed off 8 hours later in the morning.

Pruritus may continue for several weeks despite successful treatment because the killed mite and mite parts may still remain in the skin. The physician should reevaluate patients in 2 to 3 weeks to be certain that the therapy has effectively removed the infestation and that new lesions do not appear. Because the mite can live as long as 3 days off the host, it is important to disinfect and wash all bedding and recently worn clothing in hot water and not use them for at least 3 days. All family members and close household contacts should receive treatment at the same time because family members may be infested and contagious, although they may not have symptoms. They can then reinfect the entire family, even after effective therapy of the symptomatic members.

HEAD LICE

The cause of head lice is the six-legged insect *Pediculosis capitis*, which lives in the hairs of the scalp and usually passes from child to child. Often, the **nits** (lice eggs) are seen attached to the hair shaft. Under microscopic examination, the characteristic appearance of the nit can be confirmed. Occasionally, live lice are seen moving about the scalp. Usually, this is associated with pruritus, but most children are totally asymptomatic. All infested members of the family should be treated at the same time. Of the various therapies available, the first-line treatment for head lice is permethrin rinse 1% with nit removal by combing. Recently, there have been many reports of head lice that are resistant to common pediculicides. In resistant cases, malathion lotion 0.5% may be the treatment of choice.

VIRAL INFECTIONS (SEE CHAPTER 9)

Viral exanthems are commonly seen in children, who may present with fever and lymphadenopathy and then develop multiple erythematous macules and papules (**morbilliform eruption**) that involve the trunk, face, and extremities. However, often the eruptions are not diagnostic of a specific viral etiology, although in some cases, important clues obtained from the history and physical examination may be helpful in identifying a specific viral pathogen. When evaluating children for what appears to be a viral eruption, it is always necessary to obtain an adequate immunization history. **Measles** may be identified by its association with high fever, cough, rhinitis, and conjunctivitis. **Rubella (German measles)** is often less erythematous with faint, pink macules that appear first on the face and then spread to the proximal extremities. However, many other viruses may produce a similar eruption.

Varicella (chickenpox) has a more characteristic morphology. The lesions appear as tiny urticarial, edematous papules that rapidly become vesicles that often appear very translucent, as if they are dewdrops of water on the skin. The individual lesions rupture and become crusted while new lesions continue to evolve over a 5- to 7-day period. Lesions can also affect the mucous membranes. The condition is often pruritic and should be treated symptomatically. The advent of the varicella vaccine has resulted in a decreased incidence of the disease over time.

Pediatric Pearl: The lesions of chickenpox are generally in various stages.

Herpes simplex may appear as grouped vesicles on an erythematous base, usually on the lip or face in children. The initial infection may be seen as multiple punched-out-appearing mouth ulcerations. Occasionally, herpes simplex lesions may occur on the hand or other body sites, where they may be extremely painful. It is possible to mistake them for a severe deep cellulitis. Children with atopic dermatitis are at risk for **Kaposi varicelliform eruption (eczema herpeticum).** Presence of grouped vesicles on an erythematous base should

prompt the examiner to be suspicious of herpes simplex or possibly of an allergic contact dermatitis. Lesions are infectious until all are scabbed over. Treatment with oral acyclovir is often given for active suppression of recurrent disease.

Warts are common infections caused by the **human papilloma virus** (HPV) (Figure 22-14). Different types of HPV are associated with different infections on different body sites. Therapy for the individual warts is dependent on body site location. Most warts eventually resolve over a 2- to 3-year period. Treatment usually involves trying to destroy infected tissue while limiting the damage to surrounding normal-appearing tissue. Therapy may be difficult and may require multiple attempts. Treatment methods include cryotherapy with liquid nitrogen, topical salicylic acid preparations, or immunotherapy.

Molluscum contagiosum presents as skin-colored, dome-shaped papules that may have a central depressed area, giving the appearance of **umbilication** (Figure 22-15). This benign condition is caused by a poxvirus. The individual lesions range in size from 0.5 to 8 mm. These lesions can be sexually transmitted in adolescents and adults but are usually nonsexually transmitted in infants and children. Occasionally, the skin surrounding the lesions may show marked erythema and scaling (**molluscum dermatitis**). Treatment of the lesions consists of chemical or physical destruction of the overlying skin or removal of the lesion's core. The latter involves using a sharp curette, and in young children, such a procedure may be painful and cause great fear and resistance. Therefore, cantharadin is a common office-based treatment. Cure is often achieved, however some lesions may require retreatment. Without treatment, these lesions do eventually resolve spontaneously but may take months to years.

FIGURE 22-14. The common wart at the end of this child's finger has a rough surface on a base of slightly inflamed skin. Note the grouping of several papules together.

FIGURE 22-15. Patients with molluscum contagiosum often present with groups of papules of different sizes. In this child, three umbilicated papules of similar sizes are grouped together close to a much smaller, isolated papule.

DRUG ERUPTIONS

Drug eruptions often appear as urticarial papules a morbilliform eruption, or areas of erythematous macules, or large patches. The lesions may be pruritic. The onset of drug eruptions is usually between 3 and 14 days after the initial exposure to the drug. Antibiotics and antiseizure medications are common causes of drug eruptions in infants and children.

Occasionally, drug eruptions can be severe and associated with **exfoliation** (shedding) of large areas of skin **(Stevens-Johnson syndrome)**. This exfoliation can also involve the mucous membranes, conjunctiva, and possibly the trachea. It is often difficult to separate a drug eruption from the eruption associated with a viral or bacterial infection.

Trauma, Ingestions, and Burns

Jeffrey R. Avner and Young-Jin Sue

TRAUMA AND SHOCK

Trauma is the leading cause of death in children older than 1 year of age in the United States. Every year, almost 9 million children are injured, resulting in about 15,000 deaths. Almost 45% of these injuries are the result of motor vehicle accidents; other major causes are falls, firearms, bicycle accidents, drowning, and burns. Blunt trauma, as opposed to penetrating trauma, is the predominant mechanism for the majority of injuries in children. This section deals with the management of major trauma. It is important to realize that the best approach to trauma involves prevention. Prevention of unintentional injuries should be the primary goal of clinicians. To this end, pediatricians have made major strides by supporting regulations involving mandatory car passenger restraints and infant car seats, bicycle helmets, and fencing around pools.

Pathophysiology

The principles of trauma care are the same in all patients, but there are important anatomic and physiologic differences between children and adults. Children have a much greater total body surface area per weight and relatively less subcutaneous fat than adults, and stress to the body at the time of the trauma or undressing during the resuscitation can lead to increased evaporative losses and hypothermia. The resultant pathophysiologic cascade then increases peripheral vasoconstriction and causes metabolic acidosis and shock. Remember that children have a high metabolic rate with oxygen consumption almost twice that of adults. Thus, even small physiologic changes can lead to significant effects.

In injured children, shock is primarily hypovolemic. (See Differential Diagnosis for a discussion of the types of shock.) Both blunt and penetrating trauma may cause lacerations of internal organs or extremities, which may account for a significant amount of acute blood loss. Injuries to the liver, spleen, pelvis, or femur can result in loss of 20% to 40% of the circulating blood volume within an hour. Therefore, it is imperative that the physician understands how children respond to such a blood loss. The early physiologic changes in response to hypovolemia are subtle. At first, blood loss leads to tachycardia as the body attempts to maintain cardiac output and thereby preserve organ perfusion. As the blood loss increases, children exhibit evidence of increased tachycardia, slowed capillary refill, lethargy or confusion, and decreased urinary output. Clinical sign of shock, including tachycardia associated with a normal blood pressure, is termed ***compensated shock***. ***Decompensated shock*** is associated with a decrease in blood pressure.

Pediatric Pearl: The ability of the child to maintain cardiac output is quite impressive. Only when acute blood loss approaches 30% to 40% does blood pressure fall. Therefore, the physician should not rely solely on a child's blood pressure when evaluating the degree of blood loss.

Unique anatomic characteristics of children's shape and skeleton affect the type and severity of injuries. Children have a small oral cavity, a relatively large tongue, and a larynx that is more cephalad and anterior than that of adults. These factors, combined with lower respiratory reserve, often cause early respiratory compromise leading to hypoxia and hypercarbia. Children's heads are also relatively large, especially in infancy, when it accounts for over 15% of the total body surface area. Therefore, the head is particularly vulnerable and bears the brunt of injury in blunt trauma. In fact, severe head injury occurs in 80% to 90% of fatal pediatric trauma from motor vehicle crashes.

In addition, children's skeletons are particularly compliant and very resilient. Because the chest wall is elastic, blunt chest trauma may cause serious lung injury in the absence of rib fractures. The liver and spleen are also poorly protected, and there is sparse perinephric fat surrounding the kidneys. Therefore, internal abdominal injury may be present without abdominal bruising or apparent external injury. Furthermore, the child's cervical spine is quite mobile due to ligamentous laxity allowing for spinal cord injury to occur often without radiographic abnormality.

Pediatric Pearl: Children are predisposed to significant internal injury, regardless of the amount of external signs of trauma.

Clinical and Laboratory Evaluation

History

The history should be concise and should focus on the mechanism of the injury and the surrounding events. The paramedics or emergency medical technicians called to the scene report a child's initial vital signs, state of consciousness, any procedures they perform (e.g., intravenous line placement), and medications given. The timing of the injury, the timing of ancillary personnel arriving on the scene, and the timing of arrival of the patient to the emergency department are also important to estimate the amount of blood loss and the extent of injury. Past medical history should include current medical illnesses, current medications, allergies, and immunization status.

Physical Examination

The physical examination is closely tied to management. Trauma evaluation and management involve a "primary survey," the so-called ABCs of acute care stabilization and assessment (Table 23-1), for immediate life-threatening conditions, followed by a "secondary survey" for other types of injuries.

The primary survey begins with stabilization of the cervical spine in a hard collar and assessment of the **airway (A)** for signs of upper airway obstruction (e.g., stridor, gasping, ineffective or absent respirations). Inspection of the neck for jugular venous distension (pericardial tamponade), tracheal deviation (tension pneumothorax), or subcutaneous emphysema (pneumothorax, pneumomediastinum) is part of airway management. The next step is auscultation of **breath sounds (B)** to check whether they are present, and if so, for evaluation of their quality and symmetry. Assessment of **circulation (C)** involves palpating the presence and quality of peripheral and femoral pulses and estimating peripheral perfusion with capillary refill time (normal: less than 2 seconds). A quick neurologic examination to check for **disability (D)** is based on whether the child is awake, responds to verbal or painful stimulus, or is unresponsive. **Exposure (E)** involves complete undress of the child to check for other injuries. The primary survey should take less than 1 minute to perform.

The secondary survey includes a comprehensive physical examination from head to toe to identify all other injuries. It is important that this examination be orderly and include a rectal examination to determine the anal sphincter tone and the presence of occult blood. To assess the child's back and buttocks, it is necessary to "roll" the child to the side. This procedure usually requires two or three people to keep the child's neck in a neutral position; one person maintains the head and neck in line with the body while the others roll and inspect for injury. Often, children are transported to the emergency department on a long spinal board in order to ease transport and to immobilize the spinal column. However, once in the hospital setting, prolonged use of the spinal board can cause pressure sores, discomfort, respiratory compromise, and difficulty in properly assessing the child.

Pediatric Pearl: A child who arrives in the emergency department immobilized on a long spinal board should be removed from the spinal board after the primary survey and resuscitation phases.

Laboratory Evaluation

What laboratory studies are performed depends on several factors, including the mechanism of the trauma, the ability to assess the child, and the nature of the injuries. Radiographic studies (cervical spine, chest, and pelvic radiographs) and blood tests (complete blood count [CBC], spun hematocrit, type and crossmatch, arterial blood gas) are warranted in children with multiple injuries. A urinalysis looking for hematuria may identify a urinary tract injury. Additional studies such as computed tomography (CT) scanning of the head or abdomen may be obtained after the resuscitation and reevaluation.

TABLE 23-1

Immediate Management of the Injured Child (ABCs)

Airway and cervical spine ("C" spine)
- Protect neck with rigid cervical collar
- Assess for airway obstruction
  - Chin lift/jaw thrust maneuver, if needed
  - Prepare for endotracheal intubation, if needed

Breathing
- Administer 100% oxygen
- Place on continuous pulse oximetry monitoring
- Assess for quality and asymmetry of breath sounds
- Assess for work of breathing

Circulation
- Attach cardiac monitor leads
- Obtain intravenous access with two large-bore catheters
- Assess for signs of peripheral perfusion (pulses, capillary refill)
- Control hemorrhage

Disability
- Brief neurologic examination
- Level of consciousness (AVPU: **A**lert, responds to **V**erbal commands, responds to **P**ain, **U**nresponsive)
- Pupillary size and response to light

Exposure
- Completely undress child

The use of focused abdominal sonography for trauma (FAST) is becoming more accepted as a screening tool in the evaluation of blunt abdominal trauma. In children, the physical examination of the abdomen may be difficult and unreliable. In addition, the clinical signs of intra-abdominal injury are often subtle. The FAST examination is a rapid, noninvasive diagnostic study, performed in the emergency department, to detect free intraperitoneal fluid or the presence of cardiac tamponade. In the hemodynamically unstable child, a positive FAST examination is an indication for emergency exploratory laparotomy. In the hemodynamically stable child, a positive FAST examination should be followed by an abdominal CT scan to further delineate the presence and extent of parenchymal injury, whereas children with a negative FAST examination may be followed with clinical observation and serial abdominal examinations.

Pediatric Pearl: The use of the FAST examination is an effective and rapid screening tool for the evaluation of children with blunt abdominal trauma. This practice has reduced the need for abdominal CT scans (and the associated large radiation exposure) for many hemodynamically stable children.

Differential Diagnosis

Children with major trauma are often in shock. Therefore, the physician must be able to recognize shock and identify its cause.

Hypovolemic Shock

The majority of children with major trauma present with some degree of hypovolemia. Deep or multiple lacerations, amputations, and obvious fractures are clear causes of the blood loss. However, it is essential to be acutely aware of occult injuries, especially in children who do not respond to initial fluid therapy. A large amount of unrecognized bleeding may accompany fractures of the pelvis or femur. Despite a seemingly soft, nontender abdomen,

severe intra-abdominal injuries such as lacerations or rupture of the liver or spleen may be present. In addition, young infants with head trauma can become hypotensive from blood loss into an epidural or subdural hematoma.

Estimates of the degree of hypovolemia due to the acute loss of blood often make use of several clinical parameters. With acute blood loss of up to 15% of the total blood volume, there is little if any change in the pulse, blood pressure, respiratory rate, mental status, or urinary output. However, as the blood loss exceeds 15%, the heart rate and respiratory rate begin to rise, and children become more anxious. The decline in blood pressure and noticeable decline in urine output does not become apparent until about 30% to 40% of the blood volume is lost. This is a crucial point for management; blood pressure changes are a late finding in hypovolemic shock, whereas tachycardia and tachypnea occur earlier.

Obstructive Shock

Obstructive shock occurs when there is restriction of blood flow either to or from the heart. Children with severe injuries to the chest wall or penetrating chest wounds may have **pericardial tamponade,** which may lead to obstructive shock. Failing vital signs are associated with tachypnea, clear and equal breath sounds, neck vein distension, and distant heart sounds. Other causes of obstructive shock include **tension pneumothorax, flail chest, and hemothorax or pneumothorax.**

Cardiogenic Shock

Cardiogenic shock resulting from a **myocardial contusion or arrhythmia** may follow a direct, powerful blow to the sternum. **Commotio cordis** occurs after a sudden, direct blow to the precordium (e.g., when a Little League player is hit in the chest with a baseball) and results in ventricular tachycardia or fibrillation leading to sudden death. The impact occurs during a specific vulnerable period of the cardiac cycle (10 to 30 ms before the peak of the T wave). Rapid deceleration injury can be seen with motor vehicle accidents. Fortunately, the hearts of children have a great degree of compliance and resiliency, so that myocardial infarctions and tearing of major vessels are rare.

Neurogenic Shock

A spinal cord injury may result in the loss of tone of the blood vessels with accumulation of fluid in the peripheral circulation. Thus, the classic picture of neurogenic shock is hypovolemia without tachycardia. The absence of tachycardia differentiates neurogenic shock from the more common hypovolemic shock. Concurrent chest or abdominal trauma is often present in neurogenic shock.

Septic Shock

Septic shock is uncommon in acutely injured children. However, children who are evaluated a long time after their injury or those who have penetrating abdominal injury are at risk for the development of sepsis. In isolated septic shock, tachycardia, and normal or slightly decreased blood pressure occurs. Peripheral perfusion may be increased, leading to warm pink skin (warm shock), or decreased, leading to cool, clammy skin.

Management

In most cases, emergency medical workers notify the emergency department that they are transporting an injured child from the scene of the trauma to the hospital. At this time, the trauma team (pediatrician, emergency department physicians, surgeons, nurses, and radiology technician) is assembled. The leader of the trauma resuscitation team is usually the trauma surgeon or the emergency department physician. It should be noted that optimal management of pediatric trauma involves a pediatrician, preferably a pediatric emergency medicine physician. The pediatrician should ensure that the unique characteristics of a child's anatomy and physiology are addressed.

The initial management of children with multiple trauma begins in conjunction with the primary survey (see Table 23-1). Management proceeds in the standard sequence of the ABCs (**A**irway and cervical spine immobilization, **B**reathing, **C**irculation, **D**isability [neurologic], and **E**xposure). Immediate correction of any abnormality noted during the primary survey is necessary.

It is necessary to immobilize the cervical spine in a rigid collar, if prehospital care providers have not already performed this. A clinician should talk to the child and see whether he can talk, hear, and understand. This clinician–patient interaction helps assess airway patency and central nervous system (CNS) function. If there is difficulty maintaining a patent airway, a chin-lift and jaw-thrust maneuver are necessary; these measures should help move the mandibular block of tissue forward and away from obstructing the airway. If these simple maneuvers are not effective, manual bag–valve–mask ventilation or endotracheal intubation may be warranted.

If there are signs of inadequate breathing, it is essential to look for evidence of a tension pneumothorax (asymmetric breath sounds, hyperresonant percussion note, and tracheal deviation). To relieve a

tension pneumothorax, a physician should insert a 16-gauge needle above the third rib into the second intercostal space in the midclavicular line.

To secure vascular access, two large-bore peripheral intravenous lines should be placed (usually in the antecubital fossa) or centrally (femoral vein). These large intravenous lines are essential because the hypovolemia is often profound. If immediate intravenous access is not secured in a young child, an intraosseous line can be used. Placement of an intraosseous line involves insertion of a 14- or 16-gauge intraosseous needle (e.g., bone marrow needle or any other large-bore needle with a stylet) into the flat surface of the anterior, proximal tibia, angling slightly away from the growth plate. Rapid fluid resuscitation requires administration of Ringer lactate or normal saline in repeated increments of 20 mL/kg until adequate perfusion is restored. If blood loss continues or there is no response to the fluid boluses, rapid infusion of type-specific packed red blood cells (RBCs) is necessary. Control of any obvious source of bleeding entails the use of direct pressure or pneumatic splints.

A rapid neurologic assessment should include pupillary size and response to light, as well as a score on the Glasgow coma scale (Table 23-2). A score of 8 or less may be a sign of intracranial hypertension. In that case, it is important to elevate the head to 30 degrees and implement mild hyperventilation in an attempt to reduce the intracranial pressure until evaluation by the neurosurgeon.

It is necessary to undress the child and perform a complete, detailed physical examination, including the buttocks and back. At this time, a Foley catheter is placed unless there is evidence of urethral disruption (blood at the urethral meatus or a scrotal hematoma). Certain management options are warranted in life-threatening conditions (Table 23-3). Further treatment is based on the specific injuries identified in the secondary survey.

During this first stage of trauma management, the physician should immediately consult appropriate specialists based on the child's most serious injuries. Specialists involved in the care of the injured child often include neurosurgeons, orthopedic surgeons, anesthesiologists, and radiologists. Because specialists usually focus on their area of expertise, the pediatrician must coordinate these services. In addition, the pediatrician should provide counseling to the parents, addressing their concerns and keeping them informed of further plans for the child.

TABLE 23-2

Glasgow Coma Scale[a]

Physical Feature	*Score*

TABLE 23-3

Management Options for Life-Threatening Conditions

Finding	*Problem*	*Management*
Noisy breathing	Upper airway obstruction	Chin lift/jaw thrust
Stridor		Intubation
Neck pain or tenderness	Possible cervical spine fracture	Immobilize neck (hard collar)
Head trauma		Lateral cervical spine radiograph
Multiple trauma		
Asymmetric breath sounds and hyperresonant percussion note	Possible tension pneumothorax	Insert 16-gauge needle into second intercostal space in midclavicular line
Penetrating chest wound	Possible sucking chest wound	Loosely apply occlusive dressing Insert chest tube
Penetrating chest wound with muffled heart sounds or distended neck veins	Possible cardiac tamponade	Pericardiocentesis
Paradoxical chest wall movement	Flail chest	Positive pressure ventilation for respiratory distress
Orthostasis; pale, cool skin	Hypotension or shock	Establish two large-bore IV lines Give crystalloid boluses 20 mL/kg Transfusion Emergent: type O, Rh-negative Urgent: type-specific

IV, intravenous.

Adapted from Avner JR, Hain L: Pediatric trauma. In *Clinical Manual of Emergency Pediatrics*. Edited by Crain EF, Gershel JC, Gallagher EJ. New York, McGraw-Hill, 1992.

HEAD TRAUMA

Head trauma, a major cause of morbidity and mortality in children, accounts for 70% to 80% of childhood deaths from trauma. Head trauma is very common, but fortunately, most cases are minor and do not require hospitalization. As with other types of trauma, prevention remains the best method to reduce the effects of these injuries. To this end, the enactment of legislative policies (national speed limit, mandatory child restraints, bicycle helmets, window guards) in recent decades has led to a decrease in the incidence of accidents that may cause head trauma.

Pathophysiology

At the exact moment of head trauma, there is direct impact of the brain against the skull, causing neuronal damage. Depending on the mechanism involved, this "primary injury" may cause cerebral contusion, laceration, hematoma, diffuse axonal injury, or diffuse brain swelling. The transient brain dysfunction that accompanies such injury may be associated with disruption of normal respiration and circulation. Nothing can change the immediate effects of the primary injury because the damage occurs on impact.

Management of head trauma is centered on prevention of the "secondary injury" caused by the hypoxia, ischemia, and mechanical distortion that the primary injury sets in motion. Neuronal damage affects the autoregulation of cerebral blood flow and can lead to ischemic brain injury. At first, diffuse brain swelling

causes displacement of cerebral buffering mechanisms (spinal fluid and vascular spaces) in an attempt to preserve the intracranial pressure. However, as the swelling increases, the intracranial pressure necessarily rises and causes further ischemia and hypoxia. If uncorrected, secondary brain injury leads to irreversible brain damage or death.

Clinical and Laboratory Evaluation

History

It is always important to ascertain the time and mechanism of injury as well as the initial manifestations at the scene of the event. The clinician should ask about the occurrence of loss of consciousness, seizures, vomiting, headache, and dizziness.

Physical Examination

To look for other injuries, the physician should perform a detailed neurologic examination as well as a complete physical examination. Signs of increased intracranial pressure include hypertension, abnormal respirations, irritability, visual changes, papilledema, cranial nerve palsies, and posturing. It is important to palpate the head and neck for hematoma, depression, and tenderness. Hemotympanum and clear rhinorrhea are signs of basilar skull fracture. Check the pupils for asymmetry, size, and reaction to light and record an initial score on the Glasgow coma scale (see Table 23-2). Unexplained skin bruising or retinal hemorrhages on funduscopic examination suggests child abuse.

Laboratory Evaluation

The need for blood tests is based on the severity of injury. If the injury appears minor and the child is awake and responsive with normal vital signs, no blood tests are necessary.

Skull films are rarely helpful because they are not predictive of intracranial injury, and most skull fractures do not require treatment. Indications for skull radiographs include a penetrating injury or suspicion of a depressed skull fracture.

CT scanning is the best method to look for the presence of intracranial injury. A CT scan is indicated for prolonged loss of consciousness (over 15 minutes), seizures, abnormal neurologic examination, abnormal mental status, or significant associated injury requiring an operation.

Differential Diagnosis

Usually, it is apparent from the history or the physical examination that a child has suffered head trauma. However, the physician should always consider head trauma in the differential diagnosis if there is a change in mental status or an altered level of consciousness. Children with significant head trauma from child abuse may present with only a history of apnea, cyanosis, poor feeding, or lethargy.

- A **concussion,** the most frequent type of head injury, is an immediate, transient interruption of normal neurologic function. Affected children often experience a period of confusion or loss of consciousness and may have posttraumatic amnesia. Other clinical symptoms that suggest a concussion may have occurred include headache, dizziness, ringing in the ears, "seeing stars," slurred speech, and poor coordination.
- A **cerebral contusion** is an area of focal hemorrhage in the brain. This injury may occur at the point of impact between the brain and the skull or at the site directly opposite the impact (coup and contrecoup injury). There is often an associated concussion.
- An **epidural hematoma** is a collection of blood just outside the dura. There is arterial bleeding, usually from a tear of the middle meningeal artery. The classic presentation is concussion, followed by a "lucid interval" when the child appears well, and then neurologic deterioration. However, no lucid interval or period of loss of consciousness is apparent in many cases.
- A **subdural hematoma** is a collection of blood just beneath the dura. This occurs as the result of tearing of the dural sinuses or bridging veins. The presenting symptoms may range from nonspecific neurologic findings to coma.

Pediatric Pearl: Unlike epidural hematoma, the mechanism that causes a subdural hematoma usually also results in underlying brain injury. This explains why subdural hematomas carry a worse prognosis than epidural hematomas.

Management

As with any trauma, management begins with stabilization of the cervical spine, airway, breathing, and circulation. If abnormal respirations, loss of protective airway reflexes, or signs of increased intracranial pressure (Glasgow coma score of 8 or less) are present, then endotracheal intubation followed by manual hyperventilation is warranted. Because endotracheal intubation is difficult and necessitates adequate sedation and muscle relaxation, only experienced personnel should perform it. If hypovolemia is present, Ringer lactate or normal saline solution should be given in boluses of 20 mL/kg. Because cerebral perfusion pressure depends on the mean arterial pressure, restoration of the intravascular space is essential. Once euvolemia has been achieved, then fluid restriction to limit cerebral edema can begin. Immediate neurosurgical consultation is necessary. The head should be elevated to 30 degrees and placed midline so there is no obstruction to venous outflow from the head. Increased intracranial pressure, if present, necessitates aggressive management (see Chapters 19 and 24).

In general, it is helpful to classify children into three categories based on their initial manifestations, Glasgow coma score, and the mechanism of injury. Children with **low-risk injuries** are asymptomatic with a normal neurologic examination. Management at home with observation by a parent is sufficient. Children with **moderate-risk injuries** have a history of altered consciousness, progressive headache, persistent vomiting, seizures, amnesia, or an associated injury. A neurosurgical consultation and a CT scan are warranted. The duration of observation in the emergency department and the need for hospitalization depend on the resolution or progression of symptoms. Children with high-risk injuries present with a depressed level of consciousness, focal neurologic examination, signs of increased intracranial pressure, or penetrating injury. Emergent management and neurosurgical consultation are necessary. Children with epidural hematomas and penetrating injuries usually require immediate operative intervention. Young patients with other severe injuries may require placement of intracranial pressure monitors.

Abuse should be suspected in infants with subdural hematomas or cerebral injury out of proportion to the degree of trauma sustained (see Chapter 24). In "shaken baby syndrome," rapid acceleration–deceleration injuries cause diffuse shearing of the gray and white matter, leading to diffuse cerebral edema. Retinal hemorrhages are often seen in the fundus of these children. Unfortunately, prognosis for this type of injury is very poor.

MINOR TRAUMA

This section concentrates on the management of **lacerations, abrasions,** and **puncture wounds,** which represent approximately 35% of all injuries seen in a pediatric emergency department. These injuries are common in the summer months when children spend more time engaging in outdoor activities such as bicycling, baseball, and basketball. As with other types of injuries, toddlers are at high risk because they often lack the experience and motor coordination of older children. Most lacerations occur on the face, mouth, and scalp; children's heads represent a large part of the total body surface area and is, therefore, easily subject to injury.

Pathophysiology

Two types of lacerations—those caused by glass and those caused by animal bites—deserve special consideration, because they are more common in children than adults. Injuries involving glass are responsible for as many as 20% of lacerations. Because these lacerations are caused by very sharp edges, the wounds tend to be deep and are often associated with injuries to nerves and tendons. In addition, many of these wounds contain fragments of glass, which, if undetected, may cause delayed healing, increased scarring, neurapraxia, and increased risk of infection.

Mammalian bites are another common source of injury in children. According to estimates, dog bites account for almost 90% of bite injuries, cat bites 5%, and human bites 3%. There are distinct differences in the type of injuries caused by dogs and cats. **Dog bites** can be very powerful, generating 150 to 450 pounds per square inch of pressure. They cause lacerations, avulsions, and crush injury to soft tissue. Although **cat bites** are less forceful, they usually result in deep puncture wounds because cats have very sharp teeth. Deep puncture wounds are associated with a high inoculum of bacteria into a small space, making irrigation and debridement difficult. Therefore, the infection rate is 20% to 50% for cat bites compared with 5% for dog bites. The organisms responsible for infection also vary with the type of bite. Although *Staphylococcus aureus* and streptococcal bacteria are common in all bites, dog and cat bites often carry *Pasteurella multocida,* and human bites carry *Eikenella corrodens.*

Clinical and Laboratory Evaluation

History

The history should include when and where the injury occurred and the mechanism involved. (In wounds that are less than 12 hours old, primary closure is appropriate and does not increase the risk of infection.) The clinician should ask whether fragments of glass were present (e.g., with falls onto a shattered glass bottle). For bite wounds, it is important to identify the animal involved so that the risk of **rabies** can be better ascertained. Past medical history should include the child's immunization status and whether the child has allergies to antibiotics or local anesthetics.

With a **"closed fist injury,"** it is often difficult to obtain the correct history. This injury usually occurs when an adolescent punches someone in the mouth and sustains a small laceration over the metacarpophalangeal joint. The adolescent may not want to reveal that there was a fight and often does not seek immediate attention. This injury can force a high inoculum of virulent oral bacterium deep into the fascial planes of the hand and is associated with a high risk of infection. The patient then presents 2 or 3 days after the injury with a serious hand infection. Thus, the presence of a laceration over the metacarpophalangeal joint in an adolescent should lead to the assumption of a closed fist injury.

Physical Examination

It is important to document the wound size, depth, and location by using pictures or diagrams if necessary; record whether the bottom of the wound is visible and whether glass or other foreign material is present in the wound. The physician should check the sensation, vascular supply, and motor function distal to the injury, as well as carefully inspect the wound and identify any nerve, muscle, tendon, or vascular injury. It is also necessary to perform a complete physical examination to look for other lacerations or trauma away from the site of the injury.

Laboratory Evaluation

Unless there is an unusual amount of blood loss or a history of a bleeding disorder, no blood tests are necessary. A radiograph of the involved area is warranted if there might be an associated fracture or if the wound was caused by glass. Most glass in use today is radiopaque, so a radiograph may show a retained glass fragment not seen on visual inspection of the wound.

Differential Diagnosis

Usually, the diagnosis of a laceration is evident, and the mechanism and causative agent are readily obtained. However, if the injury is not compatible with the history or the developmental age of the child, the physician should be concerned about the possibility of child abuse.

Management

It is necessary to clean all wounds of obvious debris and clotted blood by gentle washing or soaking in saline solution. With wounds less than 12 hours old and facial wounds less than 18 hours old, primary closure is allowable. The shaving of a small amount of hair from the surrounding area may be appropriate, but it is important to **leave eyebrows intact**. A dilute povidone solution is used to clean the area around (but not inside) the wound. The infiltration of 1% lidocaine usually provides local anesthesia. The physician should be aware that the **maximum dose of lidocaine is 4 mg/kg**. For better hemostasis, a combination of lidocaine with epinephrine may be used, **except when suturing end organs such as the fingers, ears, or nose.**

Pediatric Pearl: In an effort to reduce a child's pain, anxiety, and fear of needles, which are often associated with laceration repair, topical anesthesia may sometimes replace a lidocaine injection. A solution such as lidocaine–epinephrine–tetracaine applied directly to the wound via a solution-soaked gauze for 15 to 20 minutes may be effective.

The wound should be cleaned and irrigated prior to closure. In general, normal saline is the preferred fluid for safe and effective irrigation. However, recent studies suggest that potable tap water may be as effective as normal saline for irrigation of most wounds. The clinician should extract any visible foreign body, excise necrotic skin, and debride free subcutaneous tissue. Exploration and repair of deep structures, if necessary, should occur. Deep lacerations require subcutaneous sutures (absorbable) to better oppose the skin. The clinician everts the skin edges and approximates them using the smallest nonabsorbable sutures that will do the job. **Staples,** which

TABLE 23-4

Wounds at High Risk for Infection

Cat bites
Human bites
Hand wounds
Puncture wounds
Wounds more than 18 hours old
Wounds in an immunosuppressed child

can be applied quickly, have a lower rate of tissue reactivity compared to sutures but do not allow as meticulous a closure. They are particularly useful for wound closure in noncosmetic areas (e.g., scalp, extremities) or in children with multiple traumas, when speed of repair is essential. Application of a sterile dressing completes the treatment process. A follow-up arrangement should be made for removal of nonabsorbable sutures.

Tissue adhesives such as the glue-like substances cyanoacrylates have become a popular method for faster wound closure with less need for sedation and local anesthesia. Wound closure involves approximation of the wound edges with fingers or forceps and painting the tissue adhesive over the apposed wound edges; it is necessary to hold these together for 30 seconds to allow complete polymerization of the glue. There is no need for a dressing; the adhesive sloughs off in 7 to 10 days. Lacerations of toddlers' foreheads or chins are particularly amenable to this type of repair.

Vigorous soaking and irrigation of abrasions are necessary because embedded debris is often present. A thin layer of antibiotic ointment and a sterile dressing are necessary.

High-risk wounds (Table 23-4) require consultation with a plastic surgeon. Because of the high risk of infection, primary closure of these wounds should be avoided unless a cosmetically important area is involved. **Prophylactic antibiotics** are necessary for wounds more than 18 hours old, for **most animal bites and all human bites.** However, it is important to realize that **antibiotics are no substitute for thorough wound cleaning and judicious debridement.**

Elevation of the injured area is required, and a splint may be necessary. Tetanus prophylaxis is based on the child's immunization status. For animal bites, the local health department can give advice regarding the need for rabies prophylaxis. Close follow-up is the rule for all children.

CARE OF TOXIC INGESTIONS AND FOREIGN BODIES

Toxic exposures are encountered frequently in children, in both exploring toddlers and experimenting adolescents. Successful management of poisonings requires a basic knowledge of toxicologic principles. Medical toxicology, the study of pathologic effects of exogenous substances on human physiology, is fundamental to the practice of therapeutic medicine, and a solid grounding in its principles is advantageous to the practitioner of any medical specialty. In addition, persistent history seeking, a meticulous physical examination, a few key diagnostics, and investigative curiosity are indispensable tools for the evaluation of poisoned children.

Pathophysiology

Pediatric poisonings fall into two important groups, which require distinctly different management approaches. **Accidental poisoning** occurs, for the most part, in **younger children** who have been left momentarily undersupervised. Usually, only **single agents** are ingested and, even then, in clinically **unimportant quantities.** Although the child's ability to communicate or the deductive abilities of adult witnesses may restrict the historical details, they are usually not purposeful attempts on the part of patients to mislead examiners.

In contrast, **intentional poisoning** largely occurs in **adolescents and adults**. Toxic substances may be used for recreational purposes or taken in overdose with the intent of self-harm. Often, **multiple substances** are involved in **significant quantities**. Consequently, these patients are at high risk for serious illness. For any of several reasons (e.g., avoidance of legal consequences, fear of parental reaction, seriousness of suicidal intent), patients may be unwilling to volunteer truthful information regarding the ingestion. Therefore, in the setting of an intentional poisoning, the examiner should be wary of potential inaccuracies in the patient's history.

The task of evaluating poisoned patients is simplified if the toxin can be determined with certainty. However, patients may be unable or unwilling to identify the toxic agent or agents, especially in the case of intentional overdose. In the latter case, the clinical skills of the examining physician are put to the test. Greater reliance is placed on the physical examination and diagnostic measures to offer critical clues to the identification of the toxin or toxins. In the absence of essential information, it is often necessary to prepare for the worst and enforce a period of observation.

Pediatric Pearl: If poisonings are intentional or occur in adolescents, the "worst case scenario" should be the basis of initial management, and selected standard diagnostic measures are warranted.

Clinical and Laboratory Evaluation

History

The primary goal when obtaining the history is to confirm that an ingestion has occurred and to determine the potential seriousness of the poisoning. Key questions in evaluating a poisoning include the following:

- What is the poison?
- When or over what period did the poisoning occur?
- How much poison was involved?
- By what route did the poisoning occur?
- Was the poisoning accidental or intentional?

One or more routes may result in poisoning. The most common is gut absorption following ingestion. Other routes of toxin absorption include inhalation, injection, and topical exposure. In children, in particular, the dose of the toxin per body weight is often necessary for determining the seriousness of the ingestion.

Occasionally, a patient comes to medical attention with signs and symptoms of an illness without a clear cause. Factors consistent with toxicologic causation include acute onset of illness, history of pica or previous ingestion, history of environmental stress or depression, past overdose attempts, at-risk age group (toddlers, adolescents), and a story that "just doesn't make sense." For the toddler who develops symptoms resembling a toxic exposure, knowing where the poisoning may have taken place is of help. For example, toxins found in a garage are distinct from the array of poisons available in the bathroom cabinet. Knowledge of past drug use patterns may help in the evaluation of an intoxicated adolescent. For the unknown overdose, it is necessary to conduct a dogged interrogation to identify all medications available in the home, including those belonging to other family members. If partially empty or unlabeled bottles are found, it is essential to make the correct product identification. References, pharmacists, prescribing physicians, and regional poison centers may be helpful.

Finally, the toxicologic management of a given patient must consider the patient's past medical problems, active medical conditions, current medications, and allergies. These not only may provide insight into the current clinical picture but also may alert the physician to potential contraindicated therapies or drug interactions.

Physical Examination

The physical examination provides critical clues to the severity and nature of the poisoning. It begins with the initial assessment of cardiorespiratory stability and vital signs and progresses to a rapid assessment of neurologic function and methodic head-to-toe examination. Equally important is the ongoing observation and repeated evaluation of the patient as the case unfolds. Absence of physical findings may be consistent with a nontoxic ingestion. However, early in the course of serious ingestions, children may also be free of symptoms. Countless toxins may result in nonspecific symptoms such as drowsiness, vomiting, or abdominal distress. Certain groupings of symptoms may suggest specific classes of toxins. These **"toxidromes,"** if present, are especially useful in the evaluation of the unknown poisoning (Table 23-5).

Depressed level of consciousness is a hallmark of primary CNS depressants such as alcohols, opioids, barbiturates, and benzodiazepines. CNS depression may be secondary, resulting, for example, from insulin-mediated hypoglycemia or cellular asphyxia due to carbon monoxide. Respiratory depression is a commonly seen complication of severe CNS depression. **Seizures** may result from a number of sympathomimetic agents such as

TABLE 23-5

Diaphoresis
Delirium, psychosis
Seizures

theophylline, cocaine, and amphetamines. Antidepressants, antihistamines, and isoniazid are therapeutic drugs that may also cause seizures in overdose. Camphor and pesticides, which are commonly found in the home, are two epileptogenic poisons.

Overdose of certain substances results in specific signs and symptoms (Table 23-6). **Hypotension** and bradycardia are seen with parasympathomimetic agents such as organophosphate pesticides or with sympatholytic antihypertensive agents such as β-blockers. Hypotension with tachycardia accompanies hypovolemia, which results from severe vomiting, diarrhea, and third-space redistribution that is seen with many heavy metals and plant toxins. **Dysrhythmias** occur following overdose of tricyclic antidepressants and cardiac medications such as digitalis and quinidine. In children who present with unexplained hyperthermia, sympathomimetic drugs, salicylates, and anticholinergic agents warrant consideration.

TABLE 23-6

Major Signs and Symptoms of Some Common Poisonings

Agent	*Signs and Symptoms*
Acetaminophen	No symptoms (early) Hepatic failure (late)
Iron	Vomiting, abdominal pain Hypotension
Salicylates	Hyperpnea, vomiting Metabolic acidosis
Albuterol	Tachycardia, excitation
Diphenhydramine	Lethargy, tachycardia, seizures
"Super warfarins"	No symptoms (early) Bleeding (late)
Ethanol	Lethargy, ataxia Hypoglycemia
Isoniazid	Seizures

Finally, characteristic **odors** may provide clues to the intoxicant. Most individuals are familiar with the odors of ethanol and mothballs. Methyl salicylate smells of wintergreen, and organophosphate pesticides smell of garlic. **Burns** of the oral mucosa or skin are an important physical finding following ingestion of caustic compounds.

Laboratory Evaluation

The diagnostic measures selected depend on the history, clinical appearance, and intentionality. For most accidental childhood ingestions of a single agent such as bleach, a cold preparation, or detergents, observation alone is sufficient if the child has no symptoms. After small ingestions of acetaminophen, salicylates, or ethanol, drug levels are not required if the amount ingested does not approach toxic doses, and the history is certain. For unclear reasons, ethanol is associated with hypoglycemia in young children. Therefore, it is good to offer something sweet while observing the small child who may have ingested ethanol. If the amount ingested cannot be calculated with reasonable certainty, symptoms are present, the amount consumed is great, or there is doubt concerning the verity of the history, diagnostic and therapeutic measures are indicated.

The intentional overdose requires an entirely different approach. A very low threshold for diagnostics and decontamination is essential despite the apparent triviality of the poisoning. In all adolescent or intentional ingestions where the history may be inaccurate, assays for commonly available drugs such as acetaminophen and an electrocardiogram are routinely indicated.

Blood levels may or may not correlate with clinical toxicity. For several commonly ingested agents (i.e., salicylates, acetaminophen, ethanol, theophylline), blood levels are rapidly performed in most clinical laboratories, provide useful information about prognosis, and guide therapeutic interventions. For other drugs, the mere qualitative presence in blood or urine has important implications for patient disposition. For example, finding cocaine or opioids in a small child should prompt a child welfare investigation.

Pediatric Pearl: It is impossible to screen for all agents, and the specific panels of drugs screened vary between laboratories. The toxicology screen should only be used as an adjunct to clinical suspicion regarding a specific drug or drugs, and the clinician should be familiar with the drugs included in a given screen.

Routine laboratory evaluations may help assess an unknown intoxication. Both hypoglycemia and electrolyte disturbances may result from and contribute to toxic syndromes. Immediate determination of blood glucose

TABLE 23-7

Radiopaque Compounds

Chlorinated compounds (chloral hydrate, carbon tetrachloride, *p*-dichlorobenzene)
Heavy metals (iron, mercury, lead)
Iodine
Phenothiazines
Slow-release preparations (enteric-coated analgesics)
Stuffers (cocaine- or heroin-filled packets)

is warranted in every lethargic or comatose child. Likewise, a therapeutic trial of naloxone in an obtunded child may diagnose opioid intoxication by producing abrupt arousal. It is important to use caution with naloxone in patients who are known to be habitual users of opioids because sudden administration of the antagonist may precipitate withdrawal. For toxins known to cause bleeding, coagulopathy, hepatic toxicity, renal compromise, rhabdomyolysis, or respiratory failure, the selective use of the CBC, prothrombin time (PT), partial thromboplastin time (PTT), serum chemistries, and blood gas values are indicated both to determine baseline values and to monitor the evolution of the illness.

Radiographs have selective utility in poisonings. Aside from demonstrating pneumonitis or pulmonary edema, radiographs may be of help in diagnosing ingestion of certain drugs that are radiopaque in large enough quantities. The mnemonic "CHIPSS" can be used to remember the radiopaque compounds (Table 23.7). Absence of unexplained radiopacities on the abdominal radiograph does not rule out ingestion of these substances.

The presence of an elevated anion gap metabolic acidosis (sodium − [chloride + bicarbonate]) of greater than 12 to 16 mEq/L suggests several toxins. The mnemonic "AT MUDPILES" can be used to recall the substances that cause metabolic acidosis (Table 23-8). Similarly, an elevated osmol gap (range: −5 to +15 mOsm), calculated by the equation

$$2(\text{sodium}) + \frac{\text{glucose}}{18} + \frac{\text{blood urea nitrogen}}{2.8}$$

may be associated with the toxic alcohols or diuretics. However, a nonspecific elevation of the osmol gap is seen in many other disease states (e.g., liver disease, sepsis).

TABLE 23-8

Substances Causing Anion Gap Acidosis

Alcohols
Toluene
Methanol
Uremia
Diabetic ketoacidosis or other ketoacidosis (alcoholism, starvation)
Paraldehyde or phenformin
Iron or isoniazid
Lactic acidosis
Ethylene glycol
Salicylates or strychnine

Assessment and Differential Diagnosis

Following the initial evaluation, the clinician must assess the nature and seriousness of the poisoning.

- Given the identity and quantity of the toxin involved, has a clinically consequential poisoning occurred?
- Is the patient ill now, or is the patient likely to become ill?
- Are there nontoxicologic disease processes that may be taking place instead of or in addition to the poisoning (e.g., traumatic and infectious causes, which should always be considered in the evaluation of the altered or febrile child)?
- To minimize the morbidity that may result from the poisoning, how and when should the clinician intervene?

Management

Attention to life-threatening processes is the initial priority. The basic life-support sequence of **airway (A), breathing (B),** and **circulation (C)** is central to the successful management of toxicologic emergencies (see Table 23-1).

After initial stabilization, the cornerstone of toxicologic management is **decontamination**. The objective of decontamination is to minimize systemic absorption of the toxin. For skin or mucous membrane exposure, this consists of irrigation of the contaminated surfaces. In the case of intoxication by inhalation, removal from the source of toxic vapors to fresh air and the administration of humidified oxygen are indicated. For ingested toxins, gut decontamination consists of one or more of the following: gastric emptying by emesis or lavage, the administration of a sorbent such as activated charcoal, and the addition of a cathartic.

In considering **gastric emptying,** the clinician must consider the safety of the procedure and the likelihood of removing clinically important amounts of toxin. In general, both emesis and gastric lavage may predispose individuals to aspiration if performed in patients who are lethargic, comatose, or seizing. The ingestion of corrosive agents and hydrocarbons are contraindications because both procedures may exacerbate gut mucosal damage, increase the risk of perforation, or lead to aspiration. Emesis with syrup of ipecac at home is no longer recommended as it is rarely considered an adequate substitute for medical attention. Although gastric lavage is the preferred method of gastric emptying in the hospital setting, its significant risks limit its use to very select cases.

Pediatric Pearl: Most toxicologists accept that gastric lavage still has a place in the treatment of massive, life-threatening ingestions for which alternative treatments are insufficient (e.g., sustained-release calcium channel blockers). If gastric lavage is used in an obtunded individual, measures to secure a safer airway (i.e., endotracheal intubation) must be taken beforehand.

Activated charcoal avidly adsorbs to a large variety of toxins and may be safely administered to most patients. However, it does not adsorb heavy metals, hydrocarbons, and alcohols well. Potential adverse effects of charcoal include (1) aspiration, particularly when administered forcibly to obtunded individuals, and (2) charcoal inspissation in the gut with the potential for perforation in the patient with ileus.

Cathartics are intended to decrease absorption by hastening gastrointestinal transit. In repeated doses, they may cause dehydration and electrolyte imbalance. Whole bowel irrigation with an iso-osmotic solution such as polyethylene glycol is preferred for enhancing elimination of pills or particles that have passed beyond the stomach, especially those that are not adsorbed by charcoal. Gut decontamination is most effective when instituted early, before significant absorption has occurred.

Several measures may hasten postabsorptive elimination of a substance. Examples include hemodialysis, charcoal hemoperfusion, ionized diuresis, and multiple doses of activated charcoal. For dialysis to be useful, a toxin should be small enough to traverse the dialysis membrane, should possess a small volume of distribution (i.e., largely limited to the intravascular space), and should have a low degree of protein binding. Lithium and methanol are examples of such compounds. Ionized diuresis works for weak acids such as salicylates by trapping the charged form of the drug in alkaline urine and thereby enhancing renal elimination of the drug. Multiple doses of charcoal are effective at enhancing elimination of drugs such as theophylline by adsorbing the drug, which back-diffuses into the gut, or by interrupting enterohepatic cycling of other drugs (e.g., carbamazepine).

TABLE 23-9

Some Toxins and Their Antidotes

Toxin	*Antidote and Mechanism of Action*
Acetaminophen	*N*-Acetylcysteine; prevents formation of toxic metabolite
Warfarin	Vitamin K; acts as cofactor for synthesis of coagulation factors
Organophosphates	Atropine; acts as muscarinic antagonist Pralidoxime; reactivates cholinesterase
Digoxin	Digoxin-specific antibodies; affects immunoneutralization
Lead	Dimercaprol; affects chelation
Methanol	Ethanol; competitively inhibits alcohol dehydrogenase
Nitrites	Methylene blue; helps reduce methemoglobin

A nationwide network of regional poison information centers is available 24 hours a day to medical practitioners to provide assistance in managing specific poisonings. Several resources are available: **POISINDEX**, a computerized data bank of medicinal, industrial, and environmental toxins that is regularly updated; a library of toxicologic reference texts; and a staff of medical toxicologists. In addition, the centers also may be able to supply telephone numbers for other area experts such as the local botanical gardeners or herpetologists. They may help predict the symptoms that may occur with a given toxin and are instrumental in directing the clinician toward the safest course of therapy.

Foreign body ingestion is often included in the discussion of childhood poisonings, although it is not necessarily a toxicologic problem. Most ingested foreign bodies pass through the gut with no absorption and, consequently, do not result in systemic illness. Occasionally, the size or shape of the ingested object causes it to lodge in the gut. If arrested in the lower esophagus, it should be removed endoscopically to avoid the potential for regurgitation and aspiration into the airway. Once beyond the lower esophageal sphincter, round objects such as coins rarely cause problems. Larger objects may result in obstruction and require surgical removal. Button batteries rarely fragment in the gut and usually do not require removal. However, patients who ingest button batteries warrant careful observation for signs that caustic contents have leaked, resulting in gut mucosal ulceration and abdominal pain. Although elevated blood and urine mercury levels may occur following the fragmentation of mercuric oxide button batteries, no reports of resulting systemic mercury toxicity have appeared. In contrast, the sudden absorption of the contents of a ruptured cocaine bag has nearly uniformly lethal consequences.

Several antidotes protect against or reverse the toxicity of specific toxic agents by a multitude of mechanisms (Table 23-9). The antagonism of opioids by naloxone is well-known.

After the stabilization and treatment of poisoned patients, meticulous supportive care is of paramount importance for eventual recovery. Monitoring vital signs and serial examinations, vigorous respiratory support and toilet, maintenance of fluid and electrolyte homeostasis, and the management of infectious complications are critical early in the course of the severely poisoned patient. As recovery proceeds, psychiatric intervention and preventive education is appropriate. Acute awareness of potential drug interactions, both of ingested toxins and of drugs administered therapeutically, is important throughout the treatment period.

OFFICE OR EMERGENCY DEPARTMENT CARE OF BURNS

Burns are a common cause of injury in children. Each year more than 200,000 children receive treatment for burn injuries. In addition, significant morbidity and mortality often occur. The peak incidence of burn injury occurs in toddlers (1 to 5 years of age), and the injuries usually occur as the result of scalding from hot liquids. Although burns from house fires are less common, they account for almost half of all burn-related deaths. This higher mortality is probably related to associated smoke inhalation.

Pathophysiology

Direct thermal injury causes cell death at the time of the burn. Immediate release of local mediators, especially histamine, which causes a transient increase in vascular permeability, then occurs. After a short lag period, release of additional vasoactive substances such as serotonin and prostaglandins further increases permeability. Altogether, these factors result in marked tissue edema, accentuating the ischemic damage of the injured cells.

The severity of the direct tissue injury is related to the temperature of the causative substance and the duration of contact.

Pediatric Pearl: Because the ischemic injury may extend three to seven times more deeply than the level of the direct injury, the final depth of the burn may be delayed for 4 to 5 days.

Usually, the severity can be estimated by the depth of the burn. **First-degree burns** such as sunburn involve only the epidermis. These red and painful burns do not blister and resolve without scaring in 3 to 5 days. **Second-degree burns** are partial-thickness burns that involve the entire epidermis and varying degrees of dermis. Superficial second-degree burns (involving the top one-half of the dermis) are usually red or mottled with blisters, swelling, and intense pain. Healing occurs in 1 to 2 weeks without scarring. Deep second-degree burns appear mottled with a broken epidermis and a wet or weeping surface. Depending on the amount of nerve destruction, these burns may or may not be painful. Healing occurs slowly, often resulting in a scar. **Third-degree burns** are full-thickness burns involving damage to all layers of the skin and subcutaneous tissue. The skin is broken with a white or leathery appearance. The burn surface is usually dry and painless because the nerve endings are destroyed. At this level there is no functional barrier to bacterial infection. Healing is prolonged and may necessitate skin grafting. Fourth-degree burns extend from the skin through the subcutaneous tissue and fascia to the bone. Tissue necrosis, edema, and coagulopathy are extensive and may cause systemic toxicity. These burns usually require skin grafting.

Clinical and Laboratory Evaluation

History

The history-taking process should involve learning more about the circumstances that resulted in the burn injury. It is essential to ascertain whether the mechanism of the injury (e.g., explosion, thrown from vehicle, house fire) may have caused internal injuries or fractures. Determination of the circumstances of the injury, the nature of the agent involved, and the duration of exposure is important. Flash burns from fires or scalding from boiling water usually cause second-degree burns, whereas fires, explosions, hot grease, or hot oil often cause third-degree burns. Questions about the nature and duration of smoke inhalation and fire are warranted. Exposure to combustion of carbon-containing products such as wood (with house fires), methane (with clogged heating vents), or gasoline (with blocked automobile exhaust) should prompt concerns about carbon monoxide poisoning. Any conflict between the circumstances of the injury and the severity or appearance of the burn as well as the degree of supervision may lead the physician to suspect child abuse or neglect. The child's tetanus immunization status is important to determine; it may be necessary to administer a booster.

Physical Examination

It is appropriate to consider the physical examination in terms of the ABCs for burns.

- **Airway:** Signs of upper airway obstruction (stridor), which may occur as a result of thermal injury to the pharynx, and clinical signs that may indicate the presence of inhalation injury (Table 23-10) may be evident.
- **Breathing:** Signs of respiratory distress (retractions, wheezing, tachypnea, cyanosis) may result either from direct inhalation injury to the lung or from the effects of smoke inhalation and carbon monoxide production. In addition, significant burns to the chest wall, especially if they are circumferential, may impede chest wall excursion and cause hypoxia.
- **Circulation:** Increased vascular permeability and edema formation around the injured tissue can cause significant fluid loss. This may be worsened by associated internal injuries. Assessment of circulation includes examination of pulse rate, capillary refill, skin color, skin temperature, quality of peripheral pulses, and mental status.

TABLE 23-10

Clinical Signs Associated with Inhalation Injury

Singeing of nasal hair
Carbon deposits in the oropharynx
Oropharyngeal edema
Facial burns
Carbonaceous sputum
Altered mental status

- **Depth:** Estimates of the depth (degree) of the burn are based on clinical appearance, as previously described (see Pathophysiology).
- **Extent:** Estimates of the total extent of the burns may involve use of the "rule of 9s" (Table 23-11) or the system that dictates that one surface of the child's hand represents 1% of body surface area. It is important to note any circumferential burns of the chest and extremities.
- **Fractures:** This includes identification of fractures and internal injuries.
- **Globes:** In the presence of facial burns, it is necessary to inspect the eyes for burns, abrasions, and foreign material.

Laboratory Evaluation

For minor burns, no laboratory tests are indicated. If exposure to smoke or other combustible gases occurred, an arterial blood gas and co-oximetry for determination of carboxyhemoglobin levels are appropriate. If there are major burns (more than 10% to 15% second-degree burns) or associated injury, then baseline blood tests (CBC, electrolytes, PT, PTT, type, and crossmatch) and urinalysis (for hemoglobin and myoglobin) should be obtained. In children with respiratory distress, inhalation injury, or significant chest wall burns, an arterial blood gas is warranted.

Differential Diagnosis

Burn injury is usually apparent from the history and physical examination. Two specific types of burns—chemical and electrical—require special mention. Chemical burns often have prolonged exposure and penetrate deep into the dermal layers. Electrical burns are usually very serious, despite their initial minor appearance because the electrical current can destroy muscles and blood vessels deep in the contact site. Affected patients may develop cardiac ischemia or dysrhythmia (if the current passed through the heart) as well as complications from muscle breakdown (myoglobinemia).

The physician should also be aware of burns that are characteristic of child abuse: patterned or small circular burns (from an iron, lighter, or cigarette), sharply demarcated burns of the extremities or buttocks (from intentional immersion in scalding bath water), or other burns not consistent with the history.

TABLE 23-11

Rule of 9s for Estimating the Extent of Burns

	Child (%)	*Adolescent (%)*
Head	18	9
Each arm	9	9
Trunk	18	18
Back	18	18
Each leg	14	18

Management

Management should proceed based on the evaluation of the "ABCs" (see Table 23-1). If signs of airway compromise (e.g., stridor) or signs associated with the development of upper airway obstruction following inhalation injury are present (see Table 23-10), endotracheal intubation should be used to secure the airway. Direct laryngoscopy with a flexible endoscope, by an experienced emergency medicine or ear, nose, and throat physician, may help assess the degree of pharyngeal edema. It is important to provide 100% oxygen to all patients with suspected smoke inhalation or signs of respiratory distress. Nebulized β_2-agonists (albuterol) are indicated for signs of bronchospasm (e.g., wheezing). For children with cardiovascular compromise or more than 10% second-degree burns, intravenous fluid resuscitation with normal saline or lactated Ringer solution is appropriate. As already noted, there is significant fluid loss at the site of the burn. The amount of intravenous fluids required is the child's maintenance fluid requirement plus additional fluids to compensate for the loss through the burned tissue (2 to 3 mL/kg body weight/% body surface area burned). One-half of the calculated fluid deficit should be administered in the first 8 hours. Placement of a Foley catheter to monitor urine output is appropriate, and insertion of a nasogastric tube to decompress the stomach is also warranted. Circumferential burns of the extremities may cause vascular compromise and a compartment syndrome. Significant burns to the chest may cause respiratory compromise. These types of burns may necessitate an immediate surgical intervention such as an escharotomy. In this procedure, an incision is made for the entire length of the eschar in order to allow the skin edges to separate and to relieve the tension.

Once the child is stabilized, the physician should focus on wound care. Burns can be extremely painful, so prompt sedation and analgesia is essential. Unlike adults who can express their pain with complaints, children's cries are often not appreciated by the providers as a sign of pain, thereby delaying the administration of pain medications. Thus, as soon as the ABCs are secured, children should receive sedation. The method of sedation depends on the experience of the physicians and existing emergency department protocols. A dose of morphine (0.1 mg/kg given intravenously, intramuscularly, or subcutaneously) is usually effective and has the advantage of being readily reversed with naloxone if needed.

Room temperature, saline-soaked gauze pads can be used initially to cover the burned areas. Do *not* apply ice or cold dressings because of the risk of developing hypothermia. Notify the hospital's burn service (plastic or general surgeon) for any significant burns. To dress the burns, remove the saline gauze and clean the burns gently with saline solution, using an aseptic technique. It is appropriate to remove devitalized tissue, but intact blisters (which themselves provide a sterile dressing) should remain. The application of topical antimicrobial agents to all second- and third-degree burns is warranted. A *thin* layer of Silvadene can be applied to the burns, but because the silver can leave a hyperpigmented scar, bacitracin is preferred for cosmetically important areas such as the face. Recently, studies suggest that carboxymethylcellulose-based hydrofiber products may provide a faster healing, more cost-effective alternative to Silvadene. A single layer of fine-mesh gauze followed by two or three layers of fluffed absorbent gauze is used to provide a closed dressing. If needed, give a tetanus booster. Certain types of burns require hospitalization (Table 23-12). The use of hyperbaric oxygen for burn management and carbon monoxide poisoning is controversial.

TABLE 23-12

Burns that Require Hospitalization

Second-degree burns over >10% BSA
Third-degree burns over >2% BSA
Significant smoke inhalation
Associated injuries (e.g., fracture, head trauma)
Perineal burns
Second-degree burns involving face, ears, hands, or feet
Second-degree burns that are circumferential or cross a joint
Electrical burns
Deep chemical burns
Suspected child abuse

BSA, body surface area.

Pediatric Intensive Care

Lorry R. Frankel and Saraswati Kache

A clerkship rotation in the pediatric intensive care unit (PICU) is too brief to allow for a complete understanding of the therapeutic regimens used in the unit. However, students should learn how to recognize a critically ill child and those diseases that necessitate an intensive care unit (ICU) admission. Common etiologies requiring PICU admissions include organ failure, trauma, severe infections, and postoperative management after significant surgical procedures. The common endpoint to all of these disease processes is often referred to as the systemic inflammatory response syndrome (SIRS). An initial insult—trauma, infection, surgery, and the like—triggers the patient's inflammatory mediator cascade, which leads to a specific set of signs and symptoms often being noted on physical examination. The role of the intensivist is twofold in caring for such critically ill children. First, the multiple abnormal physiologic parameters in a critically ill patient must be noted in the context of the entire patient; that is, one organ system should not be treated to the potential detriment of another organ. An expression often used in managing critically ill patients is "do not lose the forest through the trees." Second, the intensivist often can only provide supportive care to the patient as the underlying disease process runs its natural course. Students should therefore focus on treating the entire patient, not normalizing individual abnormal values, and understand the supportive care that can be provided for various forms of organ failure.

The PICU functions in two ways: (1) primarily, to support critically ill children and give them time to heal, and (2) to provide a safe and efficient environment for the multidisciplinary team working with children and their families. The average mortality rate in the PICU is approximately 2% and most children requiring PICU admission survive. Occasionally, an admission to the PICU is prolonged, and, in a few cases, children succumb to their disease. Pediatricians should be aware of the psychosocial dynamics encountered between children, parents, the extended family, and the teams of health care professionals. Appropriate and frequent communication and disclosure of information in an honest, open fashion with the parents and caretakers of a critically ill child is an important part of caring for that child.

In most active academic PICUs, the patient "mix" is evenly divided between medical and surgical patients. Most patients are admitted emergently, and 20% to 30% of these may be admitted via a critical care transport service. The remainder of the admissions may be scheduled surgical patients who require aggressive management postoperatively due to instability or a high level of monitoring and nursing care not available on general care units. These children may need mechanical ventilation, invasive intravascular monitoring, and frequent attention by both the nursing and medical staff.

ORGANIZATION OF PEDIATRIC INTENSIVE CARE UNITS

PICUs are usually directed by a physician certified in pediatric critical care medicine and staffed by physicians appropriately trained in pediatric critical care medicine. Other subspecialists (anesthesiologists, cardiologists, pulmonologists, cardiovascular surgeons, and surgeons) may also provide care in this environment. A hospital critical care committee helps formulate policy for the PICU (e.g., admission and discharge criteria for PICU patients) and a **quality assurance** program. Admission and discharge criteria must be specific and clearly define which patients are to be admitted to the PICU or, if available, an intermediate care unit (Table 24-1).

The quality assurance program offers the opportunity to examine clinical practice patterns and their influence on patient outcomes. An example of a quality assurance project might include surveys of extubation criteria, rates of catheter-associated blood stream infections (CABSI), reintubation rates for failed extubations, and

TABLE 24-1

Admission and Discharge Criteria in Pediatric Intensive Care Units

PICU

Admission Criteria

Patients with invasive monitoring (e.g., arterial lines, central venous pressure lines, pulmonary arterial lines, intracranial pressure monitoring devices)

- Evidence of respiratory impairment or failure
- Cardiovascular compromise, including shock and hypotension (hypertensive crisis may be managed in the ICU)
- Acute neurologic deterioration, which includes status epilepticus, coma, or evidence of increased intracranial pressure
- Acute renal failure requiring dialysis
- Bleeding disorders that require massive transfusions

Discharge Criteria

When the following discharge criteria are met, the PICU attending physician will arrange the transfer of the patient to an appropriate setting within the hospital or to a referring hospital. The primary attending physician will be notified of such discharge from the PICU. Discharge from the PICU may take place when the patient's disease process reverses itself to the point that the patient:

- Requires no invasive monitoring
- Requires no airway protection (intact cough and gag reflexes)
  - Requires no invasive mechanical respiratory support
- Is hemodynamically stable
  - Has a stable neurologic status

PIICU

Admission Criteria

- Patients who do not require respiratory assistance for acute respiratory failure but require continuous monitoring of vital signs, noninvasive blood gas analysis (e.g., O_2 saturations, transcutaneous PO_2 and PCO_2), including those patients who require chronic ventilatory assistance with tracheostomies or noninvasive mechanincal support (e.g., BiPAP)
- Patients who are in **early** cardiovascular failure and require continuous monitoring of vital signs and noninvasive monitoring
- Patients with a patent airway who require observation for acute neurologic deterioration (e.g., some head trauma patients)
- Patients who have multiple organ failure but require nursing care not available in other parts of the hospital (e.g., acute renal failure, diabetic ketoacidosis, trauma victims)

Discharge Criteria

- Patients who no longer require level of skilled nursing care provided in the *PIICU*
- Patients whose disease process has reversed itself to the point that they can be safely managed in other parts of the hospital

BiPAP, biphasic positive airway pressure; *ICU*, intensive care unit; *PICU*, pediatric intensive care unit; *PIICU*, pediatric intermediate intensive care unit.

evidence of airway injury following intubations performed by different techniques. Another quality assurance issue, especially in the era of managed care, is the overutilization of PICU beds.

TECHNIQUES FOR MONITORING CRITICALLY ILL INFANTS AND CHILDREN

Most PICU patients require some type of respiratory support, and many also need cardiovascular support. All patients in the PICU have continuous noninvasive monitoring provided and many will often have continuous invasive monitoring as well (Table 24-2). Normal values for heart rate, blood pressure, and respiratory rate vary according to the age of the patient. Therefore, age-specific criteria must be used for setting monitor alarms.

The pulse oximeter has dramatically improved patient care and often is considered the fifth vital sign (temperature, respiratory rate, heart rate, blood pressure, and oxygen saturation) in the ICU. A pulse oximeter consists of a light source and a photo detector that must be applied to a narrow enough portion of the body for light to traverse a capillary bed. Light is emitted from the light source and absorbed by the various substances on route before being detected by the photo detector on the other side. The change in light absorbance between oxygenated and deoxygenated blood, and during systole and diastole, helps determine a patient's oxygen saturation. Its accuracy is somewhat dependent on tissue perfusion; therefore, its utility may be limited in patients with significant vasoconstriction and poor perfusion. Transcutaneous monitoring of oxygen (PO_2) or carbon dioxide (PCO_2) tension is of limited use in the PICU.

Near-infrared spectroscopy (NIRS) is a new noninvasive monitor, which allows for the measurement of mixed venous saturation of local tissues. This technology is being evaluated in cardiac surgery and some PICU patients. Data collected to date suggests that monitoring the central nervous system (CNS) NIRS in relation to the splanchnic NIRS may prove more effective.

Capnography measures the end-tidal CO_2 concentration in exhaled gas and is more commonly used in intubated patients. The highest concentration of CO_2 sampled in the respirator circuit represents the alveolar CO_2 concentration, which should be very close to the arterial ($PaCO_2$) concentration. In patients with acute pulmonary disease where intrapulmonary shunting exists, the end-tidal CO_2 reading may not be accurate. Furthermore, neither pulse oximetry nor end-tidal CO_2 devices can provide data about arterial pH, which is usually a critically important part of the patient's assessment. Thus, these noninvasive modalities are usually supplemented by **arterial blood gas** sampling in critically ill patients. Other noninvasive monitoring techniques used in the PICU are detailed in Table 24-2.

Invasive monitoring is often utilized in patients who are in shock or in need of infusions of vasoactive agents. Central venous access is used for the administration of vasoactive drugs as well as for the determination of **central venous pressure (CVP),** which reflects the right atrial pressure, that is, preload to the right heart (i.e., right atrial filling). **Pulmonary artery thermodilution (Swan-Ganz) catheters** are used in children much less commonly than in adults, and can measure CVP, pulmonary capillary wedge pressure (which reflects left atrial and usually left ventricular filling pressures), cardiac output, and mixed venous oxygen saturation. These data allow the calculation of both systemic and pulmonary vascular resistances, oxygen consumption, and intrapulmonary shunt fractions.

Intracranial pressure (ICP) monitoring devices assist in the management of intracranial pathology commonly encountered with severe head injuries, severe CNS infections, or Reye syndrome (see Neurologic Intensive Care). The specific monitoring device used depends on the clinical indications, the neurosurgeon's familiarity with different types of devices, and the location in the cranium where it can be most safely inserted. The monitor may be placed on top of the dura (epidural device), under the dura (subdural device), or directly into the ventricular system (intraventricular monitor). Intraventricular devices have the added advantage of being useful for therapeutic removal of cerebrospinal fluid (CSF). Each of these devices may be associated with a variety of complications including infection, bleeding, injury to brain tissue, and monitor malfunction. The more invasive devices (i.e., subdural and intraventricular monitors) are associated with a greater risk of infection and thus are usually removed after 5 to 7 days.

BASICS OF ASSISTED VENTILATION

Mechanical ventilation is utilized in children with either pulmonary or nonpulmonary causes of **respiratory failure**. Pulmonary pathologies that result in the need for mechanical ventilation include airway obstruction, severe pneumonias that result in respiratory failure (increase in $PaCO_2$ and respiratory acidosis), accumulation of significant amounts of fluid in the pleural space, injuries to the chest wall that produce an unstable thoracic cage, and obstructive disease processes such as bronchiolitis or asthma. Nonpulmonary indications for ventilatory support

TABLE 24-2

Pediatric Intensive Care Unit (PICU) Monitoring Devices

Monitoring Device	*Site*	*Parameters Being Measured*	*Monitoring Limitations/Concerns*
Noninvasive Monitoring			
Cardiorespiratory	Chest leads	Heart rate, rhythm, respiratory rate	Only provides recording in leads I, II, III and not a full 12-lead ECG; may have difficulty with dysrhythmia recognition
Transcutaneous	Chest	$PaCO_2$	Surface electrodes that warm the skin to 43° C can cause thermal injuries; must be changed every 3–4 hours; useful in neonates only
Pulse oximetry	Digits/nasal bridge/ears	Continuous O_2 saturation values	Very useful in well-perfused patients
Capnography	End of endotracheal tube	Breath-by-breath analysis of CO_2 in intubated patients' end-tidal CO_2	Need graphic picture to determine end-tidal plateaus
Blood pressure	Arm cuff	"Dinamap" can cycle blood pressure every 1–5 minutes	Inappropriate cuff size can measure false hypotension or hypertension
NIRS	Forehead/flank	Mixed venous saturation of local tissues	Not reflective of true mixed venous saturation, maybe more effective as comparison between CNS and splanchnic circulation
EEG	Scalp surface	Provides for continuous monitoring of cranial electrical activity	Requires specialized technician for placement
Invasive Monitoring			
Arterial	Dorsalis pedis, radial, posterior tibial, axillary, femoral	Continuous blood pressure monitoring; able to draw frequent blood gases and other labs	Expertise in placement and monitoring; may require cut-down technique; clot at catheter tip may compromise distal perfusion in the cannulated vessel

(Continued)

TABLE 24-2

Pediatric Intensive Care Unit (PICU) Monitoring Devices *(Continued)*

Central venous access	Femoral, subclavian, external/internal jugular	Central venous pressure monitoring useful in shock states and for administration of vasoactive agents	Requires expertise in placement, especially in young infants; multilumen catheter allows for administration of multiple drips simultaneously
Pulmonary artery ("Swan-Ganz") catheter	Placed through sheath in internal jugular, femoral, or subclavian vein	Cardiac output, pulmonary capillary wedge pressure, systemic and pulmonary vascular resistance, Indications: any form of shock in which adequate CO, SVR, PVR measurements my help direct therapy	Less commonly used in children; helpful in titration of therapy; complications—arrhythmias, pulmonary emboli/infarction
Intracranial pressure monitoring	Subdural bolts; epidural fiberoptic devices; intraventricular catheter	Intracranial pressure when CNS pathology is associated with significant cerebral edema; indicated in trauma patients with Glasgow coma scale score ≤8	Neurosurgeon usually inserts device; requires expertise in monitoring; intraventricular catheters may also be used for therapeutic intervention if required by draining CSF

CNS, central nervous system; *CSF*, cerebrospinal fluid; *EEG*, electroencephalogram; *NIRS*, near-infrared spectroscopy; *PEEP*, positive end-expiratory pressure; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance.

include CNS pathologies that produce either ineffective respiratory efforts (e.g., Cheyne-Stokes respirations) or none at all (apnea), severe cardiac failure with the development of pulmonary edema, multisystem organ failure as seen in sepsis, massive gastrointestinal (GI) hemorrhage, intra-abdominal masses or ascites that produce pressure on the diaphragm and result in decreased lung volumes, and severe forms of trauma.

The usual physiologic indications for mechanical ventilation include one or more of the following: **hypoxia** (i.e., PaO_2 less than 60 mm Hg, or SaO_2 less than 90% in an FIO_2 greater than 0.50 to 0.60), **hypercarbia** (i.e., $PaCO_2$ greater than 55 to 60 mm Hg), or **respiratory acidosis** (pH less than 7.25).

Once the decision has been made to begin mechanical ventilation, the equipment and pharmacologic agents appropriate for the patient's age and weight must be readied. Necessary adjuncts include oxygen (in tanks or via a central system), proper-sized face masks, ventilation bags, laryngoscopes (blades vary in size from 00 for neonates to 3 for older children and can be either straight or curved), and endotracheal tubes (2.5 to 8.0 mm in diameter). The size of the tube selected depends on age and the underlying disease process (e.g., patients with croup may require a smaller tube).

Pediatric Pearl: A useful formula to determine size of endotracheal tubes is:
Tube size = (Age [in years] + 16) ÷ 4

Appropriate doses of medications should be calculated and drawn up before intubation. If children are apneic or comatose and have virtually no airway protective mechanisms, an endotracheal tube can be placed emergently with little resistance. However, it is more common for patients to be alert; therefore, pharmacologic

agents are used to sedate and relax children so the tracheal intubation can be performed safely and efficiently. Commonly used agents include narcotics (morphine or fentanyl), benzodiazepines (diazepam or midazolam) and muscle relaxants (either a depolarizing agent such as succinylcholine or a nondepolarizing agent such as vecuronium). Other agents that may be used include short-acting barbiturates (thiopental) and dissociative anesthetics such as ketamine. The specific combination of pharmacologic agents used will vary depending on the underlying disease process necessitating intubation; for example, head injury versus status asthmaticus.

During intubation, patients should be monitored for heart rate and oxygen saturation and should receive the highest concentration of oxygen possible. Positioning patients on their back with some neck extension and chin lift facilitates the insertion of the laryngoscope blade and the endotracheal tube (Figure 24-1). Once the tube has been inserted, the accuracy of the tube location is determined by auscultation of both lung fields, evidence of condensation of gas in the tube, color change of the Pedi-Cap detecting CO_2, and a postintubation chest radiograph. Choice of nasotracheal versus oral intubation depends on the preference of the individual physician and the underlying disease process afflicting the patient. Although technically more difficult, nasal tubes offer more stability and are better tolerated. Complications from endotracheal tubes include injury to the glottis and subglottic areas, right mainstem intubation, pneumonias, and esophageal intubations.

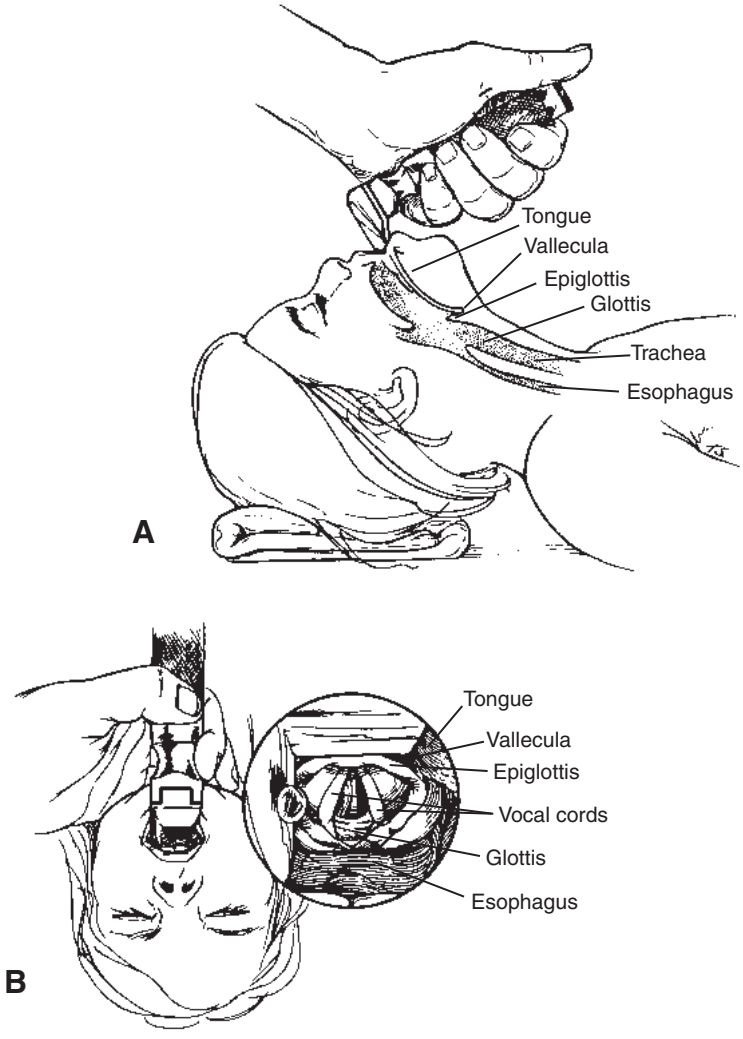

FIGURE 24-1. **(A)** Position of the head for direct laryngoscopy. Note the laryngoscope is held in the left hand. The endotracheal tube is advanced with the right hand. **(B)** Visualization of the glottic area at the time of intubation.

Once intubated, the patient is connected to a ventilator. The following simple formula for compliance is worth memorizing because it provides the basis of understanding pulmonary and ventilator interactions.

$$\text{Compliance} = \text{Volume/Pressure}$$

By tracking some simple ventilator parameters, this equation allows the physician to monitor patient progression or recovery from the primary disease process. Some important terms regarding conventional ventilation are listed in Table 24-3.

There are several ways the modes of ventilation can be divided. One method is by assessing the amount of support the ventilator is providing for the patient.

- Assist control (AC): This mode provides the maximal support for the patient. Every breath, whether mechanical or spontaneous, is fully supported. Each breath has the same peak inspiratory pressure (PIP) or tidal volume (Vt) and inspiratory time (I_t). Pressure support is unnecessary in this mode.
- Synchronized intermittent mandatory ventilation (SIMV): This mode can provide minimal-to-moderate amounts of ventilatory support. The ventilator breaths, as determined by the set respiratory rate, are fully supported breaths. These ventilator breaths deliver the set PIP or Vt and the set I_t. All spontaneous breaths above the set ventilator rate only receive the set pressure support. As the set ventilator rate is weaned, the patient is forced to do more of the work of breathing. Should the patient tolerate a minimal rate without developing respiratory distress, she or he may be ready for extubation.
- Continuous positive airway pressure (CPAP): In this mode, no ventilator breaths are provided; only the CPAP or positive end-expiratory pressure (PEEP) and pressure support are set. Note that the amount of support provided is determined by the level at which the pressure support is set. With a minimal pressure support, this mode provides the minimal amount of support and the patient is forced to do all the work of breathing. This is an ideal mode to test for an adequate respiratory drive, particularly in patients with impaired neurologic status, either from an underlying disorder or from oversedation.

TABLE 24-3

Common Terms in Mechanical Ventilation

Abbreviation	*Term*	*Definition*
PIP	Peak inspiratory pressure	Point of maximal airway pressure
PEEP	Positive end-expiratory pressure	Pressure maintained in airways at end of exhalation
P	Delta pressure	Difference between PIP and PEEP
Vt	Tidal volume	Volume of gas entering patient's lung during inspiration
I_t	Inspiratory time	Duration of time in inspiration
E_t	Expiratory time	Duration of time in expiration
MAP	Mean airway pressure	An average of the airway pressure throughout the respiratory cycle
R	Rate	Respiratory rate as set on the ventilator
PS	Pressure support	The amount of inspiratory pressure over the set PEEP that is supported with each spontaneous breath; provides a form of assistance to the patient
HFV	High-frequency ventilation	An unusual form of mechanical ventilation that uses very small tidal volumes and very rapid rates

A second method of dividing modes of ventilation is by the mechanism that the ventilator actually provides support for the patient.

- Pressure mode: In this mode, the operator sets the PIP and the machine determines the volume delivered to the patient based on the patient's pulmonary compliance. As the patient's compliance improves, the tidal volume delivered by the ventilator per breath will increase; conversely as compliance worsens, the tidal volume delivered decreases. This mode can be used both in AC or SIMV. The greatest advantage of the pressure mode is that it provides greater ventilatory support by using a decelerating flow pattern, and for stiff, noncompliant lungs, this is the preferred mode of ventilation. The disadvantage is that a minute ventilation is not guaranteed.
- Volume mode: The operator sets the tidal volume and the ventilator determines the pressure required based on the pulmonary compliance. As the compliance improves, the PIP required to deliver the set tidal volume decreases; conversely, as the compliance worsens, the PIP required increases. The volume mode can be used both in AC or SIMV. The advantage of the volume mode is that a minute volume is guaranteed. The drawbacks are that it cannot be used in a patient with a large leak around the ETT, and it is not optimal for poorly compliant lungs.

Finally, tracheal intubation and mechanical support can be associated with many complications, as with all procedures. Airway complications from mechanical ventilation include direct injury to the airway and the development of subglottic stenosis. The main pulmonary complication of mechanical ventilation consists of ventilator-induced lung injury of which the culprits are volutrauma, barotrauma, and oxygen toxicity. Volutrauma occurs due to the repetitive opening and closing of alveoli, particularly with exposure to high tidal volumes of greater than 10 mL/kg, causing shear stress and triggering further inflammation. Alveolar injury from exposure to excessive pressures, that is, PIP greater than 35 cm H_2O, is defined as barotrauma (see Figure 24-2). Finally, constant exposure to high levels of oxygen, FiO_2 greater than 60%, can lead to oxygen toxicity from free radical production.

FIGURE 24-2. Graphic comparison of tracings from volume-cycled ventilation (peaked wave form) versus time-cycled ventilation (square wave form). In this example, the patient is administered the same tidal volume with both techniques. However, this is achieved with a lower airway pressure using the time-cycled, pressure-limited technique, which allows for a reduction of airway injury from barotrauma.

RESPIRATORY DISEASES THAT REQUIRE PEDIATRIC INTENSIVE CARE

Impending respiratory failure must be recognized and stabilized on a timely basis. Failing to do so can subject children to prolonged periods of hypoxemia and acidosis. Such conditions can cause neurologic damage or death. The primary respiratory pathologies that lead to PICU admission can be categorized according to several criteria: the specific anatomic sites that are affected; the specific age groups that are at risk; the specific symptoms (e.g., stridor, wheezing, tachypnea, or dyspnea) they produce; or specific etiologies. Understanding the anatomic relationships in the airways of children and how they differ from those of adults leads to a recognition of how they predispose children to a unique array of airway diseases.

UPPER AIRWAY OBSTRUCTION

Pathophysiology

Upper airway obstruction can be a life-threatening event, especially because the severity of the situation may be overlooked by individuals unfamiliar with children. Disorders of the upper airway are far more common in children because of structural factors that make the child more vulnerable to infectious agents, allergens, foreign body aspiration (small objects or foods such as peanuts, popcorn, and grapes), toxins, and traumatic injuries (Table 24-4).

The respiratory mechanism of the pediatric patient varies from the adult in both anatomy and physiology. As a child grows, the airway enlarges and moves more caudally as the cervical spine elongates. The pediatric airway overall has poorly developed cartilaginous integrity, allowing for more laxity throughout the airway. This laxity can cause more airway collapse, that is, malacia, during periods of CNS depression as

TABLE 24-4

Common Causes of Airway Obstruction

Infections
Viral croup
Epiglottitis
Supraglottitis
Tracheitis
Pharyngeal/peritonsillar abscess
Severe hypertrophy of tonsils or adenoids
Congenital
Webs
Vocal cord paralysis
Tracheomalacia or laryngomalacia
Subglottic stenosis
Vascular abnormalities (hemangiomas, vascular rings)
Acquired (Other than Infectious)
Trauma, either external or internal (e.g., subglottic stenosis)
Foreign body aspirations
CNS Disorders
Head trauma
CNS infections
Status epilepticus
Neuromuscular disorders
Drug-induced dysfunction (e.g., narcotics, anesthetics, tranquilizers)

CNS, central nervous system.

may occur postanesthesia. Another important distinction is the narrowest point in the airway in adults is at the cords; whereas in children, it is below the subglottic space. An important aspect of the narrow airway in children is that resistance is significantly increased. The formula for resistance is:

$$R = 8 (l / r^4)$$

where R is resistance, l is length, and r is radius.

Therefore, as the airway narrows secondary to inflammation, the resistance dramatically increases as the effective radius is inversely proportionate to the radius to the fourth power. Thus, a small amount subglottic edema, as can occur with croup or from intubation, will significantly increase the work of breathing for an infant. The most common presenting symptom in a child with airway obstruction is **stridor,** and this may be accompanied by alterations in respiratory rate and effort.

Differential Diagnosis

The most commonly encountered forms of severe upper airway obstruction are caused by infections. Acute croup syndromes may be caused by viruses or bacteria. Classically, **croup** (also known as **acute laryngotracheitis**) is

caused by viral agents such as parainfluenza, influenza, or respiratory syncytial virus (RSV). Bacterial infections may produce either **epiglottitis** (*Haemophilus influenzae*, although now rare due to routine childhood immunization) or **bacterial tracheitis** (*Staphylococcus aureus*). A syndrome of acute **supraglottitis** has also been described and is associated with viral illness. Viral croup syndromes are usually self-limiting and require very little in the way of PICU care. However, children with epiglottitis, tracheitis, or supraglottitis may require instrumentation of the airway in order to overcome the obstruction. Other serious causes of upper airway obstruction include severe tonsillar and adenoidal hypertrophy, acute tonsillitis, or a retropharyngeal abscess.

Foreign body aspiration is another major cause of upper airway obstruction in children, especially in young toddlers. Other common causes of airway obstruction include congenital anomalies of the airway, congenital defects of the tracheobronchial tree, vascular anomalies that produce extrinsic compression on the trachea or bronchi (vascular rings), and acquired problems such as neoplasm. Sometimes, these conditions produce only mild symptoms until an upper respiratory tract infection occurs, at which time severe obstruction may result.

Pediatric Intensive Care Unit Management

Children who present with acute airway obstruction should be continuously monitored for heart rate and O_2 saturation. They should be maintained in a position of comfort; if stable and not in impending respiratory failure, this may be on the parent's lap. An anesthesiologist and a pediatric surgeon or otolaryngologist should be notified, and equipment for emergency airway access should be at the bedside. Oxygen or racemic epinephrine may be administered, and the patient should be frequently reassessed for signs of improvement or progressive decompensation. In patients progressing to respiratory failure, airway stabilization in a controlled fashion is preferred to an emergent uncontrolled situation.

Careful history taking is warranted, and if the history is appropriate for the aspiration of a foreign body (e.g., a toddler who eats peanuts and then coughs), the diagnostic and therapeutic procedure of choice is **rigid bronchoscopy**. This is usually performed under general anesthesia in the operating room. However, if the history is not definitive for foreign body aspiration or the symptoms are unusual, the clinician may wish to examine the airway at the bedside. **Flexible fiberoptic bronchoscopy** is ideal for this purpose and can help identify congenital airway anomalies such as **hemangioma, subglottic stenosis** (either acquired or congenital), **tracheomalacia,** or **laryngomalacia,** or may demonstrate a pulsatile mass resulting from a **vascular ring** producing extrinsic compression of the airway.

A lateral radiograph of the neck region may assist in identifying a swollen epiglottis; however, it is important to minimize diagnostic procedures (e.g., blood drawing for arterial blood gases, intravenous injections, radiographs) until the patient's airway is secured. A careful examination by an experienced physician should be performed so that the obstruction is not worsened. In children with suspected **epiglottitis,** attempting to visualize the obstruction by direct laryngoscopy may lead to acute total airway obstruction. Such patients are usually taken to the operating room with either a pediatric surgeon or an otolaryngologist and an anesthesiologist present in case intubation is not possible and a tracheostomy is required. Once they are intubated, such patients are brought to the PICU. Additional problems that need to be addressed in caring for these patients are the need for sedation and the possibility of associated pulmonary disease (e.g., pneumonia or pulmonary edema) or a systemic disease that may accompany infection. Chapter 10 provides more complete details on the clinical and laboratory findings in children with croup and epiglottitis.

By the time many children with upper airway obstruction reach the PICU, a diagnosis has usually been made and the airway has been secured. These children usually benefit from positive pressure ventilation because of associated pulmonary disease. Patients with epiglottitis are usually intubated the shortest period (1 to 3 days). Those with viral croup and tracheitis may require 5 to 8 days of airway support. Bacterial infections require antibiotics directed against specific pathogens. The use of steroids for treatment of croup syndromes remains controversial. Once patients are extubated, racemic epinephrine is effective in reducing airway swelling that often accompanies the postextubation period.

In children with a **peritonsillar** or **retropharyngeal abscess,** surgical drainage of the abscess is required in addition to aggressive medical management with antibiotics. Some centers place an endotracheal tube prophylactically to maintain the airway and prevent aspiration of infected contents.

In addition to oxygen and various medications used to reduce air edema (racemic epinephrine and steroids), Heliox has been successfully used in pediatric patients. Heliox is administered as a 70% helium/30% oxygen mixture. The density of helium is less than that of nitrogen, so that at any given gas flow rate there is less turbulence. This improves gas exchange by lowering airway resistance and reducing the work of breathing.

SMALL AIRWAYS AND PARENCHYMAL LUNG DISEASE

Pathophysiology

In this broad category of lung pathologies, the most common conditions are **bronchiolitis, asthma,** and **pneumonia,** each of which can produce significant respiratory compromise (Table 24-5). Most infectious diseases of the airway are viral in nature, and most of the care required for these patients is supportive. When the clinician is able to diagnose a bacterial agent or a specific virus for which antiviral therapy is available (e.g., cytomegalovirus), specific therapy can be added to supportive measures.

Bronchiolitis is probably one of the more complicated acute pulmonary diseases encountered in the young child (see Chapter 9). Bronchiolitis is an acute inflammation of the small airways that results in bronchoconstriction via chemical mediators such as the leukotrienes (L4), increased mucous secretion, epithelial cell destruction, and edema of the airways. Bronchiolitis can produce small airway disease accompanied with severe wheezing similar to that in asthma. In addition, significant parenchymal injury associated with the infection may exist; on chest radiography, this may be interpreted as pneumonia or atelectasis.

Differential Diagnosis

Bronchiolitis is predominantly a disease of infancy and is usually caused by viruses. Young infants are particularly susceptible because of small airway diameter, an unstable chest wall, the potential for fatigue of the respiratory muscles, and a very reactive pulmonary vascular bed. **RSV, parainfluenza, influenza,** and **adenovirus** have been associated with this disease. RSV is probably the most common and usually produces epidemics of

TABLE 24-5

Types of Lower Airway Disease in Children

Infections
Bronchiolitis (RSV, parainfluenza, influenza)
Pneumonia (viral or bacterial)
Allergic
Status asthmaticus
Foreign body
Usually food, but may be plastic toys
Vascular anomalies
Usually produce stridor, but may result in collapse of bronchus and produce atelectasis
Pulmonary edema
Cardiogenic pulmonary edema secondary to congestive heart failure in children with either congenital or acquired heart disease
Secondary to upper airway obstruction
Noncardiogenic pulmonary edema (ARDS)
After severe pulmonary injury or systemic illness
Neurogenic pulmonary edema following severe neurologic insult
Chronic disorders
Bronchopulmonary dysplasia
Cystic fibrosis
Aspiration
Swallowing disorders
Gastroesophageal reflux
Esophageal abnormalities
Brainstem injury that results in poor cough and gag reflexes

ARDS, adult (or acute) respiratory distress syndrome; *RSV*, respiratory syncytial virus.

severe bronchiolitis, typically in the winter months. Infants who are most at risk are those with underlying cardiopulmonary diseases (e.g., congenital heart disease, bronchopulmonary dysplasia that is seen in graduates of neonatal intensive care units who have had severe lung disease) and immunocompromised children. Infants with bronchiolitis infrequently require hospitalization, and only a small percentage (3% to 7%) of those admitted to the hospital with bronchiolitis require intensive care.

Asthma is another severe form of reversible airway disease that may require admission to the PICU. Acute deterioration in asthmatic patients is often secondary to an allergen in the environment that produces a cascade of inflammatory reactions resulting in increased mucus production, bronchiolar edema, and bronchoconstriction (see Chapter 18). These patients present with wheezing and dyspnea that are similar to the symptoms of bronchiolitis, but the patients are usually beyond infancy.

Other acute lung injuries that may necessitate care in the PICU are bacterial and other types of pneumonias; inhalation injuries (hydrocarbon, smoke); severe aspirations; and lung injuries following trauma. These events can produce a very complex and severe inflammatory response that results in a lung injury called the **adult (or acute) respiratory distress syndrome (ARDS),** which is the end product of a series of chemical reactions that produce severe necrosis and both alveolar and interstitial disease. Although the mortality rate for pediatric patients with ARDS is improving, it remains quite high at 25% to 50%. Unlike the respiratory distress syndrome seen in neonates where hyaline membranes form as a result of an inability to manufacture surfactant, hyaline membrane formation occurs despite adequate surfactant production in adult respiratory distress syndrome. Further details on the clinical and laboratory evaluation of patients with small airway disease can be found in Chapter 18.

Pediatric Intensive Care Unit Management

Supportive measures in children with small airway disease, such as bronchiolitis, include adequate hydration, oxygen therapy to maintain an arterial oxygen saturation of more than 90%, and bronchodilators to decrease airway resistance. The $PaCO_2$ and pH must be monitored for evidence of impending respiratory failure. Patients who are retaining CO_2 out of proportion to their ventilatory rate and effort may require endotracheal intubation (Table 24-6). The ventilatory requirements for these patients can be problematic because they may have both increased airways resistance secondary to severe small airway disease and decreased lung compliance secondary to alveolar disease. A slow rate and long expiratory time is the ventilatory strategy often used in these patients to facilitate lung emptying. If a degree of hypoxemia secondary to alveolar disease is noted, long inspiratory times are also implemented to recruit collapsed portions of the lung. Children often require sedation and possibly muscle relaxants in order to tolerate these ventilator settings.

Adjuncts to the previously described treatments include the use of aerosolized bronchodilators and the maintenance of fluid and electrolyte balance. Albuterol, administered in both intermittent and continuous treatment regimens, may provide some benefit by decreasing small airway disease. The nutritional status of these children may also require careful attention. If infants do not tolerate enteral feeding, **total parenteral nutrition** is indicated.

TABLE 24-6

Treatment of Respiratory Failure

Basic Interventions

- Oxygen by mask, tent, or nasal prongs: maintain oxygen saturation of >90%
- Hydration: if the patient is in respiratory distress, keep status of NPO
- Mechanical ventilation: indicated if the patient is apneic or has evidence of significant respiratory distress or failure
  $PaCO_2$ >60–65 mm Hg
  pH <7.25
  PaO_2 <60 mm Hg in an FIO_2 >0.5

NPO, nothing by mouth.

Initial treatment of patients with status asthmaticus should include aggressive aerosolized bronchodilator therapy with albuterol, usually continuous, and atrovent. Steroid therapy should be initiated early to either prevent or control the secondary inflammatory phase. Other adjunct therapies to be considered include magnesium sulfate, terbutaline, aminophylline, and Heliox. Intubation should only be considered in asthmatic patients with either a depressed mental status or significant progressive hypoxia. A careful search should be performed for causes of acute exacerbation in these patients (e.g., presence of intercurrent infections such as *Mycoplasma pneumoniae*). Because inspissated, tenacious mucus often contributes to the need for mechanical ventilation in asthmatic children, fiberoptic bronchoscopy may bring about dramatic improvement. Less invasively, DNAase may enhance the clearance of mucus.

Acute lung injury (ALI) and adult respiratory distress syndrome (ARDS) are the end result of an aggressive inflammatory process. Present scientific thinking suggests that the balance between proinflammatory mediators and anti-inflammatory mediators is deranged. The inflammation results in increased permeability of pulmonary capillaries and alveoli, a protein-rich pulmonary edema, surfactant depletion/inactivation, and ultimately (after 5 to 7 days) development of pulmonary fibrosis. Loss of pulmonary vasomotor tone occurs due to refractory hypoxemia resulting in mild pulmonary hypertension. ARDS is a heterogeneous process; that is, different portions of the lung manifest varying degrees of disease.

Treatment of ARDS is primarily supportive with maintenance of adequate oxygenation, cardiac output, nutritional support, and prevention of secondary pneumonia, other infections, and ventilator-induced lung injury. The initiating insult should be treated; for example, antibiotics for an infectious process. Ventilator-induced lung injury is prevented by lung protective strategies, which include the following:

- FiO_2 less than 60% to avoid oxygen toxicity and use of high PEEP as required to improve oxygenation
- Maintain peak pressures of less than 35 to 40 cm H_2O or more to avoid barotrauma
- Target tidal volumes of 6 mL/kg to prevent volutrauma
- Allow for permissive hypoxia with saturations of 90% to 95% or PaO_2 55 to 80 mm Hg, ensuring that end-organ oxygenation is maintained
- Allow for permissive hypercarbia maintaining a pH higher than 7.25

These targets are often most easily accomplished by maintaining the patient on a pressure mode of ventilation to prevent barotrauma. The generated tidal volumes should be closely monitored to ensure volumes of 6 mL/kg. Nonconventional ventilation such as high-frequency ventilators have proven beneficial particularly in pediatric patients. Other management strategies with some proven efficacy include prone positioning and steroid use. Surfactant therapy and inhaled nitric oxide (NO) do not appear to have long-standing benefits. However, those patients who have a sustained response to NO may have better outcomes. Although **extracorporeal membrane oxygenation (ECMO)** has been used for rescue therapy in some patients with refractory disease, the outcomes are not encouraging.

Arterial and central venous catheters utilized for physiologic monitoring are often required. Therapy for adult respiratory distress syndrome may also include the use of bronchoscopy to retrieve inspissated mucus and bronchoscopic washing to look for evidence of infection.

SHOCK

Pathophysiology

In children, cardiovascular compromise may have many causes (Table 24-7) that share the common denominator of supply, cardiac output, not meeting demand, oxygen, and substrate delivery to the tissues. **Hypovolemia** is probably the most common cause of shock in the pediatric age group. The next most common cause of shock is **septic shock** and, finally, **cardiogenic shock**.

Clinical signs and symptoms of shock vary depending on the degree of compensation. **Compensated shock** occurs when patients have been able to maintain adequate cardiac output through compensatory mechanisms that maintain the blood pressure within a normal range. **Decompensated shock** is said to occur when patients are hypotensive and acidotic. Hypotension is considered a late finding in pediatric patients and is often a sign of impending vascular collapse. If untreated, decompensated shock progresses to multisystem organ failure. Therapy for shock is most effective when instituted in the early phases. The mortality rate in patients with shock increases as the patient progresses from compensated to decompensated shock to multisystem organ failure. Irreversible shock results in cardiopulmonary failure progressing to subsequent cardiac arrest leading to death.

TABLE 24-7

Common Causes of Shock in Children

Hypovolemic Shock
Vomiting
Diarrhea
Blood loss
Osmotic diuresis (e.g., diabetes)
Nephrotic states
Increased insensible loss (e.g., burns, heat stroke)
Distributive
Spinal cord injury
Anaphylaxis
Drug toxicity
Cardiogenic Shock
Congenital heart disease (especially left-sided obstructive lesions)
Cardiomyopathies
After open heart surgery with bypass
Myocardial ischemia
Sepsis
Barbiturate-induced coma
Mechanical ventilation effects on the myocardium
Tamponade
Trauma
Septic Shock
Sepsis (bacterial, viral, or fungal)

Pediatric Intensive Care Unit Management

The keys to successful treatment of shock are rapid recognition, assessment for multiorgan involvement, and the institution of aggressive measures to avoid irreversible shock. Initial stabilization of any patient in shock involves assessing the ABCs: airway, breathing, and circulation. Vascular access must be obtained rapidly (Figures 24-3 and 24-4). This may involve an **intraosseous catheter** for initial fluid administration (cautiously administered in patients with cardiogenic shock) until it is possible to insert a large-bore intravenous line. All patients should be placed on a cardiorespiratory monitor as well as a pulse oximeter, and oxygen should be administered. If patients do not respond to these initial measures, a fluid bolus, vasoactive drugs, or both, should be administered. All of these efforts are directed to support vital organ perfusion. Appropriate laboratory and diagnostic studies are conducted to determine the underlying cause, and specific therapy should be initiated as soon as an etiology is identified. Initial laboratory studies often include a full chemistry panel, a complete blood cell count, coagulation studies, blood and urine culture, arterial blood gas, mixed venous saturation, if possible, and a lactate. Diagnostic studies should be tailored to the patient's history and presentation; they may include chest X-ray, echocardiogram, a full-trauma workup, or

other imaging studies as indicated. Along with treating the underlying etiology, other end-organ failures should also be adequately supported, that is, blood products for a patient in DIC or renal replacement therapy for patients with renal failure.

HYPOVOLEMIC SHOCK

Hypovolemic shock is the most common cause of shock in children. Loss of circulating blood volume is followed by a series of cardiac and peripheral compensatory adjustments that attempt to restore blood pressure and perfusion to critical organs. The most common causes of hypovolemia in children are vomiting and diarrhea. Patients usually present with a history of fluid loss (e.g., severe diarrhea). However, hypovolemic shock may also be a component of **capillary leak** as occurs with SIRS, and may be seen with severe trauma or overwhelming sepsis. Hypotension is a late finding in hypovolemic shock, as blood pressure can usually be maintained during rapid volume loss by an increase in systemic vascular resistance; however, this compensation is at the expense of normal cardiac output. It is not until an approximately 50% loss of circulatory volume that blood pressure decreases below acceptable standards.

Patients with compensated hypovolemic shock usually respond to a rapid bolus (20 mL/kg) of isotonic fluids (normal saline or lactated Ringer solution). If a patient shows improvement, appropriate fluid replacement is warranted (see Chapter 4). On occasion, children may require significant amounts of fluid within the first 4 hours of resuscitation (40 to 200 mL/kg have been reported) to restore vascular filling pressures and to maintain cardiac output.

If the fluid losses surpass the compensatory ability of the body, decompensated shock occurs and children develop hypotension, tachycardia, and signs of organ hypoperfusion (decreased urine output, altered state of consciousness). This form of shock requires more aggressive support including the use of inotropic agents. Central venous access is often established rapidly deliver fluids, administer inotropes, and measure a CVP to assist in fluid management.

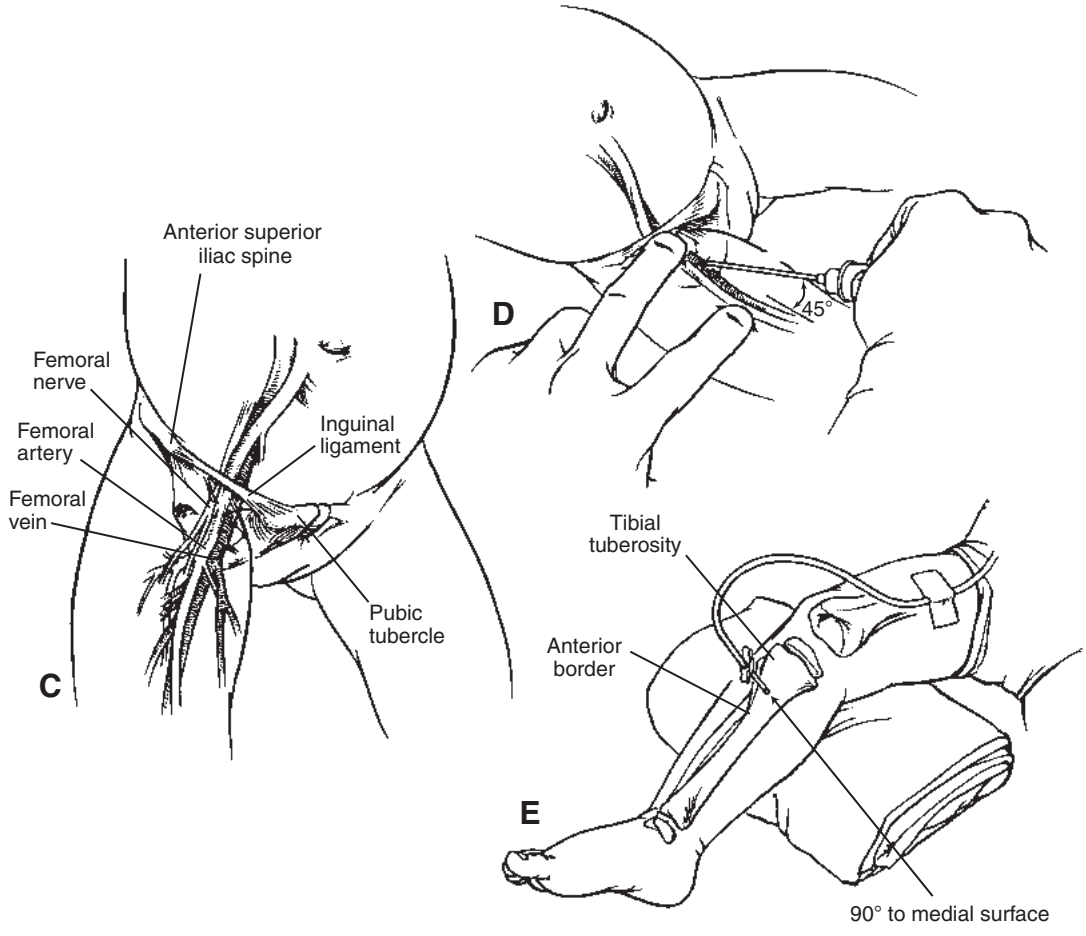

FIGURE 24-3. ***(Continued)*** **(C and D)** Femoral vein and its landmarks as well as the technique commonly used to insert a catheter. **(E)** Intraosseous catheter inserted in the tibia.

DISTRIBUTIVE SHOCK

Distributive shock results in inadequate tissue perfusion secondary to abnormalities in the distribution of blood flow to various organs. Distributive shock occurs following vasomotor paralysis, with increased venous capacitance, and when physiologic shunts redistribute blood past capillary beds. Chemical mediators play an important role in the pathogenesis of this complex phenomenon. Distributive forms of shock are seen in anaphylaxis and CNS (particularly spinal cord) injury. The alterations in hemodynamics in distributive shock are similarly complex. For example, life-threatening infections may be accompanied by depletion of intravascular volume secondary to a capillary leak phenomenon, combined with a marked decrease in cardiac contractility resulting from circulating toxins. Unlike other forms of decreased cardiac output where mixed venous oxygen saturation is decreased, in distributive shock, mixed venous oxygen saturation may actually increase, reflecting the body's inability to extract oxygen from the capillary bed.

Pediatric Pearl: The mixed venous oxygen saturation (MVO_2) is generally a good index of the ratio of systemic oxygen supply and demand. However, in distributive shock, the mixed venous saturation may increase due to the decreased ability of the tissues to extract oxygen.
MVO_2 normal value: 65% to 75%
MVO_2 in cardiogenic shock: less than 65%
MVO_2 in distributive (early septic) shock: greater than 75%

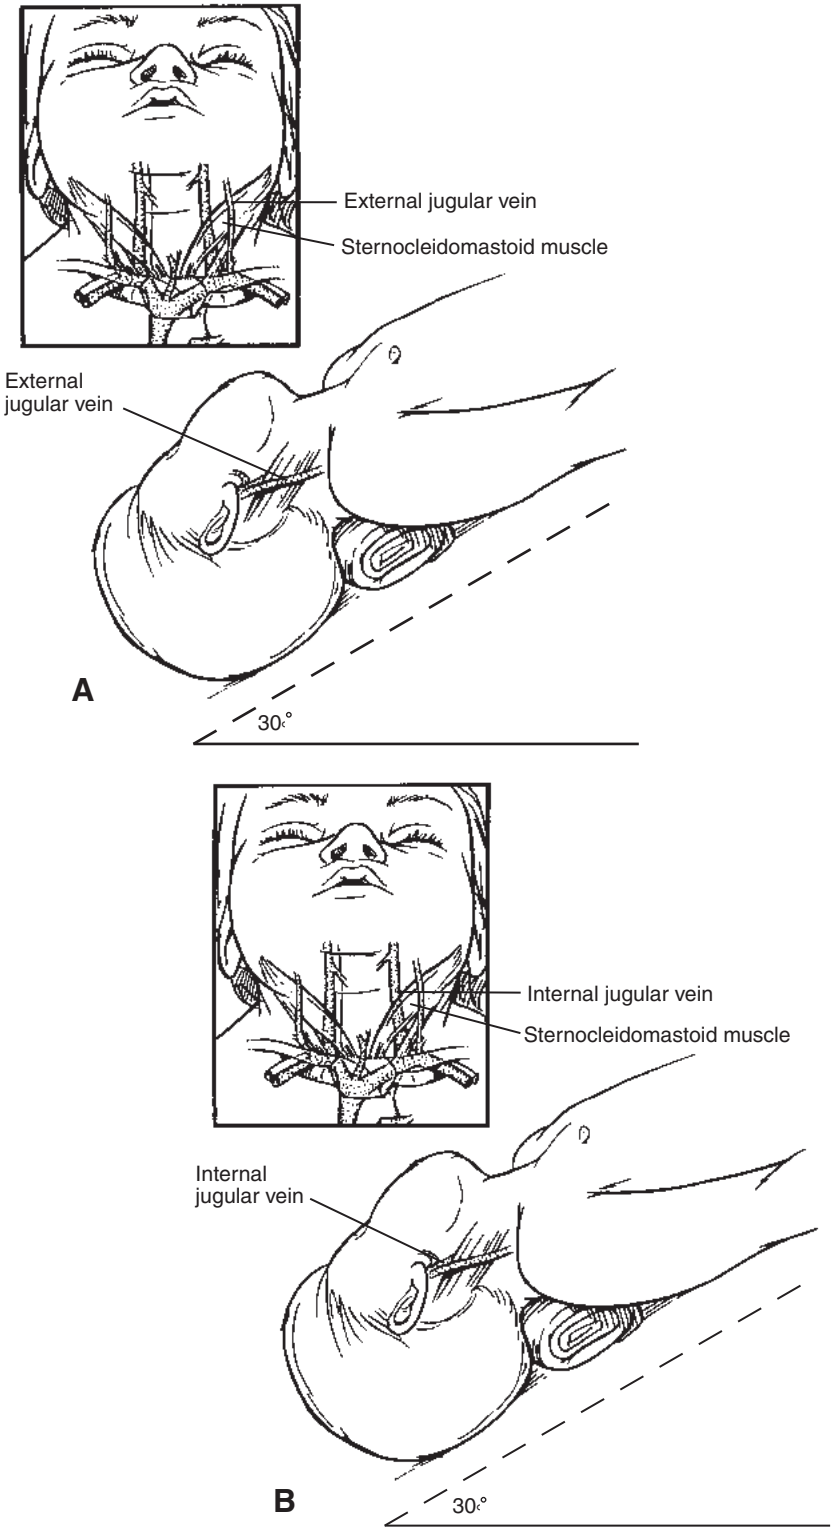

FIGURE 24-4. **(A and B)** Some sites used for central venous cannulation in the critically ill child. The veins of the neck include the internal jugular, subclavian, and external jugular. *(Continued)*

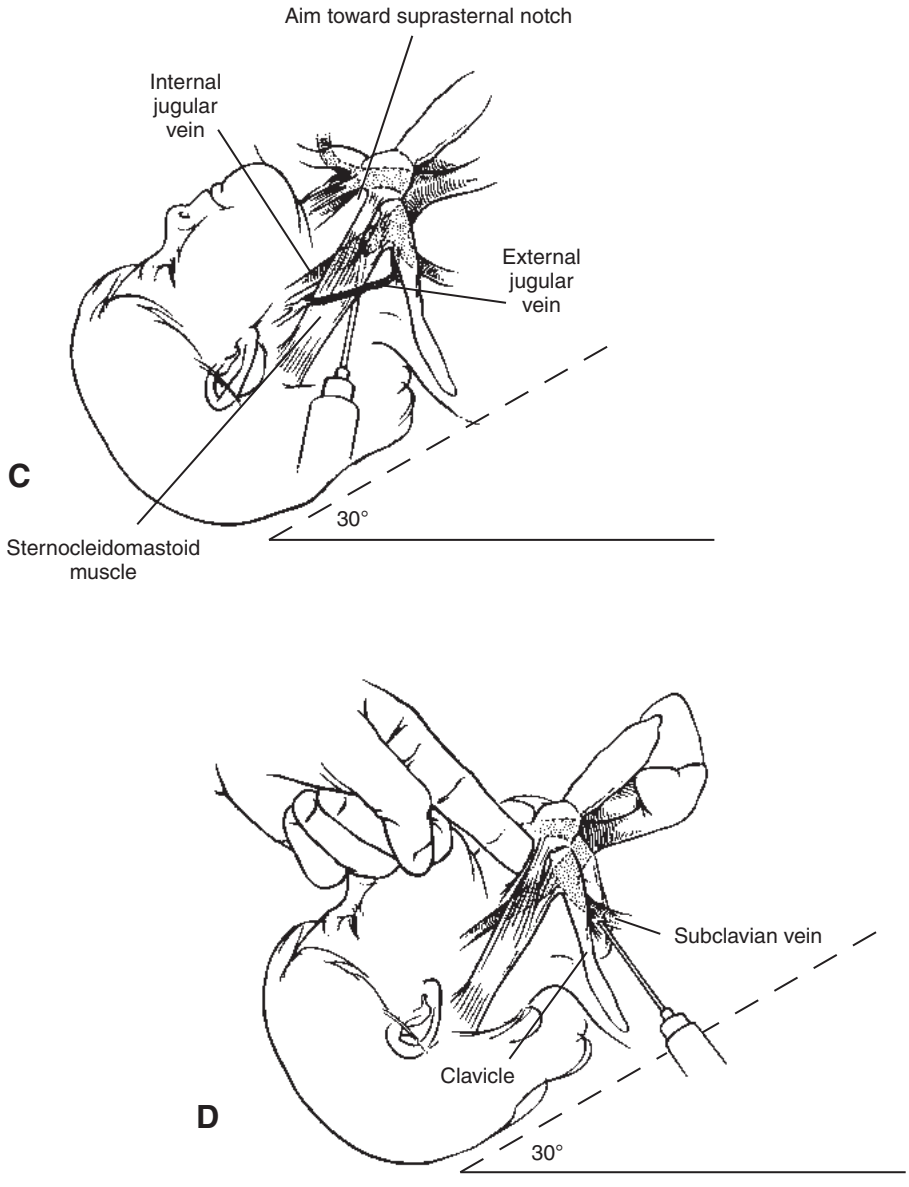

FIGURE 24-4. ***(Continued)*** **(C and D)** Techniques for the cannulation of some of these vessels.

The basic goals of treatment for distributive shock are the same as in the other forms of shock (i.e., to improve hemodynamics and avoid irreversible shock). Because patients may have both intravascular hypovolemia and alterations in cardiac output, the clinician must focus on these alterations in developing a therapeutic plan. Hypovolemia secondary to capillary leak and the third spacing of fluid requires volume replacement. The decrease in cardiac output can be reversed with adrenergic inotropic agents such as dopamine, epinephrine, or dobutamine. However, as systemic vascular resistance is often very low in patients with distributive shock, an agent with greater α-adrenergic effects, such as norepinephrine, or pure α-adrenergic effects, such as phenylephrine, should be considered.

CARDIOGENIC SHOCK

Cardiogenic shock usually results from a disease process that decreases cardiac function (**contractility**), leading to poor cardiac output. The cause may be a dysrhythmia, a pericardial effusion, a congenital heart defect, an acute infection that affects the myocardium (myocarditis), or one of the cardiomyopathies (see Chapter 13). Patients

who have undergone cardiac surgery using cardiopulmonary bypass may also develop transient cardiac dysfunction. This primary pump failure results in an inability to deliver oxygen and substrates to meet the metabolic demands of the body. These patients have tachycardia, a metabolic acidosis, and cool extremities, as systemic vascular resistance is elevated. The mixed venous oxygen saturation obtained from a pulmonary artery catheter is usually below normal (less than 65%).

The treatment for cardiogenic shock is directed toward increasing cardiac contractility. Oxygen should be administered to correct systemic hypoxemia. Acidosis should be corrected, and although usually predominantly metabolic in nature, mechanical ventilation may be of help, particularly because it also reduces the oxygen demands of breathing. Pharmacologic agents that increase cardiac contractility and reduce afterload are used to improve cardiac output (Table 24-8). Finally, temporary mechanical support of the circulation may be instituted. Venoarterial extracorporeal membrane oxygenation (ECMO) can be initiated on an urgent or emergent basis for patients experiencing acute cardiac collapse due to cardiac failure. A **left ventricular assist device (LVAD),** an external pump in which the influx is usually implanted in either the left atrium or left ventricle and in which the efflux is usually implanted in the aorta, can greatly augment cardiac output. The placement of this device is often anticipated and usually occurs in the controlled environment of an operating room. Patients requiring rapid support of their cardiac output are often initially placed onto ECMO as a "bridge" and then transitioned to an LVAD under more controlled conditions. Some LVAD devices are portable enough to allow easy ambulation. These mechanical devices should only be used if there exists a reasonable chance for recovery (e.g., ECMO for "cardiac stun" after heart surgery) or as a bridge to transplantation (e.g., LVADs for dilated cardiomyopathy).

SEPTIC SHOCK

SIRS secondary to an infection causing hypotension refractory to fluid resuscitation is defined as septic. Patients in early or "warm" shock have decreased systemic vascular resistance causing a distributive form. As the SIRS progresses, causing capillary leak, patients become hypovolemic. Eventually, the inflammatory mediators depress myocardial function causing cardiogenic shock. Treatment of these patients involves early recognition, stabilization of the ABCs, aggressive fluid resuscitation with crystalloids, appropriate antimicrobial therapy, and initiation of inotropic support as required. As with all other forms of shock, the end organs need to be adequately supported while the underlying infection and the secondary SIRS response run their course.

NEUROLOGIC INTENSIVE CARE

Examples of neurologic injury requiring intensive care include asphyxial injuries such as **near-drowning** or **near-miss sudden infant death syndrome, CNS trauma,** conditions resulting from **status epilepticus,** and **coma** after **drug ingestions** or from metabolic disorders Neurologic intensive care differs considerably from other forms of PICU management not only because failure may result in death, but also, survivors may persist in a vegetative coma state or have severe neurologic dysfunction due to either the primary etiologic event or a secondary brain injury.

The major focus of neurologic intensive care is to minimize the effects of the primary injury and to avoid secondary injury. In the initial assessment and management of children with a neurologic injury, the focus is on the ABCs of resuscitation **(airway, breathing, circulation)**. After appropriate interventions have taken place to avoid hypoxemia and hypotension, a quick yet thorough neurologic examination is performed. For this purpose of rapid neurologic assessment, the **Glasgow coma scale** is a simple, reproducible tool that also has some prognostic value. A score of less than 9 is suggestive of severe injury; these patients may require further imaging tests (CT or MRI), airway support and respiratory monitoring, and possibly ICP monitoring. The Glasgow coma scale can be used as a tool for repeated patient evaluations, both in the emergency room and in the PICU. The Glasgow coma scale is usually modified when used to assess infants and toddlers. It is important to recognize that pharmacologic agents such as anticonvulsants, analgesics, or muscle relaxants used to facilitate intubation modify the neurologic assessment.

HEAD TRAUMA

Once patients have been stabilized and an initial neurologic assessment performed, further evaluation is made to determine whether a life-threatening situation requiring surgical intervention, such as an intracranial hemorrhage, exists. This evaluation is usually performed in collaboration with both a general surgeon and a neurosurgeon. The general surgeon is responsible for ensuring that intra-abdominal or intrathoracic lesions are not

TABLE 24-8

Therapy for Shock

Volume Replacement

Crystalloids: Ringer lactate or normal saline

- Used to replace external fluid losses (vomiting, diarrhea) or third spacing due to burns, injury, and sepsis
- 20–60 mL/kg may be required in the first 1–2 hours
- Are relatively inefficient volume expanders when compared with others with a higher oncotic pressure
- May move outside the vascular space within 30 minutes

Colloids: albumin 5%, fresh frozen plasma, blood, or limit dextrans

- 10–20 mL/kg
- Help to restore the vascular compartment faster, may provide for clotting factors and increased oxygen-carrying capacity when blood is used

Inotropic and Afterload Reduction Therapy

- Oxygen, calcium, and correction of the acidosis
- Inotropic agents shift to a new position on the Frank-Starling curve

Drug	*Dose (μg/kg/min)*	*Effects*
Dopamine	2–5	Vasodilator, especially in splanchnic and renal vessels, promotes diuresis
	5–10	Increases inotropic state of heart; causes moderate tachycardia and peripheral vasoconstriction
	10–20	Produces both inotropic and chronotropic effects plus strong vasoconstriction
Dobutamine	1–10	Mostly inotropic activity; potent vasodilator
Epinephrine	0.05–0.2	Profound chronotropic and inotropic effects
	>0.2	Vasoconstrictor
Norepinephrine	0.01–1.0	Potent vasoconstrictor with some inotropic effects
Phenylephrine	0.01–0.05	Potent vasocontrictor
Nitroprusside	0.05–4.0	Potent vasodilator used in hypertensive crises or as an afterload reducer in cardiogenic shock
Milrinone	0.1–1.0	Positive inotrope especially in combination with a beta agonist like dopamine, vasodilator
Nitroglycerin	0.05–4.0	Potent vasodilator; used in pulmonary hypertensive crises
PGE_1	0.05–0.1	Potent arterial dilator used in newborns to maintain patency of the ductus arteriosus in ductal-dependent cardiac defects; may be used as a pulmonary vasodilator

PGE1, prostaglandin E_1.

responsible for the patient's altered mental condition. This evaluation is often aided by the use of head and body CT imaging. However, before patients are moved to the scanner, it is the pediatric intensivist's responsibility to ensure that they are adequately oxygenated and ventilated as well as hemodynamically stable. While in the scanner, patients should be monitored to avoid the potential for secondary injury.

In children, most serious head injuries are nonpenetrating. These result most often from falls, although **"shaken baby syndrome,"** a form of child abuse, can also produce significant intracranial injury. Less than 25% of these traumatic injuries produce significant intracranial hematomas that necessitate neurosurgical intervention. However, injuries may be so severe that small deep intracerebral hemorrhages occur secondary to the tearing of small blood vessels deep in the brain parenchyma. Rapid movement of the brain can also result in the shearing of axons, leading to diffuse brain swelling. This injury is more common in children and may result in increased ICP and secondary brain injury.

INCREASED INTRACRANIAL PRESSURE

Depending on the cause of acute neurologic deterioration, different approaches to PICU management may be indicated. If **increased ICP** is a potential problem, an ICP monitoring device should be placed by a neurosurgeon. Children may be placed in a drug-induced coma to facilitate ventilatory management and to help reduce ICP. In this situation, continuous electroencephalogram (EEG) monitoring may be performed, allowing titration of medication to an electrical therapeutic end point.

Other specific neurologic management techniques to decrease ICP include hyperventilation (only in the acute period), fluid restriction, raising the head of the bed, diuresis, osmotic agents, hypertonic saline, and appropriate use of analgesics. Hyperventilation during acute episodes of increased ICP can be quite effective in quickly decreasing the cerebral blood flow and, in turn, the ICP. This strategy should only be used for short durations (e.g., several minutes), as prolonged hyperventilation increases the risk of cerebral ischemia.

The use of pharmacologic agents such as barbiturates, calcium channel blockers, and lidocaine to lower ICP are often necessary adjuncts to the care of these critically ill children. When using these agents, the clinician must have a clear understanding of their significant side effects, especially on the cardiovascular system. Although the results of various clinical and experimental studies do not demonstrate a clear neurologic benefit from these agents, they do decrease ICP and are useful for that purpose.

Fluid management and diuretics are another important component in the treatment of increased ICP. The injured brain may develop a capillary leak syndrome due to local release of inflammatory mediators and a propensity to retain fluid, resulting in increased cerebral edema and significant secondary injury. By decreasing total body water content and increasing serum osmolarity, a gradient is established between the intracellular compartment and the extracellular compartment that draws fluid out of the cells, which thereby reduces the potential for cerebral edema formation. Thus, patients should be fluid restricted to 50% to 60% of maintenance if hemodynamically stable. Some patients may require inotropic support in order to maintain blood pressure in an appropriate range. Aggressive treatment for patients with increased ICP is continued until the pressure returns to the normal range for at least 24 hours. The clinician can then begin weaning the various treatments while monitoring the ICP closely. The ICP monitoring device is removed once the patient no longer requires it.

STATUS EPILEPTICUS

Status epilepticus (or just status) refers to the severest form of seizure activity lasting more than 30 minutes. Before a detailed workup, the intensivist must ensure that the ABCs of resuscitation are addressed. Children with severe status are at risk for losing patency of their airways and developing aspiration pneumonia or apnea. Other systemic complications of status epilepticus include blood pressure instability (early hypertension, late hypotension), hypoxia, hypercarbia, acidosis, hyperthermia, electrolyte abnormalities, and an increase in cerebral blood flow and cerebral oxygen consumption.

Once the emergency ABC assessments have been made, the intensivist then focuses on trying to stop the seizure activity. This is most commonly accomplished with intravenous anticonvulsants such as diazepam or lorazepam. If the seizure continues, a longer acting anticonvulsant such as phenytoin or phenobarbital can be used. Phenytoin is very effective in controlling tonic–clonic seizures in children. However, it has a relatively low lipid solubility and therefore may take 10 to 30 minutes before an effect is seen. Fosphenytoin, which is less caustic to peripheral veins, should be administered when available. However, rapid administration of either can induce severe cardiac depression. Phenobarbital is the least lipid soluble of these agents and therefore has the slowest onset of action, although in status epilepticus its activity may be enhanced as a result of changes in blood pH and blood pressure.

If the seizure activity persists despite the use of these agents, patients are admitted to the PICU and placed in a coma with pharmacologic agents. In this situation, the goal of therapy is to control the seizures and prevent a secondary brain injury that can occur with a persistently elevated cerebral metabolic demand as in status epilepticus. The continuous infusion of pharmacologic agents used can be either pentobarb or Versed, although a "pentobarb coma," is more commonly used. Should these agents fail, propofol or inhaled anesthetics can be considered. These patients must be maintained on continuous EEG monitoring to ensure that all epileptiform discharge is being fully controlled. These pharmacologic agents also have adverse effects on cardiovascular dynamics, and thus cardiac output needs to be monitored closely. Therapy at this level usually requires the combined expertise of a pediatric neurologist, an intensivist, and possibly a neurosurgeon. These patients may require an ICP monitoring device if increased pressure is implicated in causing the seizures. Other agents that may be useful include intravenous lidocaine (1 to 2 mg/kg/h) or rectal paraldehyde (0.15 mL/kg of a 4% solution; however, paraldehyde is no longer available in the United States).

Pediatric Surgery

Gary E. Hartman and Rebecca Evangelista

PREOPERATIVE MANAGEMENT

The principles of preoperative evaluation and management of children are similar to those of adults. Important differences are dictated by the age of the child, the condition prompting the operation, whether the operation is elective or emergent, and the presence of coexisting congenital anomalies or physiologic derangement.

ELECTIVE SURGERY

The most common elective surgical procedures in children are repair of **inguinal hernia, orchiopexy,** and **myringotomy** (placement of ear tubes) for chronic or recurrent otitis media. More than 70% of these procedures are currently performed on an outpatient basis. General anesthesia is used in all major and most minor procedures on children, unlike in adults. It is essential that preoperative evaluation focus on detecting conditions that increase the risk of general anesthesia.

Clinical and Laboratory Evaluation

History

The clinician should obtain a complete history of previous problems with general anesthesia for both the patient and patient's family members. Prematurity, especially with a history of apnea, presents a special concern because of the increased risk of **postanesthetic apnea**. The incidence of life-threatening apnea is greatest during the first 24 hours following general anesthesia, and mandates in-hospital respiratory monitoring for patients at high risk. Most authorities consider infants to be at high risk if they are (1) currently on home apnea monitors or (2) less than 52 to 60 weeks total conceptual age (gestational age at birth plus postnatal age). Recent or current upper respiratory infection also increases the risk of general anesthesia and should prompt delay of an elective procedure until the infection is clearly resolved.

Knowledge of a **congenital cardiac defect** is important for proper physiologic management as well as the opportunity to administer preoperative prophylactic antibiotics to prevent bacterial endocarditis. Obtaining a complete history of **drug allergy** or sensitivity is always extremely important. Specific inquiries of patients with myelodysplasia and congenital urinary tract malformation regarding sensitivity to latex is essential. Severe, potentially fatal allergic reactions, or anaphylaxis, associated with latex are common in these patients.

Physical Examination

It is necessary to perform a careful, complete physical examination in an attempt to detect anomalies not yet clinically apparent that may compromise the performance of or recovery from the proposed operation. In addition to concentrating on the area of surgical interest, the physical examination should focus on cardiorespiratory function. In most cases, clinical evidence of **upper respiratory tract infection** (rhinorrhea, cough), particularly **lower respiratory tract involvement** (abnormal breath sounds, wheezing), should result in postponement of the procedure. Presence of a **cardiac murmur** discovered during a preoperative evaluation warrants a full cardiac evaluation (see Chapter 13). Prophylaxis against bacterial endocarditis (penicillin, ampicillin plus gentamicin) should be instituted based on the organisms likely to be encountered in the specific operative field involved. In 2007, the American Heart Association revised the recommendations for antibiotic prohylaxis eliminating

the use for many previously recommended procedures (see Chapter 13). Prophylaxis is now recommended for patients at highest risk for endocarditis (those with prosthetic valves or materials, previous infective endocarditis, uncorrected congenital cardiac defects, or defects repaired with prosthetic material or residual defects).

Laboratory Evaluation

The need for routine laboratory studies is usually quite limited. In the past, most hospitals required every patient entering the operating room to have a minimum of a complete blood count (CBC), urinalysis, and chest radiograph. A routine preoperative chest radiograph, in the absence of pulmonary or cardiac symptoms, is no longer recommended because of the extremely low incidence of anomaly detection. Most centers no longer require mandatory laboratory examinations for elective operative procedures unless there is clinical suspicion of an abnormality. However, it is necessary to obtain a hematocrit if the patient appears anemic, and a type and cross-match if blood loss is possible. Preoperative autologous or directed blood donation may be appropriate if significant blood loss is anticipated.

General Management

On the day of surgery, all centers require that patients refrain from ingesting solids or liquids for some time prior to the operation. This helps reduce acidity and volume of gastric contents in an effort to decrease the risk of aspiration during induction of anesthesia. In children, this time has been shortened to 6 to 8 hours for solids and 2 hours for clear liquids. If major gastrointestinal (GI) procedures are planned, most surgeons restrict oral intake for 8 to 12 hours prior to the operation. A bath with antibacterial soap the evening before the operation significantly reduces bacterial colonization and the risk of infection. Hair removal is rarely necessary in children; if necessary, it should be performed with a hair clipper in the operating room.

EMERGENCY SURGERY

If the surgical condition is such that an elective operation is not possible, any physiologic derangement that increases the risk of general anesthesia or of the procedure itself should be corrected, provided that the procedure is not unduly delayed. In patients requiring emergency surgery, attention must be directed at correcting hemodynamic, respiratory, GI, and metabolic derangements.

Hemodynamic Abnormalities

Hemodynamic abnormalities are usually the result of hypovolemia, primarily from loss of fluid and occasionally from loss of blood. Correction of hypovolemia with isotonic fluid or blood is critical to prevent cardiovascular collapse from the vasodilation that accompanies the administration of anesthesia. It is necessary to replace fluids, as in dehydration (see Chapter 4).

Respiratory Conditions

Newborns and young children are more dependent on diaphragmatic function for adequate ventilation than older children and adults. Support with supplemental oxygen may be warranted in patients with hemodynamic instability. Severe abdominal distention resulting from intestinal obstruction, ileus, or intraperitoneal fluid may compromise respiratory status. Children may require intubation and assisted ventilation prior to surgery.

Pediatric Pearl: It is necessary to maintain a low threshold for assisted ventilation, particularly in young infants.

Gastrointestinal Dysfunction

GI dysfunction is nearly universal in seriously ill children regardless of whether the pathology is intra-abdominal. It is necessary to institute nasogastric tube placement and suction early during resuscitation to reduce the risk of aspiration and respiratory embarrassment caused by intestinal distention. If the distention or condition is not severe enough to warrant a nasogastric tube, children should at least be given nothing by mouth if the need for urgent operation is a possibility.

Metabolic Abnormalities

Metabolic abnormalities are primarily related to fluid losses that result in hypokalemic alkalosis after repeated vomiting or metabolic acidosis secondary to hypovolemia. Fever can trigger seizure activity in young children and may rise precipitously with general anesthesia. It is necessary to attempt to control temperatures higher than 38.5°C during the preparation for operation using either rectal acetaminophen or a tepid sponge bath. Other metabolic abnormalities may be due to associated medical conditions and may require substantial effort to correct without causing excessive delay of the operation.

POSTOPERATIVE MANAGEMENT: RESPONSES TO SURGERY

Stress Response

The considerations in managing children following an operation are similar to those in preoperative management with the caveat that they are superimposed on the background of a different physiologic state (i.e., that of the **stress response**) (Figure 25-1). The concept of the stress response refers to the physiologic alterations that follow significant injury (accidental or operative) or severe infection. Studies over many decades have documented the existence of the stress response in adults. Physiologic studies in newborns and young children have only recently confirmed the occurrence of a similar response in young individuals, although it is clinically apparent. The magnitude of this response is related to the magnitude of the injury and the severity of any accompanying infection.

A constellation of events, including **fever, pituitary and stress hormone elaboration,** and **increased acute phase protein synthesis,** characterize the stress response (see Figure 25-1). Patients are "hyperdynamic" and catabolic. Increases in heart rate and blood pressure are due to an increased core temperature and elevated levels of catecholamines. Sodium conservation and water conservation are driving priorities that result in elevated levels of **antidiuretic hormone, renin–angiotensin,** and **aldosterone**. Increasing amounts of available fuel meet the increased metabolic demands, with elevation of **corticosteroids** and **glucagon** and decreased levels of and sensitivity to **insulin**.

Recognizing the stress response is important because the definition of "normal" parameters for **heart rate, blood pressure, serum glucose,** and **urine volume** must be interpreted based on the phase of the stress response. Modest elevations of blood pressure are likely due to a catecholamine surge–induced increase in peripheral vascular resistance and should not be considered abnormal or a requirement for antihypertensive therapy. Similarly, serum glucose immediately after a major operation is commonly in the range of 250 to 300 mg/dL and falls naturally within 6 to 8 hours.

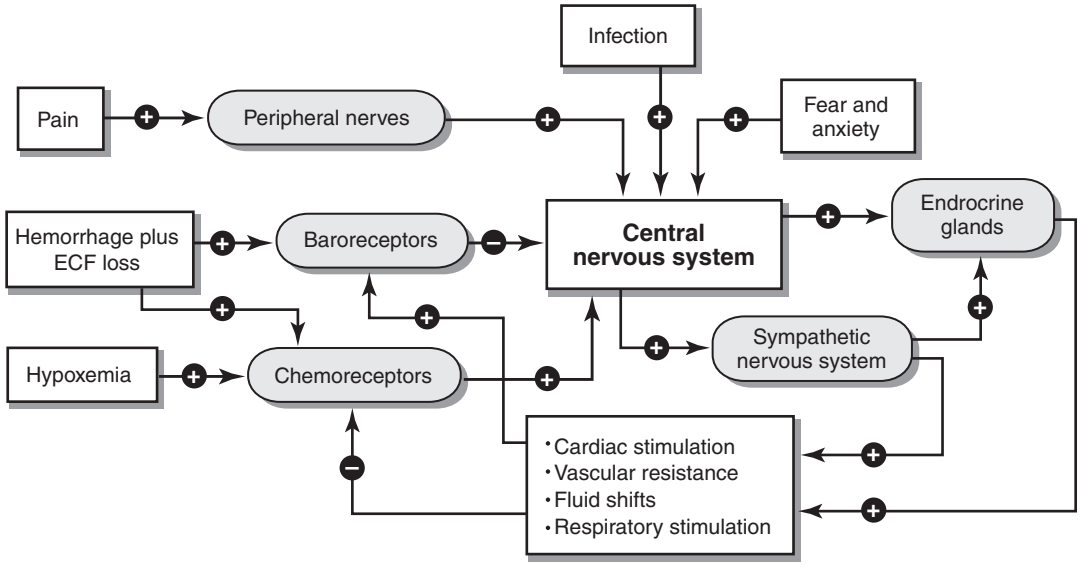

FIGURE 25-1. Stress response. Overview of the neuroendocrine reflexes induced by shock and trauma. *ECF*, extracellular fluid. From Gann DS, Ameral JF: The pathophysiology of trauma and shock. In *The Management of Trauma*, 4th ed. Philadelphia, WB Saunders, 1984, p 38.

Hemodynamic Abnormalities

Hypovolemia, the most common hemodynamic abnormality in children following an operation, continues for some time following the procedure. Fluid loss, which occurs during surgery from exposure of the peritoneal or pleural surfaces, is usually of extracellular fluid. Replacement with isotonic solutions is necessary. Urine volume, which is decreased as a result of elevated antidiuretic hormone, is no longer an adequate single monitor of intravascular volume status. It is necessary to monitor the heart rate, peripheral perfusion, acid–base status, serial hematocrit, and mental status all for proper volume assessment. Frequent physical examinations are crucial.

Pediatric Pearl: Hemodynamic parameters such as central venous pressure or pulmonary artery wedge pressure can supplement, but should never replace, a physical examination.

In the setting of severe sepsis or myocardial dysfunction, the use of inotropic drugs such as dopamine or dobutamine may improve hemodynamic performance. Clinicians should neither use these agents instead of or before adequate volume replacement nor should they use them solely to achieve a normal blood pressure. Adequate tissue perfusion, not mean arterial blood pressure, is the major barometer of resuscitation.

Respiratory Response

In addition to any respiratory compromise imposed by the condition requiring operation, both general anesthesia and an abdominal or thoracic incision can further exacerbate respiratory dysfunction. General anesthesia produces **respiratory ciliary paralysis** lasting 24 hours or more. This ciliary dysfunction, combined with airway dehydration and decreased cough and respiratory excursion due to discomfort, impairs clearance of airway secretions, leading to atelectasis and mucous plugging. Adequate analgesia, humidified oxygen, respiratory effort, and mobilization minimize these problems. Prolonged effects of anesthesia, aspiration pneumonia, and hemodynamic instability are the primary reasons for assisted ventilation in postoperative children.

In neonates, the primary indications for ventilatory support are (1) excessive abdominal wall tension resulting from closure of abdominal wall defects and (2) the risk of pulmonary hypertension associated with congenital diaphragmatic hernia. After a repair of abdominal wall defects, the decreased compliance resulting from the tight abdominal wall requires ventilatory pressures significantly higher than would normally be necessary. As the abdominal wall gradually relaxes, the inflation pressures can be returned to more standard levels to prevent hyperinflation or barotrauma.

Gastrointestinal Response

Paralytic ileus accompanies nearly every major operation in children. The duration of the ileus depends on the magnitude of intestinal dysfunction present preoperatively, the magnitude and type of operative procedure, and the presence of any intervening complications. The ileus characteristically resolves in the small bowel first, then the stomach, and then the colon. Although a return of bowel sounds is an encouraging sign, the passage of flatus and stool herald true resolution of the ileus.

Nasogastric decompression remains an important tool in postoperative management of children, especially young children who may swallow large amounts of air while crying or sucking on a thumb or pacifier. Single-lumen tubes offer the advantage of a large lumen, but can become obstructed by mucus or gastric mucosa when placed on continuous suction. For this reason, intermittent suction is preferred and patency can be maintained by frequent irrigation with a small volume of saline. Double-lumen or sump tubes are specifically designed for continuous suction, but the suction lumen size is limited because of the additional sump lumen, and they are particularly prone to obstruction. Any tube placed across the gastroesophageal junction increases the risk of gastroesophageal reflux and aspiration. Therefore, the tubes should remain in place only as long as necessary and should be kept maximally functional.

Metabolic or Nutritional Response

The postoperative neuroendocrine milieu produces predictable alterations in the metabolism of electrolytes and energy sources. **Serum sodium** falls as a result of increased antidiuretic hormone levels and sodium losses through the GI tract. This tendency is aggravated if excessive amounts of hypotonic fluid are used for resuscitation or

maintenance fluid. **Serum glucose** is predictably elevated immediately following an operation, but should fall within 6 to 8 hours. Normal amounts of glucose, 4 to 6 mg/kg/min, can be infused on return from the operating room in all but extreme cases. Insulin administration in nondiabetic children causes a precipitous fall in serum glucose and is dangerous in the immediate postoperative period.

The stress response is characterized by increased secretion of catabolic hormones. Presumably, this provides glucose and amino acids to the area of injury in adequate amounts. The body's ability to induce **positive nitrogen balance** during the early recovery phase has commanded great attention. It is now well documented that adults and older children can be driven into positive nitrogen balance within 24 hours after surgery. What is not clear is whether this is desirable. Available studies in adults suggest that in previously well-nourished patients, the infectious complications of parenteral nutrition equal or outweigh any metabolic benefits. However, patients with significant acute weight loss (20% to 25%) may benefit from early nutrition. In previously well-nourished patients who are expected to ingest near-normal enteral calories by 7 days after the operation, the risks of parenteral nutrition are probably not justified.

COMMON PEDIATRIC SURGICAL CONDITIONS

ACUTE ABDOMINAL PAIN

Pathophysiology

Abdominal pain is classified as **visceral, somatic,** or **referred**. Visceral pain fibers are located in the muscular wall of the hollow viscera and in the capsule of solid organs. They respond to changes in geometry, primarily stretch, and their threshold is lowered by inflammation and ischemia. Visceral pain is transported via the autonomic nervous system and is perceived as dull, aching, or cramping. Because this pain is transmitted via bilateral fibers of the sympathetic system, it is perceived in the midline. The location of the pain is related to the embryologic origin of the involved viscera. Structures of foregut origin produce epigastric pain, structures of midgut origin produce periumbilical pain, and structures of hindgut origin produce lower abdominal visceral pain.

Visceral pain from the hollow viscera is due to distention or disordered motility caused by intestinal obstruction, gastroenteritis, or ureteral or biliary calculi. Visceral capsules of the solid organs may be stretched by passive congestion or hemorrhage. Although visceral pain is usually the earliest sign of an intra-abdominal process, it is nonspecific and frequently associated with nonbilious reflex vomiting.

Somatic pain is the type of pain that arises from the abdominal wall and parietal peritoneum. It is mediated by the spinal nerves that innervate the abdominal wall and enter the spinal cord through the dorsal root ganglia. Somatic pain, which is stimulated by changes in pH or temperature that may accompany chemical or bacterial inflammation, is sharp or pricking and generally constant. More localized than visceral pain, somatic pain is usually perceived in one of the four abdominal quadrants: right lower and upper and left lower and upper. To determine its cause, the clinician must be familiar with the organs located in each of the quadrants and their pathologic processes.

Referred pain is the term used when pain is perceived in an area of the body other than the site of its origin. It occurs because afferent neurons arising from different sites have shared central pathways. Irritation of the left hemidiaphragm (levels C3, C4, and C5) by blood from a ruptured spleen may be associated with pain in the left shoulder because of the somatic innervation of the shoulder by the same nerve roots. Knowledge of the patterns of referred pain can assist in diagnosis in cases with equivocal or confusing abdominal findings.

In children, the most common cause of acute abdominal pain requiring surgical intervention is **appendicitis** (see Chapter 15). Obstruction of the appendiceal lumen by inspissated stool is the initial pathophysiologic event. This is associated with visceral pain perceived in the periumbilical region because of the midgut origin of the appendix. As the intraluminal pressure increases, the blood supply to the wall of the appendix is compromised, producing necrosis and eventual perforation. Inflammation of the appendix progresses to involve the parietal peritoneum, which produces somatic pain in the right lower quadrant. Perforation with spillage of fecal material and bacteria results in generalized peritonitis with diffuse abdominal pain and toxemia.

Clinical and Laboratory Evaluation (Figure 25-2)

History

The duration, location, and intensity of abdominal pain are essential features of the history. Colicky pain is usually due to hyperperistalsis (e.g., in intestinal obstruction or attempted passage of ureteral or biliary calculi).

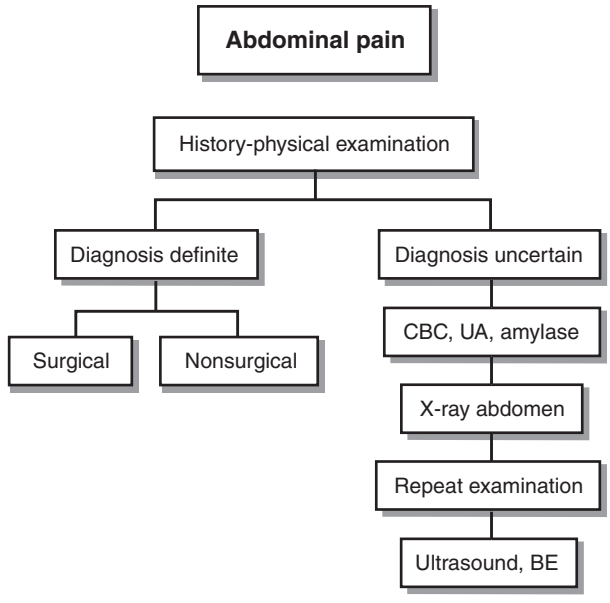

FIGURE 25-2. Flow diagram for diagnostic evaluation of children with acute abdominal pain. *BE*, barium enema; *CBC*, complete blood count; *UA*, urinalysis.

Constant pain is usually visceral in origin. Location of the pain is helpful in narrowing the diagnostic possibilities, particularly with somatic pain. If pain is localized to one quadrant of the abdomen, the organs in that quadrant and their disease processes determine the likely diagnosis. Vomiting preceding the pain, especially in association with diarrhea, favors gastroenteritis over appendicitis. Vomiting associated with early appendicitis is reflex in nature and usually follows the onset of pain. Appendicitis proceeds to perforation within 72 hours of onset of symptoms; therefore, visceral pain lasting longer than 3 days is rarely due to appendicitis. Progression of the pain from a periumbilical to a right lower quadrant location is classic for appendicitis. It represents the progression from visceral to somatic pain, a progression highly suggestive of a surgical condition.

In evaluating children with abdominal pain, it is important to question patients or parents specifically about symptoms related to other abdominal organ systems (genitourinary, hepatobiliary, pancreatic). Flank pain, dysuria, urethral discharge, menstrual cycle, or menstrual abnormalities are important historical points.

Diarrhea may be a symptom of **viral gastroenteritis; inflammatory bowel disease;** or, occasionally, **appendicitis**. In gastroenteritis or infectious enterocolitis, diarrhea is frequent, large in volume, and foul smelling. Children with appendicitis may have frequent, small-volume loose stools as a result of irritation of the sigmoid colon from the inflamed appendix.

Knowledge of preexisting conditions is also important because other nonsurgical conditions such as **sickle cell disease** and **porphyria** can cause abdominal pain. **Nephrotic syndrome** is associated with a significant incidence of abdominal pain from **primary bacterial peritonitis** requiring antibiotics, but not surgery.

Physical Examination

Inspection of the patient and the abdomen reveals important diagnostic clues. Appendicitis with local or generalized peritonitis causes the child to lie still, frequently with the thighs flexed and the knees elevated. Movement increases the pain because of the inflamed peritoneum and abdominal wall. Colicky pain associated with intestinal hyperperistalsis or ureteral or biliary obstruction causes the child to writhe in agony and frequently assume a knee–chest position in an attempt to minimize the discomfort. It is essential to interpret the results of auscultation, an important part of the abdominal examination, in light of the clinical context. Bowel sounds are categorized according to frequency and pitch. Hyperactive bowel sounds are related to hyperperistalsis as seen in gastroenteritis or the early stages of appendicitis. Hypoactive bowel sounds indicate decreased peristalsis, which is typical for paralytic ileus associated with sepsis or the peritonitis resulting from a perforated appendix.

Palpation is frequently the most important portion of the abdominal examination. The goal of palpation is to detect direct tenderness associated with inflammation of the abdominal wall and peritoneum. It is important

to gain the child's confidence with a slow, cautious manner. Distracting the child with conversation while the examining hand gently palpates each quadrant is a useful strategy. Resistance of the abdominal wall muscles to palpation signifies irritation of the parietal peritoneum from underlying inflammation. **Rebound tenderness** refers to pain elicited by induced movement of the abdominal wall. The most sensitive method of detecting rebound tenderness is by gentle percussion in each quadrant.

Pediatric Pearl: The combination of direct and rebound tenderness is a powerful indication of an underlying inflammatory process, usually one that requires surgical intervention.

Rectal or pelvic examination is necessary to complete the physical evaluation of abdominal pain. The information gained by rectal examination includes the presence or absence of fecal impaction or constipation, rectal wall tenderness, and a palpable mass in the right perirectal fossa or adnexal regions. In sexually active girls, the pelvic examination is directed at detecting adnexal masses or evidence of sexually transmitted diseases that cause **pelvic inflammatory disease**. Prepubertal girls may have an imperforate hymen, producing abdominal pain when the initial menses accumulates in the vaginal and endometrial canals. This condition manifests as a bulging hymen with blood behind it.

Laboratory Evaluation

Laboratory studies often are not helpful in establishing the diagnosis of appendicitis. However, they are important in excluding other conditions that may mimic appendicitis or other acute surgical conditions. A CBC is routine. An elevated white blood cell (WBC) count with a left shift neither confirms nor excludes appendicitis. In fact, appendicitis commonly occurs in the face of a normal WBC count. Anemia, especially microangiopathic anemia with thrombocytopenia, is highly suggestive of **hemolytic-uremic syndrome,** which may manifest as severe abdominal pain (see Chapter 20, Acute and Chronic Renal Failure). Similarly, sickle cell anemia is associated with abdominal pain resulting from visceral infarctions or abdominal pain crises. Thrombocytosis may be a sign of **Henoch-Schönlein purpura** (see Chapter 20).

Urinalysis is crucial if urinary symptoms are present or if the pain is lateral or flank in location. Appendicitis may be associated with a mild pyuria or hematuria of 20 to 30 cells/high power field but should not be associated with bacteriuria. Proteinuria and microscopic hematuria are found frequently in hemolytic-uremic syndrome and Henoch-Schönlein purpura. Serum amylase and liver function tests are appropriate in children with abdominal trauma or if the pain is epigastric or radiates to the back.

Radiography is not necessary if a diagnosis is secure on the basis of the history and clinical examination. If the diagnosis is in doubt, plain abdominal radiographs, ultrasound, computed tomography (CT), or, occasionally, a barium enema may be helpful. It is appropriate to evaluate supine and upright films of the abdomen for severe constipation, fecalith, ileus or small bowel obstruction pattern, and pneumoperitoneum. Calcified fecaliths are present in 20% of children with appendicitis. Pneumoperitoneum is rare. Ultrasound has been used to augment clinical examination with good reliability. However, because the results must be interpreted with clinical suspicion, false-positive and false-negative rates are approximately 10%. Ultrasound is particularly helpful in girls in whom tubo ovarian anomalies may simulate appendicitis and in young children with perforated appendicitis. Rapid CT with "triple contrast" (enteral, intravenous, rectal) has accuracy rates equal to skilled ultrasonography and is used in many centers in preference to ultrasound. With the improvements in ultrasonography and CT, a barium enema is rarely needed in diagnosing appendicitis but is helpful, particularly in cases of inflammatory bowel disease.

Pediatric Pearl: It is necessary to obtain plain radiographs of the chest if children have a history of cough or significant upper respiratory infection. Right lower lobe pneumonia is a well-known cause of abdominal pain that is sometimes strikingly similar to appendicitis.

Differential Diagnosis

The differential diagnosis of acute abdominal pain includes a number of conditions (Table 25-1). It is critical to distinguish between conditions that require a surgical solution and those that resolve spontaneously or with

TABLE 25-1

Most Frequent Causes of Abdominal Pain in Children by Age Group

Preschool	*School Age*
Gastroenteritis	Gastroenteritis
Appendicitis	Appendicitis
Intussusception	Ovarian cyst/torsion
Hemolytic-uremic syndrome	Henoch-Schönlein purpura
Pneumonia	Inflammatory bowel disease

nonoperative measures. Most children with acute abdominal pain are ultimately labeled as suffering from gastroenteritis or abdominal pain of unknown origin. Appendicitis is the most common surgical condition producing abdominal pain in children.

Occasionally, after the initial examination and laboratory and imaging studies, diagnosis of the abdominal pain is still uncertain (see Figure 25-2). In such cases, the most reliable method of excluding a surgical condition involves admission for intravenous hydration and serial examination by the same observers. Progression of pain, especially with the development of direct abdominal tenderness and muscular rigidity, is the most reliable indicator of a process requiring operative treatment. Resolution of pain and resumption of oral intake while under observation are the most reliable signs that the child is not in need of surgery.

Management

Conditions that require operative therapy include **appendicitis, Meckel diverticulitis,** and **torsion of the ovary or omentum**. Removal of a nonperforated appendix may involve conventional laparotomy or laparoscopic techniques. Perioperative antibiotics are usually warranted, although there is some controversy as to their necessity. Recovery from the associated ileus is usually prompt, and in most children, discharge follows 1 to 2 days after the operation. Perforated appendicitis is much more complicated, requiring 5 to 7 days of broad-spectrum antibiotics. A prolonged ileus requiring nasogastric suction and intravenous hydration may be necessary. Drains are used for well-formed abscesses and, in some centers, for all children with perforated appendicitis.

Meckel diverticulitis, which is clinically indistinguishable from appendicitis, requires resection of the involved intestine followed by anastomosis. Again, nasogastric suction and intravenous hydration are necessary for 2 to 5 days along with antibiotics. Recovery from resection of an infarcted ovary or segment of omentum is similar to that seen after surgery for nonperforated appendicitis.

INTESTINAL OBSTRUCTION

Pathophysiology

Propulsion of food and liquids through the GI tract requires coordinated peristalsis and adequate lumen size. Disordered peristalsis and intrinsic or extrinsic narrowing of the lumen may produce similar symptoms, specifically vomiting, abdominal distention, pain, and absence of flatus or stool. Disordered peristalsis, as in paralytic ileus or intestinal dysmotility, is considered a functional obstruction, whereas narrowing of the lumen from any cause is considered a mechanical obstruction. Intraluminal obstruction may result from abnormally thick meconium in newborns, enteric contents in patients with cystic fibrosis, or a bezoar of organic or inorganic objects ingested by patients with severe neurologic abnormalities.

Intestinal obstruction is classified as complete or incomplete; the distinction is based on a combination of clinical and radiographic criteria. **Complete obstruction** is evident by the lack of flatus or stool and radiographic absence of intestinal gas beyond the point of obstruction. **Incomplete obstruction** is marked by continued passage of flatus or stool and by radiographic evidence of gas beyond the obstruction. Intestinal obstruction is also classified according to location (small bowel versus colonic) and etiology (i.e., adhesive, intussusceptive, malignant). Symptoms relate to the level of obstruction and its completeness. Patients with obstructions of the

stomach, duodenum, and upper jejunum present with vomiting early after the obstruction occurs with little, if any, abdominal distention. Patients with obstruction of the lower small bowel and colon present with delayed onset of vomiting and prominent distention.

Once established, intestinal obstruction results in pooling of secretions and fluid in the intestinal lumen, intestinal wall, and peritoneal cavity. Fluid loss may be dramatic and consists of losses from the extracellular compartment. In many types of intestinal obstruction, especially if the obstruction is complete, vascular supply to the intestine is compromised. Initially this is due to venous congestion but can proceed to arterial insufficiency with intestinal necrosis and perforation if not relieved within a few hours. In the absence of vascular compromise, an untreated intestinal obstruction produces progressive intestinal dilation and fluid loss.

Clinical and Laboratory Evaluation

History

In evaluating children with possible intestinal obstruction, specific attention should be focused on the GI system. Specific aspects of vomiting are important, including onset, frequency, and whether the vomitus is bilious or nonbilious. Obstruction of the stomach or duodenum proximal to the ampulla of Vater results in nonbilious vomiting, whereas all obstructions distal to the ampulla are accompanied by bile-stained emesis. Bile staining, which frequently signifies a mechanical obstruction or severe paralytic ileus, is generally considered to suggest a surgical condition until proven otherwise. Pain from intestinal obstruction is crampy and midline as a result of the distention and increased peristalsis. The progression of pain in severity and frequency, especially if it is localized, is suggestive of intestinal ischemia.

A history of stooling pattern is helpful, particularly in newborns. **Meconium** is first passed within 24 hours of birth in 95% of normal infants. Failure to pass meconium in the first 24 hours is highly suggestive of an obstruction, in particular, **Hirschsprung disease**.

Pediatric Pearl: Even after an intestinal obstruction becomes complete, stool and flatus may continue to pass as a result of evacuation of the bowel distal to the obstruction. Therefore, the passage of stool or flatus cannot be used to date the onset of obstruction or to exclude obstruction.

Fever is unusual in the absence of intestinal perforation and may suggest an alternate diagnosis such as gastroenteritis or urinary tract sepsis. Other non-GI symptoms can help identify the abdominal symptoms as secondary findings resulting from a paralytic ileus. History of previous abdominal surgery is extremely important. The illness that prompted the initial procedure may recur, or **adhesions** that form after the initial procedure can cause obstruction.

With possible obstruction in neonates, it is necessary to explore the maternal history for evidence of **polyhydramnios** (increased amniotic fluid volume), which is associated with obstruction of the upper jejunum and proximal GI tract. A history of anomalies such as **cystic fibrosis** or **Hirschsprung disease** in siblings should alert the clinician to the possibility of these or associated conditions. A history of congenital heart disease, especially those with abnormal visceral–atrial situs, can be associated with **malrotation**.

Physical Examination

General inspection yields important information regarding hydration status and systemic toxicity. In newborns, evidence of genetic or developmental anomalies should be specifically sought. Infants with Down syndrome have an increased incidence of Hirschsprung disease and duodenal atresia, and those with other syndromes may also have an increased risk of GI anomalies.

Inspection of the abdomen should focus on the presence or absence of distention, visible discoloration, or evidence of previous operations. Abdominal distention in intestinal obstruction is due to multiple dilated loops of small bowel or colon and generally signifies obstruction of the mid-small bowel or beyond. In small children in whom the abdominal wall is thin, erythema frequently heralds the presence of underlying peritoneal inflammation; this condition is seen earliest in the midline and lateral to the rectus muscles where the abdominal wall is thinnest.

Auscultation of bowel sounds is an essential part of the examination. High-pitched sounds of increased frequency are the classic findings of intestinal obstruction. Decreased frequency of bowel sounds or a silent abdomen is found in children with paralytic ileus or obstruction complicated by intestinal ischemia.

Palpation of the abdomen should focus on the detection of abdominal wall tension or resistance, or the presence of palpable loops of bowel or abdominal masses. A sausage-shaped mass in the right upper quadrant or epigastrium may be palpable in early cases of **intussusception** before marked distention of the small bowel occurs. In infants with suspected **pyloric stenosis,** careful palpation of the upper abdomen should reveal a palpable olive-sized mass in 80% of patients with this condition. The infant must be relaxed, which can be facilitated by a pacifier and flexing the thighs.

Pediatric Pearl: The technique of sham feeding is especially effective in allowing deep palpation. After placement of a nasogastric tube, the infant is allowed to take Pedialyte or glucose water from a bottle while an assistant aspirates the stomach with a syringe. This technique quiets the infant, relaxes the abdominal wall, and keeps the stomach from distending.

The characteristic "olive" is transverse in orientation, mobile, 1 to 2 cm in length, and located in the epigastrium or right upper quadrant. If an "olive" is palpable, no further diagnostic studies are necessary.

Examination of the groin is essential; **inguinal hernia** is the single leading cause of intestinal obstruction in children. It is necessary to examine children for hernias from the side, with the testis grasped in the examiner's dominant hand, unlike in adults. The fingers of the nondominant hand are used to palpate the spermatic cord at the level of the pubis. The presence of bowel or fluid in the hernia sac produces a thickened spermatic cord. The distinction between fluid and intestine is usually straightforward, but difficult cases may be aided by transillumination of the scrotum or, in small infants, bimanual examination of the internal ring with a digit in the rectum.

Rectal examination itself may be diagnostic, as in the case of **imperforate anus,** where the absence of a communication or the presence of a dimple makes the diagnosis. Typical rectal examination findings in Hirschsprung disease are absence of a rectal vault and a snug feel to the examining digit. Large pelvic masses may produce rectal obstruction and be easily palpated by rectal examination. Occasionally, the intussusceptum (invaginated bowel) of an intussusception is palpable as a rectal mass; these rarely prolapse through the anus.

Laboratory Evaluation

Laboratory studies in children with an intestinal obstruction should focus on detecting complications such as dehydration and sepsis. A CBC with a differential and platelet count is usually warranted to exclude complicating anemia or a left shift that raises the suspicion of intestinal ischemia or associated sepsis. A right shift producing lymphocytosis may suggest severe gastroenteritis, simulating obstruction. Serum electrolytes and renal function are important in identifying electrolyte abnormalities, such as hypokalemic alkalosis, from recurrent vomiting. Azotemia and acidosis from intravascular volume depletion are common complications of intestinal obstruction.

Radiographic studies help identify the cause of obstruction. Workup should begin with plain radiographs of the abdomen obtained in two or three views. In addition to a supine film, a film in the upright or lateral decubitus position is necessary to identify air-fluid levels and to detect a small pneumoperitoneum from possible perforation. In newborns, a lateral view with the patient prone or held upside down may help demonstrate air in the rectum in cases of imperforate anus or suspected Hirschsprung disease.

In most instances, the diagnosis is not obvious from plain radiographs, and a contrast study, usually a contrast enema, is necessary. If meconium ileus or its postneonatal equivalent is suspected, the enema should be performed with a water-soluble contrast agent. The contrast material can break up the thickened enteric contents due to its hyperosmolarity, which causes movement of water into the intestinal lumen. In cases of gastric outlet or duodenal obstruction, injection of air through the nasogastric tube may be as helpful as injection of radiopaque contrast. Ultrasound has been very helpful in confirming the diagnosis of pyloric stenosis in infants without palpable masses. More complex imaging studies are rarely, if ever, necessary in the evaluation of intestinal obstruction.

Differential Diagnosis

The differential diagnosis of intestinal obstruction in children is highly dependent on age and symptoms (Table 25-2). In newborns, the combination of history, physical examination, and plain radiographs of the chest and abdomen can make the diagnosis quite certain. A contrast enema is usually performed to confirm the diagnosis or to exclude additional atresias or anomalies.

TABLE 25-2

Causes of Intestinal Obstruction in Children by Age Group

Newborn	*Infants*	*Children*
Inguinal hernia	Inguinal hernia	Inguinal hernia
Hirschsprung disease	Intussusception	Adhesions
Atresia	Malrotation	Meconium ileus equivalent
Malrotation	Duplication	Appendicitis
Meconium ileus	Appendicitis	
Imperforate anus	Pyloric stenosis	

Management

Diagnosis and treatment should proceed simultaneously. Systemic derangements of hydration, electrolytes, and sepsis are urgent priorities. Both nasogastric suction and intravenous resuscitation with an isotonic solution such as normal saline or lactated Ringer solution should begin promptly. Clinical evidence of dehydration and hypovolemia after evaluation of skin turgor, peripheral perfusion, mental status, and urine volume may warrant bolus infusions of 10 mL/kg. It is necessary to initiate broad-spectrum antibiotics because of the risk of translocation of bacteria and systemic sepsis, even in the absence of intestinal infarction.

The diagnosis and degree of obstruction determine the definitive therapy. Most obstructions from postoperative adhesions resolve with nasogastric suction, fluid replacement, and nutritional therapy. This is especially true if the obstruction is incomplete and it is early in the postoperative period. Complete obstructions from postoperative adhesions usually require operative treatment.

Initial treatment of obstructions from **incarcerated inguinal hernias** involves manual reduction of the hernia in addition to general resuscitative measures. It is rare that incarcerated hernias are truly irreducible in children. After reduction of the hernia, monitoring infants for evidence of intestinal injury and continued obstruction is necessary. Hernia repair is appropriate when patients have stabilized and intestinal and scrotal injuries have resolved.

Pyloric stenosis is frequently associated with significant hypokalemic alkalosis. Preoperative preparation should concentrate on adequate potassium replacement, which is determined by serum concentrations of potassium and chloride. A low serum chloride level with an elevated bicarbonate level indicates persistent potassium depletion regardless of the serum potassium level. Division of the hypertrophied muscle (pyloromyotomy) is all that is required to relieve the obstruction; it produces excellent results. Entry into the lumen of the pylorus is infrequent but can be disastrous if not recognized and repaired at the time of surgery.

The usual treatment for **imperforate anus** and **Hirschsprung disease** is a temporary colostomy followed by definitive reconstruction at the age of 12 to 18 months. **Intestinal atresias and malformations** such as duplication require limited intestinal resection with primary anastomosis. **Malrotation and adhesive obstructions** require lysis of adhesive bands and resection only if segments are nonviable.

Meconium ileus is a special circumstance. If it is not complicated by intestinal ischemia and is recognized on contrast enema, nonoperative relief with enemas of hyperosmolar contrast agents may be appropriate. Refluxing these agents into the dilated segment of intestine allows for the mixing of the agent with the abnormally thick meconium; this can result in a change in the consistency of the meconium so that it can pass through the colon and resolve the obstruction. It is not unusual for repeat administrations of the agent to be necessary. If these attempts are unsuccessful, operative therapy should consist of attempts to milk the material into the colon by injecting Gastrografin or *N*-acetylcysteine into the lumen. Resection is appropriate only if the bowel is nonviable. Because these patients (who most likely have cystic fibrosis) will have difficulty with absorption in the future, limited resection is necessary.

Pediatric Pearl: Meconium ileus in newborns is strongly suggestive of cystic fibrosis.

Meconium ileus equivalent is the term applied to the same type of obstruction occurring in older children with cystic fibrosis. It is very common in these patients. Relief usually involves nonoperative methods. However, other conditions that require operation (adhesions, intussusception) may also occur and warrant consideration in the differential diagnosis.

ABDOMINAL MASS

Pathophysiology

Most abdominal masses in children produce few, if any, symptoms other than the presence of the mass itself. The exceptions are unusually large tumors that produce respiratory compromise if they are located in the upper abdomen or produce rectal or bladder obstruction if they are located in the pelvis. **Vascular tumors** that trap platelets or produce congestive heart failure are usually confined to the liver. Some tumors may produce symptoms as a result of secretion of hormones: **Neuroblastomas** may produce vasoactive intestinal peptide, resulting in watery diarrhea; **Wilms tumors** may be associated with hypertension caused by renin production; and **pheochromocytomas** cause episodic hypertension and diaphoresis as a result of catecholamine excess. The GI masses associated with pyloric stenosis, intussusception, or intestinal duplication are usually overshadowed by the GI obstructive symptoms (see Intestinal Obstruction).

Clinical and Laboratory Evaluation (Figure 25-3)

History

Maternal history and careful questioning regarding GI function are important in evaluating newborns with an abdominal mass. **Polyhydramnios** (increased amniotic fluid volume) is often associated with high-level intestinal obstruction, and **oligohydramnios** (decreased amniotic fluid volume) is associated with impaired renal function. In older children, abdominal pain and vomiting usually indicate that the mass is GI in origin, whereas hematuria obviously directs attention toward a renal lesion. A history of unusual eye movements (**opsoclonus–myoclonus**) suggests the presence of a neuroblastoma.

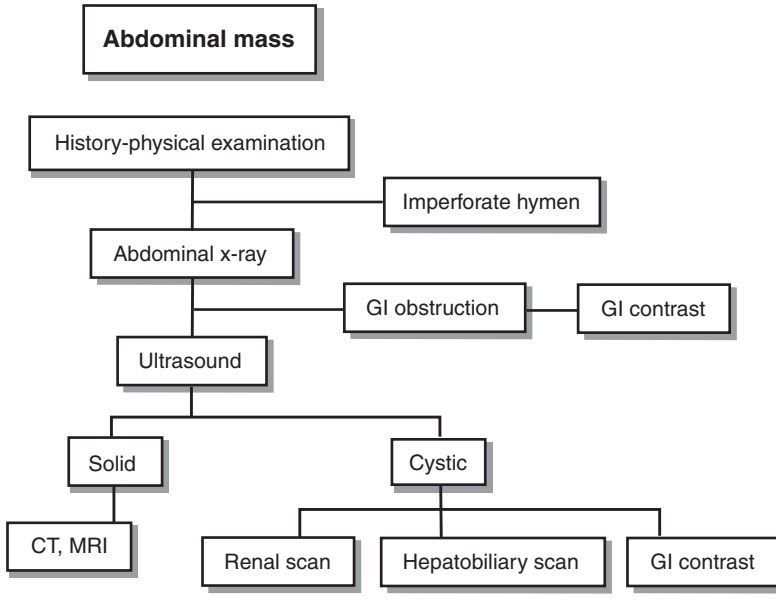

FIGURE 25-3. Flow diagram for the diagnostic evaluation of children with an abdominal mass. *CT*, computed tomography; *GI*, gastrointestinal; *MRI*, magnetic resonance imaging.

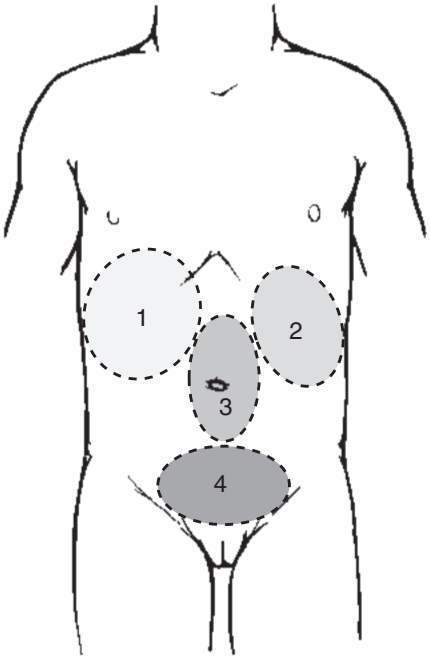

FIGURE 25-4. Likely organ of origin of abdominal mass by location. *1*, liver, gallbladder, kidney, adrenal; *2*, spleen, stomach, kidney, adrenal; *3*, pancreas, retroperitoneum, mesentery, bowel; *4*, bladder, uterus, ovaries.

Physical Examination

Location of the mass is the most important piece of information obtained from a careful abdominal and rectal examination (Figure 25-4). Upper abdominal masses are related to the liver, spleen, adrenals, or kidneys. Bilateral flank masses are almost always renal (e.g., those seen in polycystic disease). Midline lower abdominal masses are likely to be related to the bladder, vagina, ovaries, or retroperitoneum. In small children with palpable masses, transillumination may offer quick reassurance that the lesion is cystic.

General examination should specifically look for subcutaneous nodules, periorbital ecchymosis, superficial hemangiomas, and jaundice. Pallor and weakness suggest systemic disease and tachypnea, whereas rales and wheezing suggest congestive heart failure associated with a vascular malformation. Congenital aniridia, hemihypertrophy, and Beckwith-Wiedemann syndrome are associated with an increased incidence of Wilms tumor.

Laboratory Evaluation

A CBC may reveal evidence of marrow involvement with anemia or thrombocytopenia, leukemia with elevated WBC, or thrombocytosis in some solid tumors. Serum determinations of α-fetoprotein and β-human chorionic gonadotropin and of urine vanillylmandelic acid and homovanillic acid are warranted in children with solid tumors.

Plain radiographs of the abdomen may be helpful if calcification suggestive of neuroblastoma or teratoma is identified. A contrast study of the GI tract is indicated if evidence of an intestinal obstruction is apparent on plain films. Ultrasonography to distinguish cystic from solid masses and to identify the likely organ of origin should be next. Further cross-sectional imaging such as CT or magnetic resonance imaging for evaluating solid tumors is generally necessary. In the case of solid renal masses, ultrasonographic evaluation of the inferior vena cava and right atrium to detect tumor thrombus prior to any attempts at resection is also warranted.

Differential Diagnosis

The differential diagnosis of an abdominal mass in children depends on age, the cystic or solid nature of the mass, and the presence of associated symptoms (Table 25-3). In newborns, most lesions are cystic, although neuroblastoma and teratoma occur with some frequency. In older children, most lesions are solid, with neuroblastoma and Wilms tumor being the most common. It is necessary to refer children with solid tumors to a pediatric oncology center early in the evaluation to facilitate diagnostic studies and to ensure a multidisciplinary approach to treatment.

TABLE 25-3

Types of Abdominal Masses in Children

Cystic	*Solid*
Hydronephrosis	Neuroblastoma
Multicystic dysplastic kidney	Wilms tumor
Adrenal hemorrhage	Teratoma
Ovarian cyst	Hepatoblastoma
Choledochal cyst	Mesoblastic nephroma
Hydrometrocolpos	Hemangioendothelioma
Mesenteric cyst	Infantile polycystic kidneys
Intestinal duplication	Rhabdomyosarcoma

Management

After careful diagnostic evaluation, patients with solid tumors need either a diagnostic biopsy or tumor resection. The method of confirming the diagnosis and the decision whether to attempt resection depend on the type of tumor and the presence of distant or local spread. This decision is usually made in consultation with a pediatric oncologist, a pediatric surgeon, and a radiotherapist. Malignant tumors usually require additional chemotherapy or radiotherapy. If dissemination is widespread or if complete resection cannot be performed, chemotherapy may be warranted before resection is attempted.

Cystic lesions may require operative therapy, medical management, or observation. **Adrenal hemorrhage** is a neonatal condition that resolves spontaneously, although it must be distinguished from a **cystic neuroblastoma** by measuring urinary catecholamines. Serial ultrasound examinations are used to monitor its resolution. **Ovarian cysts** are common in newborns, resulting from stimulation from maternal hormones. Recent studies using prenatal ultrasonography have shown that many of these cysts resolve spontaneously, particularly if they are 3 cm or less in diameter. **Ovarian cysts with torsion** require operative therapy in an attempt to preserve the ovaries and the fallopian tube.

Obstructive uropathy requires further investigation, including voiding cystourography, renal nuclear scan, and possible cystoscopy. Chronic suppressive antibiotic therapy is used in children with severe **vesicoureteral reflux** and partially obstructing uropathy.

Cysts of the mesentery, bowel wall, or **extrahepatic biliary tree** require excision with reconstruction. **Hydrometrocolpos,** which presents in the neonatal period or at the onset of menses, warrants excision of the imperforate hymen or, in cases of distal vaginal atresia, vaginal reconstruction.

Pediatric Subspecialties

PEDIATRIC ORTHOPEDICS

James G. Gamble

Musculoskeletal conditions account for about 20% of a pediatric outpatient practice, and students will encounter patients with orthopedic diseases on the wards. These musculoskeletal conditions cover a wide range of pathologic categories, and therapeutic interventions range from the surgical emergency of a septic hip to the simple assurance and observation necessary for the common complaint of intoeing gait. The purpose of this section is to review the musculoskeletal conditions most likely encountered during a pediatric rotation. These conditions can be classified into the following categories: **congenital, developmental, infectious, traumatic,** and **physiological**.

Congenital

One of the most commonly encountered congenital orthopedic conditions is **talipes equinovarus**, or **clubfoot**. This condition affects approximately 1 in 1,000 live births, being bilateral approximately half of the time. It is more common in males than in females. The deformity is obvious at birth as the foot is adducted, supinated, and in equinus. Many genetic syndromes have associated clubfeet, and these conditions must be ruled out in the neonate.

Clubfoot can be either supple or rigid. A supple, or positional, clubfoot is usually due to intrauterine packing or positioning, and can be corrected passively. The prognosis is excellent with simple stretching exercises performed by the parents or occasionally with one or two corrective casts.

Rigid clubfoot is not due to intrauterine packing and the exact etiology is obscure. The rigid, or true clubfoot cannot be corrected passively and requires early, aggressive treatment. The feet are supinated, inverted, and in equinus.

The Ponseti treatment of clubfoot involves a series of above knee casts that gradually correct the varus and rotation of the foot, followed by a tendo Achillis lengthening (TAL) to correct the equinus. Once the deformity has been corrected, usually after 2 to 3 months of casting and TAL, the infant must use a night splint until about 3 years of age to prevent recurrence. Successful outcomes are high with the Ponseti treatment, but children with unilateral clubfoot will always have a foot length and calf girth about 10% smaller than the contralateral side.

Developmental

Developmental conditions occur in previously normal infants and children. The most common developmental conditions include **developmental dysplasia of the hip (DDH)**, **Legg-Calve-Perthes disease**, **slipped capital femoral epiphysis (SCFE)**, and **adolescent idiopathic scoliosis (AIS)**.

DDH is a spectrum of hip disease that includes acetabular dysplasia, hip subluxation, and complete dislocation of the femoral head out of the acetabulum. Stability of the neonatal and infant hip comes from the thick capsular ligaments, and if these ligaments are lax or stressed and stretched due to breech position, the result can be DDH. The incidence of DDH is about 1.5 in 1,000 live births. The key to a successful outcome is early diagnosis and treatment. The gold standard for diagnosis within the first 4 months of life is the Ortolani and Barlow tests.

To perform the Ortolani test, the child must be supine and relaxed. The hips and knees are flexed to 90 degrees, and the hips are abducted with the thumb and forefingers while applying a gentle lift under the trochanteric region. The test is positive if the examiner feels a clunk as the dislocated femoral head slides into the acetabulum. An easy way to remember the significance of this test is that with the **O**rtolani the hip is **O**ut.

The Barlow is a provocative test to detect a reduced but unstable hip. Again, the child is supine and relaxed, with the hips and knees flexed to 90 degrees. With the examiner's thumb on the inner thigh and the fingers along the lateral trochanteric region, the thigh is adducted with gentle downward pressure along the longitudinal axis of the thigh. The test is positive if the examiner feels the femoral head slip out of the acetabulum, but the sensation is more like a sliding or a slosh than the Ortolani clunk. For both of these tests, the child must be relaxed. It is difficult to get an accurate clinical assessment if the child is kicking and crying.

After the age of about 4 months, the most sensitive clinical test is limited abduction and the Allis or Galeazzi sign in which the knees appear uneven (Figure 26-1). Children should have at least 60 degrees of symmetrical abduction in flexion. The Trendelenburg sign, or dropped pelvis, is a late sign once the child has started to walk.

From 6 weeks of age until 4 to 6 months, the most valuable imaging study is the ultrasound. An ultrasound before the age of 6 weeks is not recommended as false positive rates are high, resulting in overdiagnosis. Radiographs are unreliable before the age of 4 to 6 months. Once the femoral head ossific nucleus appears around 6 months, the ultrasound becomes less reliable, and the most valuable imaging study is an AP radiograph of the pelvis.

Treatment of DDH diagnosed within the first 6 to 8 months of life is with the use of a Pavlik harness. From 6 to 18 months, treatment is operative with a percutaneous adductor tenotomy, closed reduction, and spica cast application to maintain the reduction. From 18 months to around 2 1/2 years, the child needs an open reduction of the hip and spica cast application. Over the age of 2 1/2 years, a child needs an open reduction, femoral shortening, and pelvic osteotomy to achieve a successful outcome.

Legg-Calve-Perthes disease, or simply "Perthes disease," is an avascular necrosis of the femoral head, first described by Arthur Legg from Boston, Jacques Calve from France, and Georg Perthes from Germany. They realized that this condition had a better prognosis than tuberculosis of the hip, which was prevalent at the beginning of the 20th century. The cause of the avascular necrosis still remains a mystery.

Perthes disease is most common around the ages of 6 to 8 years. The child presents with a limp and often complains of knee pain. One of the classic pearls of pediatrics is that in a child with a limp and knee pain, think hip pathology. A radiograph is usually sufficient to diagnosis Perthes disease. The femoral head is flattened, irregular, and sclerotic.

A magnetic resonance imaging (MRI) is helpful in staging the condition and determining treatment. The goal of treatment is to contain the soft, cartilaginous femoral head within the acetabulum until the blood supply returns, usually a 2- to 3-year process.

SCFE appears in the pre- to early adolescent period, usually around the ages of 9 to 13 years when children have a growth spurt. Like Perthes, the etiology of SCFE is a mystery, but many patients are obese and have sustained some type of trauma, either an acute episode or repetitive microtrauma. The patient presents with a limp and can complain of groin, hip, thigh, or knee pain. Examination discloses a shortened, externally rotated lower extremity with decreased internal rotation of the hip.

A radiograph can usually clinch the diagnosis. The hip has a "melted ice-cream cone" appearance, as though the femoral head has melted off the femoral neck.

Treatment for SCFE is operative with percutaneous, in situ screw fixation followed by 4 weeks of crutch-assisted ambulation.

AIS is a curvature of the spine in the coronal plane, usually first noticed in early adolescents. Roughly 80% of the patients are girls, and 80% of the curves have a convexity in the right thoracic area with a compensatory left lumbar curve. Small curves under 20 degrees are common (1% to 3%); clinically significant curves over 30 degrees have a prevalence of about 1 to 3 in 1,000. The most sensitive clinical examination for AIS is the Adams forward bend test where the child bends at the waist as to touch the toes. The examiner looks down the back for rib asymmetry or uses a scoliometer (basically a fancy level) to measure the angle of trunk rotation. A careful neurologic examination is important to rule out conditions such as syringomyelia, neurofibromatosis, or Friedreich ataxia.

Patients with clinically significant rib or trunk asymmetry should have a standing radiograph of the spine. The Cobb angle, automatically calculated on most digital radiographic systems, is used to quantify the scoliosis. An MRI may be obtained in suspected cases of neurologic involvement or in unusual curves such as left thoracic scoliosis or long C-type curves.

In general, patients with AIS and a Cobb angle less than 20 degrees are treated with observation, and the risk of scoliosis progression after menarche is minimal. Patients with curves measuring from 20 to 40 degrees are treated with a brace. Those with a curve greater than 40 degrees usually require surgery.

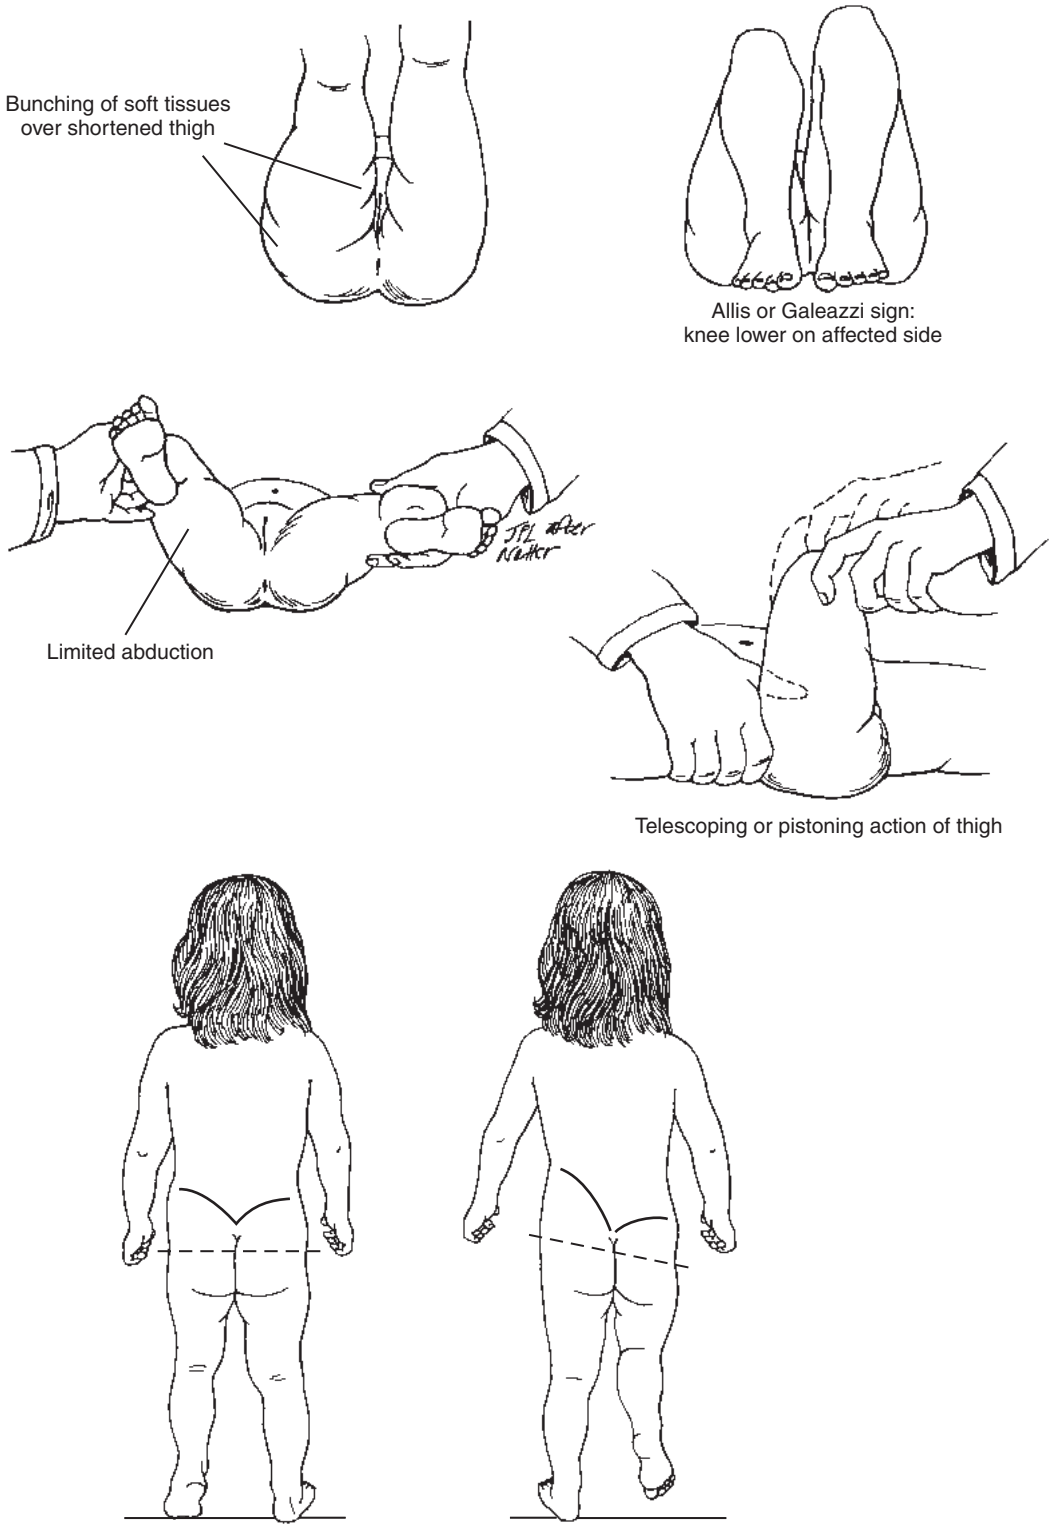

FIGURE 26-1. After about 4 months, the most sensitive test is limited hip abduction and uneven knees. Telescoping or pistoning of the thigh and Trendelenberg gait are late findings after the child has started to walk. Modified after illustrations by Frank K. Netter, MD, from Hensinger RN: *Ciba Clin Symp* 31:1. 1979. Copyright 1979, CIBA Pharmaceutical Company, Division of CIBA-GEIGY Corporation.

Infectious

The majority of bone and joint infections result from hematogenous seeding of bacteria into the joint synovium or into the sluggish juxtaepiphyseal circulation of the bone. **Septic arthritis** most often occurs in children younger than 5 years of age and in boys twice as often as in girls. Septic arthritis of the hip requires obligatory operative drainage, whereas infection of the ankle, knee, shoulder, and elbow can, at times, be managed with arthrocentesis and intravenous antibiotics. In general, **osteomyelitis** requires surgical drainage.

Patients present with a fever, malaise, and limp if it involves the lower extremity. The examination discloses resistance to movement and pain on passive range of motion. Patients have an elevated sedimentation rate, elevated C-reactive protein, and an elevated white blood cell (WBC) count with a shift to the left. Radiographs may show only soft tissue swelling, and an MRI, while not particularly cost-effective, discloses an effusion and periarticular edema, and in the case of osteomyelitis, intense bone marrow edema. It is important to obtain blood cultures and perform a joint aspiration before beginning intravenous antibiotic treatment.

Once all the cultures have been obtained, the patient may be started on intravenous antibiotics, usually a combination of drugs that includes coverage of *Staphylococcus aureus* as this microorganism causes 70% of the cases, although the age of the patient is important. The most common isolates from newborn infants are *S. aureus*, group B streptococcus, and gram-negative bacteria. Older infants are prone to *Hemophilus influenza* infections, and those over 5 years of age are prone to *S. aureus* infections.

Septic arthritis of the hip may be secondary to osteomyelitis of the proximal femur because the metaphysis of the proximal femur is located within the hip capsule.

Traumatic

The most common traumatic conditions are **sprains, strains, fractures,** and **overuse conditions**. It is important to understand the difference between a strain and a sprain and to be familiar with the Salter classification system for fractures involving the growth plate.

A **strain** is an injury to the muscle, the tendon, or its attachment to the bone. The most common strains involve the hamstrings, the hip adductors (groin), the Achilles tendon, and the rotator cuff of the shoulder. The most common site of failure is at the junction where the myofibers blend into the collagenous fibers of the tendon (the muscle tendon junction). The history and physical examination are usually sufficient to make the diagnosis. The child with a strain has sudden onset of pain, usually associated with sports activity. The site of injury is swollen and may have ecchymoses. On palpation, the patient has tenderness over the muscle or tendon, and the patient may be reluctant to move the extremity or to bear weight. Radiographs, while usually negative, are valuable to rule out physeal fractures. An MRI shows increased T2-weighted signal at the injury site, although this is not a cost-effective way to make the diagnosis.

Treatment can be summarized by the acronym **RICE** and **time**: R stands for rest; I for ice; C for compression; and E for elevation. Time means time away from sports activities, usually for 4 to 6 weeks followed by another 4 weeks of physical therapy rehabilitation before returning to sports. Ice is always preferable over heat. Ice compression packs applied to the injured area, 30 minutes on, 30 minutes off, decreases pain and swelling and speeds the healing process. (Frozen peas in a plastic bag make an excellent applicant.) Compression in the form of an elastic bandage speeds the removal of local hemorrhage and tissue edema, as does elevation. Nonsteroidal anti-inflammatory drugs (NSAIDs) should not be started for 2 to 3 days as they can increase bleeding into the tissues of a fresh injury. The child should undergo rehabilitation before reentry into sports. Physical therapy can be started after 2 to 3 weeks when the acute pain and swelling has subsided.

A **sprain** is an injury to a ligament. Ligaments are the collagenous structures that hold bones together at joints. Sprains are classified as follows: Grade I with tearing of a few fibers, mild swelling, and focal tenderness; Grade II with tearing of many fibers, considerable swelling, and pain, but mechanical stability; and Grade III with complete rupture and joint instability. The most common sprains in children involve the anterior talofibular ligament at the ankle and the medial collateral (MCL) and anterior curiae ligaments (ACL) at the knee. Ankle and MCL sprains are treated with RICE, rehabilitation, and gradual return to sports activity. Unfortunately, there is an epidemic of pediatric ACL injuries, and they require reconstructive surgery and extensive rehabilitation before a patient may return to sports.

Fractures in children are different from those in adults for three important reasons: (1) children's bones are less brittle and can fracture in a greenstick fashion; (2) children have great remodeling potential so fractures do not need to be perfectly aligned; and (3) damage to the growth plate (the physis) can result in later deformities.

The **Salter-Harris classification scheme** has withstood the test of time because it has prognostic value and implications for treatment. Type I fractures are nondisplaced separations through the physis. They have the best prognosis and require simple immobilization for 3 to 4 weeks. Type II fractures are displaced through the physis and exit out the metaphysis. Type II fractures have a good prognosis and usually require manipulative reduction and immobilization for 4 to 8 weeks. Type III fractures go through the physis and exit into the joint, and Type IV fractures begin in the joint, go across the growth plate, and exit out the metaphysis. Types III and IV fractures have a guarded prognosis and require accurate, operative reduction, and internal fixation to prevent growth deformity. Type V fractures are crush injuries to the physis, and they have the worse prognosis because the crush or compression at the time of injury kills physeal cells. There are no treatments that can regenerate these cells, and the inevitable deformities will need reconstructive treatment.

The most common fractures treated nonoperatively on an outpatient basis involve the clavicle, wrist, both bones of the forearm, tibia, and fibula. The most common fractures treated operatively involve the elbow, femur, ankle, and hip. Pediatric hip fractures are surgical emergencies due to the risk of avascular necrosis of the femoral head.

More than 30 million children and adolescents participate in recreational sports, often involving multiple sports with either practice or competition every day. This level of sports participation has contributed to a tremendous increase of **overuse conditions.** The most common overuse condition is **Osgood-Schlatter disease**, a failure in tension of the secondary ossification center of the knee. The condition is most common during the adolescent growth spurt in athletically active teens.

The patient with Osgood-Schlatter has swelling and focal pain to palpation of the tubercle. The remainder of the examination is normal. Radiographs are minimally helpful because the normal tubercle can have condensations and apparent fragmentation. The key to diagnosis is the clinical finding of swelling and pain directly over the tubercle.

Treatment of Osgood-Schlatter disease is absolute rest: no running, jumping, hiking, biking, sports, physical education, or backyard pick up games for 4 to 6 weeks. Once the tubercle is nontender, the child needs 4 to 6 weeks of physical therapy before reentry into sports to help prevent recurrence.

Physiologic

Rotation and angular conditions of the lower extremity are the most common musculoskeletal conditions students will encounter in the pediatric outpatient clinic. These include **metatarsus adducts** (MTA) of the feet, **internal tibial torsion** (ITT) of the legs, **genu varum** and **valgum** (bowed legs, knock knees) at the knee, **medial femoral torsion** (anteversion) at the hip, and the most common gait deviation, **in-toeing**. Most rotational and angular conditions, while of concern to anxious parents, fall within 2 standard deviations of normal and are considered physiologic variations. MTA appears from birth to 6 to 8 months, ITT and genu varum and valgum from 6 months to 3 years, and femoral anteversion and intoeing gait after 2 to 3 years. The best way to document and follow rotational and angular conditions is with the use of the **torsional profile**.

Metatarsus adductus is extremely common. The feet are shaped like a kidney bean with a concave medial border and a convex lateral border. A deep crease traverses the center of the foot from medial to lateral. The condition is often confused with clubfoot, but in MTA, the foot is flexible and the ankle motion is normal. An MTA is evaluated using the heel bisector method. Think of the infant's heel as an oval with an imaginary line that bisects the heel and extends past the toes. The normal heel bisector passes between the second and third toes. Mild MTA has a heel bisector to the third toe. Moderate MTA has a bisector to the fourth toe, and severe MTA is to and past the fifth toe. A **flatfoot**, or **valgus foot**, has a heel bisector toward the great toe.

Flexible metatarsus adductus resolves spontaneously, but rigid MTA needs stretching and possibly cast treatment.

For most cases, both MTA and ITT result from intrauterine packing of the fetus. ITT and bowing of the knees usually become a parental concern when the child is cruising or beginning to walk.

ITT is evaluated using the thigh foot axis. The child is placed prone on the examination table, and using either goniometer or eyeball estimation, the angle formed by lines through the long axis of the thigh and the long axis of the foot is determined. With a little practice, the student can estimate this angle as internal/external to within 10 degrees.

Treatment of ITT, as well as metatarsus adductus, usually involves what is called "orthopedic psychotherapy" (OP), a technique of reassurance. OP involves five easy-to-learn behavioral responses that are useful when dealing with a variety of conditions that will auto-resolve but are worrisome to parents. (1) First, attentively listen to the parent's concerns. Parents need to know that their doctor understands their concerns. (2) Next, verbally acknowledge their concern as in, "Yes, I see what you mean." (3) Educate the parents about the natural history

of the condition. (4) Get the parents actively involved in some form of intervention such as stretching, massage, or in the case of older children, activities that favor posture education such as gymnastics, ballet, or ice-skating. (5) Finally, offer a follow-up evaluation in 6 to 8 months. This simple, but useful set of interactions can alleviate parental concern in a cost-effective manner without ordering unnecessary radiographs or other diagnostic tests.

Using the tibiofemoral angle as a quantitative tool, Salenius and Vankka documented the pediatric angular history of the knees. Due to fetal packing, most infants have apparent bowing at birth. By the age of 1.5 to 2 years, the tibiofemoral angle is neutral. Around the age of 3 years, most children are in valgus, then gradually reduce the tibiofemoral angle to slight valgus by the early teens.

Abnormal knee **varus** or **valgus**, as in Blount disease or skeletal dysplasias, are rare compared to the frequency of physiologic variants. Many cases of "bowed knees" are actually ITT. The way to tell the difference is with the "cover-up" test. With the child supine and knees in extension, observe the apparent bowing at the knees. However, when the extremity is slightly internally rotated so the patella is in a neutral position and the examiner covers up the lower leg and foot, then the tibiofemoral angle at the knee is neutral and the bowing disappears. The child has ITT and not bowing of the knees. The cover-up test is a valuable way to demonstrate the true nature of the condition to the parents and easily leads into a discussion of the natural history of physiologic derotation with growth.

Femoral torsion is the relationship of the axis of the femoral neck to the transcondylar axis of the femur at the knee. Most adults have about 7 to 10 degrees of medial femoral torsion, but neonates have 30 to 40 degrees.

Increased medial femoral torsion (delayed physiologic derotation) is twice as common in girls as in boys. Children with increased medial femoral torsion prefer to sit in the "W" position and they walk with an in-toeing gait. Femoral torsion is evaluated with the child prone, the hips in extension, and the knees in flexion (Figure 26-2). The leg acts as an arm of a goniometer as the legs rotate outward (medial hip rotation) and

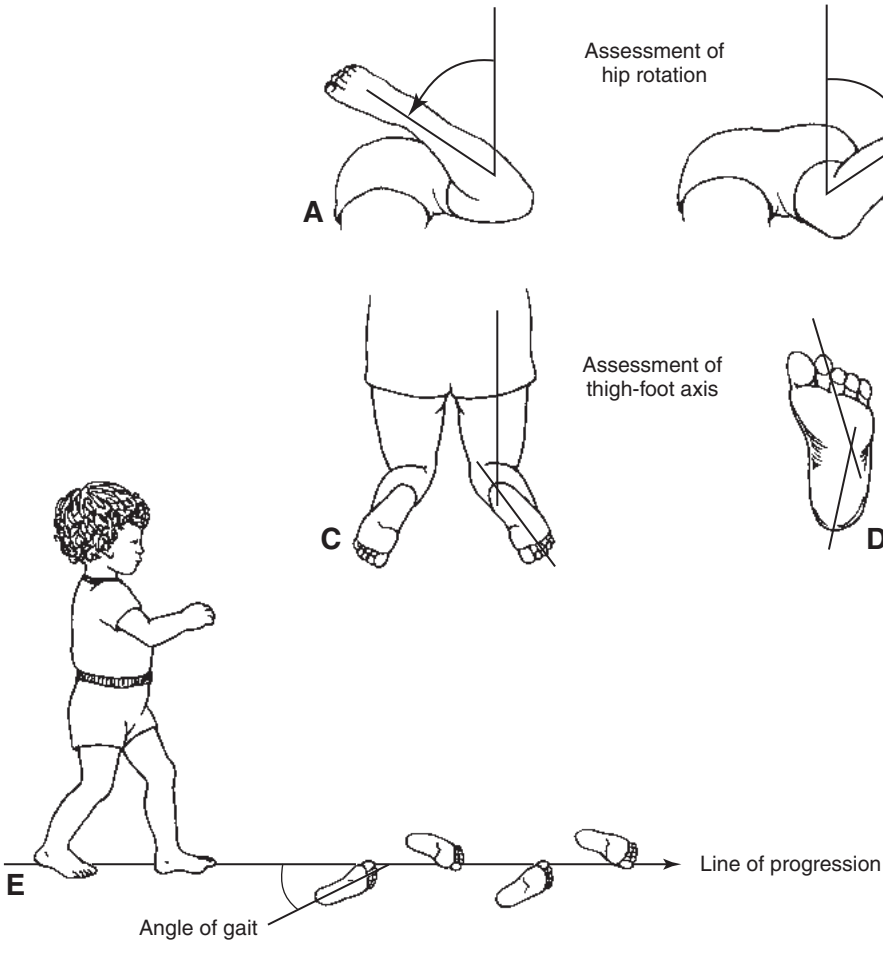

FIGURE 26-2. Evaluation of femoral torsion.

rotate inward (lateral hip rotation). The normal values have a wide range, although most children who sit in the "W" position have medial rotation greater than 75 degrees.

There is no scientific evidence that any form of treatment (shoes, orthotics, braces, or therapy) has any influence on the natural history that is a gradual resolution toward the adult levels during the preadolescent and adolescent growth spurts. The key to successful treatment, and the prevention of unnecessary shoes, braces, and radiographs, is successful communication in the form of OP, as mentioned previously. Consider telling parents to expect 1.5 to 2 degrees of correction per year, recommend activities such as ballet or gymnastics that involve gross motor skills, and offer annual follow-up to ensure gradual autocorrection.

The torsional profile is a compilation of these evaluations in the form of a chart. This profile can tell if a gait deviation is coming from the hips, knees, feet, or a combination thereof.

Children with musculoskeletal diseases represent a unique subgroup of patients with orthopedic concerns. It is important to understand the spectrum of orthopedic conditions and to appreciate the difference between normal variants and pathology as discussed in this section. The Suggested Readings at the end of this chapter are meant as a start to a better understanding.

OTORHINOLARYNGOLOGY

Gary Green and Alan G. Cheng

Pediatric otolaryngology is a diverse field that entails caring for pediatric patients with problems in the ear, nose, throat, and the head regions. This surgical specialty has grown tremendously in recent years because of advances in the management of numerous areas such as airway reconstruction, endoscopic sinus and skull base surgery, and rehabilitation, including cochlear implantation for the hearing impaired. The material included in this chapter is an overview of several common otolaryngologic problems that might be encountered in either an outpatient clinic or an inpatient setting. They are otitis media, obstructive sleep apnea, stridor, head and neck masses, hearing loss, and epistaxis. For those interested in a more in-depth discussion on any of these or other topics in otolaryngology, several excellent references are listed (see Suggested Readings).

OTITIS MEDIA

Otitis media is a major health problem in infants and children. It is one of the most common reasons for "sick visits" in pediatric offices, with 50% to 90% of children experiencing at least one episode within the first 2 years of life. One needs to be familiar with the various types of otitis media, their treatments, and possible complications: acute otitis media (AOM), recurrent otitis media, and otitis media with effusion (OME).

Acute Otitis Media

AOM is characterized by the rapid onset of symptoms that may include otalgia, fever, or irritability. The most common causes are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis*. History and pneumatic otoscopy are the key elements for diagnosing AOM. Bubbles, air-fluid levels, and otorrhea are obvious signs. Other signs on otoscopy that consistently predict infection include red color, decreased mobility, and bulging tympanic membrane position.

Pediatric Pearl: The light reflex is an inconsistent finding in AOM, and it should not be the sole basis for diagnosis.

Treatment of AOM includes antipyretics and analgesics as well as appropriate antibiotics such as amoxicillin or trimethoprim–sulfamethoxazole. Cefaclor and amoxicillin–clavulanate are appropriate in those children who fail to respond to initial therapy. A more in-depth approach to the topic of AOM can be found in Chapter 9.

Recurrent Otitis Media

Multiple bouts of AOM with resolution between episodes are called recurrent OM. The bacteriology of these infections is usually identical with that of AOM, although recurrence soon after a course of antibiotics may signify the presence of a resistant organism. Children who have frequent bouts of AOM in rapid succession should

be evaluated for underlying conditions that may predispose ones to ear infections (e.g., immunodeficiency, atopy, nasal obstruction, cleft palate, and immotile cilia syndrome).

If there is no evidence of the aforementioned abnormalities, the physician must next decide how to treat the recurrent infections. Two common methods are (1) antibiotic prophylaxis and (2) myringotomy and tube placement with or without adenoidectomy.

Prophylaxis is a once-daily dose of antibiotics throughout the entire respiratory infection season (frequently 3 months). Evaluation every 6 to 8 weeks for new-onset effusion or "breakthrough" AOM is appropriate. If either condition occurs, one should consider myringotomy and tube placement.

Myringotomy and insertion of tubes is one of the most common surgical procedures performed on children. This procedure effectively prevents the symptoms of AOM, although persistent otorrhea occurs in 5% to 15% of patients, a complication that is treated with oral or topical antibiotics. Other rarer complications include persistent tympanic membrane perforation, atrophic tympanic membrane, granuloma formation, tympanosclerosis, cholesteatoma, and ossicular disruption.

Adenoidectomy performed concurrently with myringotomy and tube placement remains controversial. Some studies appear to show that adenoidectomy decreases the frequency of OM. Moreover, the effect is independent of adenoid size, which suggests that the location of the adenoid and its reservoir of pathogenic bacteria are as important to the pathogenesis of OM as is physical obstruction of the eustachian tubes. Therefore, the decision for or against adenoidectomy should be individualized. Children with chronic upper airway obstruction or recurrent or chronic OME (see the following) after previous myringotomies with tube insertions may be good candidates for adenoidectomy.

Otitis Media with Effusion

Fifty percent of children with OME may be asymptomatic. Recent literature indicates that two-thirds of effusions contain bacteria, with one-half of these containing *H. influenzae, S. pneumoniae,* or *M. catarrhalis*. Physical examination may reveal a retracted or bulging tympanic membrane, which may be opacified or translucent, and fluid may be amber or bluish. There should be no history of ear pain, fever, or other symptoms suggesting an AOM.

OME is usually associated with an upper respiratory infection and resolves without treatment. Observation alone is recommended because this condition is often self-resolving. OME can cause mild-to-moderate conductive hearing loss. Studies examining the effects of OME on communication development indicate that OME may be associated with learning disorders, attention and auditory processing deficits, and deficits of higher order auditory processing (i.e., signal detection in background noise). However, opponents of these studies believe that while early deficits have been documented in some children, the long-term consequences are negligible.

Persistence of the effusion for longer than 2 months, frequent recurrences (i.e., OME for 4 of 6 months), changes in the tympanic membrane, or concurrent sensorineural hearing loss and speech delay should be taken into account when making treatment decisions. Recent guidelines support close observation and monitoring if OME is not associated with these problems, although many physicians begin with a trial of antibiotics. Even with unilateral hearing loss, the recommendation is expectant observation. However, with an effusion for 3 months or more and evidence of bilateral hearing loss, intervention is recommended; the most supported procedures are myringotomy and placement of tympanostomy tubes. Decongestants, antihistamines, and topical nasal corticosteroids may occasionally be beneficial.

Complications of Otitis Media

The complications of otitis media may be divided into two types: extracranial and intracranial (Table 26-1). Causes of complications are spread of infection beyond the air cells of the temporal bone or bony destruction. Factors that influence the spread of infection include the type and virulence of the infecting organism, antibiotics, host response, anatomic barriers, and drainage.

Signs of complications range from headache, seizures, and spiking fevers to vertigo, sudden hearing loss, facial palsy, and subperiosteal abscess. A child who is suspected to have such complications needs immediate evaluation by an otolaryngologist. Complications related to AOM typically require drainage (incision and drainage and/or myringotomy tube placement), surgical debridement (mastoidectomy) if bony destruction is present, and high-dose intravenous antibiotics. Consultation with neurosurgic and infectious disease specialists is indicated if intracranial complications are present.

TABLE 26-1

Complications of Otitis Media

Aural
Hearing loss (conductive and sensorineural)
Otorrhea
Tympanosclerosis (scarring of the tympanic membrane)
Acute and chronic tympanic membrane perforation
Chronic otomastoiditis
Cholesteatoma
Acute mastoiditis with bony destruction
Ossicular erosion
Labyrinthine erosion/labyrinthitis
Facial nerve paralysis
Intracranial
Meningitis
Lateral sinus thrombosis
Extradural abscess
Subdural abscess
Brain abscess

ADENOTONSILLITIS AND OBSTRUCTIVE SLEEP APNEA

The palatine tonsils are paired structures located along the lateral wall of the oropharynx, whereas the adenoids (pharyngeal tonsils) are found on the posterior–superior wall of the nasopharynx, in close proximity to the eustachian tubes and sinus ostia. Both are composed of lymphoid tissues that enlarge until puberty and then regress. Their immunologic function is complex; they appear to affect both local immunity (i.e., antibody production to specific bacteria) and systemic immune surveillance. However, there is no evidence that adenotonsillectomy adversely affects immune function.

The microbiology of the adenoids and tonsils is similar. Although group A β-hemolytic streptococcus is the organism most physicians associate with adenotonsillitis, *S. pneumoniae, S. aureus,* and *H. influenzae* as well as Epstein-Barr virus, herpes simplex virus, and various anaerobes may also play important roles.

The tonsils are easily visualized in the oropharynx. To evaluate their inferior extension, the clinician should use a tongue depressor. The degree of tonsillar enlargement should be graded on the basis of obstruction of the airway: 1 + (less than 25%), 2 + (25% to 50%), 3 + (51% to 75%), and 4 + (more than 75%). Erythema, exudate, tonsilloliths, or other abnormalities may also be present.

It is often difficult to visualize the adenoids without the use of special equipment (nasopharyngeal mirror or fiberoptic nasopharyngoscope). Therefore, the best methods to diagnose adenoid hypertrophy are by clinical history (nasal obstruction, snoring, mouth breathing) and physical examination (hyponasal speech, adenoid facies, and mouth breathing). An X-ray of the lateral neck is also a useful adjunct.

The drug of choice for treating adenotonsillitis is penicillin (clindamycin or erythromycin for allergic children), although antibiotics effective against β-lactamase-producing organisms may be warranted in resistant cases.

The indications and contraindications for adenotonsillectomy have been well-documented (Table 26-2). One common indication is recurrent infection. In one study, researchers demonstrated that tonsillectomy is effective at preventing recurrent tonsillitis–pharyngitis; however, this particular study required that children had at least seven episodes in 1 year, five episodes annually for 2 years, or three episodes annually for 3 years to

TABLE 26-2

Indications and Contraindications for Tonsillectomy and Adenoidectomy

Absolute Indications for Tonsillectomy
Obstructive sleep apnea
Recurrent acute or chronic tonsillitis
Tonsillitis resulting in febrile convulsions
Peritonsillar abscess
Tonsillar hypertrophy obstructing respiration or deglutition
Biopsy for pathologic diagnosis (e.g., lymphoma post-transplant lymphoproliferative disorder)
Absolute Indications for Adenoidectomy
Recurrent middle ear disease secondary to eustachian tube obstruction
Adenoid hypertrophy obstructing respiration
Sinusitis or its complications secondary to adenoid obstruction of the posterior sinus ostia
Relative Indications for Tonsillectomy and Adenoidectomy
Recurrent sore throats
Recurrent or chronic rhinitis
Recurrent upper respiratory infections
Snoring or mouth breathing
Failure to thrive
Large tonsils or tonsillar debris
Cervical lymphadenopathy
Tuberculous adenitis
Systemic diseases secondary to streptococcal infections (e.g., rheumatic fever, rheumatic heart disease, nephritis)
Contraindications to Tonsillectomy and Adenoidectomy
Blood dyscrasias (e.g., leukemias, purpuras, aplastic anemias, hemophilia)
Uncontrolled systemic diseases (e.g., diabetes, heart disease, seizure disorders)

be in the study. One should not use these criteria dogmatically, but should consider surgical intervention when these infections have a significant effect on the everyday functioning of the child (i.e., missing a significant amount of school or work because of illness). Guidelines shared by the American Medical Association (AMA) and the American Academy of Pediatrics (AAP) recommend tonsillectomy for children with four or more documented episodes of pharyngitis annually.

Obstructive sleep apnea disturbs a patient's rest and can present as loud snoring, periods of apnea, restlessness, enuresis, daytime fatigue, and difficulty with concentrating. It is another common indication for surgery.

Pediatric Pearl: Children with obstructive sleep apnea may initially present with complaints of daytime sleepiness, lack of energy, and poor school performance. Careful questioning uncovers a history of loud snoring and restless sleeping.

Rare complications of untreated, severe sleep apnea include cor pulmonale and failure to thrive. The diagnosis may be made by recording the individual during sleep and listening for apneic episodes or, more accurately, by a sleep study that records the frequency of apneic and hypopneic episodes.

The most common complications of adenotonsillectomy are pain and bleeding. Postoperative bleeding may occur within the first 24 hours or between the 5th and 10th postoperative day. Less common complications include hypernasal speech (encountered in children with undiagnosed submucous cleft palate or after laceration of the soft palate) and tongue or tooth trauma.

STRIDOR

Stridor, a harsh noise caused by turbulent flow of air through a partially obstructed airway, is one of many physical signs diagnostic of airway compromise. It is a high-pitched sound that can be audible during the inspiratory phase, expiratory phase, or both (biphasic). The differential diagnosis of noisy breathing can be extensive (Table 26-3), but stridor is usually caused by narrowing at the level of the larynx or trachea. Classically, inspiratory stridor is caused by an obstruction above the level of the vocal cords, biphasic at or immediately below the level of the vocal cords (subglottis), and expiratory more distal along the tracheobronchial tree.

Pediatric Pearl: Epiglottitis is a medical emergency that requires prompt attention by a physician capable of securing the airway by either intubation or tracheotomy. If the diagnosis is suspected, direct visualization of the larynx is usually performed in the operating room.

A detailed history and careful physical examination are more important in identifying the cause of stridor than radiographic and laboratory tests. Attention should be paid to the timing of the stridor (see previous), position that worsens

TABLE 26-3

Differential Diagnosis of Airway Obstruction

Upper Airway
Choanal atresia
Pharyngeal mass
Large tonsils and adenoids
Macroglossia
Craniofacial anomalies
Larynx
Laryngomalacia
Vocal cord paralysis
Supraglottic/glottic masses/cyst (e.g., hemangioma, papilloma)
Subglottic stenosis
Infectious process (e.g., croup, epiglottitis)
Lower Airway
Tracheomalacia
Tracheal stenosis
Aspirated foreign body
Tracheoesophageal fistula
External compression (e.g., vascular ring)

the stridor (supine versus upright), and if there are associated feeding difficulties. It should be determined if a patient is acutely ill and in need of airway protection (e.g., epiglottitis, bronchial foreign body) or not. For the latter, a bedside fiberoptic scope examination by an otolaryngologist can yield useful information on the nasal, oral, and laryngeal anatomy and often etiology of the stridor. The following describes several commonly encountered causes of stridor.

Laryngomalacia is a narrowing of the soft tissue and cartilaginous structures above the vocal cords (arytenoids and epiglottis), leading to a dynamic collapse during inspiration. The typical presentation begins in 1- to 6-month-old children with inspiratory stridor that worsens in a supine position and during feeding. Diagnosis is by history and fiberoptic laryngoscopy. Because it is often associated with gastroesophageal reflux, the first-line treatment is antireflux medication. Surgical intervention is reserved for those who continue to have failure to thrive despite medical treatment.

Croup, also known as laryngotracheobronchitis, is often caused by the parainfluenza virus. The swelling caused by this infection leads to narrowing of the larynx and trachea, and thus, the associated stridor (usually inspiratory). The onset of symptoms is often abrupt and the patient has a classic barking cough. History is often sufficient for making this diagnosis. Treatment with humidified air and steroids is often effective; racemic epinephrine may be used in more severe cases.

Vocal cord paresis/paralysis involves weakness or paralysis of one or both vocal cords, causing the airway to narrow and leading to the production of stridor, typically biphasic. Since the vocal cords also function to protect one from aspirating liquid and food contents, an immobile vocal cord(s) can also lead to symptoms of aspiration such as choking or recurrent pneumonia. While there are many causes of vocal cord paresis/paralysis, its diagnosis can be arrived by history; physical examination with special attention to the volume, quality, and range of the patient's voice/cry; and fiberoptic laryngoscopy.

Subglottic stenosis is a narrowing of the trachea immediately below the vocal cords. Because this is the narrowest portion of the airway in neonates and infants, additional narrowing leads not only to biphasic stridor, but also to symptomatic airway compromise. Known risk factors of subglottic stenosis include traumatic or prolonged intubation, Down syndrome, and Wegener granulomatosis. Although patient history, physical examination, and fiberoptic laryngoscopy are helpful especially with ruling out other causes of stridor, bronchoscopy under anesthesia is necessary for diagnosis and determining the degree of stenosis. Several factors including the severity of stenosis dictate treatment, which ranges from observation to laryngotracheal reconstruction and tracheostomy.

PEDIATRIC HEAD AND NECK MASSES

Head and neck masses are frequent and can be divided into three main categories: congenital, infectious, and neoplastic. Among congenital masses, common diagnoses include branchial cleft cysts, lymphatic malformations, teratomas/dermoid cysts, and thyroglossal duct cysts. Infectious masses may be caused by bacterial or viral lymphadenitis, systemic bacterial or viral infections such as cat scratch disease and mononucleosis, and mycobacterial collections involving *Mycobacterium tuberculosis* and atypical Mycobacteria. Although less common, the concern for a neoplastic process often prompts evaluation. Possible neoplastic diagnoses include lymphoma, thyroid cancer, rhabdomyosarcoma, hemangioma, and less commonly, tumors of the salivary glands and metastatic cancer.

When evaluating a child with a head and neck mass, one needs to pay attention to the history: the age of onset, duration, change over time, and whether the mass is painful and associated with systemic signs (e.g., fever, weight loss, night sweats). Recent illnesses or life events can sometimes provide important clues: upper respiratory infection (lymphadenitis), exposure to animals (cat scratch disease), trauma (hematoma), and recent travel (tuberculosis). History of immunodeficiency and personal/family history of malignancy are also crucial to elicit.

A physical exam of the mass should reveal the location, size, and quality (soft/firm/hard, mobile/nonmobile, tender/nontender, fluctuant/nonfluctuant, solitary/multiple). When lymphadenopathy (generally bigger than 1 cm) is present, the extent should be determined (single, regional, systemic, unilateral/bilateral) by palpating cervical, auricular, clavicular, axillary, and inguinal regions. The surrounding skin should be evaluated for erythema, blanching, discharge, communication, induration, and necrosis. In general, lymph nodes that are firm or fixed; larger than 1 cm; and persist for more than 2 weeks, especially supraclavicular nodes, are concerning for malignancy. When such information is nonconclusive, imaging studies such as ultrasound, computed tomography (CT) scan, or MRI can often be complementary.

Described as follows are characteristics of two commonly seen congenital head and neck masses: branchial cleft cysts and thyroglossal duct cysts. Additional etiologies are included in Table 26-4.

Branchial cleft abnormalities range between cysts, sinuses, and fistulas. They are congenital, but may not be noted until later in life or after an antecedent upper respiratory infection when they become infected. On physical exam, they are typically located in the lateral neck, anterior to the sternocleidomastoid muscle. The diagnosis

TABLE 26-4

Common Etiologies of Pediatrics Head and Neck Masses

Congenital
Branchial cleft cyst

Hematoma
Thyroid hyperplasia
Parathyroid hyperplasia
Granulomatous disease
Kawasaki disease

is often supported by an ultrasound or CT scan with contrast. Although this anomaly most often originates from the second branchial arch, those associated with the first, third, or fourth branchial arches also exist. Surgical excision of branchial cleft abnormalities is the treatment of choice because of the high risk of infection.

Unlike branchial cleft anomalies, **thyroglossal duct cysts** are midline masses. They develop from incomplete involution of the thyroglossal duct and may therefore be located anywhere from the foramen cecum at the base of the tongue down to the lower midline neck. Because of their connection to the tongue and the hyoid bone, these masses elevate with tongue protrusion and swallowing. Like branchial cleft anomalies, these may be secondarily infected, but have the additional, though rare, potential for malignant transformation. Diagnosis is primarily based on physical examination and imaging studies such as ultrasound and CT scan. Treatment is surgical excision of both the cyst and its associated tract in the hyoid bone.

HEARING LOSS

Congenital hearing loss affects 1 to 2 per 1,000 children. Universal newborn screening for hearing loss has resulted in considerably earlier diagnosis and intervention. Current recommendations are for universal screening

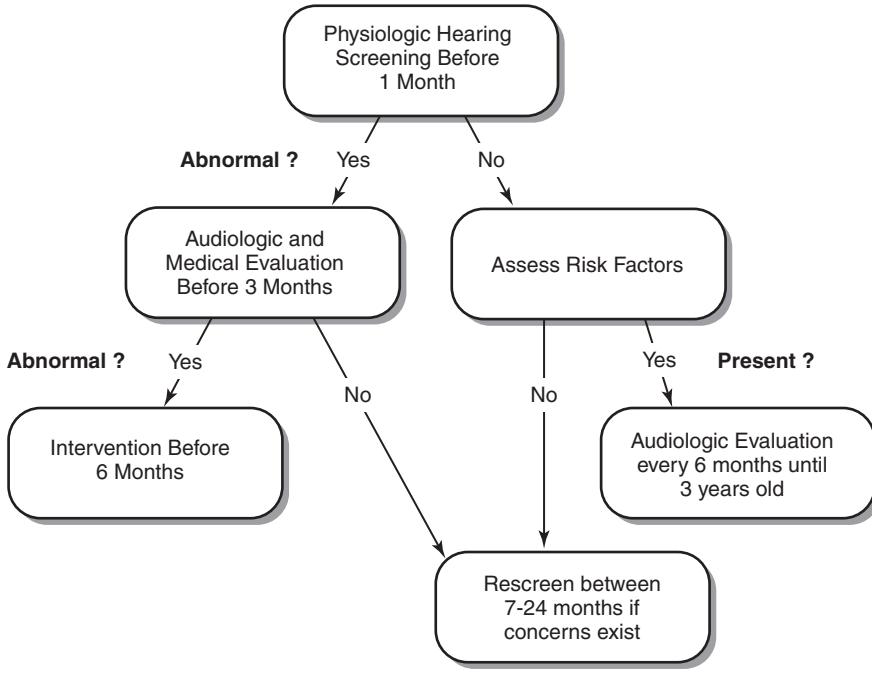

FIGURE 26-3. Screening and diagnosis of pediatric hearing loss.

before 1 month of age (usually before leaving the hospital after birth) (Figure 26-3). Suggested initial testing includes either auditory brainstem responses or otoacoustic emissions, which are relatively inexpensive, simple, and validated techniques. Abnormal tests are followed up by further audiologic evaluation by 3 months of age. Periodic hearing screening should be done for children aged 4 to 11 months with a follow-up formal audiology if necessary.

Hearing loss is categorized as conductive (defects in the transmission of sound from outer or middle ear to the inner ear), sensorineural (defects in the cochlea and inner ear, auditory nerves, or central processing), or mixed. The vast majority of congenital hearing loss is sensorineural. A careful history should screen for known risk factors including low birth weight (under 1,500 g), Apgar scores of less than 4 at 1 minute or less than 6 at 5 minutes, neonatal intensive care unit admission, severe hyperbilirubinemia, infection, use of ototoxic medications, and family history of hearing loss. A physical exam should focus on the face (e.g., craniofacial deformities, malformations, presence of albinism, or forelocks) and ear (e.g., pinna deformities, pits), otoscopy for the external canal and tympanic membrane, musculoskeletal examination (e.g., deformities, strength), and skin (e.g., café au lait spots, neurofibromas, depigmentation). Concordant workup for underlying cause, guided by history and exam, may include assays for TORCH antibody (toxoplasma; other infections: VDRL/FTA-ABS [Venereal Disease Research Laboratory/fluorescence treponemal antibody absorption] for syphilis, rubella; cytomegalovirus [CMV]; herpes simplex virus), electrocardiogram (ECG) for syndromes accompanied by cardiovascular dysfunction, CT scan for aplasia of inner ear, and an ophthalmologic evaluation for possible concurrent visual impairment.

The most common cause of prenatal hearing loss is maternal-fetal transmission of intrauterine infection (TORCH complex). In fact, CMV is the leading infectious cause of congenial sensorineural hearing loss. Other perinatal causes include hypoxic ischemic encephalopathy, hyperbilirubinemia, infection, and ototoxic medications. When these risk factors are absent, genetic causes are likely and are divided in nonsyndromic and syndromic groups. Nonsyndromic causes are the most common, with mutation at the connexin 26 (a gap junction protein) loci being the leading cause. Inheritance is autosomal recessive and genetic testing for this gene is often recommended. The next most common genetic mutation is that of pendrin, which can occur as a syndromic or nonsyndromic form. Since its mutation is linked to problems with tyrosine iodination, it can lead to goiters and hypothyroidism. Hearing loss in association with prolongation of the QT interval on ECG (Jervell and Lange-Nielsen syndrome) is due to a mutation in either the *KCNE1* or *KCNQ1* potassium channel gene. Other less common causes of inherited, syndromic hearing loss have been described and are listed in Table 26-5.

TABLE 26-5

Hearing Loss Syndromes

Usher Syndrome
Inheritance: Autosomal recessive
Associations: Sensorineural hearing loss, vestibular dysfunction, retinitis pigmentosum, cataracts, mental retardation
Diagnosis: History and physical, electroretinography, hearing testing, genetic testing
Pendred Syndrome
Inheritance: Autosomal recessive
Associations: Sensorineural hearing loss, multinodular goiter
Diagnosis: History and physical, thyroid panel, perchlorate testing, genetic testing
Waardenberg Syndrome
Inheritance: Autosomal dominant
Associations: Sensorineural hearing loss, vestibular problems, craniofacial defects, abnormal pigmentation (skin depigmentation, white forelock, dystopia canthorum)
Diagnosis: History and physical and genetic testing
Treacher Collins Syndrome
Inheritance: Autosomal dominant
Associations: Conductive hearing loss (auricular deformation, atretic/stenosed external acoustic canal, ossicular anomalies, ossification of the tympanic membrane), sensorineural hearing loss, or mixed, mandibulofacial deformities
Diagnosis: History and physical, genetic testing
Apert Syndrome
Inheritance: Autosomal dominant
Associations: Conductive hearing loss (stapes fixation), craniofacial deformities, syndactyly
Diagnosis: History and physical
Neurofibromatosis
Inheritance: Autosomal dominant
Associations: Conductive hearing loss, vestibular dysfunction, and facial paralysis due to acoustic neuromas, optic gliomas, iris hamartomas, peripheral neurofibromas, café au lait spots
Diagnosis: History and physical, CT of temporal bones
Alport Syndrome
Inheritance: X-linked
Associations: Sensorineural hearing loss, glomerulonephritis (hematuria, proteinuria, uremia), cataracts
Diagnosis: History and physical, urinalysis, serum BUN and Cr

CT, computed tomorgraphy; *BUN*, blood urea nitrogen; *Cr*, creatinine.

Pediatric Pearl: Hearing loss predisposes one to speech and language delay. Early diagnosis and intervention with hearing aids and/or cochlear implantation are therefore critical.

For hearing loss presenting later in life, history should focus on comorbid disease (neurologic, cardiovascular, renal, hematologic), predisposing infections (recurrent AOM, otitis externa, meningitis), previous surgery, head and neck trauma (**tympanic membrane** [TM] perforation, barotrauma, volume trauma), ototoxic medications (aminoglycosides, loop diuretics, chemotherapeutics), and developmental milestones (motor, social, and linguistic), as well as associated symptoms such as dizziness, vertigo, gait abnormalities, visual changes, and seizures. Physical examination should concentrate on hearing testing (Weber and Rinne tests) and otoscopy (AOM, otitis externa, immobility/hypermobility of TM). There are numerous causes of temporary, acquired hearing loss in children (cerumen, AOM, otitis externa). One should remember that causes of congenital hearing loss may also be applicable here because the signs and symptoms of hearing loss may not become apparent until later in life. For children over 3 years of age, conventional hearing testing may be applied.

Treatment should aim to restore optimal hearing as early as possible to preserve and promote speech and language function. Earlier intervention has been proven to improve language development. Current recommendations suggest that all infants with demonstrated hearing loss on follow-up assessment by 3 months should have personalized intervention started by 6 months of age. Certain conductive hearing deficits may be amenable to surgery (recurrent otitis media treated with tympanostomy tubes, stapes fixation for otosclerosis, removal of cholesteatoma, and so on). Hearing loss due to infection should be treated with antibiotics or antivirals aimed at the causative agent, with possible steroid use (dexamethasone) to reduce inflammation around the vestibulocochlear nerve. For most other conditions, treatment relies on early use of hearing amplification (hearing aids, assistive listening devices), ideally by 6 months, combined with speech and language counseling. Bilateral, severe or profound sensorineural hearing loss refractory to hearing aids for 6 months may be treated with **cochlear implants**. As in all cases, this should be done in discussion with family preference, with the knowledge that cochlear implantation before the age of 4 years significantly augments speech and language development. Incorporating school and education agencies into a multidisciplinary team with audiologists, otorhinolaryngologists, and speech pathologists provides comprehensive treatment.

EPISTAXIS

Epistaxis is a common complaint in the pediatric population. This condition, which is typically a self-limited process caused by a mild mucosal abrasion, may be the first sign of a more serious underlying disease.

The nasal cavity receives blood from the internal and external carotid artery systems. The most common (90%) bleeding site, called the Kiesselbach plexus or Little's area, is located along the anterior septum and corresponds to the convergence and anastomosis of arteries from both systems. However, bleeding sites may be located in any part of the nasal cavity.

The **initial intervention for epistaxis** should consist of **digital pressure** applied to the nares for 10 minutes. In the majority of cases, this maneuver is sufficient. Bleeding that cannot be controlled with pressure may require the application of topical vasoconstrictors (Neo-Synephrine 0.25%), evacuation of clot from the nasal cavity, cautery (silver nitrate), or packing with a self-expanding nasal tampon. An experienced physician may choose to place a vaseline nasal pack or pack the nasopharynx for improved hemostasis.

After the bleeding has been controlled, the physician should obtain a careful history, keeping in mind the differential diagnosis of epistaxis (Table 26-6). The duration of the epistaxis, previous episodes, and their frequency of occurrence as well as easy bruisability, any history of nasal trauma (including picking), nasal drug abuse, or recent upper respiratory infections are all pertinent, as is a family history of bleeding disorders.

Prior to discharge, the clinician must address the underlying cause of the epistaxis. Humidification of the home environment is important. Normal saline sprays and Vaseline ointment help prevent crusting and moisten the mucosa. It is crucial to advise patients against nose picking.

Severe bleeding may rarely require surgical ligation of the internal maxillary, anterior ethmoid, or posterior ethmoid artery, or embolization via selective artery catheterization. Children with severe epistaxis require hospitalization for observation. Those with severe or recurrent epistaxis require a more thorough medical workup to ensure that epistaxis is not a sign of an underlying illness.

TABLE 26-6

Etiology of Epistaxis in Children

Common Causes
Inflammation Upper respiratory tract infections Autoimmune disease (e.g., Wegener granulomatosis) Rheumatic fever
Trauma Dry air Injury, external, with or without fracture Patient induced (nose picking) Foreign body
Allergic rhinitis with or without accompanying inflammation
Uncommon Causes
Alterations of intravascular factors of hemostasis
Platelet abnormalities (e.g., idiopathic thrombocytopenic purpura) Coagulation defects (e.g., hemophilia)
Hypertension
Neoplasms

UROLOGY

Lane S. Palmer and Lisa Menasse-Palmer

TESTICULAR TORSION

Testicular torsion is the most common cause of acute scrotal pain and swelling in children and affects 1 in 4,000 males. When promptly diagnosed, the best chance of testicular salvage occurs within 8 hours of the event. Torsion may occur prenatally and manifest itself as a nontender scrotal mass at birth or may present anytime through puberty as a surgical emergency.

Pathophysiology

Torsion of the testes may occur above the investment of the tunica vaginalis that surrounds the testicle (extravaginal torsion); this is commonly seen in the perinatal period (Figure 26-4A). Intravaginal testicular torsion is more common in older children and adolescents and occurs when the testicle twists within the tunica vaginalis. The predisposing anatomic abnormality in this variant is the "bell-clapper deformity," where the tunica vaginalis has a high insertion onto the spermatic cord (see Figure 26-4B). In either type, twisting initially impedes venous return, resulting in venous thrombosis; subsequently, arterial blood flow is compromised, leading to ischemic necrosis. Unless spontaneous correction or surgical reduction occurs, infarction will lead to testicular atrophy.

The immediate inciting event leading to testicular torsion is poorly understood. Some factors that have been proposed include cremaster muscle hyperactivity, scrotal trauma, changes accompanying puberty including hormonal (rising testosterone) or anatomic (increased testicular volume) maturations, and vigorous exercise.

Clinical and Laboratory Evaluation

Testicular torsion typically presents as acute onset of pain that may gradually increase in intensity. The pain is usually localized to the affected testes and scrotum, but may be referred to the inguinal region or lower abdomen.

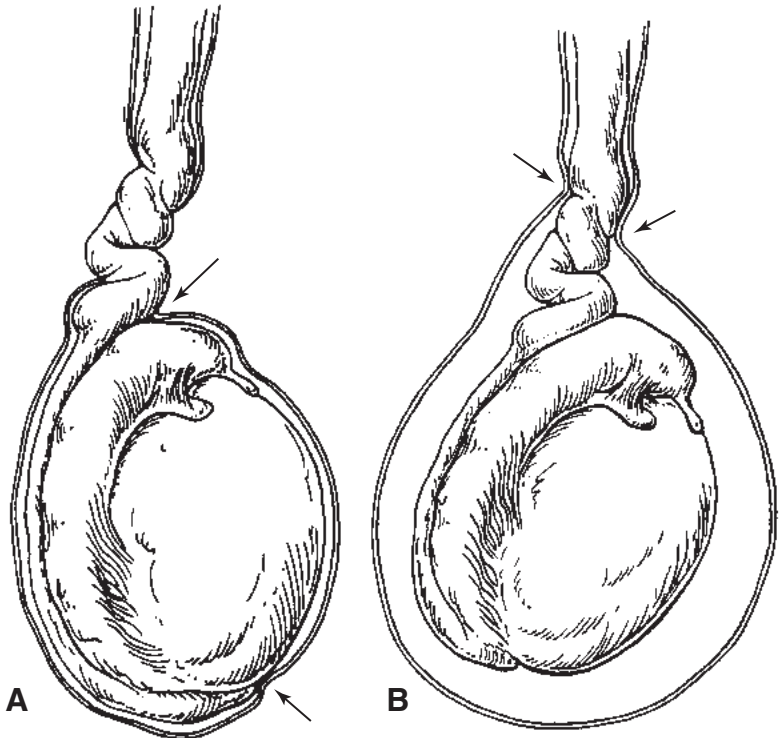

FIGURE 26-4. Anatomic relationship between the testis and tunica vaginalis in extravaginal (A) and intravaginal (B) torsion. From Gosalbez R Jr, Woodward JR: Testicular torsion calls for urgent intervention. *Contemp Urol* 4(8):76–84, 1992. Copyright Medical Economics Publishing.

Previous episodes of transient pain with or without swelling of this type may suggest intermittent testicular torsion. Nausea, vomiting, and anorexia often occur. Fever is a very uncommon sign and, if present, is usually low grade.

Physical examination reveals an exquisitely tender testicle. The testicle may ride high or lie transversely in the scrotum and the cremasteric reflex is reliably absent. Prehn sign, relief of pain by elevation of the testicle, is not dependable. Scrotal erythema and edema as well as a reactive hydrocele may be found as the ischemic process proceeds. "Knots" in the spermatic cord may be palpable above the testicle.

Laboratory data demonstrate a normal or only modestly elevated WBC count. Urinalysis is usually normal, although the presence of WBCs does not exclude the diagnosis of testicular torsion. If the clinical diagnosis remains in doubt, a technetium-99m pertechnetate scan to evaluate testicular blood flow can assist in making a diagnosis. Decreased blood flow to the testicle results in an area of decreased radioactive activity or a "cold spot" on the scan. A long-standing torsion or missed torsion manifests as a hyperemic rim surrounding the cold spot. Scrotal ultrasonography with duplex Doppler will also display absent flow to the twisted testicle, is often easier to obtain, but is more operator dependent than a radionuclide study. If the diagnosis of testicular torsion is clinically in question, radiologic studies should be initiated only if they would not delay surgical intervention more than 6 hours after the onset of symptoms.

Differential Diagnosis

The acute pain and swelling found in testicular torsion can be attributed to several conditions, including testicular torsion, acute epididymitis or orchitis, incarcerated hernia, torsion of a testicular appendage, and acute hydrocele (Table 26-7). Briefly, an infectious process of the testicle or epididymis may be associated with dysuria, urinary frequency and urgency, urethral discharge, pyuria and bacteria on urinalysis, and increased flow on nuclear scan and Doppler ultrasound. Hernias are palpable, and incarceration may be associated with bilious vomiting and abdominal pain. The appendix testes and appendix epididymis, Müllerian and Wolffian duct remnants, respectively, may twist and are palpable as focally tender areas at the upper pole of the testes or head of the epididymis. An ischemic appendix testes may appear as a "blue dot" visible through the scrotal skin; radionuclide scans and ultrasounds are normal or demonstrate increased flow.

TABLE 26-7

Differential Diagnosis of Acute Scrotal Pain and Swelling

	Incarcerated Hernia	*Torsion of the Testes*	*Acute Hydrocele*	*Inguinal Lymphadenitis*	*Torsion of the Appendix Testes*	*Acute Epididymitis*
Age	Infancy	Preadolescence	Infancy	Any	Preadolescence; younger than torsion of testes	Adolescence; if infant, anatomic anomaly likely
Onset of Pain	Sudden, severe; increases when testes lifted	Sudden, severe	Gradual; may be painless	Gradual, mild	Sudden, moderate; localized to one pole "blue dot"	Gradual, may become severe; early on, limited to epididymis and cord
Groin Swelling	Yes	No	Maybe (hydrocele of cord)	Below inguinal ligament	No	No
Overlying Redness	Yes	Yes	No	Yes	Yes	Yes
History	Prematurity; hernia noted on prior examinations	Trauma to scrotum; cryptorchidism	None	Lower extremity infection	Trauma to scrotum	Urologic instrumentation; catheterization
Mobility of Mass	Fixed at groin	Movement increases pain	Yes, mobile	Fixed below inguinal ligament	Fixed on testes	Relief of pain when lifted
Transillumination	Sometimes	No	Yes	No	No	No
Associated Features	Intestine palpable at internal ring on rectal examination; bowel obstruction; bilious vomiting	Testes lies transverse, high in scrotum; right lower quadrant pain, GI symptoms, fever, leukocytosis may mimic appendicitis	Internal ring normal on rectal examination; canal empty above mass	Canal, testes, and scrotum normal	Canal normal; "blue dot" at superior pole	Associated urethritis leads to dysuria, pyuria, and urgency
Management	Early reduction, surgical repair in 1–2 days; immediate surgery if unable to reduce	Immediate surgery, including contralateral exploration and fixation	Nonoperative; hydrocelectomy if persists after 2 years of age	Antibiotics	Symptomatic; excision if scrotum is explored	Antibiotics

GI, gastrointestinal.

From Nakayama DK, Rowe MI: Inguinal hernia and the acute scrotum in infants and children. *Pediatr Rev* 11(3):90, 1989.

Management

Testicular torsion is a surgical emergency. Prompt, accurate diagnosis is imperative for surgical salvage of the testicle. The best testes survival is obtained when orchidopexy is performed within 8 hours of the onset of symptoms; only about 10% of twisted testicles are spared orchiectomy if surgery is performed after 24 hours. Irrespective of the fate of the twisted testicle, orchidopexy is performed on the contralateral testes to prevent its torsion. Manual detorsion with sedation as an emergent temporizing measure may be attempted; however, if it is successful, elective bilateral orchidopexy is indicated as acute retorsion may occur.

PHIMOSIS

Problems related to the foreskin (prepuce) occur commonly in ambulatory pediatric settings. At birth, the prepuce normally obscures the glans and meatus (physiologic phimosis) and can be retracted in 4% of boys. By 6 months of age, 20% of boys have a fully retractable foreskin; the number increases to 50% by 1 year of age and to 90% by 3 years of age.

Pathophysiology

Phimosis is defined as nonretractability of a previously retractable foreskin. Smegma and skin oil production allow for the natural separation of the prepuce from the glans. Injury from forcible retraction of the prepuce and local infection from poor hygiene are the most common causes of true phimosis. These processes lead to scarring of the preputial ring and eventual fibrosis. The trapped penis implies the retraction of the glans and the closure of the circumcised skin over the glans.

Clinical and Laboratory Evaluation

In some boys with phimosis, urine will distend the prepuce causing a "ballooning" during voiding. The presence of linear scars can be seen if there has been traumatic retraction of the prepuce. Areas with entrapped smegma can often be seen under the surface of the skin and be confused for cysts. Similarly, the extrusion of smegma from under the prepuce is often seen with any degree of preputial retraction; this white-yellow material is often confused for an infectious discharge. Smegma is a cheesy, solid material and not liquid, as seen with infection. In contrast, infection associated with phimosis (**posthitis**) often presents as preputial edema, erythema, and tenderness.

Management

Physiologic phimosis should be treated expectantly. A foreskin that has never been retracted and is not inflamed, infected, or scarred requires no treatment. Although some physicians believe that forcible retraction of the foreskin is important for satisfactory hygiene, this often causes significant pain, fright, skin cracking, bleeding, and ultimately, scarring. When there is an indication for treatment of phimosis, the options include a course of topical steroids and manual retraction, which is effective in over 80% of patients when properly performed. Circumcision after the newborn period is a surgical procedure performed under general anesthesia. The prepuce is removed and sutures are used to reapproximate the skin. The most common complications of circumcision include bleeding and resulting skin abnormalities (excess, asymmetry).

PARAPHIMOSIS

Pathophysiology

Paraphimosis is the inability to place the foreskin in its natural position following retraction. A preputial ring can act as a tourniquet, resulting in venous congestion and edema of the glans and foreskin. Enlargement of the glans worsens the paraphimosis and may progress to arterial occlusion. Necrosis and gangrene may develop if the process continues.

Clinical and Laboratory Evaluation

Paraphimosis appears as a grossly edematous prepuce located proximal to the glans. A tight ring of skin is noticeable at the base of the edematous prepuce and glans. Impingement on the urethra may interfere with the urinary stream or cause urinary retention in the extreme case.

Management

Treatment of paraphimosis involves firmly grasping the glans to reduce the edema followed by manual replacement of the prepuce over the glans. If this fails, an incision of the constricting preputial ring is essential, if necessary, with a dorsal slit. After reduction, application of ice and the administration of oral antibiotics may help. A secondary circumcision can be performed after the inflammation abates.

POSTHITIS/BALANITIS

Pathophysiology

Posthitis and **balanitis** refer to inflammation of the prepuce and glans; accompanying cellulitis may or may not be present. In uncircumcised boys, they may occur secondary to phimosis or may result in phimosis following the inflammatory process. In circumcised boys, contact dermatitis from urine or soap may induce balanitis.

Clinical and Laboratory Evaluation

The penis appears erythematous, swollen, warm, and tender at the glans (balanitis) or prepuce (posthitis). If the infection affects the urethral meatus, a secondary meatitis may result. Children may complain of dysuria and voluntarily refrain from voiding because the urine makes contact with the inflamed area. A purulent discharge may exude from under the prepuce. Fever is uncommon.

Management

Medical management is appropriate. In the majority of cases, warm sitz baths and topical antibiotics are satisfactory. Management should include oral antibiotics to treat a cellulitis. A dorsal slit (incision of the dorsal aspect of the prepuce) can assist with drainage of the purulent material. Circumcision can be performed electively after the inflammation has subsided.

HYPOSPADIAS

Hypospadias is the congenital displacement of the urethral meatus ventrally on the penis. The incidence of this common anomaly is 1 in 300 boys and is often associated with chordee (fibrous tissue that creates an abnormal ventral penile curvature). The urethral meatus may be located anywhere from the distal glans to the penoscrotal junction and perineum. Fifty percent to 70% of hypospadias are located anteriorly on the glans, corona, or distal penile shaft (Figure 26-5). The etiology of hypospadias is unknown, but may be multifactorial; there is a familial risk of 8% to 14% if fathers or brothers are affected.

Pathophysiology

A working knowledge of urethral embryology is essential for understanding the development of hypospadias. The male urethra forms between 8 and 15 weeks of gestation. The urethral folds, which line the two edges of the urethral plate, fuse in the midline and become tubular in a proximal to distal direction. The terminal urethra forms from an ectodermal plug that channels its way from the distal glans and meets the endodermally derived urethra at the subcoronal position. Anomalous fusion of the urethral folds or abnormal formation of the ectodermal plug results in hypospadias.

Clinical and Laboratory Evaluation

A thorough inspection of the external genitalia is warranted. The prepuce is generally deficient ventrally and may be redundant dorsally (dorsal hood). The shaft skin proximal to the meatus is usually thin. The location of the meatus may be anywhere—just below a dimple at the very distal glans or hidden between the halves of a bifid scrotum or in the perineum. Chordee may be present on inspection or may be elicited only by an "artificial erection" (intraoperative injection of saline into the corpora cavernosum); it may be mild or almost 90 degrees in ventral deflection. The urinary stream is generally unaffected, but may be deflected downward by the location of the meatus. It is necessary to palpate the scrotum for the presence of both testes and any associated inguinal hernias.

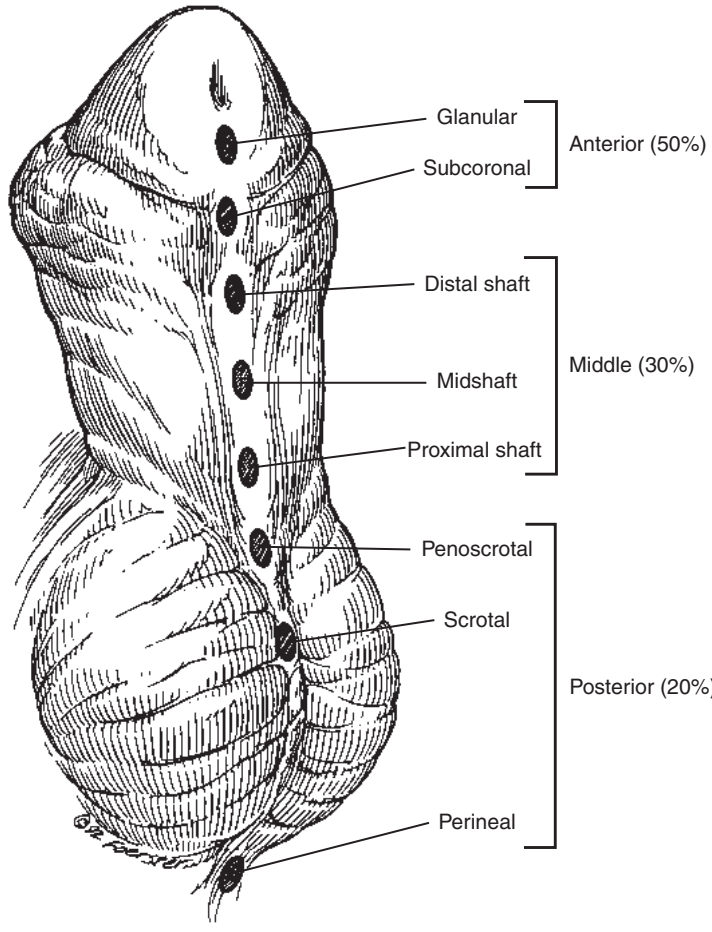

FIGURE 26-5. Classification of hypospadias. From Duckett JW Jr: Successful hypospadias repair. *Contemp Urol* 4(4):42–55, 1992. Copyright Medical Economics Publishing.

Differential Diagnosis

Hypospadias may be an isolated condition or associated with other anomalies including cryptorchidism and inguinal hernia. It may represent a form of intersex, particularly when located proximally or associated with unilateral or bilateral cryptorchidism. It is important to remember that when hypospadias is related to a possible intersex state, sex assignment should be delayed and may not correspond to the child's karyotype.

An impalpable testes may reflect a chromosomal abnormality (mixed gonadal dysgenesis), androgen insensitivity, or true hermaphroditism. If neither gonad is palpable, the pediatrician should consider a defect in steroidogenesis (congenital adrenal hyperplasia).

Management

Treatment involves surgical reconstruction, usually performed at 6 to 18 months of age. The surgical goal is to provide the child with a normal-appearing and functioning penis. The first portion of the surgery involves correction of the chordee, sometimes simply by releasing the skin or by placating the corpora or placing a graft. Second is the urethral reconstruction so that the meatus is at the tip of the glans. The foreskin is frequently used in the repair; thus, circumcision should *not* be performed pending consultation with a pediatric urologist. Repair of distal hypospadias is generally an ambulatory procedure, whereas more proximal repairs may require brief hospitalization.

CRYPTORCHIDISM

Undescended testes, or cryptorchidism, is the most common urogenital congenital anomaly. It has an incidence of 3.4% at birth, which decreases to 0.8% by 1 year of age.

Pediatric Pearl: Low birth weight and prematurity are associated with higher rates of cryptorchidism.

Histologic changes in the cryptorchid testes are found by the second year of life and pose a risk for malignancy and infertility. Thus, undescended testes require treatment before a child's second birthday.

Pathophysiology

Although the mechanism of testicular descent is not well understood, postulated theories include traction on the gubernaculum, differential growth of the body wall, increased intra-abdominal pressure, and hormonal factors. Embryologically, testicular descent begins during the eighth week of gestation with attachment of the gubernaculum. The transabdominal phase of testicular descent from the abdomen to the internal inguinal ring is finished by week 12. A dormant period exists until week 28, after which the transinguinal phase begins leading the testes from the internal inguinal ring into the scrotum. Testicular descent may become arrested at any point in development.

Biopsy of cryptorchid testes, particularly intra-abdominal testes, demonstrates histologic abnormalities. These include a decreased number of germ cells, greater number of hormonally dormant Sertoli cells, increased collagen deposition, and fibrosis around the seminiferous tubules. The contralateral testes, even if normally descended, may also demonstrate abnormal histology. Fertility is generally reduced, and 20% of men may remain infertile despite surgical correction in childhood.

Testicular neoplasm is 20 to 45 times greater in undescended testes, with an overall incidence of 4% to 11%. Seminoma is the most common malignancy. Although correction (hormonal or surgical) does not reduce malignant potential, it does allow for self-examination and earlier tumor detection.

Clinical and Laboratory Evaluation

Undescended testes may be classified according to location: truly cryptorchid (arrested in the normal path of descent), ectopic (arrested in an abnormal position), or retractile (able to be brought into the scrotum followed by retraction) (Figure 26-6). The truly cryptorchid testes may be located anywhere along the normal pathway of descent, including the abdomen. Ectopic testes are found outside of the normal pathway. Testes that are found high in the scrotum that can be brought to the normal position, albeit temporarily, are **retractile** and are not at an increased risk of infertility or malignancy. Physical examination should also focus on the size and shape of

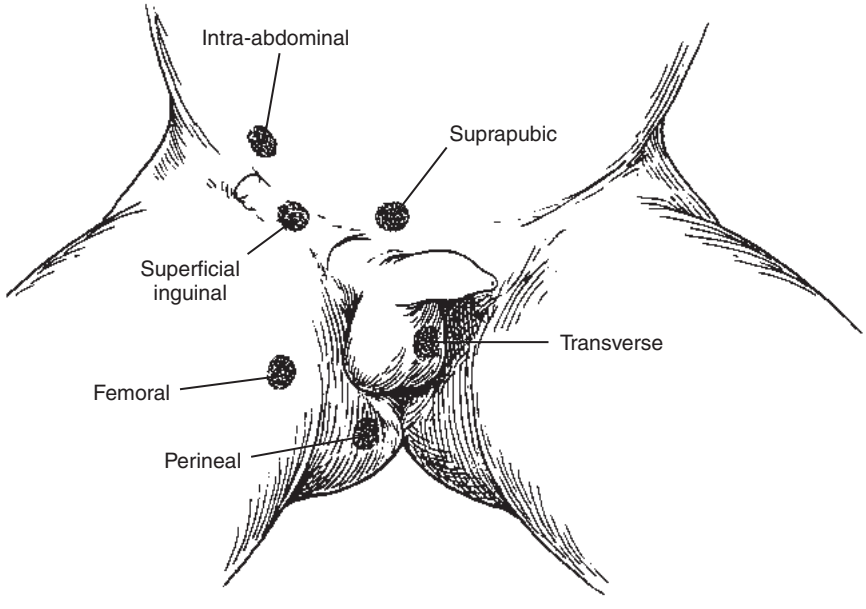

FIGURE 26-6. Location of undescended testes. From Freedman AL, Raijfer J: Cryptorchism: Reliable surgery amid uncertainties. *Contemp Urol* 4(1):59-70, 1992. Copyright Medical Economics Publishing.

the penis because cryptorchidism in the presence of an abnormal phallus may reflect a hormonal aberration or an intersex condition.

In the case of bilateral impalpable cryptorchidism, it may be helpful to evaluate serum hormone levels. Low testosterone and high gonadotropin levels suggest primary testicular failure or absent testes. If normal or low levels of gonadotropins and testosterone are present, a stimulation test with human chorionic gonadotropin can be performed to assess the presence of functioning testicular tissue. An increase in serum testosterone implies functioning testicular tissue; it is necessary to determine the location.

Differential Diagnosis

The truly cryptorchid testes may be an isolated feature or associated with intersex (refer to Hypospadias, Differential Diagnosis). Retractile and ectopic testes are generally isolated findings unrelated to an intersex condition.

Management

The following general principles apply to the management of undescended testes (Figure 26-7):

- Surgical correction (orchidopexy) is the primary treatment modality in the United States, whereas hormonal stimulation is more common in Europe.

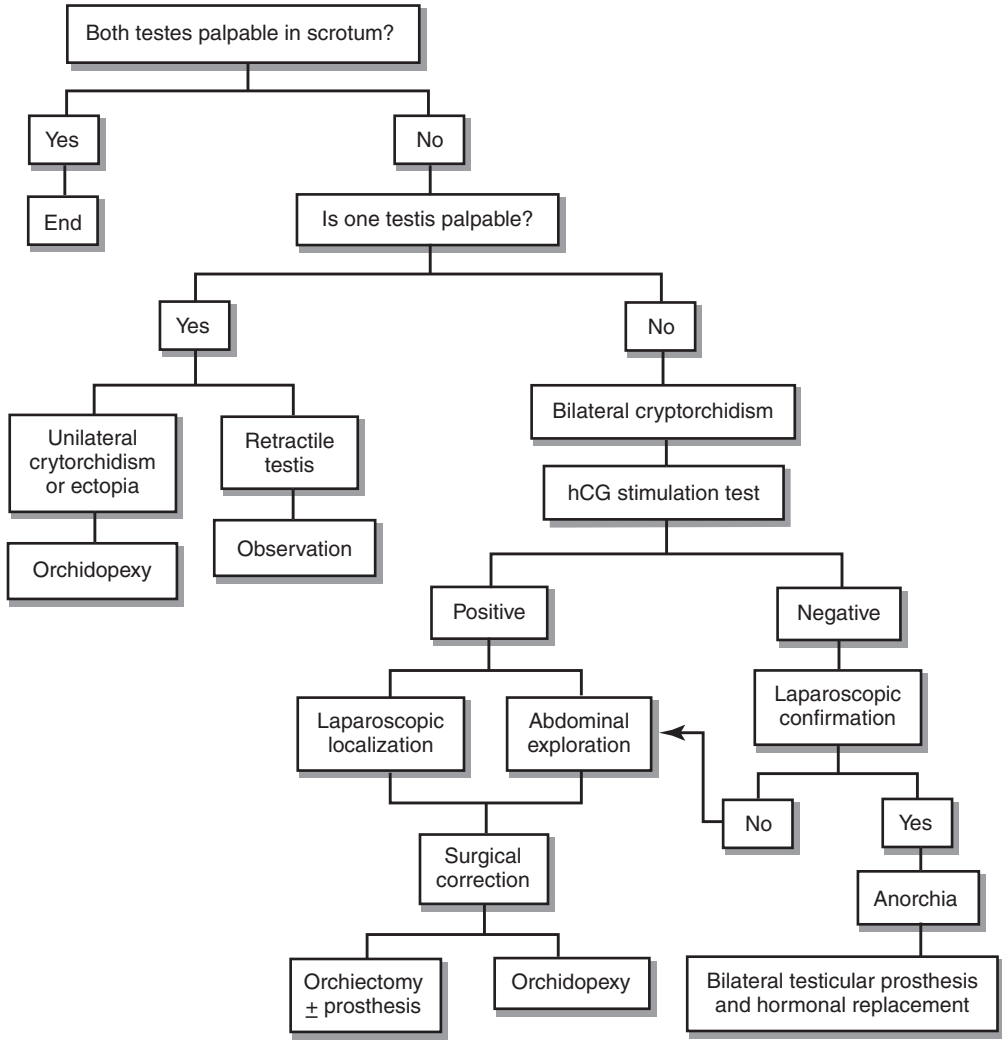

FIGURE 26-7. Algorithm for the evaluation and management of undescended testes. *hcG*, human chorionic gonadotropin.

- Treatment should be instituted before 1 year of age.
- Radiographic studies are of limited value in searching for or confirming undescended testes.
- Laparoscopy is the most accurate modality to identify intra-abdominal testes.

VESICOURETERAL REFLUX

The retrograde passage of urine from the bladder to the ureter, **vesicoureteral reflux (VUR),** is commonly found during the evaluation of urinary tract infections (UTI) and prenatal hydronephrosis. Although the exact incidence is not known, a familial tendency is reported with approximately 30% of siblings having VUR. The importance of detecting VUR lies in the prevention of infection and subsequent impairment of renal function. VUR may be minimal or may grossly deform the renal collecting system and ureter. The international classification system of VUR is depicted in Figure 26-8.

Pathophysiology

VUR can be divided into **primary** (abnormal mechanics at the vesicoureteral junction unrelated to obstruction or abnormal voiding) and **secondary** (related to obstruction or abnormal voiding). The ureter passes through the bladder at an oblique angle such that the roof of this tunnel compresses the ureter as the bladder fills with urine. The ratio of the tunnel length to ureteral diameter is purportedly important in maintaining competence of this mechanism (minimal ratio of 3:1). Any aberrancy in this valvular mechanism can lead to VUR. Similarly, any distortion of the ureteral orifice or displacement from its normal position can result in VUR. These abnormalities include ureteral duplication, ectopic ureteral location, and ureterocele (cystic dilatation at the ureteral orifice). Furthermore, high bladder pressures or obstruction to the flow of urine (posterior urethral valves, tumors, urethral strictures) may lead to disruption of the normal valvular mechanism.

VUR in the presence of infected urine poses a significant threat to renal function. Bacteria gain entry to the renal medulla through abnormal papilla, stimulating an immune response. Superoxide, released to kill the bacteria, damages the tubular cell wall and produces a renal scar. Scarring leads to contraction of the renal parenchyma overlying the affected papilla and loss of function (reflux nephropathy). At its worst, end-stage renal disease ensues with subsequent need for dialysis or renal transplantation.

Clinical and Laboratory Evaluation

The first febrile UTI or a history of VUR in a sibling or parent should prompt a search for VUR. Symptoms may reflect either the UTI (fever, vomiting, failure to thrive, dehydration, lethargy) or VUR (mild flank pain, hypertension). Accurate documentation of infected urine obtained from urethral catheterization,

suprapubic aspiration, or a "clean-catch" in older children is acceptable; urine cultures from bagged specimens are valuable only if negative prior to administration of antibiotics and this practice should be avoided.

After documentation of a UTI, the radiographic evaluation begins with a sonogram of the bladder and kidneys. The presence of hydronephrosis or dilated ureters raises the possibility of VUR, although low-grade VUR is not excluded by a normal sonogram. **Voiding cystourethrography (VCUG)** is then performed by placing a urethral catheter and filling the bladder with iodinated contrast. Fluoroscopic or static images of the urinary tract looking for the presence of contrast in the ureter or renal collecting system confirm the diagnosis. The grading of reflux is based on the VCUG results. The presence of renal scarring and assessment of renal function can best be made by dimercaptosuccinic acid (DMSA) nuclear scan. Cystoscopy is reserved for those children who require surgical correction or who have a suspected bladder or urethral anomaly.

Differential Diagnosis

VUR is one cause of hydronephrosis or hydroureter. Other conditions are possible (Table 26-8).

Management

The goals of managing VUR is to prevent recurrent UTIs and pyelonephritis and, in so doing, avert the development of cortical scarring with loss of function and hypertension. The lower the grade, the higher is the chance of spontaneous resolution (90% for grade 1 vs. 40% to 50% for grade 5). While awaiting spontaneous resolution or deciding on surgical management, chemoprophylaxis is instituted; amoxicillin is used in the first 2 months of life and then often changed to either trimethoprim-sulfamethoxazole (risk of kernicterus or megaloblastic anemia) or nitrofurantoin (risk of pulmonary fibrosis).

Surgical indications include breakthrough UTIs, new renal scarring, noncompliance with prophylaxis, persistent high-grade reflux, and parental choice. Surgery for high grades of VUR involves the reimplantation of the ureter with a longer submucosal tunnel, allowing greater compression of the ureter by the bladder muscle. For the lower grades of reflux, this surgery is also applicable to lower grades of reflux (success rates greater than 98%) or the endoscopic injection of a bulking agent submucosally under the affected ureter (success rates about 70% to 80%).

PEDIATRIC OPHTHALMOLOGY

Debbie Alcorn

EYE ANATOMY

The upper and lower eyelids each contain a fibrous plate called the tarsus. This gives the eyelids their strength and stability. The upper tarsal plate is larger than the lower tarsal plate. The lashes emerge from the edge of the eyelid, called the eyelid margin. The medial canthus is the junction of the eyelids medially, whereas the junction of the eyelids temporally is the lateral canthus (Figure 26-9). The opening between the upper and lower lid is the palpebral fissure.

The outer part of the eye is the sclera. It is generally white and opaque, extending posteriorly and circumferentially to form the structural wall of the eyeball. The visible sclera is covered anteriorly by a translucent vascular membrane, the conjunctiva. The conjunctiva stretches over the sclera of the eyeball and folds around in the upper and lower fornices to cover the inner side of the eyelids (here called the palpebral conjunctiva).

The cornea is the transparent optically clear dome overlying the colored part of the eye (iris). It is the main refractive surface of the eye. The junction between the cornea and the sclera is the limbus. Just posterior to the pupil is the lens of the eye, which focuses light onto the retina. The space between the iris and cornea is the anterior chamber. It contains fluid, the aqueous humor, which drains out of the eye through the anterior chamber angle—the junction of the cornea and iris. It is obscured by the edge of the cornea/scleral junction (the limbus), so specialized mirror lenses are used to view angle structures. Fluid drainage through the angle structures is important to keep the intraocular pressure at a normal level (relevant in glaucoma).

All of these structures compose the anterior segment of the eye. All structures behind these are referred to as the posterior segment. The clear gelatinous material comprising the inside of the eyeball is called the vitreous body. Lining the inner wall of the back of the eye is a thin and clear membranous structure called the retina. It receives and processes visual input to be conducted to the brain along axons that travel in the optic nerve. The retina contains blood vessels, and derives its blood supply from these as well as from a vascular layer between it and the sclera (called the choroid/choriocapillaris). The central retina, responsible for sharp central vision, is called the macula. The central, most specialized, part of the macula is the fovea.

The eyes are encased by four bony walls forming the orbit. The medial wall separates the orbit from the ethmoid sinuses and is the thinnest (paper-thin) orbital wall (the lamina papyracea). The inferior wall is second to the medial wall in thinness. It separates the orbit from the maxillary sinus. The lateral wall is the thickest. The superior orbital wall/orbital roof separates the orbit from the anterior cranial fossa.

Blood vessels and nerves, including the optic nerve, exit the orbit posteriorly through foramina at the orbital apex. The two optic nerves partially decussate at the optic chiasm, with 54% of fibers (those from the nasal retina/temporal visual field) crossing at the chiasm. Visual input from the left-sided visual field is therefore passed to the right cerebral hemisphere, and vice versa. Axons carrying visual input then are carried through the brain, with processing occurring at multiple locations including the primary visual cortex in the occipital lobe.

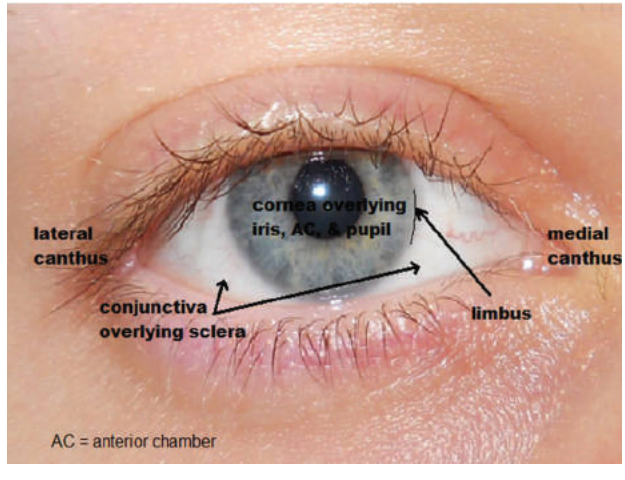

FIGURE 26-9. Anatomy of the eye.

The optic nerve (CN II) carries visual information as well as the afferent fibers for pupil function. The efferent fibers for pupil constriction (parasympathetics) travel in CN III. Visual acuity develops such that children should start to fixate and follow objects by about 8 to 12 weeks of age.

Pediatric Pearl: The presence of an afferent pupillary defect implies disease of the optic nerve (or retinal disease severe enough to affect the majority of the input to the optic nerve).

There are seven extraocular muscles: the four rectus muscles (medial, lateral, superior, and inferior), two oblique muscles (superior and inferior), and the levator palpebrae superioris muscle. The four rectus muscles originate near the orbital apex and insert on the sclera approximately 6 mm posterior to the limbus. The lateral rectus muscle (innervated by CN VI) performs abduction of the globe, and the medial rectus (innervated by CN III) performs adduction. The primary function of superior rectus muscle (innervated by CN III) is elevation, but it also performs intorsion (rotation of the eye nasally) and adduction. Similarly, the inferior rectus is innervated by CN III and primarily performs depression but also extorsion and adduction. In addition to the four rectus muscles, there are two oblique muscles. The superior oblique muscle (innervated by CN IV) travels along the medial orbital wall from the orbital apex to the anterior orbit just below the medial brow. There, it curves around the trochlea and inserts on the top of the eyeball, just underneath the superior rectus muscle. The superior oblique is primarily involved in extorsion, secondarily with depression and abduction. Finally, the inferior oblique muscle courses from the anteromedial orbital wall to insert on the posterior aspect of the eye, near the macula. This muscle performs extortion as well as elevation and abduction.

PEDIATRIC OPHTHALMOLOGY BASICS

Trauma

Pediatric Pearl: Eye conditions warranting emergent ophthalmology evaluation include ruptured globes, orbital fractures with suspected entrapment, retrobulbar hemorrhage with proptosis, orbital cellulitis, retinal detachment (RD), and alkali burns.

Orbit

Orbital Fracture. The bony walls of the orbit, especially the inferior and medial walls, are vulnerable to fracture from blunt injury to the orbit. This is typically a blow-out type injury from the acute increase in intraorbital pressure from direct impact. In many cases, this is not a severe injury and requires no specific treatment. Most patients will heal and never need surgical repair. The orbital floor can be fractured in conjunction with more extensive fractures of the midface, involving the orbital rim and/or the zygomatic complex. However, pediatric patients in particular are susceptible to entrapment of the extraocular muscles within the bony fracture. This is more likely with small fractures, and can occur via a trapdoor effect. Signs of muscle entrapment include pain with attempted eye movement (especially opposite from the fracture site), diplopia, nausea, and bradycardia. Entrapment is frequently an indication for urgent surgical repair. Repairs may also be done (less urgently) for very large fractures causing enophthalmos from protrusion of orbital contents through the fracture. An orbital CT scan should be obtained when an orbital fracture is suspected in a trauma setting. The eye itself must be carefully examined to rule out any associated intraocular damage.

Retrobulbar Hemorrhage. As the name denotes, this is bleeding behind the eye and can be very concerning. If enough blood accumulates in this enclosed space, the eye is pushed forward (becoming proptotic) and may raise the intraocular eye pressure to high levels as well as causing pressure on the optic nerve. It should be treated urgently with a lateral canthotomy and cantholysis (cutting both the tissue just beyond the lateral canthus and the underlying tendon). Signs of retrobulbar hemorrhage include proptosis, eye pain, elevated intraocular pressure, and decreased vision. An orbital CT scan should be obtained when it is suspected, but if there is a high index of clinical suspicion for a retrobulbar hemorrhage, the lateral canthotomy/cantholysis should be performed first.

Traumatic Optic Neuropathy. The optic nerve can be damaged by orbital trauma both via direct and indirect mechanisms. As the name suggests, direct traumatic optic neuropathy results from direct compression/impingement of the optic nerve, usually by bony fragments or an orbital foreign body (such as a bullet). Indirect traumatic optic neuropathy is caused by compression of the optic nerve without direct impingement (e.g., compression by soft tissue swelling). Signs of traumatic optic neuropathy are decreased vision with an afferent pupillary defect (the affected pupil appears to paradoxically dilate when a light is swung from the normal eye to the abnormal eye, and similarly, the normal pupil constricts when the light is swung from the abnormal eye to the normal eye). A CT scan should be obtained to determine direct versus indirect etiology.

Eyelids

Laceration. Eyelid lacerations can be very disfiguring as well as affecting the lacrimal system. They require specialized repair in the following settings: full-thickness, eyelid margin involvement, and/or canaliculus (tear duct) involvement at the medial canthus. Often in pediatric cases of children sustaining dog bites, the injury is medially and one must be highly suspicious for a laceration involving the lacrimal system.

Globe

Ruptured Globe. Any blunt or penetrating injury may result in a full-thickness injury to the eyeball, potentially with expulsion of intraocular contents. Warning signs for a ruptured globe include decreased vision, peaked or irregular pupil, protrusion of pigmented material through a wound, deformed globe, and/or 360 degrees of elevated (chemotic) subconjunctival hemorrhage. Whenever a ruptured globe is suspected, a CT of the orbits should be performed to look for an intraocular foreign body or evidence of other injury. A protective shield should be placed over the eye, and any manipulation should be minimized until urgent surgical repair can be performed.

Cornea/Conjunctiva

Corneal Abrasion. An abrasion of the surface epithelium of the cornea can result from any mechanical trauma. Symptoms include eye pain (the most prominent symptom), decreased vision, redness, tearing, and foreign body sensation. The epithelial defect can be seen easily by staining the ocular surface with fluorescein dye. The area of absent epithelium will absorb the dye and fluoresce under a blue light. The abrasion usually heals within days (depending on size). Injuries from organic material are at higher risk of infection and should consequently be followed more closely. Treatment is with topical ophthalmic antibiotic ointment or ophthalmic solution (drops). Topical anesthetic can be administered to aid in examination, but should never be given for the patient's personal use, as it inhibits epithelial healing and can cause severe corneal damage with prolonged use.

Foreign Body. Small fragments of metal, wood, or other material can sometimes become embedded in the cornea or conjunctiva. Symptoms include foreign body sensation, tearing, and eye pain. It is important to verify that the foreign body has not caused a full-thickness penetrating injury. If the globe appears grossly formed without obvious injury, this can be done by a Seidel test (applying concentrated fluorescein from a strip to the foreign body site, shining a blue light on the eye, and watching for a focal area of yellow fluorescence from leakage of fluid). The presence of leakage is a positive indication and means the injury is likely full-thickness.

Foreign bodies can often be removed with copious irrigation, and this is the preferred method, especially in children. In a cooperative older child or teenager, these may be removed with a 25G needle. However, consultation with an ophthalmologist may be helpful for difficult or firmly embedded foreign bodies and particularly for those directly over the visual axis.

Chemical Injury. Chemical burns can be very damaging to the eyes and cause severe problems both acutely and in the future. (Long-term problems include scarring of the cornea, eyelids, and/or conjunctiva). Children are especially vulnerable to this type of injury from accidental exposure to household chemicals. In the case of a chemical burn, first and foremost the eye should be copiously irrigated. This is ideally done with saline, but it is far more important to irrigate quickly. Irrigation should be performed with the best liquid at hand—even soda is better than most household chemicals. If possible, the type of chemical should be determined, and the ocular pH checked. Basic chemicals are actually more damaging than acids as they cause saponification and breakdown of the corneal tissue. The eye should be copiously irrigated with several liters of saline, and irrigation should not be stopped until the pH reaches 7.0. An ophthalmologist should be consulted to evaluate the eye for severity of damage. Severe burns can lead to permanent lid scarring and secondary ocular surface disease.

Pediatric Pearl: Chemical injury to the eyes should always be treated with immediate and copious irrigation. Alkaline injuries are more damaging than acidic burns.

Subconjunctival Hemorrhage. Subconjuctival hemorrhage is usually the result of direct trauma or a sudden increase in intrathoracic pressure (i.e., Valsalva) or hypertension or coagulopathy. The vessels of the conjunctiva are very fragile and can easily burst with minimal manipulation (rubbing). A subconjunctival hemorrhage appears as a focal patch or confluent redness between the conjunctiva and sclera. It is seldom painful, but occasionally there is some slight discomfort. Subconjunctival hemorrhages are generally benign and, like a bruise elsewhere on the body, will spontaneously resolve within a week or two. They can also be associated with blood dyscrasias.

Anterior Chamber

Traumatic Iritis. Trauma to the eye can cause inflammation of the iris, with release of pigmented iris cells and inflammatory WBCs into the anterior chamber. The most prominent symptom is photophobia; patients can also experience eye pain and blurred vision. Treatment of iritis typically consists of topical steroid eyedrops to facilitate resolution of the inflammation. An ophthalmologist should be consulted for evaluation and treatment.

One must always be aware of the potential complications of the use of topical ophthalmic steroids; including cataracts, glaucoma, and/or infections. Topical steroids albeit very helpful in the proper setting, must be used judiciously and followed appropriately.

Hyphema. Hyphema is blood in the anterior chamber. This appears as a red layering of blood inferiorly, between the cornea and the iris. Symptoms are blurred vision, photophobia, and sometimes eye pain. In some cases the blood is nonlayering, as in instances when the patient has been lying down, or if the amount of blood is insufficient or too diffuse to settle (called a microhyphema). Trauma is often the precipitating cause, but other systemic etiologies in infants and children must be considered, such as retinoblastoma, juvenile xanthogranuloma of the iris, or bleeding diatheses (from a blood dyscrasia and/or leukemia). If the hyphema precludes a view of the fundus, an ultrasound or CT scan is indicated to rule out an intraocular tumor in suspected cases.

Medical management of hyphemas remains controversial. Most agree that hyphema patients should rest (historically, strict bedrest) and wear a shield to protect the eye. Some use topical steroid eyedrops to aid in the resolution of the blood/inflammation. Some use cycloplegic agents to keep the pupil dilated, to facilitate fundus viewing, as well as to diminish movement of the iris vessels. Some advocate the use of oral antifibrinolytic agents (i.e., aminocaproic acid or tranexamic acid) as they have been shown to reduce the incidence of rebleeding in these patients, although they can be associated with significant, potentially worrisome side effects (e.g., hypotension, GI upset). Hyphemas may rebleed in 30% of cases. These patients need to be followed closely by an ophthalmologist to monitor intraocular pressure and possible rebleed (highest risk during the first 5 days after injury) and to evaluate for later sequelae such as glaucoma.

Iris

Traumatic Mydriasis. When the pupil on the side of injury appears to be dilated or irregular without an afferent pupillary defect, this may be due to damage (think of it as shock) to the iris muscle. It often resolves with time. Traumatic mydriasis is frequently seen in concert with traumatic iritis. An irregular or peaked iris may indicate a ruptured globe.

Vitreous/Retina

Vitreous Hemorrhage. Severe trauma can also result in bleeding in the posterior segment, thus filling the vitreous cavity. The primary symptom is blurred vision, sometimes preceded by floaters (black spots perceived by the patient). The retina may not be clearly visualized on direct ophthalmoscopy. Traumatic vitreous hemorrhage most frequently results from tearing of a retinal blood vessel. Suspicion should be very high for a retinal tear because the retina may be torn simultaneously, and urgent evaluation by an ophthalmologist is warranted. The patient may require evaluation with an ocular ultrasound.

Retinal Detachment. Classic symptoms of a retinal detachment (RD) are floaters and flashes of light, with progressive spread of a patch of blurred vision from the peripheral visual field toward central vision. RDs are uncommon in children except in the setting of trauma or preexisting conditions (i.e., retinopathy of prematurity [ROP], high myopia, Stickler syndrome). Evaluation by an ophthalmologist should be done quickly, as early surgical repair may provide the best chance of preserving vision.

Amblyopia

Amblyopia is a unilateral or, less frequently, a bilateral reduction in vision. Amblyopia may be caused by visual deprivation (i.e., congenital cataract, ptosis/droopy eyelid, RD), strabismus, or anisometropia (inequality of refraction between the two eyes). The prevalence of amblyopia in the North American population is 2% to 4%. Most amblyogenic visual loss is preventable if detected early and appropriately treatmented. Thus, children must be identified at an early age when treatment is most successful.

The goal in any amblyopia treatment is to maximize the vision. Treatment is individualized to the etiology and the patient. Treatment may involve (1) eliminating the visual obstruction (i.e., removal of the congenital cataract or repair of the RD, or eyelid surgery to correct the ptosis), or (2) forcing the use of the poorer seeing eye (i.e., with patching of the good eye or optical penalization, or blurring of the good eye), and (3) correction of any significant refractive error.

Pediatric Pearl: Amblyopia can result from any cause of visual deprivation (including strabismus, cataract, and/or ptosis) and may lead to permanent visual compromise. It should be managed aggressively with patching (or an equivalent treatment) and treatment of the underlying cause. Children must be evaluated at an early age to prevent permanent visual loss.

Strabismus

Strabismus is ocular misalignment, whether horizontal, vertical, or torsional. The prefix denotes the type of deviation: "eso" is inward deviation of the eyes; "exo" is outward deviation of the eyes; "hyper" or "hypo" denotes a vertical deviation. The most common type of strabismus in children is esotropia, accounting for more than 50% of ocular deviations in the pediatric population.

Pseudoesotropia is the false appearance of esotropia when the eyes are actually well aligned. The "apparent" esotropia is caused by a broad flat nasal bridge, prominent epicanthal folds, or a narrow interpupillary distance. The parent or physician may notice more "white" (sclera) showing on one side versus the other. But on objective testing, there is no movement on cover/uncover testing, and the corneal light reflexes are centered. No treatment or intervention is required unless true strabismus develops.

The most frequent form of strabismus is infantile (classic "congenital") esotropia. This is by definition present before 6 months of age, though typically not truly present at birth. It is typically large-angle and quite marked. Infants with infantile esotropia generally require eye muscle surgery to straighten the eyes, but should continue to be followed by an ophthalmologist as other eye alignment problems often occur months to several years later (inferior oblique overations and dissociated vertical deviation).

Some children have an accommodative type of esotropia in which the inward deviation is associated with accommodation and thus require glasses in a hyperopic (farsighted) prescription to help align their eyes. These children typically present between 6 months and 6 years of age. Initially, it is only an intermittent deviation, but then may become constant if not treated. This is why it is most important that all children undergo a cycloplegic refraction (to check if they need a prescription for glasses) and assess their full refraction.

Exotropia is an outward deviation of the eyes. Approximately 70% of babies will have a transient exotropia at birth, which usually resolves by 2 months of age. Most young children with pathologic exotropia will have an intermittent form that manifests when they are tired, sick, and/or daydreaming.

Retinopathy of Prematurity

ROP is a devastating disease that occurs in premature and low-birth-weight infants. It is a proliferative (neovascular) retinopathy that can lead to tractional RD and permanent blindness in advanced forms. If an infant is born prematurely, the retinal vascular growth may be interrupted. There may be **vasoconstriction** of the as yet incompletely vascularized retina, and subsequently, the ischemic retina releases vasculogenic mediators. These mediators may cause harmful retinal neovascularization. In many cases, the disease will spontaneously regress, but the damage is severe when it does not.

Screening is indicated for infants with a birth weight less than 1,500 g (or 1,500 to 2,000 g with concern by the pediatrician), or a gestational age less than 30 weeks. The first retinal exam should take place at 4 to 6 weeks postnatal age or at 31 to 33 weeks (whichever is later). The frequency of the exams depends on the severity of disease identified. Treatments include laser therapy to the avascular retina in cases of progressive disease. Severe cases may warrant vitreoretinal surgery.

Cataract

A cataract is a cloudiness or opacification of the lens, most often seen in older patients; it is a normal process that happens with age (rates do differ in people; can occur earlier in patients with diabetes, a history of eye trauma, or inflammatory eye conditions). There is a subset of cataracts, however, seen in children. Most pediatric cataracts are congenital, but they can also be caused by trauma (unilateral cataracts with appropriate history) or infection. Cataracts, which appear sufficient in size (generally bigger than 3 mm) or opacity to affect a child's vision, warrant surgery. The lenticular opacity may be detected by a decreased red reflex or a white reflex (leukocoria), signs of amblyopia, or preference for the other eye. A cataract present at birth and causing visual deprivation should be operated on within 2 months (or whenever the baby is cleared for general anesthesia and stable). Placement of intraocular lenses (a standard practice for adult patients) is controversial in children. No good accommodative intraocular lenses (providing both good distance and near vision) are currently available at this time.

If the lenticular opacity is not visually significant, surgery is deferred. The child must be monitored closely for vision, alignment, and ocular preference. Amblyopia treatment may be indicated.

Nystagmus

Nystagmus is a repetitive rhythmic movement of the eyes, a few beats of which are normal in many people in a far eccentric gaze (i.e., looking far off to the sides). There are two phases: the slow drift away, followed by a fast jerk (saccade) back to fixation. The most common type of nystagmus in childhood is sensory deprivation nystagmus, secondary to poor vision and lack of sufficient visual stimuli to develop a normal fixation reflex. Searching/wandering nystagmus is classically correlated with visual acuity worse than 20/200, pendular nystagmus (equal fast and slow phases) with vision better than 20/200 in at least one eye, and jerk nystagmus (unequal slow and fast phases) with vision in the range of 20/60 to 20/100.

Other common forms of nystagmus seen in children include congenital nystagmus and manifest latent nystagmus. Congenital nystagmus is usually horizontal, conjugate, and directed in the direction of gaze. It disappears with sleep and is worse with distance gaze and fixation. Manifest latent nystagmus occurs in patients with strabismus who are amblyopic or suppressing one eye (functionally monocular). The fast phase occurs in the direction of gaze. A rare unilateral form of nystagmus (monocular nystagmus of childhood, the Heimann-Bielschowsky phenomenon) with small amplitude vertical movements, is concerning and warrants an MRI scan to rule out optic nerve/chiasm glioma.

Glaucoma

Glaucoma is a retinal and optic nerve damage usually from relative increased intraocular pressure, which occurs rarely in children. But when it does, it can result in significant visual loss, eye pain, and eye deformity. Signs of congenital glaucoma include eye pain, tearing, blepharospasm, and photophobia (and may manifest as crying and irritability in light). There is often corneal edema (hazy appearance, sometimes even bluish hue, to the cornea). There may be breaks in the posterior aspect of the cornea, which may be horizontally oriented (called Haab striae). The cornea itself is often enlarged, and positioned more vertically than horizontally. When long-standing, the high eye pressures of glaucoma result in pathologic enlargement of the eye (buphthalmos). The classic hallmark of glaucomatous optic nerve damage is the presence of "cupping," an enlargement of the optic cup relative to the entire optic disc. Particularly sensitive for this is asymmetry between the cup-to-disc ratios in each of the patient's eyes.

When glaucoma is suspected, the child should be promptly referred to a pediatric ophthalmologist, as surgery is usually indicated and earlier treatment will improve prognosis. Management is chronic and frequently frustrating. It should be noted that while most classic childhood glaucoma is congenital, it can also result from other causes, such as chronic eye inflammation and trauma. Congenital glaucoma, unlike adult forms, generally requires surgical intervention, as topical and/or systemic medications do not suffice. Congenital glaucoma needs to be effectively controlled prior to 1 year of age to have the best chance of a positive outcome.

INFECTIONS

Conjunctivitis

Neonatal Conjunctivitis

Toxic chemical. Prophylaxis of neonatal conjunctivitis is mandatory in all states, but sometimes results in toxic conjunctivitis, particularly from silver nitrate solution. It is seen acutely in the first 24 hours and resolves spontaneously over several days.

TABLE 26-9

Distinguishing Features of Conjunctivitis

Condition	*Features*
Viral conjunctivitis	Red eye(s) with clear/serosanguinous discharge and follicular reaction on palpebral conjunctiva. May have corneal findings (small subepithelial infiltrates). Often associated with viral URI.
Bacterial conjunctivitis	Red eye with mucopurulent discharge and papillary reaction on palpebral conjunctiva.
Allergic conjunctivitis	Red eye with chemosis, prominent itching, papillary reaction on palpebral conjunctiva, and possibly some eyelid swelling.

URI, upper respiratory infection.

Gonococcal. This usually develops on postnatal days 2 to 5 but may be delayed for a few weeks, resulting from exposure during birth. It is characterized by hyperacute, highly purulent discharge, marked lid swelling, and corneal involvement. Chemosis can be marked and/or hemorrhagic. The keratitis may be so severe as to cause a corneal ulcer or corneal perforation. Treatment is with systemic ceftriaxone, as well as topical antibiotics and frequent and copious irrigation.

Bacterial conjunctivitis demonstrates mucopurulent discharge and develops over days 5 to 10. It is treated with topical antibiotics.

Herpes simplex can cause conjunctivitis, beginning anywhere from day 5 to 30. Discharge is clear/serous, and there can be a keratitis with dendritic fluorescein staining. It is usually unilateral. Antivirals should be used to prevent systemic spread and later complications.

Chlamydia. This usually presents at days 5 to 10 and is notable for a follicular reaction on the palpebral conjunctiva. They may manifest variable eyelid swelling and a serous discharge. Infants should be treated with topical therapy as well as systemic erythromycin to prevent chlamydia pneumonitis and later rhinitis or otitis (Table 26-9). Infants and parents/caregivers must be tested.

Conjunctivitis in Older Children

See Table 26.9

Preseptal and Orbital (Postseptal) Cellulitis

Infections of the tissues around the eye can arise from external trauma, an extension of sinusitis, and/or eyelid glandular dysfunction. Preseptal/periorbital cellulitis and orbital cellulitis are anatomically divided by the fibrous orbital septum that stretches from the globes to the orbital rim and serves as a barrier to penetration of the orbit. Orbital cellulitis is a severe condition that can potentially be life- or vision-threatening. It requires hospitalization, careful monitoring, and treatment with IV antibiotics. Whenever suspected, an orbital CT scan should be obtained to look for a focal abscess. Signs and symptoms of orbital cellulitis include proptosis, limitation/pain with eye movement, and/or chemosis. If one of the following four is present, the patient clinically demonstrates orbital cellulitis (versus preseptal): decreased visual acuity, an afferent pupillary defect, decreased extraocular motility, and/or optic disc edema.

Dacryocystitis and Nasolacrimal Duct Obstruction

Dacryocystitis is an infection of the lacrimal sac (part of the tear drainage system from the puncta to the nasolacrimal duct and nose) that frequently occurs in the setting of a dacryocystocele and nasolacrimal duct obstruction. It presents as an elevated, red, tender mound just below the medial canthus, along the side of the nose. Firm pressure on the mound (Crigler massage) results in expression of purulent material from the puncta. This should be treated with antibiotics, aggressive massage, and management of underlying nasolacrimal duct obstruction. Otolaryngology consultation should also be obtained to look for nasal cysts, as these are present in approximately 20% of patients and can lead to difficulty breathing, with hypoxia during feeding.

Approximately 2% to 4% of normal neonates will have nasolacrimal duct obstruction, which presents as increased tearing. Most resolve spontaneously by 6 weeks and 90% resolve by 6 months. If the duct obstruction does not resolve spontaneously, surgical probing should be undertaken.

OTHER CONDITIONS

Ptosis

Congenital ptosis can be unilateral or bilateral and is characterized by a drooping upper eyelid (with limited lid excursion). Affected children may lack an upper eyelid crease and often assume a chin-up position to be able to see and fuse. They should be allowed this altered head position. Cases range in severity. Severe ptosis is worrisome because it can result in visual deprivation amblyopia from occlusion of the visual axis. These children may require early surgery to correct the ptosis. Milder cases may be monitored visually and the amblyopia appropriately treated.

Chalazion/Hordeolum

A hordeolum is the acute form and a chalazion is the chronic form of a focal swelling of the eyelid near the lid margin (commonly called a stye). A hordeolum is red, tender, and inflamed, whereas a chalazion is nontender and uninflamed. They result from obstruction of a meibomian or zeis gland orifice (glands that line the eyelid margin and secrete the oily part of the tear film). Treatment is with frequent hot compresses and eyelid scrubs. Children can also be treated with oral antibiotics (i.e., erythromycin) for inflamed lesions. These may wax and wane, be very chronic, and become very large. They may require surgical excision.

Retinoblastoma

Retinoblastoma is a tumor of the retina, the most common malignant ocular tumor of childhood. Presenting signs and symptoms include leukocoria (a white pupil/"white" red reflex), loss of vision, amblyopia, and/or secondary strabismus. Most bilateral and familial cases are diagnosed in the first year of life, whereas sporadic unilateral cases are diagnosed between 1 and 3 years of life.

Retinoblastoma can be inherited or, more frequently, are sporadic. Sporadic cases may be due to new germline mutations or isolated mutations within the retina. Germline mutations involve the loss of a tumor suppressor gene on chromosome 13, present in all cells of the body. These patients generally develop bilateral retinal tumors, as well as nonocular malignancies, by the age of 12 months. Treatment and prognosis depend on the stage of the tumor, and therapies include chemotherapy, laser, cryotherapy (freezing), radiation, and enucleation (surgical removal of the eye). Prognosis/survival rates can be quite good when detected early. Patients with retinoblastoma require careful lifelong follow-up. Family members should also be examined. Patients with germline mutations are at risk for nonocular tumors, estimated to occur with an incidence of 1% per year of life. These secondary tumors are osteogenic sarcomas of the long bones and skull, brain tumors, soft tissue sarcomas, melanomas, lung cancer, breast cancer, and Hodgkin lymphoma. Those patients who received external beam radiation before 1 year of age have a higher incidence for additional malignancies.

There is a long differential for leukocoria, including cataracts; RD; ROP; persistent fetal vasculature/persistent hyperplasia of the primary vitreous (PHPV); Coats disease; coloboma of the optic disc or choroid, vitreous hemorrhage; Norrie disease; and toxocariasis. An abnormal red reflex always warrants prompt referral to a pediatric ophthalmologist.

Pediatric Pearl: Any child with an abnormal/white red reflex should be seen urgently by an ophthalmologist to evaluate for retinoblastoma, cataract, or other vision-threatening conditions.
