Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

Previous editions copyrighted 1998, 1990, 1983.

BOOK AID
International

Sabre Foundation

To Elaine, Evan, and Lila, whose patience made this book possible; to Drs. Fred Lovejoy and Gary Fleisher for their mentorship; and to all the toxicology fellows with whom I've had the pleasure of working.

Thank you.

Michael W. Shannon

To Dr. Edward (Mel) Otten, who first encouraged me to study the management of chemical and radiological emergencies; to Drs. James Lockey, James R. Roberts and Suman Wason, who mentored me in my unconventional approach to occupational medicine and toxicology training; to Professors Chantal Bismuth and Frédéric Baud, who afforded me the opportunity to expand my knowledge of toxicology in an international environment; to my family and colleagues, without whose constant support my participation would not have been possible.

Stephen W. Borron

I am forever grateful to my wife, Maureen, and children, Ryan, Liam, and Riley, whose unwavering love, support, and understanding during the editing process greatly contributed to the success of this work.

Michael J. Burns

CONTRIBUTORS

Cynthia K. Aaron, MD, FACMT, FACEP

Associate Professor of Medicine and Pediatrics
Wayne State University School of Medicine
Director, Clinical and Medical Toxicology Education
Children's Hospital of Michigan Regional Poison
Center
Detroit Medical Center
Detroit, Michigan

Jawaid Akhtar, MD

Assistant Professor
Department of Emergency Medicine
University of Pittsburgh Medical Center
Medical Toxicologist
Pittsburgh Poison Center
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Steven E. Aks, DO

Associate Professor of Emergency Medicine
Rush University
Director, The Toxikon Consortium
Chief, Section of Toxicology
Department of Emergency Medicine
Cook County Hospital
Chicago, Illinois

Timothy E. Albertson, MD, MPH, PhD

Professor of Medicine, Pharmacology/Toxicology,
Emergency Medicine, and Anesthesiology
University of California–Davis
VA Northern California Hospitals and Clinics
Chief, Division of Pulmonary/Critical Care Medicine
Medical Director, Sacramento Division
California Poison Control System
University of California–Davis Medical Center
Sacramento, California

Alfred Aleguas, Jr., RPH, BSPHarm, PharmD

Adjunct Faculty
University of Rhode Island College of Pharmacy
Kingston, RI
Clinical Manager
MA/RI Regional Center for Poison Control and
Prevention
Boston, Massachusetts
Staff Pharmacist
The Westerly Hospital
Westerly, Rhode Island

Linda G. Allison, MD, MPH

Professor, Physician Assistant Studies
Le Moyne College
Syracuse, New York

Angela C. Anderson, MD, FAAP

Associate Professor
Departments of Emergency Medicine and Pediatrics
Brown University Medical School
Attending Physician
Department of Pediatric Emergency Medicine
Rhode Island and Hasbro Children's Hospitals
Providence, Rhode Island

Juan C. Arias, MD

Postdoctoral Fellow
Department of Surgery
Division of Emergency Medicine
The University of Texas Health Science Center at
San Antonio
San Antonio, Texas

Alexander B. Baer, MD

Clinical Instructor
Department of Emergency Medicine
University of Virginia
Charlottesville, Virginia
Attending Physician
Rockingham Memorial Hospital
Harrisonburg, Virginia

Frédéric J. Baud, MD

Professor of Critical Care Medicine
Hôpital Lariboisière
Université Paris VII
Paris, France

Carl R. Baum, MD, FAAP, FACMT

Associate Professor of Pediatrics
Yale University School of Medicine
Attending Physician, Pediatric Medicine
Director, Toxicology Service
Director, Center for Children's Environmental
Toxicology (toxikid.org)
Yale–New Haven Children's Hospital
New Haven, Connecticut

Martin Belson, MD

Medical Toxicologist
National Center for Environmental Health
Pediatric Emergency Medicine
Children's Healthcare of Atlanta
Atlanta, Georgia

John G. Benitez, MD, MPH, FACMT, FACPM

Associate Professor of Emergency Medicine,
Environmental Medicine, and Pediatrics
University of Rochester
Managing Director and Associate Medical Director
Ruth A. Lawrence Poison and Drug Information Center
University of Rochester Medical Center
Rochester, New York

Neal L. Benowitz, MD

Professor of Medicine, Psychiatry, and
Biopharmaceutical Sciences
University of California-San Francisco
Chief of Clinical Pharmacology
San Francisco General Hospital
San Francisco, California

David P. Betten, MD

Assistant Clinical Professor
Department of Emergency Medicine
Michigan State University College of Human Medicine
East Lansing, Michigan
Attending Physician
Sparrow Health System
Lansing, Michigan

Brian Christopher Betts, MD

Chief Resident
Internal Medicine Department
University of Minnesota
Minneapolis, Minnesota

P R E F A C E

This fourth edition of *Clinical Management of Poisoning and Drug Overdose*, is re-titled to include the name of its creators, Lester Haddad and Jim Winchester. While neither of them was formally trained in medical toxicology, Lester and Jim were visionary in recognizing the need for a comprehensive toxicology textbook. From the first edition in 1983 to the 3rd edition in 1998, Haddad and Winchester compiled the key information that clinicians who manage poisoned patients would need; they were successful in their goal of providing a resource that was clear, succinct, and evidence-based, without expansive discussions of underlying molecular biology or exhaustive literature reviews. Equally important, with each edition, Haddad and Winchester recruited medical toxicologists as authors, in order to present recommendations from those who were recognized experts in the field. With plans to write a fourth edition, Drs. Haddad and Winchester entrusted us to continue their vision for this textbook. We are honored to assume this responsibility and hope that we have been successful in maintaining its value. As with previous editions, we write *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose* for emergency physicians, pediatricians, internists, occupational/environmental medicine physicians, and public health officials, as well as medical toxicology fellows, house officers, and medical students.

The subspecialty of medical toxicology continues to evolve rapidly. For example, since the last edition of the textbook, no less than 4 new antidotes have entered clinical practice. The number of board certified medical toxicologists now exceeds 300 with these experts providing consultation to poison centers, academic medical centers, emergency departments, laboratories, and government agencies. With the growth of medical toxicology as a subspecialty has also come the same maturation that all new clinical fields undergo. Included in the process of maturation is greater rigor in medical toxicology research, the development of basic science research niches by medical toxicologists, and success with receiving extramural funding from NIH and other agencies that support the principles of high-quality research that advances human health.

The establishment of medical toxicology as a distinct clinical subspecialty has greatly benefited poisoned patients. Gone is the era in which there was debate about

whether there was a well-defined body of knowledge about poisonings that called for the creation of a distinct subspecialty; medical toxicologists are now recognized as possessing expertise that truly makes a difference in patient outcome after a poisoning. The U.S. Department of Health and Human Services, in acknowledgement of the importance of poison centers and the medical toxicologists who direct them, has begun to fund poison centers as a vital part of public health.

In order to meet the needs of clinicians, this 4th edition of *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose* has added several new features. First, to make this edition as authoritative as possible, we recruited practicing toxicologists to write each chapter. Parenthetically, this is also the first edition in which all the editors are medical toxicologists, who have primary practices in pediatrics, emergency medicine, and occupational/environmental medicine. Second, along with Elsevier, we have attempted to create a textbook with international appeal and value. Contributors to this edition include medical toxicologists in England, Australia, and elsewhere. Our hope is that clinicians from all countries will find each chapter useful and relevant to their practice. Finally, in an era of frequent acts of terrorism and other disasters, we have created a new section, *Disasters and Terrorism*. New chapters, including *Principles of Children's Environmental Health*, *Ill-Defined Toxic Syndromes* and *Performance Enhancers*, reflect new medical issues that clinicians regularly face.

The three of us thank our superb group of contributors who provided their thorough and conscientious expertise in each chapter. We thank the supportive staff of Elsevier, particularly Todd Hummel, who helped us navigate the project from beginning to end. We thank our families and loved ones, who permitted us to devote the many hours needed to create a work such as this. Finally, we extend to our readers the hope that this text will benefit them in their pursuit of knowledge about principles of poison management and in the care of their patients.

SECTION A

CONCEPTS IN MEDICAL TOXICOLOGY

1

The History of Toxicology

MICHAEL W. SHANNON, MD, MPH

Although it is difficult to provide a strict definition of *poison*, in its broadest definition the term denotes any substance that has the ability to harm a living organism from either the plant or animal kingdom. However, in the discipline of clinical toxicology, poison generally refers to any agent that can kill, injure, or impair normal physiologic function in humans.^{1,2}

The history of toxicology, including its writers, poisons, and poisoners, is extensive and colorful; the field can clearly claim a lineage that traces back more than 10,000 years. Over these millennia, the science (and art) of poisons and poisoning has been punctuated by events that provide a useful perspective. This chapter provides an overview of select events that have shaped the practice of medical toxicology.

HISTORICAL TIMELINE

Ancient Times

Throughout these early years of recorded history, the use of poisons was well described. The Sumerians of Mesopotamia are given credit for chronicling (circa 1400 BC) the world of poisons in their descriptions of the spirit Gula, who was “the mistress of charms and spells.” The ancient Greeks were familiar with the toxicities of metals, particularly arsenic, and the poisonous plant hemlock (*Conium maculatum*). Developed as a tool for capital punishment, hemlock was used to execute Socrates in 402 BC. The ancient Romans also developed and utilized poisons; homicide with agents including amygdalin (cyanide) and belladonna were favored. Papyri from the period around 300 BC provide evidence that ancient Egyptians understood and exploited the toxic properties of arsenic, copper, lead, and antimony. Dioscorides (AD 40–90), a physician and pharmacologist, is credited with creating the first treatise of toxicology, the *Materia Medica* (Fig. 1-1).³ In his text, which remained an authoritative reference for the next 15 centuries, he created a

classification scheme for poisons, distinguishing between those of plant, animal, and mineral origin. Another important figure of this era was Mithradates VI, King of Turkey during the period 114–63 BC (Fig. 1-2). Mithradates lived in constant fear of being poisoned.⁴ He therefore studied antidotes extensively and can be considered a pioneer in the development of antidotal therapy. Mithradatum was the name given to one of his famous antidotes.

The Medieval Era

This period of clinical toxicology also contains unique chapters. During this time, apothecaries, corresponding to modern-day pharmacists, provided both “potions and poisons.” Commonly used poisons of this era included arsenic and other heavy metals, amygdalin, strychnine, belladonna, and aconite.

The Renaissance

By the Middle Ages, toxicology had reached great prominence. Italian alchemists often devoted their careers to

FIGURE 1-1 Dioscorides. (From Wikipedia: Pedanius Dioscorides.)

FIGURE 1-2 King Mithradates. (From Anonymous: C. Julius Caesar.)

developing lethal agents. Famous names during this period were the Borgias, a family of reputed poisoners, and Paracelsus. Born Theophrast von Hohenheim, Paracelsus (1493–1541) was an alchemist, physician, and astrologer (Fig. 1-3).⁵ He is considered one of the “fathers of toxicology.” A committed student of toxicology, Paracelsus is credited with making the famous statement, “All things are poison and nothing is without poison; only the dose makes that a thing which [sic] is no poison.” One of the most important publications of the era was *Neapolitani Magiae Naturalis*, written in 1589 by Giovanni Battista Porta. This book described different methods of poisoning the unsuspecting.

The 16th through 18th Centuries

Throughout the 16th century, the development of poisoning techniques spread rampantly across Europe as Italian alchemists migrated to France. Catherine de

FIGURE 1-3 Paracelsus, painted by a student of Rubens. (From The Alchemy Web Site: Paracelsus.)

FIGURE 1-4 Catherine De Medici. (From Anonymous: Who’s Who in Tudor history.)

Médici is credited with bringing many of the Italian techniques of poisoning to France (Fig. 1-4).⁶ During this era, the French School of Poisoners became hugely popular. In an effort to contain the growing epidemic of poisoning, King Louis XIV began to limit the availability of toxic agents; for example, he forbade apothecaries from selling arsenic and required purchasers to sign a register. The king ultimately created the *Chambre Ardente*, a council that was responsible for investigating poisonings. Many members of nobility (e.g., Queen Elizabeth) appointed food tasters to ensure that no poison had been surreptitiously placed in their food. By the 17th century, poisoning had become a scientific discipline; schools of toxicology were established in both Venice and Rome.⁷

The 19th through 21st Centuries

During these centuries, toxicology took several new paths. First, during the Victorian period (19th century), forensic toxicology was developed in an effort to apprehend poisoners. Important techniques of investigation, including postmortem analysis, began to appear. This was also a period of remarkable drug discovery and development, with many pharmaceutical agents proving, as Paracelsus said, to be both beneficial and harmful. Many infamous drugs were developed during this era, including ipecac, cocaine, opium (laudanum), and barbiturates. While all had great therapeutic value, their toxicity was at the same time discovered and eventually feared.

Another important aspect of this period was, in parallel with the industrial revolution, the birth of occupational toxicology. As many valuable but toxic consumer products were developed, the need to protect workers from toxicologic threats ushered in a new scientific and public health field. One of the most important figures of this period was Dr. Alice Hamilton (Fig. 1-5).^{8,9} Dr. Hamilton (1869–1970) was the first U.S. physician to

FIGURE 1-5 Alice Hamilton, MD.

devote herself to research in industrial medicine. Writing her first article on the topic in 1908, she went on to become the first woman on the faculty of Harvard University.

The 20th and 21st centuries have been filled with many more events and accomplishments in medical toxicology. Perhaps the most important of these has been the development of a mammoth pharmaceutical industry, which can be credited with creating new drugs at a remarkable pace. With the development and use of many drugs has come, often tragically, the discovery of unanticipated toxicities. The study of drug toxicity has also led to important new principles of pharmacology (e.g., drug interactions). Finally, in the current “era of the gene,” pharmacology has added the disciplines of pharmacogenomics, which explores the ways in which an individual’s genetic makeup predetermines how he or she will respond to a medication or even a toxin (e.g., both lead and mercury toxicity are now known to be modulated by several key genes).

Another important aspect of 20th and 21st century toxicology has been the focus on poisoning management. Over the past 50 years, poison centers have been created around the world, assisting clinicians and the public in poisoning management; prevention has become an equally important part of the poison control mission.

FAMOUS POISONERS, POISONS, AND POISONINGS

Poisoners

A 17th century Neapolitan woman known simply as Toffana (1653–1723) invented an arsenic-based face paint called *Acqua Toffana*. This potion was primarily marketed as a cosmetic; female customers would consult with Toffana to learn the proper uses of the makeup. Reportedly, many women became rich widows after wearing the cosmetic on their cheeks when in the presence of their spouses. Because of her dread of being revealed as a poisoner, Toffana continually changed her

name and residence. Authorities eventually discovered her and accused her of being an accomplice to more than 600 homicides. She was arrested and ultimately tortured and strangled in prison.

Mary Ann Cotton (1832–1873) is considered one of the most prolific serial killers in English history (Fig. 1-6).¹⁰ She is suspected of murdering more than 21 unsuspecting victims before she was caught, convicted, and hanged. Victims of Mary Cotton usually succumbed to a severe gastrointestinal disorder (“gastric fever”), ultimately traced to her penchant for using arsenic to poison her victims.

Harold Shipman (1946–2004) was one of the most prolific serial killers in modern history (Fig. 1-7). A British physician, he is estimated to have killed 250 patients between 1970 and 1988. Dr. Shipman’s modus operandi was to prey on the elderly, particularly elderly

FIGURE 1-6 Mary Ann Cotton. (From Anonymous: *The poisoners—Mary Ann Cotton.*)

FIGURE 1-7 Dr. Harold Shipman. (From British Broadcasting Corporation: *Shipman Draws 7.3M viewers.*)

women. During home visits he would inject his victims with morphine, giving the appearance that they died from the complications of their advanced years; he was also usually the signatory on the victims' death certificates. Dr. Shipman was ultimately arrested and convicted of killing 15 men and women. In 2004, while imprisoned, he committed suicide.

Shoko Asahara (born Chizuo Matsumoto [1955–]) was the founder of the religious group Aum Shinrikyo (Fig. 1-8).¹¹ In March 1995, on a Monday morning (intentionally timed to produce the greatest number of casualties), he and his followers orchestrated the release of the nerve agent sarin in multiple subway cars carrying Tokyo commuters. In the process, he became the architect of one of the most important events of domestic terrorism in history. Asahara's apocalyptic efforts actually began in 1994, when his cult first released sarin in a small residential area within the city of Matsumoto; this resulted in injury to more than 600 residents; 7 died in that incident.^{12,13} In the sarin release in 1995, however, multiple cult members effectively coordinated the widespread release of the poison. Victims developed cholinergic toxicity that was sometimes severe, consisting of miosis, vomiting, abdominal pain, respiratory distress, seizures, and respiratory failure. Ultimately 5500 casualties were produced, of which 984 were moderately affected; at least a dozen victims died.¹²

Poisons

ARSENIC

As a poison, arsenic has a long and infamous history. Ancient documents suggest this heavy metal was recognized as early as 500 BC; its first use as a poison is thought to date back to the 8th century. While arsenic was used medicinally (e.g., Fowler's solution was a widely used 18th and 19th century medication prescribed for dermatitis and for asthma), its primary use was as a poison. Stories of homicidal arsenic poisoning are found

FIGURE 1-8 Shoko Asahara. (From Wikipedia: Profile: Shoko Asahara.)

throughout history. The metal's toxicity was exploited during World War II with development of the arsenic-based chemical weapon lewisite. The Allies, working diligently, were able to develop an antidote against lewisite, British anti-lewisite (BAL).¹⁴ BAL, also known as dimercaprol, proved to be a very valuable chelator; it is still used to treat poisoning by arsenic, lead, and other metals. Other details of arsenic's history are found in Chapter 74.

COCAINE

The alkaloid derived from erythroxylon coca is a toxic medicinal that has also enjoyed a long and illustrious history. Coca chewing dates back to 3000 BC; cocaine was isolated and used as a medication in the 19th century. A popular substance, it was added to wine and other beverages, well into the 20th century.¹⁵ As a therapeutic agent, cocaine was unique because (1) it had great therapeutic value; (2) it had a very narrow therapeutic window, with toxicity, sometimes life-threatening, appearing even in those who were taking it in appropriate doses; and (3) it was highly addictive. A long list of individuals, including Sigmund Freud, Robert Louis Stevenson, and the legendary American surgeon William Halstead, became addicted to cocaine during their careers. In the 1980s, cocaine alkaloid (first known as "free-base" and then "crack") appeared, creating an even more addictive drug. Through the 1990s, crack use in the United States became epidemic, producing an extraordinarily large population of cocaine abusers. Cocaine remains one of the most widely abused drugs in the world. Chapter 42 describes cocaine and its history in greater detail.

OPIUM (LAUDANUM)

The discovery of opium dates back to ancient civilization; Hippocrates wrote of the virtues of poppy wine for medicinal purposes. In the 15th century, Paracelsus mixed it with alcohol, producing "tincture of laudanum." Through the 17th and 18th centuries, use of opium by people of all socioeconomic strata spread quickly. Like cocaine, the drug was found to have remarkable therapeutic value, which often came at the cost of hopeless addiction. In much of the 19th and early 20th centuries, the opium derivative known as laudanum was widely used to treat a range of illnesses. Heroin succeeded laudanum and equally addicted historical figures such as Elizabeth Barrett Browning, Lenny Bruce, Charlie Parker, William Burroughs, and Janis Joplin.

CYANIDE

The toxicity of bitter almonds, ground peach pits, and cassava were known well before cyanide was specifically identified in 1782. Once isolated and synthesized, the toxin, being a potent pesticide, was a boon to the agriculture industry. However, its lethal effects on those who were inadvertently exposed after improper handling were also quickly discovered. Cyanide's greatest infamy, however, is associated with its use during the Hitler regime when, as part of his ethnic cleansing campaign ("The Final Solution"), millions were executed with Zyklon-B, a cyanide-based substance used in the gas

FIGURE 1-9 Zyklon B, a cyanide-containing substance used during the Holocaust. (From Anonymous: Judaism.)

chambers of occupation camps (Fig. 1-9). Cyanide continues to be used as a homicidal agent, in gas chamber executions that are part of capital punishment. The agent is discussed further in Chapter 88.

Poisonings

History records many poisoning events made infamous by the large number of individuals affected. Large scale poisonings have included:

- War-related events (e.g., the use of chemical weapons during both World Wars)
- Industrial catastrophes (e.g., Minamata Bay, Japan, and Bhopal, India)
- Climactic/geological events (e.g., the London smog and Lake Nyos “eruption”)
- Pharmaceutical disasters (e.g., eosinophilia-myalgia syndrome, gasping baby syndrome, and thalidomide disasters)
- Food-borne poisonings (e.g., “St. Anthony’s fire” and aflatoxin epidemics)
- Domestic terrorism (e.g., sarin release in Tokyo subways)

A brief description of several of these events is described below.

EOSINOPHILIA-MYALGIA SYNDROME

In 1989, an illness appeared in the United States, characterized by the onset of myalgia, arthralgia, weakness, rash, and scleroderma-like skin changes. Associated laboratory findings included evidence of rhabdomyolysis and a striking eosinophilia.^{16,17} Known as *eosinophilia-myalgia syndrome* (EMS), the disease rapidly spread throughout the United States. Epidemiologic investigation quickly traced the disease to use of the dietary supplement L-tryptophan, which had become a popular remedy for insomnia, premenstrual syndrome, depression, and other maladies. Further investigation linked the development of EMS to use of L-tryptophan from specific

manufacturing lots.^{18,19} By March 1990, the Centers for Disease Control and Prevention (CDC) had identified almost 1500 cases of EMS with at least 38 deaths. Ultimately, the L-tryptophan produced by a single manufacturer was incriminated.^{20,21} Careful inspection of the manufacturing site revealed that a significant production change had recently occurred; the former technique, in which tryptophan was produced by a fermentation process involving the bacterium *Bacillus amyloliquefaciens*, was altered by the introduction of a new strain of *B. amyloliquefaciens*. As a result, there appeared to be increased synthesis of several tryptophan intermediates. A specific chemical contaminant, di-tryptophan aminal of acetaldehyde (DTAA) was specifically incriminated (Fig. 1-10) in the development of EMS.^{22,23} Closure and immediate changes in the manufacturing process led to the disappearance of this disorder as quickly as it began. However, many victims were left with enduring health problems.²⁴

GASPING BABY SYNDROME

In spring 1981, an unusual illness appeared in neonatal intensive care units (NICUs). NICU staff noted that newborns who had been clinically stable would suddenly develop multisystem disease, severe metabolic acidosis, and a haunting gasp, which signaled their death. Known as *gaspng baby syndrome*, the illness spread across NICUs nationally. In June 1981, a New Orleans neonatologist, Dr. Juan Gershanik, noted in a postmortem urine analysis for organic acids that large amounts of hippuric acid, a known metabolite of benzyl alcohol, were found. Noticing that vials of bacteriostatic water containing 0.9% benzyl alcohol were present throughout the NICU, Dr. Gershanik reported his suspicion that gasping baby syndrome was the result of excessive benzyl alcohol administration secondary to the liberal use of bacteriostatic saline.²⁵ Other pediatricians began to report similar suspicions.^{26,27} The Food and Drug

FIGURE 1-10 Di-tryptophan aminal of acetaldehyde (DTAA), incriminated in the etiology of the eosinophilia-myalgia syndrome. Original (A) and revised (B) structures are shown.

Administration and American Academy of Pediatrics soon recommended that bacteriostatic saline no longer be used in NICUs. When this occurred, neonatal mortality rates around the country fell dramatically; reports of mortality rates falling from 50% to 2% appeared.^{28,29} There was also a noticeable fall in the incidence of kernicterus and intraventricular hemorrhage among ill neonates.^{28,30} Ultimately, conservative estimates were that benzyl alcohol was responsible for more than 300 neonatal deaths and thousands of permanent neurologic disabilities.

THE THALIDOMIDE DISASTER

Thalidomide was developed as a sedative-hypnotic; it became popular soon after it was first marketed in 1957. Known as Contergan in Germany, Distaval in England, and Kevadon in Canada, thalidomide quickly became the third-largest selling drug in Europe; by 1960, it was being sold around the world. Its reported efficacy in the treatment of hyperemesis gravidarum led to even greater use of the drug by pregnant women. However, when the Merrell Company of Cincinnati submitted a New Drug Application to market Kevadon in the United States on September 12, 1960, a young, new FDA scientist, Dr. Frances O. Kelsey, was assigned to perform the review (Fig. 1-11). Dr. Kelsey was dissatisfied with the safety data submitted for thalidomide and denied approval of the drug.³¹ In the midst of FDA battles with Merrell, in November 1961, McBride and Lenz, working independently of each other, both published reports suggesting a link between the use of thalidomide and development of phocomelia and other limb abnormalities (Fig. 1-12).³² As little as one dose of thalidomide, taken during a critical period of gestation, was found to produce a range of devastating birth defects. The drug was withdrawn in 1962, but not before it had produced more than 10,000

FIGURE 1-11 Food and Drug Administration scientist Frances O. Kelsey, credited with preventing the sale of thalidomide in the United States.

FIGURE 1-12 Thalidomide-associated phocomelia.

children with limb abnormalities. Dr. Kelsey, credited with preventing the thalidomide disaster from occurring in the United States, was awarded the Gold Medal Award for Distinguished Federal Civilian Service by President John F. Kennedy.

MINAMATA BAY

From 1932 to 1968, the Chisso Corporation near Minamata Bay, Japan, dumped an estimated 27 tons of mercury compounds into Minamata Bay. In 1956, four inhabitants of Minamata Bay were noted to have an unusual neurologic disease, thought initially to be infectious.¹² Investigation quickly led to the discovery that many people of the region had similar symptoms of diffuse numbness, slurred speech, and tunnel vision. Ultimately more than 50,000 were affected, with more than 2000 unequivocally having what became known as Minamata disease. The range of symptoms in adults included tingling sensations, muscle weakness, ataxia, tunnel vision, slurred speech, hearing loss, and abnormal behavior. Approximately 30 offspring of the inhabitants were born with severe, devastating neurologic disease, which included spasticity, mental retardation, seizures, and visual disturbances (Fig. 1-13).³³

FIGURE 1-13 Childhood victim of Minamata disease. (Photo by W. Eugene Smith. From McCann HG: Mercury found in midwest rain.)

LONDON SMOG

On December 4, 1952, an unusual temperature inversion struck London. This climatic event trapped the polluted air that was being regularly discharged from the millions of coal fires that burned daily.³⁴ For the subsequent week, concentrations of smog became so thick, visibility fell to a few yards; concentrations of ambient particulate matter were as high as $400 \mu\text{g}/\text{m}^3$.³⁴ Thousands of Londoners developed respiratory ailments, including pneumonia, bronchitis, and asthma. An estimated 12,000 citizens died from respiratory problems produced by “The Great London Smog” (Fig. 1-14).

LAKE NYOS

On August 21, 1986, Lake Nyos, a large volcanic lake located in Cameroon, released a massive cloud of carbon dioxide. Being heavier than air, the carbon dioxide descended on the villages located in a valley 250 m below. Witnesses described loud rumbling sounds made by the lake followed by the appearance of an enormous white cloud; an estimated 10^9 m^3 of volcanic gas was released.¹² Victims succumbed quickly to the anesthetic effects of high-concentration carbon dioxide. Upon arrival of the medical teams, 1700 humans and all animal and insect life in the region were dead.¹²

BHOPAL

One of the most significant industrial disasters in history occurred on the morning of December 3, 1984, at a large chemical plant in Bhopal, India. The plant, owned by Union Carbide, contained large storage tanks of methyl isocyanate gas (the compound was used as a precursor to the pesticide carbaryl). Without warning, during the dark hours of early morning, a methyl isocyanate tank ruptured, spreading the toxic gas across the streets of Bhopal. Wakened by suffocation, large numbers of victims arrived to local hospitals with sudden blindness and respiratory distress. More than 200,000 were affected by the gas; the death toll was estimated to be approximately 2500.¹² Many Bhopal survivors were left with chronic, disabling lung disease.^{35,36}

JONESTOWN, GUYANA

The Reverend Jim Jones was a religious zealot who in 1977, after creating the People’s Temple in San Francisco, created the township of Jonestown in Guyana, South America, bringing with him more than 1000 followers (Fig. 1-15). Initial reports from Jonestown indicated that

FIGURE 1-14 London smog, 1952. (From National Public Radio: London during the killer smog.)

FIGURE 1-15 Reverend Jim Jones.

Jones’s disciples lived in apparent happiness. However, when several residents sent reports of cruel treatment, coercion, and bondage to relatives in the United States, Congressman Leo Ryan went to Jonestown to investigate abuse allegations, bringing with him an 18-member party of officials, reporters, and members of “Concerned Relatives of Peoples Temple Members.” Arriving in Jonestown in November 1978, Congressman Ryan was prevented from interviewing inhabitants and carrying out his planned investigation. When he attempted to leave Jonestown, he was gunned down at an airstrip by Jones disciples. On November 18, 1978, fearing that additional authorities would soon come and possibly close Jonestown, Reverend Jones called for the mass suicide of his disciples. All drank or were forced to drink a grape flavored beverage that contained Valium and cyanide. The 276 children were killed first; a total of 914 died, including Reverend Jones, who died of a self-inflicted gunshot wound (Fig. 1-16).³⁷

FIGURE 1-16 The mass suicide at Jonestown, Guyana, 1978.

ST. ANTHONY'S FIRE

Described by a 9th century writer, St. Anthony's fire, which has appeared several times in history, was the popular name for epidemic ergotism that resulted from the ingestion of rye that had been contaminated with the fungus *Claviceps purpurea*. Also referred to as "dancing mania," outbreaks of St. Anthony's fire appeared repeatedly between the 13th and 16th centuries. It was not until the 17th century that its cause was identified. The last reported outbreak occurred in France in 1951.³⁸ There are also beliefs that women accused of witchcraft in the Salem trials of 1692 had ergot-induced psychosis and seizures.³⁹ Victims of St. Anthony's fire would typically develop burning pain and gangrene of the extremities, convulsions, hallucinations, and psychosis; death would often ensue. Ergot's powerful vasoconstrictive properties were responsible for the severe extremity vasospasm that produced pain and gangrene. Central nervous system effects were the apparent result of the alkaloid's effects on serotonin receptors. Interestingly, the study of ergot alkaloids led to the development of the hallucinogen lysergic acid diethylamide (LSD), as well as therapeutic agents including ergotamine, dihydroergotamine, methysergide, and others.

THE DEVELOPMENT OF MEDICAL TOXICOLOGY

Since the early 20th century, organized efforts in poisoning management and prevention have led to the development of medical toxicology as a clinical discipline that is distinct from other medical subspecialties. Key events in this process were the establishment of poison control centers, followed by the creation of important supporting organizations.

Poison Control Centers

By the 1930s, childhood poisoning had become a common cause of unintentional injury to children, accounting for almost 50% of significant childhood accidents. Household products (e.g., lye) were a particularly common source of severe and often fatal poisoning. However, there was little information on the toxicity of household products that could be used in prompt and effective management of childhood poisoning. In the 1930s, Dr. Jay Arena, a pediatrician at Duke University, began to compile data on the household products, providing advice to local clinicians. Dr. Arena is credited with writing one of the first modern textbooks on poisoning management.

Prior to the 1950s, there was no formal system for poisoning treatment in the United States.⁴⁰ By this time, there were well over 250,000 different brand name products on the market. Health care professionals presented with cases of acute poisoning usually had little knowledge of what ingredients were contained in these new products, making it difficult to treat these patients. A Chicago pharmacist, Louis Gdalmann, began recording information on the toxicity of various products on small cards; he also developed a data collection form that he

would use when he provided consultations. In November 1953, he helped to establish the first poison center in the United States at Presbyterian-St Luke's Hospital. In 1958, the American Association of Poison Control Centers (AAPCC) was formed. From here, poison centers proliferated: By 1970, there were almost 600 centers nationally. At the same time, poisoning fatalities in children dropped dramatically. The AAPCC was instrumental in creating multiple preventive efforts, including the establishment of National Poison Prevention Week and enactment of the Poison Prevention Packaging Act. As poison centers increasingly served the function of a public health agency, the AAPCC developed a means for monitoring and reporting epidemiologic data, known as the Toxic Exposure Surveillance System (TESS). Annual data from TESS are now published by the AAPCC for use by those who are interested in tracking the epidemiology of poisoning (www.aapcc.org). In 2002, a universal telephone number for access to poison control centers (800-222-1222) was established, simplifying access to poison centers.

The Subspecialty of Medical Toxicology

As principles of poisoning management and prevention established themselves, several organizations were created to support the clinicians who provided this care. In 1968, the American Academy of Clinical Toxicology (AACT) was formed. Consisting of physicians, pharmacists, scientists, and veterinarians, the AACT began to expand the focus of poisoning beyond childhood exposures to adult poisonings, including intentional exposures (attempted suicides), workplace exposures, drug interactions, envenomations, and environmental toxicology. Around the world, similar organizations were established, including the European Association of Poison Centres and Clinical Toxicologists (EAPCCT), the Canadian Association of Poison Control Centers (CAPCC), and the Australian Society of Clinical and Experimental Pharmacologist and Toxicologist (ASCEPT).

As these efforts evolved, it became clear that toxicology had evolved into a well-defined medical specialty. As such, standards for training and certification were needed. In 1974 the AACT created the American Board of Medical Toxicology (ABMT), a physician-only organization responsible for establishing fellowship training guidelines and creating a certifying examination. Medical toxicology fellowships began to appear; the first board examination in medical toxicology was given in 1974. However, the field of medical toxicology suffered from ABMT's position as an independent certifying organization, rather than a member of the American Board of Medical Specialties (ABMS) which, by this time, had established itself as an umbrella organization that housed the specialties and subspecialties recognized by the American Medical Association. The ABMT and medical toxicology therefore struggled to gain the same stature as ABMS specialties and subspecialties. This led to efforts by ABMT leaders to find parent organizations within the ABMS who would sponsor medical toxicology as a new, defined clinical subspecialty. These efforts culminated in

1992 with three ABMS boards—the American Board of Pediatrics, the American Board of Emergency Medicine, and the American Board of Preventive Medicine—agreeing to make medical toxicology a jointly supported subspecialty. The Subboard in Medical Toxicology was formed, providing the first ABMS certifying examination in 1994. Simultaneously, the ABMT was reestablished as the American College of Medical Toxicology (ACMT), with the goal of being a scientific organization that provides support to the medical toxicology community.

Currently, there are approximately 300 practicing, board-certified medical toxicologists, indicating the relative youth of the field. These individuals have vital roles in medicine and public health, being in federal agencies (e.g., the Food and Drug Administration, and Centers for Disease Control), medical directors of poison control centers (a requirement for poison center certification), directors of occupational health programs, and physician-scientists.

CONCLUSION

Throughout recorded time, toxicology has been part of the fabric of society. While its history has been dark at times, the evolving clinical specialty of poisoning management/prevention and the establishment of medical toxicology as a subspecialty have provided important public health advances. The science of toxicology will undoubtedly continue to provide both important discoveries and other memorable events in future years.

A A General Approach to Poisoning

MICHAEL W. SHANNON, MD, MPH

Medical toxicology is one of the most important and dynamic fields in medicine today, since the practicing physician is continually faced with the management of poisoning, drug overdose, and adverse drug effects. The abuse of both prescription and illicit drugs in the United States continues unabated. Because the process of drug approval is more rapid, it is often not until the agent has been in use for some time, during the postmarketing period, before its toxicity is fully appreciated.

Defining the incidence of human poisoning is not easy. There are multiple sources of data on drug overdose and substance abuse. The Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers tabulates referrals for human poisoning called into the nation's poison centers. In 2004, it recorded 2,395,582 exposures, with 1106 deaths; analgesics were the most common cause of a fatal outcome.¹ The National Institute of Drug Abuse surveys emergency department visits through its Drug Abuse Warning Network (DAWN), and in 2002 reported that a total of 4427 deaths resulted from drug abuse, with cocaine being the most commonly implicated agent.^{1,2}

However, these sources vastly underestimate the number of toxic events in humans. For example, reports of intoxicated patients who die from trauma, drowning, and fires are not consistently included in any national data set, nor are those of patients with medical complications from therapy, such as chemotherapy or anesthetics. Morbidity that results from chronic abuse (e.g., heart disease from cocaine or nicotine abuse and cirrhosis from alcohol abuse) or industrial exposures, and the long-term effects of environmental hazards, is not rigorously compiled and is probably impossible to quantify.

The most common causes of poisoning-related death in the United States have been carbon monoxide poisoning, cocaine use, and tricyclic antidepressant overdose.¹ Poisoning with analgesics, aspirin, and acetaminophen also remains a leading cause of death. Calcium channel blocker overdose has surpassed digitalis overdose as the most common cause of cardiovascular drug-related death.

DEFINITION

To *poison* means to injure or kill with a substance that is known or discovered to be harmful. Thus, the term *poisoning* connotes clinical symptomatology. It also

implies that the toxic exposure is unintentional (e.g., in the case of an elderly patient who misreads a drug label). In contrast, the term *overdose* implies intentional toxic exposure, either in the form of a suicide attempt or as inadvertent harm secondary to purposeful drug abuse. The terms *poisoning* and *drug overdose* often are used interchangeably, especially when prescription drugs are the agents, even though by definition a drug overdose does not produce poisoning unless it causes clinical symptoms.

Poisoning has a bimodal incidence, occurring most commonly in children who are 1 to 5 years of age and in the elderly. Overdose, whether motivated by suicidal intent or the result of abuse, occurs through adulthood. Toxic exposure in those between the ages of 6 and 12 years is uncommon; when it occurs, the patient must be assessed carefully to ensure that psychiatric follow-up is provided when indicated.¹

THE GENERAL APPROACH TO POISONING

The general approach to the poisoned patient can be divided into six phases: (1) stabilization; (2) laboratory assessment; (3) decontamination of the gastrointestinal tract, skin, or eyes; (4) administration of an antidote; (5) elimination enhancement of the toxin; and (6) observation and disposition.

Emergency Management

Because overdose patients are often clinically unstable when discovered, resuscitation with establishment of the airway, adequate support of ventilation and perfusion, and maintenance of all vital signs (including temperature) must be accomplished first. Continuous cardiac and pulse oximetry monitoring is essential. Rapid-sequence intubation (RSI) may be indicated in patients with an airway in jeopardy. Naloxone, 2 mg intravenously (IV); thiamine, 100 mg intravenously (IV); and 50% dextrose, 50 mL IV (if patients are shown on Dextrostix testing to be hypoglycemic) are generally given to all adults in coma, once an IV line has been established and appropriate blood studies have been performed.^{3,4} Maintenance of blood pressure and tissue perfusion may require the provision of volume, correction of acid-base disturbance, administration of pressor agents, and antidotal therapy. Table 2A-1 lists the common emergency antidotes.

TABLE 2A-1 Common Emergency Antidotes

POISON	ANTIDOTE	DOSE*	COMMENTS
Acetaminophen	N-acetylcysteine	140 mg/kg initial oral dose, followed by 70 mg/kg every 4 hr × 17 doses or intravenously as 150 mg/kg × 15 minutes then 50 mg/kg × 4 hr then 100 mg/kg × 16 hr	Most effective within 16–24 hr; may be useful after chronic intoxication
Atropine, anticholinergics	Physostigmine	Initial dose 0.5–2 mg (IV); children, 0.02 mg/kg	Can produce convulsions, bradycardia
Benzodiazepines	Flumazenil	0.2 mg (2 mL) (IV) over 15 sec; repeat 0.2 mg (IV) as necessary; initial dose not to exceed 1 mg	Limited indications; recommended only for reversal of pure benzodiazepine sedation
β blockers	Glucagon	Adult: 5–10 mg (IV) initially Child: 50–150 μg/kg (IV) initially Continuous infusion as needed	Stimulates cAMP synthesis, increasing myocardial contractility
Calcium channel blockers	Calcium chloride 10%	1 g (10 mL) (IV) over 5 min as initial dose; repeat as necessary in critical patients; doses up to 10 g may be necessary to restore blood pressure	Avoid extravasation; tissue destructive
	Insulin/glucose	0.5–1.0 U/kg initially then 0.5–1.0 U/kg/hr as needed to maintain systolic blood pressure	Monitor serum potassium and glucose
Carbon monoxide	Oxygen	1–3 atmospheres	Hyperbaric oxygen may be indicated
Cyanide	Amyl nitrite, then sodium nitrite, then sodium thiosulfate	Administer pearls every 2 min Adult: 10 mL of 3% solution over 3 min (IV) Child: 0.33 mL (10 mg of 3% solution)/kg over 10 minutes Adult: 25% solution, 50 mL (IV) over 10 minutes Child: 25% solution, 1.65 mL/kg	
Digitalis	Digoxin antibody fragments	Varies by patient weight, serum digoxin concentration, and/or dose ingested	
Hydrofluoric acid	Calcium	Topical exposure: Apply calcium gluconate gel; if pain is not relieved, administer 10% calcium gluconate 10 mL in 40 mL D ₅ W via IV (Bier block) infusion; if pain is not relieved, administer calcium gluconate by intra-arterial infusion over 4 hr Ingestion: 10% calcium gluconate (IV)	Monitor for hypocalcemia; treat electrolyte disturbances aggressively
Iron	Deferoxamine mesylate	Initial dose: 40–90 mg/kg (IV or IM), not to exceed 1 g; Infusion: 15 mg/kg hr (IV)	Higher infusion doses may be needed in severe overdose to achieve chelant excess; monitor and treat hypotension
Metals			
Mercury	British antilewisite (BAL), also known as dimercaprol	4–6 mg/kg IM, every 4–8 hr	Contraindicated if patient has a peanut allergy or G6PD deficiency
Arsenic			
Gold	DMSA (succimer), CaNa ₂ EDTA	10 mg/kg/dose, bid × 28 days 35–50 mg/kg/day (maximum 1.0–1.5g), bid or as a continuous infusion	Monitor liver function tests, add BAL if lead level > 70 μg/dL in children, > 100 μg/dL in adults
Lead			
Methanol	Ethyl alcohol	500 mg/kg of 10% ethanol, then continuous infusion of 100 mg/kg/hr	Watch for hypoglycemia, hypothermia, and lethargy in children; solution is hyperosmolar, requiring central venous catheter in children; maintain serum ethanol concentration at 100 mg/dL
	Fomepizole	15 mg/kg loading dose, 10 mg/kg every 12 hr IV	Significantly safer than ethanol
Nitrites (and other methemoglobin formers)	Methylene blue	1–2 mg/kg of 1% solution (IV) over 5 min	Can produce hemolysis in high dose; give no more than 7 mg/kg/day in adults, 4 mg/kg/day in children; severe or resistant cases may require exchange transfusion

Continued

**TABLE 2A-1 Common Emergency Antidotes (Cont'd)**

POISON	ANTIDOTE	DOSE*	COMMENTS
Opiates and opioids	Naloxone	Adults: 0.4–2.0 mg (IV or IM) Child: 0.01–0.1 mg/kg (IV or IM)	Larger doses may be necessary after severe overdose or overdose of synthetic agent, e.g., propoxyphene
	Nalmefene	Adult: 1 mg (IV) Child: 0.25 µg/kg (IV)	
Organophosphates, nerve agents Carbamates (severe exposure)	Atropine	Adult: 0.5–2 mg IV Child: 0.05 mg/kg Child: 0.05 mg/kg	Enormous doses of atropine may be needed in severe cases
	Pralidoxime (2-PAM)	Adult: 1 g (IV) then 500–1000 mg/hr as needed Child 15–40 mg/kg then 15–40 mg/kg/hr	Must be added to atropine if nicotinic or central symptoms are present
Tricyclic antidepressants	Sodium bicarbonate	Sodium bicarbonate 1–2 ampules (IV), bolus or infusion	Administer if QRS interval is ≥ 100 msec; maintain serum pH at 7.45–7.55; avoid severe alkalosis

cAMP, cyclic adenosine monophosphate; DMSA, dimercaptosuccinic acid; EDTA, ethylenediaminetetraacetic acid; G6PD, glucose-6-phosphate deficiency; IM, intramuscularly; IV, intravenously.

*Dosage listed may require modification or adjunctive therapy according to specific clinical conditions; see each specific chapter for details.

BOX 2A-1 CLINICAL CONDITIONS AND EXAMPLE AGENTS IN THE POISONED PATIENT THAT MAY NECESSITATE ENDOTRACHEAL INTUBATION

Corrosive ingestion (sodium hydroxide, sulfuric acid)
 Corrosive inhalation (ammonia, chlorine)
 Envenomation (hymenoptera, crotalid)
 Anaphylaxis (hymenoptera)
 Pulmonary edema (opioids, chemical weapons [e.g., choking agents])
 Bronchorrhea (organophosphates or nerve agents)
 Severe central nervous system (CNS) depression (ethanol, opioids, barbiturates)
 Cerebrovascular accident (cocaine)
 Seizures (isoniazid, theophylline)
 Aspiration (hydrocarbons)
 Hypercarbia (CNS depressants, nerve agents, botulism)

ADVANCED AIRWAY MANAGEMENT

In addition to basic airway management, many victims of poisoning require advanced management that includes endotracheal intubation. Clinical situations in which endotracheal intubation may be necessary in poisoned patients are numerous (Box 2A-1). Intubation offers the advantages of complete airway control, protection from aspiration of gastric contents, provision of a route for suctioning of secretions, and a means of optimizing both oxygenation and ventilation. However, the process of intubating an awake patient is difficult and is associated with potential adverse effects, including coughing, gagging, vomiting, tachycardia or bradycardia, hypertension, hypoxia, and increased intracranial pressure. Moreover, emergency intubation can be challenged by vocal cords that are obscured by secretions, unusual airway anatomy, a full stomach, or active vomiting.

Therefore, this task requires a thorough understanding of advanced airway management principles and of their application in a manner that prevents worsening of the clinical situation. RSI is a method of rapidly obtaining airway control with minimal physiologic disturbance. The process of RSI involves a patterned sequence of preparation, drug administration, intubation, and postintubation management.⁵⁻⁷

In the emergency department, RSI has historically had its greatest role in the patient with severe head trauma in whom intubation could exacerbate already increased intracranial pressure. However, because it is designed to blunt or prevent all adverse responses associated with endotracheal intubation, RSI is the ideal method of intubation in the poisoned patient. With the use of drugs having a short duration of action, RSI also is advantageous because it is a measure that permits temporary airway control for the patient with mildly compromised airway reflexes who requires gastrointestinal decontamination (lavage followed by activated charcoal administration) but who does not require prolonged intubation. RSI requires several essential steps that include the use of pharmacologic agents (Table 2A-2). To be performed safely, RSI must occur in the following sequence.

Evaluation

The clinician must first evaluate the patient's airway to determine the necessary equipment and the best technique for safe intubation. Particular attention should be directed to abnormalities in the cervical spine and temporomandibular joint because these will significantly impede rapid and uncomplicated intubation. If there is any question about the stability of the cervical spine, immobilization must be maintained. The oral cavity should be closely examined for the presence of foreign bodies.

TABLE 2A-2 Pharmacotherapy Used in Rapid Sequence Intubation

AGENT	DOSE*	
Pretreatment Agents		
Atropine	0.01–0.02 mg/kg (minimum, 0.1 mg; maximum, 1.0 mg)	
Lidocaine	1–2 mg/kg	
Sedatives and Anesthetics		
BARBITURATES		
Sodium thiopental	3–5 mg/kg	
Methohexital	1 mg/kg	
BENZODIAZEPINES		
Midazolam	0.1 mg/kg	
ETOMIDATE	0.1–0.3 mg/kg	
KETAMINE	1–2 mg/kg	
OPIOIDS		
Fentanyl	2–5 µg/kg	
PROPOFOL	2–4 mg/kg	
Skeletal Muscle Relaxants		
DEPOLARIZING AGENTS		
Succinylcholine	1–2 mg/kg	
NONDEPOLARIZING AGENTS		
	DEFASCICULATING DOSE	FULL DOSE
Pancuronium	0.01–0.05 mg/kg	0.1 mg/kg
Vecuronium	0.01–0.05 mg/kg	0.1–0.2 mg/kg
Atracurium		0.5 mg/kg
Rocuronium		0.5–1.0 mg/kg

*Doses listed are for intravenous administration.

Preparation

Before intubation, all necessary equipment must be present so that serious delays or unforeseen complications can be prevented. An IV line should be established and the patient connected to a cardiac monitor and pulse oximeter. The equipment necessary for endotracheal intubation is outlined in Box 2A-2. The proper functioning of all equipment should be ensured before it is used. Appropriate endotracheal tube size also should be determined (Table 2A-3). Unanticipated difficulties with intubation are common; “difficult airway” equipment (e.g., illuminated or fiberoptic-directed endotracheal tubes) should be kept close at hand.

Preoxygenation

Oxygen should be administered for 2 to 3 minutes before intubation; this produces a washout of nitrogen from the lungs, replacing this gas with an oxygen reservoir. The oxygen reservoir allows several minutes of apnea during which intubation can be performed without the risk of producing hypoxia. Assisted ventilation with bag-valve-mask apparatus should only be

BOX 2A-2 EQUIPMENT NEEDED FOR ENDOTRACHEAL INTUBATION

Syringe for endotracheal cuff inflation
 100% oxygen
 Face mask
 Bag-valve apparatus
 Suction equipment
 Catheter
 Yankauer suction tube
 Stylet
 Magill forceps
 Oral airway
 Nasopharyngeal airway (“trumpet”)
 Laryngoscope handle and blades
 Endotracheal tubes
 Tongue depressors
 Syringe for endotracheal cuff inflation
 Tape
 Tincture of benzoin

TABLE 2A-3 Age-Specific Endotracheal Tube Sizes

AGE	INTERNAL DIAMETER (mm)
Infant	
Premature	2.5
Full term	3.0
1–6 mo	3.5
6–12 mo	4.0
Child	
2 yr	4.5
4 yr	5.0
6 yr	5.5
8 yr	6.5
10 yr	7.0
Adolescent and Adult	
12 yr	7.5
≥14 yr	8.0–9.0

Accompanying principles:

1. Small sizes are necessary for nasotracheal intubation.
2. Endotracheal tubes two sizes smaller than age appropriate should be immediately available.

provided if the patient’s own respiratory efforts are inadequate because it risks inflation of the stomach, which increases the likelihood of vomiting. Patients who are breathing spontaneously should be given 100% oxygen by face mask for several minutes before intubation.

Pretreatment

Pretreatment involves the administration of pharmacologic agents that prevent adverse physiologic changes that may occur during intubation. Agents included in this category are lidocaine and atropine.

IV administration of the anesthetic lidocaine appears to blunt the increase in intracranial pressure that

accompanies intubation. Although scientific proof of lidocaine's efficacy is sparse, it is appropriate—particularly in the patient with suspected intracranial hypertension—to administer lidocaine, 1.0 to 2.0 mg/kg IV, 3 to 4 minutes before intubation.⁸⁻¹⁰

Bradycardia can accompany RSI in two circumstances. In young children, both posterior pharyngeal stimulation and administration of succinylcholine can result in severe bradycardia. Therefore, in children younger than 5 years, atropine should be administered before induction. The dose of atropine is 0.01 to 0.02 mg/kg (maximum, 1.0 mg). No less than 0.1 mg of atropine should be administered because smaller doses can produce paradoxical bradycardia.

Severe bradycardia can also occur in patients of any age who have been exposed to medications or toxins with negative chronotropic actions. For example, in patients who have ingested β antagonists (e.g., propranolol), calcium channel blockers, and digoxin, RSI can produce an abrupt decrease in heart rate or frank cardiac arrest. Therefore, in patients who are undergoing RSI after exposure to these agents, atropine should either be administered prophylactically or kept immediately available should emergency administration become necessary.

Induction

Induction consists of two components: administration of a sedative/anesthetic agent to produce unconsciousness, and the subsequent administration of an agent that produces complete skeletal muscle relaxation (paralysis); both actions facilitate intubation. Because administration of these drugs leads to apnea and paralysis, it is essential that induction proceed quickly and efficiently; this underscores the importance of having all intubation equipment immediately available and in working order.

A number of medications of different pharmacologic classes are used to produce sedation before skeletal muscle relaxation (see Table 2A-2). These drugs include benzodiazepines, opioids, barbiturates, propofol, etomidate, and ketamine. Among the benzodiazepines, midazolam, when given in a dose of 0.1 mg/kg IV (up to a range of 5 to 6 mg in an adult), is ideal because its effects are rapid in onset and short in duration. The drug also offers the advantage of producing muscle relaxation and amnesia. Opioids are another class of drugs that can be used; however, many opioids, such as morphine, may prompt histamine release, with resultant hemodynamic changes. Fentanyl in a dose of 2 to 5 μ g/kg is highly effective at producing rapid sedation and relaxation with minimal cardiovascular change. Several barbiturates can produce rapid sedation and relaxation. The most popular of these is sodium thiopental (dose 3 to 5 mg/kg). Equally effective but with a shorter duration of action are methohexital, propofol, and etomidate. Finally, ketamine is a dissociative anesthetic that can produce rapid onset of a state in which the patient is insensitive to pain but maintains an awake appearance and continues to have protective airway reflexes. The typical IV induction dose of ketamine is 1 to 2 mg/kg. Unlike other sedatives/

anesthetics, ketamine can produce significant elevations in pulse, blood pressure, intracranial pressure, and myocardial oxygen consumption, and such an increase in any of these could worsen the patient's clinical condition. Because ketamine has a potent bronchodilating effect, it retains its important role as an induction agent in the patient with severe bronchospasm.¹¹⁻¹³

After administration of a sedative/anesthetic, skeletal muscle relaxation is performed. Skeletal muscle relaxants, all of which interrupt acetylcholine function at the myoneural junction, are typically divided into depolarizing and nondepolarizing categories. Depolarizing agents, of which succinylcholine is the model drug, produce muscle depolarization before paralysis; this results in initial generalized muscle fasciculation. Nondepolarizing relaxants produce paralysis without initial depolarization. The nondepolarizing skeletal muscle relaxants include pancuronium, vecuronium, atracurium, and rocuronium.

Succinylcholine is the most popular muscle relaxant because it has several desirable properties, including a rapid onset of action (less than 1 minute) and an extremely short duration of action. Customary paralyzing doses of succinylcholine are 1 to 2 mg/kg IV.

Despite its efficacy and popularity, succinylcholine can produce several adverse effects. These include hyperkalemia, prolonged paralysis, malignant hyperthermia, and hemodynamic changes. Hyperkalemia, which can be severe, has been most commonly associated with administration of succinylcholine to those with burns, crush injuries, select neuropathies (e.g., Guillain-Barré syndrome), and myopathies (e.g., childhood muscular dystrophies). Prolonged paralysis can occur in those who have a genetic deficiency in serum cholinesterase, the enzyme that inactivates the drug. Prolonged paralysis may also occur in patients with liver disease, the elderly, and those who have ingested anticholinesterase insecticides (carbamates or organophosphates). Malignant hyperthermia is a syndrome characterized by muscle rigidity, hyperthermia, autonomic disturbances, acidosis, rhabdomyolysis, myoglobinuria, renal failure, and coagulopathy. Occurring in genetically predisposed individuals, malignant hyperthermia may appear without warning in those who are given inhalation anesthetics or succinylcholine. The mortality rate associated with this syndrome is approximately 5% to 10%. A malignant hyperthermia-like picture can also occur in children with skeletal muscular disorders (e.g., muscular dystrophy) who are given succinylcholine. Finally, succinylcholine-induced muscle depolarization can lead to transient increases in intracranial and intra-abdominal pressure, with accompanying changes in cardiac output.¹⁴ Because of these potential adverse effects, nondepolarizing muscle relaxants are often recommended as adjuncts to or substitutes for succinylcholine use. As adjuncts, nondepolarizing agents, when given before succinylcholine, can prevent muscle fasciculation and its attendant physiologic effects. The so-called "defasciculating dose" of a nondepolarizing agent is approximately one tenth the full dose of that agent. For example, pancuronium can be given in a dose of 0.01 mg/kg IV before the

administration of succinylcholine to prevent fasciculation. Nondepolarizing agents can also be used solely for skeletal muscle relaxation. However, they generally have a much slower onset of action (as long as 3 to 5 minutes) and produce a longer duration of paralysis. Also, many nondepolarizing agents stimulate histamine release, producing significant hemodynamic changes. Therefore, they are not ideal agents for RSI. Rocuronium appears to have the most rapid onset of all nondepolarizing agents, approaching that of succinylcholine with regard to time to complete muscle relaxation in the less than ideal conditions generally found during emergency intubation.¹⁵ Significant warnings to succinylcholine use in the pediatric population have been recently added, based on the possibility of life-threatening cardiac arrhythmias. According to these new warnings, children with undiagnosed myopathies (e.g., a muscular dystrophy) could develop hyperkalemia sufficient to produce a cardiac disturbance.¹⁶

Intubation

Suction must be immediately available when intubation is performed. The patient undergoing emergency intubation often has a full stomach; the risk for vomiting and aspiration is therefore significant. This risk is minimized both by the RSI technique and by the direct application of pressure on the cricoid cartilage (Sellick's maneuver), which occludes the esophagus. Adequate preoxygenation and limiting the duration of the intubation attempt to less than 20 to 30 seconds should prevent significant hypoxia.

The differences between the airway of the child and that of the adult have important implications for endotracheal intubation.

1. The child has a relatively large tongue; this makes direct visualization of the larynx difficult.
2. The child has larger tonsils, which also obscure visualization.
3. The infant's larynx is located more cephalad than that of the adult. As a result, the angle between the tongue and the glottis is more acute, and visualization of the larynx is impaired.
4. The subglottic area of the infant is the narrowest part of the larynx and may impede the passage of an endotracheal tube passed through the vocal cords.

Postintubation Management

Immediately after successful endotracheal intubation, placement of the endotracheal tube must be confirmed by detection of bilateral equal breath sounds on chest auscultation, end-tidal carbon dioxide monitoring, or chest radiography; of these, chest auscultation is the least sensitive method and should never be used in isolation to confirm endotracheal tube placement. After confirmation, the tube should be secured either with a strap or with benzoin and adhesive tape. Inflation of the endotracheal tube cuff should be performed to minimize aspiration of gastric contents (although aspiration of activated charcoal around cuffed endotracheal tubes is a

frequent occurrence). Until recently, because the airway of the young child has an area of narrowing ("physiologic cuffing"), cuffed endotracheal tubes were not used in the pediatric patient. Pediatric cuffed tubes are now available; their use is encouraged in most circumstances. If long-term intubation is necessary, sedatives/anesthetics and nondepolarizing muscle relaxants should continue to be administered.

In unskilled or unprepared hands, emergency endotracheal intubation can have disastrous consequences. Even when performed by the most experienced hands, this complex procedure can have complications that should be anticipated so that they can be quickly recognized and treated. These complications include:

- Dental or oral cavity trauma
- Gagging and vomiting
- Hypoxia
- Hypercarbia
- Bradycardia
- Tachycardia
- Hypertension
- Hypotension
- Increased intracranial pressure
- Pneumomediastinum
- Pneumothorax
- Cardiac arrhythmias
- Myocardial ischemia or infarction
- Aspiration
- Laryngospasm
- Esophageal intubation
- Tracheal injury

Circulatory Support

Poisoned patients often present to the emergency department with hypotension or frank shock. Provision of circulatory support through interventions that may include volume expansion, vasopressor therapy, antidote administration, and correction of electrolyte and acid-base disturbances is essential in initial management.

Many medications and toxins produce hypotension (Box 2A-3). Depending on the ingested substance, the low blood pressure may have a number of causes. For example, blood pressure depressions may occur from direct depression of myocardial contractility (e.g., quinidine), disturbances of central nervous system cardiorespiratory centers (e.g., clonidine), severe gastrointestinal fluid losses (e.g., acetaminophen, iron, arsenic, ricin, mushrooms), peripheral vasodilation (e.g., angiotensin-converting enzyme inhibitors), or a combination of these effects (e.g., theophylline, calcium channel blockers, tricyclic antidepressants). Hypotension also can result from the secondary effects of toxins (e.g., cocaine-induced myocardial infarction). Finally, blood pressure disturbances in the poisoned patient may represent accompanying trauma (e.g., severe spinal cord injury or internal hemorrhage). With the multitude of possible causes, the clinician, on the basis of the known pathophysiology of a particular drug and after having performed a thorough physical assessment, should determine, if at

all possible, the probable cause of hypotension if he or she is to provide a specific intervention.

VOLUME EXPANSION

Appropriate cardiac output relies on the adequacy of intravascular volume. After poisoning, intravascular volume may decrease abruptly. This decrease can be absolute, occurring as a result of a direct loss of intravascular volume (e.g., pulmonary edema, gastrointestinal pooling), or relative, resulting from severe peripheral vasodilation (e.g., angiotensin-converting enzyme inhibitor or α -antagonist overdose). In either case, hypotension should first be treated with the administration of volume-expanding agents.¹⁷

Many fluids are acceptable for emergency volume expansion. Normal saline and lactated Ringer's solution are generally the most readily available isotonic agents. Adults should receive up to 500- to 1000-mL boluses of isotonic fluid while blood pressure is monitored; children should be given 10 to 40 mL/kg. After the administration of each bolus, the patient should be reassessed for improvements in cardiac output.

Alternative fluids that can be used for volume expansion in the poisoned patient include albumin and whole blood. Each of these fluids has a role that is best determined by the pathophysiologic mechanism responsible for the hypotension. Being colloid rather than crystalloid in nature, these fluids in theory maintain intravascular volume better than saline solutions do. In clinical situations in which a "leaky capillary syndrome"

is mechanistically the source of intravascular volume loss, the use of colloid solutions may be preferred. Whole blood is most valuable in situations in which there is frank blood loss. With severe hemolysis (e.g., after arsine or stibine exposure), exchange transfusion with whole blood may be necessary.

Usually, the adequacy of volume expansion is determined clinically by an increase in blood pressure. Other clinical signs of improved cardiac output include resolution of cyanosis and normalization of capillary refill time. Central venous pressure and Swan-Ganz catheter monitoring, although invasive, provide the best evidence of appropriate intravascular volume.

Fluid overload is a potential complication of volume expansion. This is most likely to occur in patients who receive excess fluids over a short period of time. Also, after an overdose of a myocardial depressant such as tricyclic antidepressants or quinidine, a fluid bolus that could be tolerated by a healthy individual can produce pulmonary edema in the overdose patient. Therefore, administration of modest boluses of fluid is generally recommended; if cardiac output remains inadequate after fluids have been given, vasopressor therapy should be initiated.

VASOPRESSOR THERAPY

In the patient with severe hypotension, vasopressor therapy is necessary if blood pressure is not satisfactorily improved after volume expansion. Vasopressors are drugs that can be administered to maintain cardiac output. These agents have specific effects on the heart or blood vessels, augmenting myocardial function or increasing vasomotor tone, or both. With rare exception, vasopressors used in the acute management of hypotension are short-acting drugs that must be given by continuous IV infusion.¹⁷

Vasopressors generally act at adrenergic (α and β), D (dopamine), or glucagon receptors (Table 2A-4). The adrenergic system has been further defined with the recognition of two major α -adrenergic receptor subtypes (α_1 and α_2) and three β -adrenergic receptor subtypes (β_1 , β_2 , and β_3). Coupled with intracellular G proteins, these membrane-bound receptors effect an intracellular chain of events that includes changes in the activity of adenylate cyclase. This action goes on to modulate the level of intracellular cyclic adenosine monophosphate (cAMP), which in turn alters phospholipase activity or opens gated calcium channels. Although the cellular mechanisms of this system have become much better defined, the general principles of vasopressor action remain unchanged. For example, α -adrenergic receptor agonists produce vascular smooth muscle contraction. β_1 -Adrenergic receptor agonists produce increased heart rate and contractility, whereas β_2 -adrenergic receptor agonists promote generalized smooth muscle relaxation (including bronchial and vascular). Vasopressor therapy is designed to improve cardiac output through manipulation of the specific receptor most appropriate for the clinical situation. A number of vasopressors can be used to provide blood pressure support (see Table 2A-4). The

TABLE 2A-4 Common Vasopressors by Dose Range and Mechanism of Action

AGENT	RECEPTOR TYPE			
	α -ADRENERGIC	β_1 -ADRENERGIC	β_2 -ADRENERGIC	DOPAMINERGIC

indications for the use of these drugs vary slightly, depending on the clinical circumstance.

Epinephrine

Epinephrine elevates blood pressure primarily through its α -adrenergic-stimulating properties. This effect also is valuable in improving myocardial and cerebral blood flow. Because it also has prominent β -adrenergic agonist effects, epinephrine is variably effective at producing marked increases in blood pressure. Epinephrine therapy is initiated at a dose of 0.1 to 0.5 $\mu\text{g}/\text{kg}/\text{min}$. Epinephrine is particularly effective in intoxications associated with hypotension and bronchospasm (e.g., Hymenoptera envenomation and anaphylactic reactions).

Norepinephrine

Norepinephrine stimulates both α - and β -adrenergic receptors, with slightly greater stimulation of α -adrenergic receptors. The effect is improved vasomotor tone in conjunction with increased myocardial chronotropy and inotropy. Norepinephrine infusions are typically initiated in a dose of 0.1 to 0.5 $\mu\text{g}/\text{kg}/\text{min}$.

Dopamine

Dopamine is a precursor of norepinephrine. The most popular of vasopressors, dopamine appears to have at least three mechanisms of action: (1) promotion of norepinephrine synthesis, (2) a tyramine-like effect that stimulates release of preformed norepinephrine, and (3) direct stimulation of vascular dopamine receptors.

The cardiovascular effects of dopamine are variable, depending on the infusion rate. At relatively low doses (1 to 2 $\mu\text{g}/\text{kg}/\text{min}$), the drug dilates renal and mesenteric vessels without marked increases in heart rate or blood pressure. At doses of 2 to 10 $\mu\text{g}/\text{kg}/\text{min}$, β -adrenergic receptor stimulation predominates, producing significant increases in cardiac output. Finally, at doses greater than 10 $\mu\text{g}/\text{kg}/\text{min}$, α -adrenergic receptor stimulation is the primary action, resulting in marked

peripheral vasoconstriction. The general dose range for dopamine infusion is 2 to 20 $\mu\text{g}/\text{kg}/\text{min}$.

Dopamine is safe and effective for any type of drug-induced hypotension. In the past, there have been theoretic concerns that dopamine's β -adrenergic effect in the face of phenothiazine or tricyclic antidepressant intoxication would increase the peripheral vasodilatation associated with overdose, exacerbating hypotension. However, experimental data and clinical experience have failed to confirm this adverse effect from dopamine use. Also, with hypotension after monoamine oxidase inhibitor overdose, dopamine's effects are somewhat unpredictable; it may be relatively ineffective (owing to the lack of preformed norepinephrine), or it can produce an exaggerated response (because of its tyramine-like action).

Dobutamine

Dobutamine is a synthetic catecholamine with almost exclusive β -adrenergic receptor-stimulating effects. Its primary mechanism of blood pressure improvement is direct myocardial inotropy; thus, reflex peripheral vasodilation may occur with its use. Unlike dopamine, dobutamine does not release preformed norepinephrine. The usual dosage range for dobutamine is 2 to 20 $\mu\text{g}/\text{kg}/\text{min}$, although doses as high as 40 $\mu\text{g}/\text{kg}/\text{min}$ have been used. High-dose infusions often increase myocardial oxygen demands, which, if unmet, can result in myocardial ischemia. Nonetheless, dobutamine is extremely effective in syndromes of heart failure.

Phenylephrine

Phenylephrine has both α - and β -adrenergic receptor-stimulating properties, although its α -adrenergic receptor actions predominate. Phenylephrine is a potent stimulator of vasomotor tone; it is therefore very effective in patients in hypotensive states resulting from severe peripheral vasodilation (e.g., following overdose with an α -adrenergic antagonist, such as prazosin or a phenothiazine neuroleptic, e.g., chlorpromazine). Phenylephrine

infusions are given in a typical dose range of 0.1 to 0.5 $\mu\text{g}/\text{kg}/\text{min}$.

Amrinone

Amrinone is a novel, nonadrenergic cardiac stimulant that improves myocardial contractility while inducing vasodilation. Its mechanism of action appears to be direct inhibition of phosphodiesterase; the result of this is increased intracellular cAMP activity, an action that increases transmembrane calcium flux, potentiating cardiac chronotropy and inotropy. Amrinone's effects have been compared with those of dobutamine and nitroprusside combination therapy. Amrinone may be particularly valuable in the treatment of calcium channel blocker intoxication; its inhibition of cAMP breakdown results in greater phosphorylation of L-type calcium channels, potentially increasing their permeability. Experimental data support its role in this specific poisoning.¹⁸ Amrinone can be used to treat syndromes of left ventricular failure but should not be administered in the presence of myocardial ischemia; like dobutamine, it may increase myocardial demands, resulting in infarction. Because of its potent vasodilating action, amrinone may cause a hypotensive response in those with low intravascular volume. The usual dosage range for this agent is 5 to 15 $\mu\text{g}/\text{kg}/\text{min}$; the total daily dose should not exceed 10 mg/kg per day.

Glucagon

Glucagon is a single-chain pancreatic polypeptide that is an effective inotropic and chronotropic agent. Its mechanism of action is direct stimulation of myocardial glucagon receptors; these receptors, when stimulated, increase the formation of myocardial cAMP. The resultant effect is positive inotropy and, to a lesser degree, positive chronotropy. Glucagon is theoretically most effective after β blocker overdose, in which decreased β -adrenergic receptor activation leads to diminished cAMP production. The hormone may also provide therapeutic benefit in hypotension after calcium channel blocker overdose.¹⁸ Glucagon is given in an initial dose of 1 to 10 mg (50 to 150 $\mu\text{g}/\text{kg}$ in children). If effective in augmenting blood pressure, it can be given as a continuous infusion of 5 to 10 mg/hr (100 $\mu\text{g}/\text{kg}/\text{hr}$ in children). Some preparations of glucagon are marketed as a lyophilized compound with a 0.2% phenol-based diluent for reconstitution. While single doses of such a product can be given after standard reconstitution, glucagon for continuous infusion should be reconstituted with saline to prevent phenol toxicity. Adverse effects from glucagon include hyperglycemia, nausea, vomiting, and ileus.

Calcium

Calcium plays a key role in regulating cardiac inotropy through its binding to troponin C, an action that permits interaction between actin and myosin. Although most of the calcium that produces this change resides in an intracellular calcium pool, extracellular calcium does diffuse into cells and contributes to increased contractility. Although diffusion of calcium into the myocardium is “gated”—that is, it is tightly controlled—high con-

centrations of extracellular calcium, particularly in the face of channel blockade (e.g., after overdose of calcium-channel blockers), sometimes improve contractility. Administration of IV calcium chloride is indicated in the management of hypotension resulting from calcium channel blocker overdose (see Table 2A-1), hyperkalemia, and hypocalcemia.

Clinical Evaluation

A thorough history taking and physical examination are essential to the diagnosis of the toxic patient. Poisoning should be suspected in any patient who presents with multisystem disturbance until proven otherwise. Although the initial manifestations of poisoning are myriad, a patient with acute poisoning often presents with coma, cardiac arrhythmia, seizures, metabolic acidosis, or gastrointestinal disturbance, either together as symptom complexes or as isolated events. Symptom complexes, or toxidromes (Table 2A-5), may give clues to an unknown poisoning. For example, a patient with a history of depression who presents with coma, seizures, a widened QRS complex or evidence of dysrhythmia on electrocardiography, and dilated pupils has likely taken a tricyclic antidepressant. Hepatic, renal, respiratory, and hematologic disturbances are generally delayed manifestations of poisoning.

The clinical evaluation, in addition to the history taking and physical examination, includes an assessment of major signs of toxicity presented by the patient and evaluation of the laboratory data.

HISTORY

When one suspects poisoning or drug overdose, the primary goal of history taking is identification of the toxic agent. Sometimes diagnosis is easy, as in the case of the toddler who ingests iron tablets in the mother's presence. Sometimes it is difficult, as in the case of the patient who is hiding a history of drug abuse and passes out at work or who has an unexpected seizure. Prior medical or psychiatric history, current medications, and allergies should be obtained from family or friends if the patient is unable to relate the information. The following questions may be revealing:

- What other medicines are in the house?
- What was the patient doing that day?
- Does the patient live alone, did he or she just lose a job, or have there been recent emotionally traumatic events?
- Is the patient eating a special diet or taking a new health food, alternative medication, or performance enhancer?
- Could the patient inadvertently have taken too much of a prescribed medication?
- If it can be identified, is the substance nontoxic? (See Box 2A-4.)

PHYSICAL EXAMINATION

The physical examination can help in determining the extent of poisoning and may reveal the presence of a

TABLE 2A-5 Examples of Symptom Complexes, or Toxidromes

TOXIDROME OR COMPLEX	CONSCIOUSNESS	RESPIRATIONS	PUPILS	OTHER	POSSIBLE TOXIC AGENT/MECHANISM
Cholinergic	Coma	↑↓	Pinpoint	Fasciculations Incontinence Salivation Wheezing Lacrimation Bradycardia	Organophosphate insecticides, carbamates, nicotine
Anticholinergic	Agitation, hallucinations, or coma	↑	Dilated	Fever, flushing Dry skin and mucous membranes Urinary retention	Anticholinergics (atropine, Jimson weed, antihistamines)
Opioid	Coma	↓	Pinpoint	Track marks Hypothermia Hypotension	Opiates, opioids
Extrapyramidal	Wakefulness	↑	—	Torsion of head/neck	Phenothiazines, haloperidol, risperidol
Tricyclic antidepressant	Coma (initially, agitation)	↓	Dilated	Cardiac arrhythmia Convulsions Hypotension Prolonged QRS interval	Tricyclic antidepressants
Sedative/hypnotic	Coma	↓	Midsized or small	Hypothermia Decreased reflexes	Sedatives, barbiturates
Salicylates	Agitation or lethargy	↑	Midsized or small	Hypotension Diaphoresis Tinnitus Alkalosis (early) Acidosis (late)	Aspirin, oil of wintergreen
Sympathomimetic	Agitation, hallucinations	↑	Dilated	Seizures Tachycardia Hypertension Diaphoresis Metabolic acidosis Tremor Hyperreflexia	Cocaine Theophylline Amphetamines Caffeine

BOX 2A-4 NONTOXIC INGESTIONS

Abrasives	Elmer's glue	Petroleum jelly (Vaseline)
Adhesives	Fabric softeners	Play-Doh
Antacids	Fish bowl additives	Polaroid picture coating fluid
Antibiotics	Glues and pastes	Putty (less than 2 oz)
Baby product cosmetics	Hand lotions and creams	Rubber cement
Ballpoint pen inks	3% hydrogen peroxide	Sachets (essential oils, powder)
Bath oil (castor oil and perfume)	Incense	Shampoos (liquid)
Bathub floating toys	Indelible markers	Shaving creams and lotions
Birth control pills	Ink (black, blue)	Soap and soap products
Bleach (<5% sodium hypochlorite)	Iodophil disinfectant	Spackles
Body conditioners	Laxatives	Suntan preparations
Bubble bath soaps (detergents)	Lipstick	Sweetening agents (aspartame)
Calamine lotion	Lubricant	Teething rings
Candles (beeswax or paraffin)	Magic Markers	Thermometers (mercury)
Chalk (calcium carbonate)	Makeup (eye, liquid, facial)	Toothpaste with or without fluoride
Colognes	Matches	Toy pistol caps (potassium chlorate)
Cosmetics	Mineral oil	Vitamins with or without fluoride
Crayons marked AP, CP	Modeling clay	Watercolors
Dehumidifying packets (silica or charcoal)	Newspaper	Zinc oxide
Deodorants	Pencil (graphite lead, coloring)	Zirconium oxide
Deodorizers, spray and refrigerator	Perfumes	

Nontoxic is defined as producing little to no toxicity when ingested in small amounts.

**TABLE 2A-6** Important Clues on Physical Examination

CLINICAL FINDING	DIAGNOSTIC EXAMPLE
Needle tracks	Intravenous drug abuse
Characteristic odor of breath	Gasoline
Destruction of nasal mucosa/cartilage	Cocaine abuse
New significant heart murmur	Infective endocarditis
Pulmonary edema	Heroin abuse
Boardlike abdomen	Black widow spider bite
Salivation and lacrimation	Organophosphates
"Boiled lobster" skin	Boric acid poisoning

toxic syndrome, of any underlying disease, or concomitant trauma. Repeated assessment, especially of vital signs and of cardiac, pulmonary, and neurologic status, is critical to proper management of the toxicologic patient. The physical examination also can provide valuable clues as to the particular toxin involved (Table 2A-6).

Vital Signs

As part of the initial evaluation, complete determination of vital signs, including measurement of body temperature initially and throughout the emergency department assessment, is mandatory. Obtaining a core body temperature measurement may be necessary. Hyperthermia can occur with a number of ingestions and in infectious illness, but it is characteristic of poisoning with salicylates, anticholinergics, monoamine oxidase inhibitors, and dinitrophenol; it is occasionally also seen after intoxication with phencyclidine, LSD, or cocaine, especially following seizures. Life-threatening malignant hyperthermia following drug overdose may occur. Hypothermia is common and may occur because of exposure to cold, hypoglycemia, or overdose of a number of sedatives, especially barbiturates, ethanol, carbamazepine, narcotics, and phenothiazines. Bradycardia can be seen with overdose of digitalis, cholinergic agents, β blockers, and calcium channel blockers, but it also may be seen with hypothermia or spinal cord trauma. Hypertension is characteristic of intoxication with cocaine, amphetamines, phencyclidine, and sympathomimetics.

Skin

The skin should be examined for needle tracks, burns, bruises, or lacerations. Needle tracks may be confined to the groin or other areas that are not readily visible. A "boiled lobster" appearance suggests ingestion of a boric acid-containing roach powder insecticide. Generalized flushing suggests an allergic reaction, niacin overdose, anticholinergic poisoning, scombroid fish poisoning, or an alcohol-disulfiram reaction.

Diaphoresis suggests hypoglycemia, salicylate or organophosphate poisoning, hyperthyroidism, drug or alcohol withdrawal, or shock from cardiac or other etiology. Jaundice may follow overdose of acetaminophen, aspirin, iron, carbon tetrachloride, mushrooms, copper, or phosphorus. Petechiae and ecchymoses suggest coumadin overdose. Bullae may be secondary to skin

hypoxia or prolonged pressure and are seen after sedative-hypnotic overdoses (especially barbiturate overdose), carbon monoxide poisoning, and thermal burns. Bullae may also follow rattlesnake envenomation. Bullous lesions or soft tissue swelling should prompt evaluation for rhabdomyolysis, an occasional finding in patients following prolonged coma or severe hyperthermia, such as in cocaine abuse.

Breath

It is important to smell the patient's breath. Alcohol is the most common odor detected on the breath of an intoxicated patient in the emergency department. The accurate identification of other odors varies greatly among physicians. A fruity odor may be detectable in the patient with diabetic ketoacidosis. Cyanide poisoning can be associated with the smell of almonds. The smell of cleaning fluid suggests carbon tetrachloride poisoning. Gasoline, camphor, hydrogen sulfide, ether, turpentine, methyl salicylate, paraldehyde, phenol, and organophosphate insecticides all have characteristic odors. Arsenic and tellurium intoxication is associated with the odor of garlic.

Ear, Nose, and Throat

A nasal examination may reveal chronic insufflation of cocaine. An edematous, often elongated uvula may be seen with marijuana use or exposure to corrosive agents.

Lungs

Auscultation of the lungs may provide diagnostic clues. In narcotic or tricyclic antidepressant overdose, pulmonary edema may be a complication, leading to the appearance of adventitious noises. In all overdose patients, aspiration pneumonitis, the result of a depressed gag reflex, is a possibility. Inhalation of toxic gases may produce wheezing and pulmonary compromise. Pneumothorax may be detected in patients who smoke cocaine, methamphetamine, or any other heated, impure substance. Mediastinal emphysema from marijuana or crack cocaine smoking also may be detected by auscultation.

Heart

Examination of the heart may reveal a new murmur, which in an intravenous drug abuser suggests endocarditis. Bradycardia is common after the overdose of four classes of cardiac agents: calcium channel blocker, β blocking agents, digitalis preparations, and central α_2 antagonists (e.g., clonidine or guanfacine). A ventricular arrhythmia on electrocardiography in a young patient suggests cocaine toxicity. An irregularly irregular heartbeat that is new in a patient on an alcoholic binge suggests atrial fibrillation—the so-called "holiday heart" syndrome.

Abdomen

A boardlike abdomen in a patient with a history of spider bite is characteristic of black widow envenomation. Examination of the abdomen in an overdose patient often reveals an adynamic ileus. In patients with abdominal pain, a surgical abdomen must be ruled

out. Hepatomegaly suggests liver congestion (e.g., with pyrrolizidine toxicity).

Neurologic Assessment

All patients should undergo a careful neurologic examination. Issues of major concern are concomitant head trauma and spinal cord trauma in comatose patients. Serial neurologic examinations are key to proper assessment (see discussion of coma in section on Level of Consciousness).

Extremities

The extremities should be evaluated to detect thrombophlebitis, fracture or dislocation, or vascular insufficiency. Rhabdomyolysis and the compartment syndrome are definite concerns in overdose patients, especially in those with prolonged coma or underlying trauma.

ASSESSMENT OF MAJOR SIGNS OF TOXICITY

The toxicologic patient presenting in the acute setting often exhibits the following, either alone or in combination: coma, cardiac arrhythmia, metabolic acidosis, gastrointestinal disturbance, and seizures.

Level of Consciousness

Consciousness is defined as an awareness of self and the environment. Coma is unarousable unresponsiveness. Wakefulness implies the ability to be aroused. These three functional states are mediated by the ascending reticular activating system, a tract that courses through the diencephalon, midbrain, and pons. Diseases produce coma either by diffusely affecting the brain or by encroaching upon the brainstem. Coma may be produced by (1) a supratentorial mass lesion, such as a subdural hematoma; (2) a brainstem lesion (uncommon); or (3) metabolic disorders that widely depress or interrupt brain function.

One of the most common manifestations of acute poisoning is coma. The principles of coma management are relatively straightforward. Patients in coma must be stabilized initially by establishment of an airway, proper oxygenation with continuous pulse oximetry, insertion of an IV line with normal saline, and resuscitation, if necessary (see earlier section on Emergency Management). The clinical evaluation of the comatose patient is invaluable not only in determining the depth of coma and assessing for trauma, but also in providing a baseline for repeated clinical assessment. Coma can be assessed either using the simple AVPU (Alert, responsive only to Verbal stimuli, responsive only to Painful stimuli, Unresponsive) or Glasgow coma scales.

The major causes of coma in patients seen in the emergency department include poisoning (e.g., carbon monoxide poisoning), drug overdose, head trauma, cerebrovascular accident, anoxia, infection (e.g., meningitis), and diabetes and other systemic disorders such as renal failure, hepatic coma, and cardiac arrhythmia. The physician must rule out each condition before establishing the diagnosis of poisoning.

Supratentorial structural lesions are suggested by a rapid progression of signs, including changes in

respiratory pattern, disconjugate gaze, lateralizing signs, or loss of doll's eyes movements.

A metabolic cause of coma may be indicated by the persistence of the pupillary light reflex; a depression of respiration and consciousness more pronounced than other neurologic signs; preceding altered mental states; asterixis or fasciculations, or both; the presence of a ciliospinal reflex; and extracranial signs, such as jaundice. Repeated assessment of the comatose patient is critical to proper management of poisoning.

Pupils

Evaluation of the patient's pupils is most helpful. Midpoint fixed pupils or a unilateral dilated pupil suggests a structural lesion. Pinpoint pupils suggest overdose of opiates, clonidine, organophosphate insecticides, nerve agents (e.g., sarin), chloral hydrate, phenothiazines, or nicotine. Dilated pupils are nonspecific.

Ocular Movements

A disturbance of ocular movements (e.g., loss of doll's eyes movements) suggests a structural lesion. *Nystagmus* suggests intoxication with phenytoin, phencyclidine, carbamazepine, and, occasionally, ethanol.

Respirations

It is important to note abnormal patterns of breathing. Posthyperventilation apnea, Cheyne-Stokes respirations, and apneustic breathing strongly suggest that a structural lesion is the cause of the patient's coma. Central neurogenic hyperventilation is a classic presentation of brainstem injury. Kussmaul breathing can occur after salicylate or dinitrophenol poisoning. Compensatory hyperventilation may accompany methanol or ethylene glycol poisoning or other toxin-producing metabolic acidosis. Respiratory arrest is a common presentation in the patient who has taken a central nervous system depressant and may lead to multisystemic dysfunction resulting from severe hypoxic injury.

Motor Function

Decorticate and decerebrate posturing suggests a structural lesion. It is important to realize that patients with poisoning or drug overdose (e.g., tetrodotoxin intoxication) may appear brain dead; have fixed, dilated pupils; be in an unresponsive coma; and lack the cold caloric response, yet recover fully in time.

CARDIAC ARRHYTHMIA

A 12-lead electrocardiogram and continuous cardiac monitoring are essential for any patient with significant poisoning. Evidence of an arrhythmia or other important diagnostic clues may be present on electrocardiography, such as a widened QRS complex in cyclic antidepressant overdose or a prolonged QT interval in trazadone or arsenic poisoning overdose. Box 2A-5 lists common toxic causes of cardiac arrhythmia.

The patient with life-threatening cardiac arrhythmia or cardiac arrest should be managed on the basis of the general principles of resuscitation and the American Heart Association's advanced cardiac life support

BOX 2A-5 COMMON TOXIC CAUSES OF CARDIAC DISTURBANCES
Conduction Disturbances
Prolonged PR Interval

Digoxin and other digitalis compounds
Lithium

Prolonged QRS Interval

Chloroquine, quinine, quinidine, and related compounds

Calcium channel blockers
Carbon monoxide
Clonidine
Cocaine
Theophylline

(ACLS) guidelines. If cyclic antidepressant overdose is suspected, administration of IV sodium bicarbonate is indicated for correction of ventricular arrhythmia or conduction disturbances. Sodium bicarbonate may also be effective in the treatment of other overdose by other agents associated with prolongation of the QRS interval, including diphenhydramine and cocaine. Administration of IV calcium chloride is the primary therapeutic measure for calcium channel blocker overdose. Use of digoxin antibody fragments is indicated for digitalis poisoning, and glucagon for β blocker overdose (see Table 2A-1). In referred patients who have already been hospitalized elsewhere, ventricular arrhythmia may be due to hyperkalemia because renal failure may have ensued; in such patients, IV sodium bicarbonate, glucose/insulin, and, if necessary, calcium chloride administration may be warranted. Magnesium has a singular role in the treatment of drug-induced prolongation of the QT interval, a conduction disturbance that is often the prelude to torsades de pointes and other life-threatening disturbances.¹⁹ In all intoxicated patients, correction of hypoxia, metabolic acidosis, and fluid and electrolyte disturbance serves to reduce the incidence of cardiac arrhythmias.

BOX 2A-6 CAUSES OF A HIGH-ANION GAP METABOLIC ACIDOSIS

Iron
Isoniazid
Lactic acidosis
Metformin
Methanol
Salicylates
Uremia

METABOLIC ACIDOSIS AND DISTURBANCES IN SERUM OSMOLALITY

Causes of a high-anion gap metabolic acidosis are listed in Box 2A-6. The assessment of metabolic acidosis includes not only arterial (or, less ideally, venous) blood gas analysis, but also studies of serum sodium, potassium, chloride, carbon dioxide, blood urea nitrogen (BUN), creatinine, glucose, acetone, serum osmolality, and urine pH, as well as urinalysis. Determination of the anion gap is helpful in the diagnosis and management of poisoning.

The clinician can measure serum osmolality either directly by determining the freezing point (osmometry) or by calculation. The formula for calculating osmolality is

$$\text{Serum osmolality} = 2 \times \text{Na}^+ (\text{mEq/L}) + \text{BUN} (\text{mg/dL})/2.8 + \text{Glucose} (\text{mg/dL})/18$$

When laboratory data are expressed in international (SI) units, the formula for calculation of serum osmolality simply equals $2 \times \text{Na} + \text{BUN} + \text{glucose}$. The normal serum osmolality is 280 to 295 mOsm/L. An osmometer measurement indicating a serum osmolality that is more than 10 mOsm/L greater than the calculated osmolality is termed an osmolar gap; it suggests the presence of an osmotically active substance that is not accounted for by the calculated osmolality. Causes of an osmolar gap are listed in Box 2A-7. The most common cause of an osmolar gap is consumption of an alcohol. The osmolar gap can be used to estimate the serum concentration of an alcohol, based on that alcohol's molecular weight (Table 2A-7). A substance contributes to osmolality only if it achieves relatively high blood levels and has a low molecular weight. Most drugs or intoxicants cannot be detected with use of the osmolar gap.

GASTROINTESTINAL DISTURBANCE

The causes of toxic gastrointestinal disturbance are many. The patient with iron, arsenic, or ricin poisoning has severe, repeated episodes of vomiting and may develop gastrointestinal hemorrhage. Theophylline overdose also causes persistent retching. Acute lithium and arsenic poisoning characteristically produce massive diarrhea. Patients with acute mercury poisoning have a mucous-type diarrhea, with the subsequent development

of hemorrhagic colitis. One of the most striking presentations is caused by phosphorus poisoning, which produces luminescent vomitus and flatus. The early presentation of organophosphate or nerve agent exposure is similar to that of acute gastroenteritis and is characterized by abdominal cramps, vomiting, and diarrhea, with subsequent development of neurologic signs. Poisoning from mushrooms (see Chapter 23), toxic marine life (see Chapter 25), botulism, and food (see Chapter 26) should be included in the differential diagnosis. Chemotherapeutic agents (see Chapter 56) are well-known causes of toxic gastroenteritis.

The management of gastrointestinal disturbance in the toxic patient includes following the general principles of blood, fluid, and electrolyte resuscitation, when indicated; judicious use of parenteral antiemetics to control persistent vomiting; specific measures such as antidotal therapy (e.g., in iron or organophosphate poisoning); or interventional therapy, such as charcoal hemoperfusion (in theophylline overdose) or hemodialysis (in lithium overdose), when indicated.

SEIZURES

Common agents that cause seizures are listed in Box 2A-8. Almost any drug or toxin is capable of producing a seizure. Delayed seizures occurring during a recovery period may be a sign of sedative-hypnotic or alcohol withdrawal.

Seizures should be managed first with establishment of an airway and oxygenation. Patients with a simple isolated seizure may require only observation and supportive care, whereas repetitive seizures or status epilepticus, which can be life threatening, must be managed aggressively. Some seizures are particularly difficult to control, such as those seen with theophylline or cocaine overdose.

The standard regimen for seizure control in overdose of an unknown agent is use of the full therapeutic dosages of benzodiazepines (e.g., diazepam or lorazepam), followed by administration of phenytoin or a barbiturate (e.g., phenobarbital or pentobarbital). In patients with status epilepticus, RSI may be necessary and the use of thiopental is indicated, with electroencephalographic monitoring to ensure control of electrical seizure activity; the use of additional paralytics, such as pancuronium bromide, may be warranted.

Specific measures to control seizures may be indicated, such as administration of pyridoxine for isoniazid-induced seizures.

LABORATORY EVALUATION

Box 2A-9 lists specific blood studies whose results may be used for diagnosis and to direct therapy of the overdose patient. In every significant poisoning, routine studies include a complete blood count; determination of serum electrolytes, glucose, BUN, creatinine, and calcium; urinalysis; prothrombin time; pulse oximetry; end-tidal CO₂ monitoring, and 12-lead electrocardiography. Arterial blood gas analysis is necessary for evaluating respiratory status and acid-base abnormalities, particularly in the comatose or seizure patient. The measurement of serum salicylate and acetaminophen levels is generally added in the case of the patient with overdose of an unknown substance, because these agents are often co-ingestants or are contained in combination drugs. Measurement of hepatic enzymes is important in the evaluation of acetaminophen toxicity. The advantage of a toxicologic drug screen in initial management is equivocal. Box 2A-10 gives a partial list of drugs and toxins not commonly

BOX 2A-9 TOXICOLOGIC BLOOD STUDIES THAT MAY DIRECT THERAPY

 Mushrooms
 Venoms

detected with routine drug screening. Further laboratory blood studies are tailored to assess the individual diagnostic and therapeutic needs of the patient.

It is extremely important to remember to “treat the patient, not the lab.” One should never withhold therapy while waiting for a confirmatory drug level in a critical patient, such as a patient with tricyclic antidepressant overdose who is exhibiting a widened QRS complex. In contrast, performing hemodialysis on a completely asymptomatic patient with lithium overdose on the basis of one test result indicating an elevated serum lithium concentration would be equally unwise.

Serial blood level determinations are often helpful in guiding therapy in patients undergoing hemodialysis; in patients in whom concretions have formed, such as those with barbiturate, iron, salicylates, or meprobamate intoxication; or in patients receiving antidotal therapy (e.g., serial measurement of lead level is useful in patients receiving IV CaNa_2EDTA for management of lead poisoning).

A urinalysis is necessary. Performing a urine pregnancy test is wise in all women of childbearing age. Urine

 Drug packets

pH monitoring is helpful in the management of salicylate overdose. Urine is the best specimen to use for “drug screening” purposes. A urinalysis is also useful in the early identification of acute renal failure or rhabdomyolysis with myoglobinuria.

The intravenous drug abuser requires special blood testing, such as evaluation for human immunodeficiency virus, a hepatitis profile, a blood culture to identify bacteremia, and evaluation for rhabdomyolysis.

Chest radiography is an aid for diagnosing aspiration pneumonia or pulmonary edema. Box 2A-11 lists agents that are radiopaque on plain film radiography of the abdomen. Computed tomography may be useful if underlying trauma is suspected. Finally, lumbar puncture may be indicated for ruling out meningitis in a patient with fever and coma.

Decontamination of the Eyes, Skin, and Gastrointestinal Tract

OCULAR DECONTAMINATION

See Chapter 15.

DERMAL DECONTAMINATION

Being the largest and most superficial organ in the body, the skin is often subject to exposure to toxins and is affected in 7.9% of reported cases. At least 50% of occupational illnesses involve the skin. The effects of these exposures can be local or systemic (Box 2A-12).

The skin provides many barriers to the absorption of toxins. The stratum corneum forms an important first barrier and is highly effective when it is completely intact. However, when skin wounds are present, when the wounds are wet, and when exposure is to certain highly lipophilic substances (e.g., organophosphate insecticides), significant absorption of toxin through the skin can occur. The skin of infants is notable for being more permeable than that of adults to substances of all classes.

BOX 2A-12 TOXINS ASSOCIATED WITH SYSTEMIC TOXICITY AFTER DERMAL ABSORPTION

Aniline dyes
 Camphor
 Dinitrophenol
 Hexachlorophene
 Hydrofluoric acid
 Lindane (γ -benzene hydrochloride)
 Organophosphate insecticide
 Nerve agents
 Nitrobenzene
 Organic mercury
 Phenol
 Thallium

The range of dermal toxins is broad. Most of these substances are corrosive agents capable of producing burns that may become full thickness (i.e., third degree). Other types of agents are irritants, sensitizers (including photosensitizers), allergens, vesicants, and exfoliants.

Management

As with ocular exposures, the general principles of management after exposure to dermal toxins are many. As soon as a toxic dermal exposure is recognized, decontamination efforts should begin. If the victim is immersed in a toxic fluid, the first step in management is his or her extrication without injury to the assistant. The victim should disrobe him- or herself at the scene. If the victim requires assistance, undressing should be done as safely as possible. Protective gear should be donned before assistance with decontamination is rendered. Unless the agent is highly reactive (e.g., elemental sodium), it is appropriate to wash the victim thoroughly with water, preferably in a nearby decontamination shower. Generally speaking, water should not be used to decontaminate skin in exposures to sodium, phosphorus, calcium oxide, chlorosulphonic acid, and titanium tetrachloride. When emergency medical personnel arrive to the scene, they should continue skin decontamination. Again, if the agent is known to have significant dermal absorption, emergency medical personnel should provide themselves every available level of self-protection. Certain toxins such as organophosphates can contaminate the air within the ambulance and produce ill effects among personnel if prehospital decontamination efforts are inadequate.

Upon arrival at a health care facility, the victim may require quarantine, depending on the nature of the agent. Skin decontamination in a decontamination shower should continue. Particular caution should be exercised in the decontamination of victims of organophosphate insecticide or organophosphate-based nerve gas exposure; health care personnel have been overcome secondarily by contaminants on victims when they assisted in their care without donning proper protective gear.

TABLE 2A-8 Specific Interventions for Toxic Dermal Exposure

TOXIN	THERAPEUTIC INTERVENTION
Hydrofluoric acid	Calcium gluconate
Instant-bonding adhesive ("Super Glue")	Polyoxyethylene sorbitan (Neosporin)
Elemental sodium	Mineral oil
Organophosphate insecticide	Protected decontamination

Water is the most commonly used skin decontaminant and is highly effective for most dermal exposures. In select cases, specific agents should be used to assist in management (Table 2A-8).

Without exception, toxin-induced skin burns should be treated according to existing burn management guidelines. These include wound débridement and dressing, monitoring for infection, fluid management, and surgical consultation when appropriate.

ELIMINATION OF POISON FROM THE GASTROINTESTINAL TRACT

After the ingestion of a toxic substance, with the exception of agents that have a direct toxic effect on the gastrointestinal tract (e.g., iron or corrosives), that substance must be systemically absorbed and circulated before it reaches a target organ and exerts clinical toxicity. Preventing the absorption of toxin is therefore the foundation of treatment after ingestion of a toxin has occurred. The term *gastrointestinal decontamination* (GID) has been coined to describe those interventions that are useful in preventing toxin absorption. With the exception of rare interventions such as gastroscopy, GID is considered to have only three components: (1) gastric evacuation, (2) administration of adsorbent, and (3) catharsis. Gastric evacuation is accomplished through gastric lavage. Syrup of ipecac, once used as an emetic for treatment of toxic ingestions, is no longer routinely recommended for this purpose. There are several agents that can adsorb toxic substances, reducing their systemic absorption and subsequent toxicity (Table 2A-9). Of these, activated charcoal is the most important adsorbent; there are few substances that activated charcoal will not adsorb (Box 2A-13). Catharsis, once an integral part of management, also has a diminishing role in the treatment of poisoned patients.

Gastrointestinal decontamination is discussed in greater detail in Chapter 2B.

ANTIDOTES

With the development of sophisticated new antidotes and the changing spectrum of clinical poisoning, the use of emergency antidotes is assuming an increasing role in clinical toxicology. However, antidotes are useful in only a fraction of poisonings.¹ Table 2A-1 lists the common emergency antidotes. In poisoning with a known substance, early antidote use is indicated for emergency stabilization, often within the first hour.

**TABLE 2A-9** Adsorbents Used in the Management of Toxic Ingestions

ADSORBENT	TOXIN
Activated charcoal	Pharmaceuticals, organic agents
Cholestyramine	Organochlorines (chlordecone, lindane)

Sodium

Corrosives

Sodium hydroxide
Sulfuric or nitric acid

Hyperbaric oxygen can provide oxygen at pressures greater than normal atmospheric pressure, which is given as 1 atmosphere (atm) or 760 mm Hg. Three atmospheres is the maximal pressure humans can tolerate over a reasonable period of time; hyperbaric units generally do not exceed 2.5 to 2.8 atm. The use of hyperbaric oxygenation is becoming standard therapy for patients with significant carbon monoxide poisoning, and it is becoming more available (see Chapter 87) for carbon tetrachloride poisoning, and possibly for cyanide and hydrogen sulfide poisoning.

Admission to an intensive care unit following antidotal therapy for further management and observation is generally indicated. Further discussion of each antidote and its use is provided in the chapter on the specific poison.

ELIMINATION ENHANCEMENT OF ABSORBED SUBSTANCES

There are multiple methods by which agents in the systemic circulation, whether ingested or administered parenterally, can be removed. The four most clinically useful means of elimination enhancement are (1) multiple-dose activated charcoal, (2) hemodialysis, (3) hemoperfusion, and (4) urine alkalinization. Potential roles for these interventions are found in Table 2A-10 and Box 2A-14. Further discussion of elimination of a substance that has already been absorbed is provided in Chapter 2C.

OBSERVATION AND SUPPORTIVE CARE

Observation and supportive care are the mainstays of therapy for the poisoned patient. Indiscriminate use of gastric lavage, antidotes, and drugs should be avoided. All too often, the toxic agent is unknown, multiple drugs have been taken, or the patient is too unstable to undergo an aggressive therapy such as hemodialysis. Monitoring of vital signs, cardiac telemetry, and oxygen saturation is mandatory.

Hospitalization in an intensive care unit is generally indicated for the patient with serious poisoning. Multi-system monitoring with blood studies and assessment of other parameters are indicated, and upon detection of any specific system disturbance, appropriate subspecialty consultation is warranted.

Some agents such as iron, mercury, acetaminophen, paraquat, carbon tetrachloride, and *Amanita phalloides* toxin have a latent phase, in which the patient appears to recover from the initial insult, only to decompensate 24 to 72 hours postingestion. Patients with overdose of sustained-release capsules, such as calcium channel blocker or theophylline preparations, also may have delayed manifestation of poisoning. Rarely, the tricyclic antidepressants have been known to cause fatal arrhythmia up to 3 days following ingestion. Some effects are not seen until later, such as hypertension following phencyclidine ingestion, hemorrhagic colitis following mercury ingestion, and disseminated intravascular coagulation following snakebite. One must also watch for the delayed pulmonary (see Chapter 9), hepatic (see Chapter 11), renal (see Chapter 12), and hematologic (see Chapter 14) manifestations of poisoning.

BOX 2A-14 EFFICACY OF MULTIPLE-DOSE ACTIVATED CHARCOAL IN ENHANCING DRUG ELIMINATION**Effective**

Phenobarbital
Theophylline
Carbamazepine
Salicylates
Digitoxin
Dapsone

Questionably Effective

Anticholinergic/antihistaminic agents
Sustained-release pharmaceuticals
Thyroid hormone
Valproate

Unlikely to Be Effective

Aminoglycoside antibiotics
Anticholinergic/antihistaminic agents
Calcium channel blockers
Phenothiazines
Propoxyphene
Tricyclic antidepressants

Patients may require observation because of an underlying disease that may be exacerbated because of the overdose, such as diabetes, congestive heart failure, cardiac rhythm disturbances, or chronic lung disease. Observation may be necessary to evaluate or treat complications, such as in a patient with an overdose who fell and sustained trauma or in a patient who develops aspiration pneumonitis or interstitial pulmonary edema.

The IV use of illicit drugs is associated with multiple complications; observation is especially indicated for patients experiencing these complications, which include bacterial endocarditis, rhabdomyolysis, and neurologic sequelae.

DISPOSITION

The disposition of the patient with intoxication may involve medical and psychiatric care as well as social follow-up. All patients admitted to the hospital with intentional overdose warrant close observation and the institution of suicide precautions. These patients may need appropriate restraint or observation if further injury or additional overdose attempts are to be prevented. Overt or subtle attempts or gestures indicate the need for psychiatric evaluation. Often, outpatient follow-up is necessary; for example, a child with kerosene ingestion

may require further examination and chest radiography, and a child who has ingested anticoagulant rat poison may require serial outpatient monitoring of prothrombin times. The issue of child abuse or neglect may need consideration whenever a pediatric patient is treated. Finally, long-term follow-up may be indicated; for example, hepatitis and HIV testing may be needed in the IV drug abuser.

B Decontamination

STEPHEN W. BORRON, MD, MS

CONTROVERSY AND CONSENSUS

The treatment of toxic exposures by application of decontamination procedures has a long history. Logic suggests that removing even a portion of a toxic dose of a substance before it can act on the organism should improve outcomes. However, clinical and experimental studies have often failed to demonstrate the anticipated benefits. As a consequence, a number of consensus conferences and position statements have been developed to address various decontamination methods. The most recent iterations of these documents are briefly reviewed here. It should be recalled in the decision-making process that the conclusions of an expert panel are limited by the quality of the available evidence base. A number of case series and randomized clinical trials examining decontamination methods have been published, with numbers of patients in the range of 300 to 1000 or more.¹⁻⁴ Unfortunately, most of the randomized clinical trials investigating decontamination methods have lacked sufficient statistical power to discern important differences for outcomes involving any specific toxicant. In fact, there are noteworthy basic obstacles to performing reproducible, informative decontamination studies. Overdose patients frequently misrepresent or are ignorant of what dose of a compound they have taken or when the exposure occurred. Clearly, decontamination procedures should have greater effect when applied early, before significant absorption has taken place. Yet many studies include patients who are already significantly poisoned (i.e., symptomatic due to absorption), in whom decontamination measures would be expected to have little impact, unless the exposure is ongoing. Enrolling a large number of patients with similar clinical presentations (single drug, similar quantity of drug ingested and time since ingestion) is very difficult in a single center or even multiple centers. Confirmation of exposure by laboratory studies is often unavailable, requiring the clinician to depend on the history (which may be inaccurate) and physical findings (which may be nonspecific) in arriving at the diagnosis of poisoning. There are likewise problems with randomization schemes,⁵ and basic inclusion and exclusion criteria.

In addition, there are problems with the process of evidence-based reviews themselves. Language bias occurs in some evidence-based reviews,⁶ such that non-English language publications, potentially of good quality, are often excluded from consideration. In addition, the premises on which the evidence review is based may not be universally applicable. The conclusions reached, based on studies performed in urban tertiary care centers where hospitals are capable of providing state-of-the-art intensive care, may not apply equally to a remote

hospital in a rural area, or even less so to a clinic in a developing country. Thus, while careful consideration should be given to position papers and consensus conference proceedings, individual judgment will necessarily enter into the decision to employ any decontamination method for a given case of exposure. Unfortunately, an unintended consequence of the publication of position papers is that they may in fact squelch further research.⁵

METHODS OF DECONTAMINATION

A number of methods of decontamination exist and may be employed depending on the circumstances of exposure. Decontamination of the skin and eyes, as well as the gastrointestinal tract, will be discussed. Extracorporeal methods of purification (hemodialysis, charcoal filtration, etc.) are covered in Chapter 2C.

SKIN AND EYE DECONTAMINATION

Decontamination of the skin and eyes is employed to reduce local tissue injury (chemical burns or irritation) and/or absorption that may result in systemic consequences. The decision to perform skin and eye decontamination is often based on the presence of symptoms, such as burning or itching. This is an insensitive evaluation method; thus, decontamination of these organs should primarily depend on careful consideration of the circumstances of exposure and the physical and toxicologic properties of the compound. Protection of personnel during eye and skin decontamination is important to avoid secondary contamination of health care providers. The choice of personal protective equipment is beyond the scope of this chapter. The reader is referred to Chapter 103 and to the recent Occupational Safety and Health Administration (OSHA) best practices document.⁷

Choice of Decontamination Methods Based on Physical Properties of the Toxicant

In almost all cases, clothing, jewelry, and shoes should be rapidly and completely removed prior to washing. It has been suggested in studies of radionuclide contamination that this process alone can remove the majority of a contaminant. This will, of course, depend on the physical properties of the toxicant but is a logical first step. Solids and dust should be gently brushed away before decontamination with a solution. In this way, the heat generated from water reactive compounds can be diminished, as is caking of solids.

In some cases, water or other decontamination solutions may be unavailable or in short supply. In such cases, dry decontamination, using an absorbent material (charcoal, flour, earth) followed by brushing or wiping may be attempted.

Choice of Decontamination Solutions

The selection of skin decontamination solutions has historically been a choice between water for polar (water-soluble) compounds and water plus a mild soap or detergent for nonpolar compounds. Water alone is typically employed for initial eye decontamination. Physiologic saline and other saline-based eye washes are often employed for eye decontamination in health care and industrial settings. The use of these solutions has been largely empiric and practical, based on widespread availability rather than on critical evaluation of their efficacy. Yano and colleagues studied water irrigation of burns involving 1 mol/L HCl in rats, measuring subcutaneous pH as a measure of penetration of the acid and efficacy of decontamination. These investigators found that maximal subcutaneous pH depression had occurred by 7 minutes following application of the acid. Animals undergoing water irrigation at 1 or 3 minutes postexposure demonstrated some benefit; however, animals irrigated at 10 minutes had no appreciable improvement in pH, compared with control.⁸ These investigators had previously demonstrated lack of efficacy of water irrigation after 10 minutes in a 2N NaOH burn model.⁹ Clearly time is of the essence in irrigation of corrosive exposures. With regard to eye exposures, Kuckelkorn and colleagues¹⁰ pointed out that water is hypotonic to corneal stroma, allowing edema and increased penetration by chemicals. They recommend use of amphoteric solutions to avoid these problems.

In recent years, a number of novel decontamination solutions have come to market. Diphoterine (Prevor Laboratories, Moulin de Verville, France), an amphoteric solution has been proposed for use in both acid and alkali exposures of eyes and skin, with emphasis on immediate irrigation (at the scene of the incident) rather than for hospital treatment. A recent article¹¹ that compared Diphoterine to physiological saline in alkaline eye burns demonstrated more rapid healing of grade 1 and 2 burns with Diphoterine than with saline. The study suffers from a number of deficiencies, including lack of randomization and significant delays and variability in initial irrigation (in the field) and secondary irrigation in hospital (with either Diphoterine or saline). Nonetheless, the time to corneal reepithelialization was approximately six times as long after saline for grade 1 burns and almost twice as long for grade 2 burns, compared with Diphoterine-treated eyes. There were an insufficient number of grade 3 burns to detect any significant difference between groups. Despite its shortcomings, this study suggests the potential for improved healing using Diphoterine in alkaline eye burns and warrants further investigation. The same study group had previously shown in a study of ammonia burns

in New Zealand albino rabbit eyes that early application (within 10 minutes) of Diphoterine rapidly corrected pH, whereas saline irrigation did not. Furthermore, saline-treated eyes had stromal edema, whereas Diphoterine-treated eyes did not.¹² The need for early irrigation is emphasized by this experimental study; however, the cited clinical study demonstrates some benefit even with delayed treatment (mean 4.7 hours).¹¹ Cavallini and Casati studied Diphoterine in experimental skin burns in rats involving 52% hydrochloric acid. Skin flushing with Diphoterine reduced substance P release during the first 48 hours after burn and was associated with better wound healing and higher concentrations of β -endorphin 7 days later when compared with normal saline or 10% calcium gluconate.¹³ Hall and colleagues¹⁴ have reviewed the chemical and physical properties and proposed uses of Diphoterine. Hexafluorine, manufactured by the same company, is proposed for treatment of exposures to hydrogen fluoride. Both Diphoterine and Hexafluorine are indicated for skin and eye decontamination.*

The National Nuclear Security Administration's Sandia National Laboratories has developed decontamination foam, referred to as EasyDECON 200 or DF 200. This product is purported to be effective against a variety of chemical and biological warfare agents, including cyanide, phosgene, mustard, VX, G agents, anthrax, *Yersinia pestis*, and corona viruses. The Illinois Institute of Technology and the Southwest Research Institute have performed tests of the ability of the compound to neutralize chemical and biological agents. While there is mention on the laboratory's website of seeking U.S. Food and Drug Administration (FDA) approval of DF 200 for personal decontamination, no peer-reviewed studies of its use in humans were identified. As such, this product cannot be currently recommended for human use.

Most authors recommend against neutralization of acid and base burns due to the risk for exothermic reaction leading to thermal burns. Simple dilution with water or milk after oral ingestion of corrosives is uncommon in Europe, but the norm after ingestions in the United States. Penner demonstrated in an ingestion model that dilution of concentrated sulfuric acid with an equivalent volume of water results in a temperature elevation of approximately 80°C. Neutralization results in even greater heat production. He suggested that vigorous gastric aspiration (likewise considered controversial given the risk for esophageal or gastric perforation) prior to cold fluid lavage is the treatment of choice in patients treated immediately following acid ingestion.¹⁵ A recent experimental study involving irrigation of rat skin exposed to 2N NaOH with 5% acetic acid suggests that neutralization may not always be contraindicated. The investigators demonstrated more rapid correction of pH, no difference in peak temperatures, and improved outcomes in animals treated with 5% acetic acid rather than water. These findings cannot

*Diphoterine and Hexafluorine are proprietary products without generic equivalents. Use of the trade name in this chapter does not constitute an endorsement.

be generalized, but indicate the need to readdress current dogma regarding neutralization.¹⁶

Duration of Decontamination

The ideal duration of eye and skin decontamination is yet to be determined. Recommendations for copious irrigation are common, without further precision. Fifteen minutes is probably the most commonly recommended duration for eye irrigation. Kuckelkorn and colleagues have recommended a minimum of 30 minutes for eye irrigation after chemical exposures.¹⁷ One retrospective study of 172 eye burn victims suggested that outcomes were better among those who had prolonged (1 to 2 hours) irrigation.¹⁸ Irrigating to a relatively neutral pH is often attempted. If this is employed, it is helpful to remember that the pH of saline for intravenous injection (often employed for eye irrigation) is appreciably acidic (approximately 4.5) so that one should wait a few minutes after irrigation to measure the pH in order to allow the patient's own tears to replace the saline irrigation fluid in the conjunctival sac.

Temperature

The appropriate temperature for decontamination fluids has also been poorly studied. While increasing temperature of decontamination liquids reduces the likelihood of hypothermia in inclement climes and improves water solubility, heat also dilates skin pores and blood vessels, which may lead to increased absorption. If excessive, it may aggravate chemical or thermal burns. OSHA's recently published *Best Practices Guide for First Receivers*⁷ recommends a 5-minute wash with tepid water, based on recommendations from the U.S. Army for chemical decontamination.¹⁹ McIntyre and colleagues recommend "warm, but not excessively warm" water for decontamination.²⁰ Eye irrigation should be performed with room temperature solutions. Careful thought should be given to environmental conditions and risk for exposure when decontamination must be done out of doors.

MASS CASUALTIES

The duration and type of skin and eye decontamination performed in mass casualty situations may vary from that in cases involving single patients based on triage considerations. Management of mass casualties is covered in Chapter 103.

Decontamination Systems

A great number of options have been developed in recent years for skin decontamination, due to the increased interest in hazardous materials and chemical terrorism issues. Examples of decontamination stretchers and facilities are shown in Figures 2B-1 to 2B-3. Many others exist. One of the overriding considerations in determining the kind of decontamination facilities and equipment to purchase should be their capacity for rapid deployment. The experience with the sarin terrorist attack in Tokyo revealed that hospitals may be rapidly

FIGURE 2B-1 Portable decontamination stretcher.

FIGURE 2B-2 Portable decontamination shower.

inundated with contaminated casualties. Decontamination protocols that are not deployable within minutes (preferably 5 to 10 minutes) after an incident may serve little purpose in protecting the facility and health care providers from contamination. Serious consideration should be given to the complexity of the setup process, one that typically will not be employed frequently. One example of a locally developed immediate deployment sheltered outdoor decontamination unit is shown in Figure 2B-4. This unit can be deployed in less than 2 minutes and provides for decontamination of both ambulatory and stretcher patients.

Personnel

It is common practice to utilize physicians, nurses, and other critical emergency department (ED) staff to do decontamination. This is probably not advisable for a number of reasons. First, decontamination does not require great technical skill, and very little stabilization

A

B

FIGURE 2B-3 A, Portable decontamination trailer. B, Portable decontamination tent.

can be performed during the decontamination process. Furthermore, if there are problems and decontaminating personnel are unable to continue, such a practice results in incapacitation of primary emergency care providers. Neither should security personnel, in general, be tasked with this responsibility, since a mass casualty situation will require their services for security itself. A number of alternatives have been suggested. Some hospitals train housekeeping staff to perform decontamination. Others have nurses from other units (burn units have extensive experience in wound care and cleaning) don protective clothing and prepare for decontamination while the ED staff prepares the decontamination facility and the ED proper to receive casualties.

SPECIAL SITUATIONS

Radionuclides

Decontamination of radionuclides from the skin may be performed in a manner analogous to chemical

exposures. Uranium hexafluoride exposures should be treated in a manner analogous to that for hydrofluoric acid burns. Wounds heavily contaminated with radionuclides may require surgical débridement and should be covered after initial decontamination. See Chapter 104 regarding radiation emergency management for further information.

Fluorides

Hydrogen fluoride, ammonium bifluoride, and other soluble fluorides may pose a unique case in terms of decontamination. While an initial quick flush with water is appropriate, the patient may benefit from rapid decontamination with a substance that can bind the fluoride. Hexafluorine has been reported to prevent significant skin burns in both humans and experimental animals when applied immediately after exposure.^{21,22} Two randomized studies in rats found, however, that Hexafluorine was no better than water in preventing electrolyte disturbances caused by fluoride^{23,24} and perhaps less effective than water or water plus calcium gluconate in reducing burn injury.²⁴ Thus, Hexafluorine's efficacy in fluoride injury remains controversial.²⁵ Researchers in hydrogen fluoride manufacturing facilities frequently recommend skin irrigation with benzalkonium chloride solution based on studies performed in pigs.^{26,27} Calcium gluconate irrigation of skin²⁸ and eyes²⁹ has also been recommended to bind fluoride and prevent further injury. Other investigators have found calcium gluconate to be no more effective than water or saline and perhaps detrimental in eye irrigation.^{30,31} In summary, the ideal decontamination of hydrogen fluoride burns to skin and eyes remains to be determined.

Phenol

Phenol is unique in its capacity to cause nonpainful burns and systemic toxicity. Water irrigation may increase phenol absorption.³² Generally accepted skin irrigation therapy consists of isopropanol^{32,33} or polyethylene glycol solutions.^{32,34}

Flammable Metals and Other Water-Reactive Materials

White phosphorus is pyrophoric (i.e., it burns in the presence of air). It is thus indispensable to provide adequate copious irrigation with water. The application of copper sulfate has been recommended,³⁵ but an experimental study in rats demonstrated increased lethality in animals receiving topical treatment with 1% copper sulfate.³⁶ Eldad and colleagues have evaluated various phosphorus burn treatment recommendations and have concluded that copious water irrigation is superior to other treatments.³⁷

HIGH-PRESSURE INJECTION INJURIES

High-pressure injection injuries should be mentioned here due to their requirement for special care and high

FIGURE 2B-4 A, Fixed immediate deployment decontamination facility at Singapore General Hospital and Drug and Poisons Information Centre. The unit is located in the drive-through ambulance bay in front of the emergency department. This shows the unit in predeployment position. B, Deployment of the unit requires turning on a few switches, which control descent of the shower heads, flexible walls, and temperature control. The unit is ready for operation in approximately 2 minutes. C, Shower heads drop out of the ceiling for self- or assisted irrigation. D, Flexible walls drop from the overhead frame, providing easy ingress, egress, and protection from elements, as well as privacy. E, The unit is ready for use. Floor drains collect the water for appropriate disposal. (Photographs courtesy of Dr. Gaerpo Ponampalam and the Singapore Drug and Poisons Information Centre.)

risk for morbidity. Wounds inflicted by pressurized paint guns or grease guns are often deceptively benign appearing on the surface. The temptation is to simply decontaminate the overlying skin and wash the puncture wound (if visible) from the surface. Such an approach may result in loss of function or even complete loss of a limb. Such wounds need to be explored thoroughly, perhaps best done in the operating room, for evidence of subcutaneous contamination.^{38,39}

TETANUS PROPHYLAXIS

All eye and skin exposures resulting in violation of the epithelium should prompt consideration of the need for tetanus toxoid administration.

GASTRIC EMPTYING

Emetics

The only emetic currently recommended for use in humans is syrup of ipecac. Previously employed emetics continue to be responsible for significant pathology, however. The administration of table salt has long been condemned in the literature⁴⁰; nonetheless, recent reports illustrate that its use has not been completely abandoned and that it remains potentially lethal.^{41,42} Liu reported that copper sulfate continues to be used in China for emetic purposes and has resulted in multiple fatalities in recent years.⁴³

The dose of ipecac is 5 to 10 mL in children 6 to 12 months of age or 15 mL in children 1 to 12 years of age. This should be followed by 10 to 20 mL water per kg body weight. Older children and adults should receive 30 mL ipecac followed by 200 to 300 mL of water. Ipecac is contraindicated in the following situations:

- Ingestion of petroleum distillates
- Ingestion of strong acids or bases
- Ingestion of strychnine or other proconvulsants
- Unconsciousness or absence of gag reflex

Ipecac has a number of potential adverse effects, including lethargy, cramps, and diarrhea. When taken chronically, it may induce muscle cramps and both skeletal⁴⁴ and cardiac myopathy.⁴⁵ It is subject to frequent abuse by patients with eating disorders, a factor that led to a review of the product's safety by the FDA in 2003.

The American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) reviewed the medical literature regarding the use of ipecac in 1997.⁴⁶ This combined task force more recently examined their previous findings and literature that had appeared since their earlier review. In brief, they concluded that syrup of ipecac should not be administered routinely in the management of poisoned patients. They pointed out that in experimental studies the amount of marker removed by ipecac was highly variable and diminished with time. Furthermore they concluded that there is no evidence from clinical studies that ipecac improves the

outcome of poisoned patients and recommended that its routine administration in the ED be abandoned. Finally, they signaled the absence of data to support or exclude ipecac administration soon after poison ingestion, the administration of ipecac potentially reducing the effectiveness of activated charcoal, oral antidotes, and whole bowel irrigation (WBI).⁴⁷

There are indications that the use of syrup of ipecac has dramatically declined in recent years, and it is likely that this trend will continue.^{48,49} Bond examined the evolving use of ipecac in U.S. poison centers, comparing rates of referral to the ED and moderate or greater outcomes in patients younger than 6 years with unintentional ingestions. This comparison was carried out according to the frequency with which centers recommended use of ipecac. Overall, use of ipecac was extremely rare (1.8%) and significant adverse outcomes even lower (0.6%). Comparing the two groups of 32 centers each, there were no significant differences in referral rates or adverse outcomes. Bond concluded that there was no reduction in resource utilization (ED referral) or improvement in patient outcome from the use of syrup of ipecac at home and that while the data could not exclude a benefit in a very limited set of poisonings, such a benefit remained to be proven. Shannon, in an editorial in the same issue, sounded the demise of ipecac on the basis of lack of proven efficacy, changing patterns in poison center approaches to the management of pediatric ingestions (including preference for activated charcoal when decontamination is indicated), and the move by the FDA to rescind ipecac's over-the-counter status.⁵⁰ This prediction was prescient, since the American Academy of Pediatrics, based on Bond's article and the factors cited by Shannon, revised its position statement on ipecac use, calling for abandonment of the regular stocking of it in the home.⁵¹

More recently, a U.S. government–convened review panel of experts published their conclusions regarding ipecac use.⁵² The panel concluded that the use of ipecac syrup might have an acceptable benefit-to-risk ratio when:

- There is no contraindication to the use of ipecac syrup.
- There is substantial risk of serious toxicity to the victim.
- There is no alternative therapy available or effective to decrease gastrointestinal absorption (e.g., activated charcoal).
- There will be a delay of more than 1 hour before the patient will arrive at an emergency medical facility.
- Ipecac syrup can be administered within 30 to 90 minutes of the ingestion.
- Ipecac syrup administration will not adversely affect more definitive treatment that might be provided at a hospital.

Given these restrictions, rural residents might consider keeping ipecac on hand for home use under poison center direction. Otherwise, these recommendations sharply limit the applicability of the drug and, thus, the induction of vomiting in general.

Gastric Lavage

The employment of gastric lavage is controversial and varies markedly depending on geographic area and the background and training of the practitioner. Gastric lavage involves blind placement of a large-bore gastric tube into the stomach, in a patient who can either protect his or her own airway or in whom the airway has been protected by an endotracheal tube, with the goal of removing toxicant remaining in the stomach through a combination of instillation of water or physiological saline, followed by suction or gravity-induced drainage. This cycle of instillation/drainage is repeated until the effluent is clear or until several liters of water/saline have been passed through the tube. This procedure has been widely popular in the past and continues to be employed in many EDs around the world. It is, however, a largely unproven therapy.

INDICATIONS

The indications for gastric lavage are recent ingestion (generally less than 1 hour, unless the ingestion involves agents that decrease gastric motility, such as anticholinergics) of a substance of sufficient quantity to be likely to cause serious harm in the absence of removal. The procedure should be given greater consideration in ingestions for which inadequate treatment modalities exist (paraquat) or in cases where delivery of proven effective therapy (antidotes or extracorporeal removal) is likely to be delayed.

CONTRAINDICATIONS

Ingestion of low-viscosity petroleum products, corrosives (acids and alkalis) and inability to protect the airway (unless tracheal intubation has been performed beforehand) are contraindications to gastric lavage.

ADVERSE EFFECTS

Serious adverse effects of gastric lavage are relatively rare but may be significant. The procedure may induce hypoxia,⁵³ perforation of the gastrointestinal tract or pharynx,^{54,55} fluid and electrolyte abnormalities,⁵⁶ inadvertent tracheal intubation, as well as aspiration pneumonitis.⁵⁷ Tracheal intubation is not completely protective against aspiration.

EFFICACY

The AACT/EAPCCT recently reviewed the animal and clinical literature regarding gastric lavage and published a position statement,⁵⁸ which states in part that gastric lavage should not be employed routinely, if ever, in the management of poisoned patients. The study group pointed out that in experimental studies, the amount of marker removed by gastric lavage is highly variable and diminishes with time and that few clinical studies have demonstrated a beneficial effect on outcome.

The quality of the gastric lavage literature is, for the most part, lacking. Few studies have the power to detect significant differences in outcome for a single toxicant, and it seems unscientific to compare outcomes after ingestion of widely varying products. Furthermore, there

are many unknowns in any clinical trial, the most significant of these being the time between ingestion and treatment and the amount of toxicant ingested. It is fair to say that the evidence for efficacy is currently deficient, but that lack of efficacy has not been proven either.

Endoscopy

The use of endoscopy in the diagnosis of caustic injuries is addressed in Chapter 98. Its use in the retrieval of foreign objects, such as batteries,⁵⁹ firearm cartridges,⁶⁰ and various pill fragments⁶¹⁻⁶⁶ has been reported in humans and studied in animals,⁶⁷ but has not been systematically addressed in humans. Faigel and colleagues report that endoscopic use of the Roth net was most effective in removal of button batteries.⁶⁷ Like other forms of decontamination, endoscopy to retrieve tablet fragments has been associated with significant complications; thus, the decision to perform endoscopy in these circumstances should be carefully weighed against the risks.⁶²

Surgical Laparotomy for Decontamination

Surgical gastrointestinal decontamination has been employed for button battery ingestions,⁶⁸⁻⁷⁰ cocaine and narcotic drug packets,⁷¹⁻⁷⁷ and bezoars of iron⁷⁸ and theophylline,⁷⁹ among others. Batteries passing the esophagus usually are expelled in the feces and are generally believed to require no intervention, although recent reports of early battery leakage have called the “wait and see” approach into question.^{80,81} Button batteries, when impacted in the esophagus, should generally be removed by endoscopy unless perforation is suspected.^{59,67,82} The trend toward use of smaller batteries by manufacturers has decreased the incidence of this problem. In the case of cocaine and heroin bodypackers/stuffers, many cases can be managed conservatively with WBI or other purgatives. Most researchers agree, however, that acute toxicity (drug leakage) and bowel obstruction are indications for immediate laparotomy.^{71,73,75}

ABSORBANTS

Activated Charcoal

Charcoal binds to diverse substances, rendering them less available for systemic absorption from the gastrointestinal tract. It is obtained as a product of pyrolysis of numerous organic compounds (petroleum, wood, peat) and “activated” by heating it to 600° F to 900° F, in the presence of steam, carbon dioxide, or air. This gives the product a small particle size and large surface area. While charcoal adheres to many substances, a significant number of compounds and classes of compounds are poorly absorbed by charcoal. These include metals (lithium, sodium, iron, potassium) and alcohols. Thallium appears to be an exception, being relatively well absorbed by charcoal.⁸³

Activated charcoal products containing sorbitol should be avoided where possible because (1) the efficacy of cathartics is lacking (see below); (2) sorbitol is emetogenic and can increase the risk for vomiting the charcoal; and (3) sorbitol administration in infants is associated with dehydration and other life-threatening events.

Single-Dose Activated Charcoal

Activated charcoal is administered as a slurry, either in water or sorbitol, orally or via a nasogastric tube. Dose recommendations vary, but generally a larger dose is considered better, to assure that binding capacity exceeds the amount of toxicant present. The recommended dose is 0.5 to 1 g/kg in children or 25 to 100 g in adults.

INDICATIONS

In general, to be maximally effective, charcoal should be administered as soon as possible after ingestion of the toxicant, preferably within 1 hour. Green and colleagues studied this issue in healthy volunteers in a randomized crossover study. After giving 4 g (the equivalent of eight extra-strength tablets) of acetaminophen to patients, then giving charcoal at 1, 2, or 3 hours after ingestion, they found no differences in the area under the curve of plasma acetaminophen. The investigators stated that “data do not support the administration of activated charcoal as a gastrointestinal decontamination strategy beyond 1 hour after drug overdose.”⁸⁴ While there are obvious problems in extrapolating toxicokinetic results from a study involving a nontoxic dose to all overdoses, the results do suggest that benefit clearly decreases over time.

As for most decontamination measures, the indications for single dose activated charcoal are controversial. The recently released revision of the Single-dose Activated Charcoal Position Statement of the AACT/EAPCCT states that single-dose activated charcoal should not be administered routinely in the management of poisoned patients, but that it may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hour previously. The researchers state that the potential for benefit after 1 hour cannot be excluded. Finally, they emphasize that there is no evidence that the administration of activated charcoal improves clinical outcome.⁸⁵

CONTRAINDICATIONS

Charcoal administration is generally considered contraindicated in ingestions of caustics, since it is probably ineffective in reducing their potential for harm and furthermore makes endoscopy difficult. Charcoal generally should not be administered when there is a high risk for gastrointestinal hemorrhage or perforation. Charcoal is likewise contraindicated in any patient in whom the airway protection is not assured. It should not be administered in the presence of hydrocarbons with high aspiration potential. Charcoal should not be administered in the case of ileus or mechanical bowel obstruction.

ADVERSE REACTIONS AND COMPLICATIONS

One of the most common adverse events associated with charcoal administration is vomiting, which occurs in approximately 7% to 15% of patients. Abdominal bloating is also quite common. Both diarrhea and constipation may occur. Complications have been described, including pulmonary aspiration and direct administration into the lungs via misplaced nasogastric tube. Aspiration appears to be relatively rare, but may have serious consequences.^{57,86-89}

Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal (MDAC) has been proposed for use in the case of drugs that undergo extensive enterohepatic or enteroenteric circulation. Drugs with small volumes of distribution are particularly susceptible to removal by adsorption to charcoal in the gut, which has sometimes been referred to as “gastrointestinal dialysis.” Although experimental and volunteer studies have demonstrated that MDAC increased elimination of a number of compounds, there is little proof of clinical benefit.

INDICATIONS

The AACT/EAPCCT has concluded that although many studies in animal and volunteer studies have demonstrated MDAC increases drug elimination significantly, there are no controlled studies in poisoned patients that demonstrate MDAC reduces morbidity and mortality. Pending further evidence of direct benefits, the study group recommended that MDAC be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.⁹⁰

CONTRAINDICATIONS

The contraindications for MDAC are essentially those of single-dose activated charcoal. The admonition for use in intestinal obstruction is of even greater import in the case of MDAC. The presence of decreased peristalsis (often associated with anticholinergic drugs and opiates) should provoke extreme caution in the administration of MDAC.

Prussian Blue

Prussian blue is an effective absorbent for the management of thallium and cesium intoxications. See Chapters 75 and 104 for further information.

Fuller's Earth

Fuller's earth is often recommended for gastrointestinal decontamination of paraquat (see Chapter 78). Although effective for this purpose, this substance is found in few hospitals. Activated charcoal is an effective absorbent of paraquat and should be employed when Fuller's earth is not available.⁹¹

ACCELERATION OF GASTROINTESTINAL TRANSIT

Cathartics

Cathartics comprise another group of compounds recommended since ancient times for the purpose of eliminating toxicants from the gastrointestinal tract. The two most common categories of cathartics are the magnesium salts (e.g., magnesium citrate, magnesium sulfate) and nondigestible carbohydrates (e.g., sorbitol). Despite their long history of use, there is virtually no evidence of their efficacy. On the contrary, cathartics may induce significant harm in certain groups of patients, particularly children and those with renal disease.

INDICATIONS

There are no evident indications for the use of a cathartic alone in the treatment of poisoning.⁹² An AACT/EAPCCT position statement concluded that experimental data are conflicting regarding the use of cathartics in combination with activated charcoal. The study group found no published clinical studies that investigated the ability of a cathartic, with or without activated charcoal, to reduce the bioavailability of drugs or to improve the outcome of poisoned patients. They went on to say that based on available data, the routine use of a cathartic in combination with activated charcoal is not endorsed and that if a cathartic is used, it should be limited to a single dose in order to minimize adverse effects of the cathartic.

DOSE

The dose of sorbitol is approximately 1 to 2 g/kg.⁹² When given in combination with activated charcoal for single dose-activated charcoal therapy, the dose should be determined on the basis of charcoal dosing. If multiple doses of charcoal are to be administered, repeated use of sorbitol is not recommended. For magnesium citrate, the dose is 4 to 6 mL/kg in children and 300 to 480 mL in adults.

CONTRAINDICATIONS

Cathartics are contraindicated in the presence of bowel obstruction, in the absence of bowel sounds, or in the case of recent bowel surgery or intestinal perforation. They should likewise not be employed in the case of corrosive ingestions or when significant electrolyte disturbances, dehydration, or hemodynamic instability are present. Magnesium-containing cathartics must be avoided in patients with renal insufficiency and heart block. Caution should be employed in patients at extremes of age.

COMPLICATIONS

Cathartics frequently cause cramping, nausea, and vomiting. Significant dehydration may occur if catharsis is excessive, with resultant hypotension. Cathartic-related

hypermagnesemia may result in cardiac dysrhythmias. Elderly patients and those with renal dysfunction are at particular risk.⁹³⁻⁹⁵ Massive doses of cathartics may result in cardiopulmonary arrest.⁹³

Whole Bowel Irrigation

WBI involves the administration, by mouth or nasogastric tube, of large amounts of an iso-osmotic polyethylene glycol electrolyte solution (Go-Lytely [Braintree Laboratories, Braintree, MA], Co-Lyte [Schwarz Pharma, Mequon, WI], and others) with the goal of removing unabsorbed toxicant from the gastrointestinal tract as rapidly as possible by rectal expulsion. One rationale for its use includes the fact that some compounds are poorly absorbed by charcoal, particularly iron and lithium. WBI may be of particular interest in the case of sustained-release or enteric-coated compounds and in the case of drug packets (body packers). The AACT/EAPCCT's consensus panel concluded that WBI should not be used routinely and that there is no conclusive evidence that it improves the outcome of poisoned patients. Based on evidence from volunteer studies, the group recommended that WBI be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, particularly in those patients who present more than 2 hours after drug ingestion. They more strongly endorsed WBI for patients who have ingested substantial amounts of iron because the morbidity is high and there are no other effective options for gastrointestinal decontamination. Another potential indication cited for the use of WBI is expulsion of ingested packets of illicit drugs.⁹⁶

DOSE

Polyethylene glycol electrolyte solution (e.g., Go-Lytely, Co-Lyte, NuLytely [Braintree Laboratories, Braintree, MA]) is administered by mouth or nasogastric tube at 25 to 40 mL/kg/hr until the rectal effluent is clear or until the desired effect is otherwise demonstrated (e.g., passage of drug packets demonstrated by imaging studies). Computed tomography (CT) with contrast has often been used to identify retained packets, but a recent case report demonstrated incomplete sensitivity of CT to detect all unexpelled drug packets.⁷²

CONTRAINDICATIONS

WBI is contraindicated in the presence of mechanical or functional (ileus) bowel obstruction or perforation and in the presence of significant gastrointestinal hemorrhage. It should likewise be avoided if the patient is hemodynamically unstable.

COMPLICATIONS

Nausea and vomiting are not uncommon. Abdominal bloating and cramping may occur. Vomiting in the case of an unprotected airway may result in pulmonary aspiration.

DECISION ANALYSIS FOR DECONTAMINATION

The decision to employ decontamination methods in an individual case must be determined based on the factors present in that individual case.

Dose Assessment

First and foremost in the decision to attempt decontamination is a determination of whether a significant exposure has occurred. This is critical for numerous reasons: (1) needless decontamination procedures may delay other definitive therapy for systemic toxicity; (2) conversely, failure to adequately decontaminate the skin may increase morbidity of contaminated patients and result in secondary contamination of health care providers and facilities; and (3) decontamination, as discussed, is not without risks. It is vital to recall Hippocrates' admonition: *Primum non nocerum*. Dose/exposure assessment is extremely difficult on an acute basis due to the great number of unknowns. Young children cannot recount the quantity or quality of what they have ingested. Self-harm attempts are often accompanied by attempts to conceal or, conversely, to exaggerate the consumption of potentially toxic compounds. It is rare that contemporaneous exposure information (air concentrations or even product identification) is available after environmental exposures associated with hazardous materials releases or acts of terror. Fear associated with these events may result in psychogenic illness at times indistinguishable from that of the toxic exposure. When doubt exists, it may be safer to decontaminate, but this should be a considered decision.

Toxic Potential

Once it is established that an exposure has occurred (or if exposure cannot be excluded) and some attempt has been made to determine the magnitude of the exposure, one must examine the toxic potential of the compound(s) in question, keeping in mind that the toxicity of combined substances is not always equal to the sum of their individual toxicities. Approaches to the treatment of poisoning are deeply rooted in personal experience and colored by bias in the literature. Recent studies have reexamined the need to decontaminate victims of certain exposures that were previously approached aggressively from a therapeutic standpoint.^{97,98}

An Integrated Approach to Decontamination Procedures

Decisions around decontamination must be individualized. A suggested approach is found in Figure 2B-5. This nonvalidated algorithm should simply be considered a pathway for considering options. There are numerous potential exceptions to the general suggestions in the figure.

WHEN SHOULD GASTRIC LAVAGE BE PERFORMED ALONE?

One might consider gastric lavage alone in the case of presentation of poisoning within 1 hour of ingestion by a highly toxic compound that is not readily absorbed by charcoal. Lithium is one such example.

WHEN IS GASTRIC LAVAGE FOLLOWED BY CHARCOAL APPROPRIATE?

Reiterating, gastric lavage is most likely to be effective in an early-presenting, potentially lethal ingestion. Cyanide is an example of a highly toxic compound that might be removed by lavage, but is also readily absorbed by charcoal.

IS THERE A ROLE FOR CHARCOAL FOLLOWED BY WHOLE BOWEL IRRIGATION?

Yes. Illicit drug packets containing cocaine or heroin may leak. A dose of activated charcoal given prophylactically (in the absence of symptoms) could theoretically absorb eventual leakage, while WBI accelerates passage of the packets. As a reminder, clinical evidence of toxicity (leakage) is an indication for laparotomy. Similarly, charcoal followed by WBI may be indicated for ingestions of enteric coated tablets.

WHEN SHOULD WHOLE BOWEL IRRIGATION BE UTILIZED?

In cases in which ingestion of a substance known to be effectively eliminated by WBI (such as lead, zinc, or iron) is not recent (and thus not likely to benefit from gastric lavage) and when the substance is not readily absorbed by charcoal, WBI alone may be indicated.

CONSULTATION

It should be clear from the discussion that the previously common "reflex arc" of ingestion-decontamination should not apply. The decision to apply a particular procedure or combination may not be simple. For this reason, consultation with a regional poison center and/or medical toxicologist is strongly suggested in cases of uncertainty.

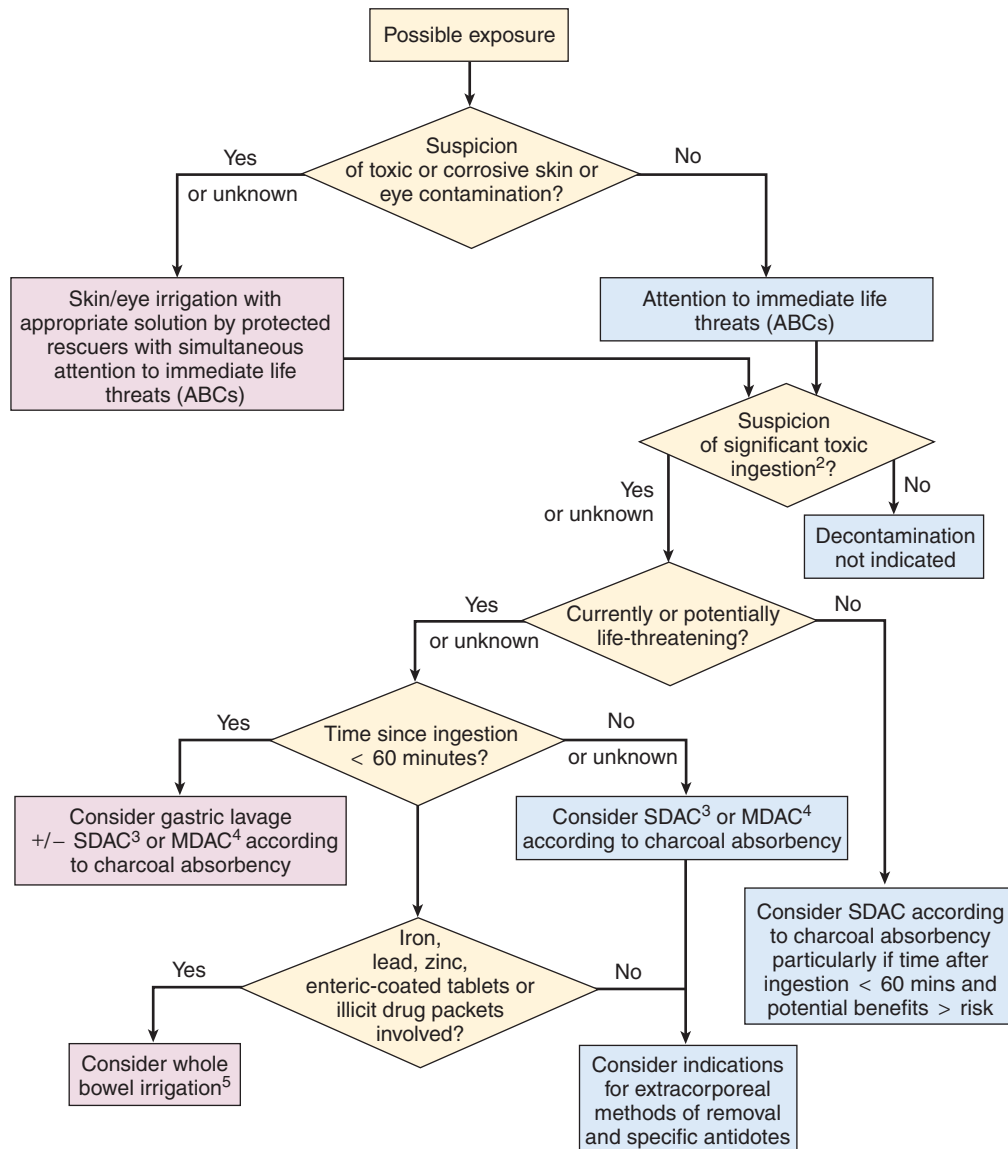

FIGURE 2B-5 This flow diagram is essentially based on the current recommendations of the American Academy of Clinical Toxicologists and the European Association of Poisons Centres and Clinical Toxicologists. These recommendations are based on weight of evidence in the published literature, but this algorithm has not been validated. See text for details on individual decontamination procedures, indications, and contraindications.

1. Irritants, corrosives, and substances toxic by skin absorption should be removed. Liquids with high volatility and potential for secondary contamination (organic solvents) should likewise be removed. When in doubt, decontamination is appropriate; however, life-saving interventions (ABCs) take precedence over decontamination. Personnel should wear protective garments appropriate to the hazard.

2. If the history is reliable and the ingestion is clearly nontoxic, no decontamination is required. The urge to “do something” should be weighed against the maxim to “first, do no harm.”

3. Single-dose activated charcoal (SDAC) is considered most effective when administered less than 1 hour after ingestion of a toxic substance. There is insufficient evidence to support or condemn its use with toxic ingestions presenting more than 1 hour later. In general, metals (lithium, iron, but not thallium) and alcohols are poorly absorbed.

4. Multiple-dose activated charcoal (MDAC) should be considered primarily if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Multiple-dose activated charcoal increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, but evidence is insufficient to support its use in these ingestions.

5. Whole bowel irrigation should not be performed in the presence of ileus or bowel obstruction.

6. If uncertainty exists about the need for decontamination procedures, contact the regional poison control center and/or a medical toxicologist.

C Principles of Elimination Enhancement

CURTIS P. SNOOK, MD ■ DANIEL A. HANDEL, MD, MPH

Once a drug or toxin has been absorbed, a number of means exist to enhance its elimination. Chapter 2D addresses extracorporeal techniques of toxin removal from the blood (e.g., hemodialysis and hemoperfusion), which, when performed on an emergency short-term basis such as for poisoning, are done intermittently using a large double-lumen catheter in a central vein with flow through the circuit driven by a pump. Other types of dialysis exist that also usually do not require arterial access and are more versatile in that they do not pose as great a hemodynamic stress to the patient; however, they also are generally much slower in their rates of clearance. One of these alternatives, multiple-dose activated charcoal (MDAC), involves use of the patient's own gastrointestinal mucosa as a dialyzer.

All of these techniques share in common with dialysis the underlying principle of filtering a toxin from the blood using a semipermeable membrane in order to enhance its clearance. A number of substance-related factors affect the clearance rates that can be achieved by dialysis techniques. First, a toxin must distribute primarily into the intravascular compartment—that is, have a low volume of distribution, in order to be removed by a dialysis technique at a clinically significant rate. Second, molecular size is important, with low molecular weight substances crossing the dialysis membrane from an area of high concentration (blood) to an area of low concentration (dialysate). Even higher molecular weight substances can cross and thus be removed from the blood by convection when dialysis is supplemented with ultrafiltration, which relies on a membrane with a high permeability coefficient and a high transmembrane pressure. Finally, high protein binding presents a large molecular size to the membrane (i.e., a protein-bound drug), thus limiting the rate of clearance, unless the toxin is adsorbed from the serum proteins such as with the use of a charcoal cartridge in hemoperfusion.

MULTIPLE-DOSE ACTIVATED CHARCOAL

Preabsorptive Elimination Enhancement

Delayed absorption may occur after toxic ingestion: (1) with sustained-release preparations, (2) if tablet conglomerates form in the gastrointestinal tract, (3) if the substance delays gastrointestinal motility, or, (4) if a poorly absorbed substance (e.g., phenytoin) is ingested. Multiple doses of activated charcoal have been used in these situations to enhance preabsorptive elimination. Whole bowel irrigation, the other treatment modality used to enhance preabsorptive elimination, appears to provide no additional benefit when administered to treat a drug overdose for which activated charcoal is an

effective adsorbent¹; it may even limit the adsorptive capacity of activated charcoal.²

Postabsorptive Elimination Enhancement

Two theories have been advanced to account for the observed acceleration of drug clearance associated with the use of MDAC after the drug's absorption from the gastrointestinal tract. One theory explains this acceleration by charcoal's interruption of the enterohepatic recirculation of hepatically metabolized drugs. The other is aptly called "gastrointestinal dialysis," a term coined by Levy in an editorial that accompanied the seminal work on this topic by Berg and colleagues.^{3,4} Using an animal model of intravenous theophylline poisoning, Kulig and colleagues measured bile theophylline concentrations and were able to demonstrate that the observed increase in theophylline clearance with MDAC was not due to interruption of enterohepatic recirculation of the drug.⁵ Arimori and colleagues demonstrated in an experimental model that the exsorption rate of theophylline into the intestinal lumen increased in proportion to the administered dose of theophylline, suggesting that the gastrointestinal dialysis effect may increase with escalating dose for some toxins.⁶

Indications

Given that overall mortality from overdose is low, that the efficacy of gastrointestinal decontamination techniques declines significantly with advancing time after ingestion, and that significant delay to clinical presentation occurs in the majority of ingestions, elimination enhancement techniques, including MDAC, have come under recent scrutiny.⁷ Tenenbein cited case reports of complications from MDAC with a lack of proven clinical benefit in arguing that its role in the treatment of poisoning required reassessment.⁸

These cautions notwithstanding, review of the available evidence suggests that MDAC can accelerate drug clearance, achieving rates comparable to more invasive techniques such as hemodialysis. Moreover, a recent study of complications associated with MDAC use found that they occurred infrequently.⁹ There are also data suggesting that MDAC improves outcome in selected poisoning cases. One report describes two presentations of the same patient with phenytoin toxicity, one in which MDAC was not used and a second in which it was; the second hospitalization was 3 days shorter despite the patient having a higher serum phenytoin level.¹⁰ A recent single-blind, randomized, placebo-controlled trial performed in Sri Lanka demonstrated a significant reduction in mortality from yellow oleander poisoning

with MDAC therapy when compared with treatment with single-dose activated charcoal.¹¹

Further study is needed to define the circumstances in which the benefits of MDAC appear to justify its risks. However, some predictions can be made based on available data. MDAC has been demonstrated to accelerate the clearance of a number of toxins (Box 2C-1). Chyka and colleagues found in a porcine model that MDAC enhanced elimination of acetaminophen, digoxin, and theophylline but not valproic acid.¹² Drugs with relatively lower intrinsic clearance (digoxin, theophylline) were cleared with MDAC more rapidly than were drugs with higher intrinsic clearance (acetaminophen). Interestingly, volume of distribution, half-life, and protein binding were not significantly correlated with MDAC enhancement of clearance. However, therapeutic doses were administered in this study, limiting application of these results to the overdose setting. A volunteer study of dapsone ingestion using a randomized crossover design along with data from two overdose cases showed a doubling of elimination with MDAC in healthy volunteers and a greater increase in the overdose patients, again suggesting that the effectiveness of MDAC also may be a function of dose for a given toxin.¹³

Contraindications

Significant adverse effects with MDAC preclude its use in patients for which no significant clinical benefit is expected. There are some drugs or drug classes for which data are conflicting (Box 2C-2). For example, the available studies suggest that MDAC likely would not be beneficial in unselected cases of digoxin poisoning. However, one volunteer study of MDAC for enhancement of digoxin clearance applied kinetic predictions to suggest that greater clearance with MDAC would occur in patients with renal impairment¹⁴; animal data support this assertion.¹² In a case of chronic digoxin poisoning, MDAC effectively accelerated drug clearance when digoxin antibody fragments were unavailable and hemodialysis had been unsuccessful.¹⁵ Box 2C-3 lists the

drugs investigated for which MDAC has not been shown to accelerate clearance.

MDAC often is poorly tolerated. Virtually all patients in one study complained of poor palatability and bloating with MDAC, with one patient withdrawing because of repeated vomiting.¹⁴ Transient constipation may occur with MDAC use in susceptible patients. Protracted vomiting also has been reported to limit the usefulness of MDAC in theophylline poisoning.¹⁶

Aspiration of charcoal is another well-recognized complication of MDAC. In one published case, an intubated patient treated for phenobarbital and carbamazepine overdose with gastric lavage followed by MDAC vomited and aspirated 12 hours after therapy was initiated, eventually dying on hospital day 15.¹⁷ Another reported patient with theophylline overdose was treated with ipecac followed by MDAC. He went on to develop convulsions followed by aspiration, eventuating in his death.¹⁸ In the most sobering case, a patient aspirated activated charcoal despite airway control.¹⁹ This patient received MDAC after intubation and gastric lavage for desipramine and thiothixene overdose. After extubation the next day, the patient vomited, aspirated charcoal, and had a cardiorespiratory arrest from which he could not be resuscitated. In a similar case, a patient who ingested thioridazine and imipramine underwent endotracheal intubation and gastric lavage after he had a seizure. He received 50 g of activated charcoal by nasogastric tube followed by 25 g and then 50 g with sorbitol every hour for 6 hours.²⁰ When the nasogastric tube was removed, the patient vomited, became cyanotic and had a respiratory arrest. Charcoal was suctioned from the patient's lungs until hospital day seven. Rau

MDAC, multiple-dose activated charcoal.

and colleagues described three deaths from charcoal aspiration among 15 patients treated with charcoal for central nervous system–depressant overdose without airway protection. Their subsequent six overdose patients were intubated prior to charcoal administration and no cases of aspiration occurred.²¹ In light of this experience, any patient at risk for aspiration (i.e., one in whom diminished consciousness, depressed airway reflexes, or seizures are present or anticipated), should have a firm indication for MDAC and a protected airway before undertaking the procedure. Equally important, there appears to be a ceiling effect for charcoal adsorption such that increasing dose or frequency beyond a certain point results in no additional therapeutic benefit.²²

Overdose victims with decreased gastrointestinal motility may develop bowel obstruction with use of MDAC. A number of cases have reported MDAC resulting in small bowel obstruction, abdominal distension, constipation, rectal bleeding, and even intestinal perforation when either the overdose itself or the therapy for the overdose involved anticholinergic drugs.^{23–28} Appendicitis in association with MDAC use has been reported.²⁹ Another patient with chronic theophylline toxicity treated with MDAC developed small bowel obstruction and was found on laparotomy to have adhesions at the ileocecal valve secondary to a previous hysterectomy; multiple pieces of charcoal were found in the bowel at the site of obstruction measuring $4.5 \times 5 \times 3$ cm in aggregate.³⁰

Cathartics are ineffective as a means of elimination enhancement after poisoning.³¹ However, to avoid constipation and charcoal inspissation, cathartics often are coadministered. Sorbitol is the usual choice because of its rapid onset and palatability. Sorbitol is typically marketed in a 70% concentration with activated charcoal because it is bacteriostatic at this concentration.^{32,33} Using excessive or multiple doses of sorbitol with activated charcoal in poisoning is associated with significant morbidity, including hypernatremia resulting in death, and should be avoided.³⁴ Magnesium citrate or sulfate occasionally are used instead of sorbitol. Patients with premonitory magnesium abnormalities or those receiving excessive doses of magnesium cathartic can suffer serious morbidity, including hypermagnesemia, which can be fatal.³⁴

Dosing

The optimal dosing for activated charcoal in MDAC is unknown. The commonly accepted dose is 1 g/kg (maximum of 50 g) of activated charcoal initially, followed by 0.5 g/kg (maximum 25 g) every 4 hours thereafter. Others have suggested a dose of 1 g/kg of activated charcoal in 4.3 mL/kg body weight of 70% sorbitol every 4 hours until the first charcoal stool appears. In children, the same weight-based dose of activated charcoal is recommended.³³ A third set of published guidelines for adults has suggested an initial dose of 50 to 100 g, with additional doses given at a rate of at least 12.5 g/hr until the patient is improving clinically and by relevant laboratory parameters. This latter set of recommendations includes lower dosing (10 to 25 g) for children younger than 5 years of age, smaller doses more frequently along with antiemetic use in vomiting patients, and no use of cathartics, particularly in young children.⁷ MDAC has been used safely in infants and neonates^{35,36}; it has even been used to treat neonatal hyperbilirubinemia.³⁷

Patients receiving MDAC should be intubated, ideally with a cuffed endotracheal tube, if they are obtunded or have diminished airway reflexes or seizures. The charcoal should be diluted with at least 8 mL of water per gram of charcoal. MDAC should not be administered in the presence of ileus or bowel obstruction. Co-administration of anticholinergic agents should be avoided during MDAC. Charcoal should be withheld 4 hours prior to extubation. Gastric contents should be aspirated with a nasogastric tube prior to extubation to avoid the complications previously discussed. Magnesium cathartics should be used with caution, particularly in patients with decreased renal function, and are best avoided in such patients given that safer alternatives are available. It is a common practice to give the first dose of charcoal with a cathartic, usually sorbitol, and to give subsequent doses without cathartic. The availability of only sorbitol-charcoal preparations can be problematic in hospitals with such rigid stocking patterns.³⁸ Electrolytes should be closely monitored if more than one dose of cathartic is administered.

Box 2C-4 summarizes the indications, contraindications, and dosing guidelines for MDAC use in poisoning.

BOX 2C-4 MDAC: INDICATIONS, CONTRAINDICATIONS, AND DOSING GUIDELINES

Indication

Life-threatening ingestion of substance adsorbable by activated charcoal
Evidence or anticipation of ongoing absorption (rising drug levels later than expected, sustained-release preparations)

Contraindication

Anticipation or presence of decreased mental status, anticipation or presence of seizures, or decreased gag reflex without a cuffed endotracheal tube in place for airway protection
Ileus or bowel obstruction

Dosing Guidelines

Activated charcoal:
1 g/kg followed by 0.5g/kg every 4 hr
Sorbitol: If used with the first dose of AC:
adult: 4.3 mL/kg body weight of 70% sorbitol;
child: 4.3 mL/kg body weight of 35% sorbitol;
subsequent doses in aqueous suspension of 8 mL water/g AC

AC, activated charcoal; MDAC, multiple-dose activated charcoal.

CONTINUOUS VENO-VENOUS HEMOFILTRATION

Continuous veno-venous hemofiltration (CVVH) and similar modalities used for what is termed “continuous renal replacement therapy” increasingly are being used in the therapy of critically ill patients, including those suffering from poisoning. CVVH offers a number of useful advantages over traditional dialysis techniques. First, it can be used in patients with renal failure who are hemodynamically unstable and require large volumes of parenteral nutrition. In CVVH isotonic fluid is removed from the femoral vein slowly and continuously rather than in 1- to 4-L increments over a 2- to 4-hour treatment session, the typical pattern for hemodialysis (HD). Also, the diffusion clearance inherent to HD results in the return of a hypo-osmolar fluid to the intravascular space, resulting in a further loss of intravascular volume in comparison with CVVH. The latter restores volume losses with isotonic replacement fluid and fluid refilling from the overhydrated body parenchyma.³⁹ Second, trained nursing staff can administer CVVH, though it requires their continuous attention. Finally, the typical rebound in serum drug levels from redistribution observed after HD are not seen with continuous modalities such as CVVH.

The main disadvantage of CVVH in comparison with HD is the slower rate of toxin removal it can achieve. This disadvantage is significant if rapid toxin removal is critical to the patient’s survival, which often is the case. Thus, the use of CVVH for a toxin whose elimination is enhanced by dialysis techniques should be considered only when hemodynamic instability precludes the use of HD, when HD is not available, or if the inherently slower rate of toxin removal is clinically acceptable.

CVVH does not require arterial access—a pump is used to provide the pressure gradient necessary for filtration. Anticoagulation is required to optimize the lifespan of the apparatus (which requires replacement when it becomes clotted). However, the need for anticoagulation is less than for arteriovenous techniques because of the controlled blood flow provided by the pump, particularly in smaller pediatric circuits.⁴⁰ Animal data demonstrate that CVVH can achieve adequate flow rates with pediatric-sized filters and circuits.⁴¹ The blood is passed through a highly permeable hemofilter, forming an ultrafiltrate made up of plasma and filtered solutes. Hemodiafiltration refers to the use of a dialysate fluid on the opposite side of the filter from the blood flowing in a counter current direction. Table 2C-1 summarizes the relative advantages and disadvantages of CVVH, continuous arterial-venous hemofiltration (CAVH), HD and peritoneal dialysis (PD).

Indications

Box 2C-5 lists the toxins for which CVVH has been shown to speed elimination. Toxin-related factors determining clearance by CVVH include the sieving coefficient (dependent upon molecular weight and protein binding)

TABLE 2C-1 Advantages and Disadvantages of CAVH, CVVH, HD, and PD⁴⁰

TECHNIQUE	ADVANTAGES	DISADVANTAGES
CAVH	Less hemodynamic instability Ease of administration	Slower clearance rates Systemic anticoagulation Highest risk of clotting and air emboli
CVVH	Less hemodynamic instability Ease of administration	Slower clearance rates Systemic anticoagulation Higher risk of clotting and air emboli
HD	Faster clearance rates	More hemodynamic instability
PD	Faster clearance rates	More hemodynamic instability Peritoneal complications: Increased abdominal pressure Decrease in ventilation Peritoneal plural leaks Peritonitis Contraindicated if recent abdominal surgery

CAVH, continuous arterial-venous hemofiltration; CVVH, continuous veno-venous hemofiltration; HD, hemodialysis; PD, peritoneal dialysis.

and the volume of distribution.⁴² CVVH has been useful in a number of poisoning-related complications and in one condition that can result from poisoning. Hepatic and renal failure from acetaminophen have been managed successfully with CVVH in conjunction with aggressive supportive measures.⁴³ CVVH has been used for hyperphosphatemia from tumor lysis syndrome in conjunction with hemodialysis.⁴⁴ Myoglobin in an animal study and in humans from drug- and exercise-induced rhabdomyolysis has been removed successfully by CVVH.⁴⁵⁻⁴⁷ Severe lactic acidosis induced by propofol improved significantly with the use of CVVH.⁴⁸ CVVH has been shown to be safe and effective in treating radiocontrast-induced acute renal failure after percu-

taneous coronary interventions.³⁹ Hypothermia is associated with poisoning, particularly when central nervous system depressants result in excessive exposures to cold ambient temperatures. CVVH has been used with success in rewarming a patient with severe accidental hypothermia.⁴⁹

Contraindications

Toxins for which CVVH has not been shown to speed elimination are listed in Box 2C-6. One patient treated with a lorazepam infusion developed toxicity from the propylene glycol diluent, despite receiving CVVH with dialysis (CVVHD), suggesting that the glycol was not effectively removed.⁵⁰ Care should be exercised in choosing the replacement fluid; lactate-buffered solutions have been reported to induce hyperlactatemia.⁵¹ Since CVVH requires systemic anticoagulation, contraindications include recent surgery and gastrointestinal or intracranial hemorrhage. However, regional heparinization can be used with those patients for whom CVVH is necessary but who cannot tolerate systemic heparinization.⁴⁰ Trisodium citrate is a useful alternative to heparin as a regional anticoagulant with CVVHD to minimize the risk of hemorrhage and thrombocytopenia. However, caution should be exercised in patients with decreased hepatic function as use of trisodium citrate in this context is associated with severe hypercalcemia.⁵²

A summary of the indications and contraindications for CVVH in poisoning are listed in Box 2C-7.

PERITONEAL DIALYSIS

Though the first use of peritoneal dialysis PD dates back to 1923,⁵³ experiments with peritoneal lavage were carried out as early as 1877.⁵⁴ Numerous advances have been made since this early work was done, including the addition of substrates to the dialysate to enhance the elimination of certain drugs. Given the ease in most medical centers of obtaining HD, PD has fallen out of favor in most instances for the treatment of acute intoxication, although it continues to be used as a bridge when HD is not available or as an adjunct to enhance elimination. Because of its “second-tier” status, recent literature and research on its use in poisoning are sparse.

Method

The peritoneal surface area of an adult has been estimated to be 22,000 cm²,⁵⁵ allowing this structure to serve as an excellent semipermeable membrane for dialysis. PD involves in principle the passive movement of drug or toxin down its concentration gradient from the intravascular space in capillaries dispersed throughout the lining of the peritoneum into the dialysis solution infused into this cavity. As with other dialysis techniques, PD is particularly effective in removing drugs with small volumes of distribution and low protein binding.⁵⁶ The intermittent method of PD involves the use of one

Valproate¹¹⁴

CVVH, continuous veno-venous hemofiltration.

BOX 2C-7 CONTINUOUS VENO-VENOUS HEMOFILTRATION: INDICATIONS AND CONTRAINDICATIONS

Indications

Dialyzable toxin
low volume of distribution
low protein binding
molecular weight < 10,000 daltons
Hemodynamically unstable patient or hemodialysis not available or impractical (small children)
Drug-induced rhabdomyolysis
Drug-related hypothermia
Hyperphosphatemia
Toxin-induced lactic acidosis
Radiocontrast-induced acute renal failure

Contraindications

Hemodynamically stable enough for dialysis (relative)
Underlying contraindication to anticoagulation (relative)
High toxin clearance critical to patient survival
Absence of adequate nursing care

catheter to introduce the dialysate by gravity, removing it at a later time through the same access.⁵⁴ This process also can be carried out using two catheters.⁵⁶ Two liters of fluid (1200 mL/m² or 50 mL/kg in children) are used per exchange, with the fluid typically left in the peritoneal cavity for 45 to 60 minutes.⁵⁵ In contrast, during continuous ambulatory peritoneal dialysis (CAPD), dialysate is left in the peritoneum for much longer periods of time. Extending this period beyond 72 hours or leaving the catheter in place between courses of PD increases the risk of infection.

Various additives, such as glucagon, albumin, prostaglandin E₂ (PGE₂), lipids, furosemide, streptokinase, and chelating agents, have been added to dialysis fluid in the attempt to enhance elimination with varying degrees of success.⁵⁷⁻⁵⁹ A mildly hypo-osmolar solution is used to prevent water removal during dialysis, with electrolyte concentrations similar to that of extracellular fluid.⁵⁴ When the osmolality of the dialysate is increased, increased solute removal occurs at the expense of a negative fluid balance with each exchange.⁵⁵

Disadvantages and Complications

Whereas PD can be a continuous process, its elimination rate is significantly less than that of HD and other more invasive methods of extracorporeal therapy. Blood flow via mesenteric circulation in PD cannot be adjusted as it can in HD, and the mechanics of instilling and draining

dialysate into and from the peritoneum limit achievable clearance rates.⁵⁷ The time required to eliminate a given amount of toxin is three to six times greater with PD than with HD, depending on the properties of the agent. The elimination of small molecules that are highly membrane permeable is rate-limited by blood and dialysate flow rates, whereas the elimination rate of large molecules depends primarily on membrane surface area.⁶⁰ In severe poisoning from a dialyzable toxin, the difference in achievable clearance rates between HD and PD can have enormous clinical significance, as one case series of methanol poisoning illustrates.⁶¹ Thus, PD should not be substituted for HD in such cases unless the latter is absolutely inaccessible. If HD is not available in one treating facility but patient transfer is possible, the patient should be transferred. PD may be used as an adjunct during the transfer to speed toxin elimination.

Similar to other methods of extracorporeal elimination enhancement, PD can produce electrolyte shifts and loss of serum proteins. Pulmonary complications, including bronchitis/pneumonia, pleural effusions, and atelectasis, also are known adverse effects.⁵⁴ Bowel perforation from catheter misplacement occurs with an incidence of 1.3% according to one report.⁶² The other major complication of PD, especially CAPD, is peritonitis, which usually limits the long-term use of this technique.⁵⁵ The dialysate additive icodextrin has been reported to cause a blistering skin reaction that resolves upon cessation of the use of the substance.⁶³

Indications

PD can be used for toxins of up to 10,000 daltons in molecular weight and when a filtration rate of no greater than 15 mL/min is required.⁶⁴ It can be used when HD is not currently available and the patient's clinical status is critical. It can be used also when anticoagulation is contraindicated due to comorbidities.⁶⁵ PD has been more widely used in the pediatric population, especially in the contexts of acute renal failure seen in hemolytic-uremic syndrome, congestive heart failure, chronic renal failure, and hyperkalemia.^{55,62} Because of the difficulties of vascular access in small children as well as the difficulty in removing excess fluid gained between courses of dialysis without causing profound hypotension, PD offers distinct advantages in this population.

The toxins for which PD hastens clearance and those for which its effects on clearance have been equivocal are listed in Boxes 2C-8 and 2C-9, respectively. Note that there are toxins listed in Box 2C-7 that are eliminated by the kidneys, such as baclofen, for which PD has been found useful in poisoning accompanied by renal failure even though PD effects on clearance are small when renal function is normal. Also, PD has proven useful in treating toxin-induced renal failure apart from effects on toxin clearance. Hypercalcemia from overadministration of vitamin D in an anephric child has been effectively

treated with PD.⁶⁶ PD does not effectively remove the digoxin-Fab complex in the treatment of digoxin poisoning in the context of renal failure.⁶⁷

Contraindications

In the pediatric population, PD is contraindicated when there is severe intraperitoneal hemorrhage that is sometimes seen in hemolytic-uremic syndrome with thrombocytopenia.⁵⁵ The presence of focal peritonitis, a fecal fistula or colostomy, abdominal adhesions, and recent abdominal surgery with use of a prosthetic material, a major vascular anastomosis, or an open wound, are relative contraindications for PD.⁶⁵

Box 2C-10 lists the toxins for which peritoneal dialysis has not been found effective in accelerating clearance. A summary of the indications and contraindications for peritoneal dialysis in poisoning are listed in Box 2C-11.

D Hemodialysis and Hemoperfusion

JUAN C. ARIAS, MD ■ STEPHEN W. BORRON, MD, MS

Chapter 2C addresses the use of peritoneal dialysis, various forms of hemofiltration, and multiple-dose activated charcoal (MDAC) as so-called “gastrointestinal dialysis.” This chapter discusses the more classic methods for extracorporeal removal of toxicants, namely, hemodialysis (HD) and hemoperfusion (HP). In addition, we briefly discuss a newer methodology, the molecular adsorbents recirculating system (MARS, also referred to as albumin dialysis), which was developed primarily for the treatment of fulminant liver failure (FLF), but has recently been employed in the treatment of a variety of poisonings.

As has been pointed out in previous chapters, extracorporeal methods for toxicant removal should be viewed as important adjuncts rather than as primary approaches to specific poisonings. The most effective method of removal of toxicants from the body in most cases is maintenance of properly functioning kidneys, liver, and lungs through excellent supportive care. The ultimate evaluation of efficacy of extracorporeal methods is in fact through direct comparison with spontaneous elimination by the body.¹ In the absence of careful attention to resuscitation and supportive care, these adjuncts may be of little use; they may even be dangerous. Further-

more, while dozens of toxicants have been shown to be removed by HD or HP,² evidence-based support for significant clinical improvement from these procedures is often lacking. As will be shown, each of these procedures has benefits and risks, which must be carefully weighed against other methods of treatment.

It is difficult to ascertain the frequency with which HD and HP are employed in the treatment of poisoning. Based on the most recent Toxic Exposure Surveillance Survey,³ it would appear that use of HD ($N = 1730$) largely exceeds that of HP ($N = 30$). Both procedures were far more commonly performed in adults older than 19 years (93% of HD cases and 90% of HP cases) than in children. Use of these extracorporeal removal techniques in children younger than 6 years was rare (seven cases of HD, one case of HP). These figures are undoubtedly underestimates of real use, since reporting to poison centers by physicians is voluntary and incomplete. Nonetheless, they suggest that extracorporeal purification therapies have a limited role in management of poisoning in the United States.

METHODOLOGY

Hemodialysis

HD requires the passage of blood from the body through an external circuit, in which it is anticoagulated and placed in sustained contact with a selectively permeable membrane prior to being returned to the patient. Opposite the membrane and flowing in countercurrent direction is a heated dialysate, the composition of which can be varied according to the indications for dialysis. The variation of electrolyte concentrations, addition of buffers, and sometimes other additives allow the operator to manipulate the passage of these elements from one side of the membrane to the other. HD operates on the basis of three principles: diffusion, osmosis, and ultrafiltration.⁴ Diffusion relies on concentration gradients, with solutes moving from an area of higher concentration to an area of lower concentration, ultimately resulting in equilibration. Osmotic pressure results in the movement of water from one side of a semipermeable membrane to the other, dependent on a higher concentration of solutes on the other side. Manipulation of plasma sodium concentrations (sodium profiling) during dialysis can induce a net flow of water from cells into the plasma, allowing for its ultimate removal from the plasma. Ultrafiltration involves movement of fluid across the membrane due to the presence of a pressure gradient. This principle allows control of fluid loss during dialysis and can be manipulated via varying dialysate pressure (pressure control) or by variation of dialysate flow volumes (volumetric control). Volumetric control is more common in modern dialysis machines. In the case of toxicants, diffusion into the dialysate is the primary end point, although amelioration of acid-base and electrolyte conditions is often an important additional goal.

Dialyzer specifications (blood flow rate, surface area, and membrane construction) determine, in part, the

efficacy of drug or chemical removal from the blood. Pharmacodynamic and pharmacokinetic factors (molecular weight, lipid solubility, protein binding, toxicant concentration gradient, and volume of distribution [Vd]) are equally critical factors which will be discussed in further detail below.²

Hemoperfusion

HP implies the passage of blood through a device containing adsorbent particles.² It may be performed alone or in combination with HD and has been employed for a number of years in the management of poisonings. Resin HP with variants of Amberlite XAD (Rohm & Haas, Philadelphia, PA) was viewed as promising in the 1970s and 1980s. However, very few recent reports of resin HP have been published.⁵⁻¹⁰ This is likely in part due to unavailability of medical-grade resin cartridges in many geographic areas. Activated charcoal appears to be the most commonly used adsorbent material based on published reports, but hospital availability of even these cartridges appears to be limited. A recent survey of New York City 911-receiving hospitals revealed that only about one third of those surveyed had charcoal hemoperfusion (CHP) cartridges readily available (only one hospital had pediatric cartridges). Just 3 of 34 responding hospitals had used CHP within the previous 5 years. Reasons cited by the authors for limited cartridge availability and use of CHP were decreasing clinical use of phenobarbital and theophylline and improved efficacy of HD.¹¹

CHP irreversibly binds water- and lipid-soluble drugs and chemicals in the molecular weight range of 113 to 40,000 Da, a much larger range than that for HD (<~300 Da). Plasma drug extraction ratios for HP are superior to those for HD for acetaminophen (paracetamol), digoxin, glutethimide, paraquat, phenobarbital, and theophylline.² However, further examination of this list may reveal, in part, why HP is seldom employed in the United States. *N*-acetylcysteine is effective for acetaminophen poisoning, widely available, and less invasive. Digoxin Fab fragments are far more effective than HP in binding and eliminating digitalis glycosides. Glutethimide is rarely prescribed in the United States. Paraquat poisonings are rather rare in the United States, and HP has not been shown to alter outcomes, despite of reduction of plasma concentrations.¹² As mentioned previously, phenobarbital and theophylline have largely been replaced in clinical use by other agents, and the less invasive MDAC has been shown to be effective in reducing plasma concentrations of these agents, although it has not been proven to alter outcomes.¹³

Molecular Adsorbents Recirculating System

The Molecular Adsorbents Recirculating System (MARS) is a relatively new method of extracorporeal decontamination, which employs dialysis across a membrane impregnated with albumin and a 20% albumin dialysate,

thus attracting highly protein-bound substances. In addition, charcoal and anion exchange resin cartridges are employed to filter the dialysate, regenerating it for continued use.¹⁴ MARS may be of interest in the setting of poisons that have a predilection for liver toxicity, as the system is capable not only of removing certain hepatotoxins, but also reducing hyperbilirubinemia, restoring hemodynamics, diminishing hepatic encephalopathy, and improving renal function.¹⁴ MARS has been used to maintain patients in liver failure during the peritransplant period.¹⁵⁻¹⁸ The existing data for MARS in general are encouraging, but the evidence base is limited.¹⁹ This caveat is even truer in the setting of poisoning.

GENERAL PRINCIPLES FOR EXTRACORPOREAL DECONTAMINATION

Modalities and Susceptible Substances

A number of factors determine the suitability of use of HD or HP as extracorporeal methods of removal of a given toxicant. In the case of HD, chemical and drug removal are determined by factors as blood flow rate, dialysate flow rate, dialyzer surface area, and pore structure of the chosen membrane and by pharmacodynamic and pharmacokinetic factors such as molecular size (usually <300 Da), lipid solubility, protein binding, Vd, and concentration gradient. For HP, the selection of filter material has historically been important (charcoal vs. resin cartridges). With scarce availability of resin cartridges, the choice has essentially reverted to charcoal. HP is typically reserved for drugs with a low Vd and high protein binding,²⁰ but as mentioned previously, compounds of larger molecular weight may be removed. HD frequently causes hypotension, whereas this is reportedly less often a problem in HP. As such, in instances where hemodynamic instability after poisoning is an issue, HP may be preferable even if less efficacious for a particular toxicant. Vasopressors such as dopamine and norepinephrine are absorbed by the cartridges and therefore should be administered in the circuit after the sorbent. A definite role for MARS therapy in poisoning has not yet been established. In general, substances that are highly bound to albumin and poorly susceptible to other forms of treatment, including HD and HP, should prompt consideration of MARS, particularly in the setting of liver failure.

Molecular Weight

In order to be effectively hemodialyzed, toxicants should ideally be of low molecular weight (<300 Da).²¹ Examples of toxicants of low molecular weight are methanol (32.04 Da), ethanol (46.07 Da), ethylene glycol (62.07 Da), lithium carbonate (73.89 Da), butoxyethanol (118.20 Da), aspirin (180.15 Da), and theophylline (180.17 Da).²¹

Volume of Distribution

A low molecular weight alone is not sufficient, however, to assure effective dialyzability. For example, nortripty-

line has a molecular weight of 299.85 Da, but is poorly removed by HD. This is due to its very large Vd.²² The Vd is the theoretical volume into which a drug distributes in the body and is generally expressed in liters or liters/kg body weight. Substances with a small Vd (<1 L/kg) reside to a greater extent in the bloodstream and can generally be effectively removed by using extracorporeal methods. The Vd of a drug is the most important determinant of the efficacy of HP.²⁰ Even when extracorporeal methods are very efficient in removing toxicants from the blood, if the theoretical Vd is high, the pharmacodynamic effect achieved is likely to be minimal, as the concentration at the drug target tissue may be virtually unchanged.

Protein Binding

A third critical factor in predicting efficacy of extracorporeal methods is protein binding. HD is of limited value for substances that are highly protein bound. CHP, on the other hand, remains effective in cases of drug overdose with substances of high protein binding capacity.²⁰ A study conducted in 12 patients treated with HP, with drug overdoses involving 20 different drugs, showed that the efficacy of drug removal through adsorption by activated charcoal was dependent on the binding affinity, which is related to the protein binding percentage. This study concluded that drugs that are protein bound at levels of up to 95% are effectively removed from the blood with HP.²⁰ Following HD or HP, substances with a higher Vd and high protein binding percentage tend to redistribute from storage tissues to plasma. For this reason, a single extracorporeal substance removal session may be insufficient.²¹

Water Solubility

Water solubility is also an important factor in determining dialyzability. Water-soluble substances like ethanol, methanol, ethylene glycol, salicylates, theophylline, lithium, and valproate tend to have limited distribution in adipose tissues, thus limiting their Vd. This property makes them ideal for extracorporeal drug removal.

WHEN SHOULD HEMODIALYSIS OR HEMOPERFUSION BE CONSIDERED?

Poisoning by a substance susceptible to extracorporeal removal is not in itself an adequate justification for the procedure.² In general, extracorporeal methods should be reserved for poisonings for which toxic metabolic activation is anticipated (e.g., methanol, ethylene glycol), for which blood concentrations or the amount of toxicant absorbed foretell very serious toxicity, and for patients who have not improved despite of appropriate supportive care (volume repletion, acid-base correction, use of vasopressors, ion-trapping diuresis, and administration of specific antidotes). Winchester² identifies six clinical considerations for HD or HP in poisoning: (1) progressive deterioration; (2) depression of midbrain function leading to hypoventilation, hypothermia, and hypotension;

(3) development of, or predisposition to, complications of coma, such as pneumonia or septicemia; (4) impairment of drug excretion; (5) poisoning of substances possessing metabolic and/or delayed effects; and (6) poisons extractable at a rate exceeding endogenous elimination. These considerations could be condensed to (1) patients who are very sick or likely to become so and (2) toxicants for which HD/HP are effective in removal and known to make a clinical difference in outcome.

Toxicant Blood Concentrations

Blood concentrations of certain toxicants (e.g., methanol and ethylene glycol) have been proposed as indicators for HD. Historically, a plasma concentration of 50 mg/dL has been used as a threshold for the need for dialysis in both ethylene glycol²³ and methanol²⁴ poisonings. The availability of fomepizole, a safe and effective inhibitor of alcohol dehydrogenase, has altered the indications for HD.²⁵⁻²⁸ While HD continues to be a useful and often necessary adjunct in the treatment of toxic alcohol poisonings, an elevated blood concentration of the alcohol alone is no longer considered sufficient to require HD.

Metabolic Acidosis

Severe metabolic acidosis accompanying methanol and ethylene glycol, as well as other toxic alcohol poisonings, is a clear indication for HD, regardless of blood concentration. In these cases, HD not only effectively removes the toxicants and their acidic metabolites, but helps in directly correcting the acid-base balance of the patient. Even when the toxicant's molecular weight, protein binding, or Vd do not conform to the criteria necessary for dialyzability, HD should be considered in the setting of severe metabolic acidosis and/or renal failure. An example of this can be found in overdoses by metformin. Metformin would be expected to be poorly dialyzable on the basis of its very large Vd. However, metformin toxicity results in severe metabolic acidosis, which may be ameliorated by application of HD techniques.^{29,30}

SPECIAL POPULATIONS

Children

Both HD and HP may be performed in children, but both pose greater challenges than in adults. Vascular access is obviously more difficult in small children. For this reason, peritoneal dialysis has been historically used more often in children. However, use of peritoneal dialysis for acute renal failure in children appears to be decreasing and use of HD increasing over time.³¹ As mentioned before, availability of CHP cartridges suited to use in children may be extremely limited, even in major metropolitan areas.¹¹ However, it appears that if antidotal therapy for ethylene glycol is administered before the onset of renal insufficiency, HD, even in

children, may be safely avoided.³² Given the long half-life of methanol, HD is still considered advisable in children after treatment with fomepizole.³³

Chronic Renal Failure

Obviously, poisonings by substances normally eliminated by the kidneys may require HD or HP in patients with chronic renal failure.³⁴

COMPLICATIONS OF HEMODIALYSIS AND HEMOFILTRATION

Both HD and HP are associated with potential serious complications (Box 2D-1). The most serious complications associated with HD include hypotension (which by extension may lead to myocardial or brain infarction) and bleeding associated with anticoagulation. An addi-

BOX 2D-1 POTENTIAL ACUTE COMPLICATIONS OF HD AND HP

Catheter-Related Issues	Dialysate-Related Issues
Hemorrhage	Electrolytemias
Thrombosis	Acid-base disorders
Infection	Treatment water contamination
Central vein stenosis	
Anticoagulation-Related Issues	Charcoal Cartridge-Related Issues
Gastrointestinal hemorrhage	Electrolytemias
Intracerebral hemorrhage	Thrombocytopenia
Cardiac tamponade	Leukopenia
Heparin-induced thrombocytopenia	Hypocalcemia
Heparin-related thrombosis	Multiple Etiology Issues
	Pulmonary embolism/air embolism
Hypotension-Related Issues	Disequilibrium syndrome*
Mesenteric ischemia	Cardiac arrhythmias
Ischemic pancreatitis	Angina
Myocardial infarction	Cardiac arrest
Transient ischemic attack	Fever (bacteria, contaminated dialysis water)
Cerebral infarction	Muscle cramps
	Anaphylactoid reactions to membranes
	Severe hemolysis
	Hypoglycemia

*Nausea, vomiting, headache, blurred vision, confusion, and fatigue potentially leading to seizures, coma, and arrhythmias.

Adapted from Rahman MH: Acute hemolysis with acute renal failure in a patient with valproic acid poisoning treated with charcoal hemoperfusion. *Hemodial Int* 2006;10(3):256-259; Himmelfarb J: Hemodialysis complications. *Am J Kidney Dis* 2005;45(6):1122-1131; and Davenport A: Intradialytic complications during hemodialysis. *Hemodial Int* 2006;10(2):162-167.

tional significant consequence is reduction of therapeutic levels of drugs, which may result in unmasking of conditions protected by these agents. Complications appear to be relatively fewer in HP, but may nonetheless be important. HP is associated with the destruction of platelets, such that significant thrombocytopenia and bleeding may occur. This complication has been reduced by coating of the sorbent particles with a polymer solution.² Hypocalcemia likewise may occur.³⁵ Rahman and colleagues recently reported on the case of a patient treated with CHP for valproate poisoning. Despite of the use of coated charcoal, the patient developed severe hemolysis, which the researchers attributed to mechanical damage to red cells by the high flow rate through the cartridge. The patient required packed red blood cells, platelets, and fibrin transfusions, developing oliguric-anuric renal failure that required 23 days of HD over a period of several weeks. She ultimately regained her normal renal function.³⁶

RISK AND COST-BENEFIT CONSIDERATIONS

Transfer

HD and HP are not universally available. Thus, transfer to centers capable of performing these procedures may at times be required. The decision to transfer a patient for these therapies should rest on evaluation of several elements: (1) Is the patient stable for transport? (2) Will the patient's outcome likely be significantly better if the procedure is undertaken? (3) Are there acceptable alternatives to HD or HP? Each of these issues should be studied prior to committing a patient to prolonged and expensive or potentially hazardous transport to another facility for extracorporeal decontamination procedures.

As mentioned above, HD and HP have significant potential for complications. In certain poisonings, such as ethylene glycol and methanol intoxications, where HD was formerly routinely prescribed in the presence of high blood concentrations, recent improvements in specific antidotes have led to therapeutic alternatives. For example, if a patient with significant ethylene glycol poisoning arrives at the hospital before the onset of acidosis and renal failure, early treatment with fomepizole alone may preempt the need for HD.^{25,26,28} Even in the case of methanol, HD may be avoided in selective cases after early treatment with fomepizole.²⁸ Methanol's elimination half-life is much greater than that of ethylene glycol, however, and may require prolonged antidotal treatment in the absence of HD.

Intensive Care Unit Admission

Requirement for acute HD and/or HP generally implies costly intensive care unit (ICU) admission. As mentioned above, early administration of fomepizole may forego the need for HD and ICU admission in ethylene glycol and selected methanol poisonings, if administered prior

to the onset of acidosis and end-organ damage (renal failure or visual disturbances). While fomepizole is relatively expensive, a multiple-day ICU admission and HD might exceed drug costs. In other situations, HD or HP may shorten ICU or hospital stays and be cost conscious procedures. A formal cost-benefit analysis of these various treatment options would be useful.

EVALUATION OF EFFICACY

The evaluation of efficacy of extracorporeal methods of blood purification should ultimately rest on improvement in patient outcomes. However, a good outcome after HD or HP is not equivalent to established efficacy. Indeed, the literature is replete with case reports of the "successful use" of HD and HP in cases of poisoning in which the procedure may have had little impact at all on outcome. As mentioned in the beginning, the efficacy of extracorporeal purification procedures must be compared with the efficacy of elimination of the substance in question by the kidneys, liver, and lungs. Thus, one cannot estimate the utility by simply measuring blood concentrations before and after HD/HP.¹ Rather, the amount of extracted drug should be measured directly in the dialysate or via elution from the cartridge, or alternatively, indirectly from hourly differences in simultaneously arterial (inlet)–venous (outlet) concentrations multiplied by the purification system blood flow.¹ These amounts can then be compared to the concentrations in urine (determination of spontaneous renal clearance) and to the quantity believed to have been absorbed to determine efficacy. Before and after blood concentrations give some idea of the combined efficacy of corporeal and extracorporeal elimination, but the interpretation may be clouded by ongoing intestinal absorption or redistribution of the toxicant. Elimination by other routes (pulmonary, sweat) should be likewise considered.

TOXIC SUBSTANCES AMENABLE TO EXTRACORPOREAL ELIMINATION

The list of toxic substances that have been subjected to HD and/or HP is quite long. Winchester² provides a list of more than 200 substances removed with dialysis and HP. As already mentioned, the ability to remove a toxic substance by HP or HD is not equivalent to an indication for these procedures. One must take into account the patient's underlying health (renal or hepatic insufficiency), the toxicity of the absorbed substance, the presence of or likelihood of advancing to severe illness, the availability of these procedures, and the availability of acceptable alternatives (good supportive care, antidotes). A list of a few substances that have frequently been subjected to extracorporeal removal follows (Table 2D-1). The list is not comprehensive and does not necessarily imply an indication for HD/HP. The reader is referred to individual chapters for detailed indications for these and other forms of therapy.

TABLE 2D-1 “COP, I’VE STUMBLERD”

SUBSTANCE	SEE CHAPTER	HEMODYALYSIS (REFERENCES)	HEMOPERFUSION (REFERENCES)
Carbamazepine	40	(39–42)	(42–44)
Osmolal gap, increased	31, 32	(45–47)	
Propylene glycol	32	(47,48)	
Isopropanol	32	(49,50)	
Valproic acid	40	(51–58)	(51,57,58)
Excess acids (severe metabolic acidosis of toxic origin)	64, 90, 98	(29,59–61)	
Salicylates	48	(62–64)	
Theophylline	65	(11,65,66)	(65,66)
Uremia due to nephrotoxic drugs	12		
Methanol (formate)	32	(27,28,33,46,67,68)	
Barbiturates/butoxyethanol	40	(69–71)	(69,74,75)
Lithium	30	(76,77)	
Ethylene glycol/ethanol	32, 31	(68,78,79)/(80)	
Diethylene glycol/triethylene glycol	32	(81,82)	

This mnemonic serves as a reminder of some common substances encountered in poisonings potentially subject to removal by extracorporeal purification methods. Selected references are provided. Presence of a substance in this chart does not imply that extracorporeal methods are necessary or advisable. Clinical judgment is required.

SPECIFIC SUBSTANCES REMOVED BY CONVENTIONAL HEMODIALYSIS AND HEMOPERFUSION

Toxic Alcohols and Glycols

The alcohol and glycols generally have toxicity that is inversely related to molecular weight. This, along with limited protein binding, small volumes of distribution, and relatively high water solubility, makes them particularly amenable to removal by HD. Ethylene glycol (see Chapter 32B) has a molecular weight of 62 Da, it has no significant protein binding, and it distributes primarily in total body water ($V_d = 0.6\text{--}0.8\text{ L/kg}$), rendering it readily removable by HD.^{21,83} Additionally, glycolate, the toxic by-product of ethylene glycol responsible for acidosis, is effectively removed by HD.^{59,60} The indications for HD in ethylene glycol poisoning have been reviewed.^{26,28,49} Pizon and Brooks have stated that an extremely high ethylene glycol level should be considered an indication for HD regardless of the patient’s acid-base status or renal function due to hyperosmolarity.⁷⁸

Methanol (see Chapter 32A) is likewise small (32 Da), with minimal protein binding and a V_d of 0.6 L/kg.

Formic acid, the toxic by-product of methanol responsible for acidosis and retinal toxicity, is removed by HD.⁶¹ Hovda and colleagues have suggested that HD may be performed on an “elective” basis in selected methanol poisonings if patients are rapidly treated with bicarbonate and fomepizole.^{27,84} Several researchers have recently reviewed the indications for HD after methanol poisoning.^{24,28,85}

Isopropanol (see Chapter 32C) may also be removed by HD, although the indications for HD are limited, due to generally good outcomes with supportive care.^{49,86} HD has been proven to be effective in removing both isopropanol and acetone from the plasma.⁴⁹ Lacouture and colleagues have recommended HD in cases where the blood isopropanol concentration exceeds 400 mg/dL.⁸⁷

Salicylates

Salicylates (see Chapter 48) are compounds of low molecular weight. They are moderately to highly protein bound (50%–90%), with very small volumes of distribution. Although salicylates are highly protein bound at therapeutic concentrations, the fraction of unbound drug increases in the setting of overdose, rendering it amenable to removal by HD or HP. Early HD is recommended due to the high propensity of salicylates to cause serious toxicity and death.⁶⁴ The importance of concurrent alkalinization of the urine has been underscored by Higgins and colleagues.⁶³ Because of acid-base and electrolyte abnormalities associated with salicylate poisoning, acute HD, rather than HP, is generally preferred.²¹

Theophylline

Theophylline (see Chapter 65) has a low molecular weight and small V_d with moderate protein binding. Shannon addressed the use of HD and HP in theophylline poisoning in a 10-year prospective, observational study.⁶⁶ The study included acute, chronic, and acute-on-therapeutic poisonings. The incidence of major toxicity was significantly greater in those undergoing HD. Shannon concluded that while HP provides a higher theophylline clearance rate than HD, the latter appears to have comparable efficacy in reducing the morbidity of severe theophylline intoxication and is associated with a lower rate of procedural complications.⁶⁶

Lithium

Lithium carbonate (see Chapter 30) remains a commonly used therapeutic agent in the treatment of bipolar disorder. While its V_d is low, it concentrates in brain matter, rendering effective treatment more difficult. It has minimal protein binding and a very small molecular weight, and thus is amenable to treatment with HD. Indications for dialysis remain controversial.⁸⁸ Recently, newer forms of extracorporeal purification for lithium poisoning have been proposed⁸⁹ (see Chapter 2C) which allow slower removal of lithium without rebound levels.

Carbamazepine

Carbamazepine has a relatively low molecular weight (236 Da), but a fairly large Vd (1–2 L/kg) and is about 80% protein bound at therapeutic levels. Its active metabolite 10,11-epoxide (CBZE), is approximately 50% protein bound.^{42,44} Because of the high protein binding, activated charcoal and CHP have generally been favored in treatment; however, high-efficiency dialysis may also be effective.⁴⁰

Valproic Acid

Valproic acid (see Chapter 40) is a low molecular weight (144 Da) anticonvulsant with a small Vd and saturable protein binding. At therapeutic concentrations, 90% to 95% of valproic acid is protein bound, but in overdose the degree of protein binding is relatively less (i.e., there is more unbound drug available for extracorporeal purification). Saturation of protein binding sites occurs at levels greater than 150 µg/mL, at which 54% to 70% of the drug is protein bound. At a level of 300 µg/mL, 35% of valproic acid is protein bound,^{51,57,58} rendering it amenable to extracorporeal drug removal techniques.^{55,90} Both HP and HD, alone and in combination, have been used in cases of valproate toxicity. Valproic acid elimination has been shown to be enhanced about tenfold by the use of extracorporeal methods.⁵⁷ While the half-life of the drug is effectively diminished, the precise role of these procedures in valproate toxicity remains to be established.⁵⁸

SUBSTANCES REMOVED BY MARS

A nonexhaustive list of substances for which MARS has been used in poisoning includes theophylline,⁹¹ cytotoxic mushrooms,⁹²⁻⁹⁷ phenytoin,⁹⁸ acetaminophen (paracetamol),⁹⁹ and a copper-chromium-containing solution.¹⁰⁰ MARS appears to improve liver failure from multiple causes, but further prospective studies are needed to determine the role this technique should play in patient care.¹⁴

SUMMARY

In conclusion, HD and HP remain important, but secondary methods of treatment in poisoning by specific substances. These modalities cannot be substituted for excellent supportive care, and in some cases the need for them has been supplanted by effective antidotes. Both HD and HP are associated with complications and are not universally available. Careful evaluation of individual cases should guide the decision to use extracorporeal circulation. MARS or albumin dialysis may be of clinical benefit in selected poisonings.

Laboratory Diagnoses and Drug Screening

JOHN D. OSTERLOH, MD, MS ■ CHRISTINE A. HALLER, MD

Clinical laboratory tests that indicate the effects or presence of drugs can be useful in the emergency evaluation of the patient with an overdose. However, the majority of toxicologic diagnoses and therapeutic decisions are made on the basis of clinical findings, even though advances in technology have provided the potential ability to measure many toxins. It is easy to extol the technologic virtues of new toxicologic measurement techniques, but the application of these laboratory techniques is limited by practical considerations. The time required for analysis is often longer than the critical time course of an overdose case. Also, laboratories cannot support the cost of performing the variety of procedures, maintaining the instruments, supporting the regulatory and administrative infrastructure, and providing the training and specialized labor needed for analyzing every toxin.

The interpretation of laboratory toxicologic measurements requires that the relationship between the presence or the concentration of a toxin and its pharmacologic or toxicologic effects be known. For most toxins, our knowledge of such relationships is limited or unstudied, precluding the meaningful use of advanced technologic measures in direct clinical evaluations. Even when well studied, no clear relationship may exist. For example, a toxin at an effector site may not be in rapid equilibrium with the sampled fluid (e.g., lithium in the serum is not representative of lithium in the brain during the first 24 hours of an acute overdose); or the measured toxin

may be metabolized to an unknown, unmeasured, and active metabolite. Occasionally, limited information about pharmacologic relationships for common drug toxins has been derived from the monitoring of low-dose therapeutic situations. However, predictions based on pharmacokinetics or pharmacodynamics of drugs administered in the therapeutic range do not always extrapolate to overdose (e.g., theophylline elimination is first order at therapeutic doses and zero order in overdose).

Although the utility of many toxicologic measurements may be limited, the proper use of certain laboratory tests (both drug tests and biochemistry tests) in the emergency setting can be applied to many toxicologic presentations. A consensus paper on use of toxicologic tests for emergency evaluation of the overdosed patient was recently published.¹ This chapter reviews the utility, reliability, and application of toxicologic testing in the emergency evaluation of the intoxicated patient. Other situations are delimited, such as toxicologic testing for forensic cause of death, driving while intoxicated, methadone compliance programs, and surveillance drug screening (employee, athlete). Throughout this chapter, it is emphasized that appropriate use of such testing should be considered in the context of the clinical presentation of the patient. Frequently, intoxicated patients are diagnosed by signs and symptoms, or recognition of specific toxidromes. Common laboratory tests used in selected toxidromes are listed in Table 3-1.

TABLE 3-1 Selected Toxicologic Syndromes by Class of Drugs and Common Tests Ordered

CLASS OF DRUG	SIGNS	POSSIBLE CLINICAL, LABORATORY, AND TOXICOLOGIC TEST
Opiates and opioids	CNS depression (somnolent → coma) Slowed respiratory rate T° normal or low If BP decreased, pulse may not increase Miosis DTR usually decreased	Naloxone ABG GLU DAU
Alcohols, barbiturates	CNS depression (stuporous → coma) Ataxia T° usually decreased DTR decreased Metabolic acidosis with ethanol, methanol and ethylene glycol If BP decreased, pulse may increase	Calorics, thiamine ABG ALT, PT OG, AG Ca, Mg GLU DAU Serum or breath ethyl alcohol
Anticholinergics	Delirium Increased pulse, increased T° Skin is flushed, warm, dry (no sweating) Decreased bowel sounds Urinary retention Blurred vision Arrhythmias, prolonged QT	ABG EKG CK, K Cr/BUN CDS

TABLE 3-1 Selected Toxicologic Syndromes by Class of Drugs and Common Tests Ordered—(Cont'd)

CLASS OF DRUG	SIGNS	POSSIBLE CLINICAL, LABORATORY, AND TOXICOLOGIC TEST
Stimulants	Acute psychosis (nonreality) Increased pulse, increased BP, increased T° Increased respiratory rate Agitation Increased muscle tone/activity Dilated pupils Sweating Seizures	ABG EKG CK GLU K Cr/BUN DAU
Tricyclic antidepressants	Anticholinergic syndrome Hypotension Coma Seizures Sinus tachycardia Supraventricular tachycardia (early) Widened QRS, QT Ventricular arrhythmias	ABG EKG K DAU or CDS TCIS
Benzodiazepines	CNS depression Mild (if any) respiratory depression BP, pulse, T° are not greatly affected DTR intact	ABG DAU
Phenothiazines	Decreased BP, decreased T° Rigidity, dystonias, torticollis Miosis Anticholinergic syndrome (see above) Seizures	ABG CDS EKG
Salicylates	Nausea, vomiting, abdominal pain Respiratory alkalosis Metabolic acidosis Confusion Diaphoresis Hypoglycemia	ABG GLU K, AG Quant
Theophylline	Tachycardia Hypokalemia Hypotension Seizures	ABGs K Quant GLU
Iron	Nausea, vomiting, abdominal pain GI bleeding Hypotension Hypovolemia Acidosis Renal failure Cardiovascular collapse	ABGs K Hgb GLU TIBC Quant ALT, PT
Lithium	Tremor, chorea Ataxia, rigidity, hyperreflexia Abdominal pain Lethargy, confusion Seizures	Na, K, Cr CK EKG Quant
Isoniazid	Metabolic acidosis Seizures Hepatitis	ABG, K, ALT, CK
Oral hypoglycemics	Hypoglycemia Coma Diaphoresis	GLU Ketones
β blockers	Bradycardia Hyperglycemia Hypotension with slowed cardiac conduction	EKG GLU K CDS
Acetaminophen	Increased ALT, PT	ALT PT BILI Quant
Hydrocarbon inhalants	Stupor, confusion, headache Ataxia Liver injury Respiratory depression Cardiac arrhythmias	ABG ALT Chest x-ray EKG

ABGs, arterial blood gases; AG, anion gap; ALT, alanine aminotransferase; BP, blood pressure; BILI, bilirubin; BUN, urea nitrogen; CDS, comprehensive drug screen; CK, creatine kinase; CNS, central nervous system; Cr, creatinine; DAU, drugs of abuse screen; DTR, deep tendon reflex; EKG, electrocardiogram; GLU, glucose; K, potassium; Na, sodium; OG, osmolal gap; PT, prothrombin time; Quant, quantitative drug determination; T°, temperature; TCIS, tricyclic immunoassay screen.

Blood glucose analysis may be ordered in any of the above syndromes involving altered mental status.

USE OF MEDICAL AND TOXICOLOGIC TESTS

Medical tests can be categorized as belonging to one of three types: monitoring, diagnostic testing, and screening.² For each type, there is a different purpose for applying the test and a different prior probability that the test condition exists (Table 3-2). This prior probability dramatically affects the reliability of a test for each of these situations (see later section on Toxicologic Screens). In the monitoring of a patient, the change in a highly prevalent test condition—such as blood pressure, body temperature, or therapeutic drug concentrations—is being followed. The most important requisite for this type of test is precision or the ability to detect change. Thus, therapeutic drug monitoring and quantitative toxicologic tests that follow drug concentrations over time (e.g., lithium) must be precise. Diagnostic tests are applied in situations in which the presence of one of several test conditions is highly likely or suspected. Because various alternative disease conditions would have moderate probabilities of existing based on the diagnostician's evaluation, specificity is the more important attribute for “rule-in” diagnostic testing (i.e., no misidentification of a test condition). Diagnostic tests aid in making choices from a limited set of alternatives or confirming a highly likely diagnosis. For example, a patient with chest pain may have a myocardial infarction, esophagitis, neurologic or musculoskeletal injury. Electrocardiography findings and troponin testing can be applied to increase or decrease the probability of myocardial infarction as the cause of the symptoms. Occasionally, diagnostic tests are used to rule out other diseases. In this special case, the necessary attribute of the test is sensitivity. Often ruling out is not the original intent of a particular diagnostic test, representing the potential for clinical misapplication. Toxicologic panel testing or screening (e.g., comprehensive drug screen or coma panel) can be considered a diagnostic test when overdose is considered in the differential diagnosis and when the initial medical evaluation does not provide a clear picture of what is causing the signs or symptoms. Such testing may help answer the question, Is the patient's condition due to drugs or a disease, and secondarily, which drug(s) are involved? Screening tests must have good sensitivity (finding all cases) if they are to detect

the test condition in a low-prevalence situation. An example of this is screening for phenylketonuria in newborns. In the application of this test, there is no prior suspicion or preselection, and all newborns are tested. Nonspecificity arising from the screening tests can be corrected with subsequent, more specific testing.

The prior probability of a test condition (e.g., drugs present) will strongly influence the reliability (i.e., predictive value of a positive or negative test result, also known as posterior probabilities) at given values of sensitivity and specificity.³ In employee drug screening programs (low prior probability of drugs being present), toxicologic methods are adapted in order to improve sensitivity for finding low concentrations of drugs, or for detecting only a few drugs in unselected populations.^{2,4} Without such adaptations, the ratio of false-positive results to true-positive results would be high in this low-prevalence setting. In emergency toxicologic testing, procedures are designed to detect a larger number of drugs at high concentrations in patients clinically suspected of overdose (i.e., high prior probability, diagnostic situations). Thus, with regard to these definitions, the term *toxicologic screen* is a misnomer.

This raises the issue of what types of laboratories perform these tests. The development and use of toxicologic methods have evolved from a number of varied situations. Medical examiners investigating cause of death have other forensic evidence that often suggests a drug-related cause (raising the prior probability that the test condition exists in those forensic specimens). The concentrations of drugs or toxins are frequently very high, so analytic sensitivity is often not an issue; however, the type of tissue examined may frequently alter the ability of the analytic technique to detect a toxin. In surveillance drug screening (e.g. employee, athlete), low concentrations of drugs are expected for a small group of selected drugs of abuse, but these tests are applied to populations in which the prevalence of persons abusing drugs is low. So, additional confirmatory procedures are often necessary. Compliance programs (e.g., criminal justice, substance abuse) also test individuals for drug use. However, the prevalence of drug use in this selected population is much greater than in surveillance programs, as are the concentrations of the few drugs monitored. In each of these situations, the toxicologic methods are tailored to specific needs.

TABLE 3-2 Types of Medical and Toxicologic Test Situations

TYPE OF MEDICAL APPLICATION	PURPOSE	PRESELECTION OF POPULATION	PRIOR PROBABILITY (OR PREVALENCE) OF TEST CONDITION	PRIMARY ATTRIBUTE REQUIRED OF TEST	CLINICAL EXAMPLE	TOXICOLOGIC EXAMPLE
Monitoring	Measure change	Yes	85%–100%	Precision	BP, T°	TDM
Diagnostic	Categorize, confirm	Yes	30%–85%	Specificity*	Troponin	Tox “screen”
Screening	Find	No	0%–30%	Sensitivity	PKU	Employee drug testing

BP, blood pressure; PKU, phenylketonuria; T°, temperature; TDM, therapeutic drug monitoring.

*Specificity is the primary attribute for the commonly used “rule-in” or confirmatory diagnostic tests. Most diagnostic tests are not “rule-out” by design. If used this way, sensitivity is the primary attribute required.

The laboratory performing emergency toxicologic testing must consider the prevalence and the types of drugs that must be tested and should adapt methods to the sensitivity, specificity, accuracy, and precision required in their locale (see later section on Analytic Accuracy of Toxicologic Screens).^{1,2} Also, before any test is applied, it must be (1) analytically valid (i.e., defined and tested for detection limits, the calibration-response relationship, precision, referenced accuracy, dynamic range, interferences), (2) reliable (i.e., have appropriate clinical sensitivity, specificity, and predictive value), and (3) demonstrate utility (i.e., the test result will assist the clinician in making a diagnosis or in effecting a change in the course of therapy or disposition of the patient).

DRUG TESTING TECHNIQUES

The techniques for detecting the presence of drugs include a variety of chromatographic methods, immunoassays, chemical tests, and spectrometric techniques. Each of these general techniques can be developed or adapted so that they detect a large number of drugs and chemicals, or they can be focused specifically to detect and quantitate only certain drugs. The analysis of drugs, chemicals, or toxins is predicated on the matching of the properties or behavior (e.g., chemical, chromatographic, or light absorption) of a substance with that of a valid reference compound; that is, the analysis is comparative. For a laboratory to be able to test for a particular drug, it must possess that drug for the comparative process. Because the biologic sample matrix may contain components that can interfere with the detection of a drug, isolation of the drug from the biologic matrix is often necessary before characterization procedures are applied. With regard to usefulness, immunoassays and gas or liquid chromatographic techniques have the widest applications for single and multiple drug screens, respectively, or for quantitation. The major techniques have been compared for their sensitivity and specificity to commonly screened illicit drugs.^{5,6} Most broad screening methods are limited by the range of drugs detectable at one time or by sensitivity. In addition, methods can vary considerably with respect to individual drugs. For example, without application of derivatization techniques, ease of detection for morphine would be ranked as follows: immunoassay > thin-layer chromatography > gas chromatography. In contrast, in the detection of trazodone, the order may be reversed.

Chemical spot tests have been used in the past as initial quick screening tests for certain drugs. They rely on the chemical reactivity of the drug in the presence of specific reagents. These tests are usually not applied in settings in which a high degree of sensitivity or specificity is required (e.g., not in employee drug testing). A few of these tests (e.g. Trinder's for salicylate, ferric-perchlorate-nitrate [FPN] test for phenothiazines) offer rapid application and adequate accuracy when applied in emergency settings in which high drug concentrations are present.⁷

Spectrometric assays may require a chemical reaction (direct or enzymatic) that converts the target drug into a

light-absorbing species. These assays were commonly used in the distant past for the routine determination of barbiturates, acetaminophen, salicylates, quinidine, methaqualone, and chlorthalidone. Still in use today are the spectrometric assays for carboxyhemoglobin, methemoglobin, and cyanide. In uncomplicated cases, these three methods have adequate accuracy for quantifying spectrometric chemicals in overdose situations. However, spectrometric methods are prone to interference. For example, sulfhemoglobin and the antidote for methemoglobin, methylene blue, cause false elevation of methemoglobin levels with the co-oximetry method (see other examples in Tables 3-3 and 3-4). Many spectrometric assays have been replaced by enzymatic or immunologic assays, which can be performed on automated analyzers that perform a variety of other laboratory tests.

Immunoassays are available for rapid identification of about a dozen individual classes or specific drugs in urine and for quantitation of about a dozen drugs in serum. Most immunoassay methods are easily adapted to automated analyzers used in the general hospital laboratory for performing other clinical diagnostic tests. Any immunoassay relies on the ability of a drug-specific antibody to bind to either labeled drug (which may be bound to a fluorescent molecule, to an enzyme, or attached to a solid matrix) or to the free drug in a sample. Immunoassay techniques are available with a variety of analytic end points based on aggregation-light transmission, enzyme product formation, fluorescent polarization, and other principles. The most common immunoassay techniques used for the detection of drugs are the enzyme immunoassay (Fig. 3-1), fluorescent polarization immunoassay, and immunoaggregation assay. Each specific drug assay is commercially available as a kit, but kits are available for only a limited number of drugs. Usually such assays have analytic sensitivity in excess of that needed for the detection of overdose concentrations and use preassigned cutoff values that determine positive versus negative results. When immunoassays are used as initial screens; their results may require confirmation by a second method, depending on the pretest probabilities, sensitivity, and specificity. For example, employee drug testing with an immunoassay will require confirmatory testing. When a testable drug is suspected in an intoxicated patient (high prior probability), confirmatory testing is not usually needed, excepting immunoassays for the amphetamine class of drugs, which have many cross-reacting substances (see Table 3-3).^{8,9} If the clinician is applying the test as a screening type test (rather than confirming a diagnosis), then confirmation should be requested.

Point-of-care testing is now widely available because advances in technology have resulted in an increasing number of commercial hand-held test kits for rapid qualitative screening for drugs of abuse. These are immunoassay based. Products such as Triage (Biosite Diagnostics, San Diego, CA) and OnTrak Testcup-er (Roche Laboratories, Nutley, NJ) incorporate various immunoassay systems into a single-use unit with premade reagents and preset thresholds for detection of select

**TABLE 3-3** Qualitative Toxicologic Methods Used in Urine, Detection Intervals, and Interferences

DRUG/GROUP	REAGENT/METHOD NAME	TYPE OF METHOD	DOSAGE DETECTABLE* (DETECTON INTERVAL)	INTERFERENCES, NONSPECIFICITY†
Salicylate	Trinder's	SC	TD (<1 day), OD	Salicylamide, diflunisal, ketonuria, phenylketonuria, proteinuria, sulfonamides, hippuric acids (toluene, xylene) [‡]
Acetaminophen (p-aminophenol)	Ortho-cresol (rarely used)	SC	TD (<1 day), OD	N-acetyl cysteine, phenols from throat lozenges and mouthwashes, [‡] proteinuria
Phenothiazines (metabolites)	Forrest or FPN (ferric-perchlorate-nitric)	SC	TD for some (<3 days) OD	Salicylates, ketonuria, [‡] proteinuria
Ethchlorvynol	Diphenylamine (rarely used)	SC	OD (<3 days)	
Phencyclidine, methadone, tricyclics	Tetrabromophenophthalein ethyl ester (rarely used)	SC	OD	Other narcotics, antihistamines, antipsychotics [‡]
Chloral hydrate (trichloroethanol)	Fujiwara	SC	OD (<2 days)	Other chlorinated hydrocarbons
Opiates (morphine, codeine)	EMIT, FPIA, KIMS, CEDIA, RIA, CMI	IA	RD (<3 days), OD	Other opiates (hydrocodone, hydromorphone, oxycodone, dihydrocodeine), morphine from poppy seeds, adulterants, [§] rifampin, ofloxacin
Barbiturates	EMIT, FPIA, KIMS, CEDIA, RIA, CMI	IA	RD (<4 days), OD	Other less used barbiturates, NSAIDs adulterants [§]
Benzodiazepines (as oxazepam metabolite)	EMIT, FPIA, KIMS, CEDIA, RIA, CMI	IA	TD for some, OD (days to weeks)	Other less used benzodiazepines, [§] NSAID's less sensitive to triazolam, lorazepam, clonazepam, alprazolam, flunitrazepam (diazepam, nordiazepam, chlordiazepoxide, temazepam, midazolam, oxazepam are typically detected)
Amphetamines (amphetamine/methamphetamine)	EMIT, FPIA, KIMS, CEDIA, RIA, CMI	IA	RD (<2 day), OD	Newer generation assays react with MDA, MDMA, STP, and l-methamphetamine (in V1ck's inhaler). Older assays cross-reacted with many adrenergic amines, [¶] chlorpromazine [‡]
Marijuana (11-nor-9-carboxyl-tetrahydrocannabinol)	EMIT, FPIA, KIMS, CEDIA, CMI	IA	RD (<1 wk single use, <2 mo if chronic use), OD	Dronabilol, hemp products, pantoprazole (?); adulterants [§]
Cocaine (benzoylecgonine)	EMIT, FPIA, KIMS, CEDIA, CMI	IA	RD (<2 days), OD	Few, teas made from coca leaf, adulterants [§]
Phencyclidine	EMIT, FPIA, KIMS, CEDIA, CMI	IA	RD (<1 wk), OD	PCP analogues, ketamine, chlorpromazine, diphenhydramine, dextromethophan, venlafaxine
Ethanol	Enzymatic	SC	RD (<1 day), OD	Microbiologic production of ethanol in poorly stored urine
Tricyclics	CMI, others	IA	TD, OD	Quetiapine, diphenhydramine, atomoxetine, carbamazepine

CEDIA, cloned enzyme donor immunoassay; CMI, colloidal gold microparticle immunoassay; EMIT, enzyme multiplied immunoassay technique; FPIA, fluorescent polarization immunoassay; IA, immunoassay; KIMS, kinetic interaction of microparticle spheres; MDA, methylenedioxyamphetamine; MDMA, methylenedioxymethamphetamine ("Ecstasy"); NSAID, nonsteroidal anti-inflammatory drug; PCP, phencyclidine; RIA, radioimmunoassay; SC, spectrochemical (color change); STP, 2,5-dimethoxy-4-methylamphetamine.

*Method sensitive to overdose dosage (OD), therapeutic dosage (TD), or recreational dosage (RD) for window of time detectable in parentheses.

[‡]Not all reagent/methods cross-react to the same extent.

[§]Requires large amounts.

[¶]Adulterants; see text.

^{||}Negative interference.

[¶]Adrenergic amines such as phenylpropanolamine, ephedrine, pseudoephedrine, fenfluramine, phenteramine, isometheptene, and propylhexidrine. Also ranitidine, ritodrine, methylphenidate, labetalol, sertraline, trimethobenzamide, and others in the past. Also drugs metabolized to amphetamine: famprofazone, seligiline.

drugs in urine. Several studies have demonstrated excellent concordance of point-of-care devices with central laboratory analyzers.^{9,10} These devices may be advantageous in smaller clinical laboratories receiving small numbers of toxicology samples. However, because of limitations in specificity and sensitivity with immunoassays, these products should be utilized as

preliminary tests that require clinical correlation or confirmation by standard laboratory methods.

Chromatographic assays are widely used in emergency toxicology because a large number of drugs can be detected on a single chromatogram. Sensitivity is adequate for detecting the presence of many common pharmaceuticals at concentrations seen in overdose. For most

TABLE 3-4 Potential Interferences for Quantitative Serum Drug and Chemistry Tests Used in Emergency Toxicology

DRUG OR TOXIN	METHOD*	CAUSES OF FALSELY INCREASED BLOOD LEVEL
Acetaminophen	SC (rare use)	Salicylate, salicylamide, methyl salicylate (each will increase acetaminophen level by 10% of its level in mg/L); bilirubin; phenols; renal failure (each 1 mg/dL increase in creatinine = 30 mg/L acetaminophen)
Amitriptyline	HPLC, GC	Cyclobenzaprine, diphenhydramine
Carboxyhemoglobin	IA	Cyclobenzaprine, thioridazine, chlorpromazine, atomoxetine
	SC	Fetal hemoglobin (lipemia or high methemoglobin also may falsely decrease on some instruments)
Chloride	SC, EL	Bromide (0.8–1.0 mEq/L Cl = 1 mEq/L Br)
Creatinine	SC (rare use)	Ketoacidosis (may increase creatinine up to 2–3 mg/dL); cephalosporins; creatine (e.g., with rhabdomyolysis)
	EZ	Lidocaine metabolite, 5-fluorouracil
Digoxin	IA	Endogenous digoxin-like natriuretic substances in newborns and in patients with renal failure (up to 1 ng/mL), pregnancy, and liver failure. Oleander and bufotoxin glycosides cross-react as digoxin. Elevations after digoxin antibody (Fab) administration. Rarely, human antimouse antibodies in patient.
Ethanol	SC (rare use)	Other alcohols and ketones in oxidation methods.
	EZ	Isopropanol from venipuncture disinfectant. Patients with elevated LDH and lactate.
Ethylene glycol	SC	Other glycols; elevated triglycerides
Iron	SC	Deferoxamine causes 15% lowering of total iron-binding capacity (TIBC). Lavender-top Vacutainer tube contains EDTA, which lowers total iron.
Isopropanol	GC	Skin disinfectant containing isopropyl alcohol used before venipuncture (highly variable, usually trivial, but up to 40 mg/dL).
Lithium	F, EL	Green-top Vacutainer specimen tube (contains lithium heparin) may cause marked elevation (up to 6–8 mEq/L)
	SC	Quinidine, procainamide
Methemoglobin	SC	Sulfhemoglobin (cross-positive, 10% by oximeter); methylene blue (2 mg/kg dose gives transient false-positive up to 15% methemoglobin level); hyperlipidemia (triglyceride > 6000 mg/dL, may give false methemoglobin up to 28.6%) Falsely decreased level with in vitro spontaneous reduction to hemoglobin in Vacutainer tube (~10% of value/hr). Analyze within 1 hr.
Osmolality	Osm	Lavender-top (EDTA) Vacutainer specimen tube (15 mOsm/L); gray-top (fluoride-oxalate) tube (150 mOsm/L); blue-top (citrate) tube (10 mOsm/L); green-top (lithium heparin) tube (theoretically, up to 6–8 mOsm/L)
Salicylate	SC	Falsely normal if vapor pressure method used (alcohols are volatilized) Diflunisal, ketosis, salicylamide. Accumulated salicylate metabolites in patients with renal failure (~10% increase).
	IA	Diflunisal
	SC	Decreased or altered salicylate level; bilirubin; phenylketones
Theophylline	HPLC	Rarely, acetazolamide, cephalosporins. Endogenous xanthines and accumulated theophylline metabolites in renal failure (minor effect).
	IA	Caffeine. Accumulated theophylline metabolites in renal failure.

EDTA, ethylenediaminetetraacetic acid; EL, electrochemical; EZ, enzymatic; F, flame emission; GC, gas chromatography; HPLC, high-pressure liquid chromatography; IA, immunoassay; LDH, lactate dehydrogenase; SC, spectrochemical; TLC, thin-layer chromatography.

chromatographic procedures, drugs first must be extracted from serum or urine. In many cases, further chemical derivatization is necessary for making drugs compatible with the chromatographic phase or detection system. For example, in the detection of morphine by gas chromatography, the extracted morphine may be *N*-acetylated (or other derivative) to decrease its polarity, increase its volatility, and enhance its detectability. The partially isolated drug (extract) is separated from other solutes during its interaction with the chromatographic stationary phase. There are three general types of chromatography used in toxicologic analyses: thin-layer chromatography, gas chromatography, and high-performance liquid chromatography.

In thin-layer chromatography (TLC), extracted drugs are dried onto silica gel-coated plates. During the migration of a solvent up the plate, separation of the components and drugs in the extract is achieved by their

differential interaction with the silica gel and solvent (Fig. 3-2). Chemical reactants sprayed on the plate localize (detect) the drugs, and the drugs' locations are compared with the locations of reference drugs migrated parallel to the unknown extract. Usually a series of different chemical reactions are used in this process. The "staining" sequence and the ability to specify the migration distance of each drug endow TLC with the specificity that often is unachievable with the use of more elaborate procedures. However, with TLC, the analytical sensitivity for most drugs is limited to about 1.0 mg/L or greater, varying with the drug being tested, the detection method, and the amount of starting sample material. Many potent drugs may not be detectable with this technique (e.g., digoxin, lysergic acid diethylamide [LSD]) because of extremely low concentrations. TLC for drug detection in emergency situations has become standardized owing to the availability of commercially

FIGURE 3-1 Principle of an enzyme immunoassay. A drug-specific antibody inhibits an enzymatic reaction because of a drug label on the enzyme. The greater the amount of free drug in the sample, the less the inhibition by the antibody and the faster the reaction of the enzyme system.

prepared TLC systems (e.g., ToxiLab, Ansys, Inc., Irvine, CA). This has allowed expertise in the TLC identification of drugs to be less technologist dependent and results to be similar from laboratory to laboratory (see Fig. 3-2). Comigration of 30 or more drugs can be carried out on a single plate, allowing for drug identification with the use of information in a reference compendium. TLC will probably remain a common technique when testing for a broad range of unknown drugs.

High-performance liquid chromatography (HPLC) is similar in many respects to TLC. Drugs are separated within tightly packed columns, and high pressure is applied to the columns to elute the drugs. Column materials for HPLC may be silica gel, as with TLC, or nonpolar phases (e.g., alkyl groups) bonded to small particles. With the former, the drug is eluted with organic solvents, and with the latter, solvents miscible in aqueous buffers are used. Often, drugs eluting from the end of the column are detected on the basis of their absorption of ultraviolet light. Other detection techniques are based on refractometry, conductivity, electrochemical (redox) reactions, and mass spectrometry. Drugs are identified only by the time that it takes for each to be eluted from the column (retention time). HPLC systems have not been widely used in broad drug screening partly because of the narrow range of drug polarity that can be analyzed in one run. However, systems that change the composition of eluting solvent during a single run (gradient systems) or those that use multiple-column processing can broaden the detection window. Certain

automated instruments have been shown to be useful in screening for a wide variety of drugs of overdose,^{11,12} as well as the use of HPLC/mass spectrometry. Because of this high selectivity (resolution or separation of similar drugs), much HPLC work is directed toward the screening for classes of similar compounds, confirming the presence of selected agents or for quantitating specified drugs. Quantitation involves the measurement of the sizes of peaks relative to those of a standard compound added in a fixed quantity to all samples (internal standard). With extraction and evaporation of the extracting solvent, detection limits of 0.01 to 1.0 mg/L often are achieved with HPLC.

Gas chromatography (GC) requires that the extracted drug be volatile at the temperatures inside the GC column (80° C to 300° C). Drugs and toxins can be chemically modified to make them more volatile. During injection onto the beginning of the column, the solvated drugs are heated. Drugs in the gas phase are separated from each other by interaction with the “liquid” stationary phase (at high temperatures) on the column. Drugs eluting from the column can be detected on the basis of their thermal conductivity, combustibility, ability to donate electrons or capture β -particle beams, ionization, and other characteristics. The range of selective detectors for GC is quite broad. One mode of detection that merits discussion is gas chromatography/mass spectrometry (GC-MS). A portion of the effluent gases from GC are ionized by bombardment in an electron beam or other methods. The detected molecular fragments that result are characteristic of the eluting drug. When only unique fragments are monitored, the sensitivity can extend into the nanogram-per-liter range.

For both GC and GC-MS, the range of drugs that can be run on a single column is wide, but it is also limited by volatility and polarity. Current GC applications for screening of the many drugs seen in overdose cases are derived from methods developed in the 1970s.¹³ With the introduction of capillary columns and MS detection, many similar drug molecules can be screened with good resolution (specificity).⁶ An example of a chromatogram of standards used in emergency urine screening is shown in Figure 3-3. After extraction, evaporation of solvent, and reconstitution, the mixture is injected and volatilized into the gas stream of the column. As with other similar systems, about 0.05 to 0.5 mg/L of a large number of drugs is detectable. A common simple GC application is the determination of volatile alcohols, in which ethanol, methanol, isopropanol, and other volatile solvents can be identified and quantitated quickly.

EMERGENCY SERUM QUANTITATION OF OVERDOSED DRUGS

Rationale and Use

Serum quantitation of drugs or toxins in overdose are used for (1) diagnosis; (2) monitoring the course of the patient; (3) determining whether toxicity is occurring but not yet clinically apparent; (4) satisfying criteria for

FIGURE 3-2 Diagram of a standardized thin-layer chromatography system for identification of a wide spectrum of drugs (ToxiLab). Drugs from urine were extracted and plated in the middle of lane A and chromatographed. Lanes 1 to 4 are standard drugs comigrated with lane A. Sequential staining with chemical reagents (phases I through IV) and migration distance aid in the identification of the unknown drug in lane A. Amitriptyline (A) and its metabolite nortriptyline (a) are detected. Other metabolites (b) are also detected. (Courtesy of ToxiLab, Ansys, Inc., Irvine, CA.)

therapeutic interventions (e.g., dialysis); and (5) evaluating the efficacy of those interventions.^{2,14,15} In the emergency setting, relatively few quantitative drug measurements meet these goals. These drugs include acetaminophen, salicylates, theophylline, digoxin, ethanol, methanol, valproic acid, ethylene glycol, iron, carbon monoxide, and lithium (Table 3-5).^{1,2}

Two criteria must be satisfied in order for drug quantitation to be useful. First, clinical indicators that would otherwise reveal the status or condition of the patient must be absent. If the suspected toxin is known or its presence highly probable and if toxicity is apparent (i.e., clinical effects are observed), knowledge of drug concentration is of limited utility, except in patients with an overdose of any drugs listed in the previous paragraph. For most patients with drug intoxication, clinical indicators provide immediate evidence of the severity of the poisoning and are of greater value than measurements of drug concentration. For example, the clinical manifestations in the patient with an overdose of a tricyclic antidepressant indicate the course and severity of the ingestion. The second criterion that must be satisfied for measurements of drug concentrations to be useful is evidence of a concentration-effect relationship.

Unfortunately, only a few drugs have established concentration-effect relationships, and many more remain unstudied.¹⁵ In therapeutic drug monitoring, concentration-effect relationships may be clearly established for the end points of efficacy or low-level toxicity. These therapeutic relationships cannot simply be extrapolated to the overdose setting. For instance, carbamazepine has anticonvulsant properties at therapeutic concentrations of 5 to 10 mg/L, but may cause seizures when taken in overdose. Similarly, a therapeutic dose of theophylline may have a half-life of six hours, but in overdose amounts, the half-life may be much longer.

Quantitation of drug concentrations is indicated for drugs that may require hemoperfusion (e.g., theophylline, phenobarbital) or hemodialysis (e.g., salicylates, methanol, valproic acid), either as a criterion to initiate the therapy or to assess its efficacy (see Table 3-5). Quantitation of drug concentrations may also be required when a clinician is deciding whether to treat a patient with certain antidotes (e.g., Fab fragments for digoxin overdose) and when chelation therapy is being considered (e.g., deferoxamine for iron poisoning). Certainly, other clinical data may alter how the balance of clinical management is carried out. For example, it is well known that hypo-

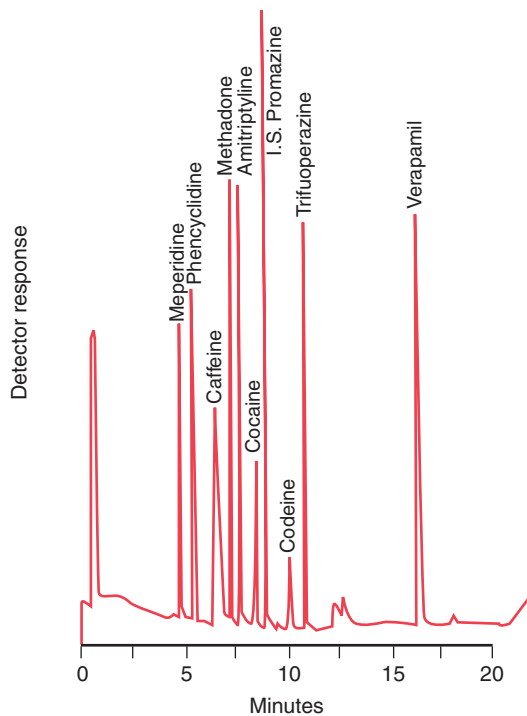

FIGURE 3-3 Chromatogram of a quality control urine sample containing 10 drugs after extraction from urine and detection by capillary gas chromatography with nitrogen-phosphorus detection. The concentration of caffeine and verapamil is 2.0 mg/L; that of each other drug is 0.5 mg/L. The limit of detection is about 0.05 mg/L.

magnesemia, hypokalemia, and underlying atherosclerotic heart disease are factors in the manifestation of digoxin toxicity.

Availability and Accuracy

With the increased use of quantitative serum immunoassays performed on rapid chemistry analyzers, most large hospital laboratories are able to provide a drug measurement that would usually be available as therapeutic drug monitoring assays. However, of all hospitals ($N = 5402$) capable of performing routine chemistry tests, only 63% performed assays for iron, 38% for lithium, 79% for theophylline, 51% for salicylate, and 51% for acetaminophen.¹⁶

Many emergency department (ED) physicians and medical toxicologists would like to see greater availability of serum quantitation for ethylene glycol to guide clinical management of suspected ingestions of this chemical. Because of the availability of a new antidote, fomepizole (Antizol [Jazz Pharmaceuticals, Palo Alto, CA]), the toxic effects of ethylene glycol and methanol can often be avoided, but the decision for hemodialysis is frequently made on the basis of concentrations that are greater than 25 to 50 mg/dL. Regionalized toxicology centers have been proposed as a means to increase the availability of rapid turnaround testing for a larger spectrum of toxins like ethylene glycol.

TABLE 3-5 Quantitation of Toxins: Guidance for Therapeutic Interventions

DRUG/TOXIN	MINIMAL CLINICAL PRESENTATION FOR CONSIDERATION OF INTERVENTION	CONCENTRATION GUIDANCE	THERAPY	RATIONALE FOR INTERVENTION
Acetaminophen	History of ingestion	>150 mg/L @ 4 hr, >50 mg/L @ 12 hr	NAC	Prevent hepatotoxicity
Theophylline	Hypotension Tachycardia	>100 µg/mL (acute OD only)	HP/HD esmolol	Prevent seizures
Phenobarbital	Coma	>100 µg/mL	HP/HD	Shorten coma time
Lithium (chronic)	Altered mental status, or tremor (greater concern if preexisting renal insufficiency)	>2.5–4 mEq/L (chronic OD only)	HD	Minimize CNS effects, prevent seizures
Methanol	AG metabolic acidosis + osmolar gap	History and CP for antidote >50 mg/dL for HD	4MP, ethanol, HD	Avoid blindness, fatality
Ethylene glycol	AG metabolic acidosis + osmolar gap	History and CP for antidote >50 mg/dL for HD	4MP, ethanol, HD	Reduce acidosis and avert renal injury
Salicylate	AG metabolic acidosis, respiratory alkalosis	>30 mg/dL to initiate intervention	Bicarb, HD	Promote salicylate elimination, prevent pulmonary and cerebral edema
Digoxin (acute)	AV block, hyperkalemia, bradycardia (acute)	>2.5–4 ng/mL (acute OD only)	Fab	Avoid cardiovascular failure
Iron	History of ingestion	>500 µg/dL	Deferoxamine	Avoid cardiovascular collapse, renal and hepatic failure
Carbon monoxide	Headache, dizziness, nausea, confusion, coma	Carboxy hemoglobin >5%	Oxygen, possibly hyperbaric therapy	Prevent neurologic sequelae

AG, anion gap; AV, atrioventricular; CNS, central nervous system; CP, clinical presentation; Fab, digoxin-specific antibodies; HD, hemodialysis; HP, hemoperfusion; 4MP, 4-methylpyrazole; NAC, N-acetylcysteine.

*For additional clinical effects, see Table 3-1.

The interassay imprecision for quantitative serum assays that are used in emergency toxicology is generally less than 5%. Not only must serum quantitation techniques be adequately precise to recognize a change occurring from one time point to another, but they should also be accurate (i.e., near to a true value) so that management decisions may be made relative to predetermined decision values. The accuracy and interlaboratory variability of quantitative serum measurements may be assessed on the basis of results from proficiency testing programs.¹⁶ In general, accuracy and agreement of results obtained by different laboratories are favorable for drugs measured commonly and by uniform techniques (e.g., antiepileptic drugs). For drugs that are measured infrequently and by more diverse methods, the results obtained are more diverse. Currently, interlaboratory coefficients of variation less than 8% and biases less than 15% have been demonstrated for the quantitation of most therapeutic drug monitoring-type drugs.¹⁶

Altered Analytic, Pharmacokinetic, and Pharmacodynamic Relationships in Overdosage

Serum drug quantitations must be evaluated with respect to each patient's clinical condition, drug pharmacokinetics, and timing of the specimen. The variation from person to person in the metabolism of medications and

toxic chemicals (Fig. 3-4), the interactions of disease processes and medications, the altered pharmacologic properties of drugs at overdose concentrations, and the potential for interference in assays may affect how a measured drug concentration is interpreted.^{2,15} For example, when taken in overdose, salicylates are more toxic than the linear extrapolation of effects of therapeutic concentrations would predict. This difference is the result of the elevation of free (unbound) concentrations with increasing serum concentrations, an increase in central nervous system penetration at acidic blood pH, and the saturation of metabolic pathways in the presence of the higher concentrations.

Interpretation of drug levels may be altered by the consideration of several factors together. For instance, a renal failure patient receiving normal doses of digoxin may have no digoxin-related symptoms even though the patient has a serum digoxin level of 4 ng/mL. Falsely measured digoxin-like substances in renal failure may raise the patient's measured "digoxin" level by up to 1 ng/mL. In addition, cross-reaction of accumulated metabolites due to poor renal clearance may falsely elevate the measured level an additional 2 ng/mL. While quantitative measurements tend to be highly specific, other drugs and disease states can produce analytical interferences, leading to false results (see Table 3-4). In contrast, a different patient with a measured digoxin level of 2 ng/mL may exhibit digoxin-related toxicity that is due to a coexisting hypokalemia.

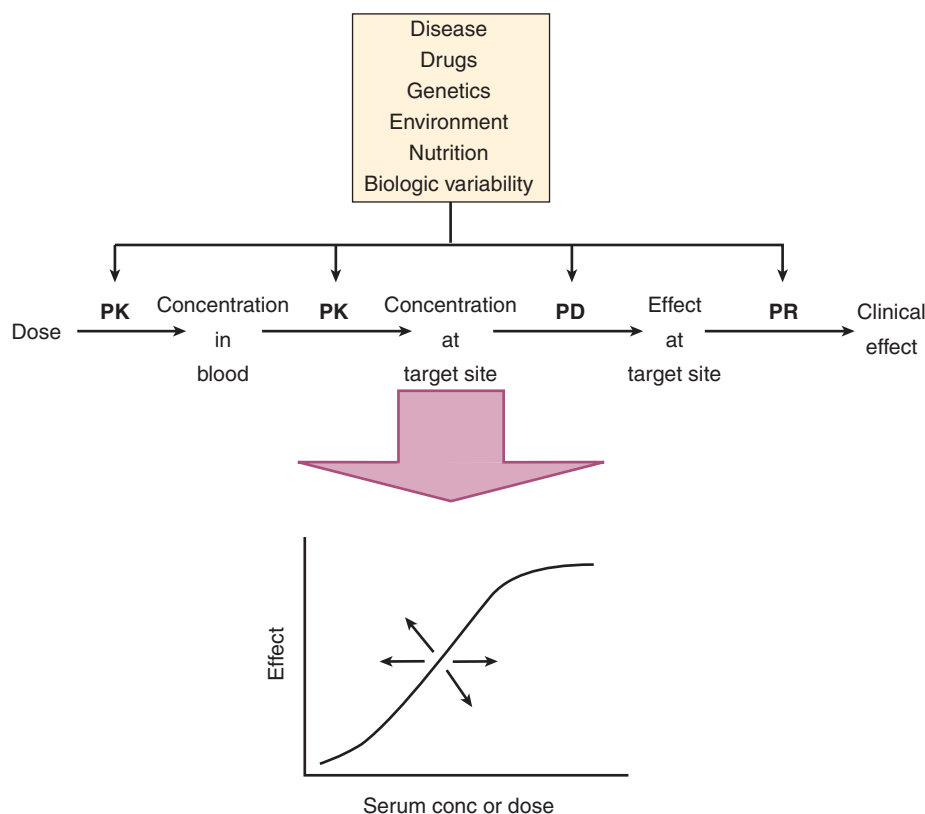

FIGURE 3-4 Factors producing altered pharmacologic relationships. PD, pharmacodynamics; PK, pharmacokinetics; PR, physiologic response to pharmacologic effect.

When drug levels are ordered from the laboratory, they must be interpreted with an understanding of the drug's pharmacokinetics and sample timing. For instance, lithium and digoxin exhibit slow distribution from the central blood compartment into peripheral tissues, and an elevated level soon after ingestion may not be a reliable predictor of toxicity. Postdistributional (equilibrated) levels better reflect concentrations associated with toxicity at peripheral target sites. In addition, some drugs exhibit significant delays in reaching peak levels after overdose due to erratic absorption profiles (e.g. carbamazepine), slowing of gut motility (acetaminophen combined with diphenhydramine), or slow dissolution due to sustained-release formulations (lithium, divalproate). In these situations, repeated quantitative measurements may be required.

TOXICOLOGIC SCREENS

Types of Screens

A toxicologic screen is a combination of many different laboratory procedures that is aimed at identifying the drugs most commonly encountered in emergency toxicology. Screens may include as many different assays as are necessary for the identification of target drugs. Alternatively, to shorten turnaround times, screens can be focused or abbreviated so that they test for only a few common, critical, or difficult-to-recognize drugs. The numbers and types of drugs on the screen can be adapted somewhat to reflect regional differences in drug prevalence.^{1,17} Ultimately, the availability of accurate, inexpensive commercial methods is often the greater determinant.

COMPREHENSIVE SCREENING

Comprehensive screening may include spot tests, immunoassays, TLC, and GC-MS procedures and may require 3 to 4 hours of intensive labor. Such broad screens or searches are applied to urine specimens and may include 80 to 200 target drugs or toxins. Because the search is wide and the prior probability is low for detection of a particular toxin, many laboratories will not report a drug's presence unless the agent has been detected on two procedures or unless the single method is known to be highly specific for a highly prevalent intoxicant (e.g., GC for ethanol). For instance, initial identification of codeine by immunoassay would be considered only presumptive and not reportable. Subsequent confirmation (e.g., by TLC or GC-MS) would make the result reportable. Lack of confirmation or the absence of initial identification would be reported as "not detected." Confirmation is not always a requirement in clinical testing, depending on clinical prior probability, the specificity of the single test used, and the implications of a positive test result.

A comprehensive approach to screening with multiple complementary methods will detect most common drugs used in overdose concentrations,¹⁸ yet only 6% of hospital or clinic laboratories are enrolled in proficiency

testing for comprehensive screening. This fact suggests that the capability to perform such comprehensive testing is not widespread.¹⁶ Drugs that are typically included on a comprehensive toxicologic screen are listed in Box 3-1, and toxins that are not usually detectable in such toxicologic screens are listed in Box 3-2. Many of these undetectable drugs are either not very prevalent or not very toxic, but many important toxins are not routinely detected in comprehensive screening procedures (e.g.,

BOX 3-1

TYPES OF COMMON DRUGS INCLUDED ON MOST CHROMATOGRAPHICALLY BASED COMPREHENSIVE "TOX SCREENS"

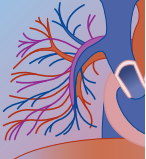

Volatiles: ethanol, methanol, isopropanol, acetone
 Barbiturates/sedatives: amobarbital, secobarbital, pentobarbital, butalbital, butabarbital, phenobarbital, glutethimide, methaqualone
 Antiepileptics: phenytoin, carbamazepine, phenobarbital
 Benzodiazepines: as parent drugs or metabolites, chlordiazepoxide, oxazepam, diazepam, alprazolam, lorazepam, temazepam
 Antihistamines: diphenhydramine, chlorpheniramine, brompheniramine, triphenelamine, trihexiphenidyl, doxylamine, pyrilamine
 Antidepressants: amitriptyline, nortriptyline, doxepin, imipramine, desimipramine, trazodone, amoxapine, sertraline, fluoxetine
 Antipsychotics: trifluoperazine, perphenazine, prochlorperazine, chlorpromazine, olanzepine, risperidone
 Stimulants: amphetamine, methamphetamine, phenylpropanolamine, ephedrine, methylenedioxymphetamine (MDA), methylenedioxymethamphetamine (MDMA, or "Ecstasy")
 Narcotics analgesics: morphine, codeine, oxycodone, hydrocodone, hydromorphone, meperidine, pentazocine, propoxyphene, methadone
 Other analgesics: salicylates, acetaminophen
 Cardiovascular drugs: lidocaine, propranolol, metoprolol, quinidine, procainamide, verapamil
 Others: caffeine, cyclobenzaprine, hydroxyzine, nicotine, oral hypoglycemics, strychnine

BOX 3-2

TOXINS NOT DETECTABLE BY CHROMATOGRAPHICALLY BASED EMERGENCY TOX SCREENS, CLASSIFIED BY AREA OF DIFFICULTY

Too polar: antibiotics, diuretics, isoniazid, ethylene glycol, lithium, lead, iron
 Too nonpolar: steroids, Δ^9 -tetrahydrocannabinol (THC)
 Too nonvolatile: plant and fungal alkaloids, some phenothiazines
 Too volatile: aromatic and halogenated hydrocarbon solvents, anesthetic gases, noxious gases (hydrogen sulfide, nitrogen dioxide, carbon monoxide)
 Concentration too low: (Potent drugs or drugs with large volumes of distribution): clonidine, fentanyl, colchicine, ergot alkaloids, LSD, dioxin, digoxin, THC
 Toxic anions (too polar): thiocyanate, cyanide, fluoride, bromide, borate, nitrite
 New drugs: e.g., buspirone, aripiprazole

Nonchromatographically based tests may be available for some toxins as separate tests.

ethylene glycol, γ -hydroxybutyrate [GHB], isoniazid, and cyanide). Assays for drugs not included in the toxicologic screen can often be requested as separate quantitative tests. Clinicians can help reduce clinical false-negative results (which can occur when a test is ordered that is not capable of detecting the suspected agent) by knowing which drugs and toxins are not included on the screens at their hospitals. Clinical laboratories should inform ED staff when method changes are made that affect test specificity, or when drug assays are added or dropped from toxicologic screens.

DRUGS-OF-ABUSE SCREENS

A smaller screen for illicit drugs also is commonly offered and available with a rapid turn-around time. A drugs-of-abuse screen typically consists of six to eight immunoassays for common illicit substances tested in urine, with confirmation procedures performed as needed or requested by the clinician. The drugs-of-abuse screen might include such drugs as opiates (morphine, codeine), amphetamines, cocaine, and propoxyphene and is typically most used by the emergency and psychiatric services. Drugs-of-abuse screens are based on immunoassays that have been developed and primarily marketed for use by drug surveillance programs and not for overdose diagnostic use. Hence the cutoff concentrations used for determination of a positive or negative may be inappropriately low for use in assessing an overdose patient. For an assay with a low-level cutoff, the positive detection of the drug may be due to earlier drug use that is unrelated to the current clinical condition (see Table 3-3 for detection intervals). Communication between the laboratory and the treating physician is essential for selection of the appropriate sequence and choice of tests, clinical correlation of results, to speed analysis, and to help the laboratory make the best use of its resources.

CONFIRMATORY TESTING

In testing for illicit drug use, it is recommended that preliminary results be confirmed by a second specific test, whether at the time of the report or later, because false-positive documentation in the clinical record may have negative consequences for the patient. Also, the clinical laboratory should include a list of major cross-reacting substances (see Table 3-3) when a positive result is reported if not confirmed by a second method.^{1,2} The detection and reporting of some highly prevalent and nonillicit drugs may not require confirmation because this higher prior probability combined with a test of fairly good specificity allows for adequate confidence in the test result (e.g., predictive value of the positive test is high). Also, because some drugs often are present in drug-using populations that may be seen in the ED, or because they contribute little to the clinical picture, no testing may be needed. For example, although some hospital laboratories test for marijuana, it is not recommended in emergency situations because (1) it is highly prevalent in the drug-using population that may overdose on more serious drugs, (2) it is rarely considered responsible for serious toxicologic effects,

and (3) it is excreted in urine for long periods of time after use and thus may not be temporally related to the acute clinical picture.

SPECIMEN REQUIREMENTS

Urine specimens submitted for toxicologic analysis should be collected in a preservative-free container and transported to the clinical laboratory as soon as feasible. A specimen volume of approximately 30 mL will be adequate for most toxicologic analyses. Stability of most drugs is expected for 24 hours in urines stored at 25°C, for as long as 2 weeks for specimens refrigerated at 2° C to 8° C, and for years in specimens frozen at -20° C to -80° C. Generally, urine is analyzed for diagnostic testing and serum is analyzed for quantitative determinations. Other specimen types are used in other toxicologic testing situations (Table 3-6).

Rationale and Use of Toxicologic Screens

In the emergency setting, urine and blood can be obtained as soon as a toxicologic etiology is considered in the differential diagnosis. Drugs-of-abuse screens can confirm the clinical suspicion of a few common drugs relatively quickly. It is unlikely that comprehensive screening will produce results that will affect early diagnosis or emergency management (see later section on Clinical Utility of Toxicologic Screens), but if the initial diagnosis remains unclear, a comprehensive screen may help determine the etiology in a small percentage of cases. Testing of urine specimens identifies the greatest number of drugs in easily detectable quantities. When compared with assays using serum or gastric aspirates, urine yielded the highest rate of positive findings.^{18,20} Comprehensive screening of serum or blood is not widely available, although it is possible with the application of newer techniques. The analytical limitations of serum screening include lower concentrations of drugs found in serum, small sample size, and the incompatibilities of serum with some testing methodologies. In some cases, however, drugs may not have reached the urine in measurable quantities soon after ingestion, allowing earlier detection in the plasma. Also, some drugs are highly metabolized, and thus little of the parent drug may be detectable in the urine. Although gastric samples often contain high concentrations of the parent drugs, testing of gastric aspirates should not be performed routinely. In one study, patients who had undergone gastric lavage for initial management had the following proportion of positive results for the presence of drugs on analyses of specimens: urine, 93%; serum, 54% (samples screened for sedative-hypnotics and ethanol); and gastric aspirate or lavage effluent, 38%.²⁰

When ordering a toxicologic screen, the clinician should write suspected drugs or drug classes and the key symptoms or the working diagnosis on the requisition. This facilitates both the screening process and the communication of results back to the ordering physician. For instance, if a toxicologic screen is ordered and

TABLE 3-6 General Advantages and Disadvantages of Some Common Specimen Types for Use in Drug Monitoring and Toxicologic Testing

TISSUE OR FLUID	ADVANTAGES	DISADVANTAGES
Whole blood or red cells	May reflect tissue levels or body burdens Concentration-effect relationships may exist Available	Harder to process than serum Sampling time in relation to dose must be known Requires some distribution into red cells
Serum or plasma	May reflect dynamically active fraction of drug Concentration-effect relationships may exist Available	Easier to process than blood Sampling time in relation to dose must be known In overdose, less sensitive detection than for many drugs found in urine Less useful and often not possible for toxins concentrated in red cells due to variability or sensitivity issues
Saliva	May reflect serum concentrations or unbound (free) concentrations Usually available	Variable acquisition of a reliable specimen Requires additional method validation (vs. serum-based methods)
Urine	When quantitated, may reflect daily exposure or intake of short half-life drugs that are eliminated by kidneys In overdose, a wider number of drugs in higher concentrations are present for detection Usually available	Less direct relation to tissue concentrations or effects than serum or blood Collection interval may be important May not be applicable to drugs that are highly lipophilic, highly metabolized, or not renally eliminated
Gastric aspirate fluid	In overdose, high concentrations of parent drug may be present without metabolites	Little relation to tissue concentration or effect, but may identify some intoxicants
Hair	When quantitated, may represent an accumulative dose May indicate timing or history of exposure per segment of hair	Use not established for most drugs or toxins Potential for external contamination Potential effect of hair treatments
Meconium	May reflect maternal (and fetal) exposures to drugs during last 2 months of pregnancy	Limited to sampling only the first day of newborn life Difficult specimen to process

clonidine is specified as the drug suspected of causing pinpoint pupils and respiratory depression, the laboratory can inform the clinician that the screening methods would be unlikely to detect clonidine, but that testing for opiates could be performed. In another case, a physician may order only a test for amphetamines in urine because the patient is “acting bizarrely.” In this case, a comprehensive screen may be recommended by the laboratory since several other drug classes, including antihistamines, belladonna alkaloids, and dextromethorphan, can cause altered behavior. The best method of communication is the use of a requisition form containing adequate prompts and sufficient space for written comments. In a survey addressing the use of these forms, only 48% had space for the listing of suspected drugs.²¹

Drugs Found in Drug Overdose

Two and one quarter million cases of accidental (85.2%) or intentional (11.6%) poison exposures, with about 800 deaths, are reported annually by poison control centers in the United States.²² The number of recorded poisoning deaths occurring in the United States in 1995 was 18,549 as reported by the National Center for Health Statistics.²³ Since only 5% of intoxication deaths are reported to poison control centers, the total number of poison exposures in the United States may be underestimated.²⁴ The low incidence of fatality reflects the low toxicity of exposure in the majority of cases and

the effect of medical treatment; however, drug ingestions (i.e., not other toxins) accounted for 77% of poison-related deaths. The drug categories responsible for the deaths reported by poison control centers in order of frequency were analgesics (narcotic and non-narcotic), sedative-hypnotics/antipsychotics, antidepressants, stimulants (including amphetamines, cocaine, and phencyclidine), cardiovascular drugs, and alcohol.²² The top five drugs found in various situations are listed in Table 3-7.^{22,23,25,26} The incidence of detection of barbiturates and ethanol has decreased, while that of benzodiazepines, other sedative-hypnotic drugs, and stimulants, particularly cocaine, has increased. A retrospective review of records from an inner city ED from 1988 to 1997 found that cocaine was the most common drug presentation, accounting for 33% of drug-related visits.²⁵ In contrast (see Table 3-7), poisoning mortality data from the National Center for Health Statistics report a slightly different spectrum of toxic exposures associated with death, listing opiates, motor vehicle exhaust gas (carbon monoxide), cocaine, psychotropic drugs, analgesics, and ethanol as the more common causes.²³ Although exposure to a single drug is implicated in 92% of reports, 48% of fatal cases involved two or more substances.²² Unintentional exposures account for the majority of pediatric poisonings and usually involve single substances. Drugs are responsible for only a minority of all exposures in children (27%), but they account for a large portion of intoxications, hospital admissions, and deaths, particularly among

TABLE 3-7 Top Five Drugs Involved in Emergency Department (ED) Visits and Poisoning Deaths

RANK	POISON CONTROL DEATH REPORTS (AAPCC 2001)	POISONING DEATHS NATIONAL CENTER FOR HEALTH STATISTICS (NCHS 1995)	HOSPITAL/ED CHART REVIEW RUSH-PRESBYTERIAN-ST. LUKE'S HOSPITAL (1988–1997)	DRUG-RELATED ED VISITS (DAWN 2001)
1	Analgesics	Opiates	Cocaine	Ethanol
2	Sedative-hypnotics/ antipsychotics	Motor vehicle exhaust gas	Opiates	Cocaine
3	Antidepressants	Cocaine	Marijuana	Marijuana
4	Stimulants street drugs	Tranquilizers/psychotropics	Benzodiazepines	Benzodiazepines
5	Cardiovascular agents	Analgesics/antipyretics	Phencyclidine (PCP)	Analgesics

Drug Abuse Warning Network (DAWN) data are underreported and only a small fraction of ED cases are reported to the American Association of Poison Control Centers (AAPCC). Poison Control Center deaths represent only 5% of deaths seen in the NCHS database.

teenagers.^{22,27-29} Drugs found on emergency toxicologic screens mimic these trends, but vary by report because of regional differences, ordering patterns, and the composition of the screens.³⁰ However, comprehensive screening can detect up to 84% of the fatal drugs and around 90% of drugs involved in ED visits.^{18,31}

Analytic Accuracy of Toxicologic Screens

Currently, testing in emergency hospital laboratories can be assessed by hospital laboratories' participation in proficiency testing programs administered by the College of American Pathologists.¹⁶ For immunoassay-based drugs-of-abuse screening, the proportion of false-positive results is generally low (less than 1% for 12 drug classes), and false-negative results also account for less than 1% of results among the 2900 laboratories responding, with some notable exceptions (35% false-negative results on one barbiturate challenge, 27% false-negative results on one marijuana challenge). Although other surveys indicate higher false-negative rates, these low rates are due in part to the restricted nature of this testing, in that the laboratories expect that only these few classes of drugs are present or absent in these samples. In actual clinical practice, the occurrence of false-positive results is higher due to cross-reactive drugs and other interferences (see Table 3-3), especially when confirmation is omitted.

In comprehensive toxicologic screening, the incidence of false-negative results on testing for an infrequently tested drug, such as ethchlorvynol, can be as high as 52%, compared with about 6% for a common drug such as codeine.¹⁶ The false-negative rate for these less commonly tested drugs is due to poor validation of analytical parameters for these agents, particularly cutoff concentrations or the limits of detection. Also, false-negative results may be due to a problem of the proficiency testing survey, in that the laboratory fails to state it has no method for detecting the drug in question. The occurrence of false-positive results is lower in part because of high drug concentrations seen in cases of overdose and because of the use of complementary confirmatory techniques. However, even when using several methods, including GC-MS technology, misidentification of drugs can occur. Many false-positive and some false-negative

results on these surveys may also be due to misidentification within a drug class (i.e., pentobarbital for amobarbital). Thus, the impact of this error on clinical diagnosis would be small.

Testing accuracy will vary depending on the purpose of the testing program (e.g., forensic cause of death, surveillance, compliance) and the analytical strategies employed. For instance, adulteration detection is particularly important in urine drug surveillance programs; methods include visual scrutiny of the sample for abnormal foaming, color or odor, alterations in specific gravity, creatinine concentration, temperature, pH, and tests measuring specific adulterants (nitrites, glutaraldehyde, pyridinium chlorochromate). False-negative results due to interference from intentional adulteration are much less likely in emergency toxicologic screening. Common adulteration techniques include dilution (by ingestion or direct addition of water), substitution (with purchased urine or the urine of another person or animal), ingestion of weak acids or bases (e.g., vinegar or bicarbonate, respectively) to influence the excretion of basic or acidic drugs, the use of interfering substances to alter test results (e.g., benzalkonium chloride), and the addition of strong chemicals (e.g., soap, bleach, or glutaraldehyde) to impair biologically based immunoassays.³²⁻³⁴

Accuracy of the Clinical Diagnosis

Although several early studies indicated that information on drug ingestion was unreliable or unavailable in 75% of 167 drug overdose cases,^{35,36} numerous studies indicate that the correct drug or class of drug could be identified in 80% to 85% of the cases by recognition of toxidromes,³⁷ or by consideration of the patient history, physical examination, basic laboratory tests, and a few quantitative drug tests.³⁸ Generally, diagnoses are incorrect or unknown in less than 15% of cases when initial findings were compared with data collected during extensive follow-up and other toxicologic testing.³⁷⁻³⁹

Clinical Reliability of Toxicologic Screens

Overall, clinical reliability of toxicologic screens depends on (1) analytic sensitivity and specificity, (2) whether a particular laboratory routinely tests for the expected

drugs, and (3) the prior probability of overdose. The prevalence of positive results on drug screens in overdose cases is about 50% to 80%. Prevalence of positive screens will show regional and temporal variability reflecting changes in patterns of drug abuse. In addition, prevalence of drug use differs with patient demographics. For example, dextromethorphan is an increasingly commonly abused substance among adolescents, and may be more prevalent than substances such as cocaine or methylenedioxymethamphetamine (MDMA, or “ecstasy”), which are detected in increased frequency in young adults. If it is assumed that the prior probability of drugs being present in a patient who appears to have an overdose is 50% and if the comprehensive toxicologic screen has a sensitivity of 70% to 90%, then the predictive value of a negative test result is 63% to 83%. If the specificity is from 90% to 100%, then the predictive value of a positive test result is 83% to 100%. Thus, in this case, the rule-in value of the toxicologic screen is better than its rule-out value. Kellerman and associates¹⁹ indicated that most physicians tend to use toxicologic screens to rule out drug toxicity as a diagnosis and are less likely to use these screens for rule-in purposes. Such use is disconcerting if the positive predictive value of toxicologic screens is higher than their negative predictive value in high-prevalence settings. On the other hand, when diagnostic choices are few and the working diagnosis is unlikely to be drug intoxication, rule-out testing is reasonable. For example, if a patient was highly suspected to have a non-drug-induced metabolic coma, the prior probability of involvement of detectable drugs might be considered very low (e.g., 5%) in light of other data indicating metabolic causes (e.g., liver failure). With this prior probability and the same specificity and sensitivity of the toxicologic screen, the predictive value of a negative test result is from 76% to 90%, and the predictive value of a positive test result is 33%; hence, the rule-out value is better (see discussion in the ensuing section on Clinical Utility of Toxicologic Screens).

Clinical Utility of Toxicologic Screens

Do the results of toxicologic screens alter the diagnosis or change patient management? Toxicologic screens may have limited utility for the following reasons:

1. Diagnostic and management decisions are made before toxicologic test results are returned.
2. Benign diagnostic intervention may preclude the need for these tests (e.g., response to naloxone in opiate intoxication).
3. Few specific interventions or antidotal therapies depend on toxicologic test outcomes.⁴⁰
4. The incidence of overall morbidity is low (less than 1%^{22,41}), in the setting of optimal patient management, including decontamination and supportive therapy.
5. Toxicity is often apparent on presentation.
6. There is a lack of rapid commercial assays for some drugs commonly involved in emergency room evaluations (e.g. oxycodone, ketamine, GHB).

Clinical features allow for identification of a toxic syndrome and also can be prognostic of outcome.³⁹ Alternatively, the drugs that cause most of the deaths (see Drugs Found in Drug Overdose) are frequently detectable by screening, including some drugs unsuspected by the physician. Studies from the 1970s and 1980s assessed the utility of toxicologic screens with retrospective chart reviews to find alteration in management or diagnosis, and some used prospective assessment with the completion of questionnaires by physicians receiving drug test results. These studies indicated that the impact of screening on clinical diagnosis and management is low (less than 15%).^{39,42-45} Kellerman and associates⁴⁵ had examined the utility of toxicologic screens most carefully. In prospective evaluations before and after the return of toxicologic screen results, they showed that diagnostic certainty increased by a mean value of 16.5% (the prior probability of drug toxicity was 75.5% and increased to a posterior probability or post-test probability of 92.0%) and that these changes in diagnostic certainty occurred in 66% of the 183 cases evaluated. These researchers concluded that other clinical information obtained by physicians may have inflated the estimated utility of toxicologic screens in the diagnostic process. More recent studies using current technology for pediatric intoxications have confirmed these impressions.^{46,47} In a retrospective review, Belson and Simon found that in 227 of 234 comprehensive drugs screens done on children in the ED, the diagnosis was suspected by clinical presentation, was found by limited serum drug quantitation, or the detected intoxicant was considered clinically insignificant.⁴⁶ For differentiating drug-induced from functional psychosis in psychiatric evaluations, the utility of toxicologic screening has also been examined,^{48,49} both indicating that the disposition of the patient within the hospital was unaltered by test results. However, one study found that the diagnosis was aided in 82% and clinical management was changed in 25% when point-of-care drug testing was used. Many of the studies cited have focused only on positive toxicologic screen results. The impact of a negative test result is difficult to assess, but may also be considered contributory to the diagnostic and treatment process, if an intervention is avoided.

OTHER TOXICOLOGIC TESTING SITUATIONS

Surveillance Testing

Outside the realm of emergency toxicology testing are specialized applications of toxicologic testing in selected populations, including (1) workplace or employee drug surveillance programs (see <http://workplace.samhsa.gov/>), (2) program compliance testing (e.g., methadone maintenance or addiction rehabilitation programs), and (3) athletic drug testing for adherence to antidoping rules and regulations of amateur and professional sports organizations. Generally, the aim of these types of testing is to detect substances of low prior probability that may

indicate physical or mental impairment or violation of an established drug use policy. Often these testing circumstances have legal ramifications. In addition, there are mandated procedures and policies to follow, such as reporting requirements and chain-of-custody documentation. Therefore, the ED is not a good venue for the collection of such specimens. The specific use and combination of methods applied in emergency toxicology testing is different and should not be misapplied to these specialized situations.

Sexual Assault

ED staff may be required to obtain urine or blood specimens in situations of suspected drug-facilitated sexual assault or by order of arresting officers. Such testing will require specific procedures for collection and submission to a reference laboratory or program. For example, “date rape” agents such as flunitrazepam and GHB require send-out testing to a specialized reference laboratory. Urine and serum specimens of this type should be frozen and retained until such analysis is requested.

Maternal and Infant Drug Screening

Testing mothers and infants for the presence of drugs is sometimes useful in explaining the clinical state of the infant, if the drug is still present in pharmacologically active amounts. However, most often this type of testing is performed as a component of an overall more comprehensive assessment of the infant’s home environment or parental care by social services. In some cases, custody decisions can hinge on the overall picture, which may include a urinary drugs-of-abuse screen.

Brain Death

Outside the ED, usually on the wards or intensive care unit, the determination of brain death may involve the exclusion of the presence of drugs that may mimic or interfere with the determination of brain death. Certain drugs, such as barbiturates, known to affect brain function at certain concentrations, may require serum quantitation in some circumstances. In other situations, the patient’s history, the time for clearance of potential drugs from the body, or a noncontributory comprehensive toxicologic screen may provide sufficient evidence that drugs are not a factor.

Environmental and Occupational Exposure Assessment

Guidelines for interpreting concentrations in chemical exposures (e.g., to metals or hydrocarbons) are usually based on timed or chronic exposure. These guidelines and cutoffs are often used for discerning excessive (but not necessarily toxic, as in workplace monitoring) exposure, rather than for identifying amounts associated with effects (i.e., for diagnosis). Although not the topic of this chapter, background levels and laboratory methods

for determining a narrow selection of commonly encountered inorganic substances (e.g., lead, mercury, cadmium, arsenic trichloroethylene, benzene, toluene, hexane, and polychlorinated biphenyls) are available. The reader is directed to other reference texts on these topics.^{50,51}

Testing for Nondrug Toxins

Few tests in this area have been developed or studied mainly due to limited commercial potential. Toxins from plants, animals, microorganisms, and chemical sources are numerous, but exposures are less frequent than drugs. Although potent and deadly toxins in these categories are many, most exposures tend to result in minimal or short-lived toxicity. Certain plant toxins such as nicotine, strychnine, and atropine can be identified on comprehensive toxicologic screens. Specific tests for digoxin (e.g., oleander), cyanide (from cyanogenic glycoside-containing plants, fire exposure, or ingestion), and carboxyhemoglobin can be ordered from the laboratories of larger hospitals. Few other specific plant and fungal toxins can be measured, and the clinician must rely on history and physical examination information to guide diagnosis and management. However, most regional poison centers have contacts with a wide variety of agencies that can help in identifying materials from plants, mushrooms, and chemicals used in agriculture.

SUMMARY

Emergency physicians who use toxicologic testing should learn the capabilities of their institutions’ laboratories: What is detectable? What is not detectable? What are the expected turnaround times? Do pharmacologic relationships exist? With regard to requests for testing, the laboratory should allow the physician to order limited test combinations. The physician can assist the laboratory in conducting the appropriate toxicologic testing by providing the differential diagnosis and a list of suspected drugs. Only a few drugs require serum quantitation for making therapeutic decisions (Box 3-3). Urine drug screening is useful in confirming drug-related presentations and may infrequently reveal the presence of other unsuspected drugs. The impact of the results of emergency drug screening on diagnosis and therapy may be minimal. Although in most applications the positive predictive (rule-in) value of comprehensive drug screening in the emergency setting is greater than its negative (rule-out) predictive value, toxicologic screening may be useful as a rule-out test when drug-related effects are of low probability in the differential diagnosis.

Future directions in the laboratory diagnosis of the intoxicated patient are likely to include additional applications of new immunoassays in point-of-care testing applications, particularly in the ED. Development of commercial assays for highly prevalent drugs of abuse such as semisynthetic opioids, GHB, and designer

BOX 3-3

SUMMARY: SITUATIONS IN WHICH TOX TESTING IS USEFUL

Overdoses That Require Serum Drug Concentration to Confirm the Diagnosis or Monitor Course and Severity

Acetaminophen	Antiepileptics and barbiturates
Salicylate	Methanol
Theophylline	Ethylene glycol
Valproate	Ethanol
Iron	

Overdoses That Require Serum or Blood Drug Concentrations as Criteria for Therapy or to Assess Effectiveness of Therapy

All drugs above	Carbon monoxide
Lithium	Lead, mercury
Digoxin	Methemoglobin
Long-acting sedatives	

Situations in Which Qualitative Tox Screens Have Utility

"Ruling in" (confirmation) a moderately probable working diagnosis of drug intoxication

"Ruling out" drug intoxication when it is highly unlikely anyway

Not for screening

stimulant amines would likely be of clinical benefit in overdose situations.

Principles of Pharmacology

DAVID N. JUURLINK, BPHM, MD, PHD ■ MARCO L. SIVILOTTI, MD, MSC

Pharmacology is the science that deals with the interactions between living systems and externally derived chemicals (xenobiotics), especially drugs used for the prevention, treatment, or diagnosis of disease. An understanding of basic pharmacologic principles is essential to allow a rational approach to commonly encountered problems in clinical toxicology. This chapter outlines many fundamental concepts of pharmacology and how those concepts relate to the care of poisoned patients.

DISPOSITION OF DRUGS AND TOXINS

Exposure to toxins can occur through environmental contamination, by intentional means (with or without the intent to cause harm), or during the course of medical treatment. Intoxication or poisoning results when a substance is present in a sufficient quantity, in the right place, and at the right time to influence one or more physiologic processes in a deleterious way. Before exerting such an effect, however, the drug or toxin must first be delivered to the target tissues. Although this may sometimes be immediate, as in the case of a caustic dermal exposure, for most drugs the rapidity, intensity, and duration of effect are heavily influenced by four related aspects of drug movement within the body: absorption, distribution, biotransformation (also called *metabolism*), and elimination.

These processes typically require passage across cell membranes. Drugs and other substances pass through membranes by a variety of mechanisms, the most important of which are passive diffusion and active transport. *Diffusion* is a passive process driven by differences in concentration, whereby drugs move down a gradient from areas of higher concentration to areas of lower concentration. Diffusion may involve movement across intercellular junctions, through transmembrane channels (pores), or directly across membranes themselves. *Active transport*, as the term implies, is an energy-dependent process in which substances usually are transported by a transmembrane carrier protein against a concentration gradient. Active transport processes differ from passive diffusion not only in their requirement for metabolic energy but also in their selectivity for a single chemical entity or group of related compounds, their saturability, and their susceptibility to inhibition. *Facilitated diffusion processes* are similar to active transport in that they demonstrate selectivity, saturability, and potential for inhibition, but they do not require energy and do not operate against concentration gradients.

Absorption

Absorption refers to movement of a substance from site of administration into the blood space. Of the various sites from which absorption can take place, the gastrointestinal tract is the most important because the majority of acute poisonings involve ingestion. Passive diffusion from the gastrointestinal tract occurs most readily with lipid-soluble, low-molecular-weight, nonionized compounds such as alcohols. The absorption of these compounds is limited only by the absorptive surface area and factors that reduce the surface interface with intestinal epithelium, such as the presence of food.

Drug absorption also may be influenced by the pH at the site of absorption. In general, absorption is reduced by ionization, because the presence of a charge decreases a drug's lipid solubility and hampers its transmembrane flux. The degree to which a drug is ionized at a given pH depends on its ionization constant (pK). The pK of an acid or base is the pH at which 50% of a compound exists in ionized form and 50% in nonionized form (Fig. 4-1). Because it is on a logarithmic scale, pH changes of a single unit can cause up to a tenfold change in concentration of either the ionized or nonionized form.

Many drugs are either weak acids or weak bases. Weakly acidic drugs (HA) (e.g., acetylsalicylic acid) can release a proton in aqueous solution, resulting in the formation of an anion (A^-), as shown in the usual Brønsted-Lowry expression below:

FIGURE 4-1 In aqueous solution, salicylic acid (HA) ionizes to yield salicylate anion (A^-) and a proton (H^+), which combine with water to form hydronium (H_3O^+). The pK_a of salicylate (3.0) is the pH at which 50% exists as HA and 50% exists as A^- . As the pH rises, more A^- is formed, although little additional ionization takes place above pH 5.0, when virtually no un-ionized salicylate remains.

Such drugs are less ionized (and therefore better absorbed) in an acidic milieu such as the stomach, which favors the left side of the above formula. Conversely, weak bases are more readily absorbed in an alkaline environment, such as when intraluminal pH is elevated by the use of antacids or gastric acid-suppressing medications. The influence of pH on drug absorption is illustrated in Figure 4-2.

The rate-limiting step for absorption of solid xenobiotics from the gastrointestinal tract is usually dissolution, a process that can be altered by changes in pH, the rate of gastric emptying, the presence of food, and the formulation. These complex relationships are relevant particularly in the setting of acute poisoning, because decisions regarding gastrointestinal decontamination (see Chapter 2B) are influenced by the likelihood that a product remains in the gastrointestinal tract. Many liquid drugs are absorbed very rapidly following ingestion, reducing the likelihood that gastrointestinal decontamination will effect a significant reduction in the overall amount of drug absorbed. Drugs formulated as capsules or tablets dissolve more slowly and may be more amenable to interventions aimed at limiting absorption. This is particularly true of drugs with modified release systems, such as enteric coatings or polymer matrices, which may release contents over 12 hours or longer.

Gastrointestinal motility also can influence the rate and extent of drug absorption. For most drugs, absorption from the stomach is minimal, and the drug gains access to the systemic circulation only after passing the pylorus. The presence of food in the stomach increases pyloric tone, slowing the delivery of drug to the duodenum. Similarly, many drugs, including opioids, salicylates, and

drugs with antimuscarinic activity (i.e., cyclic antidepressants and antihistamines), can slow gastric emptying. Reduced gastric emptying leads to delayed drug absorption and lower peak drug levels, because the drug is presented to the absorptive surface of the small intestine more slowly. In acutely poisoned patients, delayed gastric emptying may extend the window of opportunity for gastrointestinal decontamination maneuvers.¹

In the small intestine, the presence of microvilli on the luminal epithelium increases the absorptive surface area markedly. In fact, the surface area available for absorption is so much larger than the stomach that for many drugs the effects of pH on ionization are rendered insignificant. Following absorption from the small intestine, drugs enter the portal circulation and then the liver prior to reaching the systemic circulation. Many drugs undergo significant metabolic inactivation during this migration, a process variably referred to as *first pass metabolism* or *presystemic extraction*.

In recent years, it has become recognized that the small intestinal epithelium functions as an active barrier to drug absorption.² Specifically, many drugs are metabolized within the small intestine enterocyte, actively transported back into the intestinal lumen, or both. Moreover, these processes can be inhibited or induced by drugs and diet. For example, grapefruit contains bergamottin, naringin, and other flavonoids that may inhibit oxidative drug metabolism of a large number of drugs in the enterocyte.^{3,4} Consequently, absorption may increase dramatically for drugs that normally have a high degree of presystemic extraction (e.g., nifedipine and simvastatin). Conversely, St. John's wort and other compounds can both induce the oxidative metabolism of the same drugs and promote active transfer back into the lumen.⁵ This can lead to dramatic reductions in the blood levels of drugs such as cyclosporine and tacrolimus, sometimes with dramatic clinical consequences.^{6,7} A more detailed discussion of these interactions is given later in this chapter.

FIGURE 4-2 For a weak acid with a pK_a of 4.4, the low pH of gastric juice favors the undissociated species (HA). Following absorption across the lipid mucosal barrier, equilibrium favors the dissociated species (A⁻) because plasma pH is 7.4. (From Wilkinson GR: Pharmacokinetics. In Hardman JG, Limbird LE, Gilman AG [eds]: Goodman and Gilman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001, p 4.)

ABSORPTION BY OTHER ROUTES

Parenteral Absorption

Intravenous injection is the most common route by which drugs are administered parenterally and avoids first pass hepatic metabolism and other barriers to oral absorption. Because serum drug concentrations rise much more rapidly, the rate of infusion of some drugs must be carefully regulated to avoid toxicity.

Direct intramuscular injection is possible for some drugs soluble in aqueous solutions or, occasionally, as long-acting depot injections intended to minimize the need for frequent injections. Before an intramuscularly administered drug can exert an effect, absorption into the blood compartment is necessary. This rate is highly dependent on tissue perfusion and on the chemical properties of the drug and its formulation. Drugs given by subcutaneous injection may be absorbed into the blood rapidly, but this process can be purposefully slowed by the nature of the formulation. For example, Lente insulin (insulin zinc suspension) is a mixture of crystallized and amorphous insulins in a buffer that

decreases their solubility. Although this precludes intravenous administration of Lente insulin, it leads to slower dissolution in the subcutaneous tissue, resulting in more gradual absorption and a longer duration of action (see Chapter 64)⁸.

Sublingual Absorption

Some drugs can be absorbed directly into the venous capillary network of the oral mucosa. Absorption from the sublingual route generally is rapid and avoids first pass metabolism by the liver. Examples of drugs administered by the sublingual route include captopril, nicotine, nifedipine, and nitroglycerin.

Pulmonary Absorption

The lungs also serve as an important site for the absorption of certain drugs (e.g., volatile anesthetics) and many toxins (e.g., nicotine, cyanide, and carbon monoxide). Because the lungs receive essentially all of the cardiac output and because the alveoli offer an enormous surface area for absorption, many gases and very small particles (<1 μm) that enter the lower airways can be dissolved rapidly into blood.

Dermal Absorption

The stratum corneum consists of flattened, nonviable corneocytes filled with hydrophilic keratin proteins and separated by hydrophobic lamellar lipids, providing an effective barrier to the absorption of most drugs and toxins. Penetration of xenobiotics through intact skin is determined by the lipid solubility of the drug, the thickness of the stratum corneum, and the concentration gradient. Drug penetration can be enhanced by the use of an organic solvent vehicle such as carbon tetrachloride, methanol, and dimethyl sulfoxide, provided the xenobiotic partitions into the vehicle rather than escaping into the stratum corneum. Xenobiotics larger than about 1000 daltons do not penetrate adult skin easily. Inflamed, denuded, or immature skin provides a much more permeable barrier to absorption.

Distribution

Following absorption, chemicals circulate throughout the body within the blood space and translocate into other tissues in a process called *distribution*. In general, the amount of the drug or toxin at the site of action represents only a small proportion of the total amount absorbed, whereas the rest of the drug distributes in other tissues such as muscle and fat. A given drug distributes in a relatively predictable way that is governed by its chemical properties, including lipid solubility, molecular weight, and charge.

It is helpful to characterize the extent to which various drugs distribute into different body tissues. The *volume of distribution* of a drug reflects this apparent space in the body available to contain the absorbed drug, as estimated by the concentration in the blood or plasma:

$$V_d \text{ (volume units)} = \frac{\text{amount of drug in body (mass)}}{\text{concentration (mass per volume)}}$$

Importantly, V_d is a theoretical construct rather than an actual volume of fluid; hence the term *apparent volume of distribution*. Molecules that are very large (i.e., heparin and the volume expander hetastarch) are generally confined to the vascular space and have a volume of distribution approaching that of plasma, or about 40 mL/kg in adults. Drugs that are hydrophilic (i.e., lithium and neuromuscular junction blocking agents) tend to distribute throughout total body water and have a V_d on the order of 0.6 L/kg body weight. Other drugs are bound to body tissues extensively, such that only a small fraction is present in the blood. One example is amiodarone, with a volume of distribution that is highly variable but can exceed more than 100 L/kg body weight.

Typically, drugs with large volumes of distribution are highly lipophilic chemicals that concentrate within tissue compartments such as muscle or fat. Sometimes it is helpful to view these tissues as “reservoirs.” This concept illustrates why drugs with large volumes of distribution (i.e., those that preferentially distribute outside the vascular compartment) are not readily removed by extracorporeal methods such as hemodialysis. The time course of a drug’s distribution into these various compartments usually is determined by the blood flow into the compartment and the exchange kinetics between the circulation and the compartment (see Pharmacokinetics, later).

When the V_d and administered dose of a xenobiotic are known, the formula shown earlier can be used to estimate peak serum concentration. Use of the formula as written, however, presumes that all of the drug is absorbed and none is yet eliminated. It will, therefore, often overestimate serum concentration of a xenobiotic, particularly after ingestion. It is clinically useful, however, to estimate “worst case scenario” peak serum concentrations after ingestion with a known maximal quantity available of a toxicant.

The blood-brain barrier (BBB) and placenta are special barriers to drug distribution. The BBB is a specialized system of capillary endothelial cells that, unlike those in the peripheral vasculature, limits the entry of drugs and toxins into the central nervous system by a combination of physical barriers (intercellular tight junctions) and active transport processes.⁹ However, several drugs pass the BBB freely, and its permeability can be increased significantly by inflammatory processes such as meningitis. Transplacental drug passage is relevant particularly for drugs that may harm the fetus (i.e., warfarin, phenytoin, and ethanol) or, if given immediately prior to delivery, the neonate (i.e., opiate analgesics). Nearly all drugs administered during pregnancy cross the placenta to some degree, but the process is far more efficient for nonionized, lipid-soluble drugs. Like the BBB, the placenta is capable of active drug efflux and oxidative drug metabolism (discussed later in this chapter), both of which serve to minimize fetal drug exposure.¹⁰

Protein Binding

Many drugs and poisons are bound to some extent to plasma proteins, particularly albumin and α_1 -acid

glycoprotein. Binding to plasma proteins limits the extent to which drugs can traverse capillary walls and enter tissues, effectively sequestering a drug because the drug-protein complex is too large to diffuse from the vascular space. Only the unbound (“free”) fraction can do so, and as such only this portion can exert a physiologic effect. The binding involves reversible, weak electrostatic, hydrophobic, or van der Waals forces, and the extent of protein binding varies considerably among drugs. Some highly lipophilic organic compounds are very tightly bound to albumin. One such example is the anticoagulant warfarin, which is almost completely bound; only the free fraction is able to exert a biologic effect. Albumin binds weak acids more strongly than weak bases, and it generally does not bind drugs that are either hydrophilic or neutral.

When two drugs that both bind to albumin are given simultaneously, they may compete for available binding sites, increasing the free fraction of the other. Although this displacement from plasma proteins often is cited as an important mechanism by which drug interactions can be mediated, this is not the case for the vast majority of protein-bound drugs, since the free fraction generally is metabolized and eliminated relatively quickly.¹¹ Drugs and toxins also can bind to other proteins, including α_1 -acid glycoprotein, an acute phase reactant that binds to many acidic drugs (i.e., cyclic antidepressants, methadone, some local anesthetics, and antimalarial drugs).^{12,13}

Biotransformation

Most xenobiotics undergo chemical transformation before they are eliminated from the body. This process is called *biotransformation* or *metabolism*, and its products are called *metabolites*. Biotransformation generally yields products that are more polar and therefore more water-soluble. These metabolites are less able to pass through biologic membranes, are more restricted in their tissue distribution, and are more readily eliminated in the bile and urine. Biotransformation occasionally converts drugs into more toxic compounds in a process termed *bioactivation*; common examples include acetaminophen (converts to *N*-acetyl-*p*-benzoquinone imine), methanol (converts to formic acid), and chloral hydrate (converts to trichloroacetic acid).

Although biotransformation reactions can occur in many organs, the liver is quantitatively the most important site. Drug metabolizing enzymes are present in various parts of the hepatocyte; by convention, their location is indicated by the *in vitro* fraction of homogenized liver tissue in which the enzymatic activity is found. Drug metabolizing enzymes are therefore referred to as *soluble* (found principally in the cytosol), *mitochondrial*, or *microsomal* (found principally in the endoplasmic reticulum).

Biotransformation reactions generally are categorized as one of two types: phase I or phase II. Many drugs undergo sequential metabolism in phase I and phase II processes. Commonly, the small structural change imparted by phase I metabolism is necessary for phase II

metabolism to proceed. Specific examples of phase I and phase II reactions are shown in Table 4-1.

PHASE I METABOLISM

Phase I metabolism is characterized by reactions involving oxidation, reduction, or hydrolysis. The result is a less dramatic chemical alteration of the parent compound than what occurs with phase II metabolism, but the clinical consequences often are very significant, resulting in complete or partial drug inactivation or, in some instances, production of a biologically active or toxic compound.

Microsomal oxidative reactions are quantitatively the most important of the phase I metabolic processes. Most of these involve the cytochrome P-450 (CYP450) enzyme system, previously called the *mixed function oxidase system*.¹⁴ Once thought to consist of a few proteins, it is now recognized that CYP450 represents a large family of related heme-containing enzymes. The system draws its name from the maximal spectral absorbance at 450 nm when the enzymes are bound to carbon monoxide. Although more than 60 different CYP isoenzymes exist, most are relatively unimportant in humans.

By convention, the nomenclature of CYP isoenzymes involves a number (the *family*), an uppercase letter (the *subfamily*), and another number (the *form*). CYP enzymes exhibit a high degree of structural homology, which is greatest for enzymes within the same family (e.g., CYP2C9 and CYP2C19). Despite this homology, each enzyme form has a distinctive pattern of drugs they metabolize (termed *substrates*) and a distinctive pattern

of inhibition and induction by other drugs and xenobiotics (Table 4-2).

From a clinical perspective, the most important CYP enzymes in humans are CYP1A2, -2C9, -2C19, -2D6, -2E1, and -3A4.¹⁴⁻¹⁶ Collectively, these enzymes contribute in whole or in part to the biotransformation of the vast majority of drugs in common use.¹⁷ The clinical significance of induction or inhibition of CYP enzymes by other drugs is described in greater detail in Chapter 5.

The oxidation of a drug by the CYP450 enzymes is depicted schematically in Figure 4-3. In this sequence, both nicotinamide adenine dinucleotide phosphate (NADPH) and the drug are oxidized by the reduction of molecular oxygen to water. The heme iron of the CYP isoenzyme accepts one electron from NADPH via a flavo-protein reductase after forming a complex with the drug. The reduced form of the CYP-drug complex binds molecular oxygen, and another electron is introduced to

FIGURE 4-3 Electron flow pathway in microsomal drug metabolizing system. Nicotinamide adenine dinucleotide phosphate (NADPH) is oxidized by the flavo-protein cytochrome P-450 reductase (Cyt P₄₅₀), and an electron is transferred to the oxidized form of cytochrome P-450 that has formed a complex with the drug. The reduced form of cytochrome P-450 drug complex binds oxygen and another electron and is introduced to generate oxidized drug, oxidized P-450, and water. The oxidized cytochrome P-450 is then available to bind another drug molecule and continue the cycle. (Adapted from Goldstein A, Aronow L, Kalman S: Principles of Drug Action, 2nd ed. New York, John Wiley & Sons, 1974, p 243.)

generate oxidized drug, oxidized CYP450, and water. Reduction biotransformation reactions also can occur, generally under conditions of low oxygen tension.

Phase I metabolism generally reduces the biological activity of a drug, but that is sometimes not the case. Some *prodrugs* require CYP enzymes for bioactivation.¹⁸ One example is codeine, which is hydroxylated by CYP2D6 to its active metabolite morphine. Another example is the organophosphate pesticide parathion, which first must be converted to its active metabolite paraoxon for cholinesterase inhibition to take place.¹⁹ Figure 4-4 illustrates specific examples of phase I and phase II metabolism.

PHASE II METABOLISM

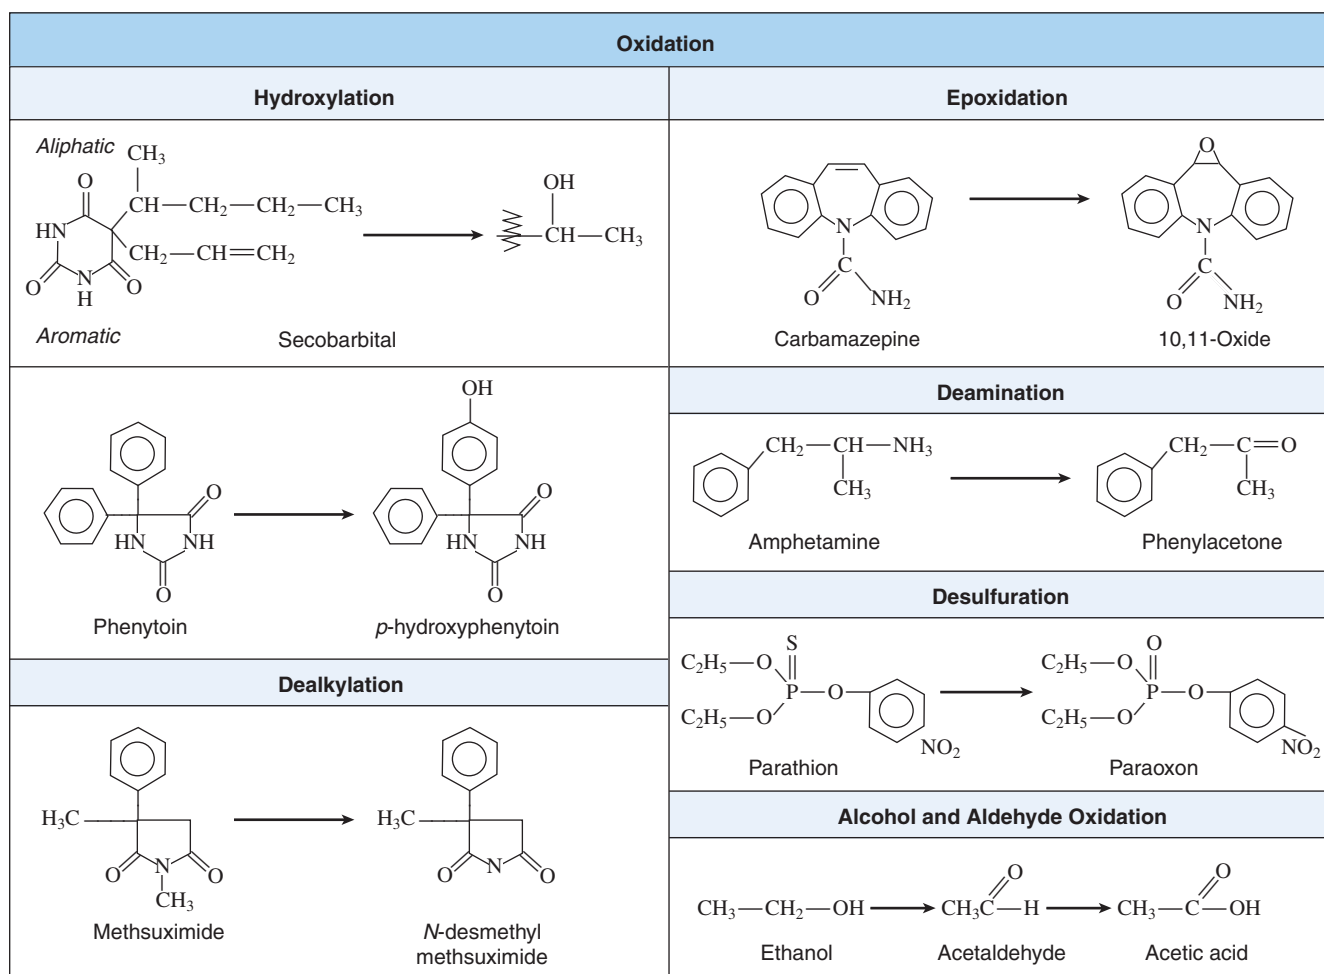

In phase II metabolism compounds are covalently attached to compounds that have a large capacity for hydrogen bonding, often in a high-energy process catalyzed by specific enzymes called *transferases*. The resulting conjugates are highly water soluble and much more easily eliminated in the urine. The most common reaction is the conjugation to activated uridine diphosphate (UDP)–glucuronic acid by the microsomal UDP-glucuronosyltransferases. Cytosolic enzymes catalyze

other phase II conjugation reactions, including the sulfotransferases that use activated 3'-phosphoadenosine-5'-phosphosulfate donors, the *N*-acetyltransferases using acetyl coenzyme A (CoA), and the glutathione *S*-transferases that deactivate electrophilic xenobiotics using glutathione. Phase II metabolism can involve parent drugs or metabolites produced by phase I metabolism. For example, acetaminophen is actively conjugated to glucuronic acid and sulfate, while its toxic phase I metabolite is conjugated to glutathione. This latter conjugate is then cleaved to a cysteine conjugate and acetylated in the kidney to form mercapturic acids.

Phase II metabolism generally yields products that are pharmacologically inert, but this is not always the case. For example, both isoniazid and procainamide are *N*-acetylated to metabolites with biological activity and toxicities different from their parent compounds (see Figure 4-4).

Excretion

Excretion is the process by which toxins, drugs, and their metabolites are removed from the body. The most important route of elimination is via the kidneys into the

FIGURE 4-4 Continued. B, Reductions and other reactions.

urine, but other routes include elimination via the intestine, lungs, bile, and sweat.

RENAL ELIMINATION

Many drugs depend on the kidney either largely or exclusively for elimination. The kidney is a highly vascular organ that normally receives about 25% of cardiac output. With the exception of very large molecules (>20,000 daltons) and drugs that are bound extensively to plasma proteins, most drugs undergo passive glomerular filtration, a process driven primarily by the pressure gradient between the afferent and efferent arterioles.

Once in the lumen, drugs may be reabsorbed through tubular epithelial cells into the peritubular blood or eliminated in the urine. The degree of reabsorption is

heavily influenced by lipid solubility, with poor reabsorption of drugs that carry an electrostatic charge. This feature sometimes can be exploited in the management of poisoned patients by therapeutic manipulation of urinary pH. The urinary excretion of weak acids (e.g., salicylic acid, phenobarbital, or chlorpropamide) is enhanced by alkalinization of the urine. Raising the intraluminal pH by the administration of sodium bicarbonate favors the formation of the ionized species, effectively “trapping” the compound in the urine and enhancing elimination. Although acidification of the urine with ascorbic acid or ammonium chloride can enhance the elimination of weak bases (i.e., amphetamine, phencyclidine, and quinidine), this rarely is done in practice because of the associated risk of metabolic acidosis and myoglobinuria. Importantly, manipulation

of urinary pH does not significantly influence the elimination of strong acids or bases, which are ionized throughout the physiologic range of urinary pH.

In addition to glomerular filtration, many drugs are actively transported into the lumen of the nephron. This generally is accomplished by one of three processes. The multidrug efflux pump P-glycoprotein (P-gp) is localized on the apical surface of proximal tubular epithelial cells and transports a wide variety of lipophilic compounds (Box 4-1), such as digoxin, colchicine, and many chemotherapeutic agents. It is encoded by the multidrug resistance protein (MDR1), named for the resultant resistance of tumor cells to vinca alkaloids and anthracyclines. Inhibition of P-gp by macrolide antibiotics, calcium channel antagonists, quinidine, and other compounds can lead to digoxin accumulation and toxicity. A variety of organic anion transport proteins (OATPs) have been characterized that nonselectively transport endogenous uric acid as well as benzyl penicillin, 3-hydroxy-3-methylglutaryl (HMG) coenzyme A inhibitors, and methotrexate. The OATPs can be inhibited by probenecid and nonsteroidal anti-inflammatory agents.^{10,20} Similarly, organic cation transport

proteins (OCTPs) transport procainamide, triamterene, and the endogenous bases choline and histamine, and they are inhibited by quinidine.^{21,22}

For drugs that are highly dependent on the kidney for elimination, the presence of renal disease hampers drug excretion and is a significant risk factor for the development of toxicity during therapeutic use. Appropriate dose adjustment and, when appropriate, selection of therapeutic alternatives can minimize the likelihood of this occurrence.

PHARMACOKINETICS

Clinical pharmacokinetics is the mathematical description of the time-dependent fate of a drug, toxin, or metabolite in the body. In other words, it is the study of “what the body does to the drug” as a function of time. Conversely, pharmacodynamics (discussed later in this chapter) describes “what a drug does to the body” as a function of dose or exposure.

The concentration of most drugs that are predominantly eliminated by the kidney can be considered to follow a “two compartment” pharmacokinetic model (Fig. 4-5). Following absorption, the drug distributes first into the *central compartment*, which includes the blood space and the richly perfused organs such as the heart, lungs, and kidneys. Once there, it may be eliminated by the kidney or undergo distribution into the peripheral compartment, which includes less well-perfused organs and tissues such as muscle and fat. A set of differential equations can be used to estimate changes in concentration and movement between compartments over time.

To illustrate, serum digoxin concentrations can be modeled using typical two-compartment pharmacokinetics. Following the oral administration of a single dose, a concentration-time curve of a drug can be generated, as shown in Figure 4-6. From the figure, three phases are apparent: an absorption phase, a distribution (α) phase, and an elimination (β) phase. The two latter phases can be described mathematically by the *half-life* (denoted as $t_{1/2\alpha}$ and $t_{1/2\beta}$, respectively). The elimination half-life ($t_{1/2\beta}$) is frequently reported in pharmacokinetic studies and reflects the time required for the drug concentration to decline by 50% after the drug is stopped.

The clinical applicability of the compartment concept is also illustrated by lithium, which is easily removed

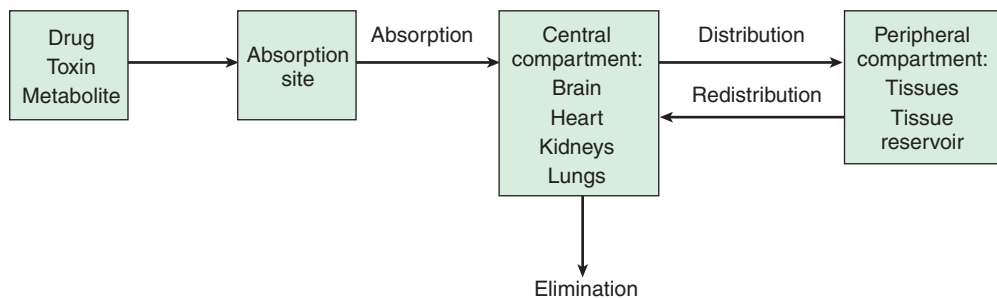

FIGURE 4-5 Example of a two-compartment model.

FIGURE 4-6 Phases of drug movement in a two-compartment model.

from the plasma compartment by hemodialysis. However, plasma concentrations rebound thereafter because lithium distributes slowly back into the vascular space from the tissue water compartment (Fig. 4-7). Similarly, the access of acetylsalicylic acid to the brain and other tissue compartments is strongly influenced by pH, and acidemia facilitates the movement of the nonionized acid across cellular membranes.

Other Types of Pharmacokinetic Models

Although compartmental models with first order transfer between compartments are widely used, they are mathematically abstract and have limited anatomical and physiologic relevance. *Physiologic pharmacokinetic models* use basic physiologic and biochemical data to describe the processes affecting chemical distribution and disposition. These models use a lumped *compartmental approach*, separating the body into a series of biologically relevant anatomical compartments of defined volumes, such as eliminating organ compartments (e.g., kidney and liver) and noneliminating tissue compartments (e.g., adipose tissue). All compartments are then connected in anatomical order based on the blood circulatory system to form an integrated model in which the transfer of drugs between compartments is governed by actual blood flow rates and tissue solubilities (partition coefficients). In contrast, *noncompartmental pharmacokinetic models* permit direct influx of drug into a central pool and indirect entry from a noncentral pool, as well as removal from either a central or a noncentral pool. The most significant advantage of noncompartmental models is that they do not assume specific compartments for chemicals or metabolites.

Types of Pharmacokinetic Processes

The elimination kinetics observed for a drug in vivo is generally described as either *first order* or *zero order*.

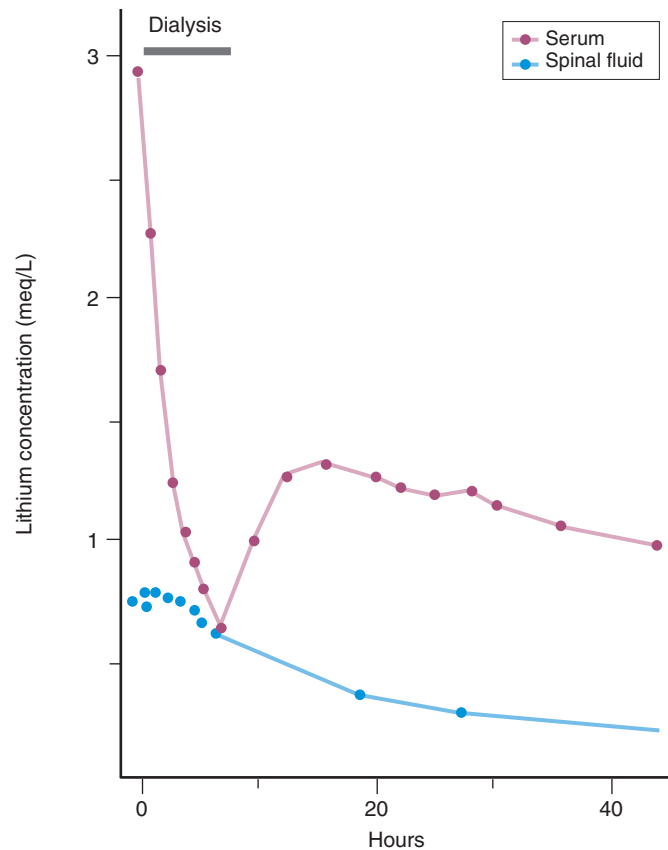

FIGURE 4-7 Serum and spinal fluid lithium levels in a 48-year-old lithium-intoxicated man who was anuric. Serum levels decline rapidly with dialysis and rise again as lithium redistributes from tissues. Spinal fluid levels respond slowly to changes in serum level. (From Amdisen A, Skoldborg H: Haemodialysis for lithium poisoning. *Lancet* 1969;2:213.)

Although the terms may at first seem confusing, they are conceptually straightforward.

FIRST ORDER KINETICS

Most drugs follow first order kinetics at therapeutic dosing, meaning that the rate at which they are eliminated from the body is directly proportional to the blood concentration. In other words, a constant proportion of the drug is eliminated per unit time. The concentration-time curve of first order drug elimination is curvilinear, but when plotted on a semilogarithmic graph (i.e., a graph with a logarithmic Y axis) yields a straight line (Fig. 4-8).

In an acutely poisoned patient, plotting serum concentrations against time allows for estimation of $t_{1/2\beta}$ after the calculation of the elimination rate constant (k_e), which is the fraction of drug eliminated per unit time, given by:

$$k_e = \frac{(\ln C_1 - \ln C_2)}{(t_2 - t_1)}$$

where C_1 and C_2 reflect drug concentration at different times t_1 and t_2 , respectively. The elimination half-life is, therefore, inversely proportional to the first order elimination rate constant, given by:

FIGURE 4-8 Concentration-time curves under zero order and first order kinetics. The *dashed upper line* illustrates the concentration-time plot for a drug with zero order elimination, whereas the *lower solid line* illustrates the concentration-time plot for a drug with first order elimination. Note that if the Y axis were expressed logarithmically, first order elimination would appear as a straight line. The time required for drug concentration to decrease by 50% is the half-life ($t_{1/2}$), a concept that does not apply in zero order kinetics since a constant amount is eliminated per unit time. The concentration (C) at any given time (t) can be predicted from the formulas shown, although the elimination rate constant must be known if first order kinetics apply. This value is equivalent to $0.693 / t_{1/2}$.

$$t_{1/2\beta} = \frac{\ln 2}{k_e} = \frac{0.693}{k_e}$$

Miscalculation of $t_{1/2\beta}$ occurs when the timing of blood samples is inaccurate or when drug administration (including absorption) is ongoing. The concept of half-life is only applicable under conditions of first order kinetics and represents the time needed for concentrations to fall by half.

ZERO ORDER KINETICS

Some medications are eliminated from the body in such a way that a constant amount (rather than a constant proportion) is removed per unit time. This sort of elimination is called *zero order kinetics* or *nonlinear pharmacokinetics* because a plot of concentration versus time is not described by a straight line on a semi-logarithmic graph. Important examples of drugs that exhibit zero order kinetics following typical doses include ethanol and acetylsalicylic acid. The rate of elimination is simply expressed as the fall in concentration per unit time.

MICHAELIS-MENTEN KINETICS

All active processes can be saturated, but they will appear not to be if the concentrations involved are below the limit of the saturable process. The rate of metabolism, therefore, depends on the substrate concentration in plasma (C_p), and is given by:

$$\text{Rate} = \frac{V_{\max} \times C_p}{(K_m + C_p)}$$

where V_{\max} is the maximum rate of metabolism (i.e., metabolic capacity) in mass per unit time and K_m is a constant with a value equal to the plasma concentration (mass per unit volume) at which the metabolic rate is half maximal. This is often referred to as *Michaelis-Menten kinetics*.

Because the metabolism of most drugs takes place at concentrations well below this threshold ($C_p \ll K_m$), these drugs exhibit first order kinetics. For some drugs however, saturation occurs at or near therapeutic concentrations. Above this threshold ($C_p > K_m$), elimination becomes zero order, and small increases in

dose can produce dramatic increases in plasma concentrations. This concept is especially relevant in the setting of drug overdose, in which concentrations are often much higher than the normal therapeutic range.

Phenytoin is perhaps the best example of a drug exhibiting Michaelis-Menten kinetics, since its K_m values often overlap with therapeutic levels.²³ For phenytoin, values of V_{\max} and K_m generally vary in adults from 100 to 1000 mg/day and 1 to 15 mg/L, respectively.^{23,24}

Clearance

Drugs are eliminated from the body at varying rates. An important kinetic concept is the *clearance* of a drug, which is the rate of its elimination by all routes relative to its concentration in a biological fluid, given by:

$$\text{CL (volume per time)} = \frac{\text{mass rate of elimination (mass per time)}}{\text{concentration (mass per volume)}}$$

Most often, the fluid of interest is blood or plasma, and these concentrations constitute the denominator of this equation. It follows that clearance can also be estimated from the slope of the elimination phase of the concentration versus time (k_e) when the volume of distribution is known:

$$\text{CL (volume per time)} = k_e \text{ (per time)} \times V_d \text{ (volume)}$$

The rate of infusion or dosing of a medication can be substituted for mass rate of elimination in the equation above under steady-state conditions, to target a therapeutic serum concentration at steady state:

$$\text{Target concentration (mass per volume)} = \frac{\text{dosing rate (mass per time)}}{\text{CL (volume per time)}}$$

By mass balance and integrating the definition of CL given above over time:

$$\text{CL (volume per time)} = \frac{\text{dose (mass)}}{\text{AUC (mass} \times \text{time/volume)}}$$

where AUC is the area under the concentration-time curve. Like V_d , clearance can sometimes assume very large

values that do not appear to be physiologic. For example, the clearance of transdermally administered nitroglycerin from venous blood may exceed 30 L per minute.

Clearance also may be thought of as the hypothetical volume of a fluid from which a substance is totally and irreversibly removed per unit time. However, because some drugs rely heavily on other organs such as the liver or bile, total body clearance (CL_{total}) is actually the sum of the clearance by all routes (i.e., $CL_{\text{kidney}} + CL_{\text{liver}} + CL_{\text{other}}$).

The clearance of a drug by an organ (or system) can be calculated if one knows the blood flow and drug concentrations in the afferent and efferent blood, using the following formula:

$$CL_{\text{organ}} = \frac{Q \times (C_{\text{IN}} - C_{\text{OUT}})}{C_{\text{IN}}}$$

where Q is blood flow (volume per time) and C_{IN} and C_{OUT} are the concentrations in incoming (often arterial) and outgoing (often venous) blood. The expression $(C_{\text{IN}} - C_{\text{OUT}}) / C_{\text{IN}}$ is sometimes termed the *extraction ratio*. If a drug is efficiently removed by an organ (typically the liver), the concentration of drug in efferent blood will be far lower than that in afferent blood and the extraction ratio will approach 1. Lidocaine, verapamil, and propranolol are examples of drugs with high hepatic extraction ratios.

The clearance of drugs and toxins can sometimes be markedly increased by hemodialysis. This is most effective with small, water-soluble molecules with minimal protein binding and a low V_d (i.e., do not partition extensively to tissues in the extravascular space), such as methanol. The clearance of drugs by a dialysis membrane can be calculated by sampling concentrations in both limbs of the dialysis circuit in a similar fashion, as outlined above.

Bioavailability

Bioavailability, denoted in pharmacokinetic equations by the symbol F , is the proportion of drug that reaches the systemic circulation. Following absorption, orally administered drugs entering the portal circulation may be partly metabolized by the liver. For some drugs, such as propranolol, this “first pass” metabolism is extensive and explains why oral doses often are much higher than intravenous doses. Inasmuch as it influences absorption (above), solubility also is an important determinant of bioavailability, with very hydrophilic drugs having limited absorption because they cannot easily pass through lipid membranes. Finally, some drugs are unstable at gastric pH (e.g., penicillin G), which significantly limits their bioavailability.

By definition, drugs administered by intravenous injection have $F = 1$, since all drug enters the blood space. The bioavailability of an orally administered drug can be determined experimentally by plotting serial measurements of drug concentration against the time from administration. Integrating the total area under this curve and multiplying by the clearance indicates the quantity of drug absorbed, which may then be compared

to the amount administered. For example, if 100 mg of a drug whose $CL = 1$ L/hour is administered by mouth and the calculated AUC is $75 \text{ mg} \times \text{hour/L}$, then $F = 0.75$.

PHARMACODYNAMICS

Pharmacodynamics describes the effects of drugs and toxins on human physiology mediated by interactions with molecules within the patient. Such effects are a function of dose and duration of exposure to drugs, a relationship that can be expressed using dose-response curves. The quantitative relationship between the dose of a xenobiotic and the magnitude of its biological effect as it relates to poisoning often is termed *toxicodynamics*.

Targets of Drug Action

In most instances, drugs interact with specialized cellular proteins in ways that alter the function of the macromolecule and, consequently, the cell itself. These target proteins often involve enzymes, ion channels, carrier molecules, and receptors. Receptors can be located at various locations in a cell, including on its surface, within the cytoplasm, or in the nucleus. The endogenous compounds that bind to these receptors are termed *ligands* and include neurotransmitters, hormones, and other autacoids. Drug-receptor interactions mediate the biological effects of the vast majority of drugs. Notable exceptions include ethanol and the volatile anesthetics, such as halothane and enflurane, which may exert their effects by altering the physical chemistry of cell membranes.

The formation of a drug-receptor complex generates a biological response, which is a function of the number of drug-receptor complexes formed:

This reaction is governed by the law of mass action, and the clinical effect is therefore proportional to drug dose. A *dose-response curve* describes the theoretical relationship between receptor occupancy and the clinical effect of a drug. The typical sigmoidal dose-response curve is shown in Figure 4-9. The X axis usually is expressed in logarithmic units and may represent a single administered dose, a serum concentration, an infusion rate at steady-state, or a more complex measure of exposure such as inhaled gas concentration multiplied by duration of exposure. The Y axis may represent the proportion that experiences a binary outcome, such as death in an animal study, or a continuous outcome, such as analgesia or fractional decrease in mean arterial pressure measured in a single individual.

RELATIONSHIP BETWEEN DOSE AND RESPONSE

A *graded dose-response curve* permits inference regarding the important concepts of *potency* and *efficacy*. Potency refers to the location of the curve along the X axis and describes the concentration of a drug needed to exert a specific physiologic effect. The potency of an agonist

FIGURE 4-9 Dose-response curves of various agonists. Y axis represents degree of drug response, and X axis represents logarithm of dose. The dose-response curve for a strong agonist (drug A) shows that half-maximal effect occurs at dose ED_{50} . Drug B is a weaker agonist (i.e., a higher dose is required for the same effect as occurred with drug A) but has equal efficacy. This curve could also represent the dose-response curve for drug A in the presence of a noncompetitive antagonist. Drug C is a partial agonist, and, although it is more potent than drug C (which has a higher ED_{50}), it is less efficacious because it has a lower maximal efficacy.

often is expressed in terms of the concentration producing a half-maximal response (the EC_{50}). For example, hydromorphone is a more potent analgesic than morphine, and it therefore has a lower EC_{50} and a dose-response curve to the left of that produced by morphine. Efficacy, on the other hand, reflects the maximum effect that can be achieved with a drug and is reflected in the height of the dose-response curve. Hydromorphone and morphine have equal analgesic efficacy despite differences in potency.

Quantal dose-effect curves differ in that the Y axis reflects the percentage of individuals with a dichotomous event (e.g., seizure, systolic blood pressure < 80 mm Hg, or death). Such curves often are expressed in terms of the *median effective dose* (ED_{50}), the dose at which 50% of individuals exhibit the specified beneficial effect. If the quantal end point is death of a group of experimental animals, the *median lethal dose* (LD_{50}) is often reported. Assuming the threshold for attaining the response is normally distributed in the population, then the shape of the dose-response curve is described by the sigmoidal probit function, which is the cumulative area under a Gaussian normal distribution.

Agonists and Antagonists

Drugs that modulate receptor function can be characterized according to their effects relative to the endogenous ligand. An *agonist* elicits cellular and physiologic effects similar to those of an endogenous ligand. Agonists may be further classified according to the mechanism by which they produce this effect. Agonists that bind to and stimulate the receptor are termed *direct agonists*. Examples include pentobarbital at γ -aminobutyric acid

(GABA) receptors; phenylephrine and isoproterenol, which mimic the effects of norepinephrine and epinephrine at α - and β -adrenergic receptors, respectively; and methacholine, which mimics the actions of acetylcholine at muscarinic receptors. *Indirect agonists* have little or no inherent activity at receptors themselves, but they can enhance the activity of endogenous ligands by increasing the amount of ligand available for binding, either by enhancing its release, impeding its removal, or impairing its catabolism at or near the effector site. An example is physostigmine, which indirectly augments the activity of acetylcholine at muscarinic and nicotinic receptors by inhibiting its metabolism by acetylcholinesterase.

Conversely, *antagonists* reduce or abolish the effects of a drug or ligand. Antagonism can be mediated by a variety of processes. Most often, antagonists act by occupying receptor sites and preventing the binding of agonists. Common examples include naloxone (an opioid receptor antagonist), pancuronium and related compounds (which block the activity of acetylcholine at nicotinic receptors in the neuromuscular junction), and flumazenil (a benzodiazepine receptor antagonist).

Chemical antagonism describes the process whereby one agent hinders the effect of another by reacting or binding to it directly. The antidotes succimer (see Chapters 71, 73, and 74), dimercaprol (see Chapter 73), and hydroxycobalamin (see Chapter 88) are examples of chemical antagonists commonly encountered in clinical toxicology. *Pharmacokinetic antagonism* assumes special importance in toxicology. It refers to instances in which one drug reduces the effect of another by decreasing its absorption (e.g., activated charcoal),²⁵ enhancing its elimination (e.g., sodium bicarbonate for salicylate intoxication), or hastening its degradation or inactivation (rarely employed in clinical toxicology but typified experimentally by the use of butyrylcholinesterase as an antagonist of cocaine toxicity and hydrolase enzymes in the treatment of organophosphate poisoning).^{26,27}

Agonists and antagonists can be classified further according to whether their effects are reversible (sometimes termed *surmountable*) or irreversible. The former is more common in clinical medicine, where agonists and antagonists often “compete” for the same receptors, and the clinical result reflects the balance of these processes. For example, 0.1 mg of naloxone is generally adequate to reverse the unwanted effects of morphine in many clinical settings, but a 50- to 100-fold higher dose may be needed in a patient with a large overdose of a more potent synthetic opioid. Irreversible agonists and antagonists are characterized by receptor dissociation that occurs very slowly or not at all, and is a characteristic feature of interactions involving covalent binding. Some clinically relevant examples include phenoxybenzamine, an irreversible inhibitor of catecholamine activity at α -adrenergic receptors, and soman, which irreversibly inhibits acetylcholinesterase (following dealkylation).

Whereas the number of available receptors for a given ligand or drug can be considered static in the acute setting, changes in receptor density can occur over time as part of an adaptive response. *Up-regulation* (or sensitization) refers to an increase in receptor density

resulting from low levels of the endogenous ligand or chronic exposure to an antagonist, while *down-regulation* (or desensitization) denotes a decrease in receptor density with prolonged exposure to large amounts of ligand or persistent exposure to another agonist. *Up-regulation* and *down-regulation* also may result from alterations in postreceptor processes (i.e., downstream signaling protein changes) and occur independently of changes in receptor density. In general, when *down-regulation* has occurred, a decreased effect is noted with continued or subsequent exposure to the same concentration of a xenobiotic.

The term *toxicodynamics* has been proposed to describe the time course of toxic effects in poisoned patients. Increasingly complicated mechanistic or empirical mathematical models are being used to estimate when such toxicity is likely to occur and how long it should last, as in the example of circulating blood cell counts following chemotherapy. The models build upon pharmacokinetic concepts, but they describe the drug effect (rather than the serum drug concentration) as a function of time.²⁸

GENETIC VARIABILITY IN DRUG RESPONSE

One of the most rapidly developing areas in pharmacology is the burgeoning appreciation of the determinants of individual variability in drug response. Genetic variation can influence any aspect of a drug's absorption, metabolism, distribution, or excretion, and it can also modulate its effects at the site of action.¹⁶

Genetic Differences in Drug Response

Pharmacogenomics is the study of the many different genes that influence drug response, whereas *pharmacogenetics* denotes the study of inherited variations in drug metabolism and response. Like other hereditary traits,

genetically determined differences in drug response are subject to significant ethnic and geographic variability, with clustering in specific populations. In most instances, variability results from single-nucleotide polymorphisms (SNPs) that can yield a gene product with only one different amino acid residue but a dramatically less functional protein. Less commonly, genetic polymorphisms or multiple allelic duplication can result in increased functional activity of the resultant protein.²⁹

The influence of genetic variability on drug absorption and excretion is perhaps best illustrated by polymorphisms in the multidrug efflux pump P-glycoprotein (P-gp). The C/C genotype is associated with greater P-gp activity and is present in 83% of individuals from West Africa but only 26% of Caucasians.^{30,31} This polymorphism confers decreased bioavailability as well as enhanced renal and biliary clearance of P-gp substrates such as digoxin, cyclosporine, and protease inhibitors (see Box 4-1), and it conversely imparts greater clinical relevance to P-gp inhibition by drugs such as macrolide antibiotics and azole antifungals.^{9,32}

Genetic variability also influences the biotransformation of many drugs and can involve either phase I or phase II metabolism.¹⁶ Polymorphisms in the CYP450 system (Table 4-3) can have dramatic effects on the safety and efficacy of treatment. For example, the antihypertensive agent debrisoquine is no longer in clinical use today because approximately 7% of Caucasian patients who took the drug experienced a profound hypotensive response. Originally labeled “debrisoquine sensitive,” these patients were later found to have no functional debrisoquine hydroxylase, an enzyme now referred to as CYP2D6. Polymorphisms of CYP2C9 also are common, and they can dramatically enhance the hypoglycemic effects of glyburide and the hypoprothrombinemic response to warfarin, two common drugs that rely heavily on CYP2C9 for inactivation.³³⁻³⁵

Genetic variation in phase II metabolism is perhaps best illustrated by variation in the metabolism of isoniazid and other drugs containing aromatic amines or

TABLE 4-3 Selected Pharmacogenetic Variants of Drug Metabolizing Enzymes

ENZYME	APPROXIMATE FREQUENCY OF POOR METABOLIZER PHENOTYPE	EXAMPLES OF CLINICALLY RELEVANT SUBSTRATE DRUGS	CLINICAL CONSEQUENCE OF POOR METABOLIZER PHENOTYPE
CYP2C9	15% of Caucasians*	(S)-warfarin	Heightened sensitivity to anticoagulant effect
CYP2D6	4% of Africans/Asians* 7%–10% of Northern Europeans 1% in Asians, Indians	Glyburide and other sulfonylureas Codeine Cyclic antidepressants Methamphetamine, MDMA Metoprolol Succinylcholine	Enhanced hypoglycemic response Decreased conversion to morphine; reduced analgesic effect Enhanced drug effect Enhanced drug effect/toxicity Slightly enhanced drug effect Markedly prolonged paralysis
Butyrylcholinesterase (pseudocholinesterase)	1 in 3500 Caucasians		
N-Acetyltransferase-2	40%–70% in Caucasians 18% in Japanese	Isoniazid Hydralazine Procainamide	Enhanced drug effect
Thiopurine S-Methyltransferase	1 in 300 Caucasians 1 in 2500 Asians	Azathioprine Mercaptopurine	Enhanced drug effect

*Frequency of genetic polymorphisms conveying at least moderate reductions in metabolic capacity.

hydrazine moieties, such as procainamide, dapsone, and hydralazine. The expression of *N*-acetyltransferase 2 (NAT2) in liver and gut mucosa is highly polymorphic, resulting in a bimodal distribution of plasma isoniazid concentrations. Patients with the slow acetylator phenotype (approximately 40% to 70% of Caucasians and 10% to 30% of Asians) exhibit reduced presystemic extraction (i.e., higher bioavailability) and slower elimination of isoniazid. Slow acetylator status may enhance the effectiveness of therapy yet increase the risk of isoniazid-associated complications such as neuropathy and hepatitis.^{36,37}

Future Applications of Pharmacogenomics

As the many genetic variations within the human genome are more completely characterized, anticipating the response of a patient to a drug before treatment is initiated will become increasingly possible.³⁸ To accomplish this, an individual's DNA would be sequenced for the presence of specific SNPs. Whereas this was previously a laborious, expensive process, DNA microarrays are increasingly available as a tool for the rapid identification of thousands of SNPs in an individual patient's genome within a few hours.³⁸

Such technology may predict not only a drug's efficacy but also the likelihood of toxicity. For example, several polymorphisms in the β_2 -adrenergic receptor have been described.³⁹ These polymorphisms significantly influence the clinical response to albuterol and may modulate its arrhythmogenicity.⁴⁰ Indeed, in the near future it is probable that the enrollment of patients in clinical trials will be governed by whether they will experience benefit or harm from a drug, as determined by their genetic makeup. Although this will make it easier for clinical trials to identify treatment effects, it will also likely hamper the generalizability of results to patients whose genetic makeup is different or not known.

Drug Interactions

MICHAEL W. SHANNON, MD, MPH

Over the past 5 years there has been an explosion of interest in the causes of adverse drug effects and potential mechanisms for preventing them. In the monograph *To Err is Human*, The Institute of Medicine identified medication-related adverse events as a leading cause of preventable death.¹ One area of concern has been adverse effects that result from drug-drug interactions, particularly since many of these effects are predictable.

The modification of drug effects has the potential to reduce the effectiveness of a drug, enhance the drug's toxicity, or both. Also, adverse interactions do not occur only between drugs; they can occur between drugs and diet (e.g., potentiation of calcium channel blockers by grapefruit juice), drugs and environmental agents (e.g., photosensitivity eruptions in those exposed to sunlight while taking sulfonamides or tetracyclines), drugs and alternative remedies (e.g., potentiation of Coumadin-induced anticoagulation by tonka beans), and between drugs and substances of abuse (e.g., serotonin syndrome in those taking monoamine oxidase inhibitors who use methylenedioxymethamphetamine [Ecstasy]).²

Drugs may interact with each other through a number of different mechanisms, which may be classified as pharmaceutical, pharmacokinetic, or pharmacodynamic (Box 5-1). Interactions through any of these mechanisms may result in unpredictable clinical effects or toxicologic responses. Pharmaceutical interactions include those that produce drug inactivation when compounds are physically mixed together before administration. For example, aminoglycosides are inactivated by certain β -lactam antibiotics when these drugs are mixed

together in the same intravenous fluid. Pharmacokinetic interactions can occur when the disposition characteristics of one compound (i.e., absorption, distribution, metabolism, or excretion) are influenced by those of another. This type of interaction may involve one or more specific aspects of a drug's pharmacokinetic profile. For example, a compound may displace a drug from its protein-binding sites, consequently increasing its elimination from the body. Finally, drugs may interact pharmacodynamically (i.e., compete for the same receptor or physiologic system), altering a patient's response to drug therapy.³ A small group of drugs is involved in serious drug interactions with some frequency (Box 5-2).

The number of known, clinically important drug interactions, combined with the ever-increasing number of available pharmacologic agents underscores the need to understand the pharmacologic basis of drug interactions. This chapter reviews the pharmacokinetic and pharmacodynamic basis of drug interactions, using clinically important interactions as examples.

EPIDEMIOLOGY

The prevalence of adverse drug interactions has been estimated to range between 2.2% and 30% in hospitalized patients and 9.2% and 70.3% in ambulatory patients.^{4,7} The emergency department is a focal point for the diagnosis or development of adverse drug reactions; emergency department surveillance data suggest that adverse drug events account for 7 per 1000

visits.⁸ The events take on multiple origins. First, patients may present to the emergency department with manifestations of an adverse drug reaction. In cases in which the diagnosis of drug interaction is not obvious, the emergency physician may be unsuspecting; the patients may even be discharged without the diagnosis being made. For example, serotonin syndrome, which often is the result of a drug interaction, is commonly overlooked by clinicians from all specialties.⁹ Additionally, an estimated 70% to 85% of emergency department encounters result in prescription therapy.¹⁰ The emergency physician therefore has a significant role in making therapeutic decisions that do not result in a predictable drug interaction.

PHARMACOKINETIC MECHANISMS OF DRUG INTERACTIONS

Gastrointestinal Absorption

Absorption is defined as the translocation of drug from its site of administration into the systemic circulation. Drugs administered extravascularly, by the oral, sublingual, or intramuscular routes, must cross several membranes to reach the systemic circulation before distribution to their sites of action. The process of absorption can be divided into and influenced by two distinct domains: rate and extent. Both domains are influenced by the physicochemical properties of the drug as well as various host factors. The physicochemical properties of a drug that affect absorption include molecular weight, degree of lipid solubility, extent of ionization at physiologic pH, and type of formulation (e.g., tablet, capsule, or liquid).

Several potential types of interactions between two or more compounds can influence the rate or amount of drug absorption from the gut (Box 5-3). For example, foods or drugs capable of altering gastrointestinal pH could theoretically modify the absorption characteristics of a compound by altering the proportion of drug that is in its ionized, less lipid-soluble state. Thus, coadministration of antacids, histamine-2 (H_2) receptor antagonists, or proton pump inhibitors, all which alter gastrointestinal pH, could substantially influence the amount of drug—particularly a weak base—that is absorbed from

BOX 5-3

MECHANISMS INVOLVED IN INTERACTIONS THAT AFFECT DRUG ABSORPTION FROM THE GASTROINTESTINAL TRACT

- Alteration of gastric emptying rate or gastrointestinal motility
- Modification of volume, composition, or viscosity of gastrointestinal secretions
- Effects of pH on drug ionization and dissolution
- Effects of mucosal and bacterial drug metabolism
- Interactions with active transport systems
- Alterations of splanchnic blood flow
- Complexation and chelate formation
- Toxic effects on gastrointestinal mucosa

TABLE 5-1 Selected Clinically Important Interactions Due to Alteration of Drug Absorption

DRUG	COMPOUND AFFECTED
Antacids	Captopril
	Ketoconazole
	Isoniazid
Cholestyramine	Digitalis glycosides
	Thyroid hormone
Sucralfate	Ciprofloxacin
	Digoxin
	Ketoconazole
	Phenytoin
	Quinolone antibiotics
	Tetracycline
	Theophylline
	Valproic acid

the stomach.¹¹ Conversely, these drugs, by decreasing gastric acid secretion, might promote an increase in the absorption of acid-labile drugs (e.g., penicillin G). Concomitant administration of antacids with other medications can lead to clinically important interactions arising from the gastrointestinal and chemical effects of the aluminum, calcium, and magnesium ions liberated from the antacid preparation.¹¹ For example, a clinically relevant interaction occurs between antacids and quinolone antibiotics (Table 5-1). Other agents may affect drug absorption. Cholestyramine resin also has been shown to reduce the systemic absorption of common pharmaceuticals. Sucralfate, another treatment for gastritis, can lower the absorption of digoxin, phenytoin, and quinolone antibiotics significantly.

Drugs that affect gastrointestinal motility may influence the gastrointestinal absorption of orally administered drugs by controlling the rate of drug delivery to the major absorptive surfaces, as well as the duration of contact with these surfaces.¹² For example, coadministration of an anticholinergic agent has been shown to increase the rate and extent of digoxin absorption; conversely, digoxin absorption appears to decrease after metoclopramide administration.¹³ Coadministration of gastric promotility agents (e.g., metoclopramide) has been shown to decrease the time to peak serum drug concentration (T_{max}) and increase the peak serum drug concentration (C_{max}), but in general it has no appreciable effect on the drugs' overall extent of bioavailability.¹² Consequently, the clinical significance of this drug interaction is unclear. Interestingly, the magnitude of the effect of gastrointestinal promotility agents on the T_{max} and C_{max} of orally administered drugs appears to be more common and much greater when the motility agent is administered intravenously rather than orally.

Distribution

Drug distribution describes the movement of a pharmacologically or toxicologically active moiety from the systemic circulation into various body compartments,

tissues, and cells. The pharmacokinetic parameter estimate, volume of distribution (Vd), is an apparent value that attempts to describe the relationship between the amount of drug in the body, including the blood. The process of distribution depends on the partition coefficient of a drug between blood and tissue, regional blood flow, and the extent of binding to plasma protein or tissues.

Alterations in drug distribution most commonly result from the displacement of bound drug from circulating plasma proteins. Acidic compounds typically bind albumin whereas basic compounds bind predominantly to α_1 -acid glycoprotein.^{3,14} The free or unbound fraction of a compound is the pharmacologically active moiety, capable of traversing cellular membranes, diffusing into tissues, and binding to receptors. As such, changes in drug binding that result in an increase in the amount of free drug may increase the amount of drug available for tissue distribution, increasing the drug's concentration at the site of action and amplifying its effect. For example, the displacement of Coumadin from serum albumin-binding sites by other highly protein-bound compounds (e.g., aspirin) represents a classic example of such an interaction.³ This traditional view of simple competitive displacement of drug from circulating proteins, however, is based on a number of assumptions, many of which have not been clinically validated.^{3,14}

A number of variables may directly influence the physiologic impact of a drug displacement interaction. For such reactions to be important clinically, both compounds must be at least 80% bound to the same protein species. In addition, the displaced compound must exhibit capacity-limited body clearance or have a relatively small apparent Vd (<0.15 L/kg).^{3,14} This last factor is likely to be the most important, because as the Vd increases, less of the total amount of drug in the body is present in the plasma compartment. Thus, with proportionately less compound to displace and a larger "space" in which to distribute, the effect of a displacement interaction would be minimal. Finally, it is important to recall that increasing the amount of free drug concurrently increases the amount of compound available for metabolism or excretion and can result in an accelerated elimination rate for the displaced drug.³

The physiologic impact of drug-drug protein displacement reactions clearly depends on the balance among a large number of variables. Importantly, after a drug overdose there is great uncertainty about the impact of a single large dose of a displacing agent on the overall biodisposition of the displaced agent. Moreover, the magnitude and duration of the interaction are determined by the normal saturability of the drug-plasma protein complex. In some cases, protein binding for some highly protein-bound drugs has clinical significance in overdose. For example, an increase in free valproic acid concentration appears to make the drug easier to remove by extracorporeal drug removal techniques, such as hemodialysis.^{15,16} These preliminary reports confirm the importance of identifying potential changes in the extent of protein binding for highly protein-bound drugs; any significant change in the

amount of free, unbound drug could affect the timing and severity of clinical manifestations and the approach to treatment.

Changes in a drug's Vd that result from altered tissue binding, although rare, are exemplified by the now well-known interaction between digoxin and quinidine.¹⁷ The decrease observed in quinidine Vd and the concurrent increase in serum digoxin concentrations most likely are due to digoxin tissue-binding displacement by quinidine. These changes in digoxin pharmacokinetics have been noted to occur after administration of a single dose of quinidine. In addition to causing tissue displacement, quinidine also decreases the renal and nonrenal clearance of digoxin. Quinine, the S-isomer of quinidine, also has been shown to interfere with nonrenal clearance of digoxin.¹⁸

Metabolism

Drug metabolism is divided into the two general categories of phase I and phase II transformation reactions.¹⁹ Phase I reactions involve structural alteration of drug, typically by processes including oxidation, hydrolysis, and reduction. Phase II reactions most commonly involve conjugation of a water-soluble moiety to the parent drug. Phase II reactions include glucuronidation, sulfation, and methylation.²⁰ Most phase I reactions are performed by the cytochrome P-450 family of isoenzymes.

The cytochrome P-450 (CYP450) enzymes are found primarily in the gut and liver. Their name is derived from the characteristic of maximal absorption at a wavelength of 450 nm. According to current nomenclature, the cytochrome isoenzymes are grouped into families (1, 2, and 3), divided into subfamilies (A through E), and specified by number.

The cytochrome isoenzymes have many features that give them great variability in action, both within and among individuals. As a result, they and their activity are a common cause of drug interactions, particularly drug-drug interactions.²¹ The four most important variables that affect CYP450 activity are genetic heterogeneity, age-related changes, enzyme induction, and enzyme inhibition.

The genes encoding for each drug-metabolizing enzyme can develop mutations that result in the production of a protein that has decreased, increased, or absent enzymatic activity.²² Examples of CYP450 isoenzymes with clinically important genetic polymorphisms include CYP2D6 and CYP2E1. Such polymorphisms can lead to unexpected drug responses.²³ However, over the last decade, technology that permits both genotypic and phenotypic probing of the cytochrome enzymes has greatly improved the ability to identify individuals with abnormal activity. This growing field of pharmacogenetics has greatly increased the ability to reduce the risk of developing adverse drug reactions by identifying susceptible individuals before their receipt of the drug.²⁴⁻²⁹

The development of CYP450 enzyme activity occurs progressively in postnatal life and undergoes additional changes throughout life. Consequently, the risk of devel-

oping a drug interaction often is a function of patient age. As an example, CYP1A2 has negligible activity in the newborn³⁰; after reaching peak activity in adults, it appears to have waning activity in the elderly years.

Induction refers to an increase in enzyme activity. Induction results either from increased production of enzyme (through enhanced transcription and translation) or through a reduction in the natural rate of enzyme breakdown.²⁹ Not all cytochrome enzymes are inducible; of the major isoenzymes, CYP1A2, CYP2C9, CYP2E1, and CYP3A are best known for having clinically relevant inducers.

CYP450 enzyme inhibition is classified as either reversible or irreversible. The most common type, *reversible inhibition*, occurs when a second substrate competes with the primary drug for the active site of the enzyme. This process also may be referred to as *competitive inhibition*. An example of such inhibition occurs after the coadministration of diltiazem and cyclosporine. Diltiazem is a reversible inhibitor of CYP3A4, the enzyme responsible for the elimination of cyclosporine. Diltiazem coadministration interferes with cyclosporine clearance, resulting in higher serum cyclosporine concentrations. Competitive inhibition is transient with the enzyme returning to normal activity once the inhibitor has been cleared. In *irreversible inhibition*, a substrate binds to a CYP450 enzyme, sometimes altering the enzyme structure and producing permanent enzyme inactivation. With irreversible inhibition, only synthesis of new enzyme can restore its normal physiologic function. Monoamine oxidase inhibitors produce such permanent effects on the enzyme.

Drugs used to treat HIV infection have a significant propensity for drug-drug interaction via the CYP450 isoenzymes.³¹

The six cytochrome isoenzymes of greatest importance are described in more detail below and are summarized in Table 5-2. Many reviews of CYP450 function and drug interactions have been recently published.^{19,20,29}

CYP1A2

Many commonly used medications, including caffeine, theophylline, tricyclic antidepressants, and warfarin, are metabolized by CYP1A2. Activity of CYP1A2 can be induced by tobacco smoke, charbroiled foods, and cruciferous vegetables. Several medications induce CYP1A2 activity, including phenytoin, phenobarbital, and rifampin. Omeprazole and ritonavir simultaneously may induce CYP1A2 and inhibit one or more other CYP isoenzymes. Inhibitors of CYP1A2 include erythromycin, ciprofloxacin, fluvoxamine, and grapefruit juice.

CYP2C9

CYP2C9 is responsible for the metabolism of medications including ibuprofen, phenytoin, and warfarin. Rifampin is a powerful inducer of CYP2C9 activity and therefore decreases serum concentrations of its substrates. Amiodarone, fluoxetine, and fluconazole are among several drugs known to inhibit CYP2C9 activity. Genetic polymorphisms occur in 1% to 3% of Caucasians, contributing to abnormally decreased enzyme activity in these individuals.

CYP2C19

Medications metabolized by CYP2C19 include several benzodiazepines, citalopram, tricyclic antidepressants, and omeprazole. Rifampin induces CYP2C19 activity, whereas fluvoxamine, fluoxetine, and ritonavir inhibit this enzyme. Genetic polymorphisms are responsible for

TABLE 5-2 Substrates, Inducers, and Inhibitors of Major Human Cytochromes

CYTOCHROME	SUBSTRATES	INDUCERS	INHIBITORS
CYP1A2	Caffeine, theophylline, tricyclic antidepressants, warfarin	Charbroiled food, omeprazole, phenobarbital, phenytoin, tobacco smoke	Erythromycin, fluvoxamine, grapefruit juice, quinolone antibiotics
CYP2C9	Diclofenac, glipizide, ibuprofen, phenytoin, tolbutamide, warfarin,	Phenobarbital, Rifampin	Amiodarone, cimetidine, fluconazole, fluoxetine, itraconazole, ketoconazole, metronidazole, ritonavir
CYP2C19	Diazepam, imipramine, nelfinavir, omeprazole, pantoprazole, propranolol,	Rifampin	Fluoxetine, fluvoxamine, omeprazole, ritonavir, sertraline
CYP2D6	Codeine, dextromethorphan, flecainide, fluoxetine, haloperidol, metoprolol, paroxetine, perphenazine, propranolol, sertraline, timolol, tricyclic antidepressants, venlafaxine		Cimetidine, dextromethorphan, fluoxetine, haloperidol, paroxetine, sertraline
CYP2E1 CYP3A	Acetaminophen, ethanol Alprazolam, astemizole, atorvastatin, carbamazepine, cisapride, cyclosporine, diltiazem, losartan, lovastatin, midazolam, nifedipine, simvastatin, terfenadine, theophylline, verapamil	Disulfiram Carbamazepine, ethanol, phenobarbital, phenytoin, rifampin, St. John's wort	Ethanol, isoniazid Cimetidine, clarithromycin, cyclosporine, diltiazem, erythromycin, fluoxetine, fluvoxamine, grapefruit juice, HIV protease inhibitors, itraconazole, ketoconazole, nifedipine, verapamil

significant interpatient variability in CYP2C19 activity. The enzyme is absent in 13% to 23% of Asians and 3% of Caucasians.²⁹

CYP2D6

CYP2D6 comprises a relatively small percentage (2% to 6%) of the total cytochrome P-450 in the liver but is involved in the metabolism of many medications (up to 25%). Multiple tricyclic antidepressants, β blockers, haloperidol, sertraline, paroxetine, and thioridazine are among the common drugs metabolized by CYP2D6. Interestingly, the conversion of codeine to the active form, morphine, is catalyzed by CYP2D6; patients with low CYP2D6 activity demonstrate a poor analgesic response to codeine.³² There are no significant inducers of this activity. However, several medications inhibit CYP2D6, the most potent being cimetidine, fluoxetine, haloperidol, and paroxetine. Genetic polymorphisms play a significant role in determining CYP2D6 activity. Approximately 1% to 3% of African American and Asian patients and 5% to 10% of Caucasians lack this enzyme, placing them at risk for increased toxicity from medications that are metabolized by CYP2D6.³² A subpopulation with higher than usual activity also has been described (“extensive and ultrarapid metabolizers”).^{25,26,33}

CYP2E1

Although CYP2E1 metabolizes a relatively small fraction of medications, it plays a significant role in the activation and inactivation of many agents. CYP2E1 metabolizes small organic molecules (e.g., ethanol, carbon tetrachloride) as well as acetaminophen and dapsone. Although only a small percentage of acetaminophen is metabolized by CYP2E1, the drug’s hydroxylation produces *N*-acetyl-*p*-benzoquinone imine (NAPQI), the putative molecule responsible for acetaminophen hepatotoxicity. Chronic ethanol use can induce CYP2E1 activity, leading to a greater percentage of acetaminophen metabolized to NAPQI, increasing the risk of hepatotoxicity from acetaminophen use. Many scientists question the existence of an important ethanol-acetaminophen interaction.^{34,35}

CYP3A

CYP3A is the most abundant, clinically significant group of cytochrome P-450 isoenzymes. The CYP3A group is composed of four major isoenzymes: CYP3A3, CYP3A4, CYP3A5, and CYP3A7. CYP3A4 is the most common and is implicated in the majority of drug interactions. However, since these enzymes are so closely related (having as much as 97% sequence homology), they often are referred to collectively by the subfamily name, CYP3A. Up to 60% of the liver’s total cytochrome P-450 is CYP3A, and nearly 50% of all clinically relevant medications are metabolized by CYP3A. The presence of CYP3A in the small intestine results in decreased bioavailability of many ingested drugs. CYP3A inducers include the glucocorticoids, rifampin, carbamazepine, phenobarbital, and phenytoin. Among the many significant CYP3A inhibitors are grapefruit juice, erythromycin, ketoconazole, clarithromycin, and verapamil.

NONMICROSOMAL DRUG METABOLISM ENZYMES

A number of compounds can impair or directly inhibit hepatic drug metabolism by interacting with non-CYP450 (nonmicrosomal) enzymes. Disulfiram (Antabuse) is a potent inhibitor of the nonmicrosomal enzyme acetaldehyde dehydrogenase, which is responsible for the metabolism of ethanol to acetic acid. Concurrent ethanol consumption and disulfiram administration leads to acetaldehyde accumulation and the classic Antabuse reaction, characterized by unpleasant symptoms that include facial flushing, throbbing headache, nausea, vomiting, sweating, palpitations, hypotension, and syncope. Another important nonmicrosomal reaction is the serotonin syndrome that results from administration of agents such as meperidine by patients who are taking monoamine oxidase inhibitors.⁹

Acetylation by the enzyme *N*-acetyltransferase (NAT) is another important, non-CYP pathway of drug metabolism. Dapsone, hydralazine, isoniazid, procainamide, and the sulfonamides are examples of drugs metabolized via acetylation. Acetylation polymorphisms are well described. Variants in the alleles coding for NAT occur in 50% of Americans, Caucasian and black, resulting in slow acetylator status. Slow acetylator phenotypes occur in 60% to 70% of Northern Europeans and 5% to 10% of Asians. Slow acetylators have an increased risk of drug toxicity, but they also experience longer drug effectiveness. Those with the fast acetylator phenotype may fail to experience the desired therapeutic response to treatment as a result of the rapid metabolism of drug.

Elimination

The most common pathway by which drugs or their metabolites are eliminated from the body is via the kidneys. Interactions that influence renal clearance of a compound primarily alter the physiologic processes of glomerular filtration, tubular reabsorption, or active tubular secretion. Additionally, agents that alter renal blood flow also may influence renal elimination. Nevertheless, for such interactions to be of clinical importance, the overall elimination of active drug must depend primarily on renal mechanisms. For example, as discussed earlier, displacement interactions may transiently increase the amount of free drug in the vascular compartment, resulting in an increase in the amount of drug available to be filtered by the glomeruli and excreted.

In contrast to displacement interactions, a number of drugs can directly influence glomerular filtration through other mechanisms. The nonsteroidal anti-inflammatory drugs (NSAIDs)—aspirin, ibuprofen, indomethacin, naproxen, and others—all have been shown to reversibly depress renal function. This drug-induced decrease in renal function most likely is a result of NSAIDs’ inhibition of renal prostaglandin synthesis and can result in increased side effects because of accumulation of other concurrently administered drugs (e.g., lithium).

Modification of the passive distal tubular reabsorption of weak acids and bases is another mechanism by which

drugs may interact and represents a potentially important therapeutic modality in the treatment of certain intoxications. An inverse relationship exists between the compound's degree of ionization and the overall amount of a compound reabsorbed from the urine—that is, the greater the amount of compound present in the urine in the un-ionized, more lipid-soluble state, the greater the amount reabsorbed. In general, for renal clearance to be sensitive to changes in urine pH, acidic and basic drugs must have pK_a values that range between 3 to 7.5 and 7 to 11, respectively. This principle of altering urinary pH has been used in the management of a number of drug intoxications, particularly those by salicylates and phenobarbital. Alkalinization of urine by either intermittent or continuous intravenous infusion of sodium bicarbonate can significantly decrease distal tubular reabsorption of both of these drugs. Intraluminal trapping of acids in their ionized form appears to be greatest when urine pH exceeds 7.5.³⁶ Although the manipulation of urinary pH to promote ion trapping and to augment renal clearance appears desirable, it is not without risk. Rapidly raising urinary pH requires an increase in blood pH, a change that may be undesirable and possibly detrimental in certain instances.^{36,37} Furthermore, clinicians must weigh carefully the associated risks of pH manipulation and the time necessary to achieve effective changes in urinary pH with the effectiveness of other therapeutic modalities and, most important, with the anticipated duration of serious symptoms.³⁶

Finally, biliary secretion represents an often overlooked but relatively important means for the elimination of a number of drugs and substrates, and a pathway with which drug interactions may occur. Parent compounds or their metabolites excreted via the bile may be reabsorbed into the systemic circulation from the distal ileum. This process of enterohepatic circulation is an important mechanism responsible for delayed and prolonged drug absorption and elimination of a number of commonly used drugs (e.g., carbamazepine). Increasing the total body clearance of such compounds by interfering with the enterohepatic circulation is the basis for administering repeated doses of oral activated charcoal as a therapeutic intervention to patients who experience intoxications involving compounds that undergo substantial enterohepatic circulation.³⁸

Drug–Nutrient Interactions

Nutritional habits may influence dramatically the response to pharmacologic intervention. The type and quantity of food consumed as well as the overall nutritional status of a patient may directly or indirectly alter drug disposition characteristics. For example, there is an extensive list of nutrients that interact with warfarin action (Box 5-4). The specific composition of a meal can markedly alter drug absorption. The most notable example of food-associated inhibition of drug absorption involves the complexation of tetracycline compounds when coadministered with divalent cation-containing

compounds (e.g., milk, cheese, antacids, vitamins). However, it is unusual for such an interaction to result in significantly decreased systemic bioavailability. What occurs more frequently is that the rate but not the overall extent of drug absorption is decreased when the drug is administered in the presence of food. The intestinal absorption of some commonly administered drugs, such as acetaminophen, digoxin, many penicillin and cephalosporin analogs, and phenytoin, may be delayed or reduced when these agents are given in the presence of food.³⁹ Conversely, the bioavailability of some orally administered drugs, including spironolactone, griseofulvin, and cefuroxime axetil, can be increased when the drugs are administered in the presence of food.

Coadministration of certain medications with enteral nutrition formulas may result in altered drug absorption and poor therapeutic effect. Subtherapeutic patient responses have been noted in patients receiving carbamazepine or phenytoin when these drugs are coadministered with enteral formulas.^{39,40} The mechanism of this drug–nutrient interaction is unknown but clearly exceeds simple drug adherence to the feeding tubing. To minimize the effect that enteral nutrition formulas may have on the bioavailability of these drugs, the tube feeding should be stopped and the tubing flushed approximately 1 to 2 hours before drug administration. Tube feeding can be resumed 1 to 2 hours later.

Papain

From Manzi S, Shannon M: Drug interactions—a review. *Clin Ped Emerg Med* 2005;6:93–102.

Both hepatic drug metabolism and renal elimination can be influenced by the type and quantity of nutrient consumed. Cabbage, Brussels sprouts, and cauliflower all have been shown to contain bioactive indoles that are potent inducers of intestinal and hepatic drug-metabolizing enzymes. Conversely, compounds present in grapefruit juice are capable of inhibiting the activity of both cytochrome and noncytochrome enzymes.⁴¹ Diets high in protein (e.g., >40% of total calories) have been shown to increase the metabolic capacity of the hepatic mixed-function oxidase system; this results in increased clearances of a number of drugs (e.g., propranolol). This increase in body clearance is not observed when similar quantities of either carbohydrate or fat are substituted for protein. In addition, diets deficient in protein are associated with altered renal hemodynamics, a condition that leads to marked decreases in glomerular filtration, which further influences a drug's body clearance and pharmacodynamics.

Pharmacodynamic Mechanisms of Drug Interactions

In patients receiving multiple drugs, the overall effects manifested are a summation of the similar or opposing but independent actions of these multiple agents on a given cell or organ system. These interactions historically have not been considered drug interactions, yet many are of extreme clinical importance. These interactions are properly termed *pharmacodynamic drug interactions* and are thought to involve drug-receptor interactions, either directly or indirectly.

The types of interactions that might occur at the receptor level are varied. Moreover, the understanding of these interactions often is confounded because simple potentiation or antagonism is distinctly uncommon. Most of these interactions occur through an interplay of receptor mechanisms controlling the function of a given tissue or organ system. In a similar fashion, drugs may interact with physiologic or biochemical control loops, a process that leads to alterations in response to normal stimuli and input signals. Finally, one drug may prevent access of another to its site of action, and thus the pharmacodynamic process is abrogated.

Direct Receptor Effects

In a few instances, drug interactions occur through direct receptor site antagonism. Consider, for example, an asthmatic patient receiving the β_2 -adrenergic agonist bronchodilator albuterol who develops angina and is treated with propranolol. The nonselective blocker propranolol clearly has the potential to inhibit the bronchodilator effect of the β_2 -adrenergic agonist drug. The use of specific receptor agonists or antagonists (e.g., naloxone, phentolamine) represents desired interactions at the receptor level that are of immense clinical importance in the treatment of poisoned patients.

Another example of direct pharmacodynamic interaction can occur during therapy with the warfarin

anticoagulants. Quinidine appears to augment the cellular uptake of warfarin, increasing warfarin's effective concentration at the site of action.

Indirect Receptor Effects

Pharmacodynamic interactions associated with indirect receptor effects are side effects of one drug that mimic the pharmacologic effects of another. Augmentation of the hypoglycemic effects of insulin and oral hypoglycemic agents by nonselective β -blocking agents is an example of agents with differing mechanisms of action that produce the same clinical effects.

The use of drugs with actions on the myocardium, cardiac conduction system, or capacitance and resistance vessels predisposes to a large number of pharmacodynamic interactions. Calcium channel blockers and β -adrenergic receptor antagonists often augment the myocardial depressant, bradycardiac, and hypotensive effects of one another when used in concert. Other effects augmented by the simultaneous administration of vasoactive drugs and β -adrenergic blocking agents include exacerbation of first-dose hypotensive effects of prazosin and enhancement of the hypertensive response during clonidine withdrawal.

The proliferation of NSAIDs (prescription and over-the-counter) have focused attention on a number of serious interactions that may occur with these agents. The sodium and water retention that result from long-term use of these agents may blunt the antihypertensive effects of angiotension-converting enzyme inhibitors (e.g., captopril, enalapril, and others), thiazide diuretics, and β -adrenergic blocking agents. These effects also may offset the benefits of diuretic therapy in mild to moderate congestive heart failure.

SUMMARY

Drug interactions remain an important consequence of pharmacologic intervention. It is clear that the pharmacologic response of a drug can be markedly influenced by concurrent administration of another therapeutic agent or food. These interactions may result in a decreased therapeutic effect or in an increase in the amount and extent of untoward reactions. Despite the well-described and real clinical consequences of certain drug interactions, this aspect of patient care often continues to be overlooked.

Drugs can interact via a number of pharmaceutical, pharmacokinetic, or pharmacodynamic mechanisms. These interactions may occur as a result of concurrently prescribed therapeutic modalities, environmental variables, or the patient's specific habits, such as diet, alcohol use, and tobacco use. The increasingly predictable nature of drug interactions underscores how important it is for all health care practitioners to understand the mechanisms of drug interactions, anticipate the possibility of their occurrence, and, ideally, prevent them.

Acid–Base, Fluid, and Electrolyte Balance

MICHAEL SHANNON, MD, MPH

The poisoned patient commonly presents with acid–base, volume, and electrolyte disturbances. The purpose of this chapter is to discuss the basic principles of acid–base balance, the regulation of body fluid volumes, intracellular and extracellular fluid, and electrolyte composition. Aberrations of these are common among intoxicated patients; an understanding of their basis and the rationale for certain intervention strategies are key in management.

ACID–BASE DISORDERS

Acid–base homeostasis may be affected by a toxic substance or its metabolite (primary disturbance) or by dysfunction or failure of various organ systems (secondary disturbance). In addition, disorders may arise because of an intervention (e.g., gastric lavage that leads to metabolic alkalosis or the use of cathartics that leads to hypernatremic dehydration).

Fundamental Concepts of Acid–Base Homeostasis

The pH of body fluids is regulated within a narrow range because of the participation and interplay of several regulatory systems. The most important systems are the lungs and the respiratory control center of the central nervous system (CNS), the kidney, and the body's buffer systems. The most important buffer system is the *bicarbonate-carbonic acid system*, which regulates extracellular bicarbonate level and partial pressure of carbon dioxide ($p\text{CO}_2$), the $p\text{CO}_2$ is regulated by the respiratory center and pulmonary system. Endogenous production of carbon dioxide leads to an increase in its concentration, which, in combination with water, forms carbonic acid; carbonic acid then readily dissociates to hydrogen ion and bicarbonate:

From this equation, the Henderson-Hasselbalch derivation is made, which states that

$$\text{pH} = \text{p}K_a + \log (\text{HCO}_3^-) / (\text{pCO}_2)$$

where pH is the logarithm of hydrogen ion concentration, reflecting plasma acidity and representing the balance between serum bicarbonate level and $p\text{CO}_2$ (the respiratory component). The normal serum bicarbonate level is 24 to 28 mEq/L, and the normal PCO_2 is 36 to 44 mm Hg.

Definitions

ACIDEMIA VERSUS ALKALEMIA

When serum pH is less than 7.36, the patient has acidemia; when serum pH is greater than 7.44, the

patient has alkalemia. The pH itself indicates neither the origin of the disorder nor whether there is physiologic compensation in response to the initial disorder. In contrast, acidosis and alkalosis are disease states that, if left unopposed, can change the plasma pH. If the initial change in bicarbonate level or PCO_2 is severe enough to override the body's buffer and defense mechanisms, then acidemia or alkalemia ensues. Acidosis or alkalosis can be present without concomitant acidemia and alkalemia, particularly if there is secondary compensation (e.g., in respiratory alkalosis accompanying a severe lactic metabolic acidosis secondary to septicemia, such that the pH is normal or even alkalemic despite the presence of metabolic acidosis).

METABOLIC VERSUS RESPIRATORY DISTURBANCES

A *metabolic acid–base disorder* is a disturbance caused by a change in serum bicarbonate level. *Metabolic acidosis* is defined as a decrease in serum bicarbonate level to less than 24 mEq/L, whereas *metabolic alkalosis* is defined as an increase in the serum bicarbonate level to more than 28 mEq/L. In contrast, a *respiratory acid–base disorder* refers to a disorder caused by a change in the PCO_2 . *Respiratory acidosis* is defined as a PCO_2 greater than 44 mm Hg, and *respiratory alkalosis* is defined as a decrease in PCO_2 to less than 36 mm Hg. Physiologically, when these disturbances occur, secondary defenses, or compensatory mechanisms, are set into play with a goal of minimizing any change in serum pH. In the normal host, metabolic acidosis results in hyperventilation and a decrease in PCO_2 , whereas metabolic alkalosis leads to secondary hypoventilation and an increase in PCO_2 . These respiratory changes, particularly hyperventilation, may be blunted or absent in severely intoxicated patients. Respiratory acidosis leads to increased renal reabsorption of bicarbonate and net acid excretion, increasing the serum bicarbonate level, whereas respiratory alkalosis leads to an increase in the renal excretion of bicarbonate accompanied by a decrease in the serum bicarbonate level. These physiologic responses are proportional to the magnitude of the initial disorder and tend to return pH toward normal—but never completely to normal.

SIMPLE/MIXED ACID–BASE DISORDERS

A *simple acid–base disorder* is defined as a single disturbance with an appropriate accompanying secondary physiologic response. A response that is disproportionate in magnitude to the appropriate response—for instance, marked respiratory acidosis accompanied by only a mild increase in serum bicarbonate level—implies the coexistence of another primary disorder and therefore is a *mixed acid–base disorder*. Mixed acid–base disorders are common particularly in critically ill poisoned patients,

such as those with salicylate poisoning who have both metabolic acidosis and respiratory alkalosis and those with ethanol intoxication who have a lactic acidosis with a concomitant respiratory acidosis occurring because of the drug's CNS depressant effect.

METABOLIC ACIDOSIS

Metabolic acidosis, characterized by a serum bicarbonate level of less than 24 mEq/L usually, but not always, is accompanied by a decrease in bicarbonate level to give a pH of less than 7.36, and thus results in acidemia. Four general mechanisms produce metabolic acidosis: a loss of extracellular bicarbonate greater than extracellular chloride (e.g., with diarrhea or renal tubular acidosis); gain of hydrogen ions exogenously or endogenously, with subsequent metabolic consumption of extracellular bicarbonate (e.g., as with formic acid production after methanol ingestion or lactic acidosis from metformin use); failure to excrete the body's obligatory daily acid load (e.g., as in renal failure); and dilution of extracellular bicarbonate. With the initial decrease in serum bicarbonate level and subsequent acidemia, secondary mechanisms initiate the return of pH toward normal. These mechanisms include extracellular buffering, intracellular buffering, the renal excretion of the acid load, and the respiratory compensatory response. Following an acid load, bicarbonate, the most important extracellular buffer, is called into action to buffer acid loss, milliequivalent for milliequivalent. After several hours, intracellular buffers also participate and buffer approximately 55% to 60% of the acid load. Excess extracellular hydrogen ions then enter the cell in exchange for sodium and potassium ions. In general, metabolic disorders such as metabolic acidosis tend to cause a greater shift of intracellular potassium to the extracellular space than do respiratory disorders. Bicarbonate itself can cause shifts of potassium ions without changes in pH. In organic acidosis, the organic acid ions (i.e., keto acids or lactic acid) can enter cells with the excess hydrogen ions, whereas chloride cannot. Therefore, organic acidosis does not cause significant potassium redistribution when compared with mineral acidosis. Although the described mechanisms act in concert to minimize drastic changes in pH, the kidney alone possesses the ability to generate new bicarbonate by excreting the excess hydrogen ions. This process begins early but takes several days and occurs due to an increase in both ammonium excretion and titratable acidity.

An initial decrease in pH stimulates the ventilatory response mediated both by peripheral chemoreceptors and the medullary receptors in the CNS, which respond to changes in cerebral interstitial pH. A characteristic of the ventilatory response is an increase in tidal volume more so than in respiratory rate. Although occurring within minutes to hours, the maximum ventilatory response to metabolic acidosis may take 12 to 24 hours and probably reflects slow movement of hydrogen ions across the relatively impermeable blood-brain barrier. The ventilatory protective effect lasts only several days,

probably because PCO_2 lowers renal bicarbonate reabsorption and results in an appropriate bicarbonate loss. Secondary hyperventilation is a physiologic response to an initial aberration in homeostasis and should be proportional to the initial decrease in serum bicarbonate level. Mathematically, the appropriate PCO_2 response is determined by the following equation:

$$\text{PCO}_2 = 1.5(\text{HCO}_3^-) + 8$$

which defines a predictable relationship between PCO_2 and bicarbonate for any degree of metabolic acidosis. Any PCO_2 responses outside the predicted range would imply the presence of a secondary primary disturbance—that is, a mixed acid–base disturbance. For example, in severe metabolic acidosis, the serum bicarbonate of 10 mEq/L would have an expected PCO_2 response of approximately 23 mm Hg; a PCO_2 greater than this would suggest concomitant respiratory acidosis along with metabolic acidosis. Conversely, if PCO_2 were less than 23 mm Hg, respiratory alkalosis with concomitant metabolic acidosis would occur. Metabolic acidosis is described as either high or normal anion-gap acidosis. The anion gap equals the serum sodium level minus the sum of the serum chloride and serum bicarbonate levels, and it represents other unmeasured anions not accounted for by chloride and bicarbonate, such as plasma proteins and albumin, needed to maintain electric neutrality. The normal anion gap is 12 ± 2 (range, 8 to 16 mEq/L). If serum albumin is less than 4 g/dL, a corrective addition of 3 for each gram of albumin below 4 must be added.

Elevated Anion-Gap Metabolic Acidosis

Metabolic acidosis with a high anion gap results from an accumulation of organic and inorganic acids and a subsequent decrease in extracellular bicarbonate level. Common causes of metabolic acidosis are listed in Box 6-1. Patients with elevated anion-gap acidosis frequently have multiple severe electrolyte disorders, a greater frequency of admission to intensive care units, and a greater

mortality rate compared with those with a normal anion gap. Most often, elevated anion-gap acidosis is accompanied by identifiable increases in organic acids levels (e.g., as in salicylate, ethylene glycol, and methanol ingestions and in lactic acidosis). Severe salicylate ingestions are associated with anion gaps in the range of 15 to 20 mEq/L, whereas ethylene glycol and methanol ingestions and lactic acidosis are associated with anion gaps greater than 30 mEq/L. Although an anion gap is most commonly associated with metabolic acidosis, it also may be present in metabolic alkalosis. This can be explained on the basis of coexisting elevated anion-gap acidosis and metabolic alkalosis (the mixed metabolic disorder), an alkalemia-induced increase in lactic acid production, or an increase in the negative charges on plasma proteins. Other causes are dehydration, therapy with sodium salts, strong acids, and certain antibiotics. Occasionally, organic acidosis (e.g., ketoacidosis) may be associated with a normal anion-gap metabolic acidosis if the organic acid excretion in catabolism equals the rate of organic acid production. Because excess organic acids are buffered milliequivalent for milliequivalent by extracellular bicarbonate, any elevation in anion gap is accompanied by a proportional decrease in serum bicarbonate level. Therefore, examination of both the decrease in serum bicarbonate level and the increase in the anion gap may suggest a mixed metabolic disorder. For instance, if the decrease in serum bicarbonate concentration is greater than the increment in the anion gap, another mechanism other than the elevated anion-gap acidosis is causing a decrease in serum bicarbonate (e.g., hyperchloremic metabolic acidosis), which therefore constitutes the mixed elevated-normal anion-gap acidosis. On the other hand, an increase in the anion gap exceeding the decrement in serum bicarbonate level suggests that another mechanism is responsible for an increase in serum bicarbonate level (i.e., metabolic alkalosis), which now constitutes a mixed elevated anion-gap metabolic acidosis/metabolic alkalosis. In lactic acidosis, the ratio of change in the anion gap to the change in serum bicarbonate is approximately 1.6 to 1.24, owing to buffering of much of the acidosis in the intracellular space.

The osmolal gap also may be helpful in establishing the diagnosis of an elevated anion-gap acidosis. The osmolal gap is the difference between the measured and the calculated plasma osmolality and is given by the following formula:

$$\text{Serum osmolality} = 1.8 \times \text{Na}^+ + \text{blood glucose (mg/dL)} / 18 + \text{BUN (mg/dL)} / 2.8$$

If the measured osmolality exceeds the calculated osmolality by 10 mOsm/kg or greater, then other osmotically active substances such as ethanol, methanol, ethylene glycol, isopropanol, and mannitol are present (see Chapters 1 and 32 for further discussion of the osmolal gap).

RENAL FAILURE

Acute renal failure and chronic renal failure are common causes of elevated anion-gap acidosis. The metabolic acidosis of renal failure is the result of the

inability to excrete the acid load. The anions contributing to the elevated anion gap are predominantly sulfate, phosphate, and other unmeasured ions. In chronic renal failure, the anion gap usually is normal until the glomerular filtration rate decreases to below 30 mL/min and is accompanied by an anion-gap increase to 17 to 23 mEq/L. Drug-induced causes of acute renal failure are discussed in Chapter 12.

LACTIC ACIDOSIS

Conversion of lactic acid back to pyruvate and in turn to glucose (via the Cori cycle) or to carbon dioxide (via the Krebs cycle) is the metabolic fate of lactic acid. However, conversion of lactic acid to pyruvate would release extracellular bicarbonate initially consumed during the generation of lactic acidosis. The normal serum lactic acid level is 1 mEq/L (range, 0.5 to 1.5 mEq/L). In most cases of lactic acidosis, there are components of increased production and decreased catabolism of lactic acid. It results most often from anaerobic metabolism whereby the cellular delivery of oxygen or its utilization is impaired, and anaerobic glycolysis with production of lactic acid results. Lactic acidosis is a common feature of severely poisoned patients and may be seen alone or superimposed on other forms of acidosis, such as alcoholic ketoacidosis, methanol intoxication, and salicylate poisoning. Lactic acidosis is associated with a profound illness that includes weakness, anorexia, impaired mentation, hypotension, tachycardia, and hyperventilation. Blood lactate levels are uniformly elevated, and the higher they are, the worse the prognosis. In the absence of renal failure, lactic acidosis is accompanied by a phosphate-to-creatinine ratio in blood greater than 3 and may be associated with hyperuricemia because lactate and urate compete for the same secretory pathways in the renal tubule. As mentioned earlier, potassium shifts from intracellular to extracellular compartments do not occur, and any associated hyperkalemia is due to another cause. Drug-induced causes of lactic acidosis are shown in Table 6-1 along with the proposed mechanisms responsible for the lactic acid production.

In the treatment of lactic acidosis, attention should be directed toward the underlying cause. In addition, cardiovascular function and ventilation must be improved, and hypovolemia and hypoxemia corrected. Although intravenous sodium bicarbonate has been standard therapy, its use in the treatment of lactic acidosis is controversial. Dichloroacetate, which stimulates pyruvate dehydrogenase, the catalyst for oxidation of lactate to pyruvate, may be helpful in its treatment, particularly if volume overload or renal failure is present.

KETOACIDOSIS

Alcohol ketoacidosis is a common clinical entity and must be considered in the differential diagnosis of elevated anion-gap metabolic acidosis in the alcoholic. Depleted glycogen storage, poor caloric intake, and the direct effect of alcohol in suppressing gluconeogenesis can lead to hypoglycemia. Hypoglycemia along with volume depletion suppresses insulin release and stimulates the release of glucagon, which predisposes to ketosis. In

TABLE 6-1 Drug or Chemical Causes of Lactic Acidosis

DRUG OR CHEMICAL	MECHANISM
Acetaminophen	Acute liver failure
Biguanides	Decreased utilization and increased production of lactate
Carbon monoxide	Tissue hypoxia
Cocaine	Seizures, vasoconstriction
Cyanide	Anaerobic metabolism
Ethanol	Acetate-induced increase in NADH/NAD, inhibition or conversion of lactate to glucose, thiamine deficiency, liver disease, seizures
Ethylene glycol	Seizures, acute renal failure, ethanol, cardiovascular collapse
Isoniazid	Seizures
Methanol	Acidemia, decreased lactate utilization, formic acid, hypotension
Salicylates	Uncoupled oxidative phosphorylation
Papaverine, nalidixic acid, iron, streptozotocin, strychnine, chloramphenicol, sorbitol, xylitol	Unknown

addition, alcohol can stimulate lipolysis to produce acetaldehyde and, ultimately, acetate, which allows for increased keto production. Alcohol increases the NADH/NAD ratio in its metabolism; this, in turn, favors the conversion of acetoacetate to β -hydroxybutyrate, and an increase in the β -hydroxybutyrate-to-acetoacetate ratio is a characteristic feature of alcoholic ketoacidosis. Lactic acidosis also may accompany the ketoacidosis as a result of hypotension, sepsis, or gastrointestinal bleeding or as a consequence of ethanol intoxication. Blood glucose level usually is normal; however, if it is in the hyperglycemic range, it suggests the presence of diabetes mellitus. The treatment is volume resuscitation, and this treatment usually effects reversal of ketosis within hours. Any accompanying electrolyte abnormalities should be corrected; also, the administration of bicarbonate is required, as is the use of insulin.

SALICYLATE INTOXICATION

The metabolic acid–base disturbance characteristic of salicylate intoxication typically is a primary mild to moderate metabolic acidosis accompanied by a primary (not compensatory) respiratory alkalosis, the result of the drug's potent respiratory stimulant action. These findings are invariable in severe aspirin toxicity unless the victim has ingested an agent that depresses respiratory drive. The origin of the acidosis is multifactorial but includes uncoupling of oxidative metabolism and salicylate stimulation of organic acid (lactic acid and ketoacid) production. Ketone products may be found in 25% of cases and may contribute to false elevations in serum creatinine.

The importance of recognizing the complex acid–base disturbances of salicylate intoxication cannot be overemphasized. Salicylate overdose is prominent among the agents and conditions that produce a mixed metabolic acidosis and respiratory alkalosis. In patients with a PCO_2 less than 30 to 35 mm Hg and/or a serum bicarbonate level of 18 mEq/L or less, a serum salicylate level should be obtained if these abnormal findings are unexplained. Salicylates are discussed further in Chapter 48.

METHANOL

Methanol intoxication is accompanied by the production of formaldehyde and formic acid; production of the latter leads to a profoundly elevated anion gap, which usually develops 12 to 24 hours after ingestion. Although controversial, formic acid seems to be the earliest cause of anion-gap elevation, although lactic and other organic acids may contribute to this disturbance. Additionally, multiple-organ failure results in decreased hepatic lactate utilization. In untreated patients, as methanol is metabolized, an early osmolal gap and normal or slightly elevated anion gap is followed by a decrease in the osmolal gap with an increase in the anion gap. Treatment includes correction of the profound acidemia with bicarbonate administration, use of fomepizole or ethanol to inhibit the metabolism of methanol, and hemodialysis to correct the profound acidemia and remove the toxic compounds. Methanol is further discussed in Chapter 32.

ETHYLENE GLYCOL

Ethylene glycol intoxication leads to serious, life-threatening anion-gap acidosis. The decrease in serum bicarbonate level is due to buffering of excess glycolic acid, which contributes primarily to the elevation of the anion gap. However, increases in lactic acid and β -hydroxybutyrate also occur with ethylene glycol intoxication, adding to the metabolic acidosis. Lactic acidosis usually occurs in the later stages of ethylene glycol intoxication; its etiology is not completely understood. Hyperchloremic metabolic acidosis may occur also from accompanying proximal renal tubular dysfunction. As with methanol, ethylene glycol is associated with an increased osmolal gap; also like methanol, the metabolism of ethylene glycol produces a reciprocal change in the osmolal and anion gaps. Treatment includes aggressive correction of metabolic acidosis and administration of fomepizole or ethanol. Hemodialysis removes ethylene glycol and its breakdown products in addition to correcting the acidosis. Ethylene glycol is further discussed in Chapter 32B.

PARALDEHYDE

Paraldehyde is a pungent, colorless liquid used primarily for the treatment of seizures; it has been supplanted by safer and more effective agents and rarely is used today. Paraldehyde is metabolized predominantly to acetaldehyde and acetic acid and ultimately to carbon dioxide and water. The drug produces an elevated anion-gap metabolic acidosis by ill-defined mechanisms, possibly by increasing the NADH/NAD ratio, which favors the conversion of acetoacetate to β -hydroxybutyrate.

TOLUENE

Toluene is metabolized to benzoic acid and hippuric acid, which accumulate to yield an elevated anion-gap metabolic acidosis accompanied by hepatic and renal failure. Long-term toluene exposure can lead to type I distal tubular acidosis and type II proximal tubular acidosis associated with Fanconi's syndrome with a normal anion gap.

MISCELLANEOUS CAUSES OF ELEVATED ANION-GAP METABOLIC ACIDOSIS

The miscellaneous causes of elevated anion-gap metabolic acidosis include ingestion of formaldehyde, ibuprofen, cocaine, theophylline, phencyclidine, cyanide, or iron.

Historically, the commonly used mnemonic for metabolic acidosis has been MUDPILES (methanol, uremia, diabetic ketoacidosis, phenformin or paraldehyde, lactate, ethanol or ethylene glycol, and salicylates). However, this mnemonic has four shortcomings: not all of its elements are toxic agents; the toxins phenformin and paraldehyde rarely are used clinically, if at all; newer agents are associated with metabolic acidosis (e.g., metformin); and common and important agents (e.g., cyanide and ibuprofen) are not included. The mnemonic therefore no longer has great clinical value.

METABOLIC ACIDOSIS WITH A NORMAL ANION GAP (HYPERCHLOREMIC METABOLIC ACIDOSIS)

Metabolic acidosis with normal anion gap results from a loss of fluid with a bicarbonate concentration greater than chloride concentration, the addition of acids with chloride as their associated anion, or the transient dilution of extracellular bicarbonate with nonbicarbonate solutions. To maintain electroneutrality, the decrease in serum bicarbonate is associated with a proportionate increase in the serum chloride level. For example, in diarrhea, bicarbonate loss is greater than chloride loss; thus, hyperchloremia develops. Accompanying this is extracellular volume contraction, which stimulates renal retention of sodium with chloride, rather than of bicarbonate, because of the increased availability of chloride. This, in turn, leads to the development of hyperchloremic metabolic acidosis. Normal anion-gap metabolic acidosis can be divided into hypochloremic and hyperchloremic forms. Box 6-2 lists the causes of normal anion-gap metabolic acidosis.

In the context of poisoning, diarrhea may occur after ingestion of many agents, including colchicine, arsenic, antibiotics, and iron. Drug-induced renal tubular acidosis (Box 6-3) may be seen with the use of amphotericin, lithium, toluene, vitamin D, and analgesics (all of which produce type I renal tubular acidosis). In contrast, type II renal tubular acidosis may be caused by tetracycline, carbonic anhydrase inhibitors, cadmium, mercury, lead, uranium, toluene, and 6-mercaptopurine. Type II renal tubular acidosis usually is accompanied by a greater than 15% fractional excretion of bicarbonate, along with aminoaciduria, phosphaturia, glycosuria, and uricosuria (Fanconi's syndrome). Type IV renal tubular acidosis may be induced by tubular interstitial disease caused by ingestion of spironolactone, triamterene, lithium, nonsteroidal anti-inflammatory drugs (NSAIDs),

- Triamterene

angiotensin-converting enzyme inhibitors, and cyclosporine. A normal anion-gap metabolic acidosis also may be seen in ingestions of elemental sulfur and of the sulfur-containing amino acids, methionine, cystine, and cysteine. Similarly, chlorine gas inhalation and intoxication with hydrochloric acid, ammonium chloride, lysine hydrochloride, arginine hydrochloride, calcium chloride, and magnesium chloride—all of which contribute to generation of chloride ions—lead to normal anion-gap acidosis.

Clinical Features, Consequences, and Treatment of Metabolic Acidosis

Acidemia and metabolic acidosis produce several cardiovascular effects. Acidemia directly impairs myocardial contractility, although it also possesses some positive inotropic action, the secondary result of catecholamine release. As pH decreases to less than 7.2, negative inotropic effects predominate and heart rate increases; as pH decreases to less than 7.1, the heart rate also may fall. Acidemia also predisposes to life-threatening ventricular arrhythmias and to arterial vasodilation and venoconstriction, both of which increase central blood volume. In combination with its negative inotropic effects, acidemia can lead to pulmonary edema. The hemodynamic consequences of acidemia lead to a vicious cycle of decreased myocardial contractility that produces tissue hypoxia and lactic acidosis, which in turn increase acidemia, further impairing myocardial contractility. All of these factors produce shock.

Acidemia induces an increase in both respiratory rate and tidal volume. Because of the Bohr effect, acidemia produces a rightward shift of the oxyhemoglobin dissociation curve. In the CNS, acidemia induces a spectrum of altered consciousness—from confusion to coma—probably as a result of changes in cerebrospinal fluid pH and, in the case of respiratory acidosis, a direct CNS depressant effect of carbon dioxide (CO_2 narcosis). Respiratory acidosis tends to have a greater effect than metabolic acidosis on mental status.

Gastrointestinal effects of acidosis include abdominal pain, nausea, and vomiting, particularly in the setting of ketoacidosis. Changes in serum potassium levels depend on the form of the acidosis (metabolic or respiratory) and the specific types of metabolic acidosis (mineral or organic), as well as other factors, including changes in serum osmolality and changes in plasma insulin, aldosterone, and catecholamine levels. Acidemia mobilizes skeletal calcium, leading to an increase in ionized calcium concentration.

The principal treatment is directed at the underlying cause of the metabolic acidosis. Factors to be considered are not only the etiology but also the magnitude of the metabolic acidosis and the rate at which it develops. The management of rapidly developing severe metabolic acidosis secondary to ethylene glycol poisoning with cardiovascular collapse is far more important than the treatment of a patient with a mildly elevated anion-gap metabolic acidosis after a seizure.

Controversy surrounds the use of sodium bicarbonate in the treatment of metabolic acidosis. Proponents recommend the use of bicarbonate sufficient to maintain a blood pH greater than 7.20 because a systemic pH less than 7.20 is associated with adverse hemodynamic effects, including reduced cardiac output, arterial vasodilation, and arrhythmias. Conversely, critics argue that bicarbonate is not helpful and might be detrimental because, in models of lactic acidosis, exogenous alkali can increase lactic acid production. Therefore, it would seem prudent to use sodium bicarbonate judiciously in the treatment of metabolic acidosis, particularly if the pH is less than 7.2 and the bicarbonate level is less than 10 to 12 mEq/L. Several formulas have been suggested to express the bicarbonate deficit. They are based on body weight and volume distribution of bicarbonate. However, these formulas should be used only as guides, especially because acidemia increases the volume of distribution of bicarbonate (e.g., at a pH of 7.1, the volume of distribution of bicarbonate is approximately 80% of total body weight). Because rapid bolus administration of bicarbonate is dangerous, large amounts should be infused slowly over 30 to 60 minutes. “Overshoot alkalosis” may be seen in lactic acidosis and in ketoacidosis when the lactic acid and keto acids are oxidized to bicarbonate under severe reductive conditions in response to exogenous bicarbonate. Bicarbonate administration also may cause hypokalemia and hypocalcemia, which present their own risks. Similarly, volume and sodium overload from sodium bicarbonate may be seen; when the presence of volume overload precludes the use of sodium bicarbonate, hemodialysis should be considered.

METABOLIC ALKALOSIS

Metabolic alkalosis is defined as an increase in the serum bicarbonate level to greater than 28 mEq/L. Usually, but not always, this is accompanied by an increase in pH to greater than 7.40. Metabolic alkalosis is quite common in hospitalized patients and is associated with significant morbidity and mortality. It develops from a net gain of extracellular bicarbonate or of one of its precursors, a net loss of hydrogen ions from the extracellular space, or a loss of fluid containing more chloride than bicarbonate from the extracellular space. Metabolic alkalosis is maintained by a decrease in the glomerular filtration rate, a decrease in the real or effective extracellular volume, hypokalemia, hypochloremia, and hypercapnia, and an increase in mineralocorticoid effects. The initial increase in serum bicarbonate level produces alkalemia, which initiates secondary mechanisms to prevent drastic changes in pH. These include extracellular and intracellular buffering, increased renal excretion of excess alkali, and a respiratory compensatory response. The initial increase in pH depresses central and peripheral chemoreceptors and leads to hypoventilation and hypercapnia, which minimize the initial increase in pH. However, the respiratory response is not as predictable as

it is in metabolic acidosis and is limited by the development of hypoxemia, which occurs as a result of hypoventilation. Any decrease in PO_2 to below 70 to 80 mm Hg stimulates ventilation, which counterbalances the effects of metabolic alkalosis—hence, the respiratory response to metabolic alkalosis is more variable. Rarely does PCO_2 increase to greater than 55 to 60 mm Hg as a response to simple metabolic alkalosis. Hypoxemia is a result of hypoventilation and, therefore, the alveolar–arterial oxygen gradient is normal. PCO_2 increases by 0.5 to 0.7 mm Hg for each milliequivalent per liter increase in serum bicarbonate level. A PCO_2 that is less than predicted suggests the presence of respiratory alkalosis along with metabolic alkalosis, whereas a PCO_2 that is greater than predicted suggests respiratory acidosis along with the metabolic alkalosis.

Causes of Metabolic Alkalosis

Metabolic alkalosis is divided into three categories: sodium chloride–responsive metabolic alkalosis, sodium chloride–resistant metabolic alkalosis, and miscellaneous. In sodium chloride–responsive metabolic alkalosis, there is a decrease in real or effective extracellular volume and hypochloremia accompanied by avid renal reabsorption of sodium chloride and a urine chloride concentration of less than 10 mEq/L (although, in diuretic-induced metabolic alkalosis, urine chloride level may be greater than 10 mEq/L) due to an increase in mineralocorticoid activity. Characteristically, there is an increase in the distal reabsorption of sodium and an increase in potassium and hydrogen ion excretion with urinary chloride levels greater than 20 mEq/L. Hypovolemia is not responsible, and administration of sodium chloride does not correct the alkalosis; rather, treatment is directed at inhibiting excess mineralocorticoid activity. Box 6-4 summarizes the causes of metabolic alkalosis that do not fall into the categories already discussed.

Metabolic Alkalosis in Poisoning and Drug Overdose

Metabolic alkalosis is a fairly uncommon acid–base disorder in the poisoned patient, but it may occur in those with eating disorders, diuretic abusers, and those with drug-induced Bartter’s syndrome. The latter may be caused by administration of aminoglycosides. Chewing tobacco and imported licorice that contains glycyrrhizic acid have potent mineralocorticoid activity; use of these products leads to metabolic alkalosis. Ingestion of excess bicarbonate may lead to metabolic alkalosis only if the kidney is unable to excrete the excess alkali or if renal failure is present. Overshoot alkalosis may occur in response to the correction of organic acidosis by excess bicarbonate.

Clinical Features of Metabolic Alkalosis

The features of metabolic alkalosis are in large part related to the specific cause; however, alkalemia per se

BOX 6-4

CAUSES OF METABOLIC ALKALOSIS

- Poststarvation refeeding

may produce neuromuscular irritability along with seizures, tetany, delirium, and hyperreflexia. Oxygen delivery to tissues is reduced because metabolic alkalosis shifts the oxyhemoglobin dissociation curve to the left. Concomitant with the alkalosis, there may be hypokalemia, hypocalcemia, decreased ionized calcium, hypomagnesemia, hypophosphatemia, and hypoxemia, which can further complicate the clinical picture.

Treatment

The primary treatment of metabolic alkalosis is to identify and manage the underlying cause. Sodium chloride is administered for sodium chloride–responsive metabolic alkalosis, and volume expansion will correct it. Sodium-resistant metabolic acidosis may respond to measures to increase the glomerular filtration rate and to correction of mineralocorticoid activity. In patients with metabolic alkalosis who are volume overloaded, such as in those with congestive heart failure, acetazolamide—a carbonic anhydrase inhibitor—may be helpful and can lead to increased renal bicarbonate excretion. In the patient undergoing continuous nasogastric suction or with protracted vomiting, the histamine-2 blockers reduce hydrochloric acid secretion and can be used as therapy. In the patient with renal failure who has significant

metabolic alkalosis, dialysate with a low bicarbonate or low acetate concentration and a low chloride concentration may be used in correcting the metabolic alkalosis.

RESPIRATORY ACIDOSIS

Respiratory acidosis generally is defined as an increase in the PCO_2 to greater than 44 mm Hg. The increase in PCO_2 and subsequent acidemia initiate changes aimed at preventing drastic changes in pH. Intracellular buffering via red cell hemoglobin, phosphate, and protein exchange intracellular sodium and potassium for the excess extracellular hydrogen ions. CO_2 retention, also known as hypercapnia, leads to increased renal hydrogen ion secretion and net acid excretion, as well as to increased bicarbonate reabsorption. Although beginning early, the maximum effect of these actions takes several days. For each 10 mm Hg increase in PCO_2 , serum bicarbonate level increases by 1 to 2 mEq/L; in chronic respiratory acidosis, for every 10 mm Hg in PCO_2 , the bicarbonate level increases 3 to 4 mEq/L. Any changes in PCO_2 or serum bicarbonate concentration outside those predicted indicate coexisting metabolic alkalosis as well as respiratory acidosis; likewise, bicarbonate levels less than those predicted imply the existence of metabolic acidosis as well as respiratory acidosis. Respiratory acidosis usually is the result of impaired ventilation secondary to CNS depression. It is one of the most common acid–base disturbances in the poisoned patient and may result from the drugs listed in Box 6-5.

Features and Treatment of Respiratory Acidosis

Altered states of consciousness are common in respiratory acidosis, as are abnormal ventilatory patterns, tachycardia, arrhythmias, diaphoresis, visual disturbances, headache, delirium, and coma. Many of the CNS effects are related to increased cerebral blood flow secondary to hypercapnia and subsequently increased cerebrospinal fluid pressure. The acidemia itself can have significant adverse hemodynamic effects. Treatment of the condition, therefore, is directed at improving ventilation.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is defined as an acid–base disturbance characterized by a PCO_2 less than 36 mm Hg; the secondary changes it produces are brought about to prevent drastic changes in pH. Intracellular hydrogen ions are exchanged for sodium and potassium to neutralize the excess bicarbonate and, thus, minimize the increased PCO_2 . The kidney decreases net acid excretion and bicarbonate reabsorption and, thus, tends to return pH toward normal. Although this process begins early, maximal response does not occur for several days. Serum bicarbonate level decreases by 1 to 3 mEq/L for each 10 mm Hg decrease in PCO_2 , whereas

in chronic respiratory alkalosis, bicarbonate level decreases by 3 to 5 mEq/L for every 10 mm Hg decrease in PCO_2 . Values outside this prediction indicate a metabolic alkalosis as well as respiratory alkalosis (when serum bicarbonate level is greater than predicted) and metabolic acidosis as well as respiratory alkalosis (when the serum bicarbonate is less than predicted). Rarely does serum bicarbonate decrease to less than 14 to 16 mEq/L in compensation. Respiratory alkalosis is the most common acid–base disorder encountered in intensive care, and the greater the degree of hypocapnia and alkalemia, the worse the prognosis. Box 6-6 lists the causes of respiratory alkalosis, of which salicylate ingestion is the most common.

Features and Treatment of Respiratory Alkalosis

The main features are related to neuromuscular irritability, with certain oral and digital paresthesias, carpopedal spasm, tetany, seizures, and altered consciousness. Significant hypocapnia leads to a decrease in

cerebral blood flow and is linked to the CNS manifestations. The small increase in anion gap may be observed secondary to an increase in lactic acid production due to an increase in tissue anaerobic glycolysis brought on by alkalemia. Treatment is directed at the primary disorder; raising the PCO_2 by administering enriched inhaled carbon dioxide or by a rebreathing mask, or simply by having the patient breathe into a bag, may hasten the recovery from this disorder.

MIXED ACID–BASE DISORDERS

Drug intoxication may result in mixed acid–base disorders (i.e., the presence of two or more primary acid–base disorders). These are common in the overdose situation, either as a result of the primary ingested or as a result of the therapeutic interventions used to correct the poisoning.

REGULATION OF BODY FLUID VOLUMES AND TONICITY

The body fluid, or *whole body water*, in an average 70-kg man consists of about 42 L of water. The fluid is divided into two distinct subgroups: the intracellular fluid and the extracellular fluid (Fig. 6-1).

Except for bone, tissues that do not contain fat (the lean body mass) are 60% to 85% water; muscle and the gray matter of brain are the “wettest” tissues of the body, being 70% to 85% water. Connective tissue and erythrocytes are the driest nonadipose tissues (60%

FIGURE 6-1 Distribution of whole body water in a 70-kg human adult. Men = 42 L; women = 35 L. Most values shown are for men.

water). Fatty tissue, in contrast, is 20% water; therefore, an obese person contains proportionately less water by weight than does a thin person. In obese individuals, whole body water decreases to closer to 40%. In general, women possess more fat than men; consequently, the water content of women is relatively less than that of men.

The water content of the body is relatively high in infancy, decreases to adult levels by late childhood, and thereafter decreases slowly but progressively with age. The gender difference in body water content develops at puberty and continues throughout life.

Intracellular water constitutes some 55% to 60% of whole body water. Excluding the relatively inaccessible bone water, total extracellular fluid water (plasma, as well as interstitial and transcellular water) makes up the difference. For an average man, total extracellular fluid water is 15 L (or approximately 20% to 25% of the body weight). The extravascular or interstitial fluid space accounts for 12 L of the extracellular fluid, whereas 3 L are present as plasma within the circulation. In an average young man, total blood volume is 6% to 8% of body weight (70 mL/kg); this gives absolute values for blood and plasma volumes of 5 L and 3 L, respectively.

Intracellular and extracellular fluid compartments are separated by cell membranes that selectively control passage of ions and nutrients but are freely permeable to water; although ionic gradients may exist across cell membranes, movement of water establishes an osmotic equilibrium, and any osmotic gradients are corrected rapidly.

INTRACELLULAR FLUID COMPOSITION

The ionic composition of body fluids can be discussed in terms of chemical equivalents. Concentrations of all ionic constituents are expressed as the sum of con-

centrations of the positive ions (cations) and negative ions (anions). Ionic balance is obligatory in order to maintain the electrical neutrality of the body fluids. The principal cations in extracellular fluid are sodium, potassium, calcium, and magnesium, whereas the principal cations in intracellular fluid are potassium and magnesium. Conversely, the principal anions in extracellular fluid are chloride and bicarbonate, whereas the principal anions in intracellular fluid are phosphate, sulfate, and proteins.

Electrical neutrality is maintained in all body fluids by a balance of cations and anions; however, in clinical practice, usually only plasma or serum sodium, potassium, chloride, and bicarbonate are measured, and it is assumed that levels of the rest of the cations and anions are balanced.

The high intracellular–low extracellular concentration of potassium and the reverse for sodium favor the movement of potassium out of and that of sodium into cells. Such ionic gradients are maintained by the presence of sodium-potassium pumps in the cell membrane and are critical in protecting cell volume. High concentrations of osmotically active anionic protein within cells, relative to the interstitial fluid, establish a Donnan equilibrium that increases the osmotic activity within the cell. Any movement of water into cells is prevented by the act of extrusion of sodium, whereas interference with the potassium-sodium pump mechanism results in cellular accumulation of sodium and chloride, with loss of potassium and resultant cellular edema.

Transcellular fluids are predominantly products of cell secretion. The composition of the fluids varies according to their cellular origin. Under physiologic conditions, secreted fluids tend to be recirculated or reabsorbed, but under pathologic (or treatment) conditions, failure to reabsorb continuously secreted fluids may lead to significant losses of volume and electrolytes, as seen with diarrhea, vomiting, and nasogastric suction. Drainage of intestinal fluids may result in considerable losses of chloride and bicarbonate (e.g., in the presence of small intestinal fistulae or with extreme diarrhea, such as that seen in cholera). Similarly, drainage of gastric and salivary juices may result in loss of considerable quantities of hydrogen ions as well as chloride. Diarrhea produced by cholera also results in massive sodium and water loss, which produces not only hypovolemia but also hyponatremia. *Third space fluid loss* refers to sequestration of fluids within cavities (e.g., pleural, pericardial, and intraperitoneal).

MOVEMENT OF WATER BETWEEN INTRACELLULAR AND EXTRACELLULAR FLUID SPACES: OSMOLARITY AND OSMOLALITY

Water moves freely across cell membranes, and an osmotic disequilibrium cannot be sustained. Thus, distribution of total body water depends on the number of active particles in the intracellular and extracellular

spaces. The osmotically driven “shifts” of body water adjust intracellular and extracellular osmolality to maintain osmotic neutrality. One osmole is the mass of a solute (or mixture of a solute) that, when dissolved in 1 L, gives a solution that has an osmotic pressure of 22.4 atm at 0°C. Osmolar concentrations generally are determined indirectly by measuring changes of the physical function of solutions, such as depression of the freezing point below that of water. Osmolality determined in this fashion (or osmoles per 100 g of plasma water) is obtained. The term *osmolality* is preferred to the commonly misused term *osmolarity* (osmoles per liter of whole plasma) and is more appropriate in considering physiologic relationships.

In practice, plasma osmolality mainly reflects plasma sodium concentration, and it must be remembered that water added to or removed from any fluid compartment behaves as though it were added to or removed from whole body water. Second, sodium added to or removed from extracellular fluid alters sodium concentration, as though it had been added to or removed from whole body water. Third, sodium concentration in plasma does not necessarily reflect changes in extracellular fluid volume because hyponatremia may exist with low, normal, or increased extracellular fluid. The same remarks apply to hyponatremia or normal serum sodium concentrations. Fourth, changes in the volume of intracellular fluid and extracellular fluid usually are proportional (and in the same direction) with a gain or loss of water, with intracellular and extracellular fluid volumes changing in opposite directions with gains or losses of restricted solutes, such as sodium and potassium. Other important solutes that contribute to plasma osmolality are glucose and blood urea nitrogen.

CELLULAR RESPONSES TO REDISTRIBUTION OF FLUID

Changes in extracellular osmolality can bring about major swelling or contraction of cells, but the primary effects are seen in the brain. Hyponatremia induced in animals causes brain swelling initially, with diminishing changes occurring within several hours. Correction of brain swelling is complete usually at 24 hours, with the brain responding to extracellular hypotonicity by losing potassium and chloride. In experimental models of hyponatremia, brain water is initially lost, with gains of sodium, potassium, and chloride soon achieved by brain cells. Between 4 hours and several days, brain water content returns to normal, and an increased osmotic activity is sustained through the generation and accumulation of organic solutes such as amino acids. Hypoglycemia also can cause an acute loss of brain water, with a return to normal levels within a few hours, principally because of changes in the concentration of ions and organic solutes. Similarly, mannitol removes water from the brain but does not result in the generation of new intracellular organic molecules (idiogenic osmoles). For this reason, mannitol is not associated with effective adaptive changes in the regulation of intracellular

volume of the brain, and, consequently, brain volume decreases.

REGULATION OF BODY FLUID VOLUMES AND DAILY FLUID BALANCE

Because sodium is the dominant cation of extracellular fluid, it is the critical determinant of extracellular fluid volume by virtue of its osmotic activity, and by virtue of its effect on renal sodium chloride reabsorption. It is the major determinant of renal water reabsorption. It is through the reabsorption of sodium and water that the kidney regulates extracellular fluid volume. The reabsorption of sodium by the kidney is an intensely and finely regulated process for the conservation of sodium and water, and also for its secondary effects on hydrogen ion excretion through bicarbonate reabsorption; it is also linked to potassium secretion. A detailed discussion of sodium reabsorption by the kidney is beyond the scope of this text, but two major mechanisms in sodium homeostasis are worth discussing in relationship to the diagnosis and management of poisoned patients.

Sodium is freely filtered at the glomerulus and is reabsorbed isotonicly at the proximal convoluted tubule, with 60% to 70% of filtered sodium being proximally reabsorbed. Consequently, the glomerular filtrate volume is reduced by 60% to 70% in the proximal tubule; this provides substantial control of fluid balance. In the descending limb of the loop of Henle, the tubule is less permeable to sodium and urea but more permeable to water; consequently, the glomerular filtrate passing through the loop of Henle increases in sodium concentration, with consequent increases in osmolality. The thin ascending limb of the loop of Henle is permeable to sodium and urea but relatively impermeable to water, whereas in the thick ascending limb of the loop of Henle there is active transport of chloride, which also facilitates sodium reabsorption. Subsequently, the ascending limb of the loop of Henle accounts for 20% to 25% of sodium reabsorption. In the distal nephron (the distal convoluted tubule and collecting duct), 5% to 10% of sodium is reabsorbed, facilitating potassium secretion, and is in part responsive to aldosterone.

Because the renal excretion of sodium is variable and, under physiologic conditions, equal to sodium intake, the kidney must vary its excretion of sodium in the wide range encountered in humans (i.e., one to several hundred milliequivalents every 24 hours). It follows that regulatory mechanisms closely govern sodium excretion. These mechanisms include: glomerular filtration; physical factors, such as postglomerular protein oncotic pressure; aldosterone; antidiuretic hormone; and atrial natriuretic peptide. These substances all are coordinated to maintain the balance of extracellular fluid volume. It is well known that infusion of saline increases glomerular filtration rate and reduces renin excretion, thereby reducing aldosterone secretion; such actions promote natriuresis, increasing urinary sodium excretion. The reverse occurs when volume contraction is present with

sodium being retained by the kidney. Compensatory mechanisms, principally mediated by antidiuretic hormone secretion, are initiated to conserve water, whereas a reduction in renal blood flow probably leads to conservation of sodium.

Antidiuretic hormone (ADH) is an octapeptide produced in the supraoptic and paraventricular nuclei of the hypothalamus. It is transported in the nerves from the hypothalamus in the posterior hypophysis and median eminence, where it is stored. In response to a variety of stimuli, ADH is released, altering the permeability of the distal tubule and collecting duct to water; the renal tubular cell contains receptors for ADH. A resultant increase in the water permeability of the distal tubule and collecting duct occurs, and, if there is hypertonicity of the medullary interstitium (brought about by the countercurrent concentration mechanism in the loop of Henle), water reabsorption occurs. The prime factor in producing ADH secretion is the plasma osmolality. A change in osmolality as small as 1% produces ADH secretion; a 1% to 2% change in osmolality initiates thirst. In contrast, a 6% change in the extracellular fluid volume is required to produce the same effect on ADH. Dehydration and hypernatremia lead to reduced renal perfusion and increased ADH secretion. The result is the excretion of small amounts of urine that are low in sodium and highly concentrated. Replacement of free water corrects the problem in patients with pure insensible water loss. In the syndrome of diabetes insipidus, water loss arises either because of a central defect in ADH production or release, or because of renal insensitivity to ADH (nephrogenic diabetes insipidus). Because of the action of ADH on the most distal sites of the nephron, it is possible for the patient to retain sodium maximally but still excrete volumes of water equal to 10% to 50% of the glomerular filtration rate. The loss of water in diabetes insipidus results in 10 to 15 L of dilute urine with a low total sodium excretion. The result is concentration of plasma and stimulation of the thirst mechanism, which leads to the ingestion of large quantities of water for replacement of water losses. Drugs known to have an effect on ADH status are shown in Box 6-7.

Detailed discussion of the factors involved in the production of hypernatremia and hyponatremia and of hyperkalemia and hypokalemia is beyond the scope of this text. However, the principal disorders associated with abnormalities of these cations in poisoned patients are shown in Table 6-2. The management of derangements of both sodium and potassium is outlined in Table 6-2.

ASSESSMENT AND MANAGEMENT OF FLUID AND ELECTROLYTE IMBALANCE

The two important clinical disturbances in fluid balance are volume overload and volume contraction. *Volume overload* is manifested by the presence of peripheral edema, ascites, and/or pulmonary edema. As a general rule, a 4% increase in whole body water is required to produce clinical signs of peripheral edema. Other signs

BOX 6-7

DRUG-INDUCED ALTERATIONS IN ANTIDIURETIC HORMONE (ADH) RELEASE AND ACTIVITY

Central Reduction in ADH Secretion

Ethanol
Phenytoin/diphenylhydantoin
Glucocorticoids
Chlorpromazine
Reserpine
Morphine*

Central Stimulation of ADH Release

Clofibrate
Chlorpropamide
Nicotine
Vincristine
Cyclophosphamide
Tolbutamide
Carbamazepine
Acetylcholine
Carbachol
Methacholine
Barbiturates
Meperidine
Prostaglandin E₁
Isoproterenol

Peripheral Reduction in ADH Activity

Lithium
Demeclocycline
Acetohexamide
Tolazamide[†]
Glyburide[†]
Propoxyphene[†]
Amphotericin
Methoxyflurane

Vinblastine
Norepinephrine

Peripheral Enhancement of ADH Activity

Chlorpropamide
Acetaminophen
Indomethacin

*Mechanism not fully elucidated; raises threshold for osmotically induced ADH secretion.

[†]Mechanism not fully elucidated; not due to reduction in ADH secretion.

of volume overload are distended neck veins and congestive heart failure, manifested by tachycardia, and a gallop on cardiac auscultation. In contrast, *volume contraction* is manifested by diminished skin turgor; dry, cracked lips; and sunken eyes. Resting or orthostatic tachycardia and hypotension also may be seen with volume contraction.

In the syndrome of inappropriate ADH (SIADH) secretion, urine sodium concentration is high, urine osmolality is high, and the blood urea nitrogen level is low; the condition is best treated with water restriction. Because of the risk of central pontine myelinolysis, serum sodium concentration in SIADH and other conditions associated with severe hyponatremia should be corrected slowly (at a rate of no more than 1 mEq/L).

In intoxicated patients, especially those with exposures producing fluid and electrolyte disturbances, body weight should be measured daily; fluid intake and output should be recorded accurately. Using these measurements, the clinician can identify significant changes in fluid and electrolyte balance.

Day-to-day management of fluid and electrolytes depends on multiple factors, including the total body deficits or excesses prior to institution of intravenous fluid therapy, the planned therapeutic interventions such as forced diuresis or hemodialysis, and the toxin. In the absence of complicating factors, one can assume the normal fluid and electrolyte requirements for a 70-kg person, which are defined as “basal” requirements, as outlined in Table 6-3.

MANAGEMENT OF RELATIVE HYPOVOLEMIA IN POISONING

In acute poisoning due to barbiturates, opioids, theophylline, tricyclic antidepressants, sedative-hypnotics, and many other drugs, an abrupt increase in the venous capacitance occurs, with a relative deficit of plasma volume. The relative hypovolemia due to increased venous capacitance also may be compounded by decreased venous return and extravascular fluid loss. These factors can result in significant hypotension. Such vasodilation often responds to augmentation of plasma volume by volume expansion. In some instances the use of vasopressor drugs may be necessary (see Chapter 2). However, improvement in central venous pressure may remain inadequate. In these circumstances a flow-directed pulmonary arterial catheter (Swan-Ganz) may be useful in assessing both central venous pressure and pulmonary capillary wedge pressure, serving as a more accurate guide to fluid replacement.

In some ingestions, aggressive volume expansion with the use of crystalloid solutions may be disadvantageous because these solutions may reduce the osmotic hydrostatic gradient, thereby increasing pulmonary capillary water. This occurrence has been implicated in the development of adult respiratory distress syndrome (“shock lung”) in severely hypotensive patients. In view of the potential adverse effects of crystalloid solutions, colloid solutions such as albumin may be preferred for the treatment of hypovolemic shock in patients who might develop pulmonary edema.

**TABLE 6-2** Principal Disorders of Sodium and Potassium in Intoxicated Patients

		DISORDER AND EXAMPLES	TREATMENT
Hypernatremia	Normal body Na ⁺	Drug-induced diabetes insipidus Sweating (salicylates, organophosphates)	Diuretics and water replacement
	High body Na ⁺	Steroids Hypertonic saline, NaCl, NaHCO ₃ Saline emetics	Water replacement
Hyponatremia	Low body Na ⁺	Osmotic diuretics (mannitol) Sweating (salicylates) Diarrhea (organophosphates, antibiotics)	Hypotonic saline
	↓ ECF volume	Diuretics (tubular and osmotic) Rhabdomyolysis Steroid deficiencies Vomiting/diarrhea/pancreatitis	Isotonic saline
	↑ ECF volume (nonedematous)	Steroid deficiency Hypothyroidism Beer-drinker's hyponatremia Drugs (see Box 6-3)	Water restriction
Hyperkalemia	↑↑ ECF volume (edematous)	Drug-induced Hepatic, renal, cardiac failure ACE inhibitors	Water restriction
	↑ True K ⁺	Acidosis Arginine hydrochloride Digitalis intoxication Geophagia K ⁺ -sparing diuretics Steroid deficiency NSAIDs Hemolysis Rhabdomyolysis Salt substitutes Penicillin β blockers Heparin	Correct Stop drug Glucose/insulin Ion exchange resins Dialysis
Hypokalemia	Without K ⁺ deficit	Respiratory alkalosis (salicylate or respirator induced)	K ⁺ replacement
	With K ⁺ deficit	Nasogastric suction, vomiting Alcoholism Inadequate K ⁺ replacement Laxative abuse Drug-induced diarrhea Excessive steroids Licorice abuse Osmotic diuretics (mannitol, glucose) Diuretics Carbenicillin/penicillin/aminoglycosides	K ⁺ replacement

ACE, angiotensin-converting enzyme; ECF, extracellular fluid.

TABLE 6-3 Daily Basal Fluid, Electrolyte, and Caloric Requirements

WATER/ELECTROLYTE REQUIREMENTS	BASAL REQUIREMENTS	METABOLIC REQUIREMENTS	CALORIC REQUIREMENTS
Water	1.5–2.0 L*	100 mL/100 cal	0–10 kg: 100 cal/kg
Sodium	75 mEq	2–3 mEq/100 cal	11–20 kg: 1000 cal plus 50 cal/kg over 10 kg
Potassium	60 mEq	2–3 mEq/100 cal	>20 kg: 1500 cal plus 20 cal/kg over 20 kg
Magnesium	8 mEq	—	
Chloride	—	4–6 mEq/100 cal	

*Insensible losses (approximately 700 mL) plus volume equivalent to urine volume.

A General Principles

JOHN HARRIS TRESTRAIL III, BSPHARM, RPH

At a Glance...

- The real science of forensic toxicology began in 1814, with the work of physician M.J.B. Orfila.
- Poisoners are nonconfrontational, and the majority of known poisoners are male.
- All things are potentially poisonous; it all depends on the dose.
- Analytical toxicology can tell you that a poison is present, but not why it is there.
- Approximately 41% of known poisoners have multiple victims.
- To prove death was due to a poison, it must have been absorbed and in systemic circulation.
- Every death with no visible signs of violence is a poisoning until facts prove otherwise.
- The Center for the Study of Criminal Poisoning is an organization that assists investigators on an international level.

While toxicology admits of being extensively applied to other medical sciences, it is in medical jurisprudence that its power and extent are most evident.

Sir Robert Christison, British toxicologist

A relatively new area for clinical toxicologists to enter, as consultants or expert witnesses, is for the use of their knowledge of poisons in the investigation of crimes in which these agents have played a role. The two major examples of this activity are in cases of product tampering, and murder by poison. It is the attempt of this chapter to review some of the principles of the forensic sciences as they apply to the area of toxicology. For brevity in these discussions, the author has used the term *he* in the description of the poisoner, but the reader can correctly substitute the term *he/she* without being in error.

WHAT IS FORENSIC TOXICOLOGY?

Forensic toxicology is that branch of the science that deals with the application of the study of poisons to the law. In this respect it overlaps into many other important forensic areas such as pathology, analytical chemistry, criminal investigation, and litigation.

However, forensic toxicology as a science is still relatively young, going back only a few hundred years, and it is certainly true today that we stand upon the shoulders of giants in this field.

HISTORICAL DEVELOPMENT OF FORENSIC TOXICOLOGY

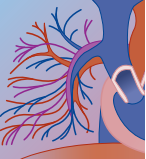

Poison is one of the oldest weapons for murder known to man. As were the stick and the stone, poisons were used long before the development of arrows, spears, and gunpowder. Even though it is an old tool for murder, writings on the subject began to appear only in the relatively recent past.

Some of the earliest writings on the subject of criminal poisoning, and its investigation, were from India. Two of these early works are the *Charaka Samhita*, and the *Susruta Samhita*, which date from around 600 to 100 BC. Another early Indian work, known as the *Veda*, provided physicians with specific directions in the detection of poisoners based on their demeanor.

The beginning of the real modern scientific investigation of toxicology, and its application to forensics, started with the work of French physician Mathieu Joseph Bonaventure Orfila (1787–1853), who was to hold the chair of Legal Medicine at the Sorbonne in Paris. With respect to forensic toxicology, Orfila was to play an important role in the famous 1840 Paris poisoning case of Marie LaFarge, by adopting the then relatively new Marsh test for arsenic.

Through his early animal experimentations, Orfila was able to determine the toxic dosages and physical effects produced by a number of poisonous compounds. His studies eventually led to the publication, in 1814, of his monumental two-volume work, *Traité des Poisons: Tirés des Règnes Minéral, Végétal et Animal; ou Toxicologie Générale [Dissertation of Poisons: Covering the Relevant Mineral, Vegetable and Animal; or General Toxicology]*. In his work, Orfila divided the then known poisons into the following six classifications: corrosives, astringents, acrids, stupefying or narcotics, narcotico-acids, and septics or petreficants. This pioneering work in toxicology has garnered him the title “Father of Forensic Toxicology.” Translations of Orfila’s popular work soon appeared in Spanish, German, and Italian. An English translation of his work first appeared in 1816, and American editions were published in 1817 and 1826. The four augmented and corrected French editions of his work were published in 1818, 1826, 1843, and 1852. Other great toxicologists studied the works of Orfila and eventually wrote their own texts on the subject of poison and its application to the law.

One of these early toxicologists was the Scottish physician Robert Christison (1797–1882), who published

his first work, *A Treatise on Poisons*, in 1829. Christison was appointed Medical Advisor to the Crown in Scotland, and from 1829 to 1866 he was the medical witness in almost every important toxicologic case in Scotland, and many in England. Further editions of his work appeared in 1832, 1836, and 1845.

Another of the British toxicologists was the physician Alfred Swaine Taylor (1806–1880), who published his work *On Poisons, in Relation to Medical Jurisprudence and Medicine* in 1848. Taylor was the leading author on the subject of medical jurisprudence in the 19th century. In his books on medical jurisprudence and poisons, which were the standard works throughout the world, he codified the legal precedents, judicial rulings, and anatomic and chemical data that bore on his special subject of study. His second British edition was published in 1859. The works of both Christison and Taylor were subsequently published in America, and became the standard references for physicians and scientists up until the beginning of the 1900s.

America did not see a book published by one of its native sons until the publication of *Microchemistry of Poisons, Including Their Physiological, Pathological, and Legal Relations: Adapted to the Use of the Medical Jurist, Physician, and General Chemist* in 1869, by physician Theodore George Wormley (1826–1897). This book was considered his highest lifetime work, as never before in America had toxicologic subjects been handled with the high degree of literary skill and with such care to detail. The steel engravings of the images of microscopic poison residues, done by Wormley's wife, remain a marvel of the steel engraver's art. His work went on to a second edition in 1885.

The first book that was dedicated totally to the criminal investigation of poisoners and their use of poison as a weapon for murder, was *Criminal Poisoning: Investigational Guide for Law Enforcement, Toxicologists, Forensic Scientists, and Attorneys*, by forensic toxicologist John Harris Trestrail III (1944–), published in 2000. In this work, the epidemiology of criminal poisoning, the characteristics and advantages of ideal poisons, pathologic aspects of poisons, techniques for investigating murder by poisons, and trial strategies for attorneys when prosecuting a case involving poisons as weapons are discussed.

For the expert consultant to be effective in the determination of the possible toxicologic consequences of exposure to a poison, he or she must be aware of both the qualitative and quantitative toxicologic information that is determined by the application of analytical toxicology to the body in question.

HISTORICAL DEVELOPMENT OF ANALYTICAL TOXICOLOGY

It is probably safe to assume that the development of the science of general toxicology closely followed along with the developments in the field of chemistry. The beginnings of analytical toxicology were not to be seen until well into the 1800s.

The individual who first made it very difficult for the poisoner to get away with his murder by utilizing the

then popular poison arsenic was Scottish chemist James Marsh (1794–1846). In 1836, Marsh developed and published a chemical test—that was to bear his name—that made it possible to detect the presence of arsenical compounds in food as well as in biologic specimens. Marsh observed that by taking a sample that contained arsenic and mixing it with zinc and sulfuric acid, the chemical reaction resulted in the production of arsine gas. The arsine gas produced by the chemical reaction, when heated, deposited a mirror of metallic arsenic on a cold surface. This test was so sensitive that it was able to detect the presence of arsenic in very minute concentrations. It now became possible to prove in court the presence of arsenical compounds, and thus the probable cause of the death of an individual. For the poisoner, the Marsh test was a definite setback. Soon after Marsh's contribution, other analytical test enhancements came into being.

Hugo Reinsch developed a test that allowed for the detection of arsenic at a level of approximately 0.00002 parts of a substance. Other analytical tests used during the first half of the 1900s included Bittendorf's test, the Gutzeit test, Hefti tests, and the Kage modification.

Over the years, with the development of more specific chemical testing and sensitive electronic instrumentation, the science of analytical toxicology has proven its invaluable role in aiding the forensic toxicologists in their work.

With the combined expertise of the forensic and analytical toxicologists, they become effective aids for the criminal investigator when dealing with a possible case of criminal poisoning.

CRIMINAL POISONING: INVESTIGATIVE ISSUES

A lack of witnesses and a crime surrounded by secrecy make the investigations of poisoning crimes very difficult. As stated by professor of forensic medicine John Glaister in his work *The Power of Poison*, "The very fact that the poisoner does not prepare his poison in the presence of the victim or before witnesses, but that the process is carried out in great secrecy, is the principal reason why the bringing home of the guilt of the criminal concerned becomes even more involved."¹

The basic tenet in investigating a possible homicidal poisoning begins with considering it in the first place. If one does not look for the possibility of a poisoning, one will never be able to find it. Basically, the poisoner does not worry about disposing of his victim, for he counts on the medical establishment to do it for him. As a murderer, the poisoner wants his victim's death to appear most natural, which will result in the issuing of a death certificate and will not raise suspicion. This lack of suspicion will eventually lead to the burial or cremation of the remains, and thus the hiding of the most important evidence of the crime: the body. The body of the victim is the major source of important clues that tell the tale of what happened.

If poison is found in the body of a victim, the first question that is raised is why the substance is there at all.

One must always remember that analytical toxicology only tells one that a poison is there; it does not answer the question of why the poison is there.

SOURCES OF POISON IN THE VICTIM

There can be many reasons why there may be a quantity of a potential poison found in an individual.

The source was accidental. Toxic levels of poisons can enter the body from such sources as the environment (e.g., arsenic in the ground water), or the exposure may have been occupational (e.g., lead from shooting ranges, automobile battery recycling, or other occupational sources).

The source was natural. Poisons can be found in the body after the consumption of certain food sources (e.g., arsenic after a large seafood meal or from the consumption of contaminated herbal remedies). High levels of a suspected poison can also be found in the body due to a medical condition (e.g., copper from Wilson's disease).

The source was self-administered. The victim might have received a toxic amount of a substance from a source that was administered by the victim himself (e.g., from misuse of a product, from substance abuse like a "hot shot," or from suicidal intent).

The source was administered by another individual. The victim might have received a toxic amount of a substance from a source that was administered by another individual (e.g., substance abuse, product tampering, or homicidal intent).

If it is determined that the source of the poison was administered by another individual with homicidal intent, then the question arises for the investigators as to who might be a suspect they should begin to investigate. What are some characteristics of the homicidal poisoner that could guide their investigation?

THE HOMICIDAL POISONER'S CHARACTERISTICS

To date no major scientific studies have been conducted that would allow one to create the criminal investigative analysis (sometimes erroneously referred to as a psychological profile) of the homicidal poisoner. However, some of the commonalities thought to be exhibited by this group of criminals include the following: non-confrontational, cowardly, greedy, fantasist, artistic, immature, possession of vanity (think they will not be discovered), and possessing a limited mind without sympathy.^{1,2} Because of the nature of the crime, it is very possible that a poisoner shares some commonalities with a bomber, whose commonality has been worked on by the U.S. Federal Bureau of Investigation.

In 1996, criminal investigators Westveer, Trestrail, and Pinizzotto³ published the results of the first epidemiologic study of criminal poisoning in the United States. Their study group results came from an analysis of

criminal poisonings reported to the Department of Justice through the Uniform Crime Report program. Their investigation found that during the decade 1980 to 1989, in the 202,785 homicides reported, there were a total of 292 poisoning cases, in which there was a single offender associated with a single victim. This represented 14 poisonings per 100,000 reported homicides. Some of the information that was revealed in this study group of 292 poisoning murders is listed below.

Gender Relationships

Victims were equally divided between male and female.

If the victim was female, the offender was usually a male.

If the victim was a male, the offender was equally a male or female.

Offenders were male twice as often as female.

Racial Relationships

Victim and offender were usually of the same race.

Victims were mostly white.

If the victim was white, the offender was usually a male.

If the victim was black, the offender was equally a male or female.

Black victims were males twice as often as females.

White victims were equally male or female.

For both black and white offenders, there were twice as many males as females.

Age Characteristics

Victims were most numerous in the 25 to 29 year age range.

Offenders were most numerous in the 20 to 34 year age range.

Other Findings

Poisonings averaged 1.47 per million population per year.

The unknown offender rate for poisonings was 20 to 30 times higher than in nonpoisoning homicides!

An analysis of 900 cases of known criminal poisonings collected by the author of this chapter found the following:

Sex of offender: male (45%), female (38%), unknown (17%), showing that the majority of known poisoners are male. It is assumed that males perpetrate most murders, but poison is probably the preferred weapon of females. It is very possible that females are better at getting away with their crime due to their almost universal domestic roles: preparation of meals, taking care of the sick, and cleaning up the home.

Background of offender: dentist (1%), general public (68%), minister (1%), nurse (5%), juvenile (2%), pharmacist (1%), physician (7%), political (3%),

scientist (1%), unknown (11%). This seems to indicate that the vast majority of known poisoners are members of the general public, with no specific medical or scientific background.

Poison used: arsenic (26%), cyanide (9%), strychnine (6%). These top three agents represented 41% of the poisons used.

Number of victims: single (59%), multiple (41%). This shows that in known cases, poisoners were able to carry out multiple homicides before their crimes were eventually detected.

Motive for the crime: individual profit (23%), personal cause (10%), domestic (9%), nonspecific motive (5%), political extremism (6%). Most of the time, the motive for a poisoning murder revolves around money or the elimination of a significant other due to abuse or to obtain another significant other.

Location of the crime: United States (42%), Great Britain/England (21%), France (6%), Italy (4%). This analysis is naturally biased by the literature and news media available for analysis.

Overall, these studies seem to once again support the hypothesis that murder by poison is one of the easiest homicides to remain undetected. There is no other form of homicide that produces a serial killer rate as high as the 41% found in the poisoner group, as well as an unknown offender rate, which is 20 to 30 times higher than other forms of homicide.¹

Certainly, further studies are warranted to try and determine if there are any commonalities found among the criminal poisoners. However, these studies await a focus of determination from interested parties, along with adequate funding to support this important research. Interviews of convicted poisoners whose cases are without appeal could be conducted in a manner similar to those studies already carried out that have looked for commonalities in convicted offenders of serial rape or serial murder.

With all of the unknown offenders and lack of witnesses, is there anything that could guide the investigators as they look into who might have caused the death of the victim? The answer is yes. There are observable clues that might indicate that something untoward might have happened to the victim.

WHEN SHOULD AN INVESTIGATOR'S SUSPICION BE AROUSED?

Here are some questions regarding signs that should quickly arouse suspicion in the toxicologist or criminal investigators that something in the "natural death" is not what it initially appears:

1. Was there a sudden death in a normally healthy individual?
2. Was there any interference in getting medical attention for the victim?
3. Was there the failure of a "natural disease" to respond to standard treatment?

4. Were relatives or friends not sent for during the victim's illness?
5. Are there no visible signs of violence?
6. Was there any history of a "cyclical illness" (in which the victim was ill at home, got better in a medical facility, then returned home and became ill again)?
7. Were there any common symptoms in a group of individuals?
8. Is there anyone around the victim with knowledge of poisons?
9. Was anyone anxious to dispose of food, drink, or medications?
10. Was a request made that there be no autopsy?
11. Was a request made for a rapid cremation?
12. Is the cause of death being vehemently insisted on by anyone in a possible suspect group?
13. Is anyone in a possible suspect group attempting to guide the investigation?

Certainly, the presence of one or more of these signs does not indicate that there was definitely a poisoning, or point the finger at the murderer, but all in all, any of these observed signs should make the investigator pause and ask the question, "Am I dealing with a possible homicidal poisoning in this case?" The prime mandate is that every death with no visible signs of violence is a poisoning until facts prove otherwise. Only through the constant practice of this rule will the victims of poisonings be found and given justice.

When it has been determined that a possible poisoning has occurred, what agencies or groups can an investigator turn to for assistance in the investigation of criminal poisoning?

ORGANIZATIONS AND RESOURCES FOR FORENSIC TOXICOLOGY

National and international organizations dealing with the specialty of forensic toxicology include the following: Society of Forensic Toxicologists (SOFT), The International Association of Forensic Toxicologists (TIAFT), and the toxicology section of the American Academy of Forensic Sciences (AAFS). These organizations deal mostly with the area of analytical toxicology, and more information on these organizations can be found at their individual websites.

There is also an organization that specializes mainly on the aspects of the investigation of criminal poisoning. The Center for the Study of Criminal Poisoning (CSCP) was founded in 1997 in order to provide an international mechanism for the exchange of information on homicidal poisonings. To these ends, the CSCP carries out the following activities:

1. Maintaining a database on criminal poisoning cases.
2. Providing training workshops on the investigation of murder by poison.
3. Conducting forensic research projects.
4. Encouraging international communications on criminal poisonings.

The CSCP has developed a reporting tool to be used in the sharing of information on homicidal poisoning cases and tampering incidents, and has made it available internationally to law enforcement agencies as well as forensic pathologists. This homicidal poisoning case registry reporting form is provided in Figure 7A-1 for duplication and submission of reports to the CSCP.

Once the investigation has proven that there is sufficient proof that a criminal poisoning has occurred, and that there is a suspect, the strategy for trial planning must begin.

CRIMINAL POISONING: LEGAL ISSUES

Murder by poison is one of the most difficult types of crime to take to litigation. One of the major problems is that in the vast majority of poisoning cases, there are no witnesses to the criminal action. This makes almost all of the available evidence indirect, or as it is otherwise termed, *circumstantial*.

The main question to be resolved by the court is whether the accused killed the deceased by poison. As stated by Wigmore,⁴ the main question for the prosecution

FIGURE 7A-1 Homicidal poisoning case registry.

really resolves into three component questions of fact, each of which must be proved:

1. That the deceased's death was caused by poison.
2. That the poison was administered to the deceased by the accused.
3. That the accused was aware of the lethal nature of the administered substance.

Unless it can be proved by pathologic examination and/or analytical toxicology evidence that the deceased died from a poison, it is futile to inquire as to who might have murdered the person by this method. In attempting to prove that the poison was administered by the accused, one must be able to prove that the accused had an opportunity to administer the toxic agent. Lack of opportunity to administer the poison is one of the strongest arguments used for the accused by defense counsel. It is also important for the prosecution to be able to prove that the accused had possession of the poison and that no other person could possibly or probably have administered the poison. In proving that the accused had knowledge of the lethal nature of the compound in question, it is important for one to look at the educational background of the accused, references in his possession, and his possible access to information through vocation or avocation. One must always remember to consider access to information by computer from various Internet resources.

One of the difficulties in court is getting all the parties to agree on whether the agent in question is really a poison, by the acceptable definition of a poison.

Definition of Poison

Although it sounds easy, it is often very difficult to come up with an acceptable legal definition of what is a *poison*. The definitions of *poison* may differ by the laws of various states. Some of the definitions found in the legal literature include the following:

"Poison: is any substance, where introduced into the system, either directly or by absorption, produces violent, morbid or fatal changes, of which destroys living tissue with which it comes in contact." [Watkins vs. National Elec. Products Corp., C.C.A. Pa., 165, F.2d 980,982.]

"Poison: any substance which, when relatively small amounts are ingested, inhaled, absorbed, or applied to, injected into, or developed within the body, has chemical action that may cause damage to structure or disturbance of function producing symptomatology, illness, or death." [Stedman's Medical Dictionary, 26th ed., Williams & Wilkins, Baltimore, MD, 1995.]

"Poison: any substance which when ingested, inhaled, or absorbed, or when applied to, injected into, or developed within the body, in relatively small amounts, by its chemical action may cause damage to structure or disturbance of function." [The

Sloane-Dorland Annotated Medical-Legal Dictionary, West Publishing Co., New York, NY, 1987.]

What is really the major factor in defining a poison? To almost all toxicologists, the statement made by the famous 16th-century alchemist Phillippus Theophrastus Aureolus Bombastus von Hohenheim, also known as Paracelsus (1493–1541), comes about as close to the concept of poison as can be made. In his 1564 "Third Defense," he wrote, "What is there that is not poison, all things are poison and nothing (is) without poison. Solely the dose determines that a thing is not a poison." Just like the saying "everyone has his or her price," every substance has its dose at or beyond which lethality can occur. One can kill with water just as well as drugs; the only difference is the amount (dependent on the factors of concentration and time duration of exposure) to which the victim is exposed.

CRIMINAL POISONING: TRIAL STRATEGIES

In order to be able to prove "murder by poison," the following must be absolutely locked into place:

1. The "chain of evidence" was maintained. Being able to absolutely prove who had possession of the case evidence and when he or she took possession of it.
2. Presence of the poison has been proven by analysis. Utilizing information gained from both pathologic observations and chemical testing.
3. The poison was absorbed systemically and in circulation. For a poison to kill, it has to get to the right target organ or system in a concentration that would cause damage to the site and result in a fatality.

The prosecution will also have to be able to prove the following:

1. The death was caused by the poison. This fact will be proved through a combination of information gained from the death scene investigation, pathologic examination, and chemical analyses.
2. The accused administered the poison. Proving that the defendant had the opportunity and possession of the substance, and that it was not possible or probable that any other person could have given it.
3. The accused was aware of the poison's lethality. This is done by proving the possession of knowledge gained by conversation or research from reading.

CASE EXAMPLES

The following examples of actual homicidal poisoning cases show the effective results of a combined team of individuals from the specialties of forensic pathology, forensic toxicology, analytical toxicology, death investigators, and attorneys, working together to bring justice to the victim of this heinous type of crime.

The Joanne Curley Case

Beginning in 1990, Joanne Curley of Wilkes-Barre, Pennsylvania, began administering the toxic metallic rodenticide thallium to her husband, Robert. Her motive was the \$300,000 life insurance policy on her spouse. She slowly began to administer the poison to him in his food and drink and also brought thallium-laced iced tea to him as he lay near death in the hospital. In order to throw investigators off the trail, she also administered small amounts of the poison to herself and her daughter. In 1994, under pressure from concerned family members, authorities exhumed the body of the deceased. Analysis of his hair gave a chronological time line of the administration of the poison and linked his wife as the only possible perpetrator of the occurrences. Faced with the solid evidence of analytical and forensic toxicology, and in order to avoid a trial and a possible death penalty, she pled guilty to her husband's murder.

The Ronald Clark O'Bryan Case

On October 31, 1974, the children in Pasadena, Texas, were going about their normal Halloween activities. Eight-year-old Timothy Marc O'Bryan celebrated the evening by consuming some of his holiday candy. Shortly after consuming the powdery contents of a Giant Pixy Stick, he collapsed and died. Since it was the death of a normally healthy individual, suspicion centered on the product he had consumed. Subsequent analytical toxicology tests found that the product contained not a candy powder but potassium cyanide. Tampered treats were also found in the bags of four other children, who fortunately had not consumed any of the "candy." Panic ensued around the area that a demented tamperer had struck in their community! On physical examination, it was found that the treats had been opened and crudely stapled shut. Investigation soon centered on the dead boy's father, Ronald Clark O'Bryan, a Houston, Texas, optician. Investigators found that the suspect had recently taken out \$65,000 worth of life insurance on his two children (motive), and witnesses stated that he had been making inquiries about the lethal dosage of cyanide and had attempted to purchase the same poison. At trial, without ever admitting to the crime, but with the damning forensic evidence, O'Bryan was found guilty. Ronald O'Bryan, whom the public dubbed the "Candy Man" and who nationally changed Halloween festivities forever, was executed by lethal injection on March 31, 1984.

CONCLUSION

Although the study of toxicology can be applied to all areas of living—environmental, occupational, clinical, and many others—it is in the area of its forensic application where the need for this special knowledge clearly cries out. It is with the application of our knowledge of poisons, their kinetics, toxicology, and analysis that one day the chances of success of the poisoner will hopefully begin to diminish and the chances of law enforcement's success will increase, to bring justice to the victims of this sinister and almost invisible crime.

DISCLAIMER

The information contained in this chapter is intended to serve the reader with general background information representing various aspects of toxicology as it applies to modern litigation. However, this is not intended to serve as a substitute for intensive research respecting various issues, as each case must be approached on a case-by-case basis. Some cases will require intensive research independent of this work.

B Clinical Issues

PHILIPPE E. HANTSON, MD, PHD

At a Glance...

- The major obstacle to organ transplantation is the lack of suitable donors, but poisoned patients are often overlooked as potential organ donors.
- Extremely strict brain death criteria have to be applied in this particular setting.
- Experience with grafts obtained from intoxicated donors is limited, but the results appear similar to those observed with nonpoisoned donors. To date, no failure has been related to a toxic origin.
- Each case needs to be evaluated on an individual basis according to the clinical, biologic, and morphologic findings in the donor, and to the knowledge of the toxicologic properties of the compound.

INTRODUCTION AND EPIDEMIOLOGY

Postmortem studies are particularly important in cases of fatal poisoning, not only to determine the cause of death but also to collect data on the target organs of some specific poisonings. They usually combine a morphologic analysis and a study of the toxicokinetics of the substance. This question is essential when organ donation is considered from a donor declared brain dead after acute poisoning. Even though this occurrence seems exceptional, poisoned donors should not be systematically overlooked as potential organ donors.^{1,2} Current data available from the transplant coordination organizations indicate that poisoned patients represent less than 1% of all organ donors.

The purpose of this chapter is to present the experience of organ donation after fatal poisoning and to discuss organ acceptability criteria.

In 1994, Leikin and colleagues published a series of 17 poisoned patients who were accepted as organ donors.³ The toxicants involved were ethanol (n = 8), cocaine (n = 5), carbon monoxide (n = 5), barbiturates (n = 2), cannabis (n = 1), lead (n = 1), and phenylpropanolamine (n = 1), with six patients having had multidrug involvement. There were 41 recipients, including 32 kidney transplantations and 9 liver transplantations. There were two fatalities in the early postoperative phase in the liver group, but it was concluded that death was definitely not related to the toxic origin of the graft. In the kidney group, renal function immediately after the procedure was good in 28 of 32 patients (1 graft loss occurred on day 5 due to thrombosis, 3 had transient dysfunction) and remained satisfactory at 8-month follow-up in 31 of 32 cases.

The experience of a single center in Belgium was described in a series of 21 poisoned donors collected over an 8-year period.^{4,6} In this center, poisoned donors

in brain death status represented 7% of all the organ donors for this time period. The toxicants involved were benzodiazepines (n = 2), tricyclic antidepressants (n = 1), benzodiazepines and tricyclic antidepressants (n = 1), barbiturates (n = 2), insulin (n = 2), carbon monoxide (n = 3), cyanide (n = 1), methaqualone (n = 1), paracetamol (acetaminophen) (n = 1), and methanol (n = 7). On the whole, 58 grafts were obtained: 39 kidneys, 6 hearts, 2 lungs, 9 livers, and 2 pancreases. Overall recipient survival rates at 1 year and 5 years were, respectively, 100% and 88% in the kidney group, 100% and 100% in the pancreas group, 67% and 67% in the liver group, 50% and 33% in the heart group, and 100% and 100% in the single case of lung transplantation. One liver graft and one kidney graft failed to function after 1 month. Two additional kidney grafts and one liver graft failed after a longer delay. The analysis of the causes of mortality or morbidity (graft loss) did not reveal any correlation with the toxic origin of the grafts.

CRITERIA FOR ORGAN AND DONOR ACCEPTABILITY

Several criteria have to be met when organ donation is considered after fatal poisoning⁷:

1. The first crucial issue is the accuracy of the brain death diagnosis in the presence of drugs influencing the central nervous system.⁸ Even if brain death is basically a clinical diagnosis, confirmatory tests may be required. The confirmatory tests may demonstrate the absence of cerebral blood flow (four-vessel angiography, radioisotope technique, and transcranial Doppler) or the absence of cerebral electrical activity (electroencephalography [EEG], multimodality evoked potentials). Cerebral four-vessel angiography is the gold standard in this condition; however, this test is invasive and cannot be easily repeated at the bedside. There are several limitations to the use of EEG because this technique is very sensitive to hypothermia, drugs, and metabolic disorders. In experienced hands, multimodality evoked potentials investigations were found to be extremely helpful in this particular setting.⁸
2. The patient considered as a potential organ donor should not be exhibiting any clinical sign of toxicity associated with the toxic exposure.
3. The possible damages to the organs to be harvested are to be carefully evaluated. Direct toxic injuries may be found in the target organs of poisoning, while indirect injury due to anoxia or metabolic disorders may be noted in the other organs. Usually, the same methodology as for nonpoisoned donors can be applied. This is mainly based on routine

laboratory analysis (biologic markers) and on morphologic examination; tissue biopsies after organ harvesting are then particularly helpful.

4. Due to tissue storage with some substances, there is a theoretical risk for secondary poisoning of the recipient. This risk should be limited by a perfect understanding of the toxicokinetics of the concerned toxin.
5. The problem of organ donation from nonintravenous drug abusers remains an open issue.^{1,9} It is important that, particularly in the drug abuse population, all potential organ donors undergo a thorough infectious disease screening prior to transplantation to exclude as far as possible the transmission of an infectious agent (hepatitis B and C, human immunodeficiency virus). Such screening, however, will not detect the donors who are still in the window of infectivity.

SPECIFIC SUBSTANCES

Psychotropic Drugs

Multiple organ procurements have been performed after fatalities due to benzodiazepine or barbiturate overdoses.^{4,6} Heart donation after barbiturate poisoning is possible provided hemodynamic disturbances have been corrected.

Theoretically, with tricyclic antidepressants (TCAs), there is a risk of accumulation of the toxic substance in some tissues (lung, kidney, heart, liver). The literature includes at least one case that describes the possible transmission to the recipient of TCAs stored in the liver graft.¹⁰ The heart is obviously a target organ of TCA poisoning, and heart donation is contraindicated; moreover, extremely high TCA concentrations can be found in the myocardium at postmortem analysis. For the other organs, it seems advisable to wait until the donor plasma TCA concentration falls well below 2000 ng/mL. This cannot always be achieved because sustained high blood concentrations are sometimes observed after massive TCA overdose. Furthermore, quantitative analyses of TCAs are not universally available.

Few data with regard to the more recent selective serotonin reuptake inhibitors (SSRIs) exist. Mortality directly due to SSRI overdose is low, but severe serotonin syndrome may rapidly progress to cardiac arrest, coma, seizures, or multi-organ failure with disseminated intravascular coagulation. Cardiotoxicity due to SSRIs is usually low and can be identified on the electrocardiogram (ECG) (conduction abnormalities, prolonged QT interval). Death may exceptionally result from malignant arrhythmias. This obviously contraindicates heart donation. In a single case report, the heart was procured from a donor who died from ventricular fibrillation following venlafaxine and fluoxetine overdose.¹¹ High doses of vasopressors were initially required in the donor before the heart was finally accepted. The recipient suffered multiple episodes of supraventricular arrhythmias during the postoperative

phase, and it was speculated that SSRI accumulation in heart tissue might have played a role.

Before considering organ donation, it must be remembered that some SSRIs (e.g., fluoxetine) and their metabolites have a prolonged elimination half-life, suggesting the possibility of tissue storage (e.g., in the lung) with these agents.

ACETAMINOPHEN

Surprisingly, a relatively few number of heart or kidney transplantations have been reported from donors who died from acetaminophen poisoning.⁹ Both oliguric and nonoliguric acute renal failure has been described following acetaminophen overdose, mostly as a component of multi-organ failure complicating fulminant hepatic failure.¹² It occurs rarely in the absence of clinical or biochemical evidence of liver damage. Histologic findings are consistent with acute tubular necrosis. Kidney donation may be considered in fatal acetaminophen poisoning according to the laboratory data and the results of renal biopsy. There is no direct evidence that acetaminophen causes cardiotoxicity.¹³ Nonspecific ECG changes have been noted in patients with acetaminophen overdose. Postmortem studies revealed histological features in some cases that were consistent with toxic myocarditis, such as diffuse myocardial damage with interstitial edema or bands of necrosis and hemorrhage. It is very likely that other factors contributed to toxicity, because such lesions have been widely observed in fulminant hepatic failure not due to acetaminophen poisoning. At least three cases of uncomplicated heart transplantations have been reported in this setting.¹³ The lung is also not directly damaged in case of acetaminophen poisoning, and lung donation is possible. Finally, pancreatitis seems also to be extremely rare after acetaminophen overdose.

CARBON MONOXIDE

Fatalities due to accidental exposure to carbon monoxide (CO) are still quite common, but it should be noted that few of these fatalities could result in organ procurement. CO reduces both the oxygen-carrying capacity of hemoglobin and oxygen delivery to tissues. CO binds to the cytochrome oxidase system to reduce cellular utilization of oxygen. As expected, tissues most sensitive to oxygen deprivation (central nervous system, myocardium) are most sensitive to CO toxicity. The pathologic substrate for myocardial toxicity from CO poisoning is the subendocardial region, characterized by scattered areas of necrosis, hemorrhage, and muscle fiber degeneration; these lesions are similar to those observed in anoxia from another origin.

There are many case reports of successful kidney, pancreas, lung, or liver transplantation from CO-poisoned donors.^{14,15} The possibility of heart donation still remains controversial, in spite of the positive experience that has frequently been published (Table 7B-1).¹⁶⁻²⁵ Of concern are the reports of impaired cardiac contractility during the postoperative phase where the role of CO toxicity can be at least suspected.²¹ This is in agreement with an isolated report showing a

Abn, abnormal; COHb, carboxyhemoglobin; CPR, cardiopulmonary resuscitation; ECG, electrocardiogram; Echo: echocardiography; NI, normal; —, not available; ↑, increased; +, alive; X, deceased.

depression of myocardial contractility following acute CO poisoning in a patient who had no electrocardiographic, angiographic, or biologic evidence of myocardial infarction; electron microscopy of the endomyocardial biopsy showed ultrastructural changes in the mitochondria that are a primary target of CO intracellular toxicity. Some donors described in the literature had received prolonged resuscitation and vasopressors before the harvesting procedure. Some had an abnormal ECG or echocardiography, with increased cardiac enzymes. Therefore, it seems of utmost importance to exclude from heart donation the donors presenting these features. The determination of CO blood levels is not helpful for the decision to remove or not remove the heart, although myocardial ischemia following CO poisoning is usually seen with carboxyhemoglobin levels above 25%.

Theoretically, lung donation is possible after pure CO poisoning.²³ When CO intoxication occurs following smoke inhalation, there is an increased risk for chemical or thermal injury to the lung.

CYANIDE

Acute pure cyanide poisoning is rare. Cyanide inhibits mitochondrial cytochrome-*c* oxidase activity. This results in a shift of aerobic to anaerobic metabolism, eventually leading to adenosine triphosphate depletion and lactic acidosis. Cyanide is distributed to all the tissues via the blood; its concentration in red cells is much greater than that in plasma. Cyanide is metabolized in the liver by an

endogenous enzyme, rhodanase, to thiocyanate. Half-life for the conversion of cyanide to thiocyanate from a nonlethal dose in humans is between 20 minutes and 1 hour. As expected, the brain and the heart are particularly sensitive to cyanide-induced hypoxia. Collapse of the cardiovascular system requires cyanide doses higher than those necessary for injury to the central nervous system. This explains why brain death may be observed in patients who underwent successful cardiopulmonary resuscitation after cyanide exposure. The experience with organ donation following fatal cyanide exposure is summarized in Table 7B-2. At least two cases of successful heart transplantation have been described in the literature.²⁶⁻²⁸ In addition, there are numerous reports of cornea, kidney, pancreas, or liver transplantations.²⁹⁻³⁴ There is a theoretical risk for transmission of poisoning to the recipient. However, the elimination half-life of cyanide in patients treated with antidotes is usually much less than 24 hours. In forensic medicine, a blood cyanide of greater than or equal to 1.0 mg/L (38.5 µmol/L) is generally considered to represent a potentially toxic concentration.³⁵ No clinical symptoms develop with whole blood concentrations below 0.2 mg/L (7.7 µmol/L), and organ harvesting may then be proposed. It has also been shown that, during the course of pure cyanide poisoning, a plasma lactate concentration of at least 8 mmol/L was indicative of a toxic blood cyanide concentration (at least 1.0 mg/L). It seems therefore imperative to achieve the correction of lactic acidosis before any procedure.

**TABLE 7B-2** Literature Data on Organ Procurement from Cyanide-Poisoned Donors

ORGANOPHOSPHATES

The liver and kidneys were harvested from a 17-year-old boy who was declared brain dead 5 days after the voluntary ingestion of an unknown amount of malathion.³⁶ Blood and tissue concentrations of malathion were not obtained. At the time of organ removal, there was no sign of hepatotoxicity or renal toxicity. No further cholinergic toxicity was evident after discontinuation of atropine and pralidoxime. These data cannot be extrapolated to other organophosphate compounds. Organophosphates are generally lipophilic and initially concentrate in the liver; redistribution may also occur to fatty tissues. Malathion can be activated to malaaxon but is rapidly hydrolyzed to nontoxic metabolites and excreted primarily by the kidney. Due to differences in disposition, each organophosphate compound should be analyzed on an individual basis before considering organ donation.

METHANOL

Methanol poisoning might still be regarded by some transplant physicians as an absolute or relative contraindication to organ donation. However, the experience with organ procurement from patients poisoned by methanol is growing, as illustrated by some recent publications (Table 7B-3).^{22,37-45} In contrast to the relatively rapid metabolism of ethylene glycol, methanol is slowly metabolized into formaldehyde and formate by alcohol and aldehyde dehydrogenases. Formic acid accumulation may reflect the severity of methanol poisoning. While variable concentrations of formic acid have been found in different tissues (e.g., heart, liver, kidney) at postmortem studies, it seems unlikely that a significant toxicity could be transferred to the organ recipient. The brain and the retina are the main target organs of poisoning. Brain death may be the consequence of diffuse brain edema or of hemorrhagic lesions mainly originating in the basal ganglia. The largest experience exists now with kidney donation. Kidney graft biopsies performed before transplantation revealed minor tubulointerstitial lesions as usually seen

in grafts and ascribable to an ischemia-reperfusion sequence or, in some cases, minor hydropic changes.³⁸ No glomerular or vascular lesions were observed. Fatty changes and microvesicular fat have been described in the hepatocytes in an autopsy study. However, it should be recalled that the patients poisoned by methanol are often chronic ethanol abusers. The liver can be safely procured after methanol poisoning provided that liver function tests are normal with absence of steatosis at the biopsy. The incidence of pancreatic injury (increase of pancreatic enzymes or clinically severe acute necrotizing pancreatitis) after methanol poisoning probably has been underestimated.⁴⁶ The pathophysiology remains unclear. Here also, the pancreas injury may be at least triggered by chronic ethanol consumption or ethanol administration as an antidote for methanol poisoning. This suggests that successful pancreatic transplantation may be difficult.³⁷ Experience with lung or heart transplantation is far more limited.^{22,43,44} The lung is not a target organ of methanol poisoning and transplantation is acceptable. As for the heart, it seems also that methanol poisoning is not an absolute contraindication to organ donation. There is no clear evidence that methanol or its toxic metabolites may provoke direct injury to the myocardium. Cardiac dysfunction in fatal cases of methanol poisoning is usually related to the severity of metabolic acidosis. Heart donation should only be considered when no inotropic support is required in the donor.

Before starting any harvesting procedure, it is essential to have achieved the correction of metabolic acidosis and to wait until methanol has completely disappeared from blood.

ETHYLENE GLYCOL

Ethylene glycol, due to its metabolism to glycoaldehyde, glycolic acid, and glyoxalate, causes severe metabolic acidosis. Most deaths occur during this period of metabolic acidosis, which is associated with cerebral edema, seizures, and multi-organ failure. Glyoxalate is

TABLE 7B-3 Organ Donation after Fatal Methanol Poisoning

ORGANS PROCURED	TOTAL NUMBER OF GRAFTS	IMMEDIATE OUTCOME	LATE OUTCOME (SURVIVAL RATE OR GRAFT FUNCTION)		REFERENCES

Fatalities and postoperative complications were not related to methanol poisoning.
—, not available; NI, normal.

converted to oxalate, which precipitates as calcium oxalate crystals in body tissues. Oxalate crystal deposition has been described not only in the kidney, but also in the brain and other organs. Renal failure usually occurs within 24 to 48 hours after ingestion. Because the kidney is clearly a major target organ, kidney donation remains contraindicated even though positive experiences have been reported. In contrast, there is no report of significant hepatic damage directly related to ethylene glycol poisoning, and successful liver procurement has been reported.⁴⁷ As for the heart, no transplant data are available. Cardiocirculatory failure may be a terminal event in presence of severe metabolic acidosis; heart donation should only be considered in patients with a normal ECG and echocardiography who do not require inotropic drugs.

The same precautions (correction of metabolic acidosis, absence of detectable toxicant) should be observed as in methanol poisoning.

ILLICIT SUBSTANCES

Leikin and colleagues have reported successful kidney and liver transplantations from donors who were positive for cocaine on the toxicology screen.³ However, the possibility of heart donation remains debatable.^{48,49} Cocaine is an increasing cause of intracerebral bleeding in young people and is more and more frequently identified in the biologic fluids of patients presenting with traumatic brain death. It can be assumed that the incidence of nonintravenous cocaine use is increasing among the potential organ donors in the general population. Some transplant teams have suggested liberalization of donor acceptability criteria in order to increase the heart donor pool.⁴⁹ They claim that the

outcome of patients who received transplanted hearts obtained from nonintravenous cocaine users was not significantly different from that observed with grafts procured from donors who had no history of cocaine use. This conclusion is not fully supported by some clinical observations and by our knowledge of the possible cardiotoxicity following acute or chronic cocaine use. At autopsy, cocaine-associated findings include myocarditis and myocyte and contraction band necrosis; left ventricular hypertrophy may occur after several years of cocaine abuse. For these reasons, heart donation should only be considered with extreme caution. In contrast, it does not seem that inhalation of cocaine or marijuana contraindicates lung procurement.⁵⁰

Published experience is now also appearing with the drug Ecstasy (3,4-methylenedioxymethamphetamine). Multi-organ procurements (heart, liver, kidney, kidney-pancreas, lung) were obtained from two donors who died from brain edema following ecstasy use.⁵¹ Two fatalities were observed among the eight recipients, but they were not related to a toxic origin.

UNUSUAL SUBSTANCES

Successful transplantations have been reported from donors who died from complications of long-acting anticoagulant therapy. Fatal fulminant hepatic failure due to *Amanita* poisoning led to heart and kidney donation.

CONCLUSION

Successful organ transplantation is possible with grafts coming from brain-dead donors following acute

poisoning. A thorough examination of each individual case should be performed jointly by the members of the transplant team and medical toxicologists.

SECTION B

EFFECTS OF POISONING BY ORGAN SYSTEM

8

Cardiovascular Toxicology

NANCY G. MURPHY, MD ■ NEAL L. BENOWITZ, MD ■ NORA GOLDSCHLAGER, MD

Cardiovascular complications account for a substantial proportion of the morbidity and mortality in cases of drug overdose. Drug- or toxin-induced cardiovascular syndromes include hypotension and circulatory shock, hypertension, arrhythmias, and pulmonary edema. This chapter focuses on disturbances of cardiac function, particularly circulatory failure and arrhythmias. Pathophysiology, recognition of specific types of overdose, and principles of management are discussed.

HYPOTENSION AND CIRCULATORY SHOCK

Mechanisms

Hypotension occurs after overdosage with many different types of drugs. The mechanisms of hypotension are diverse, and hemodynamic patterns vary with different drugs in different stages of overdose and according to the presence and nature of underlying medical illness. Cardiac output may be reduced as a result of drug-induced myocardial depression, relative hypovolemia resulting from venous pooling, or true hypovolemia resulting from vascular injury and fluid loss from the vascular space. Peripheral vascular resistance may be reduced because of drug-induced vascular relaxation, adrenergic receptor blockade, or depression of central vasomotor tone. Myocardial and vascular dysfunction resulting from hypoxia, acidosis, and hypotension may complicate the picture.

The importance of hypotension is that it warns the physician of possible circulatory insufficiency; blood pressure also is one of several indicators of response to treatment. The diagnosis of circulatory shock depends on evidence of tissue hypoperfusion. Urine output and markers of cellular metabolism, such as lactate, are useful indicators of hypoperfusion, but they must be interpreted in the context of physical findings, hemodynamic variables, and other metabolic parameters

(arterial blood gas, glucose).¹ In patients with underlying coronary artery or cerebrovascular disease, the development of cardiac or cerebral ischemia may limit the tolerable extent of hypotension.

Management

Hypotensive patients should be placed in an intensive care unit where vital signs, fluid intake and output, body weight, and other parameters of circulatory function can be monitored continuously. Because indirect measurements of arterial blood pressure are difficult to obtain and often do not reflect true intra-arterial pressure in hypotensive states, direct measurement of intra-arterial blood pressure is preferred.

If a patient has hypotension without signs of tissue hypoperfusion, fluids should be administered at sufficient rates to maintain urine output and to compensate for insensible losses. Fluids should be of appropriate composition to provide electrolyte needs. In many patients with signs of hypoperfusion of tissues, correction of acid-base and electrolyte disturbances and modest fluid therapy are sufficient to increase perfusion to adequate levels. However, increased pulmonary vascular permeability complicates many cases of drug overdose, and fluid therapy may cause pulmonary edema. For this reason, fluids must be administered cautiously. A reasonably safe way to administer fluids is by short infusions of small volumes (100 to 200 mL) of normal saline solution. If the clinical response is inadequate and if the patient has no evidence of pulmonary edema, the short infusions should be repeated but should not exceed a total of 1000 to 2000 mL over 1 to 2 hours. Evidence of pulmonary edema includes worsening hypoxia, decreasing lung compliance (manifested by increasing pressure necessary to ventilate a patient with a given tidal volume), and development of pulmonary rales.

If shock persists despite fluid challenge, catheterization of the pulmonary artery and measurement of pulmonary artery and pulmonary capillary wedge

pressure, cardiac output, and mixed venous oxygen saturation from the pulmonary artery is useful to monitor subsequent fluid therapy and to optimize drug therapy. The goal of fluid therapy is to reestablish adequate tissue perfusion without producing fluid overload and/or pulmonary edema. As long as the pulmonary capillary wedge pressure remains low (<12 mm Hg), further fluid can be administered. If evidence of tissue hypoperfusion persists when pulmonary capillary wedge pressures have been restored to normal or pulmonary edema is evident, pressor or inotropic agents should be administered to restore adequate perfusion. In persons with chronic cardiac failure, higher pressures (≥ 20 mm Hg) may be necessary to maintain an adequate cardiac output, and fluid therapy must be managed more on the basis of clinical assessment of pulmonary edema than on filling pressures per se.

Hemodynamic monitoring aids in the selection of pressor or inotropic drugs. For example, if circulatory failure is associated with low or low-normal peripheral vascular resistance, norepinephrine or dopamine should be selected. Both agents primarily are vasoconstrictors with some inotropic effects. Normalization of vascular resistance is a useful end point for titration of infusion rate. The renal vasodilatory effect of low dose dopamine has made it the preferred vasopressor; however, there is no evidence that “renal dose” dopamine provides any benefit to patients with impending renal failure or with concomitant vasoconstrictor therapy. In cases of overdose with drugs that have α -adrenergic receptor–blocking effects, such as phenothiazines or tricyclic antidepressants, more selective α -adrenergic agonists, such as norepinephrine or phenylephrine, may be required.² In vasodilatory shock refractory to standard high dose vasopressors, vasopressin as an adjunctive therapy may be helpful, although this agent has been studied primarily in septic shock and postcardiotomy shock.³

If vascular resistance is normal or high and depressed cardiac output is the determining factor in circulatory failure, drugs or interventions that increase cardiac output should be selected. Isoproterenol is useful particularly when myocardial depression is associated with bradyarrhythmias, although it may be arrhythmogenic; dobutamine, a dopamine analog with relatively selective inotropic activity and less arrhythmogenic potential, is useful when heart rate is already adequate. In some patients, the addition of the phosphodiesterase inhibitor amrinone to other vasopressors has resulted in hemodynamic improvement. Amrinone is both an inotropic and a vasodilating agent and should not be used when peripheral vascular resistance is low. In patients with both myocardial depression and low vascular resistance, epinephrine or combinations of norepinephrine or dopamine and isoproterenol may be useful. Specific agents that may improve myocardial contractility are calcium and insulin/dextrose in calcium channel blocker overdose and glucagon in β -blocker overdose. If fluid replacement, vasopressors, and other inotropic agents do not reverse drug-induced shock, circulatory assist devices should be used, such as intra-aortic balloon pump or cardiopulmonary bypass.

Pressor therapy has potential risks: pressor-induced venoconstriction can increase venous return and worsen pulmonary edema, and arteriolar constriction can further reduce tissue perfusion. However, in studies of the effects of infusion of norepinephrine in patients who overdosed with sedative drugs, the positive effects of norepinephrine on cardiac output outweighed the vasoconstrictor effects, and blood pressure increased without an increase in vascular resistance.⁴

ARRHYTHMIAS

General Mechanisms

Three basic mechanisms are involved in the production and maintenance of arrhythmias: abnormal impulse formation, abnormal impulse conduction, and abnormal triggering.

ABNORMAL IMPULSE FORMATION

The sinus node is the normal pacemaker since it has the fastest intrinsic firing rate. This intrinsic firing rate is influenced by the resting membrane potential, the threshold potential, and the slope of the diastolic depolarization (phase 4). Conditions or agents that increase the slope of phase 4, lower the threshold potential toward the resting potential, or raise the resting membrane potential so that it approaches the threshold potential result in an increase in sinus rate as well as generation of automatic impulses from cells that do not normally manifest automaticity. A new site of pacing results when the rate generated by this abnormal focus exceeds the sinus pacemaker rate. Conversely, conditions or agents that decrease the rate of diastolic depolarization, raise the threshold potential toward 0, or lower the resting membrane potential so that it takes longer to reach threshold potential result in a decrease in the spontaneous firing rate.

ABNORMAL IMPULSE CONDUCTION

Delays in conduction or block of conduction of electrical impulses, together with differential refractoriness of myocardial tissues, may lead to reentry tachyarrhythmias. Such arrhythmias are initiated by early impulses that encounter refractory tissue or anatomic obstacles (e.g., scar), through which they cannot propagate because of their prematurity; thus, they travel down alternate slowly conducting pathways. If the impulses return to the area originally refractory but now excitable, the tissue is able to conduct them. This particular set of electrophysiologic circumstances (unilateral conduction delay and slow impulse transmission in alternate pathways) can lead to paroxysmal or sustained arrhythmias (Fig. 8-1).

TRIGGERED RHYTHMS

Triggered rhythms are abnormal initiations of impulses that occur as a result of afterdepolarizations, which are oscillations of the action potential during phases 2 to 4. Two types of afterdepolarizations are distinguished from each other by their temporal relationship within the

FIGURE 8-1 Drug-induced reentry: Schema of Purkinje's tissue or ventricular muscle through which impulse transmission occurs. **A**, Normal depolarization of a muscle segment. Impulses spread simultaneously down various conduction pathways to depolarize distal areas. Depolarization and repolarization proceed homogeneously. **B**, Reentry. The *hatched area* represents a local area with depressed conduction, which might be produced by a membrane-depressant drug. An impulse traveling anterogradely in an area of depressed conduction is blocked (*dark horizontal lines*); impulses traveling in adjacent pathways, however, can pass through the area of conduction delay in retrograde fashion. If tissue proximal to the depressed area is repolarized already and is now excitable, restimulation (reentry) occurs.

repolarization phase: early and delayed afterdepolarizations (EADs and DADs). EADs are the most common foci for triggered rhythms in the poisoned patient and are caused by blockade of outward potassium channels. The surplus of intracellular cations result in delay of return of the action potential to its baseline and upward oscillations of the action potential above threshold. Torsades de pointes and ventricular tachycardias often are precipitated by these triggered responses. DADs occur at the end of repolarization and result from intracellular calcium overload, as seen in digitalis toxicity or excess catecholamine states. Although triggered rhythms have not been incontrovertibly proved to be responsible for specific arrhythmias in patients, many rhythm disturbances, particularly if they are pause or bradycardia dependent or occur in association with a prolonged QTU interval, are likely due to this underlying mechanism.

Arrhythmogenesis in Poisoned Patients

In the setting of drug overdose, cardiac arrhythmias can be caused by direct or indirect sympathomimetic effects, anticholinergic effects, the effects of altered central nervous system (CNS) regulation of peripheral autonomic activity, and myocardial membrane depression. Contributing factors to arrhythmogenesis during the course of drug overdose include hypotension, hypoxia, and disturbances in acid–base and electrolyte balance.

SYMPATHETIC INFLUENCES

The action of many drugs involves the autonomic nervous system, so it is useful to understand the effects of sympathetic and parasympathetic activity on cardiac electrophysiology. β -Adrenergic stimulation accelerates spontaneous diastolic depolarization, thereby increasing the sinus rate; enhancement of automaticity in other

pacemaker tissues (atrial, atrioventricular [AV] junctional, Purkinje) may result in accelerated ectopic rhythms. β -Adrenergic stimulation also increases conduction velocity in slow (calcium-dependent) channel fibers, thus leading to more rapid sinoatrial and AV nodal conduction of impulses. The effect of catecholamines on fast channel fibers such as normal Purkinje fibers is to accelerate repolarization and shorten the action potential duration and refractory period, although effects on conduction velocity are relatively negligible. Finally, β -adrenergic stimulation enhances afterdepolarization magnitude, thereby increasing the potential for triggered tachyarrhythmias. β_1 -receptor blockade causes blunting of chronotropic, dromotropic, and inotropic effects of endogenous and exogenous catecholamines.

PARASYMPATHETIC INFLUENCES

Parasympathetic stimulation slows the rate of spontaneous diastolic depolarization, resulting in slowing of the firing rates of pacemaker tissues. Slowing of the sinus rate may result in the emergence of an escape rhythm originating in supraventricular or ventricular tissue. Delay in impulse transmission through the AV node as a result of parasympathetic stimulation may produce AV block; this “vago tonic block” usually occurs in the presence of sinus slowing and can take the form of progressive delay in impulse conduction through the AV node (Figs. 8-2 and 8-3). The effects of cholinergic stimulation on ventricular conduction tissue include the raised electric threshold necessary for induction of ventricular fibrillation, particularly in the presence of high sympathetic activity. Inhibition of cholinergic receptors results in unopposed sympathetic stimulation, which results in sinus tachycardia (rate usually < 150 beats per minute) and a modest rise in blood pressure.

An interesting arrhythmia resulting from increased parasympathetic tone has been recognized. It is characterized by supraventricular tachyarrhythmias, especially atrial fibrillation, occurring during periods of high vagal tone, such as sleep, and is not found during exercise or stress. Drugs such as digitalis or β -adrenergic blocking agents tend to precipitate or worsen these arrhythmias. These arrhythmias can be treated effectively (suppressed) by oral theophylline, if not otherwise contraindicated, or by cardiac pacing to eliminate the pause or bradycardia dependence. The underlying mechanism of production of this arrhythmia may be acetylcholine-mediated shortening and dispersion of atrial refractory periods, resulting in inhomogeneous atrial repolarization and depolarization sequences. Because these arrhythmias do not connote underlying heart disease, their recognition is important. Anticholinergic effects also may rarely predispose to AV nodal reentrant tachyarrhythmias via differential effects on nodal conduction velocity and refractoriness of reentrant pathways.

MEMBRANE DEPRESSION

In a drug-overdosed patient, a direct effect on myocardial membranes is another important mechanism contribut-

FIGURE 8-2 MCL₁ tracing recorded during ipecac-induced emesis in a patient with alleged barbiturate overdose. During the Valsalva maneuver of vomiting, marked slowing of sinus rate with prolongation of the PR interval occurs, resulting in a prolonged pause in rhythm terminated by a ventricular escape beat. Sinus slowing with or without concomitant AV block, such as depicted here, is due to hypervagotonia, and the arrhythmia is known as *vagotonic block*. This has no prognostic significance for underlying heart disease. The arrhythmia usually is transient and requires no specific treatment.

ing to arrhythmogenesis. Depressant effects on membrane responsiveness are exemplified by quinidine, which inhibits the fast sodium current, so that for a given resting membrane potential depolarization is associated with a reduced rate of voltage change and a reduced maximum achieved voltage. As a result, impulse conduction is slowed. In addition, membrane depressants shift the threshold potential toward 0, thus requiring stimuli of greater intensity to initiate the action potential. Additional effects of quinidine include prolongation of the action potential duration and refractory period, which prolong repolarization time. These electrophysiologic effects result in slowed repolarization and depolarization times, especially in His-Purkinje tissue. These events are reflected in the surface electrocardiogram (ECG) as a prolongation of the QT interval and, in toxic doses, of the QRS duration. With severe intoxication, intraventricular block and asystole supervene, with inability to generate a response for any stimulus strength; this is manifested clinically by failure to respond to cardiac pacing at high stimulus voltage.

The basis for the arrhythmogenic effect of quinidine lies in part in its ability to produce disparate depolarization and repolarization times in His-Purkinje tissue and to delay impulse transmission. The production of unidirectional conduction block and the delay in impulse propagation in other areas enable reentry

tachycardias to occur. Quinidine and quinidine-like agents also can cause a form of polymorphous ventricular tachycardia, termed *torsades de pointes* (Fig. 8-4), probably due to triggered rhythms when occurring in the setting of a long QTU interval, as discussed previously.

The arrhythmogenic effects of most drugs during overdose are best understood as the combination of autonomic influences, membrane-depressant effects, and triggered rhythms. Our analysis attempts to categorize them in this way.

Management of Arrhythmias

Hypotension, hypoxia, and acid–base and electrolyte disturbances occurring during the course of drug overdose may contribute to arrhythmia production and should be corrected (Table 8-1).

SUPRAVENTRICULAR ARRHYTHMIAS

Sinus tachycardia and other supraventricular arrhythmias usually respond to supportive therapy and subside as the offending drug is excreted, but if they are associated with hemodynamic compromise, especially in patients with preexisting coronary or cerebrovascular disease, specific therapy is warranted. For excess sympathetic activity, benzodiazepines and a β_1 -selective blocker, such as esmolol or metoprolol, are appropriate. Physostigmine may be indicated for anticholinergic drug ingestions. However, with concomitant evidence of cardiac membrane depression, as occurs with overdose of tricyclic antidepressants, such an approach may itself be hazardous, as discussed later. If the supraventricular tachycardia is due to theophylline toxicity, administration of esmolol or metoprolol is useful in slowing a rapid ventricular response to atrial fibrillation or flutter without significant compromise in blood pressure. Electrical cardioversion is an acceptable alternative when arrhythmias are life threatening and fail to respond to pharmacologic treatment.

VENTRICULAR ARRHYTHMIAS

Pharmacologic therapy for drug-induced ventricular arrhythmias is similar to that used in the setting of acute myocardial ischemia. An important exception exists in cases of overdose of membrane-depressant drugs such as quinidine or tricyclic antidepressants; in these instances, similar sodium channel blocking agents such as

FIGURE 8-3 A 13-year-old girl ingested 325 mg of phenylpropanolamine and presented with a headache and blood pressure of 130/100 mm Hg. The electrocardiogram showed sinus arrhythmia with Wenckebach-type AV block, reflecting surges of vagal tone. The vagal discharge is a reflex response to phenylpropanolamine-induced vasoconstriction and hypertension.

FIGURE 8-4 V₁ rhythm strip showing polymorphous ventricular tachycardia occurring abruptly and without warning. This particular arrhythmia often is referred to as *torsades de pointes*, reflecting a twisting of the QRS complexes around the electrocardiographic baseline. It occurs in association with prolongation of the QT interval due to any cause (including idiopathic) and may be seen also in acute ischemic heart disease. In this tracing, the QT interval, measured from other leads, was 0.56 seconds.

TABLE 8-1 Arrhythmias and Their Management

TYPE	COMMENT	TREATMENT
Tachyarrhythmias		
All		Correct hypotension and acid–base and electrolyte disturbances No specific treatment indicated. If hemodynamic compromise, β blockade
Sinus tachycardia	Usually can be made to vary with respiration, exercise, carotid sinus massage	
Ectopic atrial tachycardia	If 2:1 AV conduction ratio, suspect digitalis toxicity	If hemodynamic compromise, β blockade, sotalol, amiodarone, or calcium channel blockade. If digitalis toxic, withdraw digitalis
Atrial flutter	Adenosine produces sufficient AV block to discern atrial activity. If QRS rhythm is regular and slow (<100), suspect AV block, which might be due to digitalis toxicity and/or β - and calcium entry blocker overdose	Direct current cardioversion (low energy levels usually suffice); pace termination; IV verapamil, diltiazem, esmolol, or metoprolol will slow ventricular rate; procainamide IV ibutilide for pharmacologic conversion
Atrial fibrillation	May appear to be regular at more rapid rates. Distinguish from multifocal atrial tachycardia by lack of defined atrial activity	Intravenous diltiazem, verapamil, esmolol, and/or metoprolol or amiodarone to slow ventricular response (if necessary). Direct current cardioversion if an accessory pathway is known or suspected and ventricular response is rapid
Junctional tachycardia	No variation in rate with respiration, exercise. Distinguish from sinus tachycardia with long PR interval or ventricular tachycardia (if QRS complex is wide). May be due to digitalis toxicity	If rate is rapid, β blockade, physostigmine,* pace termination; direct current cardioversion
Ventricular ectopy (couplets, triplets, multiform complexes, sustained tachycardia, fibrillation)	If due to membrane-depressant drugs, other drugs in this class are to be avoided. If due to bradycardia, increase basic rate	IV lidocaine, β blockade, isoproterenol, magnesium, and/or cardiac pacing if due to bradycardia or associated with long QT. Direct current cardioversion or defibrillation. Procainamide IV if sustained monomorphic ventricular tachycardia in ischemic setting. IV amiodarone if hemodynamically destabilizing rapid ventricular tachycardia
Bradyarrhythmias		
Sinus bradycardia, including sinus arrest, sinoatrial block, and vagotonic bradycardia		No specific therapy. If hemodynamic decompensation, IV atropine, isoproterenol, cardiac pacing
Vagotonic AV block	AV block with varying PR intervals is associated with slowing of sinus rates. Seen in states with high vagal tone, including sleep and specific situations such as suctioning or endoscopy	No specific therapy. Atropine, oral theophylline, if sustained. Note: Atropine should not be administered if vagotonic rhythm is a reflex response to drug-induced hypertension, because it will aggravate the hypertension
AV block type I (Wenckebach)		If hemodynamic compromise, atropine, IV isoproterenol, cardiac pacing
Type II (Mobitz II) high-degree or complete block	If atrial rate is increased by atropine or isoproterenol, increase in degree of AV block may occur	Cardiac pacing

AV, atrioventricular; IV, intravenous.

*May be hazardous if associated with membrane-depressant drug overdose.

procainamide and disopyramide are contraindicated. Selection of secondary drugs depends on the particular overdose; thus, benzodiazepines and a β_1 blocker might be indicated for sympathomimetic drug overdose, magnesium or digitalis antibodies for digitalis overdose, and high dose magnesium (1 to 2 g over 1 to 2 minutes) and overdrive pacing or isoproterenol for polymorphous ventricular tachycardia with a long QT interval (torsades de pointes).⁵ Sustained ventricular tachycardia and fibrillation require electrical conversion or defibrillation; intravenous administration of amiodarone can be used to attempt to prevent recurrence.

WIDE COMPLEX TACHYCARDIA OF UNCERTAIN ORIGIN

The ECG occasionally shows a regular wide complex QRS rhythm without readily discernible atrial activity; the origin of the QRS rhythm may thus be uncertain. Rate alone is not a useful criterion in distinguishing ventricular tachycardia from supraventricular tachycardia with intraventricular aberration, especially in a patient suffering from a drug overdose. QRS morphology, on the other hand, can be helpful. Ventricular tachycardia is suggested by very bizarre QRS complexes; superior deviation of the mean frontal plane QRS axis; qR, RR', or R waves in leads aVr and V₁; rS or QS in leads aVL and V₆; or concordance (similarity) of QRS morphology in the precordial leads. Supraventricular tachycardia with intraventricular aberration is suggested by QRS morphology that closely resembles typical bundle branch block patterns. Past ECGs with which to compare current ones may be helpful if they have shown a previously present bundle branch block pattern or ventricular premature complexes that resemble the present rhythm (Fig. 8-5).

The relationship of ventricular to atrial activity may afford another clue to the origin of the QRS rhythm. Establishing this relationship when atrial activity is not easily seen on the surface ECG often requires placing an electrode catheter in the esophagus or right atrium to register atrial electrical signals. The simultaneous recording of a surface ECG lead and intracardiac or intraesophageal electrogram permits recognition of atrial activity. If this activity occurs independently of (is dissociated from) the regular ventricular rhythm, the QRS rhythm is almost certainly ventricular tachycardia. If atrial activity occurs irregularly at rates faster than the regular ventricular rhythm, the rhythm is atrial fibrillation. Atrial activity that is dissociated from the regular ventricular rhythm suggests a junctional or ventricular tachycardia. If atrial activity occurs at a rate that is a multiple of the QRS rate, atrial flutter or atrial tachycardia with some degree of block is suggested. If a 1:1 relationship between atrial and ventricular activity is demonstrated, the direction of impulse transmission (AV or ventriculoatrial) is not known; only by changing the conduction ratios may the correct diagnosis be made. For example, if carotid sinus massage is applied in a patient with regular wide complex tachycardia and 1:1 AV relationship and ventricular asystole occurs despite persistence of atrial activity, the rhythm was supraventricular in origin (Fig. 8-6). Some patients with hyperkalemia have a wide QRS complex rhythm without discernible P waves, in which the QRS complexes are nevertheless stimulated via the His-Purkinje system by the sinus node. This rhythm is termed *sinoventricular conduction*. The absence of P waves is due to hyperkalemia-related atrial arrest, and treatment of the hyperkalemia results in restoration of atrial muscle depolarization and appearance of P waves.

FIGURE 8-5 These lead I rhythm strips were obtained from a 40-year-old woman who ingested 6 g of amitriptyline (Elavil). In **A**, the rhythm is sinus with a long PR interval. In strips **B** and **C**, recorded within a 20-minute period, no P waves are seen and the QRS complexes are broad and bizarre. Close scrutiny reveals that the QRS complexes in strips **B** and **C** resemble those in strip **A** except that they are more aberrant. The value of previously recorded tracings when evaluating a wide complex tachycardia, as in strip **C**, is illustrated by these electrocardiograms.

Management of hemodynamically significant wide complex tachycardia while the diagnosis is being established should include carotid sinus massage as a readily applied initial maneuver but should be directed toward the potentially most life-threatening arrhythmia. Thus, intravenous lidocaine should be used for presumed ventricular tachycardia as the agent of first choice. When the nature of the overdose is unknown, however, electrical cardioversion may be the procedure of choice to avoid compounding the problem of arrhythmia and hemodynamic instability, provided there is reasonable certainty that the rhythm is not sinus in origin. Failure to convert a wide complex tachycardia to another rhythm after direct current cardioversion should suggest that sinus tachycardia may indeed be present. Certain antiarrhythmic agents, notably flecainide, can cause monomorphic ventricular tachycardia refractory to cardioversion attempts. Amiodarone, although not well studied in the context of toxicologic emergencies, may be used for refractory ventricular arrhythmias.

Surface lead V₁

Intracardiac electrogram

Intracardiac electrogram during carotid sinus massage

FIGURE 8-6 The patient is a 67-year-old man with chronic obstructive pulmonary disease. He developed tachycardia during treatment with aminophylline. The surface electrocardiographic V₁ lead (*top*) shows a QRS duration of 0.12 seconds and no clearly discerned atrial activity. Intracardiac electrography (*middle*) reveals a 1:1 relationship between ventricular (the broad, large deflections) and atrial (the sharp, small deflections) activity. The direction of impulse transmission is not known. Carotid sinus massage (*bottom*) shows no change in atrial activity, whereas ventricular response is blocked, probably at the AV node. The change in the AV conduction ratio produced by carotid massage allows the diagnosis of atrial tachycardia to be made.

BRADYARRHYTHMIAS

Bradyarrhythmias, particularly AV block, may occur unpredictably and may require temporary transvenous cardiac pacing. Before pacemaker insertion, transcutaneous pacing and pharmacologic therapy may be necessary in an attempt to maintain heart rate, blood pressure, and cardiac output. Intravenous administration of atropine should be tried to treat sinus or junctional bradycardia, except if hypertension is present (reflex bradycardia); intravenous administration of isoproterenol may be used for unresponsive sinus or junctional or ventricular bradycardias. These agents should be used with caution, however, because both may cause significant sinus or junctional tachycardia, and isoproterenol may cause ventricular extrasystolic activity, including ventricular tachycardia. If the bradycardia is corrected but the hypotension is persistent, inotropic agents and toxin-specific agents should be used (e.g., glucagon for β -blocker poisoning).

CARDIAC PACING IN DRUG OVERDOSE

Pacemaker-related difficulties encountered in drug-overdosed patients may be related to inability to sense a suboptimal intracardiac signal or to capture (depolarize) the atria or ventricles. To be sensed properly by a pacemaker generator, an intracardiac signal must have certain characteristics: adequate amplitude, rapid rate of change of voltage, and optimal signal duration. In patients overdosed with agents that alter impulse conduction or cause or contribute to myocardial ischemia or failure, the intracardiac signal often is of too poor a quality to be sensed, leading to improper demand pacemaker function. The resulting earlier-than-expected pacing stimulus that follows unsensed spontaneous beats may cause repetitive atrial or ventricular rhythms, including ventricular tachycardia and fibrillation.

Another problem encountered in drug-overdosed patients is failure of the pacing stimulus to depolarize sufficient amounts of myocardial tissue to cause ventricular activation, resulting in failure to pace. This can come

about as a result of myocardial intercellular or intracellular edema or as a result of failure of pacing stimulus propagation throughout the muscle due to hyperkalemia, hypoxia, acidosis, or membrane-depressant agents. The failure to pace may be total, with all pacing stimuli failing to depolarize the ventricles, or intermittent, in which various degrees of pacemaker exit block may occur, including Wenckebach-type conduction (Fig. 8-7).

Because transcutaneous pacing is not effective over time, it should not be used except in emergencies and should be followed by transvenous pacing to ensure stable heart rate support.

Some patients in whom failure to pace is life threatening may require cardiopulmonary bypass or intra-aortic balloon (triggering off the pacing stimulus) support to maintain circulatory function.

PULMONARY EDEMA

Pulmonary edema frequently complicates overdose with drugs such as narcotics, sedatives/hypnotics, salicylates, and sympathomimetic agents. Acute inhalational non-cardiogenic pulmonary edema can be caused by smoke, ammonia, chlorine, nitrous oxide, and phosgene. The pathophysiology of drug-induced pulmonary edema involves increased pulmonary capillary permeability, as evidenced by normal or low pulmonary capillary wedge pressures and pulmonary edema fluid with a protein concentration similar to that of plasma. In contrast, cardiogenic pulmonary edema is characterized by increased capillary hydrostatic pressure and pulmonary wedge pressures of greater than 20 mm Hg.

The mechanisms by which sedative-hypnotic drugs produce capillary endothelial damage are not fully understood. Depression of respiration may lead to hypoxemia, precapillary pulmonary hypertension, increased vascular permeability, and, finally, extravasation of fluid. An analogy has been made to cases of pulmonary edema at high altitude, in which hypoxia

FIGURE 8-7 The patient was a 76-year-old man who had chronic congestive heart failure, recurrent ventricular tachycardia for which he was being treated with procainamide, paroxysmal AV block for which a transvenous pacing system had been implanted, and renal failure. He was admitted to the hospital with acute pulmonary edema. His serum potassium level was 5.0 mEq/L, and his serum procainamide level was 19 ng/mL. The *top* MCL₁ rhythm strip shows a paced QRS rhythm with extremely wide QRS complexes; atrial activity is not discerned. The *bottom two* continuous MCL₁ rhythm strips, recorded shortly after the top strip, show episodic failure of ventricular capture by the pacing stimuli, with a pattern suggesting Wenckebach's block of the pacing stimuli. Because there was no evidence of pacemaker generator malfunction, the failure to capture in this clinical setting was considered to result from myocardial stimulation threshold elevation and failure of impulse conduction owing to the membrane-depressant effects of the procainamide. Treatment with low-dose isoproterenol and intravenous steroids was without effect, and the patient died.

produces a similar picture, which is rapidly reversed by oxygen therapy. Ethchlorvynol, when injected intravenously, is an example of a drug that directly injures the alveolocapillary membrane. Infused salicylate, possibly by effects on prostaglandin synthesis, increases microvascular permeability. Pulsatile lymphatic activity is reduced and lymphatic drainage is retarded during barbiturate anesthesia. This also might contribute to the net accumulation of fluid in the lungs after drug overdose.

Neurogenic pulmonary edema, possibly mediated by massive sympathetic discharge, has been well described after brain injury and has been suggested to occur after overdoses of drugs such as narcotics and salicylates. Sympathomimetic drugs can cause pulmonary edema owing to severe hypertension and diastolic noncompliance. This is most common after intravenous administration. By the time such a patient is evaluated by a physician, blood pressure may be normal or even low, with evidence of hypovolemia due to sequestration of fluid into the lungs and other extravascular sites. Direct depression of myocardial function by drugs may aggravate pulmonary edema caused by pulmonary capillary damage or, in the context of fluid therapy for hypotension, may result in cardiogenic pulmonary edema in the absence of pulmonary capillary damage.

Drug-induced pulmonary edema can be present on admission or may develop subsequently during the clinical course; in either case, it complicates management of shock states. Fluid filtration into the lungs depends in part on pulmonary capillary pressure and, therefore, on left atrial pressure. A difficult clinical situation may arise in which intracardiac filling pressures adequate to maintain cardiac output may result in pulmonary transudation. Suggestions about fluid therapy

and the use of pulmonary capillary wedge pressures have been discussed. Diuretics may not be effective in treating drug-induced pulmonary edema because filling pressures are already normal or low, and further diuresis can potentiate hypotension. Infusions of albumin have been proposed to increase plasma oncotic pressure and to draw fluid from the lungs. This is not useful because the protein content of the edema fluid is of similar composition to that of plasma, and this indicates that albumin passes through vascular endothelium as freely as water.

Mechanical ventilation with positive end-expiratory pressure is an important tool used in the management of drug-induced pulmonary edema. Positive end-expiratory pressure increases functional residual capacity, reduces intrapulmonary shunting, and increases pulmonary compliance. Supplemental oxygen usually is necessary to maintain arterial oxygen tension at 60 to 70 mm Hg. Placing the patient in the prone position and using inverse ratio ventilation may improve ventilation-perfusion mismatches and oxygenation, respectively. The ventilatory technique of high-frequency oscillatory ventilation maximizes gas exchange while minimizing the complication of barotrauma.⁶

RECOGNITION AND MANAGEMENT OF CARDIAC DISTURBANCES CAUSED BY SPECIFIC DRUGS

Sedative-Hypnotic Drugs

PATHOPHYSIOLOGY

Sedative-hypnotic drugs are involved in many cases of drug overdose. Although cardiac complications per se

are uncommon, it is important to understand how this class of drugs might influence cardiovascular disturbances caused by coingested drugs. The major action of sedative-hypnotic drugs is on the CNS and results in reduced sympathetic and increased parasympathetic peripheral autonomic tone. Barbiturates have been shown to depress myocardial function in animals, but severe myocardial depression is uncommon in humans. Cardiac output is commonly reduced because of relative hypovolemia caused by increased venous capacitance and absolute hypovolemia due to fluid loss into tissues, the latter a consequence of increased vascular permeability.⁷ Cardiac output and heart rate may be lower than normal as a result of hypothermia and reduced metabolic demands. As a consequence of inhibition of sympathetic function, heart rate frequently is less than expected for the degree of hypotension.

An important complication of sedative-hypnotic drug overdose is pulmonary edema, which results from increased pulmonary vascular permeability, as just discussed. As a consequence, hypoxia and metabolic acidosis develop, and they may worsen myocardial performance and potentiate arrhythmias.

The management of hypotension and shock due to sedative-hypnotic overdose includes judicious use of fluids and pressor drugs. Because venous pooling contributes to reduced cardiac output, the Trendelenburg position (head down, legs up) may substantially increase venous return, cardiac output, and blood pressure. Infusion of modest amounts of colloid or crystalloid fluids is sufficient to correct hypovolemia and to increase cardiac output and tissue perfusion to adequate levels in many patients. Failure to achieve adequate tissue perfusion despite increased cardiac filling pressure or evidence of pulmonary edema is an indication for the use of pressor drugs, as discussed.

Sympathomimetics

GENERAL CONSIDERATIONS

Sympathetic overactivity can be caused by a number of drugs and toxins, as well as by sedative-drug withdrawal syndromes (Box 8-1). The typical manifestations are sinus or atrial tachycardia (Fig. 8-8), hypertension, seizures, hyperthermia, and, in massive ingestions, cardiovascular collapse and respiratory failure. Occasionally, ventricular irritability and, rarely, ventricular fibrillation with death are observed.

Cocaine

Cocaine is a potent sympathomimetic drug that is well known for its cardiovascular complications. It is abused for its euphoric effects but tolerance to CNS effects develops rapidly. Thus, the duration of euphoria is much shorter than the presence of the drug in the body. Repeated doses may result in accumulation of drug and cardiovascular toxicity at a time when the user exhibits neither euphoria nor a sympathomimetic toxidrome.

Cocaine is a potent inhibitor of neuronal catecholamine uptake, which is a major mechanism of limiting the action of norepinephrine. In addition to its

^{||}Phencyclidine, alcohols, and solvents may cause ataxia, lethargy, or coma.

potent sympathomimetic action, in high doses cocaine blocks fast sodium channels in the myocardium; the result is depression of depolarization and slowing of conduction velocity. This is manifested on ECG as prolonged PR, QRS, and QT intervals, similar to that seen with type IA antiarrhythmics.⁸

Other effects of cocaine include coronary artery vasoconstriction that is mediated by α -adrenergic stimulation and possibly by release of endothelium-derived vasoconstrictors, such as endothelin.⁹ A procoagulant effect of cocaine may predispose to in situ coronary artery thrombosis. The sympathomimetic effects of cocaine lead to increased myocardial oxygen demand and, in context of both the procoagulant effect and vasoconstriction, may result in myocardial ischemia, acute myocardial infarction, and arrhythmias.¹⁰

FIGURE 8-8 The patient, a 27-year-old cocaine user, was admitted to the coronary care unit for electrocardiographic monitoring after having had two syncopal spells. The MCL₁ rhythm strip shows bursts of atrial tachycardia, which terminate spontaneously, and atrial premature beats, some of which are not conducted.

Long-term cocaine use has been associated with left ventricular hypertrophy and diastolic dysfunction, systolic dysfunction, and dilated cardiomyopathy. Patchy myocardial necrosis with contraction band necrosis has been observed at autopsy and is believed to be the result of intense catecholamine stimulation of the heart. Arrhythmogenesis is thought to occur secondary to sympathomimetic activity and sodium channel blockade in the presence of myocardial ischemia, metabolic derangements, and anatomic abnormalities, as described earlier.

Management depends on specific manifestations of toxicity (Table 8-2). Hypertension is typically managed with benzodiazepines and vasodilators such as nitroglycerin and nitroprusside. Phentolamine, an α -antagonist, also can be used to counteract the vasoconstriction. Arrhythmias result primarily from β -adrenergic stimulation. β_1 -specific blockers, such as esmolol or metoprolol, should be selected rather than nonselective β blockers to avoid antagonizing the β_2 -mediated arteriolar dilation that may be opposing the α -mediated vasoconstriction. Nonselective β_2 blockade can worsen the hypertension. If the arrhythmia is a wide complex tachycardia, sodium bicarbonate should be used to counteract the sodium channel blockade effect of cocaine. Lidocaine also has been used safely in this context. Other type I antiarrhythmic drugs should be avoided.

Myocardial ischemia and infarction are important manifestations of cocaine toxicity. Treatment should

include oxygen, aspirin, nitrates, and benzodiazepines. Because vasospasm is a mechanism of myocardial ischemia in this context, calcium channel blockers should be used. Other treatment options for coronary vasoconstriction include phentolamine and labetalol (the latter in the presence of tachycardia). Propranolol should be avoided because of the potential harmful effects of β_2 blockade, as discussed previously. The decision to administer fibrinolytics in cocaine intoxication requires extreme caution because of the risk of hypertension-related complications (i.e., cerebral hemorrhage), associated trauma, and high frequency of misleading ECGs. Early repolarization variant (J point and ST elevation) is a common cause of abnormal ECG in young patients with cocaine-associated chest pain. If available, coronary angiography and revascularization with angioplasty, if required, is the preferred method of treatment of cocaine-induced acute myocardial infarction. If this is unavailable, and the patient has classic symptoms and signs of acute myocardial infarction and no contraindications, fibrinolytics can be given.

Hyperthermia results from increased muscular activity due to agitation, seizures (increasing heat generation), and intense vasoconstriction (impairing heat dissipation).¹¹ Immediate cooling and sedation are necessary to reduce morbidity and mortality. First-line agents are benzodiazepines, which treat both agitation and seizures. Haloperidol and other dopamine antagonists should be avoided because they may lower the seizure threshold,

TABLE 8-2 Treatment of Cardiovascular Complications of Sympathomimetic Drug Poisoning

MANIFESTATIONS	TREATMENT
Tachyarrhythmias	Reduce environmental stimulation,* benzodiazepines
Sinus or atrial	None, metoprolol, esmolol, verapamil, diltiazem
Ventricular	Metoprolol, lidocaine, cardioversion
Hypertension	Reduce environmental stimulation,* benzodiazepines Phentolamine Nitroprusside β blocker (β_1 -specific if possible) if associated with tachycardia
Convulsions	Lorazepam, diazepam, phenytoin, phenobarbital
Hyperthermia	Stop seizures Pancuronium if seizures uncontrollable External cooling High inspired oxygen
Myocardial ischemia/infarction	Nitrates, calcium channel blockers, thrombolysis-esmolol/metoprolol
Cardiovascular collapse	Fluids (may require massive amounts in presence of hyperthermia) Pressors (unpredictable sensitivity)

*Especially phencyclidine and hydrocarbons.

further impair heat dissipation and/or potentiate cardiac arrhythmias.⁸ External cooling measures and paralysis to reduce heat generation may be necessary to control hyperthermia. Even when muscle hyperactivity is prevented by paralysis, persistent seizure activity may cause brain injury. Therefore, electroencephalograms should be used to monitor paralyzed patients, and seizures should be controlled with anticonvulsant drugs or general anesthesia, if necessary. Ventilation with high oxygen concentrations is indicated in hyperthermia to meet the resultant extreme metabolic demands on organ systems. Acute renal failure may result from hypovolemia, hypotension, and rhabdomyolysis with myoglobinuria and may be prevented by vigorous fluid replacement, alkalization of the urine, and, possibly, the use of mannitol.

Amphetamine-Like Drugs and Over-the-Counter Products

Many amphetamine-like drugs, such as ephedrine (ma huang) and related alkaloids, are available without prescription as herbal products advertised for their weight loss and athletic performance-enhancing effects. Caffeine usually is present in these supplements and may increase the risk of adverse cardiovascular events due to potentiation of sympathomimetic effects of ephedrine. Over-the-counter medications, such as decongestants, often contain sympathomimetic agents (phenylephrine, pseudoephedrine, or ephedrine) that have the potential to cause adverse cardiovascular events. Phenylpropanolamine, which has a direct agonist effect on α -adrenergic receptors, has been removed from the U.S. market due to its association with hemorrhagic stroke in previously healthy young women.¹² Illicitly obtained amphetamines (methamphetamine, 3,4-methylenedioxymethamphetamine/MDMA) and their derivatives are widely abused for their euphoric effects. The euphoria is associated with CNS and adrenomedullary sympathetic activation, producing the sympathomimetic toxidrome. Chronic use can lead to dilated cardiomyopathy, and these patients may present in frank congestive heart failure.¹³

Amphetamines displace and release catecholamines stored in neurons, directly stimulate postsynaptic adrenergic receptors, and may inhibit monoamine oxidase, the enzyme responsible for intraneuronal degradation of catecholamines. As a result of these actions, adverse cardiovascular events have been reported in temporal association with the use of amphetamines and amphetamine-like substances. These effects include acute myocardial infarction, severe hypertension, myocarditis, and lethal cardiac arrhythmias.¹⁴ Other amphetamine-induced effects include cerebrovascular events, seizures, hyperthermia, and rhabdomyolysis. The management of amphetamine toxicity is similar to that discussed in the section on cocaine toxicity, as both the pathophysiology and manifestations of amphetamine toxicity are similar to that of cocaine (see Table 8-2).

Monoamine Oxidase Inhibitors

Clinical manifestations of monoamine oxidase (MAO) inhibitor toxicity resemble those of other sympathomimetic drugs: restlessness, hyperactivity, confusion or

stupor, neuromuscular irritability, hypertension, seizures, and hyperpyrexia. Hypertension, which most often occurs after ingestion of tyramine-containing foods or beverages or after taking other sympathomimetic drugs but can also occur after an overdose, may be severe, often is associated with severe headache, and has been associated with intracerebral hemorrhage. Hypotension also can occur after overdose.

Understanding the pathophysiology of MAO inhibitor reactions requires understanding of the role of MAO in the body. MAO is located within adrenergic neurons, where it metabolizes catecholamines and related monoamines, and in the gastrointestinal mucosa and liver, where it metabolizes dietary monoamines, such as tyramine. Inhibition of MAO within the adrenergic neuron results in accumulation of both active and relatively inactive (such as octopamine) monoamines. Octopamine and other relatively inactive monoamines act as false neurotransmitters in that they are released by neuronal stimulation into nerve endings, where they do not effectively activate vascular receptors. As a consequence, MAO inhibitors, when taken continually, may lower blood pressure. However, MAO inhibitors, by slowing monoamine metabolism, also may increase pressor responses to catecholamines released by other drugs. Most important in causing hypertension is that MAO inhibitors in the gut and liver increase the bioavailability of tyramine, which in turn releases catecholamines stored in adrenergic neurons. Ingestion of foods rich in tyramine can lead to massive catecholamine release and hypertensive crisis.¹⁵

Tranylcypromine is an MAO inhibitor that causes catecholamine release itself and, among the MAO inhibitor class of drugs, has been implicated most commonly in cardiovascular toxicity. The newer, selective MAO inhibitors have less potential to cause hypertensive crises due to drug interactions or tyramine-containing foods. However, severe adverse effects have been described with moclobemide, a reversible inhibitor of MAO-A and selegiline, an irreversible MAO-B inhibitor.¹⁶ It is important also to recognize the potential interaction between meperidine and MAO inhibitors. The combination has resulted in severe hypertension, hyperthermia, and seizures. The mechanism is thought to be related to excess serotonin effect in the brain. Therapy for MAO toxicity is similar to that of other sympathomimetic drugs.

Serotonin reuptake inhibitors (e.g., fluoxetine) do not cause direct cardiovascular toxicity but do interact with MAO inhibitors and other serotonergic medications to produce the so-called serotonin syndrome. This syndrome is associated with confusion, fever, diaphoresis, hyperreflexia, and myoclonus and usually is self-limited with supportive care.¹⁷

Theophylline and Caffeine

Cardiac toxicity of theophylline occurs in a different context from that of stimulant drugs. The most common circumstance is overdosage during therapy for obstructive airway disease, often as a result of hepatic dysfunction, which reduces the rate of theophylline metabolism. Accidental or suicidal overdose occurs often in persons

with underlying medical illnesses. The nature and severity of these medical conditions have a strong impact on the course and severity of cardiac toxicity.

The typical cardiovascular manifestations of theophylline overdose result from β -adrenergic stimulation and include tachycardia and arrhythmias (Fig. 8-9). Hypotension (rather than hypertension, as occurs with most other sympathomimetic drugs) is encountered in severe intoxications. Like amphetamines, theophylline causes systemic and local vascular catecholamine release. In addition, theophylline at high concentrations may inhibit phosphodiesterase, an enzyme that degrades intracellular cyclic adenosine monophosphate (cAMP), which, in turn, mediates β -adrenergic actions. Theophylline also directly relaxes vascular smooth muscle and acts as an adenosine antagonist. Convulsions typically occur with an overdose, and cardiac and respiratory arrest are the usual causes of death.

Management of cardiac toxicity due to theophylline ingestion in persons with chronic lung disease may be difficult. β -Adrenergic blocking agents are logical and effective treatment for supraventricular and ventricular arrhythmias, but they also may worsen airway obstruction. Relatively cardio-specific β blockers, such as esmolol or metoprolol, can be tried and the antiarrhythmic effects closely titrated against evidence of worsening airway obstruction. Esmolol is useful particularly in this instance because of its short half-life.¹⁸

Hypotension due to theophylline use usually results from peripheral vasodilation, at least early in the course of overdose. However, with prolonged β -sympathetic stimulation (many hours or even days), myocarditis with reduced ventricular function may occur late in the course of theophylline overdose. In addition, many older patients with chronic lung disease have ischemic heart

disease. Extreme tachycardia (150 to 180 beats per minute, depending on myocardial function) and hypotension may reduce cardiac output and therefore myocardial perfusion, resulting in impaired myocardial function.

Management of theophylline-induced hypotension includes correction of metabolic disturbances and arrhythmias and administration of fluids and pressor agents. If pressor drugs are to be used, it is useful to know the cardiac output and to be able to compute the systemic vascular resistance. If cardiac output is high and systemic vascular resistance is low, as in many cases of theophylline overdose, administration of vasoconstrictors such as norepinephrine and selective β -adrenergic antagonists, such as esmolol or metoprolol, are indicated. If cardiac output is low despite adequate cardiac filling pressures and systemic vascular resistance is normal or high as sometimes occurs late in the case of theophylline overdose and in persons with preexisting myocardial disease, inotropic agents such as dobutamine might be selected.

In the presence of severe toxicity, particularly in a patient with serious underlying medical disease, the persistence of theophylline in the body and the time course of toxicity may be prolonged (≥ 24 hours), and acceleration of drug removal by hemoperfusion should be undertaken.¹⁹

Caffeine is widely consumed in beverages such as coffee and colas, in over-the-counter stimulants, and in various other combination analgesic and cold medications. Caffeine has pharmacologic actions similar to those of theophylline. Caffeine potentiates the effects of sympathomimetic drugs and might contribute to stimulant-induced adverse cardiac events. For example, ephedra-containing dietary supplements often contain

FIGURE 8-9 A 56-year-old female ingested an unknown amount of theophylline in a suicide attempt. She presented in atrial fibrillation with rapid ventricular rate (180 beats per minute) and a blood pressure of 60 mm Hg. She was treated successfully with esmolol, which immediately slowed the heart rate and increased the blood pressure. The initial theophylline level was 125 mg/L, which was treated with multiple-dose activated charcoal. Dialysis was recommended but was not performed, because the second level 4 hours later was 78 mg/L. Serial cardiac enzymes revealed an elevated troponin level, indicating myocardial injury as a complication. The patient recovered uneventfully thereafter.

caffeine as well. Caffeine alone rarely causes severe cardiac toxicity, although cases of supraventricular tachycardias are reported. Patients with ischemic heart disease and preexisting ventricular arrhythmias may be particularly susceptible to these adverse events.¹³ Severe caffeine intoxication with tachyarrhythmias followed by cardiovascular collapse and death has occurred in children. We treated an adult who had ingested a massive amount of caffeine (NoDoz) and who had sinus tachycardia with a rate of 190 beats per minute, hypokalemia, hyperglycemia, metabolic acidosis, and rhabdomyolysis (Fig. 8-10).

Δ^9 -Tetrahydrocannabinol and Hallucinogens

The usual cardiovascular effects of Δ^9 -tetrahydrocannabinol (THC), the principal psychoactive component in marijuana and other cannabis products, are tachycardia,

a slight increase in recumbent blood pressure, and, with large doses or in susceptible persons, orthostatic hypotension. THC acts on widely distributed cannabinoid receptors and endocannabinoid systems. The effects of THC on heart rate result from centrally mediated sympathetic activation and reduced parasympathetic activity and systemic release of catecholamines. Orthostatic hypotension results from impaired sympathetic reflex responses and, in particular, deficient venoconstriction.

Sinus tachycardia can reach rates of 140 to 150 beats per minute or higher and, manifested as palpitations, can contribute to the anxiety reaction occasionally reported by novice users or those consuming marijuana containing unusually large amounts of THC. In otherwise healthy persons, no specific treatment other than reassurance is necessary. Patients with ischemic

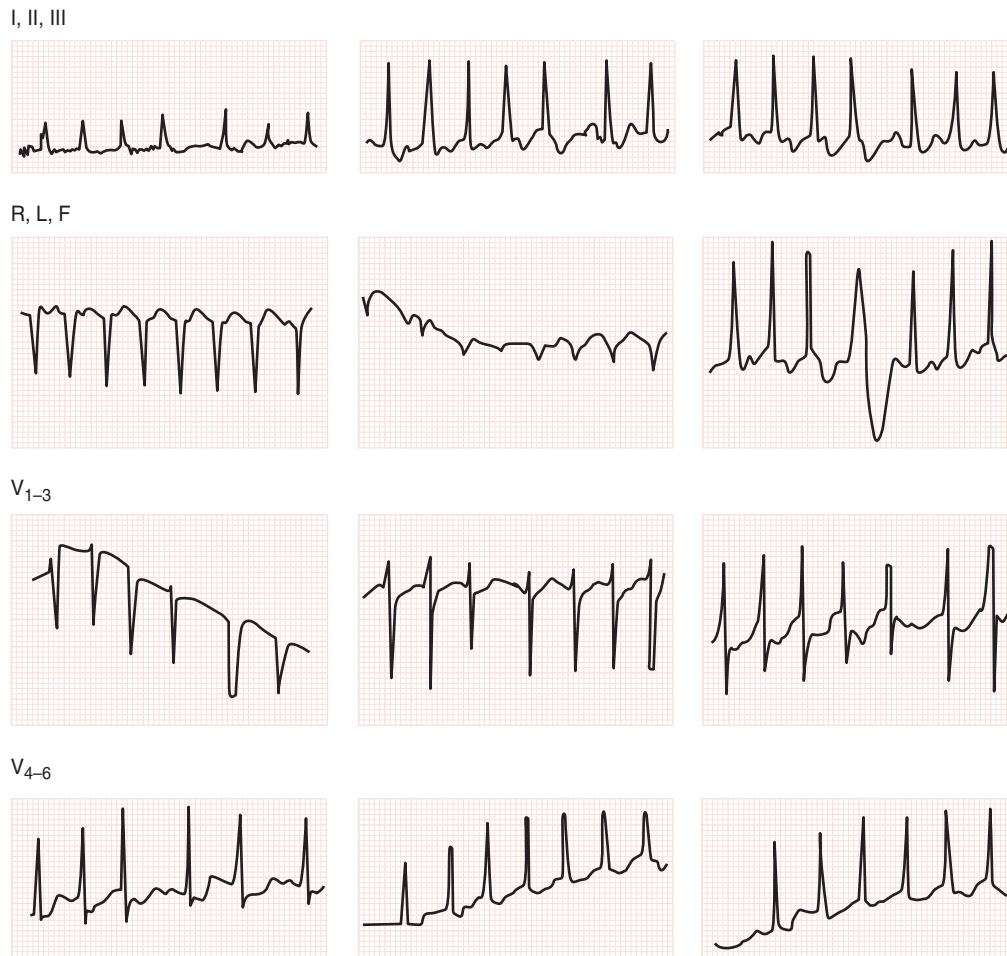

FIGURE 8-10 The patient is a 30-year-old schizophrenic woman who allegedly ingested the contents of four bottles of the over-the-counter preparation NoDoz, each containing 60 100-mg caffeine tablets. She was brought to the emergency room awake but mute and apparently hallucinating. Blood pressure was 112/74 mm Hg; heart rate, 180 to 200 beats per minute; serum potassium level, 2.2 mEq/L; and serum caffeine level, 200 μ g/mL.

This admission electrocardiogram shows a supraventricular tachycardia at a rate of about 180 to 190/min. The tachycardia is probably sinus in origin, judging from the P wave configurations. AV nodal Wenckebach's block is present and probably the result of the tachycardia rate (and the inability of the AV node to respond) rather than of the pharmacologic effects of caffeine. Ventricular ectopic complexes also are present.

The patient was treated with potassium and fluids, with prompt initial slowing of the sinus rate to 150 beats per minute, then with gradual return to normal during the next 48 hours.

heart disease are at greater risk from the effects of THC, although myocardial infarction is a rare occurrence. The combination of increased myocardial oxygen demand due to the tachycardia and increased myocardial contractility as well as decreased myocardial oxygen delivery due to effects of carbon monoxide derived from marijuana smoke may aggravate the ischemia. Persons with angina pectoris are not able to exercise as long after smoking marijuana. Ischemia combined with systemic release of catecholamines also might result in potentially severe arrhythmias. Orthostatic dizziness occasionally is reported by recreational users of cannabis, particularly after eating larger than usual quantities of THC in cookies or brownies. Patients receiving THC as an adjunct to cancer chemotherapy may exhibit orthostatic hypotension, particularly when they are dehydrated because of their disease. Hypotension responds well to placing the patient into a horizontal or Trendelenburg position and administering fluids; administration of pressors is rarely necessary.²⁰

Lysergic acid diethylamide, phenylcyclidine, psilocybin, and other hallucinogens commonly result in tachycardia and mild hypertension as part of a general sympathetic arousal syndrome. Cardiovascular disturbances rarely are serious and require only supportive care.

Ethanol

Chronically alcoholic patients with toxicologic problems are seen frequently in emergency departments. Chronic or acute cardiovascular disorders may appear as primary problems or may complicate other overdoses. Alcoholic cardiomyopathy consisting of cardiomegaly, ventricular chamber dilation, reduced myocardial contractility, and pathologic alterations in the heart muscle involving both ventricles can be diagnosed in patients in whom the sole causative agent is ethanol consumption of more than 80 g per day for 10 years or more. Alcoholic cardiomyopathy is a leading cause of nonischemic and nonhypertensive cardiomyopathy in the United States. It is a low output form of heart failure. In contrast, beriberi, which is due to thiamine deficiency, results in peripheral vasodilation and high output heart

failure. Alcoholic cardiomyopathy may result in low cardiac output, pulmonary congestion, diverse arrhythmias, or sudden death, and is treated medically like other types of congestive failure.¹³

Heavy binge drinkers may present with a sudden onset of arrhythmias, particularly atrial fibrillation or flutter with rapid ventricular response but also atrial or junctional tachycardia and ventricular arrhythmias (alcohol-induced atrial fibrillation has been termed *holiday heart*) (Fig. 8-11). The arrhythmias may be due to preclinical cardiomyopathy, electrolyte abnormalities (including deficiency of potassium, phosphate, or magnesium), or early stages of alcohol withdrawal.

Abstinence from ethanol (and other sedative drugs) may be associated with intense sympathetic hyperactivity, hypertension, and many types of tachyarrhythmias, usually supraventricular but also ventricular arrhythmias, and sudden death.

Lidocaine and β -adrenergic antagonists have been used to treat arrhythmias caused by ethanol. β blockers, verapamil, or diltiazem may be necessary to control the ventricular response rate in cases of alcohol-induced atrial fibrillation or flutter. Digoxin generally is not useful because it is not a direct AV nodal blocker. Alcohol-induced atrial fibrillation often is self-limited, resolving spontaneously in 24 to 36 hours. Metabolic disturbances, particularly hypokalemia, hypophosphatemia, and hypomagnesemia, common in alcoholic persons, may contribute to arrhythmias and should be corrected.

Hydrocarbon Solvents and Fluorocarbon Aerosols

An epidemic of sudden death was associated with widespread abuse of solvents by inhalation in the late 1960s. The reported prodrome to death was described as victims becoming increasingly excited or panicky after sniffing or inhaling the solvent, exercising, then collapsing. The presumed cause of death was ventricular fibrillation. Death by solvent abuse accounted for 12.2% of deaths reported to poison centers in 2000 in the 13- to 19-year-old age group.²¹ Recently, a case report described a witnessed arrest of a 15-year-old girl following inhalation of butane gas. Ventricular fibrillation was

FIGURE 8-11 These two continuous lead II rhythm strips were recorded in a 48-year-old alcoholic man admitted to the hospital after a syncopal spell preceded by palpitations. Sinus rhythm is interrupted by atrial tachycardia. Frequent premature ventricular complexes also are present, as well as bursts of ventricular tachycardia, which occasionally interrupt the atrial tachyarrhythmia. The rhythm was treated with intravenous lidocaine, which abolished the bursts of ventricular tachycardia but had no effect on the atrial arrhythmia. All arrhythmias resolved within 12 hours of admission. Work-up for organic heart disease was nondiagnostic, and 24-hour ambulatory electrocardiographic monitoring before hospital discharge failed to reveal any rhythm abnormalities.

documented by paramedics and treated with defibrillation and then epinephrine for the ensuing asystole. The patient survived the cardiac arrest but was left with significant neurologic impairment.²² Animal studies have shown that many solvents, such as toluene, benzene, chloroform, trichloroethane, trichloroethylene, trifluoroethane, and other fluoroalkenes (Freons), potentiate arrhythmias due to infused epinephrine. Thus, doses of epinephrine that usually produce no arrhythmias may cause ventricular tachycardia or fibrillation after solvent or fluorocarbon exposure. Solvent inhalation, even in the presence of normal oxygenation, may cause sinoatrial slowing followed by escape junctional or ventricular rhythms. The combination of depressed sinoatrial automaticity and myocardial sensitization to catecholamines, released by exercise or emotional stimuli, possibly accounts for the fatal ventricular arrhythmias. Toluene sniffing also causes renal tubular dysfunction as well as severe hypokalemia,²³ hypophosphatemia, and metabolic acidosis, which might aggravate arrhythmias. Ingestion of hydrocarbons typically is associated with a chemical pneumonitis and CNS depression; however, arrhythmias with ECG changes and elevation in cardiac enzymes suggestive of myocardial necrosis have been reported.

Obviously, little can be done to treat “sudden sniffing deaths.” However, in persons who are intoxicated with solvents or fluorocarbons, steps can be taken to lessen the risk of arrhythmias, at least according to the current hypothesis of pathogenesis. Before hospital evaluation, patients should be advised to avoid strenuous exercise. Once in hospital, they should be placed in a quiet, nonthreatening environment and sedated, if necessary. Sympathomimetic drugs such as pressors and bronchodilators should be avoided. Ventricular arrhythmias are best treated with β -blocking agents.

Sympathetic-Inhibiting Drugs

Cardiac disturbances caused by sympathetic-inhibiting drugs are listed in Box 8-2.

β -ADRENERGIC RECEPTOR BLOCKERS

Cardiac disturbances caused by β -adrenergic receptor blockers result from receptor blockade, which all drugs in this class demonstrate, and other actions such as membrane-depressant or sympathomimetic effects, which differ among drugs within the class. β -Adrenergic blockade itself is associated with AV block (usually first degree), sinus bradycardia, and the emergence of ectopic escape pacemakers in healthy hearts.²⁴ In persons with underlying cardiac conduction disease, advanced AV block with slow ventricular rates can occur. Occasionally, in the presence of severe underlying myocardial disease in which contractility depends on sympathetic activity, acute β -adrenergic receptor blockade can result in hypotension or cardiac failure, including shock or acute pulmonary edema and death. With gradual dose escalation, however, most patients with severe cardiac failure are able to tolerate β blockers with beneficial effects on mortality.

BOX 8-2

CARDIAC DISTURBANCES CAUSED BY SYMPATHETIC-INHIBITING DRUGS

Drugs

Propranolol and other β blockers
Methyldopa
Clonidine and other imidazoline derivatives
Reserpine

Small pupils[‡]
Diarrhea
Seizures[§]
Hyperkalemia
Bronchoconstriction^{||}

*Usually in patients with underlying myocardial disease.

[†]Except guanethidine and prazosin.

[‡]Particularly clonidine and prazosin.

[§]Propranolol and other membrane-depressant β blockers; rarely clonidine.

^{||}Usually in patients with previous asthma.

In previously healthy persons, drugs such as propranolol, with membrane-depressant effects, can in large doses directly depress myocardial function and result in hypotension caused by reduced cardiac output.²⁵ Drugs such as pindolol, with intrinsic sympathomimetic activity, can cause tachycardia and hypertension despite concurrent β -blockade after an overdose. Sotalol, a β blocker with type III antiarrhythmic activity, is associated with QT prolongation and the development of torsades de pointes. QT prolongation and arrhythmogenesis is dose related and occurs both with therapeutic dosing (especially in the presence of renal insufficiency) and in overdose.

Therapy is summarized in Table 8-3. Sinus bradycardia usually is well tolerated and requires no specific therapy. If sinus bradycardia results in hemodynamic compromise, atropine, glucagon, or temporary transvenous pacing should be considered. AV block resulting in hemodynamic compromise is an indication for temporary transvenous pacing, with dual-chamber preferred, if feasible.

Hypotension usually can be managed with fluids and correction of bradyarrhythmias. In the presence of myocardial depression, glucagon, which activates adenylate cyclase by a nonadrenergic mechanism, may enhance myocardial contractility and increase cardiac output.²⁶ Epinephrine, dobutamine, amrinone, and milrinone potentially are useful inotropic agents, although the doses may need to be higher than usual because of β blockade. Calcium chloride has been

TABLE 8-3 Treatment of Cardiovascular Complications of Sympathetic-Inhibiting Drug Poisoning

MANIFESTATION	TREATMENT
Bradyarrhythmias	None, glucagon,* atropine, pacing, isoproterenol
Sinus or atrial	Isoproterenol, pacing, glucagon*
Junctional and ventricular	Lidocaine
Ventricular tachyarrhythmias	Cardioversion
Hypotension	Trendelenburg's position
	Treat bradyarrhythmias if present

	Glucagon, dobutamine* (if normal or high systemic vascular resistance)
	Dopamine, norepinephrine (if low systemic vascular resistance)
Hypertension [†]	Phentolamine
	Nitroprusside

*Particularly when related to β -blocker overdose.

[†]Clonidine, methyldopa, guanethidine; note hypertension is often *transient* and is followed by hypotension.

reported to increase blood pressure after propranolol overdose that is unresponsive to other medications.²⁷

Sympatholytic Antihypertensive Drugs and Other Centrally Acting α_2 -Adrenergic Agonists

Clonidine is used in the treatment of hypertension, narcotic or alcohol withdrawal, perimenopausal hot flashes, and attention deficit hyperactivity disorder. Over-the-counter topical decongestants commonly contain imidazoline derivatives (naphazoline, tetrahydrozoline, oxymetazoline, and xylometazoline), which can cause systemic toxicity after either topical exposure or ingestion, particularly in children.

Most patients who have ingested excessive doses of sympatholytic antihypertensive drugs have sinus bradycardia and hypotension when first seen by a physician.²⁸ Drugs such as methyldopa, clonidine, and reserpine, which are active in the CNS, commonly cause sedation or coma. After an overdose of clonidine or imidazoline derivatives, miosis and respiratory depression resembling narcotic overdose also may ensue. However, hypotension and bradycardia usually are more prominent than respiratory depression after clonidine or imidazoline poisoning. The reverse is true for narcotics. Clonidine and imidazoline derivatives, by direct α -adrenergic receptor agonist activity, and methyldopa, reserpine, and guanethidine, through systemic release of catecholamines, also have been associated with transient and sometimes severe hypertension (Fig. 8-12)

Naloxone has been used in clonidine overdose with variable success and should not be relied on as the primary therapy for cardiovascular toxicity from this drug. Naloxone is recommended for cases of clonidine poisoning with severe respiratory depression and may be considered in patients with severe alteration of mental status and cardiovascular compromise. Naloxone use in topical imidazoline toxicity has not been studied.²⁹

In most cases, hypotension due to antihypertensive drug overdose is not severe and can be managed by the legs up, head down position and intravenous fluids.

When hypotension is severe in the presence of bradycardia, atropine or cardiac pacing increases heart rate and cardiac output and usually increases blood pressure. Although often not necessary, modest doses of dopamine and norepinephrine usually are effective. Hypertension resulting from use of clonidine or other sympatholytic drugs is best treated with the short-acting α -adrenergic receptor antagonist phentolamine and, if necessary, vasodilators such as nitroprusside. The hypertensive phase after clonidine overdose is relatively brief, and antihypertensive treatment should be tapered before the subsequent hypotensive effects become manifested.

Anticholinergic Drugs and Toxins

Cardiac disturbances caused by anticholinergic drugs and toxins are listed in Box 8-3.

The various anticholinergic drugs or toxins that may be ingested are too numerous to list separately. In most cases, they cause sinus tachycardia with mild hypertension. Serious arrhythmias resulting from purely anticholinergic compounds are uncommon unless a patient has underlying ischemic heart disease. For example, by increasing myocardial oxygen demand owing to tachycardia, atropine has caused ventricular tachycardia and fibrillation in patients after myocardial infarction. Many patients with anticholinergic signs have ingested antihistamine-sympathomimetic combinations or drugs such as tricyclic antidepressants or neuroleptics with both anticholinergic and membrane-depressant effects that result in more serious cardiovascular disturbances.

If treatment is necessary because of hypotension, organ ischemia, severe hypertension, or severe central anticholinergic syndrome (i.e., delirium, coma) due to use of anticholinergic drugs, the most specific therapy is administration of cholinesterase inhibitors. Physostigmine is used because it enters the brain and antagonizes the CNS and peripheral autonomic effects. Although benzodiazepines are used more commonly for treatment of agitation due to anticholinergic poisoning, physostigmine may be more effective and result in fewer

FIGURE 8-12 A 54-year-old man allegedly took an overdose of clonidine. Presenting vital signs included a pulse of 60 beats per minute and a blood pressure of 165/110 mm Hg. While in the emergency department, he complained of sudden onset of black spots in his visual field in association with this rhythm. He did not lose consciousness and his blood pressure remained in the normal range. The cardiac monitor revealed an irregular sinus bradycardia followed by sinus slowing and arrest accompanied by complete AV block. The occurrence of AV block with sinus slowing/arrest is described as “vagotonic AV block” and is consistent with both the sympatholytic and vagotonic effects of clonidine. The arrhythmia resolved spontaneously and did not recur.

*May have muscarinic as well as anticholinergic activity.

†Especially phenothiazines.

complications.³⁰ Alternatively, because anticholinergic drugs result in an imbalance between sympathetic and parasympathetic activity with a predominance of the former, β -blockers also may be effective in treating sinus and other supraventricular tachyarrhythmias. Both physostigmine and β -blockers may be hazardous when given to persons with depressed myocardial contractility; depressed AV conduction, such as after a tricyclic antidepressant overdose; or both (Fig. 8-13).

Cholinomimetic Toxins and Drugs

Cardiac disturbances and other common manifestations of poisoning by cholinomimetic drugs and toxins are listed in Box 8-4. The most common type of cholinomimetic poisoning is that due to exposure to organophosphate or carbamate insecticides resulting in excess cholinesterase inhibition.³¹ The cardiovascular effects of organophosphates are unpredictable and often change over the time course of the poisoning. Early in the course, acetylcholine stimulates nicotinic receptors at sympathetic ganglia and causes tachycardia and mild hypertension. Later it stimulates muscarinic receptors or blocks ganglionic transmission by hyperpolarization, and bradycardia and hypotension result. The most common cardiac finding in organophosphate poisoning is sinus tachycardia. In severe poisonings, however, advanced AV block, bradyarrhythmias with hypotension, and asystole may occur.

FIGURE 8-13 The strips in the *left panel* are from a 32-year-old man who had ingested 2300 mg of amitriptyline and who received physostigmine, 2 mg intravenously, for treatment of status epilepticus. Subsequently, junctional bradycardia developed and was unresponsive to atropine, and asystole occurred. Junctional rhythm was restored after treatment with epinephrine and bicarbonate. Sinus rhythm returned, the QRS narrowed during the next 12 hours, and the patient recovered fully.

The strips in the *right panel* are from a 25-year-old man who ingested 5000 mg of imipramine and 150 mg of propranolol. He received two doses of physostigmine, 2 mg intravenously, for recurrent motor seizures. After the second dose, sinus bradycardia developed and was unresponsive to atropine, and asystole occurred. After 10 minutes of closed chest cardiac massage and treatment with epinephrine and bicarbonate, sinus rhythm returned, although severe hypotension persisted. This patient's electrocardiogram results and blood pressure eventually became normal, but he died as a result of irreversible brain damage.

Delayed ventricular tachycardia of the torsades de pointes type may occur as late as 5 days after acute intoxication with organophosphates. The mechanism is believed to be a persistent imbalance between sympathetic and parasympathetic influences on the heart. The result is nonhomogeneous repolarization (associated with a long QT interval) and a predisposition to ventricular arrhythmias.

Bradyarrhythmias, if hemodynamically significant, usually can be treated effectively by administration of atropine or glycopyrrolate. Atropine or glycopyrrolate must compete with excess acetylcholine at the receptor

 Abdominal cramps
 Diarrhea
 Fasciculations
 Convulsions
 Muscle weakness and paralysis
 Respiratory failure

*May be seen in the early stages of cholinesterase inhibition and nicotine poisoning due to ganglionic stimulation.

†May be delayed up to several days after initial intoxication.

site; thus, extremely large doses are required. Doses should be increased until cholinergic signs such as salivation, diaphoresis, and bronchorrhea are reversed.³² When anticholinergic drugs are not effective, cardiac pacing is indicated. Sinus or atrial tachycardia causing hemodynamic compromise is a greater problem to treat because drugs such as propranolol that might slow the rate might also worsen bronchoconstriction or aggravate conduction disturbances later in the course of the overdose. Patients with clinical signs of cholinesterase inhibition or an abnormal ECG (including QT interval prolongation) should have continuous cardiac monitoring for the possibility of developing ventricular tachycardia. The ECG findings may remain abnormal for several days. Treatment of ventricular tachycardia is similar to that previously described for torsades de pointes, except that anticholinergic drugs also may be used to normalize autonomic influences on the heart. Pulmonary secretions (sometimes presenting as apparent acute pulmonary edema) or respiratory failure also may

result in hypoxia and acidosis, which aggravate arrhythmias and hypotension; anticholinergic drugs are the treatment of choice for bronchorrhea. Pralidoxime may be effective in reversing the neuromuscular-blocking effects of organophosphates, but it has little effect on cardiovascular toxicity.

Reversible acetylcholinesterase inhibitors, such as donepezil, rivastigmine, and galantamine, are used in the treatment of mild to moderate Alzheimer's disease. Experience with toxicity is very limited and has occurred in the context of dosing errors and unintentional overdose. These agents have a relatively high selectivity for neuronal acetylcholinesterases and a higher affinity for acetylcholinesterases than pseudocholinesterases but can, in overdose, cause peripheral cholinomimetic effects. In case reports and anecdotal experience with donepezil toxicity, presenting symptoms have consisted of nausea, vomiting, sinus bradycardia, and increased bronchial secretions.³³ Treatment should include supportive care, gastrointestinal decontamination with activated charcoal, and atropine. There is no known role for pralidoxime.

Membrane-Depressant Drugs and Toxins

TYPE I ANTIARRHYTHMIC DRUGS

Type IA, B, and C antiarrhythmic agents affect phase 0 (upstroke velocity of the action potential) and action potential durations to various degrees in different portions of the conduction system and in ventricular and atrial muscle. These differences are reflected in varying effects on the ECG (Table 8-4).

The cardiac disturbances caused by membrane-depressant drugs and toxins are listed in Box 8-5.

Quinidine is the prototypical membrane-depressant drug. Quinidine and other type IA antiarrhythmic drugs (including procainamide and disopyramide) impede the fast sodium current across cardiac cell membranes and slow conduction, particularly in the His-Purkinje system.³⁴ In toxic doses, slowed conduction and prolonged repolarization are demonstrated by progressively marked QT prolongation, QRS widening, or AV block. Loss of atrial activity and slow ventricular rhythm owing to a failure to depolarize pacemaker cells may be observed (Fig. 8-14). Ventricular tachycardia and fibrillation may occur after therapeutic doses ("quinidine syncope") as well as after overdose. Ventricular tachycardia in the presence of a long QT interval usually is of the polymorphous (torsades de pointes) type, and it is characterized by undulation of the QRS polarity about an isoelectric point (Fig. 8-15; see also Fig. 8-8).

In addition to its electrophysiologic effects, quinidine in large doses depresses myocardial contractility and relaxes blood vessels, resulting in hypotension. In cases of massive overdose, this may produce shock. Disopyramide, and quinidine to a lesser extent, also has anticholinergic effects that may result in sinus tachycardia after a mild overdose. Similarly, overdoses of type IC antiarrhythmic drugs, such as flecainide and propafenone, may result in bradyarrhythmias, conduction delays, and

depressed cardiac contractility with shock. These drugs may have a significant proarrhythmic action and can cause ventricular tachycardia, even at therapeutic doses in people with left ventricular dysfunction.

Therapeutic options for ventricular tachycardia due to quinidine or quinidine-like drugs include use of magnesium, overdrive pacing to shorten the QTU interval, lidocaine, phenytoin, and possibly amiodarone³⁵ (Table 8-5). Treatment of conduction disturbances and hypotension is discussed in the section on tricyclic antidepressant toxicity.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers (CCBs) block intracellular entry of calcium by binding L-type calcium channels located primarily in cardiac and vascular smooth muscle. The result is decreased cardiac inotropy and chronotropy and decreased vascular tone. Verapamil has depressive effects predominantly on sinoatrial (SA)/AV nodal conduction and myocardial contractility. Diltiazem is similar in action to verapamil but produces less cardiac depression at therapeutic doses. Nifedipine and other dihydropyridines act preferentially on vascular smooth muscle, resulting in vasodilation; their effect on cardiac conduction is nil in therapeutic doses.

The cardiac manifestations of toxicity are essentially an extension of the therapeutic effects. However, in overdose, the selectivity of specific agents may be lost. Serious toxicity can occur even with therapeutic doses of CCBs in persons with underlying cardiac disease, and similar effects are observed in healthy people after overdose.

Hypotension is a common feature of CCB overdose and results from different mechanisms. Vasodilation can result in hypotension due to decreased systemic vascular resistance; this is an effect of all CCBs. Other mechanisms of hypotension are negative inotropy and chronotropy that lead to decreased cardiac output, bradyarrhythmias, and shock. Inhibition of calcium entrance into the myocardial cell, which is necessary for muscle contraction, results in depressed myocardial contractility. Verapamil- and diltiazem-induced depression of slow-response cardiac cells also can result in sinus bradycardia or arrest and AV block, particularly in the setting of preexisting cardiac conduction disease.

Management should be directed at the mechanism of toxicity. For bradycardia refractory to atropine, glucagon can be used first, followed by cardiac pacing. Hypotension may be due to vasodilation or negative inotropy or both. Vasodilation should be treated with fluids and vasopressors. There are a number of treatments that counteract the negative inotropy. Calcium chloride or gluconate is recommended, particularly for the treatment of hypotension. Calcium can completely reverse the negative inotropic effects of CCBs, and it may partially reverse the electrophysiologic toxicity but appears to have no effect in reversing vasodilation. The effective dose of calcium has been debated. In general, initial bolus doses of calcium salts followed by continuous infusion with monitoring of serum calcium is a reasonable approach, using the hemodynamic profile

	Overdrive pacing
Bradyarrhythmias	Atropine
	Isoproterenol
	Pacemaker*
Hypotension	Fluids (hemodynamic monitoring advised in evidence of cardiac failure or myocardial depression)
	Treat bradyarrhythmias
	Dopamine, norepinephrine (low systemic vascular resistance)
	Dobutamine, isoproterenol (low cardiac output)
	Intra-aortic balloon pump or cardiopulmonary bypass (if intractable cardiogenic shock)

*May require high-voltage output to ensure capture.

as pacing, intra-aortic balloon pump, and extracorporeal bypass have been used successfully in refractory shock in this setting.

TRICYCLIC ANTIDEPRESSANTS AND ANTIPSYCHOTIC DRUGS

At one time, tricyclic antidepressants (TCAs) accounted for more cardiac morbidity and mortality than any other class of drugs. With the introduction of selective serotonin reuptake inhibitors, the incidence of TCA overdose has declined but the morbidity and mortality remains high. The mechanisms of TCA action include a strong anticholinergic effect, inhibition of neuronal uptake of catecholamines, membrane depression, peripheral α -adrenergic blockade, and CNS-mediated inhibition of sympathetic reflexes.

In mild and moderate cases of TCA overdose, anticholinergic effects and increased circulating cate-

cholamines result in sinus tachycardia, increased cardiac output, and normal or increased blood pressure. In severe cases, impaired His-Purkinje and intraventricular conduction and depressed myocardial contractility predominate, and hypotension is observed. Prolongation of the QRS duration is present in most cases of serious TCA toxicity. The finding of a rightward terminal 40-ms frontal plane QRS vector (130 to 270 degrees) is reported to be more sensitive than QRS widening in detecting tricyclic poisoning in adults, but not in children (who may normally have a rightward axis). In one study, the finding of a terminal R wave in aV_R greater than 3 mm was shown to be the only ECG finding that significantly predicted the development of seizures and dysrhythmias (Fig. 8-16).^{38,39} Bundle branch block, AV block with a slow ventricular rhythm, and asystole may occur in the most severe poisonings (see Fig. 8-15; see also Figs. 8-5 and 8-13). Responsiveness to electrical

FIGURE 8-16 A 14-year-old girl with a suicidal ingestion of amitriptyline presented with altered mental status. **A**, Her initial ECG revealed a QRS of 110 and a prominent R wave in aVR. The patient seized just as preparations for intubation were being made. **B**, Subsequent to termination of the seizure with lorazepam, sodium bicarbonate boluses were administered with resolution of the tall R wave in aVR and narrowing of the QRS interval to 90 ms. The patient subsequently recovered uneventfully and was transferred to the psychiatric service on hospital day 3.

stimulation is decreased so that pacing thresholds are often higher than normal; in extreme cases, the myocardium does not respond at all to pacing. Hypotension usually results from depressed cardiac output. Cardiac output may be reduced as a result of venous pooling with inadequate cardiac filling (associated with low pulmonary capillary wedge pressure) or, in more severe poisoning, as a result of myocardial depression (associated with normal or high wedge pressure).

Therapy for TCA overdoses should be tailored to the particular cardiovascular disturbance. Sinus tachycardia is the most common cardiac disturbance in TCA toxicity and usually is not associated with hemodynamic instability. Sinus tachycardia and supraventricular arrhythmias, if associated with hemodynamic disturbances (either excessive hypertension or hypotension), can, in theory, be controlled with physostigmine or propranolol. These drugs can depress cardiac conduction and their use in the past has resulted in significant toxicity, such as severe bradyarrhythmias and asystole (see Fig. 8-13). Their use is therefore not advocated in the setting of TCA overdose.

The administration of sodium bicarbonate achieves both an increased extracellular sodium concentration, overcoming the sodium channel blockade, and an increased extracellular pH, which facilitates sodium conductance (Fig. 8-17). Sodium bicarbonate also results in a decreased extracellular potassium concentration. All of these effects may result in improved membrane responsiveness and increased conduction velocity in fast-response (His-Purkinje) cells.⁴⁰ Therefore, any intraventricular conduction delay (QRS > 0.10, R in aVr > 3 mm, right bundle branch block), wide complex tachycardia, or hypotension should be treated with sodium loading and serum alkalization. Alkalization can be achieved also with hyperventilation but results in hypocapnia, which

may lower the seizure threshold, and seizures are a common and serious complication of tricyclic antidepressant overdose.

After sodium bicarbonate, lidocaine is the treatment of choice for ventricular arrhythmias. Other type IA or IC sodium channel blocking antiarrhythmic drugs (quinidine, procainamide, disopyramide, propafenone, flecainide), which have additive membrane-depressant effects, should be avoided. Overdrive pacing has been used successfully to treat torsades de pointes ventricular tachycardia caused by type IA drugs or long QT syndrome and would likely be useful in treating TCA overdose as well. Amiodarone could be considered for ventricular tachycardia or fibrillation unresponsive to lidocaine, but this has not been studied. Amiodarone impairs conduction via weak calcium channel and β -blocker effects and could worsen TCA-induced atrioventricular block.

Because both tachycardia and intraventricular conduction delay are characteristic and ventricular tachycardia is not uncommon, the diagnostic problem of a wide complex tachycardia of uncertain origin is common; diagnosis and treatment of this arrhythmia were discussed in detail in an earlier section of this chapter.

Intracardiac pacing is indicated in patients with high-grade AV block. If intraventricular conduction is worsening (i.e., if the QRS complex is widening) early in the clinical course, when the extent of ultimate myocardial depression is not yet known, prophylactic insertion of a transvenous pacemaker is advised because of the chance of sudden deterioration. The presence of sinus or ventricular bradycardia rather than the usual supraventricular tachycardia indicates severe toxicity and warrants pacing as well.

FIGURE 8-17 Lead II electrocardiograms recorded in a 40-year-old woman who ingested 6 g of amitriptyline (Elavil). The top strip (**A**), recorded on admission, shows a wide QRS rhythm and markedly prolonged QTU interval; atrial activity is not clearly discernible. Strips **B** and **C** were recorded 30 and 60 minutes, respectively, after intravenous administration of 44 mEq of NaHCO₃. In **B**, the QRS rate increased and alternation of QRS complexes is present. The QT interval remains prolonged, but the U wave is less prominent, and the QRS duration of alternate complexes has narrowed. Atrial activity still is not readily seen. In **C**, P waves precede each QRS complex and QRS duration remains prolonged, but the QT interval has shortened. This series of tracings suggests a supraventricular origin of the rhythm in strips **A** and **B**.

Hypotension is common after a TCA overdose. In many patients, hypotension can be managed successfully with fluids. If pressors are required, α -adrenergic agonists such as norepinephrine or dopamine are preferred. Dobutamine may prove to be useful in managing myocardial depression with normal or increased vascular resistance. Profound cardiogenic shock resulting from TCA overdose often is unresponsive to medical treatment and has a poor prognosis. In these cases, extracorporeal membrane oxygenation and cardiopulmonary bypass may be the only means of sustaining life until the body can eliminate the drug. Intra-aortic balloon pumping for drug intoxication associated with intractable shock has been successful.

Phenothiazines and other antipsychotic drugs have pharmacologic properties similar to those of TCAs, but arrhythmias are generally not as difficult to control, and cardiogenic shock is uncommon. Hypotension is more likely due to peripheral α_1 -adrenergic blockade and usually responds well to recumbent posture and intravenous fluids. Differences between TCAs and antipsychotic drugs probably reflect dissimilar potencies with respect to membrane actions and different concentrations in cardiac tissue. The TCAs and their potentially toxic demethylated and hydroxylated metabolites are concentrated in the myocardium to a much greater extent than are the phenothiazines. Atypical antipsychotics produce less cardiotoxicity than traditional agents. Most commonly, sinus tachycardia is the only cardiac manifestation of toxicity; supraventricular and ventricular arrhythmias have been described in overdose. Although repolarization abnormalities such as prolonged QT can occur, and sudden death has occurred in overdose, there have been no reports of torsades de pointes in the setting of overdose with atypical antipsychotic overdose.⁴¹

Drug-Induced QT Prolongation and Torsades de Pointes

Numerous medications, such as antiarrhythmics, antipsychotics, antibiotics, and antihistamines, have the potential to cause QT prolongation and thus increase the risk of arrhythmias, specifically torsades de pointes ventricular tachycardia (VT).

The QT interval encompasses both depolarization and repolarization phases of the cardiac cycle. The normal QT interval duration ranges from 300 to 450 ms (up to 470 ms in females) and a QT interval greater than 500 ms or an increase of greater than 60 ms over baseline is considered high risk for torsades de pointes VT, although the predictive value is low. During depolarization, there is a rapid influx of positive ions (sodium) and during repolarization, efflux of potassium gradually exceeds the influx of sodium and calcium. Blocking of this potassium outflow current prolongs the plateau phase of the action potential, which is manifested as QT prolongation on the ECG. Therapeutically, the resultant lengthened refractory period suppresses arrhythmias. However, blocking the outward potassium current allows excessive inward current and may result in early afterdepolarizations, which are seen on the ECG as prominent U waves (Fig. 8-18). These early afterdepolarizations eventually can reach threshold amplitude and trigger torsades de pointes VT.⁵

Torsades de pointes is a form of polymorphic VT associated with a long QT interval and a twisting polarity of the QRS. It tends to terminate and recur spontaneously with syncope, presyncope, or no symptoms. It can deteriorate into ventricular fibrillation and death.

Risk factors for torsades de pointes VT among patients treated with medications that prolong the QT interval include female gender, heart disease, hypokalemia, hypomagnesemia, bradycardia, excessive medication dose, drug interactions, and preexisting long QT or a family history of long QT. The majority of cases of torsades de pointes VT induced by noncardiac drugs had at least two of these risk factors in one study.⁴²

Treatment of drug-induced QT prolongation depends on the circumstance. Incidental finding of QT prolongation in the setting of both therapeutic use and overdose should prompt a detailed review of the above risk factors and discontinuation of the offending agent. Electrolyte abnormalities should be corrected, if present, and the patient should be monitored until the QT interval normalizes. If the patient presents with torsades de pointes VT, management should include discontinuation of the offending drug and suppression of early afterdepolarizations with magnesium, potassium, and

FIGURE 8-18 A 54-year-old man on methadone (140 mg PO daily) presented after an alleged overdose of clonazepam with mild lethargy and a sinus bradycardia of 50 beats per minute. Serum levels of potassium and magnesium were 4.4 and 1.6 mEq/L, respectively. Early in the course of his emergency department stay, he developed torsades de pointes ventricular tachycardia (A). He was defibrillated and intravenous magnesium was administered. A 12-lead ECG after resolution of the arrhythmia revealed a significantly prolonged QT interval with presence of "giant" U waves, attributed to the high dose of methadone. The prolonged QT interval resolved over 3 days and the patient was discharged with no further sequelae.

BOX 8-6 DRUGS WITH DEFINITE QT PROLONGATION AND TORSADES DE POINTES VENTRICULAR TACHYCARDIA*

Antiarrhythmics
 Disopyramide
 Dofetilide
 Flecainide
 Ibutilide
 Procainamide
 Quinidine
 Sotalol
 Other cardiac medications
 Bepiridil
 Tricyclic antidepressants
 Citalopram
 Antipsychotics
 Thioridazine
 Haloperidol
 Droperidol
 Antihistamines
 Astemizole
 Terfenadine
 Anti-infectives
 Chloroquine
 Erythromycin
 Halofantrine
 Pentamidine
 Gastrointestinal agents
 Cisapride (restricted indications)
 Droperidol
 Opioids
 Levomethadyl
 Methadone
 Arsenic
 Organophosphate poisoning

*This list is not exhaustive.

lidocaine. Increasing the heart rate to shorten the QT interval can be accomplished with overdrive pacing. If this is unavailable, isoproterenol may be used to accelerate the heart rate. Defibrillation is necessary when torsades de pointes VT degenerates into ventricular fibrillation. Please see Box 8-6 for a list of drugs that cause torsades de pointes. There is a website that lists all current drugs associated with torsades de pointes VT: www.torsades.org.

Miscellaneous Drugs and Toxins

Cardiovascular disturbances due to miscellaneous drugs and toxins are listed in Table 8-6.

DIGITALIS

Mortality and major morbidity due to digitalis overdose result from tachyarrhythmias, heart block, and hyperkalemia. Digitalis inhibits the sodium-potassium adenosine triphosphatase (ATPase) pump located on the cell membrane. In the therapeutic situation, this results in greater intracellular calcium concentrations, which is believed to account for increased myocardial contrac-

tility. After an overdose, disruption of sodium and potassium movement across membranes results in depressed conduction velocity, as described for membrane-depressant drugs. In addition, automaticity of previously nonautomatic tissue is enhanced due to increased rate of diastolic depolarization and possibly to spontaneous afterdepolarizations ("triggered" rhythms). Digitalis also may increase sympathetic and parasympathetic neural activity. Sympathetic stimulation enhances automaticity and excitability, whereas parasympathetic stimulation further decreases conduction velocity. Thus, an overdose with digitalis is characterized by arrhythmias demonstrating both increased automaticity and depressed atrioventricular and/or intraventricular conduction.⁴³

Tachyarrhythmias due to digitalis intoxication typically include ectopic atrial tachycardia with AV block (generally and classically 2:1), AV junctional tachycardia, and ventricular tachycardia (classically bidirectional) or fibrillation (Figs. 8-19 and 8-20). Ventricular arrhythmias are reported to occur more commonly in persons with underlying heart disease. Bradyarrhythmias include sinus bradycardia, sinoatrial block, second-degree and complete AV block, slow ventricular response in patients with atrial fibrillation, idioventricular rhythm, and asystole (Fig. 8-21). Digitalis rarely causes atrial fibrillation or flutter. Severe hyperkalemia due to inhibition of sodium-potassium exchange in skeletal muscle can contribute to AV block and depressed myocardial excitability (Fig. 8-22).

Digoxin-specific Fab fragments are the main treatment for severe digitalis toxicity. Digoxin-specific Fab fragments are the definitive treatment for life-threatening ventricular arrhythmias or hyperkalemia. The antibodies bind free digoxin and may completely reverse digitalis toxicity within 15 to 30 minutes.

In the event that this treatment modality is either unavailable or ineffective, therapy is directed at the specific arrhythmia and normalization of serum potassium level. Supraventricular arrhythmias rarely require specific treatment because the ventricular response is reasonably slow. Patients who have been taking diuretics may be depleted of potassium and magnesium, and supraventricular tachyarrhythmias may respond to potassium or magnesium supplementation. However, potassium may depress AV conduction, and, as described earlier, in extreme overdoses life-threatening hyperkalemia may be present.

Ventricular tachyarrhythmias may respond to lidocaine; quinidine-like membrane-depressant drugs should be avoided. Phenytoin has been reported to be effective in treating arrhythmias, because it may enhance AV conduction while depressing automaticity, but its effect is inconsistent and unpredictable. Esmolol also has been used to treat ventricular arrhythmias; however, β blockers may also worsen conduction disturbances. Cardioversion is relatively contraindicated since it may result in ventricular fibrillation or asystole.⁴⁴

Sinus bradycardia and AV conduction block, in light of the vagal actions of digitalis, may respond to administration of atropine. Cardiac pacing is indicated in patients with complete AV block or second-degree

TABLE 8-6 Cardiovascular Disturbances—Miscellaneous Drugs and Toxins

DRUG/TOXIN	MECHANISMS OF ACTION	CARDIOVASCULAR DISTURBANCES	OTHER COMMON MANIFESTATIONS
Digitalis (including foxglove, oleander, lily of the valley, and toad venom [bufotoxin])	Inhibits Na ⁺ -K ⁺ ATPase-dependent pump, increases automaticity, afterdepolarizations, decreases atrioventricular conduction velocity, increases vagal and ? sympathetic activity	Atrial tachycardia with atrioventricular block Junctional tachycardia Ventricular ectopy, tachycardia, fibrillation Sinus bradycardia Sinoatrial block High-grade atrioventricular block Slow ventricular response to atrial fibrillation or flutter Asystole	Nausea, vomiting Hypokalemia (with diuretic use) Hyperkalemia (severe intoxication)
Opiates	Central nervous system-mediated increase in parasympathetic and decrease in sympathetic tone	Bradycardia Atrial fibrillation Hypotension Long QT (methadone)	Miosis Respiratory depression Coma Pulmonary edema
Lithium	Disturbed cardiac potassium metabolism	Sinus bradycardia ST-T abnormalities Ventricular ectopy	Tremor, ataxia Confusion, stupor, coma Neuromuscular irritability, convulsions Azotemia
Ergot derivatives	Constriction of vascular smooth muscle	Cardiac ischemia (angina, coronary spasm with possible myocardial infarction) Peripheral vasospasm Gangrene	Headache (reason for excessive use of ergots)
Carbon monoxide, hydrogen sulfide	Binds to hemoglobin, preferentially to oxygen, causing chemical asphyxia	Cardiac ischemia (electrocardiographic abnormalities, myocardial infarction) Hypotension	Headache Coma Metabolic acidosis (with normal oxygen tension) Pulmonary edema
Cyanide	Binds to cytochrome oxidase, causing chemical asphyxia	Hypotension	
Arsenic	Interferes with cellular respiration	Cardiac ischemia Myocarditis ST-T abnormalities QT prolongation Polymorphous ventricular tachycardia Hypotension	Abdominal pain Vomiting, diarrhea Hepatitis Skin rash Renal failure Peripheral neuropathy (late) Chills, fever
Arsine	Hemolysis, anemia	Cardiac ischemia Peaked T waves Pulmonary edema	Hyperkalemia Hemoglobinuria Renal failure
Phosphorus	"Protoplasmic poison"	ST-T abnormalities QT prolongation Ventricular tachycardia/fibrillation Asystole Hypotension	Corrosive burns of skin and gastrointestinal tract Severe gastroenteritis "Smoking" luminescent vomitus and stool
Iron	Cellular membrane injury	ST-T wave abnormalities Hypovolemia Myocardial necrosis Hypotension	Nausea, vomiting, diarrhea Gastrointestinal bleeding Hyperglycemia Leukocytosis Metabolic acidosis Hepatic necrosis
Fluoride	Hypocalcemia Hyperkalemia	QT interval prolongation Peaked T waves Ventricular fibrillation Sudden death	Nausea, vomiting, diarrhea Tetany, hyperreflexia Respiratory depression
Organic mercury (chronic)		ST-T abnormalities QT prolongation	Sore mouth, metallic taste, vomiting, diarrhea, tremor, dysarthria, ataxia
Lead		Chest pain Cardiac failure ST-T abnormalities Hypertension	Anorexia Abdominal pain, constipation Anemia Peripheral neuropathy Encephalopathy

**TABLE 8-6** Cardiovascular Disturbances—Miscellaneous Drugs and Toxins (Cont'd)

DRUG/TOXIN	MECHANISMS OF ACTION	CARDIOVASCULAR DISTURBANCES	OTHER COMMON MANIFESTATIONS
Scorpion and spider venom	? Massive catecholamine release; myocarditis	Hypertension Tachycardia ST-T abnormalities QT prolongation Atrial and ventricular arrhythmias Pulmonary edema Hypotension	Pain at site of envenomation Anxiety Diaphoresis, fasciculations, and/or muscle spasm Abdominal pain and rigidity Paresthesias, convulsions
Ciguatera fish poisoning	Increased membrane sodium permeability	Bradycardia Hypotension	Paresthesias Abdominal pain, nausea, vomiting, diarrhea Respiratory depression Recurrent vomiting Cachexia Skeletal myopathy
Emetine (syrup of ipecac)	Inhibition of protein synthesis Disrupts oxidative phosphorylation	ST wave abnormalities QT interval prolongation Cardiomyopathy (biventricular cardiac failure)	Ventricular arrhythmias Myocardial injury
Colchicine	Cellular microtubular toxin	ST segment abnormalities Hypovolemia Hypotension Pulmonary edema Sudden death	Nausea, vomiting, abdominal pain Respiratory failure Pancytopenia, leukopenia Coagulopathy Myopathy Polyneuropathy Coma
γ -Hydroxybutyrate (GHB)	GABA _B agonism	Bradycardia Hypotension	Myoclonus Paresthesias Ataxia
Aconite (Chinese herbs—fuzi, chuanwu, cauwu)	Aconatine and related alkaloids block sodium channel	Bradycardia Ventricular tachycardia (may be monomorphic or polymorphic)	

FIGURE 8-19 Three lead II rhythm strips were recorded during a period of several hours in a 30-year-old patient who intentionally ingested 24.8 mg of digoxin. The *top strip* shows atrial fibrillation and R-on-T ventricular bigeminy. The *middle strip* shows a run of atrial tachycardia that terminates spontaneously to sinus rhythm and resumes immediately. The *bottom strip* illustrates high-degree AV block that, because of the morphology of the QRS complexes, is considered to be originating in the AV node or the His bundle. Because all these rhythms occurred and recurred within short periods, treatment was difficult and consisted of only transvenous cardiac pacing for bradyarrhythmias. All bradyarrhythmias disappeared by 22 hours, and all arrhythmias by 1 week.

FIGURE 8-20 The patient is a 69-year-old man who was admitted to the hospital with acute congestive heart failure 7 weeks after having suffered an anterior wall myocardial infarction. This MCL₁ rhythm strip was recorded after administration of 1.5 mg of intravenous digoxin during an 18-hour period. The atrial rate is somewhat irregular at about 150 beats per minute. Periods of AV nodal Wenckebach's block are present, with the second QRS complex of the period conducted aberrantly. Episodes of 2:1 AV block also are present. The serum digoxin level at this time was 4 ng/mL. The rhythm was restored to sinus after withdrawal of digoxin.

heart block or when bradyarrhythmias result in hemodynamic compromise. Correction of hyperkalemia may in itself reverse AV block.

Ingestion of plant-derived cardiac glycosides (oleander leaves, foxglove, lily of the valley, ouabain) or toad venom (bufotoxin) also can cause digitalis-like poisoning. Toad venom sold as an aphrodisiac (“Love Stone,” “Rock Hard”) and Chinese herbal medications (Chan Su, kyushin) have been banned in the United States by the Food and Drug Administration (FDA). Anecdotal reports suggest that poisonings from naturally occurring cardiac glycosides may respond to digoxin-specific Fab fragments.⁴⁵

FIGURE 8-21 These two MCL₁ rhythm strips depict examples of AV block in the setting of digitalis toxicity. **A**, Sinus rhythm and complete AV block are present. The QRS complexes are of two types: The first two have a right bundle branch block pattern, and the last three have a left bundle branch block pattern; they occur at two different rates. The long duration of the QRS complexes as well as their very slow rate suggests that the origin of these escape beats is in the distal His-Purkinje system. In this situation, atropine may not result in improved AV conduction, and temporary cardiac pacing often is required. **B**, The atrial rhythm is fibrillation. High-grade AV block is present, as evidenced by the slow ventricular response. The QRS complexes have two morphologies: right and left bundle branch block patterns. The first three complexes occur at a nearly regular rate, suggesting a ventricular escape focus. The last two complexes occur at a slower escape interval and rate, suggesting instability of the origin of the first three complexes and emergence of a yet more distal pacemaker. Again, atropine may not be of benefit in this situation, and cardiac pacing may be required.

FIGURE 8-22 The patient was a 68-year-old man who was admitted to the hospital in moribund condition. He had long-standing congestive heart failure and was being treated with oral digoxin and diuretics. His serum potassium level on admission was 10.0 mEq/L, and his serum digoxin level was 5.2 ng/mL. He died shortly after this 12-lead electrocardiogram was obtained, with electromechanical dissociation. The electrocardiogram shows absence of discernible atrial activity and an irregular, wide complex QRS rhythm having a right bundle branch block configuration. The markedly increased QRS duration suggests hyperkalemia, which in this patient may have been due in part to digitalis toxicity.

OPIATES

Although toxicity from acute opiate overdose is related primarily to respiratory depression, opiates may have significant cardiac and vascular effects. They generally have little effect on the myocardium, although norpropoxyphene, a major metabolite of propoxyphene, may be cardiotoxic. CNS effects of narcotics result in increased vagal activity. Narcotics dilate peripheral veins and arterioles, presumably through a CNS-mediated effect on sympathetic tone. Consequently, hypotension and relative bradycardia are common. Arrhythmias occur occasionally, most commonly atrial fibrillation. Quinidine and procaine, as well as other local anesthetics, commonly adulterate heroin sold on the street and may themselves contribute to myocardial depression or even cardiac arrest.

Noncardiogenic pulmonary edema is a common and serious complication of narcotic overdose. Although pulmonary edema usually occurs after injection of narcotics, it may not become evident until naloxone has been administered. Sudden reversal of narcotic-induced venodilation and venous pooling combined with pulmonary capillary injury causing fluid to enter the lungs at relatively low cardiac filling pressures most likely accounts for naloxone-induced pulmonary edema.

Therapy for opiate overdose in general includes administration of naloxone and supportive care. No specific therapy for arrhythmias usually is necessary. Naloxone may convert coarse atrial fibrillation to fine atrial fibrillation with a faster ventricular response rate rather than to normal sinus rhythm. If atrial fibrillation persists, the use of verapamil, diltiazem, or metoprolol is indicated to slow the rate. Intermittent positive expiratory pressure is beneficial in the treatment of pulmonary edema, as discussed previously.⁴⁶

LITHIUM

Cardiac toxicity of lithium overdose usually is not prominent. Administration of lithium in usual therapeutic doses produces flattening or inversion of the T wave in nearly all patients. Sinus node disturbances, manifested by sinus bradycardia or sinoatrial block, sometimes associated with ventricular ectopy, and junctional or ventricular escape rhythms have been reported in patients with lithium intoxication and during long-term therapy.⁴⁷ Ventricular tachyarrhythmias in association with lithium therapy have been reported but are uncommon. Hypotension may complicate lithium overdose, but this appears to be related to dehydration or pulmonary complications in the course of prolonged coma rather than caused by direct cardiovascular toxicity. A mechanism for the cardiac effects of lithium has been suggested by animal studies. Lithium enters myocardial cells and displaces intracellular cations, predominantly potassium. Lithium then leaves the cell more slowly than does potassium and thereby disturbs the usual transmembrane ionic currents.

Treatment is directed toward the specific arrhythmia, as described in Table 8-1, and toward acceleration of lithium elimination, as discussed in Chapter 30.

ERGOT AND TRIPTAN DERIVATIVES

Ergotamine and other ergot derivatives are used widely in the treatment of migraine headache and have resulted in significant cardiac and vascular toxicity. The basic action of ergot drugs is constriction of vascular smooth muscle (both α -adrenergic agonist and nonadrenergic effects), although many of the drugs also have α -adrenergic receptor-blocking activity. Intense constriction of peripheral arteries, with resultant coolness, pallor, or cyanosis of the extremity, sometimes progressing to gangrene, is a typical manifestation of ergotism. Intermittent claudication occurs initially, and then ischemic rest pain develops with progression of vasospasm. In addition, ergot derivatives have been reported to worsen angina or cause myocardial infarction, presumably owing to coronary vasoconstriction, particularly but not exclusively in persons with underlying coronary artery disease.⁴⁸ Intravenous administration of ergonovine was used diagnostically at one time during cardiac catheterization to provoke coronary vasospasm, but it is no longer used due to deaths related to refractory coronary spasm. We treated a patient who took excessive quantities of ergotamine tablets for severe migraine headaches; the patient had chest pain and diffuse, reversible ST segment elevation indicating coronary vasospasm (Fig. 8-23).

Amphetamine-like drugs also can produce vascular spasm similar to that produced by ergot derivatives. In particular, 4-bromo-2,5-dimethoxyamphetamine injection has produced severe vascular insufficiency and in one case led to a bilateral lower extremity amputation.

Therapy for ergot-induced vasospasm includes anticoagulation with heparin, the use of direct vasodilators such as sodium nitroprusside for peripheral vasospasm, nitroglycerin for coronary vasospasm, and α -adrenergic blockers. Rapid dilation of vessels in an intensely vasoconstricted patient results in relative hypovolemia and hypotension; thus, fluid replacement must be anticipated. If a specific vessel is affected, vasodilators should be infused intra-arterially into that vessel to allow maximal local vasodilation to be achieved without effecting excessive systemic hypotension. Nifedipine or other CCBs may prove useful also in treating ergot-induced coronary vasospasm. Other treatments with varying results have included anticoagulants, epidural anesthesia, low-molecular-weight dextran, hyperbaric oxygen, and surgical sympathectomy.

The triptans (5-hydroxytryptamine [5-HT] agonists) have eclipsed the use of other abortive migraine agents. Their therapeutic action is believed to result from constriction of extracerebral blood vessels and reduction of neurogenic inflammation. Serotonin receptors are abundant in the coronary arteries and, when stimulated, may cause vasoconstriction. Serious adverse cardiac events, such as myocardial infarction, have been described during therapeutic use of these agents. Despite their widespread use, complications associated with the triptans are rare and can be further minimized by careful selection of patients who have symptoms or risk factors suggestive of cardiovascular disease.⁴⁹ Treatment of toxicity mainly is supportive with specific

FIGURE 8-23 The patient is a 50-year-old man who was taking ergotamine for cluster headaches. When the headaches worsened, he ingested up to 10 mg/hr, developed severe substernal chest pain, and had an episode of syncope. This 12-lead electrocardiogram was recorded on admission to the coronary care unit. The rhythm is sinus with ventricular bigeminy; diffuse ST segment elevation is present, consistent with coronary artery spasm. After large oral and intravenous doses of nitrates, chest pain and ST segment elevation resolved, but recurrent episodes of pain were associated with return of ST elevation, ventricular ectopy, and bursts of ventricular tachycardia. Myocardial infarction was not documented. Selective coronary arteriography documented coronary spasm during a spontaneous attack of chest pain. Pain and ST segment elevation resolved over 2 weeks coincidentally with oral nifedipine therapy.

cardiac treatment being dependent on the presence of ECG or cardiac enzyme abnormalities.

CHEMICAL ASPHYXIANTS

Carbon monoxide, hydrogen sulfide, and cyanide inhibit oxygen transport to tissues or use of oxygen within tissues, resulting in tissue hypoxia. The usual presentation in severe cases of poisoning is coma or metabolic acidosis or both. Tachypnea (with evidence of respiratory alkalosis), tachycardia, and hypotension are common, although carbon monoxide poisoning in particular can be associated with hypertension. ECG changes, including T wave flattening or inversion, ST segment depression or elevation, and conduction disturbances, frequently are observed, and myocardial necrosis or infarction may occur. Premature ventricular contractions and atrial

fibrillation are noted occasionally. ECG abnormalities may be a misleading index of the severity of carbon monoxide poisoning, however, because ST-T abnormalities and arrhythmias are nonspecific and may not reflect the magnitude of impairment of the myocardium. Echocardiography is a useful adjunct in assessment of carbon monoxide-induced cardiac damage, especially in comatose patients or those with underlying cardiopulmonary disease.⁵⁰ ECG or echocardiographic abnormalities after carbon monoxide poisoning may persist for days or even weeks after treatment, possibly as a result of focal myocardial injury.⁵¹

Pulmonary edema may complicate acute carbon monoxide poisoning, and noncardiogenic versus cardiogenic edema resulting from myocardial damage must be differentiated. Even mild exposure to carbon monoxide

can have significant effects in persons with underlying vascular disease. With carboxyhemoglobin concentrations as low as 3%, the duration of exercise to the onset of chest pain in persons with angina pectoris, or leg pain in persons with intermittent claudication, is significantly reduced. Therapy is directed toward improving tissue oxygenation, as described in Chapter 87.

ARSENIC AND OTHER METALS

Acute arsenic poisoning, by interfering with cellular respiration, may produce an ECG picture of myocardial ischemia and may be associated with focal myocardial hemorrhage, although patients who recover have no cardiac symptoms. Acute and chronic arsenic poisoning can be associated with T wave changes and QT prolongation and with ventricular tachycardia and fibrillation. Arsenic-induced torsades de pointes VT has been reported.⁵²

Arsine gas, by causing massive hemolysis and severe anemia, also results in ECG abnormalities, most commonly peaked T waves (possibly related to hyperkalemia), but myocardial ischemia (due to severe anemia and possibly myocardial effects of arsine) also is evident. Death due to arsine exposure in patients who reach the hospital often is secondary to cardiac failure; pathology shows myocardial degeneration. Treatment should include correction of hyperkalemia, transfusion, and therapy of cardiac failure.

Elemental phosphorus and organic mercury poisonings have been associated with ST-T wave abnormalities, QT prolongation, and various arrhythmias (including ventricular tachycardia). After elemental phosphorus ingestion, shock resulting from depressed myocardial contractility and abnormally low systemic vascular resistance occurs and often is difficult to treat. Death in the early phase of phosphorus poisoning is due to shock, ventricular fibrillation, or asystole.

Although uncommon, chronic lead poisoning may be associated with myocarditis characterized by chest pain (angina pectoris saturnina), sinus tachycardia, ventricular gallop, pulmonary congestion, hypertension, ST-T abnormalities, and premature ventricular contractions on the ECG. Autopsy of children dying of lead encephalopathy has shown chronic myocarditis. Clinical features usually subside after treatment with chelating agents.

Acute severe iron (and other heavy metal) poisoning causes shock owing to vasodilation and hypovolemia, the latter resulting from vascular damage and fluid loss. Myocardial injury and dysfunction may also contribute. ECG abnormalities, including T wave inversion, may be present.

SCORPIONS, SPIDERS, AND HYMENOPTERA

Patients with poisonous scorpion stings typically show anxiety, profuse diaphoresis, and hypertension. Myocarditis, characterized by sinus tachycardia, conduction abnormalities, and ST-T abnormalities, including tall peaked T waves, QT prolongation, and atrial and ventricular arrhythmias, may be evident. In severe poisoning, pulmonary edema, hypotension, and ECG changes suggesting myocardial infarction occur. Death is due to congestive heart failure or shock or both; sudden

deaths presumably due to arrhythmias also are reported.⁵³ The clinical and myocardial histologic manifestations of scorpion sting resemble those of massive catecholamine infusion, and urinary catecholamine excretion has been noted to be increased in scorpion sting victims. Although there is little published experience in this regard, the use of α - and β -adrenergic blocking drugs for treatment of hypertension and arrhythmias is logical. Treatment of cardiac failure and shock is supportive.

Labile blood pressure, atrial arrhythmias, and cardiovascular collapse occasionally are observed in patients after black widow spider bites. Increased urinary catecholamine metabolite excretion also has suggested a role of excess catecholamines in this syndrome, and adrenergic blockers may be useful in management.

Hymenoptera (bees and wasps) stings are well known to cause anaphylaxis, manifested by hypotension, cyanosis, bronchospasm, and collapse in allergic patients. Chest pain and myocardial infarction, probably resulting from profound hypotension, occasionally occur as well.⁵⁴

GAMMA-HYDROXY BUTYRIC ACID

γ -Hydroxybutyric acid (GHB) is a naturally occurring analog of γ -aminobutyric acid (GABA), which has FDA approval for treatment of narcolepsy. GHB also has been abused as a nutritional supplement for bodybuilding, a drug of abuse for euphoria, a sexual enhancer, and a drug to facilitate sexual assault. In overdose, the typical presentation is profound CNS depression, respiratory depression, sinus bradycardia, and, occasionally, hypotension. ECG abnormalities other than sinus bradycardia, such as conduction disturbances, are not typical of GHB intoxication and should prompt investigation for the presence of other cardiotoxic substances. Treatment usually is supportive with attention to airway protection. Sinus bradycardia is responsive to atropine, if necessary, and hypotension responds to intravenous fluids. GHB-induced hypotension generally does not require pressors.⁵⁵

Withdrawal syndromes after chronic GHB use can occur after frequent use within 6 hours of the last dose. The withdrawal syndrome is characterized by nausea, vomiting, anxiety, and tremor, initially followed by autonomic instability and severe delirium. Treatment is supportive; benzodiazepines, usually in high doses, have been effective. Barbiturates and propofol have been used in refractory cases.⁵⁶

SOME OTHER NATURAL PRODUCTS

Many natural products have cardiovascular effects, and a comprehensive review of these is beyond the scope of this chapter. Three toxins have become of particular interest to poison centers and are mentioned briefly.

Ciguatera fish poisoning, caused by ingestion of fish contaminated with ciguatera toxins, produces cardiovascular toxicity as well as gastrointestinal and neurologic symptoms. Patients often experience bradycardia and hypotension, which may be quite severe. Detailed autonomic studies of one such patient revealed that the bradycardia and hypotension were due to both excessive

vagal tone and depression of sympathetic nervous responses.^{57,58} Hypotension usually responds to volume expansion and anticholinergic drug therapy.

Scombroid fish poisoning occurs after ingestion of fish that contains high levels of histamine and possibly other bioactive amines. Histamine is produced in the fish when bacteria metabolize the amino acid histidine. This elevated histamine level causes a syndrome of flushing, urticaria, diaphoresis, palpitations, gastrointestinal distress, and headache. There have been case reports of hypotension and bradycardia associated with scombroid toxicity, although these are rare manifestations. Treatment is supportive with use of antihistamines and corticosteroids, when indicated. Hypotension refractory to intravenous fluids may respond to epinephrine.⁵⁹

Aconite poisoning can occur after ingestion of Chinese herbs or teas that contain *Aconitum carmichaelii* or *Aconitum kusnezoffii*. The herbal preparations that contain these herbs include fuzi, chuanwu, and cauwu. If these herbs are not boiled for an adequate time, the alkaloids aconitine, mesaconitine, and others, which are extremely potent toxins, may be ingested. Cardiovascular manifestations include shock with bradycardia or ventricular tachycardia (either monomorphic or polymorphic) or ventricular fibrillation.⁶⁰ Several fatalities have been reported. Amiodarone and flecainide have been suggested as first-line antiarrhythmic agents for ventricular tachycardia due to aconite poisoning.

MICHAEL G. HOLLAND, MD

Acute care toxicology usually involves management of ingested toxicants. However, health care providers in occupational medicine rarely encounter toxic ingestions and are most concerned with inhalational or dermal exposures. This chapter organizes and gives a basic introduction to the toxicology of pulmonary exposures and the response of the pulmonary system to these toxicants, as well as discusses pulmonary manifestations of systemic adverse drug reactions and toxicants.

Any discussion of pulmonary toxicology would be incomplete without covering the worst industrial catastrophe in history: the Bhopal disaster. On December 4, 1984, the Union Carbide plant in Bhopal, India, released 80,000 pounds (40 tons) of methyl isocyanate (MIC). MIC is a very hygroscopic compound that is known to be quite reactive: Pressure and heat build up rapidly when it is mixed with water. MIC was used at this plant as a chemical intermediate in the production of carbamate pesticides. Somehow, water entered the vessel that contained the compound. Hours later, when the pressure within the storage tank exceeded the relief valve, the MIC vapor escaped. When the MIC was released into the ambient air, thousands of people close to the plant were immediately exposed to very high concentrations, causing severe injuries, and many victims died in their sleep. As the cloud of this irritant gas spread to the populous city of Bhopal 1 mile away, many thousands more were afflicted, and more than 15,000 people were seen in the hospital that night. Over the next several days, more than 100,000 people sought medical care. The final official death toll at the time was estimated to be greater than 2500; more recently, the deaths attributed to that single accident exceed 6000. Because of the nature of the injuries to the respiratory tract, many of those injured remain disabled today.^{1,2}

SCOPE OF THE PROBLEM

Pulmonary exposures are very common. The American Association of Poison Control Centers (AAPCC) data from 2002 reveal that inhalation exposure was involved in 154,167 cases reported to poison centers, or 6.5% of the total number of poison center cases. Inhalation exposure accounted for 103 deaths or 8.9% of the total number of fatalities. The majority of these deaths were due to carbon monoxide exposure. The AAPCC data also reveal that occupational or environmental exposures accounted for a total of 42 deaths or 3.6% of the total cases reported. Most of these were from inhalation exposure.³

Many toxic gases are produced by small specialty industries, and many of these workplaces may not have a safety officer or an industrial hygiene department that

ensures worker safety. Historically, workers in these situations have been at increased risk of having significant exposures to toxic gases and vapors, because air monitoring or engineering controls are expensive and time-consuming. With the passage of the Occupational Safety and Health Act in 1972, this situation has improved in the United States, but it remains a significant problem in less regulated, developing nations. However, a significant portion of American workers have the potential exposure to respiratory irritants. For instance, the number one chemical produced in the United States is sulfuric acid, mists or vapors of which are highly irritating to the pulmonary system. Many of the top 50 chemicals produced in the United States are toxic or irritant gases. The National Institute for Occupational Safety and Health (NIOSH) estimates that over 500,000 U.S. workers have the potential to be exposed to anhydrous ammonia alone.⁴

Firefighters and first responders may be exposed to numerous hazards, since structural fires produce many toxic gases, such as hydrogen cyanide (HCN), carbon monoxide (CO), hydrogen chloride (HCl), acrolein, sulfur dioxide (SO₂), and phosgene. The latest AAPCC data suggest that toxic gas exposure is responsible for 4.9% of workplace deaths in the United States. Of these, the major lethal gas is the colorless and odorless carbon monoxide.

When the Aum Shinrikyo cult released sarin vapors in a Tokyo subway in 1995, the world became acutely aware of the possibility of military nerve agents being used in civilian arenas. With the terrorist attacks of September 11, 2001, Americans finally became cognizant of the fact that no country is immune to terrorist acts. However, people have been using gaseous warfare agents against their enemies for centuries. For example, a mixture of pitch and sulfur was burned and the smoke used as a gas warfare agent in the war between Athens and Sparta in 428 BC. World War I was the first large-scale conflict that saw regular use of chemical warfare agents, most notably mustard gas, chlorine, and phosgene. Phosgene alone was responsible for up to 80% of deaths due to chemical agents during that war. More recently, Iraq used mustard gas against Iranian soldiers in 1988 and various chemical agents against the Kurds in the 1990s.

Most of the danger of ingested toxicants comes from the effects of systemic absorption. However, when a caustic poison such as lye is ingested, the gastrointestinal tract is the site of local toxicity/injury. Conversely, most irritant gases injure the respiratory tract, but numerous toxicants in the gaseous phase can be absorbed rapidly into the systemic circulation via the large alveolar surface area and the rich pulmonary capillary blood supply. In fact, the inhalation route approaches the rapidity of intravenous administration.

In addition to gaseous or vapor exposures causing lung injury, certain toxicants affect the lung after systemic absorption from another route, the most notable being the dication herbicide paraquat (PQ^{++}). Paraquat is actively transported and concentrated in the lung, where it is reduced by nicotinamide adenine dinucleotide phosphate (NADPH) to a monocation radical, $\bullet PQ^+$. This reactive radical rapidly reacts with molecular O_2 to form a superoxide radical, $\bullet O_2$, which then also regenerates the original PQ^{++} . The cycle can repeat itself, due to the abundant supply of NADPH and molecular oxygen in the lung. The superoxide radicals then cause lipid peroxidation and pneumocyte cell death. This seems to occur more readily when victims are treated with high fractions of inspired oxygen (FiO_2). The pulmonary injury is then followed by a proliferative phase leading to pulmonary fibrosis. Antioxidants are being investigated as treatment options.⁵

Numerous therapeutic drugs also can induce interstitial pneumonitis, such as amiodarone, tocainide, flecainide, nitrofurantoin, and hydrochlorothiazide. Cytotoxic chemotherapeutic agents typically can cause interstitial pneumonitis as well as interstitial fibrosis. Angiotensin-converting enzyme inhibitors commonly cause cough as a side effect. Pulmonary edema is well known to occur after opiate overdose, but it also can be seen with salicylates, phenothiazines, butyrophenones, and tricyclic antidepressants. The ergot derivative bromocriptine is associated mainly with pleural effusion, whereas methysergide has been associated with pleural effusion and fibrosis. Asthmatic reactions can be induced by nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin, as well as by β blockers, calcium antagonists, and dipyridamole. Leukotriene antagonists are linked to the development of Churg-Strauss syndrome, and penicillamine and certain antibiotics can cause bronchiolitis obliterans. Anorectic agents have been linked to the development of primary pulmonary hypertension.⁶

Many toxicants, such as sedative-hypnotics, cyclic antidepressant agents, or opiates, alone or in combination, cause hypoventilation and a subsequent hypoxemia seen on arterial blood gas analysis or via pulse oximetry. If this condition does not improve after administration of appropriate reversal agent, such as naloxone for opiates or flumazenil for benzodiazepines, then intubation is necessary. Any drug or toxicant that causes enough sedation to affect respiratory drive also can cause loss of protective reflexes. Aspiration of gastric contents into the airway can cause an aspiration pneumonitis and subsequent acute respiratory distress syndrome and respiratory failure. Chest radiograph examinations should be performed in all cases in which aspiration is suspected by the history of a patient with a decreased level of consciousness that has vomited. Similarly, when physical examination findings suggest aspiration (rales on auscultation of the chest, or vomitus seen on face or in airway), or when there is an alveolar-arterial (A-a) gradient (oxygenation does not improve after increasing the respiratory rate or by increasing the FiO_2), aspiration pneumonitis must be considered and chest radiograph

performed. Finally, with ingestion of hydrocarbon (e.g., gasoline, kerosene, mineral seal oil) there is a high incidence of aspiration of the hydrocarbon into the airway owing to its low viscosity, especially when vomiting occurs. Hydrocarbon aspiration causes acute lung injury via depletion of surfactant, which causes alveolar collapse and intrapulmonary shunting. Many of these patients can have minimal findings initially on chest radiograph, but they may be very symptomatic with respiratory distress with coughing and wheezing. Subsequent chest radiograph examinations can show an ARDS-type pattern. Please see Chapters 33, 34, and 93 for a detailed discussion of these toxicants.

PULMONARY ANATOMY AND PHYSIOLOGY

The lung, like the skin, is an organ that consists of a very large epithelial surface that is continuously exposed to the outside world. Unlike the skin, the lung cannot make use of multiple layers of relatively impermeable cells as a barrier, because the gas exchange function of the lung requires thin gas-permeable cell membranes between the alveolar air and the blood. Instead, the lung uses specialized mucus secretions produced by the airway goblet cells to trap and remove inhaled environmental toxicants and debris.⁷

The pulmonary system can be divided into the upper airway, the lower airway, and the lung parenchyma. The glottis is the dividing point separating the upper airway and lower airway. The lung parenchyma functional gas exchange unit, or acinus, begins at the respiratory bronchiole. The upper airway surface anatomy includes the nasal mucosa, the tongue and oral mucosa, and naso- and oropharynx. Because of similar exposures to ambient airborne gases and toxicants, the ocular mucosa is closely linked with the upper airway. The surface area of the upper airway is small, measuring a few hundred square centimeters of total area. However, because of the multiple divisions of the alveoli, the total surface area of the lower airways and lung parenchyma is huge, measuring over 70 square meters, approximately the size of a tennis court.

The cartilaginous lower airway, which consists of the trachea and the bronchi and their subdivisions, are lined with ciliated epithelial cells and goblet cells. These ciliated cells sweep the respiratory mucus (produced by goblet cells) upward, where particulates that are trapped in this mucus can be coughed out or swallowed. This upward removal system is known as the *mucociliary escalator*. Alveolar macrophages that have phagocytosed inhaled antigens and debris are removed by this system as well. The lower airways distal to the terminal bronchioles lack cartilaginous support. The acinus, or terminal respiratory unit, consists of the respiratory bronchiole, the alveolar duct, and the alveolus; this is where gas exchange takes place.

There are numerous important cell types in the lung parenchyma: alveolar epithelial cells (types I and II), interstitial cells, capillary endothelial cells, alveolar

macrophages, and Clara cells. Type I alveolar epithelial cells account for 90% of the total alveolar surface area and are the chief structural cells of the alveolar wall. These type I cells maintain the alveolar-blood barrier and are responsible for gas exchange. They are thin and flat, with a paucity of intracellular organelles. This structure facilitates gas exchange, but it renders them quite fragile and very susceptible to injury when exposed to inhaled toxicants or irritant gases. Type II alveolar epithelial cells are cuboidal cells that cover the remaining 10% of the alveolar surface. They are responsible for manufacturing pulmonary surfactant. Surfactant is composed of phospholipid bound to lecithin, and it maintains inflation of the alveolus by reducing surface tension, which stabilizes the alveolus, thereby increasing lung compliance, and reduces the work of breathing. Type II cells also are able to differentiate into type I cells to replace those fragile cells that are damaged from inhaled or systemic toxicants.⁸

Capillary endothelial cells are the most abundant parenchymal lung cells, accounting for almost one third of the cell population. They are the interface between the vascular space and the lung interstitium. They can be damaged by both inhaled irritants and systemic toxicants. When endothelial cells are injured, the resultant capillary leakage of fluid into the interstitium, and subsequently the alveolus, can cause decreased compliance, decreased diffusing capacity, and even noncardiogenic pulmonary edema.

Interstitial cells, which account for more than one third of the lung cells, are located in the area between the alveolar epithelium and the vascular endothelium. These include fibroblasts, mast cells, macrophages, and plasma cells; they perform various functions including immune response and injury repair. Exaggerated fibroblast stimulation after acute lung injury can lead to pulmonary fibrosis.

Alveolar macrophages are the first line of defense against inhaled organisms, foreign antigens, or particles that reach the alveoli. They phagocytose foreign material, and then migrate to the mucous layer to be expelled via the mucociliary escalator. They also can move into the interstitial space and gain access to the pulmonary lymphatic system. There they can release cytokines that direct further immune responses and cell recruitment. This cytokine response has implications in various pulmonary disease processes such as asthma, hypersensitivity pneumonitis, silicosis, and asbestosis.

Clara cells, which are nonciliated bronchiolar cells, contain P-450 enzymes and perform most of the metabolic activity of the lungs. Clara cells can differentiate into goblet cells, which secrete mucus, and they also can differentiate into ciliated cells to replace those lost to injury.

Because the respiratory system is directly exposed to the external environment, the lungs contain more lymphatics than does any other organ. This rich lymphatic system is responsible for manufacturing antibodies against inhaled foreign antigens, as well as initiating cell-mediated immune responses. The pulmonary lymphatic response to injury or antigenic exposures also includes

release of cytokines. Cytokines are small proteins having a molecular weight of less than 30 kD that act as chemical messengers between cells and are known to play a pivotal role in the inflammatory cascade. This has implications in the development of occupational lung diseases such as asthma, hypersensitivity pneumonitis, and organic dust toxic syndrome.

PARTICLE DEPOSITION

The pulmonary tree is assaulted constantly by particulates in the air. Whether these particulates deposit on the airway walls, reach the alveoli, or simply remain in the air stream to be exhaled depends on many factors. The factors related to the type of particle include size, electrostatic charge, and aerodynamics (i.e., whether it is a particle or a fiber). Small particles have irregular shapes, but their motion is determined largely by their aerodynamic diameter, which depends on their inertial and gravitational motion in air.

In vitro experimentation reveals that particle deposition in the airways occurs via five mechanisms: impaction, gravitational sedimentation, brownian diffusion, electrostatic deposition, and interception. Impaction occurs primarily at airway bifurcations and is most important for particles having an aerodynamic diameter of more than 1 μm . Gravitational sedimentation occurs primarily in long airway segments. Brownian diffusion affects smaller particles (<0.5 μm). Electrostatic deposition refers to particles with a charge that have been recently generated by mechanical dispersion. Finally, interception in an airway segment occurs primarily with fibers, which are defined as any particle with a length-to-width ratio of more than 3:1.⁹

In vivo, the depth and rate of respiration also affect deposition. Slow, deep respirations favor simple gravitational sedimentation, which distribute the particle more evenly in the pulmonary tree. Conversely, rapid shallow respiration favors impaction of the particles against larger central airways or at bifurcations. All this being equal, the aerodynamic diameter, or size of the particle, influences the primary location of deposition in the pulmonary tree. Larger particles (>10 μm) primarily deposit in the upper airways. Particles between 2.5 and 6 μm deposit in the lower airways, and particles smaller than 2.5 μm deposit primarily in the lung parenchyma (alveolar ducts and alveoli). Very small particles (<0.1 μm) often remain in the air stream and are exhaled.

CONTROL OF RESPIRATIONS

Efficient gas exchange depends on adequate respiratory drive, an intact and patent airway, strong muscles of respiration (diaphragm and chest wall), normal alveolar architecture, and adequate pulmonary capillary blood flow. Abnormalities among any of these components can cause respiratory compromise.

Respiratory drive is controlled by peripheral chemoreceptors located in the carotid body, as well as

central chemoreceptors located in the brainstem. The peripheral receptors detect hypoxia, whereas the central receptors detect lowered CSF pH due to increases in CO₂. Both respond to these signals by increasing the depth and rate of respiration. Toxicants that cause a decrease in these responses to respiratory drive can induce hypoxemia. Central nervous system depressants, such as barbiturates, can cause respiratory depression by blunting the normal physiologic response to stimulation of these chemoreceptors. Opioids interact at multiple receptor sites in the body. The μ -opioid receptors are responsible for most of the clinical effects seen with available opioids, and agents acting at the μ receptors show little or no selectivity between the two subtypes, designated μ_1 and μ_2 . Stimulation of the μ_1 -opioid receptor causes analgesia and the pleasurable euphoria sought by abusers. Overstimulation at the μ_2 -opioid receptor is responsible for the respiratory depression seen in opioid overdoses.

Airway compromise can be caused by ingestion of local irritants, such as caustics or diphtheria, or airway swelling induced by allergic angioedema seen in anaphylaxis or the angioedema seen with angiotensin-converting enzyme inhibitors. Chest wall rigidity induced by fentanyl, as well as respiratory muscular weakness caused by organophosphates, carbamates, and botulinum toxin, can cause respiratory failure.

Acute lung injury, formerly known as noncardiogenic pulmonary edema, can be caused by a multitude of inhaled or ingested toxicants (see later). This condition causes pulmonary capillary fluid to leak into the alveolar space, disrupting efficient gas exchange and decreasing the normal pulmonary compliance. Late sequelae of acute lung injury can include bronchiolitis obliterans fibrosa, which permanently impairs gas exchange and causes a restrictive defect. Other pulmonary reactions, such as hypersensitivity pneumonitis and certain pneumoconiosis, can induce permanent pulmonary fibrosis with impairment of gas exchange and restrictive lung disease. Aspiration of gastric contents and subsequent pneumonia/pneumonitis can impair efficient gas exchange by inducing a ventilation-perfusion mismatch, in which blood flows to an area of the lung incapable of gas exchange.

Finally, impairment of pulmonary capillary blood flow can cause ventilation-perfusion mismatch, in which ventilated areas cannot perform gas exchange due to inadequate perfusion. This can occur with any drug causing pulmonary embolus (e.g., estrogen, oral contraceptives), as well as inert substances and debris injected intravenously by drug abusers (e.g., talc, vegetable matter, cotton). Septic emboli can occur in this setting from inadvertent injection of microorganisms.

DEFINITION OF TERMS

Most laypersons and many medical professionals misuse or interchange the terms *gas*, *fume*, and *vapor*. For instance, most complaints of noxious “fumes” in the workplace

actually refer to an objectionable odor of the vapors of liquids that are in use at the time. By convention, a *gas* is defined as a substance that normally is in the vapor phase at room temperature, which occupies an enclosed space, and can be changed into a liquid by a decrease in temperature or an increase in pressure. In the strict sense, a *vapor* therefore is the gaseous phase of a substance normally in the liquid state at room temperature but that also can be changed into a liquid by a decrease in temperature or increase in pressure. *Aerosols*, of which there are two types, are dispersions of solid or liquid particles in a gaseous medium (usually air). A *fume* is an aerosol of solid particles generated by heating, usually of metals, and often is accompanied by oxidation of these metals (e.g., zinc oxide fumes form when welding galvanized metals). An aerosol of liquid particles is a *mist* that is generated by mechanical dispersion, whereas a *fog* is a mist generated by condensation. Other airborne contaminants are dusts and smoke. *Dusts* are solid particles generated either by disintegration of organic or inorganic materials, or by mechanical dispersion such as sanding or grinding, and are capable of temporary dispersion in air. *Smoke* usually is a mixture of gases, vapors, and aerosols of solids generated by incomplete combustion.¹⁰

Acute Lung Injury and Acute Respiratory Distress Syndrome

Acute lung injury (ALI) is the term given to the pathophysiologic presentation of diffuse alveolar injury. It may be a result of inhalational injury or a consequence of systemic disease, such as sepsis or severe hypovolemic shock. This disorder is defined as a syndrome of inflammation and increased pulmonary membrane permeability with multiple manifestations (radiographic, physiologic, clinical) that cannot be explained by cardiogenic pulmonary edema. *Acute respiratory distress syndrome* (ARDS) is the most severe form of ALI and is distinguished by the severity of the oxygenation deficit. Clinically, ALI syndrome is established when criteria in four categories are met:

1. *Timing*: The disorder is acute by definition; therefore, manifestations must occur within a few days of the insult.
2. *Pulmonary physiology*: The pulmonary edema is noncardiogenic; therefore, the pulmonary capillary wedge pressure must be less than 18 mm Hg and the edema fluid found in the alveolus and interstitium must be protein-rich, indicating endothelial and epithelial membrane exudates rather than a transudate from congestive heart failure.
3. *Radiography*: Chest radiographs must demonstrate diffuse bilateral infiltrates.
4. *Oxygenation*: Low ratio of partial pressure of arterial oxygen (PaO₂) to FiO₂; in other words, a large A-a gradient must be present. Specifically, ALI is present when PaO₂/FiO₂ is less than 300 mm Hg; ARDS is present when this ratio is less than 200 mm Hg.¹¹

Bronchiolitis Obliterans Fibrosa and Bronchiolitis Obliterans Organizing Pneumonia

Bronchiolitis obliterans fibrosa (BOF), also known as obliterative bronchiolitis, is a response to small airway injury where inflammation and epithelial disruption subsequently are followed by an ingrowth of granulation tissue into the airway lumen, resulting in partial or complete obstruction. The granulation tissue then organizes with resultant fibrosis, which can completely obliterate the airway lumen. BOF occurs as a result of inhalational injury to the small airways after exposure to irritant gases, mineral dusts, toxic metal fumes, or crack cocaine or from paraquat ingestion. BOF also can result from drug-induced pulmonary injury due to a wide variety of therapeutic agents, such as gold salts, sulfasalazine, and amiodarone. It also is seen in chronic rejection after lung transplantation and after certain viral infections (e.g., cytomegalovirus, respiratory syncytial virus). BOF is manifested as an obstructive defect with no response to bronchodilator therapy. Patients often have cough and significant dyspnea. Corticosteroid treatment after acute lung injury due to toxic inhalation can be effective when given acutely in large doses for 1 month. Once fibrosis has occurred, treatment largely is ineffective.¹⁰

Bronchiolitis obliterans organizing pneumonia (BOOP), also known as proliferative bronchiolitis obliterans, is characterized by an organizing intraluminal exudate. Fibrotic buds known as Masson bodies are seen in respiratory bronchioles, alveolar ducts, and alveoli. Foamy alveolar macrophages are present in alveolar spaces and inflammatory changes are seen in alveolar walls. BOOP can be caused by inhalational exposures, especially to water-soluble gases. It has been reported also after exposure to irritant gases, postinfection, in transplant rejection, as well as in many systemic inflammatory disorders such as ulcerative colitis. Chest radiographs show diffuse infiltrates and spirometry reveals a restrictive defect. Treatment is directed at the underlying cause; removal from exposure is essential, and corticosteroid treatment has shown considerable success.¹²

Interstitial Pneumonitis and Diffuse Alveolar Damage

Interstitial pneumonitis refers to interstitial collections of inflammatory cells, mild fibrosis, and reactive type II pneumocytes. This can be seen after numerous pulmonary injuries and toxic exposures, both via the inhalational route as well as systemic exposure. The healing phase can result in fibrosis and honeycombing.

Diffuse alveolar damage (DAD) is a pulmonary toxic reaction, most commonly caused by cytotoxic chemotherapeutic agents such as bleomycin, busulfan, carmustine, cyclophosphamide, melphalan, and mitomycin; it also has been reported with gold salts. The damage results from necrosis of type II pneumocytes and alveolar capillary endothelial cells. DAD has an early

exudative phase (1 week after injury) characterized by alveolar and interstitial edema and hyaline membrane formation. The late proliferative phase (2 weeks later) shows proliferation of type II pneumocytes and interstitial fibrosis. Depending on the severity of the initial injury, DAD can improve significantly after withdrawal of the drug, progress to interstitial fibrosis, and, in severe cases, may progress to honeycomb lung.¹³

HYPERSENSITIVITY REACTIONS

Asthma

Asthma is a common disorder characterized by variable airflow obstruction, airway inflammation, and airway hyper-responsiveness to various stimuli. The airflow usually is fully reversible, either spontaneously or with treatment. The definition of occupational asthma varies depending on the author, but it can be thought of as a work-related variable airway obstruction or airway hyper-responsiveness owing to an exposure in the workplace. The broadest definition includes both asthma that is *caused* by the workplace exposure and a worker's preexisting asthma that is *aggravated* by workplace exposures. This extremely broad definition might be better termed *work-related asthma*, and it is estimated that up to 33% of all asthma cases may be considered work-related using this definition, but not necessarily work-induced. Most authorities reserve the term *occupational asthma* for cases that are actually caused by the workplace exposure, and place the incidence at approximately 5%. Not surprisingly, occupational disease surveillance data indicate that occupational asthma is the most common occupational respiratory disease in industrialized nations.¹⁴⁻¹⁶

The two major types of occupational asthma are *irritant-induced* and *sensitizer-induced*. Exposure to a significant dose of an irritating gas, dust, mist, or fume can cause irritant-induced asthma (IIA) without an intervening latent period. Classically, IIA was described as only being caused by a single isolated intense exposure; more recently, it has also been described as a result of lower-level exposures that have occurred over a period of months to years. The resulting asthmatic condition may be termed *IIA* or *reactive airways dysfunction syndrome* (RADS). The condition may be short-lived or cause lifelong IIA/RADS and disability. In these cases, there is generalized airway hyper-responsiveness but no specific responsiveness to any particular agent or antigen. Treatment in these cases can be quite difficult, and long-term disability is possible.

The classic form of occupational asthma is sensitizer-induced asthma. In this type, the worker becomes sensitized to the offending agent and requires a variable amount of time between the first exposure and onset of illness. Once sensitized, however, even minute quantities of the agent may trigger a significant asthmatic response. Most cases of sensitizer-induced asthma are caused by exposure to high-molecular-weight organic compounds that are considered "complete allergens." These high-molecular-weight compounds are proteins with a molecular

weight of more than 500 d and include traditional allergens such as animal dander, microbial spores, and plant proteins. The asthma is a type I, immunoglobulin E (IgE)-mediated immediate hypersensitivity reaction. Common names often are applied to this form of sensitizer-induced occupational asthma, such as bakers' asthma (due to wheat flour exposure) and mushroom picker's asthma (due to spore exposures).

One of the most prevalent forms of sensitizer-induced asthma is latex allergy, which can affect 2% to 17% of health care workers. Natural rubber latex gloves can induce an immediate, type I hypersensitivity reaction to the protein allergens. These latex protein allergens adhere to the cornstarch powders used as donning agents. They can then become airborne and are inhaled, causing systemic exposures and sensitization. Using gloves with higher protein contents correlates with higher allergenicity. Using powder-free, low-protein gloves has been effective in reducing symptoms and decreasing markers of systemic sensitization.¹⁷

Low-molecular-weight compounds (<500 d) such as antibiotics or metals also can cause sensitizer-induced asthma, by acting as incomplete allergens or haptens that then bind to serum proteins such as albumin and become complete antigens. Other low-molecular-weight compounds, such as toluene diisocyanate and trimellitic anhydride, sensitize by other mechanisms that are poorly understood. Increased secretion of monocyte chemoattractant protein-1 by mononuclear cells may be a major mechanism in isocyanate-induced asthma. Isocyanate exposure also has been shown to induce an overproduction of matrix metalloproteinase-9, and Trimellitic anhydride also may have a direct effect on airways even in subjects who are not sensitized to the agents. In the guinea pig model, nonsensitized animals exposed to trimellitic anhydride developed airflow limitation and eosinophilic airway inflammation.¹⁸

The chemical structure of the low-molecular-weight agent seems to be an important factor in its ability to sensitize. The presence of at least two reactive groups that can then form bonds with native human macromolecules, such as albumin, conveys the ability of these agents to induce asthma in exposed workers.¹⁵ Hundreds of low-molecular-weight compounds have been implicated in inducing occupational asthma, the most well known being plicatic acid in western red cedar, toluene diisocyanate in polyurethane foam and urethane coatings industries, and abiatic acid in colophony pine rosin used in soldering fluxes in the electronics industry.¹⁹

Some agents, such as organophosphate and carbamate insecticides, have a direct pharmaceutical action of stimulating cholinergic receptors, which causes bronchoconstriction. These agents can induce airflow obstruction without prior sensitization and do not require binding to native proteins or cellular mediators. Additionally, byssinosis is a variable airflow obstruction seen in textile workers that resembles occupational asthma. The etiologic agent is unclear: it is due either to a pharmacologic reaction to the cotton, flax, or soft hemp dusts or to endotoxin from fungal or bacterial contamination of the cotton. Tolerance seems to

develop, because workers' cough and chest tightness are worse in the beginning of the workweek (Monday cough) but become milder as the week progresses. The disease occurs only in workers with longer exposure histories, or in those with higher total dust exposures. Allergic mechanisms are not active in this disorder, but a direct release of histamine and induction of inflammation are probably responsible. Recent studies suggest that chronic obstructive disease may develop in long-term workers.²⁰

When evaluating a patient who presents with significant respiratory symptoms with bronchoconstriction, the possibility of work-related asthma always must be in the differential diagnosis, especially in patients with no prior history of asthma, with asthma of recent onset, or with acute exacerbations of previously stable asthma. Careful questioning regarding the temporal relationship between the onset of symptoms as they relate to exposures at work can be helpful. Sensitizer-induced asthma can have a biphasic or dual response, in which exposure to the allergen may induce an immediate bronchoconstriction (known as the early response) and a delayed or late response some 4 to 8 hours later. The early response usually is self-limited and often resolves without specific bronchodilator therapy. This is primarily mediated by mast cell degranulation and histamine release. The late response often follows with airway inflammation, hyper-responsiveness, and obstruction. The pathophysiology of the late response is complex and not completely understood. There is a pivotal role for numerous chemoattractant substances. A specialized type of CD4⁺ lymphocyte, known as the T-helper 2 (T_H-2) lymphocyte, seems to be responsible for the chronic inflammation that is present in sensitizer-induced asthma. Cytokines such as IL-4, IL-5, and IL-13 (which are produced by T_H-2 cells) and chemokines attract neutrophils and eosinophils into the airway epithelium. The eosinophils then cause airway epithelial injury by releasing proteins, lipid mediators, and oxygen radicals. Lymphocytes are also active, and they release cytokines that activate mast cells and eosinophils.²¹

As the airway inflammatory cascade continues, the increased mucus secretion and capillary endothelial and alveolar epithelial permeability all contribute to mucosal edema and narrowing of the airway caliber. The reduced caliber causes the airflow obstruction and the resultant signs and symptoms of an acute attack.

Some workers may exhibit only the late response, becoming ill hours after leaving the workplace, when the causal relationship may not be apparent. The presence of the dual response may hinge on factors such as the type of compound, dose, length of exposure time, and concomitant use of medication. Low-molecular-weight agents generally seem more likely to induce an isolated late response, whereas high-molecular-weight "complete" allergens more commonly cause a dual response. There is, however, considerable overlap.^{10,16}

The mechanism by which chronic airway inflammation occurs in IIA/RADS is poorly understood. Direct chemical injury to airway cells causes an inflammatory response and release of cytokines and inflammatory mediators.

Neurogenic pathways are probably involved also, with the end result being airflow obstruction.

Acute treatment of occupational asthma is no different than that of conventional asthma, which consists of inhaled β agonists, supplemental oxygen, and systemic corticosteroids, as condition dictates. Severe exacerbations associated with hypoxia and/or CO_2 retention require treatment in the intensive care unit. Long-term management hinges on identifying the sensitizer, when possible, and removing the patient from further exposure. Irritant-induced RADS may have significant long-term sequelae that do not improve with removal from the workplace. Tables 9-1 and 9-2 list the exposures and occupations known to be associated with occupational asthma.^{16,18,19,22}

Hypersensitivity Pneumonitis (Extrinsic Allergic Alveolitis)

Hypersensitivity pneumonitis (HP) is an interstitial lung disease caused by a combination of type III (humoral or IgG-mediated) and type IV (cell-mediated) delayed hypersensitivity reactions that usually occur after inhalational exposure to a wide variety of organic dusts, antigens, and some chemicals. Most commonly, HP has been associated with occupations having exposures to moldy organic materials, such as moldy hay in farmer's lung and moldy grain in grain worker's lung. It can be seen also in animal handlers due to exposure to animal proteins and excreta (pigeon breeder's lung). Exposures

to various chemicals that also cause occupational asthma, such as toluene diisocyanate (TDI), trimellitic anhydride (TMA), and heated phenolic resins containing phthalic anhydride, also have been implicated in HP.²³ Some therapeutic drugs have been implicated as causing HP, such as simvastatin, dapsone, penicillamine, paclitaxel, mesalamine, gold, and chemotherapeutic agents (Table 9-3).

The pathophysiology of HP involves immune complex deposition in the lung of sensitized individuals, with the resultant release of immune mediators and cytokines, as well as inflammatory cell infiltration. Acutely this involves neutrophils, but later lymphocytes predominate. The typical presentation occurs 4 to 6 hours after an intense inhalation exposure (in an appropriate occupational setting) to the responsible antigen, and patients commonly have fever, chills, malaise, cough, and dyspnea. Chest radiographs are abnormal in greater than 80% of cases, and they often have a reticulonodular pattern or reveal patchy infiltrates. High-resolution CT scanning (HRCT) is more sensitive and has been suggested as the preferred imaging study (see later). HRCT may show reticulonodular infiltrates or ground-glass opacities. There usually is hypoxia, and patients have crepitant rales upon auscultation of the chest. Pulmonary function testing can be normal or may show a restrictive defect and a decreased diffusion capacity. The acute episode usually resolves within 1 to 3 days, and corticosteroid treatment may be of some benefit. Repeated exposures often cause a worsening of the presentation; tolerance,

TABLE 9-1 High-Molecular-Weight (HMW) Sensitizing Agents and Job Titles Associated with Occupational Asthma^{16,22}

HMW SENSITIZING AGENTS	ASSOCIATED OCCUPATIONS/INDUSTRIES
Animal Products	
Animal dander	Animal handlers, veterinary workers, farmers
Pigeons (e.g., excreta, feathers)	Pigeon breeders
Chickens, turkeys	Poultry processing
Mice	Laboratory technicians
Guinea pigs	Laboratory technicians
Wool	Wool workers, sorters
Marine organisms: prawns, crabs, oysters	Prawn workers, oyster processing, crab processing
Plant Products	
Raw Tobacco	Tobacco industry
Flours (wheat, rye)	Bakers, food processing
Enzymes	
<i>Bacillus subtilis</i>	Detergent manufacturing
Papain	Meat processing
Trypsin, Pepsin	Pharmaceuticals
Foods (spices, grains, flours)	Chefs, food industry, food preparers
Natural rubber latex	Health care workers, rubber industry
Gums (acacia, arabic, tragacanth, karaya)	Pharmaceuticals, printing
Coffee beans, tea leaves	Coffee production, tea workers
Castor beans	Castor oil production
Seeds: flaxseed, cottonseed, linseed, psyllium seed	Bakers, oil extraction, seed workers
Woods (e.g., oak, mahogany, California redwood)	Sawmills, carpenters, woodworkers
Hops	Brewery workers, farmers
Microorganisms	
Fungi, molds	Farmers, bakers, various other industries

Adapted from Holland MG: Critically injured workers. In Brent J, Wallace KL, Burkhart KK, et al (eds): Critical Care Toxicology. Philadelphia, Mosby, 2005, used with permission.

TABLE 9-2 Low-Molecular-Weight (LMW) Sensitizing Agents and Job Titles Associated with Occupational Asthma^{16,18,19}

LMW SENSITIZING AGENTS	ASSOCIATED OCCUPATIONS/INDUSTRIES
Antibiotics	
Penicillins, cephalosporins, tetracyclines	Pharmaceuticals
Drugs	
α -Methyldopa, cimetidine, hydralazine, opiates, penicillamine, others	Pharmaceuticals
Inorganic Chemicals	
Ammonium persulfate	Beauticians, chemical production workers
Fluoride	Aluminum pot-room workers
Metals	
Aluminum	Aluminum smelting
Chromium salts	Leather tanning, metal plating, hard metal
Cobalt	Tungsten carbide hard metal workers
Nickel	Metal plating
Palladium	Metal plating, jewelers
Platinum	Platinum refining, electroplating, fluorescent screen manufacturing, jewelers
Vanadium	Ferrovanadium workers (hard metal workers)
Zinc	Metal plating
Organic Chemicals	
Abietic acid (colophony pine rosin)	Soldering, electronics manufacturing
Acrylates	Glues
Aldehydes:	
Formaldehyde	Hospital workers, laboratory technicians
Gluteraldehyde	
Amines (ethanolamine)	Soldering, paint application, machining metal
Anhydrides:	
Trimellitic anhydride (TMA)	Plastics, epoxy resins
Phthalic anhydride	
Dyes	Dye industry, fabrics
Insecticides (pyrethrins, OPs)	Farmers, insecticide applicators
Isocyanates:	
Toluene diisocyanate (TDI)	Polyurethane foam manufacturing
Diphenylmethane diisocyanate (MDI)	Foundries, paint application
Plicatic acid (western red cedar)	Lumber, logging, carpenters, cabinet makers
Paraphenylenediamine	Fur dyer, chemical worker
Phenol	Chemical worker, laboratory worker
Piperazine	Chemical processing
Styrene	Chemical production, polymer industry

such as that seen in inhalation fevers, does not occur. In fact, repeated low-level exposures cause a progressive, often irreversible pulmonary fibrosis. These patients may present from a typical occupational setting with the insidious onset of a constellation of signs and symptoms, including dyspnea, cough, weight loss, and fatigue. Chest radiographs may reveal increased interstitial markings and fibrosis, and pulmonary function testing usually shows restrictive disease and decreased diffusion capacity.

The diagnosis of HP can be difficult, if not controversial. Diagnosis traditionally has relied on various non-specific clinical symptoms and signs, with demonstration of interstitial markings on chest radiographs, the presence of serum precipitating antibodies against appropriate antigens, a lymphocytic alveolitis on bronchoalveolar

lavage (BAL), and/or a granulomatous reaction on lung biopsies. However, when considered separately, none of these findings is pathognomonic for HP. Specifically, chest radiographs are normal in 20% of acute cases. Serum precipitins document exposure to the offending antigen but don't imply disease, because many co-workers with similar exposures but without disease demonstrate serum precipitins. BAL can be helpful, because a normal lymphocyte BAL count rules out all but residual disease, but an alveolar lymphocytosis is not specific to HP. Transbronchial biopsies are of limited usefulness, even when granulomas are found, because these are present in other diseases. HP gives a typical, albeit nonspecific, pattern of bilateral ground glass or poorly defined centrilobular nodular opacities on HRCT.

**TABLE 9-3** Exposures Reported to Cause Hypersensitivity Pneumonitis (HP)

DISEASE	USUAL SOURCE	PROBABLE ANTIGENS	COMMENTS
Plant Products			
Farmer's lung	Moldy hay	Thermophilic actinomycetes: <i>Faenia rectivirgula</i> , <i>Thermoactinomyces vulgaris</i> ; <i>Aspergillus</i> spp	Primary antigens are not molds but thermophilic bacteria
Bagassosis	Moldy pressed sugarcane	Thermophilic actinomycetes: <i>F. rectivirgula</i> , <i>T. vulgaris</i>	Bagasse is pressed sugarcane
Mushroom worker's disease	Moldy compost	Thermophilic actinomycetes: <i>F. rectivirgula</i> , <i>T. vulgaris</i>	
Malt worker's lung	Contaminated barley	<i>Aspergillus clavatus</i>	
Maple bark stripper's disease	Contaminated maple logs	<i>Cryptostroma corticale</i>	
Humidifier lung	Contaminated humidifier water	Thermophilic actinomycetes: <i>T. vulgaris</i> , <i>T. candidus</i> ; <i>Penicillium</i> spp, <i>Cephalosporium</i> spp; <i>Amoeba Bacillus subtilis</i>	Related exposures also can cause humidifier fever
Familial HP	Contaminated wood dust in walls		
Compost lung	Compost	<i>Aspergillus</i>	
Cheese washer's disease	Cheese casings	<i>Penicillium</i> spp	
Cephalosporium HP	Contaminated basements	<i>Cephalosporium</i>	Seen when sewage contaminates basement
Sauna taker's disease	Sauna water	<i>Pullularia</i> spp	Hot tub lung caused by atypical mycobacterium
Detergent worker's disease	Detergent	<i>Bacillus subtilis</i> enzymes	
Japanese summer-type HP	Contaminated house dust, tatami mats	<i>Trichosporon cutaneum</i>	<i>T. cutaneum</i> is an imperfect yeast
Dry rot lung	Rotting wood	<i>Merulius lacrymans</i>	
Office worker's HP	Contaminated dusts from HVAC systems	?	Multiple fungal and bacterial antigens may be responsible
Potato riddler's disease	Moldy straw around potatoes	Thermophilic actinomycetes: <i>F. rectivirgula</i> , <i>T. vulgaris</i> , <i>Aspergillus</i> spp	
Tobacco worker's disease	Moldy tobacco	<i>Aspergillus</i> spp	
Hot tub lung	Contaminated hot tub water	Atypical mycobacterium, <i>Cladosporium</i> spp	
Wine grower's lung	Moldy grapes	<i>Botrytis cinerea</i>	
Grain worker's lung	Grain dust	<i>Erwinia herbicola</i>	
Pyrethrin alveolitis	Pesticides	Pyrethrins	Pyrethrins are natural insecticides derived from chrysanthemum flowers; also a cause of occupational asthma
Animal Products			
Pigeon breeder's disease	Pigeon droppings	Altered pigeon serum	
Duck fever	Duck feathers	Duck proteins	
Turkey handler's lung	Turkey products	Turkey proteins	
Bird fancier's lung	Bird products	Bird proteins	
Dove pillow's lung	Bird feathers	Bird proteins	
Laboratory worker's HP	Rat fur	Male rat urine	
Pituitary snuff taker's disease	Pituitary powder	Bovine and porcine proteins	
Mollusk shell HP	Mollusk shells	Animal proteins	
Chemicals			
Toluene diisocyanate (TDI) HP	TDI	TDI-albumin complex	Also most common industrial chemical asthma inducer
Trimellitic anhydride (TMA) HP	TMA	TMA-albumin complex	Can also cause occupational asthma, and TMA-pulmonary hemorrhage-anemia syndrome
Diphenylmethane diisocyanate (MDI) HP	MDI	MDI-albumin complex	Can also cause occupational asthma
Epoxy resin lung	Heated epoxy resin	Phthalic anhydride	
Pauli's HP	Pauli's reagent	Sodium diazobenzene-sulfonate	

Lacasse and coworkers recently formulated diagnostic criteria for HP, relying on BAL and HRCT as the “gold standard,” and, if needed, other diagnostic procedures. BAL lymphocytosis (>30% for non- and ex-smokers; >20% for smokers) and the typical HRCT findings were required for a diagnosis of HP to be accepted without resorting to additional diagnostic procedures, such as open lung biopsy. Six significant predictors of HP were identified: exposure to a known offending antigen, positive precipitating antibodies to the offending antigen, recurrent episodes of symptoms, inspiratory crackles on physical examination, symptoms occurring 4 to 8 hours after exposure, and weight loss. The likelihood of HP in any given patient increased as more predictors were present, with a 98% probability of HP when all six were present.²⁴

Treatment of acute episodes consists of administering oxygen and admission to hospital when necessary. Corticosteroids are the only useful medications in the treatment of HP. They have benefit in the acute attacks at a dose of 1 mg/kg/day of prednisolone. However, the mainstay of treatment is withdrawal from exposures and prevention of any further contact with the inciting antigen or chemical.^{23,25}

TOXIC INHALANT INJURY

Many occupations have potential exposure to gases, and, as a result, often these have significant potential for lung injury or systemic toxicity. Gases of toxicologic importance can be divided into three major categories: simple asphyxiants, toxic or chemical asphyxiants, and irritant gases.

Simple Asphyxiants

Simple asphyxiants have no inherent toxicity other than displacing oxygen from ambient air, thereby inducing anoxia. This is especially important in confined spaces, where the lack of air movement and ventilation may allow these gases to replace oxygen. Also, many are heavier than air and tend to accumulate in low areas. In the case of the chemical production worker, confined spaces such as reactor vessels may contain no oxygen; entry for vessel cleaning requires self-contained breathing apparatus or other supplied air respirators.

The simple asphyxiants commonly encountered by workers include nitrogen, simple hydrocarbons (e.g., propane, butane), and carbon dioxide. When encountered in confined spaces, a simple asphyxiant can cause anoxic central nervous system injury due to oxygen deprivation. The degree of injury depends on the extent and duration of anoxia. Additionally, the hydrocarbon simple asphyxiant (e.g., ethylene, propylene, butadiene, isobutylene, methane, ethane) also pose a significant explosive hazard. These confined space exposures usually occur in the situation of inadequate safety training and/or lack of proper supervision; often this occurs in newly hired workers who are unfamiliar with the inherent dangers. Treatment of simple asphyxiant

exposure involves removal from the source, adequate ventilation, and supplemental O₂.

Toxic or Chemical Asphyxiants

The gases considered to be chemical asphyxiants act by either decreasing the oxygen-carrying capacity of the blood (carbon monoxide, methemoglobin producers) or by interfering with cellular use of oxygen (cyanide, hydrogen sulfide). These toxicants are covered in detail in other chapters of this text (see Chapters 88, 89, and 91).

Irritant Gases

Irritant gases cause injury patterns that are directly related to their water solubility. Highly soluble gases such as HCl, NH₃, SO₂, and formaldehyde (CH₂O) and acid vapors cause immediate irritation of the mucous membranes of the upper respiratory tract because they easily dissolve in the moisture of these tissues. They cause direct tissue injury via burning by extremes of pH in the cases of acids and bases, or by forming an acid or base quickly upon dissolution in the physiologic fluids. Ammonia reacts with water to form ammonium hydroxide, a strong alkali, with the ability to cause airway injury and sloughing. Airway injury also may be caused by a more chemically reactive substance. For example, toxic cadmium fumes can cause a pneumonitis and acute lung injury due to inhibition of cellular and enzymatic function by the metal.

Highly water-soluble irritant gases cause immediate burning in the mucous membranes of the eyes, nose, mouth, and throat. The primary site of injury, therefore, is the upper respiratory tract, for two reasons. First, this immediate onset of symptoms tends to limit the exposure; the victim does not tolerate exposures long enough for significant lower airway injury and rapidly exits the area causing the symptoms. Second, these soluble gases first deposit in the upper airways, making less concentration available to the lower respiratory tract. When exposures occur in confined spaces, or when victims have associated injuries that inhibit their ability to escape, prolonged exposures can result in lower respiratory tract and pulmonary parenchymal injury. Significant symptoms of upper tract burning and irritation with signs of mucosal and conjunctival inflammation, when accompanied by laryngeal symptoms and cough, indicates a possibility of lower respiratory tract injury and the need for admission and observation. Delayed pulmonary injury has been observed, with the onset of noncardiogenic pulmonary edema due to ARDS hours later. Long-term sequelae may include RADS/IIA, restrictive or obstructive defects, bronchiectasis, or bronchial stenosis. Conversely, the lack of upper respiratory signs or symptoms rules out any significant exposure of a highly soluble irritant gas and obviates the need for prolonged observation.^{10,23,26}

Phosgene, oxides of nitrogen (e.g., NO₂, N₂O₄; commonly designated NO_x), and ozone are poorly water-soluble gases. These insoluble gases cause little or no upper respiratory tract symptoms. In fact, the only

warning may be a nonobjectionable odor, such as freshly mown hay in the case of phosgene, or bleach-like odor of nitrogen dioxide. Because there is no initial irritation, employees often are unaware of ongoing exposure. Thus, longer exposures can be tolerated, and the concentration reaching the lower airways is higher due to lack of deposition in the upper airway mucosa. Eventually, a significant amount dissolves in the water of the lower airway and alveolus. Often, injury is then caused by formation of a new compound, usually an acid, base, or free radical. In these cases, delayed alveolar injury is possible, and onset of lower respiratory tract injury and pulmonary edema occurs 6 to 12 hours after a significant exposure.

Phosgene (carbonyl chloride) is encountered in chemical synthesis as an intermediate for isocyanate and pesticides, or as a by-product when chlorinated hydrocarbons are burned or heated. This can occur when Freon refrigerants burn in fires or when metals that had previously been cleaned with chlorinated hydrocarbon degreasers are welded or torch-cut. Phosgene also has historical significance as a World War I gaseous warfare agent, responsible for almost 80% of the deaths by chemical warfare gases. It is greater than three times heavier than air and accumulates in lower areas, making it an ideal agent for the trench warfare that was common during that campaign. Nitrogen dioxide is found in recently stored silage, especially corn grown during drought conditions, and is the agent responsible for silo filler's disease. It reacts with water in the lung to produce nitric and nitrous acids, which are likely responsible for the acute lung injury. The oxides of nitrogen begin to form within 12 hours of storage and can continue for 2 weeks. Oxides of nitrogen also form as by-products of combustion of fossil fuels or use of explosives, from lightning, and from oxidation of ambient nitrogen during high temperature arc welding. Nitric acid production workers can be exposed to NO₂ gas (the bubbles in fuming nitric acid are NO₂).

The initial alveolar injury usually results in alveolar-capillary leak, with edema and inflammation of the airway epithelium and submucosa. The fragile alveolar type I pneumocytes are particularly susceptible to injury, and irritant gases that reach the alveolus cause inflammation of the respiratory bronchioles and subsequent pulmonary edema and development of hyaline membranes and ARDS. The injury to the alveoli can be diffuse, and type II pneumocytes and fibroblast proliferate in an attempt to repair alveolar damage. In the recovery phase, resorption of hyaline membranes and exudates occurs. In some patients, the collagen deposition that follows can lead to long-term pulmonary fibrosis, whereas in others, recovery is complete.²⁷

Due to the lack of upper respiratory tract irritation associated with exposure to low solubility irritant gases, patients often go home and develop these symptoms remote from the worksite. Without a detailed occupational history, the connection to the workplace exposure may go unnoticed. The clinical picture may present as ARDS, and sepsis or some other nonoccupational cause may be suspected. Treatment consists of

O₂ and ventilatory support as dictated by the clinical picture. Recent evidence suggests that lower tidal volumes and lower airway pressures in ventilated patients may improve survival.²⁸ Depending on the severity of injury, mortality rates from severe ARDS may be significant, and patients who recover may be left with permanent pulmonary impairment. Corticosteroids probably are useful to prevent the late sequelae of BOF that is seen after nitrogen dioxide exposures. Their value in other toxic inhalation injuries is suggested by animal studies, but it is not proven in humans.¹⁰

The spectrum of water solubility is wide, and many gases do not fit neatly into categories of high, medium, or low water solubility (Table 9-4).²⁹ Medium solubility gases, like chlorine, have dissolution rates in the upper airway moisture that is midway between the highly soluble and the poorly soluble irritant gases. Significant chlorine gas exposures can cause upper airway symptoms of burning and irritation, but these may be milder than with the highly soluble gases. Exposures may be tolerated longer than that of the highly soluble gases and, therefore, may progress to lower airway injury and delayed pulmonary edema. Chlorine exerts its toxic effect by formation of hydrochloric acid and hypochlorous acid once it dissolves in the water of the respiratory tract. Clinical suspicion and careful evaluation are necessary when making disposition decisions following exposures to the medium solubility gases. When in doubt, 24 hours of observation in hospital is warranted.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is defined as a condition of airflow obstruction that is not fully reversible (as opposed to asthma in which the airflow generally is reversible). COPD is quite prevalent, with more than 16 million patients with the disease in the United States and probably even more who fit the criteria but remain undiagnosed due to the insidious onset of mild symptoms. The overwhelmingly predominant cause of COPD is tobacco smoking; however, exposures to irritating dusts, gases, and fumes probably have the capacity to induce this disorder.³⁰ Plausible evidence for this exists when considering IIA. There likely is overlap between IIA and COPD. Many IIA patients have airflow obstruction that is not fully reversible, and their disease often is more persistent than sensitizer-induced occupational asthma, as well as more difficult to treat. Other evidence is from the developing world, where exposure to smoke generated from the use of wood or fossil fuels for indoor cooking and heating that is not properly ventilated may be of importance comparable to tobacco smoking for COPD development.³¹ The American Thoracic Society has estimated that the population-attributed risk for COPD was estimated to be 15% to 20% due to occupational exposures.³² Several more recent studies lend further support to the theory that occupational exposures can increase the risk of COPD. Some of the industries with increased risk include rubber, plastics, and leather manufacturing; utilities; textile manufacturing; the

TABLE 9-4 Relative Solubilities of Common Irritant Gases²⁹

GAS, CHEMICAL FORMULA	RELATIVE VAPOR DENSITY (AIR = 1)	SOLUBILITY IN WATER	RELATIVE SOLUBILITY
Hydrogen fluoride, HF	1.86	Freely soluble in water	Very high
Hydrogen chloride, HCl	1.27	82.3 g/100 mL water	Very high
Chloramine: NH ₂ Cl (Bleach + NH ₃)	N/A (liquid)	Freely soluble in water	Very high
Formaldehyde	1.04	55 g/100 mL water	High
Ammonia, NH ₃	0.59	47 g/100 mL water	High
Fluorine, F ₂	1.31	Reactive	Medium high
Acrolein (C=C-C=O)	1.9	21 g/100 mL water	Medium high
Sulfur dioxide, SO ₂	2.263	17.7 g/100 mL water	Medium high
Methyl isocyanate (MIC), CH ₃ NCO	1.42	10 g/100 mL water	Medium high
Chlorine, Cl ₂	2.47	1.46 g/100 mL water	Medium
Phosgene (Carbonyl chloride, COCl ₂)	3.48	0.9 g/100 mL water	Low
Chlorine dioxide, ClO ₂	2.33	0.3 g/100 mL water	Low
Nitrogen dioxide, NO ₂	2.62	0.3 g/100 mL water	Low
Ozone, O ₃	1.66	0.001 g/100 mL water	Very low

armed forces; chemical, petroleum, and coal manufacturing; and the construction industry.³³ These exposures to dusts, gases, and fumes may cause COPD independent from cigarette smoking; when combined with cigarette smoking, the effects appear to be more than additive.³⁴

INHALATION FEVERS

Metal fume fever (MFF) is the classic example of an inhalational fever, but inhalational fever syndromes can occur after inhaling a wide variety of organic and inorganic materials. The same occupational settings also can give rise to HP, so it must be included in the differential diagnosis. In contradistinction to HP, these exposures can cause a self-limited, flulike illness consisting of fever, chills, generalized body aches, and malaise. Patients frequently complain of headache, sore throat, chest pain, and cough, and they may have some dyspnea. There often is an elevated white blood cell count, but generally there are no other laboratory abnormalities. Usually, there is no hypoxemia, chest radiograph abnormalities, or pulmonary infiltrates. The syndrome usually arises within a few hours after exposure and resolves within 1 day, with no residual effects. The mechanism appears to be a nonimmunologic reaction in the alveolus, causing release of cytokines and inflammatory mediators. Specifically, alveolar macrophages release cytokines interleukin (IL)-4, IL-6, and tumor necrosis factor α (TNF- α), which are known endogenous pyrogens. Complement may be activated, and T lymphocytes can release other inflammatory mediators. Repeated exposures cause a “desensitization,” or tachyphylaxis, whereby symptoms are worse at the beginning of the work week (Monday morning fever), and after repeated exposures may elicit no symptoms at all. There are no residual defects seen on spirometric evaluation.

Diagnosis is made based on the above criteria, after ruling out influenza or other infectious causes. A good occupational history is essential, as infections usually are

higher up on the diagnostic list when isolated patients present with these symptoms. A group of workers presenting with similar symptoms from the same occupational exposure setting makes it easier to consider. Treatment for the inhalation fevers is supportive, as this clinical entity is entirely self-limited. Proper education of the worker regarding the exposures that lead to this syndrome and appropriate engineering controls or fitting with appropriate respiratory protection can prevent further episodes.

Many of the occupational settings where inhalation fevers occur also harbor risks of other acute lung injuries. For instance, welding of galvanized steel produces zinc oxide fumes responsible for MMF, but welding metal with cadmium can produce acute lung injury and death; and high-temperature arc welding in a confined space can cause significant NO₂ exposure leading to ARDS. Farmers who unload silos may be exposed to silage that is contaminated with thermophilic bacteria and molds that can cause inhalation fever (silo unloader’s disease), but exposure to freshly stored silage can cause silo filler’s disease due to liberation of NO₂ (acute lung injury). Moreover, farmers with moldy hay exposure may induce hypersensitivity pneumonitis due to exposure to the fungi and thermophilic bacteria that grow in wet hay.

In contrast to inhalation fevers, the acute episode of HP often is accompanied by hypoxemia and pulmonary infiltrates on chest radiographs. Although fever is required for the diagnosis of inhalation fevers, it also may be present in HP or acute lung injury. The key distinguishing features in inhalation fevers are that chest radiographs show no abnormalities and there usually is no hypoxia, whereas these features are prominent in ARDS and HP. Repeated exposures to the causative agents of inhalation fevers causes a tolerance or significantly diminished response. Symptoms may be prominent when starting work or resuming after a vacation period. By the end of a workweek, exposures may cause no symptoms, and no permanent pulmonary sequelae develop. However, repeated insults of HP and acute lung injury after irritant

gas exposures often cause pulmonary function abnormalities and can lead to fibrosis and restrictive lung disease. Attack rates after typical exposures for the inhalation fevers can be high, often higher than 80% in one report of organic dust toxic syndrome, whereas HP occurs only in a small percentage of those exposed. Sensitization is required for the development of HP but not for inhalation fever. Repeated bouts of inhalation fevers due to certain exposures (humidifier fever) may predispose individuals to the development of HP, because these exposure settings also contain antigens responsible for HP (Table 9-5).^{35,36}

Metal Fume Fever

Heating metals to a greater temperature than their melting point, such as while welding, causes formation of solid aerosols (fumes), often with accompanying oxidation. The resultant particle size of 0.1 to 1.0 μm reaches the alveoli easily, where an acute inflammatory cell response causes release of cytokines, producing a constellation of symptoms. The classic syndrome of MFF involves a metallic taste in the mouth, fever, rigors, headache, chest pain, and dyspnea, with an abrupt onset 4 to 12 hours after exposure. Clinical tolerance to these effects occurs after regular exposure.³⁷ Zinc oxide fumes are the classic cause of MFF, and in the 18th century was predominantly seen in brass foundries, where copper and zinc are heated to form the alloy brass. This gave rise to the then-common name given to what we now know as MFF: brasser's flu or brass founder's ague. More recently it has been seen after welding galvanized steel, in which the heating of zinc in the galvanized coatings forms zinc oxide fumes.³⁸ There is some limited epidemiological evidence that other metal fumes, such as those produced when magnesium and copper are heated, can cause MFF.^{39,40}

Polymer Fume Fever

Teflon (polytetrafluoroethylene [PTFE]) can form pyrolysis degradation products when heated. Inhaling these products can lead to an inhalational fever known as polymer fume fever (PFF). PFF commonly occurs when Teflon-coated metals are welded or flame cut. Demolition of buildings with torch cutting of polymer coated wires, for example, also may cause the syndrome. It has been described in PTFE workers after smoking cigarettes that are contaminated with PTFE resins from their hands. This usually self-limited, flulike illness presents similarly to MFF, and diagnosis is based on the history of appropriate exposure. With prolonged exposures, or when higher temperatures are involved, pulmonary involvement with accompanying chest radiograph findings of consolidation are possible.⁴¹ There even has been a case of PFF from burning of the PTFE coating of a nonstick frying pan.⁴²

Humidifier Fever

Humidifier fever is an inhalation fever syndrome caused by exposure to air contaminated by humidifier water that has excessive growth of microorganisms, most notably

Pseudomonas and other gram-negative bacteria, as well as amoeba. It is a self-limited syndrome with features remarkably similar to MFF, and diagnosis usually is made after several workers from the same building present with the appropriate signs and symptoms. It occurs more often during winter months, when heated winter air is dry and these humidification systems are in common use. Non-smokers are more susceptible than smokers. Humidifier fever is not to be confused with humidifier lung, which is a type of hypersensitivity pneumonitis that occurs after repeated exposure to humidifier contaminants. There can be considerable overlap of these entities, with both syndromes occurring in different workers with the same exposure.⁴³

Pontiac Fever

Pontiac fever is simply a type of humidifier fever caused by exposure to water contaminated by *Legionella pneumophila*. In contrast with Legionnaires' disease caused by the same organism, Pontiac fever is a self-limited, flulike illness that was first described in 1968 in workers at the County Health Department Building in Pontiac, Michigan. It occurred after common source exposure to the air-conditioning system that was contaminated with *L. pneumophila*. Various other indoor water sources such as fountains, whirlpools, and spas have been implicated in causing Pontiac fever after contamination with *Legionella* species.^{44,45}

Organic Dust Toxic Syndrome

Organic dust toxic syndrome (ODTS) is a catch-all term applied to a variety of inhalation fever syndromes that occur after exposure to many different organic dust mixtures.^{38,39} Many of these dusts are associated with agricultural industries and include bacteria, fungi, grains, silage, hay, animal dander, pollen, and other complex mixtures. There seems to be a dose-response relationship, whereby higher dust concentrations and longer exposures increase the likelihood of developing the syndrome. In most instances, dust concentrations have been described as being so thick that it was difficult to see across the room. These conditions normally only occur in the agricultural setting, hence the common name "silo unloader's disease." Symptoms include fever, malaise, chest tightness, cough, and generalized aches. Hypoxia and chest radiograph abnormalities typically are absent, and the syndrome usually resolves without sequelae. However, there is a strong overlap with the causative agents of HP, and in these exposure settings HP must be ruled out.^{35,46}

PNEUMOCONIOSES

Coal Workers Pneumoconiosis and Silicosis

Fibrotic lung diseases can develop after heavy mineral dust exposures to silica quartz (silicosis), coal (coal

TABLE 9-5 Comparison of Acute Inhalation Syndromes

SYNDROME	PRIOR SENSITIZATION REQUIRED	SIGNS AND SYMPTOMS	PHYSICAL EXAM FINDINGS	PFT	CHEST RADIOGRAPHY/HRCT FINDINGS	ABG/DL _{CO} OTHER LABS	COMMENTS
Hypersensitivity pneumonitis (HP), acute	Yes	Fever, chills, malaise, cough, chest pains, dyspnea, headache	Rales on exam	Restrictive, clears upon resolution	Reticulonodular infiltrates, ground-glass opacities	Hypoxia, reduced DL _{CO}	Farmer's lung, many other terms; avoidance of further exposures and corticosteroids mainstays of treatment
HP, chronic	Yes	Insidious onset of dyspnea, weight loss	Rales	Restrictive	Fibrosis	Hypoxia; Reduced DL _{CO}	Occurs from repeated exposures, which if unnoticed and chronic may be misdiagnosed as idiopathic pulmonary fibrosis
Metal fume fever (MFF)	No	Fever, chills, malaise, cough, chest pains, dyspnea, headache; "metallic taste"	Usually normal, may have dry crackles on exam	Normal	Normal	Normal ABG, normal DL _{CO} , leukocytosis, elevated LDH	Brasser's flu; continued exposures cause less severe reactions
Organic dust toxic syndrome (ODTS)	No	Fever, chills, malaise, cough, chest pains, dyspnea, headache	Usually normal, may have dry crackles on exam	Normal	Normal	Normal	Silo unloader's disease
Pontiac fever	No	Fever, flu-like illness	Usually normal, may have dry crackles on exam	Normal	Normal	Normal	Due to exposure to <i>Legionella pneumophila</i> from contaminated indoor water sources (e.g., HVAC systems, spas)
Polymer fume fever (PFF)	No	Fever, chills, malaise, cough, chest pains, dyspnea, headache	Usually normal, may have dry crackles on exam	Normal	Normal	Normal	Continued exposures cause less severe reactions; in severe cases of overwhelming exposure a chemical pneumonitis may develop
Byssinosis	Probably	Chest tightness, cough, dyspnea, onset 1-2 hr after exposure	Wheezes	Obstructive	Normal	Usually normal	Continued exposures cause less severe reactions
Asthma, sensitizer-induced	Yes	Chest tightness, dyspnea, cough; onset usually immediate, can be delayed or both (dual response)	Wheezes	Obstructive	Usually normal, can have hyperinflation	Normal DL _{CO} , normal ABG, severe attacks may have hypoxia	Continued exposures cause increased sensitization and more severe reactions

TABLE 9-5 Comparison of Acute Inhalation Syndromes (Cont'd)

SYNDROME	PRIOR SENSITIZATION REQUIRED	SIGNS AND SYMPTOMS	PHYSICAL EXAM FINDINGS	PFT	CHEST RADIOGRAPHY/HRCT FINDINGS	ABG/DL _{CO} OTHER LABS	COMMENTS
Asthma, irritant-induced (IIA, RADS)	No	Chest tightness, dyspnea, cough; onset usually immediate, can be delayed	Wheezes	Obstructive	Usually normal, can have hyperinflation	Normal DL _{CO} ; normal ABG, severe attacks may have hypoxia	May have persistent airway hyper-responsiveness to many environmental stimuli (e.g., cold, dusts); can be difficult to treat

worker's pneumoconiosis [CWP]), and asbestos fibers (asbestosis), among others. These diseases are decreasing in incidence in the United States, owing to increased awareness, regulatory changes, and improved industrial hygiene practices. Due to the long latencies from exposure to development of disease, new cases from exposure that ceased 20 to 30 years ago are still being diagnosed. However, the exposure levels necessary to cause many of these pneumoconioses are still occurring in developing nations.

Exposure to coal mine dust and/or crystalline silica results in pneumoconiosis with initiation and progression of pulmonary fibrosis. In a recent NIOSH review, Castranova and Vallyathan describe *in vitro* and animal studies, as well as data obtained from exposed workers, which show that four basic mechanisms are operative in the initiation and progression of these pneumoconioses:

- Coal dust and silica have direct cytotoxic effects. The resulting lung cell damage causes release of proteolytic enzymes and lipases, which then leads to pulmonary fibrosis.
- Inhaled dusts are engulfed by pulmonary phagocytic cells that produce oxidants to destroy the dusts. This can exceed the amount of antioxidants present and cause lipid peroxidation, protein nitrosation, cell injury, and further lung scarring.
- Numerous cell mediators are released from alveolar macrophages and epithelial cells, which leads to infiltration of inflammatory cells like polymorphonuclear leukocytes and macrophages. Proinflammatory cytokines and various reactive species are subsequently produced, again leading to further lung injury and fibrotic scarring.
- These same alveolar macrophages and epithelial cells can secrete growth factors after initial healing from injury, which stimulates fibroblast proliferation and eventual scarring.⁴⁷

Classic findings of silicosis include restrictive lung disease associated with silicotic nodules in the hilar nodes and parenchyma, with a predilection for the upper lobes. The silicotic nodule in the hilar lymph nodes occasionally may calcify in its periphery, leading to the pathognomonic egg-shell appearance on chest radiograph. In a small portion of chronic silicosis cases, the silicotic nodules coalesce and form larger fibrotic masses, known as progressive massive fibrosis (PMF). With PMF, pulmonary architecture becomes distorted and vessels, bronchioles, and alveoli may be destroyed, and the end result is respiratory failure. These cases are caused by large amounts of dust exposures in an occupational setting that occurred over many years. They are primarily of historical interest, because dust exposures necessary to cause silicosis this severe rarely occur today, and current cases are a result of exposures that occurred decades ago.⁴⁸

Certain occupations, such as sandblasting, still can lead to chronic silicosis, and current regulatory standards and personal protective equipment may not be adequate to

prevent this disease. However, the reduction in incidence of severe silicosis has led to the use of HRCT scans to detect more subtle, early, subclinical findings such as micronodules and calcifications that are not evident on plain chest radiographs. Patients with silicosis have a high incidence of pulmonary mycobacterial infections (both tuberculosis and atypical mycobacterium), as well as fungal diseases such as cryptococcosis, blastomycosis, and coccidioidomycosis. This is likely due to an impairment of the normal pulmonary immune response by silica dust exposure that is not well understood. Silicosis has also been epidemiologically linked with systemic connective tissue diseases (CTD), such as scleroderma (termed *Erasmus syndrome*) and rheumatoid arthritis (*Caplan syndrome*). Some authors have estimated that the risk of these CTD is 2.5 to 15 times higher in silicosis patients than in those without silicosis.⁴⁸ However, more recent clinical studies have failed to show the same risks seen in older studies of miners.⁴⁹⁻⁵¹

Asbestos and Man-Made Vitreous Fibers

Asbestos is probably the best-studied occupational and environmental inhalation health hazard in humans. It is generally accepted that all six asbestos fiber types can cause pleural plaques, pleural fibrosis, interstitial fibrosis (asbestosis) of the lung parenchyma, carcinoma of the lung, and mesothelioma, but potency and risk vary with fiber type and exposure history. Dust control regulations in developed nations have become progressively more demanding compared with the 10 to 100 fiber/cc exposure concentrations of the mid-20th century.

Man-made vitreous fibers (MMVFs) are synthetic, vitreous silicate fibers widely used in present-day insulation and construction industries in industrialized nations due to the decline in the use of asbestos materials. MMVFs can be categorized into insulation wools (rock wool and slag wool), glass fibers (glass wool, continuous glass filaments and microfibers), and refractory ceramic fibers (RCFs, kaolin-wool and other high-temperature insulating fibers). There are more than 70 varieties of synthetic inorganic fibers in use today.

Respirable fibers of concern have a length-to-width ratio of at least 3:1 and an aerodynamic diameter less than 10 μm , corresponding to a measured physical diameter of less than approximately 3 to 4 μm . The current U.S. Department of Labor Occupational and Safety Health Organization (OSHA) permissible exposure limit is 0.1 fibers/cc, time-weighted average (TWA), for all six asbestos fiber types. There are no U.S. standards for MMVFs at this time.

Fibrosis from asbestos appears to arise when pulmonary macrophages, neutrophils, and other inflammatory cells release mediators such as lysosomal enzymes, arachidonic acid intermediates, proteases, cytokines, growth factors, and reactive oxygen species. This results in a chronic inflammatory process that stimulates fibroblast proliferation, causing excess collagen to be deposited in the area of the offending fiber. Continued exposure, which allows diffuse deposition of these fibers, leads to generalized

fibrosis, or asbestosis, which has a predilection for the lower lobes. Chest radiograph findings of lower lobe irregular fibrotic densities are typical, with indistinct cardiac and pericardial borders. Pleural or pericardial calcifications (plaques) are virtually pathognomonic for asbestos exposure. HRCT scanning is more sensitive than conventional radiographs for detection of pleural and parenchymal disease. The increased risk of lung cancer and mesothelioma seen in asbestos exposures may be due to the reactive oxygen species, which can cause DNA damage to critical genes coding for detoxifying enzymes.

MMVFs have been in use since the 1800s, with very few reports of pulmonary disease due to MMVF exposure, but pleural plaques have been reported in a cohort of refractory ceramic fibers (RCF) manufacturing workers in the United States. MMVFs are less durable and less respirable than asbestos fibers. Although there is some evidence that RCFs are capable of inducing lung tumors in rats and mesotheliomas in hamsters, current data do not show an excess risk of lung cancer in humans. Recent studies have shown RCF workers can develop pleural plaques without concomitant interstitial fibrosis. It is unknown whether these pleural changes signify a future risk for human mesothelioma. Long-term follow-up studies of the RCF worker cohorts are needed. At the present time, whether inhaled MMVFs represent a human carcinogenic risk is unknown.⁵²

Metal Pneumoconioses^{48,53}

Inhalation of metal dusts and fumes can induce a wide range of lung pathology, including airway disorders, cancer, and parenchymal diseases. Metal inhalation can cause granulomatous disease, giant cell interstitial pneumonitis, chemical pneumonitis, and interstitial fibrosis, among other disorders. The major offending metals are aluminum, beryllium, cadmium, cobalt, copper, iron, mercury, and nickel.

Beryllium and nickel exposure induce an immunologic reaction in the lung. Beryllium probably acts as an incomplete antigen, or hapten, and is presented by antigen-presenting cells to CD4⁺ T cells, which then react with the hapten via specific receptors. Only about 15% of workers exposed to beryllium develop chronic beryllium disease, which suggests that genetic factors play an important role. Other metals such as cadmium and mercury induce nonspecific damage, probably by initiating production of reactive oxygen species. Additionally, there is genetic susceptibility associated with increased risk in developing hard metal disease from cobalt exposure.

ALUMINUM

Occupational exposures to aluminum dusts and fumes have been associated with parenchymal lung disorders such as pneumoconiosis, fibrosis, and granulomatous lung disease. The prevalence of disease in exposed workers is relatively low when compared with beryllium exposure. The mechanisms by which aluminum causes parenchymal disease are unknown.

BERYLLIUM

Due to its light weight, low density, high melting point, and high tensile strength, beryllium has been used in the nuclear power industry and other high-technology applications. Beryllium acts as an incomplete antigen, or hapten, and is presented by antigen-presenting cells to CD4⁺ T cells, which possess receptors on their surface capable of recognizing the antigen. Workplace exposure to beryllium results in three possible outcomes: (1) workers who show no evidence of an immune response or sensitization to beryllium and do not develop chronic beryllium disease (CBD); (2) workers who become sensitized to beryllium, as demonstrated by skin testing or the blood beryllium lymphocyte proliferation test (BeLPT), but who do not have any evidence of CBD; and (3) workers who have become sensitized, as demonstrated by blood lymphocyte test or skin patch tests, and have developed CBD—a granulomatous or mononuclear cell infiltration of the lung and other tissues that is clinically indistinguishable from sarcoidosis. There is some evidence of a dose-response relationship for the development of CBD, but even nonproduction employees working nearby (e.g., secretaries, front office personnel) have developed the disease from trivial exposures. There is good evidence that the current OSHA standard of 2 $\mu\text{g}/\text{m}^3$ 8-hour TWA is not protective. Workers exposed to levels below this have become sensitized and developed CBD. The U.S. Department of Energy (DOE) recognized this and, in 1999, developed its own action level of 0.2 $\mu\text{g}/\text{m}^3$, which is also the American Conference of Governmental Industrial Hygienists's threshold limit value for beryllium.⁵⁴ The DOE requires medical monitoring and BeLPT for all beryllium-associated workers. The safe level at which no worker becomes sensitized is unknown. Workers with exposures below 0.1 $\mu\text{g}/\text{m}^3$ have become sensitized.⁵⁵ Sensitization can occur in 1% to 16%, and chronic beryllium disease occurs in approximately 2% to 6% of exposed workers, through the refining of beryllium-containing ores as well as manufacturing and use of beryllium metals, oxides, alloys, ceramics, and beryllium-containing products. However, attack rates for CBD can be as high as 17% in some highly exposed cohorts, lending evidence for some dose-response relationship. Workers who are involved in machining or grinding beryllium metal have higher exposures to beryllium dusts, and have a higher rate of CBD. Workers with evidence of sensitization or CDB must be removed completely from further beryllium exposure.

CADMIUM

Exposure to cadmium occurs in production of nickel cadmium (Ni-Cd) batteries, electroplating, and manufacture of pigments or cadmium alloys. Nonoccupational exposures occur from tobacco smoking. Cadmium has a low boiling point and, therefore, forms toxic metal fumes readily when heated, such as when soldering, welding, or making alloys. Acute inhalation of cadmium fumes can cause a syndrome initially similar to MFF. However, cadmium is toxic to the alveolar epithelium and endothelium, the mechanism of which may be an

oxidant-induced cytotoxicity. Consequences of acute exposures are a delayed chemical pneumonitis, pulmonary edema, and death. Long-term sequelae such as pulmonary fibrosis and emphysema can result. Epidemiologic studies suggest chronic exposures that do not cause an acute pulmonary injury pattern also are associated with emphysema and pulmonary fibrosis.

COBALT

Hard metal is a mixture of predominantly cobalt metal and tungsten carbide particles, with smaller quantities of other alloys (e.g., titanium, molybdenum, chromium). Cobalt alloys have great strength, hardness, and resistance to oxidation. These properties make hard metal ideal for use in drilling and grinding tools. Worker exposure to hard metal dusts occurs in the manufacturing and use of these hard metal tools.

The term *hard metal disease* (HMD) is used to refer to all the respiratory diseases that result from exposure to hard metal dust, which include reactive airways disease and the parenchymal diseases—giant cell interstitial pneumonitis, bronchiolitis obliterans, hypersensitivity pneumonitis, and interstitial fibrosis.

Workers with hard metal parenchymal diseases can have resolution of symptoms when removed from exposure early in the course of the disease, but symptoms often recur upon return to exposures at work. With long-term exposure, increasing dyspnea, restrictive lung disease, reduced diffusing capacity, and eventual interstitial fibrosis can develop. This fibrosis may continue to progress even after removal from exposure. Bizarre, cannibalistic, giant, multinucleated cells obtained via BAL typically are considered a hallmark of HMD.

Cobalt is a known sensitizer, and the pathogenic mechanism of HMD most likely is immunologic. Only a small percentage of exposed workers are affected, and there is a reversal of the helper/suppressor T-cell ratios seen on BAL specimens. Sensitized workers have positive results on skin patch tests and lymphocyte proliferation tests to cobalt salts. Genetic susceptibility also is evident in the development of HMD.

COPPER

Exposure to copper fumes may cause MFF (see earlier), as well as upper respiratory irritation and nasal septal ulceration or perforation. However, despite its widespread use, respiratory illness is reported infrequently with copper exposure and longitudinal study of copper refinery workers show no increase in respiratory diseases. Exposure to Bordeaux mixture, a solution of copper sulfate used as an antimildew agent in vineyards, has caused an interstitial lung disease in some workers.

IRON

Siderosis generally is considered a benign pneumoconiosis resulting from the inhalation of iron oxide dust. Workers may be exposed to this dust in the manufacture of iron oxide, the preparation of emery rock for grinders, and the use of these grinding tools. Siderosis also can develop due to exposure to iron oxide fumes while welding. Although clinical symptoms usually are minimal

or nonexistent, the findings on chest radiography in siderosis are often striking, with diffuse reticulonodular densities. A minority of patients can develop both restrictive disease and reduced diffusing capacity.

MERCURY

Elemental mercury is a liquid that is easily volatilized, especially when heated. Pulmonary toxicity occurs primarily from the accidental inhalation of elemental mercury vapor, usually in the home setting. It can cause an acute airway irritation and rare episodes of pulmonary edema, chronic interstitial fibrosis, or death. The pathogenesis is due to mercury's propensity to bind to sulfhydryl groups of cellular enzymes, as well as the formation of mercury-protein adducts. Once these enzymes are inactivated, subsequent oxidant injury and secondary destruction of pulmonary epithelial cells can occur. Exposure to high-dose elemental mercury vapor causes severe airway irritation, leading to tracheo-bronchitis, bronchiolitis, and, occasionally, pulmonary edema and death. Most cases of mercury vapor exposure do not result in permanent lung damage; severe cases may develop chronic interstitial fibrosis.

NICKEL

Nickel is a potent sensitizer, and roughly 10% of the U.S. population is dermally sensitized to nickel, with higher rates reported in women, possibly from more exposure to nickel-containing jewelry. Occupational exposure to nickel compounds is associated with IgE-mediated sinusitis, dermatitis, and asthma. High-dose exposures can cause chemical pneumonitis, pulmonary edema, and, rarely, pulmonary fibrosis. In the upper airway, nickel exposure is associated with rhinitis and sinusitis, anosmia, nasal septal perforation, and nasal carcinoma. In the lower airway, nickel exposure can lead to epithelial dysplasia and lung cancer. High-dose exposure to nickel carbonyl causes chemical pneumonitis and pulmonary edema. Although pulmonary fibrosis may result, complete recovery is the usual course. Response or tolerance to nickel, as in other metals, depends on genetic susceptibility and cytokine responses.

NEWER OCCUPATIONAL LUNG DISEASES

Microwave Popcorn Workers and Bronchiolitis Obliterans

Bronchiolitis obliterans, a rare, severe lung disease characterized by cough, dyspnea on exertion, and airway obstruction that does not respond to bronchodilators, can occur after certain occupational exposures. Inhalation exposure to agents such as nitrogen dioxide, sulfur dioxide, anhydrous ammonia, chlorine, phosgene, and certain mineral and organic dusts can cause irreversible damage to small airways known as bronchiolitis obliterans. Patients show an obstructive ventilatory defect without chest radiograph diffusing capacity abnormalities.

In May 2000, eight persons who had formerly worked at a plant that produces microwave popcorn were reported to the Missouri Department of Health to have bronchiolitis obliterans. Epidemiologic evidence and exposure monitoring have suggested that diacetyl (2,3-butanedione), a di-ketone used as an artificial butter flavor, is the causative agent. Workers in other plants that use artificial butter flavorings also have developed bronchiolitis obliterans.^{56,57}

Nylon Flock Worker's Lung

Even materials previously thought to be inert and innocuous can subsequently cause disease when their physical properties are altered. This is apparently the case with nylon flock worker's lung, a newly described interstitial lung disease. Flocking is a widely used industrial process in which nylon polyamide fibers are cut into short lengths and then glued to a backing fabric to produce plush, velvet-like material. The flocked material is then used to produce clothing, upholstery, and plush toys and novelty items. The majority of the industry uses a guillotine-type cutter that produces precise fiber length (called precision-cut flock), but it is slow and therefore more costly. Rotary cutters are much faster but produce more variable fiber lengths, called random-cut flock. In addition, when these rotary cutter blades become dull, they heat up and can melt the nylon or produce very small fragments that can become airborne. These small fragments have an aerodynamic diameter of less than 10 μm and cause a respirable dust found in these workplaces. This nylon respirable dust has been shown in animal models to cause an intense inflammatory reaction.⁵⁸ All cases of nylon flock worker's lung reported to date have been from the only two plants that use rotary cutters and produce random-cut flock.

A comprehensive survey of workers at these plants showed a high frequency of eye and throat irritation, respiratory symptoms, and systemic symptoms during the workday. Workers with the interstitial lung disease experienced progressive dry, nonproductive cough, and dyspnea. The mean latency from time of hire to onset of symptoms was 6 years, and the latency from onset of symptoms to diagnosis was 1 year. Most chest radiographs were normal, but some showed reticulonodular or patchy infiltrates. HRCT scans, the imaging study of choice, showed patchy ground-glass opacity, scattered areas of consolidation, diffuse micronodularity, or peripheral honeycombing. Pulmonary function testing was variable, usually showing restrictive defects, but occasionally obstructive defects or normal spirometry was seen. BAL revealed eosinophilia (>25%) or lymphocytosis (>30%), with or without neutrophilia. The biopsy specimens from affected patients revealed a characteristic lymphocytic bronchiolitis and peribronchiolitis with lymphoid hyperplasia. All those affected had improvement in symptoms as well as radiographic and functional improvement after leaving the workplace. However, complete recovery was not seen.^{59,60}

PULMONARY TOXICITY OF THERAPEUTIC MEDICATIONS

Many therapeutic medications can affect the pulmonary system. These effects include a wide spectrum of disorders such as hypoventilation due to any central nervous system depressant drugs like opioids and sedative/hypnotics and bronchoconstriction and bronchospasms from inhaled medications or any drug that can induce anaphylaxis or anaphylactoid reactions. Inflammatory and fibrotic changes in the lung can be caused by a variety of medication classes, as well as ARDS from any overdose situation resulting in prolonged hypotension and/or multi-organ failure. Also, any drug that causes enough central nervous system depression and lack of protective reflexes can lead to aspiration hazard and subsequent pneumonitis.

Pulmonary toxicity from therapeutic drug administration is reported most commonly with the chemotherapeutic agents, occurring in up to 10% of all patients receiving certain drugs. The likelihood of developing pulmonary toxicity from these agents increases with increasing age of the patient, higher cumulative dose, concurrent radiation therapy, concurrent O₂ therapy, concurrent chemotherapy, and preexisting pulmonary disease. The clinical signs and symptoms are similar regardless of the type of chemotherapeutic agent, often showing restrictive defects on spirometry and decreased diffusion capacity for single breath carbon monoxide (DL_{co}).

The common pulmonary manifestations of chemotherapeutic agents are interstitial pneumonitis, BOOP, and DAD. Tables 9-6 and 9-7 illustrate representative drugs and the toxicities seen with therapeutic use.^{13,61-70} Chest radiographs frequently have normal results despite clinical signs and symptoms and changes in pulmonary function testing. HRCT scans are very helpful in identifying parenchymal abnormalities, guiding proposed biopsy sites, and monitoring response to therapy.^{6,61-64,70,71}

SUMMARY

The fragile pulmonary system is in direct contact with airborne dusts and toxicants, and, as such, is susceptible to numerous acute and chronic effects from these exposures. This has been most prominently demonstrated in the occupational setting, where acute inhalation syndromes such as MFF, PFF, and ODTs were first described. Exposure to various antigens and/or chemical agents in the occupational setting has led to our understanding of hypersensitivity syndromes such as HP and occupational asthma. Occupational exposures to airborne dusts and fibers have caused workers to develop the historically well-known pneumoconioses such as CWP, asbestosis, silicosis, and CBD, as well as newer syndromes such as popcorn worker's lung and nylon flock worker's lung.

Pulmonary manifestations of other toxic exposures are evident in the nonoccupational settings when

TABLE 9-6 Therapeutic and Abused Drugs and Their Pulmonary Toxicities^{55-57,61}

Therapeutic Drug Class	Representative Drugs	Type of Pulmonary Toxicity Seen	Comments
β-Adrenergic blockers	Nonselective β blockers: nadolol, propranolol, timolol	Bronchoconstriction; IP, pleurisy, and PF have been reported	Timolol ophthalmic administration can cause exacerbation of asthma
	Cardioselective β blockers: betaxolol, atenolol, bisoprolol, esmolol, metoprolol	Bronchoconstriction; IP, pleurisy, and PF have been reported	
Calcium channel blockers	Verapamil, nifedipine	Bronchoconstriction (rare)	Evidence mainly from single case reports
Angiotensin-converting enzyme (ACE) inhibitors	Captopril, lisinopril	Cough, dyspnea, bronchospasms	Incidence of cough high, necessitating cessation of therapy in 10% of cases; mechanism appears to be kallikrein-prostaglandin system, with build-up of proinflammatory mediators such as substance P and bradykinin
Angiotensin II receptor antagonists	Losartan, candesartan, others	Cough	Incidence much less than ACE inhibitors; these agents have little effect on kallikrein-prostaglandin system
Antiarrhythmic agents	Amiodarone	IP, PF, ARDS, RF	Dose and time-dependent effects, lower doses much less incidence
	Flecainide	IP, ARDS	
	Tocainide Dipyridamole	IP, PF Bronchoconstriction	PF incidence 0.3% Incidence as high as 0.15% after IV use for dipyridamole-thallium imaging
Anti-inflammatory agents	Aspirin	Therapeutic: asthma, bronchospasms Overdose: hyperpnea ARDS, RF	High incidence of bronchospasms in asthmatics with nasal polyps; asthma related to increases in leukotrienes, decrease in prostaglandins due to co-ox enzyme inhibition
	Ketorolac NSAIDs	Anaphylactoid reactions Bronchoconstriction, anaphylactoid	Most NSAIDs cause exacerbations in aspirin-sensitive individuals
	Gold salts	HP, IP, PF, BOOP	Incidence < 1%; BAL shows lymphocyte predominance; also drug-induced SLE
	Penicillamine	Alveolitis, HP, SLE, pleural effusions, Goodpasture's syndrome, eosinophilic pneumonia	Occurs in sensitized individuals; also drug-induced SLE
Leukotriene antagonists	Zafirlukast, montelukast	Churg-Strauss syndrome (CSS)	CSS: allergic granulomatous vasculitis with asthma, pulmonary infiltrates
Antibiotics	Nitrofurantoin	Acute and chronic IP, eosinophilic pneumonitis	One of the most common drug-induced pulmonary diseases; acute: onset in hours to days; chronic: after years of Rx; also drug-induced SLE
	Isoniazid (INH)	HP	HP with peripheral eosinophilia; also drug-induced SLE
	Penicillin	HP, pleural effusions	Also drug-induced SLE
	Sulfasalazine	Pulmonary infiltrates, eosinophilic pneumonia, eosinophilia, BOF	Rare; effects due to metabolites 5-aminosalicylic acid and sulfapyridine
	Aminoglycosides	Respiratory muscle weakness	Occurs after excessive serum levels,? reversible with physostigmine
	Aminosalicylic acid	Hypersensitivity reactions, pleural effusions, alveolar infiltrates, cough	Incidence up to 5%; associated fever, rash, lymphadenopathy, hepatomegaly
	Amphotericin B	Decreased PFT, BO	
	Pentamidine	Bronchospasms	Seen after nebulized or IV
	Polymyxin	Respiratory muscle weakness	Occurs after excessive serum levels,? reversible with physostigmine
Antiasthmatic medications	Streptomycin	Pleural effusions	Also drug-induced SLE
	Tetracycline	Pulmonary infiltrates, pleural effusions	Also drug-induced SLE
	Ipratropium bromide	Bronchoconstriction	Paradoxical, likely due to benzalkonium in nebulizer solution
	Hydrocortisone succinate	Bronchoconstriction	Paradoxical; not seen with other steroid preparations
	Cromolyn sodium	Bronchoconstriction, pulmonary edema, pulmonary infiltrates with eosinophilia	Hypersensitivity reaction, may be IgE-mediated

**TABLE 9-6** Therapeutic and Abused Drugs and Their Pulmonary Toxicities^{55-57,61} (Cont'd)

THERAPEUTIC DRUG CLASS	REPRESENTATIVE DRUGS	TYPE OF PULMONARY TOXICITY SEEN	COMMENTS
Nebulizer and metered dose inhaler solutions	Preservatives: sulfites, alcohol, metabisulfites, benzalkonium chloride, ascorbic acid	Bronchospasms	Most have been removed; metabisulfite probably works through SO ₂ stimulation of irritant receptors; benzalkonium through release of mast cell mediators
	Emulsifiers: soy lecithin, oleic acid	Bronchospasms	
Diuretics	Diluents: sorbitan	Bronchospasms	Hypertonicity may cause bronchospasms
	Propellants	Bronchospasms	Accounts for 58%–99% of MDIs
Chemotherapeutic agents	Hydrochlorothiazide (HCTZ)	IP, noncardiogenic pulmonary edema	Rare occurrence, onset within hours of administration
	Bleomycin	IP, HP, BOOP	Pulmonary toxicity in 10% of all patients, death in 1%–2%
Drugs of abuse	Carmustine	IP, PF	PF onset can be delayed many years
	Cyclophosphamide	PF, BOF, BOOP	Incidence < 1%
	Azathioprine	IP	Incidence < 1%
	Cytarabine	NCPE	Has been fatal
	Busulfan	PF	Up to 4% incidence, insidious onset, can be delayed for years
	Chlorambucil	IP, PF	Rare case reports
	Doxorubicin	IP, PF	
	Melphalan	IP, PF	Rare case reports
	Methotrexate	IP, HP, RF, BOOP, pulmonary edema	HP incidence up to 7%, reversible
	Mercaptopurine	IP, PF	
	Mitomycin	Nonspecific pulmonary toxicity, PF	Incidence < 10%, higher in combination chemotherapy
	Nitrogen mustards	Pleural effusions, pulmonary edema	
Nitrosoureas	PF, pulmonary hypertension		
Vinca alkaloids	PF, RF, pulmonary edema	Usually only with combination chemotherapy	
Opioids	Procarbazine	PF	
	Teniposide, Chlorozotocin	PF	
Stimulants	Heroin (diacetyl morphine)	A, PF, NCPE	NCPE mechanisms: direct alveolar type II cell toxicity, neurogenic, hypersensitivity, acute hypoxic effect
	Cocaine	IP, HP, BOF, BOOP, A, pulmonary edema, RF, pneumothorax, pneumomediastinum	Inhaled crack cocaine most common form; direct toxicity, hypersensitivity, and impurities are all likely mechanisms; Rx with corticosteroids
Psychotropics	Methadone, d-propoxyphene	NCPE	Isolated case reports
	Methylphenidate	Abnormal PFT, hemoptysis	Seen with abuse only
Anticonvulsants	Phenothiazines	Pulmonary edema	Rare, single case reports
	Butyrophenones	Pulmonary edema	Rare, single case reports
	Tricyclic antidepressants (TCA)	ARDS	Due to aspiration pneumonitis and/or NCPE
HMG Co A Inhibitors "Statins"	Trazodone	Eosinophilic pneumonia, RF	
	Carbamazepine	IP	Hypersensitivity reactions
β-Adrenergic agonists	Simvastatin, pravastatin, lovastatin	HP, IP, PF	Rare case reports only; also myalgias, drug-induced SLE seen
	Ritodrine, albuterol, terbutaline	Pulmonary edema, alveolar infiltrates, bronchospasms, pulmonary embolus	Seen when given IV for tocolysis
Ergot alkaloids	Methysergide, bromocriptine	Pleural effusion, pleural fibrosis	Retroperitoneal fibrosis also seen
Anorectic agents	Fenfluramine, amphetamine derivatives	Pulmonary hypertension	

A, asthma; ARDS, acute respiratory distress syndrome; BO, bronchiolitis obliterans; BOF, bronchiolitis obliterans fibrosa; BOOP, bronchiolitis obliterans organizing pneumonia; HP, hypersensitivity pneumonitis; IP, interstitial pneumonitis; IV, intravenously; NCPE, noncardiogenic pulmonary edema; PF, pulmonary fibrosis; PFT, pulmonary function tests; RF, respiratory failure, SLE, systemic lupus erythematosus.

TABLE 9-7 Pulmonary Toxic Manifestations of Therapeutic Medications

PULMONARY TOXICITY/CONDITION	ASSOCIATED DRUGS	COMMENTS
Pulmonary eosinophilia ⁶⁵	<p>Occasionally associated: acetylsalicylic acid, carbamazepine, granulocyte-macrophage colony-stimulating factor, minocycline nilutamide, penicillamine, propylthiouracil, sulfa-containing antibiotics, sulfasalazine</p> <p>Rarely associated: beclomethasone, chloroquine, cocaine, dapsone, desipramine, diclofenac, erythromycin, heroin, imipramine, IL-2, isoniazid, isotretinoin, mesalamine, methylphenidate, paclitaxel, para-(4)-aminosalicylic acid, penicillins, phenylbutazone, procarbazine, propranolol, ranitidine, trimipramine, zafirlukast</p>	
Bronchospasms ⁶⁶	<p>Frequent: ACE inhibitors, amiodarone, amphotericin B, antidepressants, phenelzine, tranylcypromine, isocarboxazid, aspirin, β blockers (propranolol, labetalol, atenolol, timolol), carbamazepine, cyclophosphamide, D-tubocurarine, D-penicillamine ergots, erythromycin, gemcitabine, heroin, iodine radiocontrast, isoflurane, melphalan, mesalamine, methotrexate, nitrofurantoin, NSAIDs, suxamethonium, sulfonamides, vinblastine</p> <p>Drugs of abuse: inhaled cocaine, marijuana, heroin</p> <p>Occasional: acetylcysteine, adenosine, aminoglycoside antibiotics, betahistine, cephalosporins, cytokines, desensitization extracts, hydrocortisone, interferon-α, interferon-β, isotretinoin L, asparaginase, melphalan, mesalamine, methylprednisolone, paclitaxel, penicillins, propofol, prostaglandin-F2α polyethylene glycol, rifampicin, risperidone, verapamil, vandesine, zanamivir,</p>	
Cough ⁷⁰	<p>ACE inhibitors, angiotensin receptor blockers, buccillamine, desflurane, dirithromycin, fentanyl, IL-2, isoflurane, ketobemidone, L-tryptophan, methotrexate, morphine, mycophenolate, mofetil, nitrofurantoin, paroxetine, propofol, sertraline, steroids, streptokinase, sufentanil, sulfonamides</p>	<p>Also, virtually any medication delivered by the inhalational route, i.e., via nebulizers or metered-dose inhaler</p>
Pulmonary edema ⁶⁷	<p>Antineoplastic and immunosuppressant agents: cytarabine arabinoside, gemcitabine, immune globulin, interleukin, methotrexate, mitomycin, muromonab-CD3, pentostatin, tretinoin</p> <p>Cardiovascular agents: calcium channel blockers (amlodipine, nifedipine, nisoldipine, verapamil), epinephrine, phenylephrine, propranolol</p> <p>Respiratory agents: epoprostenol, nitric oxide renal agents: acetazolamide chlorothiazide/hydrochlorothiazide</p> <p>Neuropsychiatric agents: ethchlorvynol, phenothiazines, tricyclic antidepressants</p> <p>Analgesic agents: aspirin, methadone, morphine, propoxyphene, heroin</p> <p>Obstetric agents: ergonovine, tocolytics, oxytocin</p> <p>Miscellaneous agents: protamine, contrast agents</p>	
Bronchiolitis obliterans organizing pneumonia ⁶⁸ (BOOP)	<p>Antimicrobials: amphotericin-B, cephalosporin, minocycline, nitrofurantoin</p> <p>Anti-inflammatory agents: gold, sulfasalazine</p> <p>Cardiovascular agents: amiodarone, acebutolol</p> <p>Chemotherapeutic agents: busulfan, bleomycin, doxorubicin, methotrexate, mitomycin-C</p> <p>Miscellaneous: carbamazepine, phenytoin, ticlopidine, interferons-α, -β, -γ; L-tryptophan, FK 506, cocaine (illicit use)</p>	<p>Usually resolves when condition is recognized and drug withdrawn; steroid Rx often helpful</p>
Parenchymal lung diseases ⁶⁹	<p>Antirheumatic drugs: methotrexate, penicillamine, gold salts, aspirin (overdose only),</p> <p>Opiates: heroin, methadone, codeine, morphine, buprenorphine</p> <p>Thiazides: hydrochlorothiazide</p>	<p>Parenchymal diseases include pneumonitis/fibrosis, NCPE (DAD), hypersensitivity pneumonitis, eosinophilic pneumonia, BOOP</p>

environmental exposures occur as a result of hazardous materials incidents in communities, the worst example being the Bhopal disaster where an MIC release resulted in thousands of deaths and permanent injuries. The particular area of the pulmonary system injured depends largely on the water solubility of the gas involved: highly water-soluble gases affect the upper airways primarily, whereas low water-soluble gases tend to cause deeper, alveolar injury.

The generous pulmonary capillary network that allows gas exchange also provides an excellent delivery system for inhaled medications, the most common therapeutic use being administration of inhalational general anesthetics. This also is the route of administration of various drugs of abuse such as crack cocaine, marijuana, and abused inhalants. Likewise, this is the mechanism for systemic poisoning after exposure to asphyxiants, especially CO, which happen frequently in the workplace and home environments, both as accidental exposures and in suicide attempts. This generous blood supply also makes the lungs susceptible to injury by some systemically administered therapeutic medications, most notably the antineoplastic agents. A sound knowledge of inhalational effects of various agents and pulmonary effects from systemic drugs and toxicants is critical to the proper management of patients in both the occupational arena and more traditional clinical settings.

A wide variety of neurologic syndromes results from toxic exposures. Some neurotoxins produce specific and characteristic syndromes (see Chapter 10A), whereas others may produce conditions that are insidious or diagnosed as other common illnesses. Many toxins share common mechanisms and therefore manifest similar toxicities. This chapter provides a general review of neurotoxicology based on the physiologic actions of drugs and neurotoxins. It begins with a brief review of synaptic neurotransmission, because many toxins disrupt steps in this multifaceted process (Box 10-1). Each neurotransmitter system is then individually reviewed, and the toxins that disrupt its action and the syndromes that result are highlighted. Finally, a review of toxin-induced neuropathies is presented.

SYNAPTIC NEUROTRANSMISSION

Neurons are specialized cells involved with communication and information processing¹ (Fig. 10-1). The main structural features of nerve terminals are synaptic vesicles, mitochondria, elements of the smooth endoplasmic reticulum, cytoskeletal structures, and the

plasma membrane that surrounds the axon. The nerve terminal (presynaptic) plasma membrane is separated from the plasma membrane of the postsynaptic neuron by a thin cleft called the synapse. Neuronal communication is neurohumoral and occurs at the synapse via the exocytotic release of small chemicals called neurotransmitters, for which specific receptors exist on postsynaptic neurons (Box 10-2).^{2,3}

Neurotransmitters are stored in synaptic vesicles. Synaptic vesicles tend to cluster at discrete regions underneath the presynaptic plasma membrane, and each cluster behaves as an anatomic and functional unit composed of equivalent elements of neurotransmitters. Presynaptic plasma membrane shows areas of structural specialization at areas of synaptic clustering, and it is at these “active zones” that exocytosis of classic neurotransmitters occur. The neurotransmitter, on release into the synaptic cleft, binds to specific postsynaptic receptors to initiate postsynaptic activity. Synaptic vesicles, after exocytosis, are recycled and used in subsequent secretory cycles (see Box 10-2).

The activity of neurotransmitters is defined by and mediated through their interaction with pre- and postsynaptic receptors. Receptors are specialized

BOX 10-1 CELLULAR TARGETS AND POTENTIALLY NEUROTOXIC AGENTS

Adrenergic receptors:	Clonidine and imidazolines, sympathomimetics, sympatholytics, ergot alkaloids, antipsychotic agents (chlorpromazine, clozapine), yohimbine
Cannabinoid receptor:	Cannabinoid (marijuana, hashish)
Cholinesterase:	Organophosphates, carbamates, nerve gas agents, physostigmine
Dopamine receptors:	Apomorphine, bromocriptine, antipsychotic drugs
GABA receptors:	Benzodiazepine, cyclopyrrolones (zopiclone), imidazopyridines (zolpidem), barbiturates, ethanol, penicillin, muscimol (<i>Amanita muscaria</i>), bicuculline, neuroactive steroids (alphaxalone), flumazenil, baclofen
Glycine receptors:	Strychnine, brucine
Histamine receptors:	Antihistamines, TCAs
Membrane lipid:	General anesthetic drugs (e.g., halothane)
MAO:	MAO inhibitors (iproniazid, phenelzine, isocarboxazid)
Muscarinic receptors:	Curare, <i>A. muscaria</i> , <i>Atropa belladonna</i> , scopolamine, certain antipsychotics and antihistamines
Nicotinic receptors:	Nicotine, neuromuscular blocking drugs, α -bungarotoxin
NMDA receptor:	Arylcyclohexylamine (phenylcyclidine, ketamine), ethanol, domoic acid
Norepinephrine reuptake:	TCAs, reserpine, amphetamine, cocaine
Opioid receptors:	Opioid agonists (heroin, morphine, opium, meperidine, methadone) and antagonists (naloxone, naltrexone)
Potassium channel:	Barium, 4-aminopyridine, tetraethylammonium ion, cesium, polypeptide toxins from scorpion (charybdotoxin), bee (apamin), snake (dendrotoxin)
Purine receptors:	Adenosine, caffeine, theophylline
Serotonin receptor:	Atypical neuroleptics, buspirone, ondansetron, granisetron, LSD, mescaline, psilocybin, cyproheptadine, methysergide
Serotonin reuptake:	TCAs, selective serotonin reuptake inhibitors, nefazodone, venlafaxine
Sodium channel:	Local anesthetics, TCAs, tetrodotoxin (puffer fish), saxitoxin (paralytic shellfish), frog-skin poison (batrachotoxin), aconitine, veratridine, scorpion and anemone toxins

GABA, γ -aminobutyric acid; LSD, lysergic acid diethylamide; MAO, monoamine oxidase; NMDA, *N*-methyl-D-aspartate; TCA, tricyclic antidepressants.

FIGURE 10-1 A schematic representation of a synapse showing the principal structures and sites of drug action. This synapse is a hybrid for the purpose of visualization; as outlined in the text, a neuron is typically highly specialized for a specific neurotransmitter system. COMT, catechol O-methyl transferase; GABA, γ -aminobutyric acid; 5-HT, 5-hydroxytryptamine; MAO, monoamine oxidase; Ntx, neurotransmitter.

structures that have the ability to uniquely recognize a drug, hormone, or neurotransmitter. Receptors may be ligand-gated ion channels that are coupled to ion flow, G protein-coupled receptors, growth factors with tyrosine kinase activity that cause tyrosine phosphorylation, or steroid receptors that transport steroids into the nucleus.

Ligand-gated ion channels mediate fast-excitatory and -inhibitory synaptic neurotransmission in the central nervous system (CNS). The family of ligand-gated ion channels now comprises nicotinic acetylcholine, γ -aminobutyric acid (GABA) types A and C, glycine, serotonin 5-HT₃, and kainate, *N*-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptors. Activation of ligand-gated ion channels results in a conformational change and opening of a pore (ionopore) in the membrane of the postsynaptic cells. This allows the passage of ions, to which the membrane was previously impermeable. The prototypic member of this receptor family is the nicotinic cholinergic receptor; stimulation of this receptor by acetylcholine allows sodium ion (sometimes calcium ion) influx and membrane depolarization. Ionopores for other ions such as chloride ions are associated with inhibitory transmission in the CNS. Excitatory neurotransmitters commonly result in postsynaptic increased sodium or calcium ion influx, or decreased potassium efflux to result in membrane depolarization and trigger an action potential. Inhibitory neurotransmitters often

produce an increase in postsynaptic chloride influx or potassium efflux to stabilize or hyperpolarize the membrane and prevent membrane depolarization.

The G protein family of receptors (so named because it binds guanosine triphosphate [GTP]) is not linked to ionopores but to enzymes that are located within the membrane of the postsynaptic cell.⁴ These enzymes act as transducers for the action of the neurotransmitter (first messenger) from the outside of the cell to the inside and produce second messengers. G protein receptors are able to regulate the rate of second messenger production and degradation via control of the activity of a number of effector enzymes. These include isoenzymes of adenylate cyclase, phospholipase C, and cyclic guanosine monophosphate (cGMP) phosphodiesterase families. G protein-coupled receptors also regulate ionic flux through ion channels either by direct G protein regulation or via second messenger-mediated phosphorylation events.

Binding of GTP to a G protein changes the activity of adenylate cyclase. Increased formation of cyclic adenosine monophosphate (cAMP) activates specific protein kinases by phosphorylation, and these in turn phosphorylate other proteins. At some receptors, however, stimulation of the receptors causes inhibition of adenylate cyclase and a decrease in intracellular cAMP. Some receptors are linked to the enzyme guanylate cyclase, which converts guanosine triphosphate to cGMP, which in turn acts as a second messenger in a manner analogous to that of cAMP. Phosphorylation of the membrane proteins cAMP and cGMP results in changes

in membrane permeability to specific ions and in others to activation of further enzyme systems, which then mediate the biologic response. Termination of the signal involves hydrolysis of cAMP and cGMP by phosphodiesterase enzymes. Response of the postsynaptic cell can thus be influenced by drugs acting on the enzymes involved (i.e., adenylate cyclase, guanylate cyclase, and phosphodiesterase). Phosphatidylinositol breakdown, which is stimulated by phospholipase C located in cell membranes, represents another type of second messenger system. The breakdown of phosphatidylinositol 4,5-bisphosphate leads to the release of inositol triphosphate and diacylglycerol. Diacylglycerol is an activator of kinase C, whereas inositol triphosphate in turn stimulates other intracellular messengers such as calcium or calmodulin.

Calcium ions are necessary for transmission at synaptic junctions and have a dual role in neuronal secretion. Calcium influx following the action potential triggers synaptic vesicle exocytosis and regulates the amount of vesicles released. The action potential, caused by a depolarizing stimulus, begins with a transient, voltage-gated opening of sodium channels that allows sodium to enter the fiber and depolarize the membrane fully. This is followed by a transient voltage-gated opening of potassium channels that allows potassium to leave and repolarize the membrane.

Presynaptic neurotransmitter release is modulated by presynaptic receptors called autoreceptors.² Autoreceptors often are inhibitory and prevent further release of neurotransmitter from the same neuron. These receptors, however, also may be excitatory. In addition, these receptors may influence the release of neurotransmitters from neighboring neurons (heteroreceptors). Autoreceptors often are coupled to G proteins. They prevent further neurotransmitter release by increasing potassium efflux or limiting calcium ion influx, effects that hyperpolarize the membrane.

THE NEUROTRANSMITTER SYSTEM AND NEUROTOXICITY

The neurotransmitter system has many components, and toxins may interact with, augment, or disrupt any step in neurotransmission. A toxin can disrupt ionic channels, block or stimulate presynaptic or postsynaptic receptors, alter presynaptic neurotransmitter reuptake, or block neurotransmitter degradation. Many of these substances are used as pharmaceutical agents in clinical practice, and some are naturally occurring biologic toxins or man-made chemicals. The details of the processes involved in synaptic transmission vary from one transmitter to another and are discussed as the individual neurotransmitter system is reviewed.

A drug that produces a response and mimics the effect of an endogenous regulatory compound is known as an agonist. Antagonists bind to the receptor site with zero intrinsic regulatory activity to initiate a response and, therefore, cause inhibition of the agonist. Certain drugs are able to reduce the activity of receptor systems

that are active in the absence of agonists. Agonists increase the activity of receptor systems, and this opposite or negative activity is known as inverse agonism.

The Purinergic System

Adenosine and adenosine triphosphate (ATP) are purines that are released from neurons and other cells and produce widespread effects on many organ systems by binding to cell-surface purinergic receptors. ATP also is released from non-neuronal sources including platelets, mast cells, and, possibly, endothelial cells. Receptors for both adenosine and ATP are widely distributed in the nervous system and in other tissues such as the heart, intestine, and bladder. Receptors that bind adenosine or ATP are designated P₁ and P₂ purinergic receptors, respectively.⁵ Adenosine and some adenosine analogues activate adenosine receptors but not ATP receptors, and some ATP analogues activate ATP receptors but not adenosine receptors.

Four P₁ receptors, designated A₁, A_{2A}, A_{2B} and A₃, have been pharmacologically characterized and all are members of the G protein-coupled receptor superfamily. A₁ adenosine receptors are widely distributed in the CNS. Central A₁ receptor activity includes sedation, analgesia, neuroprotection, and anticonvulsant activity. Adenosine potentiates the antinociceptive action of norepinephrine in the spinal cord. Many of the central effects of adenosine are attributed to the modulation of neurotransmitter release in the CNS. Opiates have been shown to induce the release of adenosine, and some effects of opiates are blocked by adenosine receptor antagonists. In the periphery, adenosine A₁ receptors are found in the heart, where they produce negative inotropic, chronotropic, and dromotropic responses. In adipose tissue, they inhibit lipolysis and enhance insulin-stimulated glucose transport. In the kidneys, they reduce glomerular filtration pressure and produce antidiuresis.

A₁ receptor activation produces effects by inhibiting adenylate cyclase (decreased cAMP) and by increasing or decreasing phospholipase activity. Presynaptic A₁ receptor activation results in decreased calcium conductance and decreased exocytosis of neurotransmitter. Presynaptic A₁ autoreceptors antagonize norepinephrine release in the sympathetic nervous system. In addition, A₁ receptor agonists result in decreased release of epinephrine and norepinephrine from adrenal glands. In the heart, there is an increase in atrioventricular nodal refractoriness and inhibition of delayed afterdepolarizations. Postsynaptic A₁ receptor stimulation increases potassium channel conductance to produce membrane depolarization. These effects counteract those of the sympathetic nervous system and augment the actions of the parasympathetic nervous system. In the heart, adenosine activates the acetylcholine-sensitive potassium current in the atrium and sinoatrial and atrioventricular nodes. This results in shortening of the action potential duration and slowing of normal automaticity.

The A₂ receptors are classified further into A_{2A} and A_{2B} subtypes, depending on their affinity for adenosine. A₂ receptors present on sensory nerves in the carotid

body, aortic body, and pulmonary circulation, and elsewhere produce excitatory sensory input. A_{2A} receptor activation in the vascular bed classically is associated with vasodilation and hypotension. These effects are mediated in part by the elevation of intracellular cAMP and by activation of ATP-dependent potassium channels. Activation of the A_{2A} receptor on platelet membranes elevates intracellular cAMP levels, resulting in inhibition of platelet aggregation. The A_3 receptors are found throughout the brain and are heavily expressed in the pineal body, lungs, and spleen. A_3 receptor activation decreases adenylate cyclase activity and increases phospholipase C. Although the central effects of A_3 receptors are not fully elucidated, their activation appears to potentiate ischemic cellular injury.

Activation of adenosine receptors is largely neuroprotective. A_2 receptor activation preserves tissue oxygen and substrate delivery via cerebral vasodilation. A_1 receptor activation decreases tissue oxygen requirements and raises the seizure threshold. Adenosine, an adenosine agonist, is an effective antiepileptic agent in experimental animals. Similarly, drugs that are A_1 receptor system agonists have anticonvulsant properties. Conversely, drugs that antagonize the effects of A_1 receptors lower the seizure threshold. Agents that antagonize A_2 receptors produce cerebral vasoconstriction and may potentiate neurotoxicity during seizures or other conditions that limit oxygen delivery to the brain. Carbamazepine is an A_1 receptor antagonist, which may partly explain seizures that occur with overdose of this psychotropic.⁶ Caffeine, theophylline, and theobromine are three important alkaloids derived from xanthine. Methylxanthines are competitive antagonists at A_1 and A_2 receptors and may produce seizures with acute and chronic overdose. Methylxanthine-associated seizures have a reported mortality of up to 50% (see Chapter 65). The reason for this high mortality results from A_1 antagonism and consequent impaired self-termination of seizure activity.⁷ In addition, neurologic morbidity is enhanced from concurrent A_2 receptor antagonism, which produces cerebral vasoconstriction during seizures. GABA_A receptor agonism, especially by barbiturates, is most effective in preventing and terminating methylxanthine-induced seizures. Intravenous adenosine may attenuate theophylline-induced seizures by receptor antagonism or from nonspecific adenosine actions.⁸ Phenytoin remains ineffective in treating theophylline-induced seizures and may increase mortality.⁹ Dipyridole inhibits adenosine reuptake and inhibits adenosine deaminase, actions that result in raised adenosine concentrations. Benzodiazepines partly inhibit adenosine uptake, which may account for some of their anticonvulsant properties.¹⁰

ATP receptors have a wide tissue distribution. In the autonomic nervous system, ATP is released as a cotransmitter from both sympathetic and parasympathetic neurons. ATP that is released is broken down rapidly by widely distributed 5'-nucleotidases; this results in the formation of adenosine. ATP has a biphasic or inhibitory effect due to its breakdown to adenosine. The physiologic and pharmacologic actions of ATP are

mediated through activation of P_2 purinergic receptors, of which at least five subtypes (P_{2U} , P_{2T} , P_{2X} , P_{2Y} , and P_{2Z} purinergic receptors) have been identified. It is now known that the P_{2X} receptor is a ligand-gated ion channel, whereas the P_{2Y} receptor is G protein activated.¹¹ The receptors are classified largely on the basis of the relative agonist potencies of ATP and a number of structural analogues. The role of these receptors in neurotoxicity is yet to be defined.

The Catecholaminergic System

Three distinct catecholamines—dopamine, norepinephrine, and epinephrine—are involved in neurotransmission. Norepinephrine is the predominant catecholamine in peripheral tissue and sympathetic nerves. Epinephrine, formed by *N*-methylation of norepinephrine, is released from the adrenal glands and stimulates catecholamine receptors in various organs. Small amounts of epinephrine are found also in the CNS, particularly in the brainstem.¹² A few sympathetic fibers release acetylcholine (e.g., those serving sweat glands). Dopamine, the precursor of norepinephrine, also has biologic activity in the periphery, especially in the kidneys.

The amino acid L-tyrosine is hydroxylated to dihydroxy-L-phenylalanine (L-dopa) by tyrosine hydroxylase, a mixed-function oxidase located in the cytoplasm and on cell membranes. Tyrosine hydroxylase also hydroxylates phenylalanine to form tyrosine, which is then converted to L-dopa. Dopa decarboxylase, a pyridoxine-dependent enzyme, catalyzes the removal of the carboxyl group from dopa to form dopamine.³ In neurons that synthesize epinephrine or norepinephrine, dopamine diffuses into synaptic vesicles, where the enzyme dopamine- β -hydroxylase hydroxylates dopamine, forming norepinephrine. In chromaffin cells that synthesize epinephrine, the final step in the pathway is catalyzed by the enzyme phenylethanolamine *N*-methyltransferase. Catecholamines are concentrated in the synaptic vesicles and also are found free in the cytoplasmic fluid. The action of catecholamines released at the synapse is terminated by reuptake. The excess catecholamine is repackaged in storage vesicles or degraded by mitochondrial monoamine oxidase (MAO). These isoenzymes are integral flavoproteins on outer mitochondrial membranes. The MAO enzymes exist in two forms, A and B. MAO-A preferentially deaminates norepinephrine and serotonin and is selectively inhibited by clorgyline or moclobemide, whereas MAO-B acts on dopamine and is selectively inhibited by deprenyl (see Chapter 29). Catechol *O*-methyltransferase acts on extraneuronal catecholamine and is responsible for inactivation of catecholamine that is not effectively removed from the synaptic cleft.

The effects of catecholamines are mediated by cell-surface receptors.¹³ All adrenergic neurons contain G protein-coupled receptors.³ Adrenergic receptors are subdivided into two types, α and β receptors. α -Adrenergic receptor activation inhibits adenylate cyclase and decreases cellular cAMP levels, whereas β receptor

activation increases adenylate cyclase activity and increases cellular cAMP concentrations. α -Adrenergic receptors have the following order of potency for agonists: epinephrine \geq norepinephrine \gg isoproterenol. β -Adrenergic receptors have the following order of potency for agonists: isoproterenol $>$ epinephrine \geq norepinephrine.³ The α -adrenergic receptors are responsible for the excitatory actions of norepinephrine and mediate the contraction of most smooth muscles, particularly vascular smooth muscles, resulting in vasoconstriction. An exception is the gut, where α -adrenergic receptor activation relaxes smooth muscle cells. β -Adrenergic receptor activation increases the rate and contractility of the heart, relaxes smooth muscles in the bronchioles and the uterus, and causes vasodilation.

α -Adrenoceptors are divided into two types, α_1 and α_2 receptors. In peripheral tissues, α_1 adrenoceptors are located on the postsynaptic membrane, whereas α_2 adrenoceptors are located on both presynaptic and postsynaptic membranes. Stimulation of postsynaptic α receptors (α_1 and α_2) results in vasoconstriction. Stimulation of presynaptic α_2 autoreceptors, however, decreases norepinephrine release. Stimulation of postsynaptic α_2 adrenoceptors in the brainstem inhibits sympathetic nervous system output and results in sedation.

β Adrenoceptors are divided into three types, β_1 , β_2 , and β_3 receptors. Peripheral β_1 receptors are found predominantly in the myocardium. Epinephrine and norepinephrine are equivalent in potency as agonists at this receptor. Peripheral β_2 receptors are found on smooth muscle, the myocardium, and numerous other tissues. Epinephrine is 10- to 50-fold more potent at β_2 receptors than norepinephrine.^{2,3} When present, presynaptic β_2 -adrenergic receptors facilitate the release of norepinephrine from sympathetic nerves. β_3 -Adrenergic receptors are found in fat, skeletal muscle, and other peripheral tissues. Norepinephrine is 10-fold more potent at the β_3 receptor compared with epinephrine.² The physiologic role of this receptor is not fully known.

Five subtypes of the dopamine receptor have been identified. The D_1 and D_5 receptors are coupled to stimulation of adenylate cyclase. D_2 , D_3 , and D_4 receptors have an opposing effect on adenylate cyclase.¹⁴ In the brain, the principal functions mediated by dopamine are the control of movements of behavior, including motivation, cognitive function, and emotion. Newer antipsychotic agents target D_2 receptors, and the evidence suggests that patients experience fewer extrapyramidal side effects (see Chapter 38).¹⁵ In the pituitary gland, dopamine controls the release of prolactin and α -melanocyte-stimulating hormone. In the cardiovascular system, it is important in the regulation of blood pressure. Dopamine receptors have therefore been identified functionally in tissues related to these effects (e.g., pituitary gland and certain blood vessels). The antihypertensive effects of fenoldopam are mediated by D_1 receptor activation in the kidney.¹⁶ The largest concentrations of dopamine receptors, however, are in the basal ganglia and the limbic system.

Numerous drugs affect catecholamine neurotransmission. Tyrosine analogues such as metyrosine (α -methyl-*p*-tyrosine) impair the synthesis of dopamine and norepinephrine by blocking the enzyme tyrosine hydroxylase. Disulfiram and diethyldithiocarbamate inhibit dopamine β -hydroxylase and can produce sympatholytic effects by interfering with the production of norepinephrine from dopamine. Reserpine and tetrabenazine inhibit the uptake of dopamine and other catecholamines into vesicles, causing depletion of endogenous neuronal catecholamines. α -Methyldopa causes dopamine depletion by replacement of dopamine with a relatively inactive false transmitter, α -methyldopamine; this causes hypotension and sedation. Other false neurotransmitters include metaraminol and octopamine. Peripheral presynaptic antiadrenergic drugs such as guanethidine and bretylium inhibit norepinephrine release from the presynaptic terminal by depleting the nerve endings of noradrenaline. The neurotoxin 6-hydroxydopamine is taken up by an active uptake mechanism and accumulates in catecholamine-containing neurons, destroying them through the auto-oxidative liberation of hydrogen peroxide or from formation of a quinone. Indirect-acting agents are agonists or sympathomimetics that cause release of cytoplasmic norepinephrine in the absence of adrenergic receptor binding and presynaptic vesicle exocytosis. These drugs enter the presynaptic terminals and displace stores of norepinephrine from storage vesicles (e.g., amphetamine and tyramine) or inhibit reuptake of catecholamine already released (e.g., cocaine and tricyclic antidepressants) (Box 10-3).³ Indirect agents typically bind to the amine transport proteins (uptake-1 system) and interfere with uptake of endogenous catecholamines while facilitating reverse transport of cytoplasmic catecholamines into the synaptic cleft.² Indirect agents exhibit tachyphylaxis—that is, their effects diminish on repeated administration as the catecholamine pools become depleted. Tricyclic antidepressants principally interfere with norepinephrine and serotonin reuptake; dopamine reuptake is affected to a lesser degree (see Chapter 27). Amphetamine also can inhibit reuptake, whereas lithium facilitates reuptake. The MAO inhibitors block metabolism of biogenic amines (norepinephrine, serotonin, dopamine), increasing the synaptic concentration of these neurotransmitters (see Chapter 29). MAO inhibitors also act as indirect agents.

Direct-acting agents are agonists that produce their sympathomimetic effects by direct binding to and activation of α - or β -adrenergic receptors (e.g., norepinephrine, epinephrine, and isoproterenol) (see Box 10-3).³ Mixed-acting agents (e.g., phenylpropanolamine, dopamine, and pseudoephedrine) produce sympathomimetic effects both directly and indirectly. For instance, phenylpropanolamine (PPA) is a direct agonist on α -adrenergic receptors but also acts indirectly to promote release of norepinephrine from sympathetic nerve terminals. The toxicity of PPA is characterized by hypertension and a reflex bradycardia. Ingestion of α_2 -adrenergic agonists such as clonidine or other imidazolines (e.g., oxymetazoline and tetrahydrozoline) may

Data from Kandel ER, Schwartz JH, Jessell TM (eds): Principles of Neural Science, 3rd ed. New York, Elsevier Science, 1991; and Hoffman TT, Taylor P: Neurotransmission: the autonomic and somatic motor nervous systems. In Hardman JG, Limbird LE, Gilman AG (eds); Goodman & Gilman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001, pp 115-153.

produce a mixed clinical picture; stimulation of central α_2 -adrenergic receptors in the brain decreases central sympathetic outflow, whereas stimulation of peripheral α_1 -adrenergic receptors results in vasoconstriction and transient hypertension (see Chapter 62). Peripheral postsynaptic α -adrenergic antagonists (e.g., phenoxybenzamine, phentolamine, prazosin, hydralazine, and minoxidil) compete with endogenous catecholamines for binding to α_1 - and α_2 -adrenergic receptors. The α -adrenergic receptors (primarily α_1) also are blocked by tricyclic antidepressants (e.g., amitriptyline and imipramine), certain antipsychotic agents (e.g., phenothiazines, clozapine, and risperidone), antiarrhythmic agents (e.g., quinidine), and certain β blockers (e.g., labetalol and carvedilol). β Blockers primarily antagonize the effects of catecholamines at β -adrenergic receptors (see Chapter 60). β -Blocking drugs occupy β -adrenergic receptors and competitively block receptor occupancy by catecholamines and other β -adrenergic agonists. Most β -blocking drugs are pure antagonists; however, a few are partial agonists (e.g., pindolol and acebutolol) and may produce intrinsic sympathomimetic activity.

Similar to sympathomimetics, dopamine agonists can be direct, indirect, or mixed. Direct agonists bind to and activate various dopamine receptors directly, whereas indirect agents block dopamine uptake and/or stimulate presynaptic dopamine release. Direct dopamine receptor agonists include apomorphine, bromocriptine, fenoldopam, and pergolide. Indirect agonists include agents that cause dopamine release (e.g., benzotropine, diphenhydramine, orphenadrine) and those that block dopamine reuptake (e.g., cocaine, amphetamines, methylphenidate, amantadine, benzotropine, bupropion, diphenhydramine, and pemoline). Dopamine antagonists include specific receptor antagonists (e.g., antipsychotics, buspirone, metoclopramide, and amoxapine), agents that block synthesis (e.g., metyrosine), agents that prevent vesicle storage (e.g., reserpine and tetrabenazine) or cause dopamine depletion (e.g., α -methyl-dopa), or agents that destroy dopaminergic neurons (e.g., 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)).²

Sympathomimetic toxicity often leads to CNS and cardiovascular complications. Cocaine (see Chapter 42) and amphetamines (see Chapter 44) produce their clinical effects predominantly from reuptake blockade and enhanced presynaptic release of catecholamines (e.g., norepinephrine and dopamine), serotonin, acetylcholine, and excitatory amino acids (e.g., aspartate and glutamate) from central and peripheral nerve terminals. Amphetamine and cocaine toxicity often includes psychostimulatory (e.g., euphoria, restlessness, excessive speech and motor activity, tremor, and insomnia) and sympathomimetic (e.g., tachycardia, hypertension, hyperthermia, and diaphoresis) effects. Intracerebral and subarachnoid hemorrhage may occur as a result of malignant hypertension and cerebral vasculitis. The actions of pemoline and methylphenidate are similar to those of amphetamine. Many of the phenylamphetamines and amphetamines may produce hallucinations. 5-Methoxy-3,4-methylenedioxyamphetamine (MMDA) can be formed in vivo from myristicin, present in the dried seeds of the nutmeg tree (*Myristica fragrans*) and can produce psychomimetic effects when consumed in large amounts. Mescaline is an alkaloid component of the peyote cactus and produces psychotomimetic activity by its amphetamine-like actions (see Chapter 45). Cathinone, cathine, and methcathinone, related natural alkaloids found in the leaves and stems of *Catha edulis*, or khat, produces effects indistinguishable from those of amphetamines. Ephedrine is both an α - and β -adrenergic agonist; in addition, it enhances release of norepinephrine from sympathetic neurons. It is a naturally occurring drug found in various species of the plant *Ephedra* (ma huang), indigenous to China.

Blockade of the nigrostriatal dopamine receptors (primarily D_2 receptors) produces extrapyramidal symptoms such as parkinsonism, akathisia, and dystonia (see Chapter 38). Cholinergic input to the caudate and putamen appears to be unaffected, with resultant cholinergic excess. Neuroleptics and drugs such as metoclopramide cause parkinsonism through such a mechanism. Chronic manganese poisoning damages the

globus pallidus, leading to permanent neurologic damage.¹⁷ “Manganese madness” is characterized by emotional lability, hallucinations, irritability, and aggressiveness (see Chapter 75). Carbon disulfide, a volatile, lipid-soluble industrial solvent, and carbon monoxide inhalation produce parkinsonian features owing to damage to the globus pallidus. Although acute carbon monoxide poisoning has a high mortality, a delayed extrapyramidal syndrome can develop in those who recover from the acute effects. Carbon monoxide produces symmetric necrosis of the globus pallidus with demyelination of the subcortical white matter.¹⁸ Methanol poisoning produces optic atrophy and low-density lesions on computed tomography in the region of the putamen, and putaminal necrosis has been confirmed histologically.¹⁹ A plant and fungal neurotoxin, 3-nitropropionic acid, found in mildewed sugar cane, is a succinate dehydrogenase inhibitor that produces basal ganglion injury.²⁰ In 1983, some intravenous drug abusers injected MPTP, a compound produced during illicit synthesis of a narcotic related to meperidine.²¹ MPTP selectively destroys dopaminergic neurons in the substantia nigra, producing a condition indistinguishable from idiopathic Parkinson’s disease. Treatment of these side effects attempts to re-establish the dopamine/acetylcholine balance required for smooth motor movements.

A central hyperexcitation syndrome with fever, delirium, and hypertension occurs when MAO inhibitors such as phenelzine, isocarboxazid, or tranylcypromine are coadministered with phenothiazines, tricyclic antidepressants, serotonergic reuptake inhibitors, and sympathomimetic amines (amphetamine, methamphetamine, ephedrine, phenylpropanolamine) (see Chapters 10A and 29). Sympathomimetic amines commonly are found in some nasal sprays, nose drops, and over-the-counter cold preparations. MAO in the gastrointestinal tract and liver prevents access to the general circulation of ingested, indirectly acting agents such as tyramine and phenylethylamine, contained in foods such as aged cheese, yeast, chicken liver, and pickled herring. However, individuals taking MAO inhibitors do not have this protection and can suffer severe hypertensive crises after eating a large amount of tyramine-containing food. An exaggerated response to the usual dose of meperidine also has been observed.

Neuroleptic malignant syndrome (NMS) is an uncommon but life-threatening disorder that occurs in those who are sensitive to the extrapyramidal effects of antipsychotics (see Chapters 10A and 38). However, it is important to consider the diagnosis of NMS in any patient who has recently received medications that affect CNS dopaminergic pathways. Lithium, carbamazepine, and cocaine may predispose patients to the development of NMS. The syndrome may begin from a few days to a few weeks after initiation or alteration of neuroleptic drug therapy. NMS is thought to be mediated by a reduction in D₂ dopaminergic activity in certain areas of the CNS (e.g., basal ganglia and hypothalamus).²² Rigidity, catatonia, and fluctuating consciousness associated with autonomic hyperactivity, including

hyperpyrexia, and elevated serum creatinine kinase concentrations are typical features of NMS.

The Serotonergic System

Serotonin (5-HT or 5-hydroxytryptamine) is an indolealkylamine that functions as a neurotransmitter in the CNS. 5-HT also is present in many cells outside the CNS. Peripherally, 5-HT has a major role in gastrointestinal motility and is involved in platelet aggregation. 5-HT does not cross the blood-brain barrier; thus, neurons must synthesize their own transmitters. L-Tryptophan readily crosses the blood-brain barrier and is taken up into serotonergic nerve terminals via an active transport process. Hydroxylation to 5-hydroxytryptophan (5-HTP) occurs by the enzyme tryptophan hydroxylase and the cofactor tetrahydrobiopterin. This is the rate-limiting step, because the enzyme tryptophan hydroxylase is not saturated under normal conditions. Diets high in L-tryptophan can result in increased synthesis of 5-HT in the CNS. The 5-HTP is decarboxylated by the nonspecific aromatic L-amino acid 5-HTP decarboxylase to 5-HT. The mechanism of sequestration of 5-HT in storage granules is similar to that of catecholamines. 5-HT is then packaged into storage vesicles that protect it from cytosolic degradation by MAO. It is released by an exocytotic mechanism and acts on both presynaptic and postsynaptic receptors. Serotonergic transmission is terminated primarily by reuptake of the amine by a specific 5-HT transporter. After reuptake, the free indolamine is either repackaged or metabolized by MAO and aldehyde dehydrogenase to 5-hydroxyindoleacetic acid.

Several serotonin receptors have been cloned and are identified as 5-HT₁, 5-HT₂, 5-HT₃, 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇. All 5-HT receptors interact with G proteins except 5-HT₃ receptors; the latter are transmitter-gated ion channels. Within the 5-HT₁ group there are subtypes 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}. There are three 5-HT₂ subtypes, 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}, and two 5-HT₅ subtypes, 5-HT_{5A} and 5-HT_{5B}. Some serotonin receptors are presynaptic and others are postsynaptic.

Serotonin is involved in feeding, control of sleep and wakefulness, sexual behavior, mood and emotion, thermoregulation, circadian rhythmicity, drug-induced hallucinatory states, and neuroendocrine function in the CNS. It also serves as a precursor for the pineal hormone melatonin. Drugs that alter serotonin neurotransmission may have a wide array of clinical effects; the effects largely depend on the specific body area and serotonin receptor subtype affected.

Inhibition of 5-HT uptake has both an antidepressant and anxiolytic effect. Serotonin reuptake is blocked by some of the tricyclic antidepressants; however, the selective serotonin reuptake inhibitors (SSRIs), such as sertraline, fluoxetine, and venlafaxine, are more potent inhibitors of serotonin uptake than of norepinephrine and increase serotonin concentrations in the presynaptic cleft. Trazodone and nefazodone are weak cyclic antidepressants that weakly block 5-HT reuptake and antagonize 5-HT₂ receptors. The antidepressant effects

of MAO inhibitors are partly mediated by their prevention of 5-HT catabolism. Bupirone represents a new class of anti-anxiety agent whose anxiolytic action is related to agonism at the 5-HT_{1A} receptor in the brain. 3,4-Methylenedioxymphetamine (MDMA [“Ecstasy”]), an amphetamine derivative, produces clinical effects primarily by causing the release of serotonin and blocking its reuptake. Other amphetamines and cocaine also promote 5-HT neuronal release and block reuptake. Certain opioids (e.g., dextromethorphan, meperidine) and psychotropics (e.g., amoxapine, tramadol) also inhibit 5-HT reuptake to produce effects.

Partial agonist activity at 5-HT_{2A} receptors mediates the psychedelic effects of central hallucinogens of the indoleamine (e.g., lysergic acid diethylamide [LSD] and psilocybin) and phenylethylamine (e.g., mescaline) class (see Chapter 45). LSD also has agonistic activity at 5-HT_{1A} and 5-HT_{1C} receptors. Lysergic acid, which is an agonist at many 5-HT receptors, is found in the seeds of several species of the morning glory family (*Rivea corymbosa*, *Ipomoea violacea*) and is produced by the fungus *Claviceps purpurea*, which grows on grain. The hallucinogenic mushrooms of the *Psilocybe* genus contain the thermostabile indole-alkylamine psilocybin and its dephosphorylated congener, psilocin. These substances are structurally related to serotonin and are about 100 times less potent than LSD. Bufotenin is the hallucinogenic indole derivative similar to serotonin found in cohoba snuff and in the skin and parotid glands of the toad *Bufo marinus*. Recently, new drugs of abuse have surfaced. 5-MeO-DIPT or “Foxy Methoxy” and alpha-methyltryptamine or AMT have similar hallucinogenic effects as psilocybin and are being seen at clubs in large metropolitan areas.²³ Metoclopramide and cisapride are 5-HT₄ receptor agonists that stimulate gut motility.²⁴

Tryptophan hydroxylase can be blocked by *p*-chlorophenylalanine, thus decreasing the concentration of 5-HT. Drugs such as reserpine that disrupt the storage of catecholamines also impair the storage of 5-HT. Atypical neuroleptics (e.g., risperidone, clozapine), in contrast with conventional agents, strongly block serotonin 5-HT₂ receptors in the frontal cortex and striatal system in addition to their antagonism of adrenergic and dopamine receptors; antagonism at 5-HT_{2A} receptors produces independent antipsychotic effects and decreases the risk for developing extrapyramidal movement disorders (see Chapter 38). A new antipsychotic, aripiprazole, has partial agonist activity at both 5-HT_{1A} and 5-HT_{2A} receptors. Mirtazapine is an antidepressant that has numerous receptor effects; part of its activity is mediated by antagonism at 5-HT₂ and 5-HT₃ receptors. The antiemetic effects of ondansetron, granisetron, and metoclopramide are mediated through 5-HT₃ receptor antagonism, and agonists at 5-HT_{1D} and 5-HT_{1B} receptors such as sumatriptan are effective in treating migraine headaches.²⁴ Ergot alkaloids are nonspecific, partial 5-HT receptor agonists/antagonists. For instance, dihydroergotamine is thought to produce its antimigraine effects via agonist activity at 5-HT_{1B} and 5-HT_{1D} activity.²⁴ Methysergide produces its effects from 5-HT₁ and 5-HT₂ receptor antagonism. Like methysergide,

cycloheptadine also is an antagonist at 5-HT₁ and 5-HT₂ receptors.

Concurrent use of two or more serotonergic drugs may result in a marked increase of serotonin in the synapses and may produce the “serotonin syndrome” (see Chapters 10A and 29).²⁵ This important pharmacodynamic interaction has been commonly reported when fluoxetine or one of the SSRIs is used in the presence of an MAO inhibitor. Moreover, other combinations seem just as capable of producing this syndrome. The SSRIs have been implicated in combination with tryptophan, dextromethorphan, and lithium.

Opioids

The term *opiate* was used originally to designate narcotic drugs derived from opium—that is, morphine and codeine and their many semisynthetic derivatives prepared from the seed capsules of the poppy *Papaver somniferum* (see Chapter 33). Later, the term *opioid* was coined to refer in a generic sense to all drugs, natural and synthetic, that have morphine-related actions, as well as to the endogenous peptides (e.g., dynorphin A, endorphin, enkephalin) later discovered to have such actions. Opioid receptors differ in their regional distribution in the CNS.²⁶ The opioids induce their biologic effects by interacting with three major classes of receptors, the δ , κ , and μ receptors. More recently an “orphan” receptor has been identified and named ORL (opioid receptor-like) because of a high degree of homology to the “classical” opioid receptors. The σ receptor, however, is no longer regarded as an opioid receptor.

Morphine and β -endorphin are potent μ receptor agonists, whereas the enkephalins are less potent. μ Receptors mediate supraspinal analgesia, respiratory depression, miosis, euphoria, and physical dependence. Most of the clinically used opiates such as morphine, methadone, and codeine selectively interact with the μ opioid receptor. Naloxone and naltrexone are more potent antagonists at μ receptors than at δ or κ receptors. The κ receptor mediates spinal analgesia and sedation but not respiratory depression. Agonists at the κ receptor are less addictive and do not produce respiratory depression as severely as do μ agonists. Tramadol is a centrally-acting, partial μ -opioid receptor agonist that is structurally similar to morphine. It also inhibits the uptake of norepinephrine and 5-HT, which suggests that its antinociceptive property is mediated by both opioid and nonopioid mechanisms.

The opioid receptors work by activation of G proteins, subsequent inhibition of adenylyl cyclase, and activation of receptor-operated potassium channels or suppression of receptor-operated calcium channels.²⁷ Binding to the μ and δ receptors leads to opening of the potassium channel, whereas binding to κ sites results in closing of calcium channels. As a result, membrane hyperpolarization and neuronal suppression occurs. Opioid receptors function primarily by exerting inhibitory modulation of synaptic transmission in both the CNS

and the myenteric plexus. Often they are found on presynaptic nerve terminals, where their action results in decreased release of excitatory neurotransmitters. All three major receptor sites are involved in pain modulation. δ Receptors have been implicated in cardiovascular effects, whereas κ receptors seem to have a role in salt and water balance. Both μ and δ receptors mediate the decreased gastrointestinal motility effects observed with opioids. A given opioid drug may interact to a variable extent with all three types of receptors and can act as an agonist, a partial agonist, or an antagonist at each.

Opiates and opioids in overdose cause sedation and respiratory depression. Death usually is due to respiratory failure, generally as a result of apnea or pulmonary aspiration. The respiratory depression is complicated by bradycardia and hypotension. Pinpoint pupils usually are considered to be the classic sign of narcotic poisoning. Miosis is the result of μ and κ receptor activation, which results in an excitatory action on the parasympathetic nerve innervating the pupil. Normeperidine, the metabolite of meperidine, a synthetic opioid structurally different from morphine, is known to produce seizures on multiple dosing.²⁸ The neurotoxicity of normeperidine is manifested by signs of CNS stimulation that include tremors, twitching, myoclonus, and seizures. Treatment consists of administering benzodiazepines to reduce CNS excitation. Naloxone is contraindicated because it may increase the incidence of seizures. Propoxyphene causes delusions, hallucinations, and seizures, often with naloxone-resistant cardiodepression.

Opioid-associated depression of respiration and mental status can be reversed by administration of opioid antagonists. Most opioid antagonists compete for binding with agonists at the μ receptor and reverse the effects of endogenous or exogenous ligands by eliciting no postreceptor activity. Opioid receptor antagonists have variable potency and clinical half-lives; the dose administered also determines the duration of antagonist effects.²⁷ The half-life of naloxone is shorter than that of most opioids, and patients may again manifest signs of toxicity after the effect of naloxone wears off. Nalmefene is a new injectable methylene analogue of naltrexone with a half-life of about 11 hours, which is much longer than naloxone's half-life of 1 to 2 hours. Naltrexone is an opioid receptor antagonist with effects that last up to 48 hours after oral dosing.²⁷ Numerous synthetic agents have been developed that are partial agonist/antagonists (e.g., buprenorphine, pentazocine, butorphanol, mepitazinol, and nalbuphine). Opioid reversal in opioid-dependent patients poses a risk of precipitating withdrawal symptoms. Reversal and withdrawal symptoms can be produced following the administration of either a pure antagonist or partial agonist/antagonist to the opiate-addicted or intoxicated patient.

The Cholinergic System

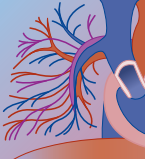

Acetylcholine is a neurotransmitter distributed throughout the CNS and peripheral nervous system (PNS). In the PNS, acetylcholine is found in somatic motor nerves,

autonomic ganglia, all parasympathetic postganglionic nerves, and a small number of sympathetic postganglionic nerves. In the PNS, the action of acetylcholine is responsible for mediating parasympathetic nerve stimulation.

The enzyme choline acetyltransferase catalyzes the acetylation of choline by acetyl coenzyme A to form acetylcholine in the motor nerve terminals. Acetylcholine is sequestered in synaptic vesicles and is released when extracellular calcium enters the neuron after depolarization. The released acetylcholine diffuses through the synaptic cleft to interact with the cholinergic receptor. The action of acetylcholine is terminated by hydrolysis by acetylcholinesterase, which is present in high concentrations in the synapse. Metabolism produces acetate and choline, and the breakdown products are used for resynthesis of acetylcholine. The enzyme acetylcholinesterase is widely distributed throughout the body in both neuronal and non-neuronal tissues. It is known as *true* or *specific cholinesterase*, unlike pseudocholinesterase, which is made primarily in the liver and appears in plasma. It has a lower affinity for acetylcholine and metabolizes some drugs, including cocaine and succinylcholine.

Nicotinic and muscarinic receptors are the two major cholinergic receptors that mediate the effects of acetylcholine. Both nicotinic and muscarinic receptors are present in the brain, and their properties are similar to those of peripheral receptors. Five muscarinic receptors, glycoproteins designated M_1 through M_5 , have been molecularly cloned and described. Many drugs with actions at peripheral cholinergic receptors are without central effects because they do not cross the blood-brain barrier. Peripheral nicotinic receptors are found in autonomic ganglia (postsynaptic neurons of both sympathetic and parasympathetic neurons) and the neuromuscular junction of skeletal muscles.²⁹ Peripheral muscarinic receptors are responsible for postganglionic parasympathetic neurotransmission; however, some sympathetic responses such as piloerection and sweating also are mediated through muscarinic receptors. Muscarinic receptors also are found in visceral smooth muscle, cardiac muscle, secretory glands, and the endothelial cells of the vasculature.

The muscarinic receptors belong to the family of the G protein-coupled receptor. The postsynaptic response initiated by acetylcholine binding to muscarinic receptors is varied and depends on receptor subtype. For instance, stimulation of M_1 and M_3 receptors results in hydrolysis of polyphosphoinositides and release of intracellular calcium.³⁰ In contrast, stimulation of M_2 and M_4 receptors is linked to adenylyl cyclase inhibition and subsequent increased potassium efflux and membrane hyperpolarization. The decreased heart rate observed from vagus nerve stimulation is mediated by M_2 receptors.³⁰ Nicotinic receptors are part of a ligand-gated channel composed of five polypeptide subunits. Nicotinic neuronal receptors show ligand specificity distinct from receptors in the neuromuscular junction (NMJ). Stimulation of these nicotinic channels at the NMJ by acetylcholine results in sodium influx, membrane depolarization, and a triggered action potential. At some

nicotinic receptors in the PNS and CNS, calcium influx may accompany sodium influx to generate postsynaptic excitatory potentials.

The cholinergic receptor agonists and the cholinesterase inhibitors comprise a large group of drugs that mimic the effects of acetylcholine. Direct cholinergic agonists are divided into esters of choline (e.g., acetylcholine and methacholine) and alkaloids (e.g., muscarine, nicotine, pilocarpine, bethanechol, and carbachol). Most cholinergic agonists bind to both muscarinic and nicotinic receptors, but a few are highly selective. Their spectrum of action depends on the receptor type stimulated—that is, muscarinic or nicotinic. The immediate peripheral clinical effects of excessive muscarinic stimulation include salivation, vomiting, diarrhea, sweating, cutaneous vasodilation, miosis, and bronchial vasoconstriction, whereas excessive nicotinic stimulation leads to muscle fasciculation, weakness, paralysis, hypertension, tachycardia, vomiting, and diarrhea (see Chapter 76). Central muscarinic agonist effects include sedation, coma, extrapyramidal movement disorders, and seizures. Central nicotinic agonist effects include seizures. Muscarinic antagonists block the actions of acetylcholine at muscarinic sites and block responses evoked by stimulation of parasympathetic nerves (see Chapter 39). At therapeutic doses, muscarinic antagonists do not bind to nicotinic receptors and neuromuscular blockers do not bind to muscarinic receptors. Ganglion blockers such as hexamethonium, mecamylamine, and trimethaphan block the action of acetylcholine and similar agonists at the nicotinic receptors of both parasympathetic and sympathetic ganglia. They are seldom used clinically.

Jimson weed (*Datura stramonium*) and deadly nightshade (*Atropa belladonna*) contain the alkaloids atropine, hyoscyamine, and hyoscyne. These alkaloids also are found in other plants belonging to the Solanaceae family. These alkaloids are competitive muscarinic receptor antagonists and in toxic amounts produce the anticholinergic (antimuscarinic) syndrome characterized by hot dry skin, hyperthermia, hyperactivity, confusion, delirium and hallucinations, and eventually coma, respiratory depression, and cardiovascular collapse (see Chapter 39). Neuroleptics, tricyclic antidepressants, antiparkinson drugs, and certain antihistamines, skeletal muscle relaxants, and glaucoma medications also have antimuscarinic activity, and overdoses may mimic atropine poisoning. Physostigmine is used as an antidote in anticholinergic poisoning. It is a tertiary amine compound that crosses the blood-brain barrier and acts as a reversible inhibitor of acetylcholinesterase.

Direct-acting muscarinic receptor agonists such as pilocarpine and choline esters produce predictable signs of muscarinic excess when given in overdose. *Amanita muscaria* contains clinically insignificant amounts of muscarine, a cholinergic agonist, but mushrooms of the genera *Inocybe*, *Clitocybe*, and *Omphalotus* contain muscarine and usually are responsible if cholinergic symptoms dominate. Peripheral effects are recognized clinically as the “SLUDGE” phenomenon of salivation, lacrimation, urination, defecation, gastrointestinal

cramping, and emesis. All the effects are blocked by atropine and its congeners. Cholinesterase inhibitors are used as insecticides and nerve gas poisons (see Chapters 76 and 105A). Nerve agents are organophosphorus compounds that are similar to but much more potent than organophosphorus insecticides. They lead to accumulation of acetylcholine, with hyperactivity at both muscarinic and nicotinic receptors and stimulation of the CNS. Atropine blocks the action of excess acetylcholine primarily at muscarinic sites, decreasing secretions, bronchoconstriction, and intestinal motility. Oximes such as pralidoxime work by reactivating phosphorylated cholinesterase enzyme and protecting the enzyme from further inhibition. They act primarily at nicotinic sites with reversal of skeletal muscle weakness and should be used in conjunction with atropine. Pralidoxime's action on muscarinic symptoms is less pronounced than that of atropine. However, early administration of the oximes after poisoning is essential because nerve agents binding to the active site of acetylcholinesterase undergo a rapid process of “aging” (i.e., the chemical bond between the nerve agent and acetylcholinesterase becomes progressively resistant to deactivators, starting minutes after nerve agent poisoning). An “intermediate syndrome” has been described 1 to 4 days after the acute phase of organophosphate toxicity, presenting with sudden respiratory paralysis, cranial nerve palsy, and weakness of neck flexors and proximal limb muscles, but this may be related to inadequate pralidoxime therapy.^{31,32} In addition, some organophosphates such as tri-ortho-cresyl phosphate cause a peripheral neuropathy associated with axonal demyelination that usually appears 2 to 3 weeks after exposure. Preceding cholinergic symptoms may be mild or even absent. These axonal effects are independent of cholinesterase inhibition and are due to inhibition of a second enzyme known as neuropathy target esterase.

Acetylcholine is also the neurotransmitter found at the NMJ. A number of biologic toxins produce effects at the NMJ. Cessation of toxic exposure usually results in complete recovery. A number of toxins disrupt neuromuscular transmission by altering the release of acetylcholine or by producing receptor blockade. The heat-labile neurotoxin botulinum produced by the anaerobic bacterium *Clostridium botulinum* produces muscle paralysis by preventing the release of acetylcholine from nerve terminals (see Chapter 26). Venoms of snakes, such as the Mojave rattlesnake, impair neuromuscular transmission by postsynaptic receptor blockade, which may be irreversible or partially reversible, in addition to inhibiting acetylcholine release (see Chapter 21B).³³ The black widow spider (*Latrodectus mactans*) and some species of tarantula produce a venom (α -latrotoxin) that causes presynaptic release and depletion of acetylcholine from presynaptic vesicles through both calcium dependent and calcium independent mechanisms (see Chapter 22A).^{34,35} Other arachnids that produce neurotoxins include ticks, funnel-web spiders, and scorpions. The funnel-web spider toxin (atraxotoxin) contains calcium channel inhibitors that can produce neuromuscular blockade. A

toxin found in the salivary glands of pregnant North American ticks (*Dermacentor andersoni* and *D. variabilis*) causes presynaptic block of acetylcholine release but can also affect conduction in small-diameter motor and sensory axons.³⁶ Removal of the tick often is curative, leading to complete clinical recovery. Drugs called *hemicholiniums* can block transmission at the neuromuscular junction by blocking the uptake of choline. Cholinesterase inhibitors such as the organophosphate compounds and carbamates inactivate acetylcholinesterase by phosphorylation, preventing acetylcholine degradation to produce a syndrome of cholinergic excess. Direct nicotinic receptor antagonists competitively block activity at the NMJ and result in weakness or muscle paralysis. NMJ blocking agents may block nicotinic receptors without activity (e.g., nondepolarizing) or may initially stimulate activity and subsequently block activity due to persistent binding (e.g., depolarizing blockade). Nondepolarizing agents include d-tubocurarine, atracurium, pancuronium, vecuronium, and rocuronium. Depolarizing blockers include succinylcholine and decamethonium. Many therapeutic drugs produce NMJ blockade by multiple presynaptic and postsynaptic actions. These agents include inhalational anesthetics (e.g., halothane, isoflurane), antibiotics (e.g., aminoglycosides, tetracyclines), magnesium salts, local anesthetics (e.g., lidocaine), corticosteroids, and calcium channel blockers.³⁷

The sodium channel of cholinergic neurons is the target of several potent poisons. Venoms of the *Centruroides* genus of scorpions of Arizona and Mexico and *Leiurus quinquestriatus* are neurotoxic (see Chapter 22B). They affect sodium channels with resultant prolongation of action potentials as well as a spontaneous depolarization of nerves of both theadrenergic and parasympathetic nervous systems. Tetrodotoxin found in the puffer fish species, suborder Tetraodontoidea, selectively blocks fast sodium channels in nerves and muscle membranes (see Chapter 25). It is found in fish (Echinodermata), the California newt (*Taricha*), blue-ringed octopus (*Hapalochlaena maculosa*), frogs (*Atelopus*), and marine bacteria. Tetrodotoxin relaxes vascular smooth muscle and blocks preganglionic cholinergic motor, sensory, and sympathetic neurotransmission. Saxitoxin, produced by the dinoflagellate *Protogonyaulax catenella* and by some bacteria, is found in plankton-eating shellfish (clams, oysters, mussels, scallops) and has an action similar to that of tetrodotoxin. Ciguatoxin, a toxin elaborated by the dinoflagellate *Gambierdiscus toxicus*, enhances quantal acetylcholine release at the neuromuscular junction by prolonging the duration of sodium channel opening. Batrachotoxin, found in the skin of a South American frog (*Phylllobates aurotaenia*), and the plant alkaloids aconitine and veratridine prevent closure or inactivation of voltage-dependent sodium channels. A second important class of sodium channel blockers includes local anesthetics such as lidocaine and related antiarrhythmic agents. This quinidine-like membrane-stabilizing effect is shared with the tricyclic antidepressants and is responsible for the cardiotoxicity. Potassium channel blockers such as 4-aminopyridine are convulsants, and polypeptide toxins from scorpion

(charybdotoxin), bee (apamin), or snake (dendrotoxin) venoms also interfere with potassium channel activity.

The Histaminergic System

The histaminergic system functions in the regulation of arousal, body temperature, locomotor activity, analgesia, regulation of biologic rhythms, feeding, drinking, and vascular dynamics.³⁸ Many of the psychotropic drugs interact with histamine receptors.

Histamine in the brain is formed from L-histidine by decarboxylation by histidine and L-amino acid decarboxylase. Unlike with the monoamines and amino acid transmitters, there does not appear to be an active reuptake process for histamine after its release. Histamine is metabolically inactivated by histamine methyltransferase.

Histamine receptors are divided into four subtypes, H₁, H₂, H₃, and H₄, and belong to the family of G protein-coupled receptors. H₁ receptor agonism leads to activation of phospholipase C, formation of diacylglycerol and inositol-1,4,5-triphosphate and subsequent activation of protein kinases, phospholipase A₂, and release of intracellular calcium.³⁹ H₁ receptors are found in the smooth muscle of the intestines, bronchi, and blood vessels. H₁ receptor activation results in smooth muscle contraction in these organ systems. H₂ receptor agonism leads to activation of adenylyl cyclase, increased cAMP, and activation of protein kinases.³⁹ H₂ receptors are found in gastric parietal cells and in the vascular system and CNS. H₂ receptor activation leads to gastric acid secretion and vascular smooth muscle relaxation. Activation of H₁ receptors on vascular endothelial cells also results in vascular smooth muscle relaxation (vasodilation). Activation of H₁ receptors on vascular endothelial cells leads to local production of nitric oxide or endothelial-derived relaxing factor and prostacyclin (PGI₂), both potent mediators of vasodilation.³⁹ H₃ receptors are found in the brain and the periphery and regulate histamine release. Recent evidence suggests that the H₃ receptor regulates the release of several important neurotransmitters (e.g., acetylcholine, dopamine, GABA, norepinephrine, serotonin), in both the PNS and CNS. The H₄ receptor is highly expressed in peripheral blood leukocytes and intestinal tissue.

Antihistamines (see Chapter 39) are related structurally to histamine and competitively antagonize the effects of histamine on H₁ and H₂ receptor sites. H₁ receptor antagonists block the bronchoconstrictive, large vessel vasoconstrictive, small vessel vasodilatory, enhanced gut motility, and increased permeability effects of histamine. H₂ receptor antagonists block gastric acid secretory and vasodilatory effects of histamine. Many first-generation H₁ receptor antagonists (e.g., diphenhydramine and pyrilamine) also possess anticholinergic effects, and the major signs of acute overdose are similar to those caused by classic antimuscarinic agents and are treated accordingly. They also may stimulate or depress the CNS, and some agents such as diphenhydramine possess local anesthetic and membrane-depressant effects when they are taken in large doses.

The Glutamnergic System

Amino acids found in the brain can function as neurotransmitters and be either excitatory or inhibitory. Glutamic acid and aspartic acid are excitatory, and the main inhibitory transmitters are GABA and glycine.

Glutamates are present in high concentration in the CNS. They do not cross the blood-brain barrier and are synthesized from glucose, glutamine, aspartate, and other precursors. The synthesis of glutamate is mediated by the enzyme glutamate dehydrogenase. Glutamate is released from nerve terminals by a calcium-dependent exocytosis mechanism similar to other neurotransmitters. Glutamate is inactivated by reuptake; several uptake transporters remove glutamate from the synaptic cleft into both neuronal and glial cells. Glutamate that is taken up into glial cells is oxidized through the Krebs cycle or converted to glutamine by the enzyme glutamine synthetase. Glutamine subsequently is released back into the synapse and then recycled back into the nerve terminal to be converted to glutamate. Glutamate is stored in vesicles for subsequent release.

Receptors for glutamate have a wide distribution in the CNS and are present on neurons that receive input from other neurotransmitter systems.⁴⁰ Glutamate receptors convey most of the fast excitatory neurotransmission in the CNS and act through both *ligand-gated ion channels* (ionotropic) and G protein-coupled receptors (metabotropic). The ionotropic glutamate receptors are named after the agonists kainate, AMPA, and NMDA. The AMPA and the kainate receptor are collectively known as the non-NMDA receptor.⁴¹ The non-NMDA receptors predominantly mediate sodium influx with activation, whereas NMDA receptor activation primarily promotes calcium ion influx. These channels also allow sodium ion influx and potassium ion efflux with activation. Metabotropic glutamate (mGlu) receptors are G protein-coupled receptors that have been subdivided into three groups, based on sequence similarity, pharmacology, and intracellular signaling mechanisms. These receptors may be excitatory or inhibitory to postsynaptic membranes. When excitatory, activation of the receptor often is associated with impaired potassium ion efflux. When inhibitory, activation of the receptor often is associated with enhanced potassium ion efflux.

At least five distinct sites of pharmacologic or regulatory significance have been identified on the NMDA receptor.⁴² There are two different agonist recognition sites for glutamate and glycine: a polyamine regulatory site that promotes receptor activation, and separate recognition sites for magnesium and zinc that act to inhibit flux through agonist-bound receptors. The NMDA receptor requires simultaneous binding of glutamate and glycine for activation.⁴³ They are known as coagonists because neither glycine nor glutamate alone can open the channel. The glycine site on the NMDA receptor is pharmacologically distinct from the classic spinal inhibitory glycine receptor in that it is not blocked by strychnine. Polyamines such as spermine and spermidine increase the ability of glutamate and glycine

to open ion channels by binding on their modulatory sites.⁴⁴ Thus, glutamate, glycine, and certain polyamines act in concert to open NMDA ion channels. Zinc and magnesium are endogenous blockers of the NMDA receptor and bind to different receptor sites. Magnesium, unlike zinc, exerts a voltage-dependent block on the open ion channel. Other voltage-dependent blockers of the NMDA receptor channels include dizocilpine (MK-801), phencyclidine, ketamine, and dextrorphan. Ethanol acts as an allosteric inhibitor at the NMDA receptor, and it is suggested that the behavioral disinhibition produced by ethanol is mediated by an action on the NMDA receptor and that the ataxia, somnolence, and CNS depression are mediated through other receptors.⁴⁵ Acute alcohol withdrawal is accompanied by excessive NMDA activity and is thought to explain some of the characteristic agitation, hallucinations, and convulsions.⁴⁶

AMPA receptors are widely distributed in the CNS, and in the absence of other excitatory activity, AMPA receptors may mediate fast depolarizing responses at most excitatory synapses in the CNS. Kainate receptors activate neuronal membrane channels that are distinguishable from those associated with NMDA and AMPA receptors on the basis of their conductance and desensitization properties. Distinct kainate receptors are involved in some neuropathologic events mediated by excitatory amino acids in the CNS.

Glutamate receptors may have a role in acute neuronal death in response to various insults to the nervous system, including anoxia, hypoglycemia, seizures, and mechanical trauma. The non-NMDA receptors also may be involved in neuropathologic processes. Glutamate receptor activation can cause seizures, and excitatory amino acid receptor antagonists may be of primary value for the treatment of epilepsy. Postischemic neuronal damage is attributed in part to overactivity of the excitatory amino acid neurotransmitter systems. Elevated extracellular glutamate levels result in glutamate receptor-mediated increase in postsynaptic intracellular calcium levels. Excitotoxicity, the "excitation to death" of neurons, results mainly from the intracellular calcium increase subsequent to overexcitation of neurons. This translocation of calcium leads to a cascade of events with formation of free radicals, activation of nitric oxide synthetase, and cell death. Nitric oxide is produced after stimulation of the enzyme nitric oxide synthetase. Nitric oxide is a novel neuronal messenger that acts with surrounding neurons, not by synaptic transmission but by diffusion between cells. In excess, nitric oxide is toxic to neurons. This toxicity is mediated largely by an interaction with the superoxide anion, presumably through the generation of the oxidant peroxynitrite. This cascade can be halted by administration of NMDA receptor antagonists.⁴⁷ Studies show that NMDA antagonists are more effective in reducing penumbral damage after cerebral arterial occlusion. Chronic neurodegenerative disorders such as olivopontocerebellar atrophy and Huntington's chorea are associated with disorders of excitatory amino acid transmission, as is amyotrophic lateral sclerosis. The role that NMDA receptors play in ischemic and nonischemic

neurotoxicity is not completely understood and under investigation.

Domoic acid was identified as the toxin in a major outbreak of food poisoning in Canada in 1987.⁴⁸ The alga *Nitzschia pungens* was found to be the source of the toxin, which contaminated blue mussels. Domoic acid is a glutamate analogue and produces neurotoxicity by overstimulation of the glutaminergic system. Dietary consumption of the chickling (not chick) pea *Lathyrus sativus* or other potentially neurotoxic *Lathyrus* species is associated with lathyrism characterized by spastic paraparesis. The offending agent in the pea is thought to be β -*N*-oxalyl-amino-L-alanine (BOAA). The cycad *Cycas circinalis* has a BOAA-like constituent, β -*N*-methylamino-L-alanine (BMAA), and may be the cause of the motor neuron disease that occurs in Guam. Phencyclidine and ketamine are known as *dissociative anesthetics* because they produce a feeling of being apart from one's environment. They are antagonists at the *N*-methyl-D-aspartate subtype of the glutamate receptor and act by blocking the ion channel (see Chapter 43). The primary antiepileptic action of felbamate is believed to be at the strychnine-insensitive glycine binding site at the NMDA receptor. It is shown also to weakly potentiate GABA receptor binding. Lamotrigine, another antiepileptic drug, is thought to act by inhibiting the release of glutamate. Nimodipine inhibits release of glutamate by blockade of voltage-gated calcium channels.

The GABAergic and Glycinergic Systems

The amino acids GABA and glycine are the primary inhibitory neurotransmitters that mediate fast postsynaptic inhibition in the nervous system. Their action is to bind specifically to GABA and glycine receptors, respectively.

Glucose is the principal precursor for GABA production, although glutamate, pyruvate, and other amino acids can act as precursors. Glutamic acid is formed from the transamination of α -ketoglutarate, formed from glucose metabolism in the Krebs cycle by GABA α -oxoglutarate transaminase. Glutamic acid decarboxylase catalyzes the decarboxylation of glutamic acid to form GABA. The cofactor is pyridoxal phosphate. Pyridoxal phosphate is synthesized from pyridoxine (vitamin B₆) by the enzyme pyridoxine kinase. The action of GABA released into the synaptic cleft is inactivated by a high-affinity, sodium-dependent uptake process. Enzymatic breakdown entails transamination to succinic semialdehyde by GABA transaminase. The next step is oxidation to succinic acid by succinic semialdehyde dehydrogenase, with the succinic acid then entering the Krebs cycle.

GABA receptors predominate in the brain, where they have a widespread distribution.⁴⁹ Three types of receptors for GABA have been characterized. GABA_A receptors open chloride channels, causing hyperpolarization and inhibition of the recipient neuronal cell. GABA_A receptors are multimembered, with five subunits assembled into a functional complex. The five major binding sites are for GABA, benzodiazepines, barbiturates, picrotoxin, and the anesthetic steroid.

These binding domains serve to modulate the receptors to GABA stimulation. The binding of GABA is enhanced by benzodiazepines, barbiturates, certain steroids, etomidate, propofol, chloral hydrate, meprobamate, ethanol, and zolpidem (see Chapters 34, 35, and 36); these agents serve as indirect receptor agonists. The binding of GABA is inhibited indirectly by flumazenil, penicillins, aztreonam, MAO inhibitors, tricyclic antidepressants, maprotiline, amoxapine, and organochlorine insecticides. GABA_B receptors belong to the G protein-coupled receptor superfamily. Activation of GABA_B receptors results in presynaptic inhibition by impairing calcium ion influx and neurotransmitter release or postsynaptic inhibition by increasing potassium ion efflux and cellular hyperpolarization. GABA_B receptors are activated by baclofen and γ -hydroxybutyrate (GHB) and antagonized by phaclofen and saclofen (see Chapters 37 and 46). GABA_C receptors are the newly identified member of the GABA receptor family. They are also linked to chloride channels, with distinct physiologic and pharmacologic properties. In contrast with the fast and transient responses elicited from GABA_A receptors, GABA_C receptors mediate slow and sustained responses. Pharmacologically, GABA_C receptors are bicuculline- and baclofen-insensitive, and they are not modulated by many GABA_A receptor modulators (such as benzodiazepines and barbiturates).

A number of agonists bind to the binding site and elicit GABA-like responses. Muscimol is a naturally occurring GABA analogue isolated from the hallucinogenic mushrooms *A. muscaria* and *A. pantherina* that acts as a potent, direct receptor agonist (see Chapter 23).⁵⁰ Benzodiazepines enhance GABAergic transmission indirectly. Benzodiazepine binding results in an increased affinity of GABA for its receptor and an increased frequency of chloride channel opening (see Chapter 35).⁴⁹ A wide variety of nonbenzodiazepines, such as β -carbolines, cyclopyrrolones (zopiclone), and imidazopyridines (zolpidem), also bind to the benzodiazepine site to enhance GABAergic transmission.⁵¹ Pure benzodiazepine overdoses usually are not fatal. However, the newer, short-acting agents may increase greatly the frequency of complication, especially when benzodiazepines are combined with other CNS depressant drugs and alcohol. The benzodiazepine antagonist flumazenil is one of several 1,4-benzodiazepine derivatives that binds with high affinity to the benzodiazepine receptor and acts as a competitive antagonist at this receptor. Thus, flumazenil is an indirect GABA_A antagonist. Caution in flumazenil administration is warranted in mixed overdoses, when benzodiazepine may provide a neuroprotective or cardioprotective action.

Barbiturates facilitate GABA-mediated synaptic transmission by increasing the duration of chloride channel opening with GABA binding (see Chapter 36).^{49,52} At pharmacologic concentrations, some barbiturates (e.g., pentobarbital) are known to allosterically increase binding of benzodiazepine and GABA to their binding sites. At high concentrations, certain barbiturates (e.g., pentobarbital) act as direct agonists and directly open

chloride channels.⁵² The allosteric regulation of GABA_A receptor function by neuroactive steroids is well known, and the steroid recognition site provides a potentially important target in the development of new therapeutic agents.⁵³ General anesthetics, including barbiturates, volatile gases, steroids, and alcohols, enhance GABA-mediated chloride conductance.⁵⁴ Gabapentin, an amino acid structurally related to GABA, is being used currently in the treatment of epilepsy. Gabapentin appears to have GABA-mimetic properties; it may increase GABA concentrations by stimulating glutamic acid decarboxylase, the enzyme that produces GABA from glutamate (see Chapter 40). The anticonvulsant valproic acid is an indirect GABA agonist; it increases GABA concentrations by increasing activity of glutamic acid decarboxylase and inhibiting GABA transaminase and succinic semialdehyde dehydrogenase, enzymes that degrade GABA. Vigabatrin (γ -vinyl-GABA), an anti-epileptic, is an irreversible inhibitor of GABA transaminase and increases GABA concentration. Topiramate and tiagabine, both anticonvulsants, are indirect GABA agonists. Alcohol is known to augment GABA-mediated chloride flux, and ethanol may exert some of its effect by enhancing the function of the GABA receptor.⁵⁵

Bicuculline, a plant alkaloid, is a competitive GABA antagonist and is selective for the GABA_A receptor that controls chloride permeability. Picrotoxin found in the berries of the shrub *Anamirta cocculus* is a GABA_A receptor channel blocker. The active principle picrotoxin works on the gating process of the channel. Penicillin is a chloride channel blocker with a net negative charge that occludes the chloride channel by interacting with the positively charged amino acid residues within the channel pore. Pyridoxal phosphate antagonists such as isoniazid and other hydrazines, such as monomethylhydrazine in the mushroom *Gyromitra (Helvella) esculenta*, produce seizures by impairing GABA synthesis (see Chapter 23).⁵⁶ Intravenous pyridoxine is used to combat the toxicity. Cyanide inhibits glutamic acid decarboxylase, thereby decreasing GABA, and it may partly account for seizures occurring in cyanide toxicity.⁵⁷ The chlorinated hydrocarbons inhibit the action of GABA by binding to the picrotoxin site on the GABA_A receptor to produce seizures.⁵⁸ Baclofen is an orally active GABA-mimetic agent and acts as a GABA_B agonist.⁵⁹ It causes hyperpolarization by increasing potassium conductance and has presynaptic inhibitory functions. Baclofen in an overdose produces drowsiness, coma, seizures, respiratory depression, and arrhythmias (see Chapter 37). The sedative/hypnotic effect of GHB is mediated by GABA_B receptor and specific GHB receptor agonism (see Chapter 46). Similarly, the sedative/hypnotic effects of γ -butyrolactone and 1,4-butanediol, which both are readily bioconverted to GHB, are mediated by these receptors.

Glycine is another inhibitory neurotransmitter that mediates fast postsynaptic inhibition in the nervous system. Like GABA_A, the postsynaptic glycine receptor is linked to a chloride channel. Activation of the glycine receptor causes chloride channel opening, hyperpolarization of the postsynaptic membrane, and inhibition of neuronal firing.⁶⁰ The glycine receptors are

predominantly found in the spinal cord and the brainstem. Glycine also is likely the inhibitory neurotransmitter in the reticular formation. Glycine is present in the forebrain, where it functions as a coagonist of the NMDA glutamate receptor. At this receptor, glycine promotes the actions of glutamate, the major excitatory neurotransmitter in the CNS. The pharmacology of the glycine receptor is known less extensively than that of the GABA receptors. They are defined by their antagonism by the convulsive alkaloid, strychnine, in contrast to the strychnine-insensitive glycine-binding site that is associated with the excitatory NMDA subclass of the glutamate receptor. This explains why strychnine's effect is localized to the medulla and spinal cord only.

Strychnine, an alkaloid found in the seeds of the tree *Strychnos nux-vomica*, increases the level of neuronal excitability by selective antagonism at glycine receptors (see Chapter 24). The clinical picture simulates that of generalized seizures and is characterized by diffuse skeletal muscle contraction, muscular rigidity, opisthotonus, trismus, rhabdomyolysis, myoglobinuria, and acute respiratory and renal failure. Strychnine is used primarily as a rodenticide and is found sometimes as an adulterant in illicit drugs such as cocaine or heroin. Barbiturates and diazepam are effective antagonists of strychnine. *Calycanthus* species (Carolina allspice) contain the strychnine-like toxin calycanthine, which may produce convulsions. Tetanus toxin inhibits the release of glycine from nerve endings in the brainstem and spinal cord.

TOXICITY SPECIFIC TO THE PERIPHERAL NERVOUS SYSTEM

Neurotoxins almost invariably produce polyneuropathy and rarely are implicated in focal neuropathy. Neurologic dysfunction usually occurs as part of a systemic toxicity.⁶¹ The neurotoxicity may occur in isolation, however, and then need to be differentiated from other nontoxic causes of neuropathies. The development of a neuropathy is directly related to continued exposure to a particular toxin. The neuropathy often improves when the exposure is discontinued. If the neuropathy progresses after removal of a suspected toxin, then other causes should be considered (Box 10-4).

Diseases of the peripheral nervous system can be classified in two ways. The first categorization depends on the distribution: focal, multifocal, diffuse, proximal, distal, symmetric, or segmental. The second system depends on the anatomic location of the pathologic process: muscle, neuromuscular junction, or peripheral nerve. Further differentiation is based on involvement of the neuron, axon, or myelin.

Symmetric Generalized Neuropathies

The most common form of drug- or toxin-induced neuropathy is a symmetric distal axonopathy. The neuropathy reflects failure of axonal transport and begins distally, where the axons are most vulnerable, and

BOX 10-4 CHARACTERISTIC FEATURES OF TOXIC NEUROPATHY

Consistent pattern of neurologic dysfunction
 Reproducible pathophysiologic or pathologic findings
 Temporal relationship between exposure and onset of the clinical finding
 Nonfocal disorder
 Neurotoxicity improves with cessation of exposure

predominantly affects long and large-diameter axons, progressing proximally. Axonopathies usually have a subacute onset with gradual progression and clinically are reflected by a symmetric, distal, diffuse, stocking and glove-type sensorimotor loss. Sensory signs and symptoms initially predominate over motor deficits. Withdrawal of the toxic insult is necessary for recovery, which often is prolonged and slow. Axonal regeneration occurs at a rate of 2 mm/day, with recovery in an order reverse to that of the initial loss (i.e., proximal before distal).

Demyelinating neuropathy is characterized by lesions that occur in the myelin sheath or Schwann cells. The axons usually are spared. The onset usually is subacute, and the involvement in myelinopathy, unlike in axonopathy, is predominantly distal and motor because the heavily myelinated large motor fibers are more severely affected than the small-diameter myelinated and unmyelinated sensory fibers. The demyelination may be patchy, however, with early proximal involvement. Areflexia is characteristic, and sensory symptoms are minimal. Recovery from a myelinopathy usually is rapid, early, and complete when compared with that from an axonopathy. The buckthorn toxin, found in high concentrations in the endocarp of the fruit of *Karwinskia humboldtiana*, and perhexiline are the few toxins causing a peripheral myelinopathy.

Toxic injury to the cell body directly is termed a *neuropathy*. The dorsal root ganglions are especially involved. This vulnerability is because of a poorly formed nerve-blood barrier and the fenestrated blood vessels with increased vascular perfusion. Neuronopathies rarely are the cause of toxic insults. Neuronopathies are characterized by the rapid or subacute onset of motor or sensory deficits. The neurologic defect mirrors the nerve root involved and can occur anywhere. Recovery is variable and often incomplete because of incomplete neuronal recovery. Toxic neuronopathies can be caused by mercury, pyridoxine, and doxorubicin.

Acute and chronic heavy metal exposure may produce neuropathies. Metal compounds tend to be stored in bones, from where they may be gradually released into the circulation, subsequently delaying recovery time. Other system (i.e., hematopoietic, renal, and gastrointestinal) dysfunctions usually accompany the neuropathy. Arsenic produces a generalized axonal peripheral neuropathy with predominant sensory involvement (see Chapter 74). Symptoms of toxicity usually appear 5 to 10 days after ingestion, with painful dysesthesias and

numbness in the feet and hands. Arsenic reacts with the sulfhydryl groups on various enzymes necessary for cellular metabolism. Both inorganic and organic lead is neurotoxic. Lead intoxication produces a demyelinating neuropathy with predominantly motor involvement (see Chapter 73). Lead intoxication in children, unlike that in adults, may produce an encephalopathy rather than a peripheral neuropathy. Mercury exposure causes a subacute, diffuse, predominantly motor neuropathy (see Chapter 71). Thallium compounds have been used as rodenticides, and toxicity produces an axonal neuropathy with prominent systemic features that include alopecia and autonomic dysfunction (see Chapter 75). Aluminum has been implicated in the causation of dialysis encephalopathy, a progressive acute syndrome found in patients undergoing dialysis (see Chapter 75).

A number of organic compounds also produce neuropathies. The rodenticide Vacor causes a severe, rapid-onset distal axonopathy with associated autonomic dysfunction and diabetes mellitus due to necrosis of pancreatic β cells (see Chapter 79).⁶² The neuropathy can be prevented by nicotinamide, and Vacor may inhibit nicotinamide dinucleotide-dependent enzyme with disruption of an axonal-dependent process. Peripheral neurotoxic organic solvents include *n*-hexane and methyl-*N*-butyl ketone, carbon disulfide, and trichlorethylene.⁶³ *n*-Hexane and methyl-*N*-butyl ketone are metabolized to 2,5-hexanedione, the active agent that damages the peripheral nerves. Methyl ethyl ketone enhances the neurotoxic effects of *n*-hexane and methyl-*N*-butyl ketone without itself being neurotoxic. Trichloroethylene may cause trigeminal neuropathy through its breakdown product, dichloroacetylene. Allyl chloride, used in the manufacture of epoxy resin, produces a characteristic distal axonopathy with sensory loss and loss of ankle jerks. Acrylamide monomer, unlike its polymer, is neurotoxic and produces a distal axonopathy involving large myelinated fibers. Ethylene oxide, commonly used as a sterilizing agent, produces a distal sensorimotor axonopathy with numbness, weakness, and areflexia (see Chapter 80). Residual ethylene oxide in dialysis tubing after the sterilization process may contribute to peripheral neuropathy in patients undergoing long-term hemodialysis.⁶⁴ Methyl bromide exposure causes a distal symmetric axonopathy with involvement of the pyramidal tracts and cerebellum. Polychlorinated biphenyls have been associated with outbreaks of neuropathy when cooking oil has been contaminated with tetrachlorobiphenyl (Table 10-1).⁶⁵

CONCLUSION

An exciting future lies ahead in neurotoxicology. The knowledge of normal brain physiology and its response to insult has grown tremendously. The number of new antidepressants has greatly increased. Clinical trials of drugs that treat ischemic and traumatic brain injury are under way. The results of these studies will further expand the understanding of neurotoxicity and lead to the development of better therapies.

TABLE 10-1 Selected Neurotoxins That Produce Neuropathy

TOXINS	EXPOSURE RISK	PATHOLOGIC FINDING	CLINICAL FEATURES
Arsenic	Metallurgy, pesticides, wood preservatives, pigments, ant stakes, weed killers	Axonopathy (S > M)	GI distress, psychosis, hyperkeratosis, hyperpigmentation, Mees' lines, anemia
Lead	Lead production, solders, batteries, pigment, insecticides, auto radiators, moonshine, construction workers, folk medicine (<i>azarcon</i> and <i>greta</i>)	Axonopathy (M > S)	GI distress, microcytic anemia, basophilic stippling, encephalopathy, acute tubular dysfunction, gout, hyperuricemia
Mercury	Gold and silver extraction, dental amalgams, fungicides, environmental contamination, thermometers	Axonopathy (M > S)	GI distress, tremor, ataxia, gingivostomatitis, neuropsychiatric disturbances
Thallium	Manufacture of optical lenses, photoelectric cells, and costume jewelry; rodenticide	Axonopathy (M > S)	GI distress, delirium, seizures, coma, alopecia, choreoathetosis, ataxia, tremor, Mees' lines
Carbon disulfide	Insecticides, rayon fiber production	Axonopathy (MS)	Encephalopathy, parkinsonian syndromes, nystagmus, psychosis
Acrylamide	Production of acrylamide resins	Axonopathy (MS)	Irritant, contact dermatitis, ataxia
Allyl chloride	Epoxy resin and glycerin production	Axonopathy (S > M)	Irritant, pulmonary edema
Ethylene oxide	Sterilizing agent, solvent, plasticizer, chemical intermediate	Axonopathy (MS)	Convulsions, arrhythmias, leukemia
Hexacarbons (e.g., hexane)	Solvents	Axonopathy (SM)	GI dysfunction, hyperhidrosis, autonomic dysfunction
Methyl bromide	Insecticidal fumigant, fire extinguisher ingredient	Axonopathy (MS)	Irritant, dermatitis, tremor, seizure, coma, dementia, psychosis, extrapyramidal symptoms
Trichloroethylene	Typewriter correction fluid, insecticides, spot removers, paint removers	Myelinopathy	Extrapyramidal dysfunction, degreaser's flush
Polychlorinated biphenyls (PCBs)	High-temperature insulators, transformers, carbonless copy papers	Myelinopathy	Chloracne, hepatic transaminitis, porphyria
Organophosphates	Pesticides	Axonopathy (M > S)	Cholinergic symptoms, agitation, seizures, coma
Vacor (PNU)	Rodenticides	Axonopathy (M > S)	Nausea, vomiting, autonomic dysfunction, insulin-dependent diabetes mellitus

GI, gastrointestinal; M, motor; S, sensory.

A Drug-Associated Neuromuscular Syndromes

MICHAEL BEUHLER, MD

A “neuromuscular disorder” refers to a pathophysiologic state created by an abnormal interaction between nerve and muscle. In toxicology, most neuromuscular disorders relate to an abnormal interaction between the central or peripheral nervous systems (CNS or PNS) and the motor innervation of skeletal muscles. Drug-associated neuromuscular disorders are typically adverse effects that occur during therapeutic, occupational, or recreational use or overuse of various xenobiotics. These disorders may be dose related or idiosyncratic, mild or severe, reversible or irreversible, and can occur early or late following exposure. Three drug-associated neuromuscular disorders will be extensively reviewed in this chapter. For discussion of other drug-associated neuromuscular disorders, you should refer to the specific chapter covering a particular drug. For instance, extrapyramidal movement disorders are discussed in Chapter 38, the Antipsychotic Agents.

When exposure to a xenobiotic produces, with some regularity, a specific constellation of neuromuscular physical signs and symptoms, they are referred to as syndromes. Syndrome designations are often reserved for disorders that are associated with significant patient morbidity. The majority of drug-associated neuromuscular syndromes are manifested by exaggerated muscular tone and resultant hyperthermia. Although the pathophysiologic mechanisms underlying the neuromuscular hyperactivity are frequently unique, clinical signs and symptoms often have significant overlap, thus making accurate diagnosis difficult. Recognition of the unique clinical features of each syndrome will facilitate diagnosis and assist treatment. In this chapter, the neuroleptic malignant syndrome (NMS), serotonin syndrome, and malignant hyperthermia (MH) will be reviewed and the similarities and differences of their etiology, pathophysiology, clinical findings, and treatment will be highlighted.

NEUROLEPTIC MALIGNANT SYNDROME

Please also see Chapter 38.

Introduction, History, and Epidemiology

This syndrome was first described in 1960 when fever and rigidity were associated with haloperidol therapy.¹ During the 1960s, the syndrome was increasingly recognized as a separate entity from lethal catatonia. By the 1980s, NMS had become widely accepted as a complication of neuroleptic use. During the past 10 to 15 years, the mortality rate from NMS has declined due to a wider recognition of patients at risk, earlier diagnosis, decreases in neuroleptic dosing, the use of newer and safer atypical antipsychotics, and improvements in critical care.

From retrospective studies, the incidence of NMS has been estimated to occur in 0.02% to 3% in patients treated with neuroleptics.² Prospective studies estimate an incidence of 0.07% to 0.9%.³⁻⁵ The incidence of NMS appears to be decreasing. This is likely due to the use of lower doses of neuroleptics, the use of atypical agents (see Chapter 38), and earlier recognition with prevention of full syndrome development. Stricter criteria for diagnosis may now limit the reporting of NMS. In addition, new cases are less likely to be published in the current literature now that the syndrome is well characterized.

There does not appear to be a gender or age preference for NMS, but it is more common in men and adults due to greater frequency of neuroleptic use in these patient populations. Patients with neuropsychiatric disorders such as Parkinson’s disease and catatonia and those with severe forms of functional psychiatric disorders are at greater risk for developing NMS.² Patients with preexisting organic brain syndrome appear to have a higher risk for mortality and morbidity from NMS.

NMS has been reported with several types of medications that result in decreased CNS dopamine tone. The high-potency neuroleptics such as haloperidol, fluphenazine, and thiothixene are probably more likely to cause the syndrome, but it has been reported with lower-potency neuroleptics as well. Although haloperidol has been associated with more documented cases of NMS, this may reflect more widespread use of this antipsychotic rather than greater absolute risk with this particular agent. Even the newer, atypical agents, which have a decreased propensity to produce extrapyramidal side effects (EPS) (e.g., risperidone, clozapine, olanzapine, and quetiapine), have been associated with NMS.^{2,6,7} Non-neuroleptic dopamine antagonists (e.g., amoxapine and metoclopramide) have caused episodes of NMS. Drugs that result in lower levels of dopamine (e.g., reserpine, tetrabenazine, and α -methyl tyrosine) have been associated with NMS. NMS has also been reported following the abrupt cessation of dopamine agonists (e.g., levodopa/carbidopa and amantadine) used for the treatment of Parkinson’s disease.^{8,9}

There are several purported risk factors for developing NMS. They include large doses of neuroleptics and/or rapid dose escalation, a positive history of NMS, antecedent agitated behavior, dehydration or infection (e.g., pneumonia or sepsis), the presence of electrolyte disorders (e.g., hypo- or hypernatremia), and concomitant treatment with other psychotropic agents (e.g., lithium, anticholinergic agents). Lithium is thought to decrease striatal dopamine synthesis, thus theoretically predisposing to NMS.¹⁰ Lithium is associated with its own neurotoxicity that may be mistaken for NMS. Thus, the diagnosis of NMS should be made with caution for

patients who are treated with lithium and neuroleptics simultaneously.^{11,12}

NMS is an idiosyncratic reaction to neuroleptic therapy and is not the result of overdose. For patients with NMS, serum levels of neuroleptics are typically in the normal range. Overdose of certain traditional neuroleptics (e.g., chlorpromazine, thioridazine) may occasionally produce short-lived patient agitation and hyperthermia. The clinical course (abrupt onset over minutes to hours and duration of 1 to 2 days) is distinctly different from that of NMS (gradual onset over days and duration of 1 to 2 weeks).

NMS-like symptoms had been reported for years prior to the initial use of neuroleptics. This separate syndrome with similar clinical characteristics is called lethal catatonia (or malignant catatonia). In its final or advanced stages, lethal catatonia is clinically indistinguishable from NMS. The patient often has gradual worsening of psychiatric symptoms that include moodiness and melancholia for several days preceding the full syndrome. Typically, 1 to 2 days prior to developing lethal catatonia patients develop severe agitation and mania. Following this period, they develop catatonia, labile blood pressure, muscular rigidity, and mottled skin, similar to NMS. It is often difficult to differentiate lethal catatonia from NMS. The absence of a change in antecedent antidopamine drug therapy by history and presence of prodromal psychiatric symptoms suggest a diagnosis of lethal catatonia.¹³

Pathophysiology of Neuroleptic Malignant Syndrome

The pathophysiology of NMS has been investigated for decades but has not yet been fully elucidated. NMS is theorized to be the result of a relative dopamine blockade (specifically D₂-receptor blockade) in the mesolimbic, mesocortical, nigrostriatal, and hypothalamic brain regions.² This is largely based on the observation that the syndrome occurs in the presence of dopamine depletion or antagonist therapy, is associated with temperature abnormalities (controlled by preoptic anterior hypothalamic dopamine tracts), and motor symptoms are exaggerations of extrapyramidal neuroleptic side effects. However, there are some limitations to the dopamine antagonist or hypofunction theory.

The syndrome has been reported to occur at therapeutic serum neuroleptic levels, and effects last much longer than expected based on the elimination kinetics of neuroleptics. The syndrome has been reported to continue despite a subtherapeutic concentration or absence of neuroleptic in the CNS. This is partly explained by the counterhypothesis that NMS effects persist due to dopamine receptor hypersensitivity or increased number of dopamine receptors. However, one would expect the patient to manifest signs and symptoms often associated with dopamine excess (i.e., choreoathetoid movements, hallucinations), when CNS dopamine receptors are no longer occupied and activated due to drug metabolism. Such stigmata are not commonly reported with NMS. There does, however,

seem to be some temporal relationship between the duration of symptoms and the triggering agent's half-life, as demonstrated by depot injections generally being implicated in longer clinical courses than immediate-release oral or intramuscular formulations.

There is a link between serotonin (5-HT) and dopamine activity. The newer antidepressants have 5-HT_{2A} antagonism, which is thought to increase dopamine tone in the striatum and prefrontal cortex (by disinhibition). This 5-HT antagonism is thought to limit adverse effects (e.g., EPS) and contribute to the antipsychotic drug effects. Selective serotonin reuptake inhibitors (SSRIs) aggravate haloperidol-induced dystonia and parkinsonism in monkeys (by a decrease in brain dopamine).¹⁴ Treatment of rats with agents that increase 5-HT enhances catalepsy after blockade of dopamine receptors.¹⁵ This suggests a dopamine-serotonin relationship, with increased 5-HT tone causing decreased dopamine tone.¹⁶ There are several cases of EPS and NMS triggered by SSRIs in the literature.^{17,18}

Clinical Manifestations of Neuroleptic Malignant Syndrome

NMS is most often characterized by fever, muscular rigidity, altered mental status, and autonomic dysfunction.^{2,19} Fever and muscular rigidity are usually present but not required for diagnosis. The reported signs and symptoms of NMS syndrome are listed in Table 10A-1. Increased muscle tone is often present (97%), being described as "lead pipe rigidity," usually by those familiar with that phrase's linkage to NMS. The rigidity may have a cogwheeling component. Other EPS symptoms (dystonia, dysphagia, gait abnormalities) may be present. Tremor (mild to severe, fine or coarse) has been reported. Mutism may be part of the syndrome and is occasionally described associated with fearful facial expressions. Elevated temperatures are common (98%) although not universal.^{2,20} Other symptoms associated with NMS include diaphoresis, tachypnea, tachycardia, and altered mental status (97%).² Urinary incontinence is uncommonly reported. Seizures are rarely reported, and should prompt investigation for another diagnosis.

Diagnosis of Neuroleptic Malignant Syndrome

The diagnosis of NMS is clinical and based on suggestive history and physical findings along with a high level of suspicion in the appropriate clinical setting. By history, the patient must have recently had a dopaminergic agent started, the dose increased, or an intervention that decreased CNS dopamine tone.

Several clinical diagnostic criteria are available to facilitate the diagnosis of NMS. The disadvantage of applying rigid diagnostic criteria is that borderline or atypical cases will be excluded, possibly delaying proper therapy. This is particularly important since NMS is a heterogeneous disorder that exists along a severity continuum from moderate to very severe cases. Atypical cases may not have rigidity or elevated temperature and

TABLE 10A-1 Signs and Symptoms of Neuroleptic Malignant Syndrome (NMS)/Serotonin Syndrome/Malignant Hyperthermia

CLINICAL FEATURES	NMS	SEROTONIN SYNDROME	MALIGNANT HYPERTHERMIA
Triggering agent	Neuroleptic	Proserotonergic agent	Succinylcholine or inhaled anesthetic
Onset	Slow (hours to days)	Fast (minutes to hours)	Very fast to fast (minutes to hours)
Duration	Long (days to weeks)	Short (1–2 days)	Short (1–3 days)
Agitation	Sometimes	Yes	No
Confusion	Yes	Sometimes	Unusual
Hyperactivity	No	Yes	No
Bradykinesia/stupor	Yes	No	Unusual
Myoclonus	No	Yes	No
Shivering	No	Yes/sometimes	No
Tremor	Sometimes	Yes	No
Pupils	Mid-sized	Large	Not specific
Hyperreflexia	No	Yes (especially lower extremities)	No
Rigidity	Severe	Sometimes	Severe
Rigidity type	Extrapyramidal (leadpipe)	Pyramidal (clasp-knife)	Generalized
Hyperpyrexia	Yes	Yes	Severe
Tachypnea	Yes	Yes	Yes
Tachycardia	Yes	Yes	Yes (severe)
Hypertension	Sometimes	Yes	Sometimes
Leukocytosis	Yes	Uncommon	Not typical
Elevated creatine phosphokinase	Severe	Mild	Severe

can make diagnosis difficult. A flexible definition is probably in the patient's best interest to allow for initiation of aggressive supportive treatment. In general, it is important to initially exclude any alternative diagnoses (e.g., infection) (see later section on Differential Diagnosis).

There are no laboratory studies that confirm the diagnosis of NMS. The laboratory abnormalities that have been associated with NMS are relatively nonspecific. They include markedly elevated creatine phosphokinase (CPK), increased white blood cell (WBC) count, myoglobinuria, and occasionally, diffuse slowing on electroencephalography (EEG). Serum iron levels have been reported to be low with NMS and have been suggested as a useful marker. Serum iron, however, appears to decrease with inflammatory responses, and thus has no prognostic significance.^{21,22}

There is significant variation in the time between the administration of the "triggering" medication and the onset of NMS. Reports range from days to weeks from the addition or change in the medication to development of signs and symptoms of NMS. Once the illness begins, symptoms progress slowly and peak over a period of 24 to 72 hours. The total duration of the illness varies greatly. The duration of illness appears to be longer for patients who received depot neuroleptics as compared with oral or immediate release intramuscular formulations. The disease often has a fluctuating clinical course, irrespective of the treatment. Improvement is usually observed within 48 to 96 hours of discontinuation of the triggering medication. Full recovery, however, is slow and often takes 10 or more days. Full recovery may occasionally take several weeks, and some NMS signs and symptoms improve while others persist.² For example,

patients can have improvement of their rigidity and resolution of elevated serum CPK, but still have altered mental status and hyperthermia.

Mortality appears to be related to the severity of hyperthermia and the degree of alteration of consciousness. Mortality from NMS usually results from renal failure, pulmonary embolism, respiratory failure, acute respiratory distress syndrome, cardiovascular collapse, or disseminated intravascular coagulation (DIC). This stresses the need for aggressive supportive care. Postmortem examination is unlikely to demonstrate specific CNS findings.

Persistent neurologic sequelae have been reported following episodes of NMS. These persistent neurologic findings include cognitive dysfunction, catatonia, continued rigidity, dystonia, and amnesic symptoms.^{23,24} Medical complications (such as hypoxic encephalopathy) can result in prolonged symptomatology. The patient may also have exacerbations of underlying psychiatric illness after removal of neuroleptics and/or treatment with dopamine agonists.

SEROTONIN SYNDROME

Please also see Chapter 29.

Introduction, History, and Epidemiology

Although not initially recognized as a distinct clinical entity, serotonin syndrome has existed for over half a century. The first published description of the syndrome occurred in 1955 when a fatal case of "toxic encephalitis"

was noted after meperidine was administered to a patient taking iproniazid for pulmonary tuberculosis.²⁵ The use of L-tryptophan in conjunction with monoamine oxidase inhibitors (MAOIs) in the 1960s caused a similar illness marked by hyperactivity that was due to excess CNS serotonin levels.^{26,27} It was not until 1982, however, that the syndrome was fully characterized and the term *serotonin syndrome* appeared in the literature.²⁸

Several studies have attempted to estimate the frequency of serotonin syndrome; all of them suffer from varying degrees of methodologic problems. Despite these study limitations, the incidence of severe serotonin syndrome is quite low during therapeutic dosing of non-MAOI agents. There have only been approximately 200 cases of serotonin syndrome reported in the literature since it was initially characterized. This low reporting, however, may not reflect a true incidence. This illness, like NMS, has a continuum of severity. Thus, the incidence of the syndrome will depend on the flexibility of clinical criteria used for diagnosis. It is likely that mild signs and symptoms of serotonin excess occur frequently with many different proserotonergic agents. The severity of these symptoms, however, is mild enough to be overlooked by both patients and treating physicians and thus will not be diagnosed as serotonin syndrome. A recent surge in popularity of SSRIs over traditional antidepressants as well as increased education (and thus recognition) of the signs and symptoms of serotonin syndrome may lead to an increased incidence of syndrome diagnosis. In addition, the recent increased use of psychoactive medications in children is expected to increase the incidence of serotonin syndrome in this age group.

There does not appear to be an age or gender preference for the development of serotonin syndrome. Underlying organic brain disease may be a risk factor that predisposes patients to the development of the syndrome. The incidence of serious morbidity and mortality associated with serotonin syndrome varies greatly and is related to individual host factors (i.e., comorbid illness), drug combinations (i.e., the “dose” of serotonin stimulation), and the timeliness of diagnosis and treatment.

Most cases of serotonin syndrome occur with combination therapy of more than one proserotonergic agent, but it has been reported with serotonergic monotherapy and recreational use of indoleamine and phenylethylamine derivatives (e.g., “Ecstasy”). Although serotonin syndrome is usually an adverse drug interaction that follows the combination of therapeutic doses of proserotonergic agents, it will also occur following proserotonergic drug overdose.

Pathophysiology of Serotonin Syndrome

Serotonin syndrome is caused by increased CNS 5-HT receptor activation. Usually, increased 5-HT receptor activation is due to significantly elevated CNS levels of 5-HT, which occurs as a result of proserotonergic agent activity. It is helpful to think of serotonin syndrome not as an on/off phenomenon, but as a continuous spectrum of toxicity caused by increased CNS 5-HT levels. This is

similar to the spectrum of illness severity that exists for NMS. Unlike NMS, however, serotonin syndrome is not an idiosyncratic reaction but a dose-effect phenomenon caused by the combination of proserotonergic agents. Some investigators have advocated calling it serotonin toxicity, which is a more accurate description of the phenomenon. In many well-documented cases of serotonin syndrome, however, serum drug levels are often in the therapeutic range. Serum levels of proserotonergic drugs, however, may not correlate with end-organ concentrations or, more importantly, elevated CNS serotonergic activity.

There are several different groups of 5-HT receptors found in the CNS. Most of the symptoms seen in serotonin syndrome are believed to be caused by stimulation of the postsynaptic 5-HT_{2A} receptor.^{29,32} This receptor is a G protein linked to phosphoinositide-specific phospholipase C as well as a K⁺ channel (causes depolarization).³³ Although stimulation of the 5-HT_{1A} receptor generates stereotypical behavior in mice once thought to be analogous to serotonin syndrome in humans, it is not believed to contribute significantly to the pathologic consequences of serotonin toxicity, and specific antagonists do not provide protection against serotonin syndrome lethality in a rat model.^{30,31}

The stimulation of 5-HT_{2A} receptors may occur in several different ways: increased 5-HT synthesis (e.g., L-tryptophan); increased 5-HT release (e.g., amphetamines); decreased 5-HT catabolism (e.g., MAOIs); decreased 5-HT reuptake (e.g., SSRIs); direct 5-HT receptor stimulation (e.g., 5-methoxy-*N,N*-dimethyltryptamine [DMT]); and increased postsynaptic 5-HT response by secondary messenger systems (e.g., lithium). Serotonin syndrome may also be precipitated following the withdrawal of an agent with 5-HT_{2A} antagonist effects in a patient with 5-HT receptor up-regulation/hypersensitivity or in a patient on an SSRI.³⁴

The propensity of an agent to cause serotonin syndrome is often directly correlated with its ability to increase brain serotonin levels or to directly stimulate 5-HT_{2A} receptors. Usually a combination of pharmaceutical agents is required to elicit serotonin syndrome, but it has been reported following overdose of single agents.^{35,36} For instance, serotonin syndrome was noted to occur in 14% to 16% of patients who overdosed on SSRIs in one study. In addition, overdose of MAOIs produces a toxic syndrome that significantly overlaps with serotonin syndrome. It is much more common for serotonin syndrome to occur when two agents are combined that raise brain serotonergic tone by two different mechanisms. For example, many of the severe or fatal serotonin syndrome episodes have been due to an MAOI interaction with a selective serotonin uptake inhibitor.

Serotonin reuptake inhibition appears to be a very commonly encountered cause of serotonin syndrome. The SSRIs paroxetine, clomipramine (a tricyclic antidepressant [TCA]), sertraline, fluoxetine, and venlafaxine (a serotonin norepinephrine reuptake inhibitor [SNRI]) have all been implicated as causes of serotonin syndrome. Besides clomipramine, the other TCAs (e.g., imipramine, dothiepin, and amitriptyline) have a much

lower affinity for the 5-HT reuptake transporter.^{37,38} These TCAs have rarely caused serotonin syndrome but do not usually cause significant morbidity unless combined with an MAOI. It has been hypothesized that chlorpheniramine and, possibly, brompheniramine can contribute to serotonin syndrome due to SSRI properties of these drugs.^{37,39} Duloxetine, a novel SSRI, is also likely capable of causing serotonin syndrome.

Certain synthetic opiates have SSRI activity and have been implicated as agents capable of precipitating serotonin syndrome when combined with other proserotonergic agents. These opiates include tramadol, meperidine, dextromethorphan, methadone, and pentazocine.⁴⁰ Tramadol may have serotonin-releasing properties in addition to being an SSRI.⁴¹

Traditional, irreversible, nonselective MAOIs (e.g., tranylcypromine, phenelzine, and clorgyline) and the newer, reversible, nonselective MAOIs (e.g., moclobemide) are readily capable of precipitating serotonin syndrome when combined with other proserotonergic agents (see Chapter 29).^{40,42} Selegiline, a selective, irreversible MAOI-B inhibitor, may cause serotonin syndrome at higher doses since MAO selectivity is lost at supratherapeutic doses.^{43,44} Linezolid, a newer antibiotic that has reversible MAO activity, has the potential to cause a serotonin syndrome.

Several drugs of abuse (e.g., hallucinogenic amphetamines, alkyltryptamines, and lysergamides) can potentiate 5-HT CNS activity and result in serotonin syndrome-like toxicity, either alone or in combination with other agents. The direct serotonin receptor agonists (e.g., lysergic acid diethylamide (LSD), 2,5 dimethoxy-4 methylamphetamine (DOM), DMT, and serotonin-releasing agents (e.g., cocaine and 3,4-methylenedioxymethamphetamine [MDMA]) may produce serotonin syndrome-like toxicity.⁴⁵⁻⁴⁷ L-tryptophan is converted to serotonin in the CNS and has caused serotonin syndrome when combined with an MAOI or SSRI.

Several substances have been implicated in causing serotonin syndrome whose contributing mechanism is not well understood. Lithium is believed to contribute to serotonin syndrome because it causes an inhibition of phosphatases, thus resulting in increased intracellular inositol phosphates and potentiating the secondary messenger effects of serotonin.^{33,48} Trazadone and nefazodone have been implicated in several cases of serotonin syndrome, even though they appear to have 5-HT_{2A} antagonistic properties and are not particularly potent 5-HT uptake inhibitors.^{37,40,49} Buspirone is a direct 5-HT_{1A} agonist and has been implicated in causing serotonin syndrome, although its effect appears weak.^{46,50} Sumatriptan (a 5-HT_{1D} agonist) has been implicated as a cause of serotonin syndrome through uncertain mechanisms.^{39,51} It appears that 5-HT₃ antagonists (e.g., ondansetron and similar antiemetics) are unlikely to cause serotonin syndrome, although this is controversial.⁵² Bromocriptine and L-dopa increase brain serotonin levels and can theoretically facilitate the development of serotonin syndrome.⁵³

It is important to understand the pharmacokinetic and pharmacodynamic characteristics of certain pro-

serotonergic agents. For example, fluoxetine and its active metabolite, norfluoxetine, have long elimination half-lives.⁴⁰ This means that there will be significant serotonin uptake inhibition long after the agent is stopped. Thus, a “washout” period of 4 weeks is recommended after drug discontinuation. Another example is the use of irreversible MAOIs. Patients will require 4 to 5 weeks for the effect of these enzyme inhibitors to completely resolve. Significant P-450 interactions (and the effect of genetic polymorphisms) are observed with several of the psychiatric medications and can result in potentiation and prolongation of their effect. For example, paroxetine has significant CYP2D6 inhibition, which can increase serum levels of other medications metabolized by CYP2D6.

Clinical Manifestation of Serotonin Syndrome

There is a great range in the severity of the clinical signs and symptoms of serotonin toxicity. It can manifest as unpleasant side effects reported with routine SSRI use to a hyperthermic, life-threatening syndrome. Typical signs and symptoms include CNS changes (i.e., agitation, confusion, anxiety, headache, mydriasis, hallucinations, insomnia, and dizziness), autonomic hyperactivity (i.e., hypertension, hyperthermia, tachycardia, tachypnea, flushing, diaphoresis, and shivering) gastrointestinal effects (i.e., nausea, vomiting, abdominal pain, and diarrhea), and neuromuscular abnormalities (i.e., clonus, myoclonus, tremor, sweating, trismus, hyperreflexia, ocular clonus, and muscular rigidity).⁵⁴⁻⁵⁶ Although not pathognomonic, hyperreflexia, clonus (myoclonus and ocular clonus), and/or symmetric rigidity (more prominent in the lower extremities) are characteristic findings associated with serotonin syndrome.

Diagnosis of Serotonin Syndrome

As with NMS, the diagnosis of serotonin syndrome is clinical and based on suggestive history and physical findings. There are no laboratory tests that confirm the diagnosis. Diagnosis is best made by excluding other etiologies (see later section on Differential Diagnosis) and application of preestablished criteria. The use of strict diagnostic criteria is not recommended because it will not allow the inclusion of atypical cases of serotonin syndrome. Absolute frequency of symptoms is impossible to determine due to the limited nature of case reports. Of note, serotonin syndrome is not a manifestation of EPS and should not be associated with dyskinesia or cogwheeling.

One of the marked differences between serotonin syndrome and NMS is the time course of symptom onset and duration of illness. With serotonin syndrome, symptom onset often occurs rapidly or within minutes to hours after introduction of or an increase in dose of the proserotonergic agent. In contrast, with NMS, symptom onset occurs gradually and insidiously over days following the introduction of an antidopaminergic agent. One of the diagnostic criteria for serotonin syndrome is that

symptoms should begin soon after starting a serotonergic agent, and in almost all situations they have started within 24 hours of the addition of the medication. The majority of episodes are mild, and relatively short-lived. Most patients recover from serotonin syndrome within 24 hours, but patients with a severe syndrome may have signs and symptoms for 2 to 3 days.

Laboratory analysis is not useful for making a specific diagnosis; it appears to be better suited for eliminating alternative diagnoses. Nonspecific findings include elevated WBC count, increased CPK, and mild metabolic acidosis. In general, the CPK elevation is not usually as severe as what is observed with NMS or MH, but significant elevation is occasionally seen with critically ill individuals. Laboratory analysis may help identify drugs of abuse as well as assisting in the identification and treatment of complications associated with serotonin syndrome (e.g., hypoxia, pneumonia, rhabdomyolysis, renal failure, hepatic transaminitis, and DIC). Life-threatening complications of serotonin syndrome commonly occur in patients with severe and prolonged neuromuscular hyperactivity and resultant hyperthermia.

MALIGNANT HYPERTHERMIA

Introduction, History, and Epidemiology

Malignant hyperthermia (MH) was first described in 1962.⁵⁷ It is an idiosyncratic drug reaction triggered by inhaled anesthetics and/or by the depolarizing paralytic succinylcholine. It is a disease that primarily occurs in the operating room, with an incidence of about 1 in 12,000 to 1 in 40,000 general anesthetic cases.⁵⁸ It is believed that the number of susceptible patients is likely higher since 50% of patients in whom the syndrome develops have had prior anesthesia without manifesting MH.^{59,60} It is thought that those of African descent have a much lower rate of the genetic defect than whites.⁶¹ There are several different proteins linked to the disease and several different genetic differences within each gene. For example, there have been more than 20 different abnormal ryanodine receptor genes (RYR1) identified alone.

MH is different from the other two “neuromuscular” syndromes in that the pathology is maintained without further stimulation at the neuromuscular junction. It is a disease of abnormal cytosolic calcium physiology that occurs in skeletal muscle cells and results in a cascade of pathophysiologic changes that culminate in a hypermetabolic state. When it was first recognized and reported, MH was associated with significant mortality (approximately 80%). Fortunately, the mortality rate has fallen to about 5% with aggressive, early treatment with dantrolene. There is a swine model (porcine stress syndrome [PSS]) that has allowed significant research in the field. The PSS model, however, is limited; unlike humans, the genetic defect in the swine model is limited to one specific change in the ryanodine receptor.

A syndrome of excessive susceptibility to stress resulting in morbidity clinically similar to MH has been

reported, without any of the usual MH triggers.⁶² In this MH-like syndrome, individuals experience elevations in temperature, labile blood pressure, acrocyanosis, muscle cramping, fasciculations and elevated CPK with certain environmental “stressors.” These “stressors” have included long car rides, bad news, increased external temperatures, medical illness and excessive activity. There may be a family history of mysterious sudden death, or of muscle cramps and easy fatigability with exercise. This has been termed the human stress syndrome, and individuals may be at higher risk for exertional heat stroke. This syndrome is believed to share a similar pathology with MH, but without the antecedent exposure to anesthetic/paralytic agents.^{62,63} MH gene abnormalities have been found in some patients with this stress-induced syndrome and exercise-induced rhabdomyolysis.⁶⁴⁻⁶⁶

Pathophysiology of Malignant Hyperthermia

Under normal physiologic conditions, elevated intracellular calcium levels trigger contraction. The ryanodine receptor of the sarcoplasmic reticulum is associated with the dihydropyridine receptor (DHPR, L-type calcium channel) of the cellular membrane, and a structural change of the DHPR (which occurs during depolarization) is believed to open the ryanodine receptor. This elevated intracellular calcium stimulates more calcium release from the sarcoplasmic reticulum (calcium-induced calcium release). An increase in inositol-1,4,5-triphosphate is also responsible for mobilizing stored calcium through its own sarcoplasmic reticulum receptor (InsP₃).

MH is caused by a cascade of biochemical changes in skeletal muscle, culminating in markedly increased metabolic rates within muscle cells. Sustained muscle contraction and rigidity typically occur. Acute toxicity is marked by elevated intracellular calcium levels. Many MH patients (and the heat-intolerant swine) have a defect in this ryanodine receptor that is believed to trigger excessive calcium release from the sarcoplasmic reticulum. The specific defect may be attributed to increased rates of calcium-induced calcium release. Some (but not all) studies have hypothesized that there are higher basilar intracellular calcium concentrations within MH-prone muscle cells.^{67,68} This increased intracellular calcium concentration would cause increased metabolic rate and increased activity of the sarcoplasmic Ca²⁺/ATPase. The increased metabolic rate can occur without having contracture.⁵⁸ Higher levels of cyclic adenosine monophosphate (cAMP) are found in MH patients during exercise when compared with control patients, providing additional evidence for an alteration in the secondary messenger system.⁶⁹ The cell membrane sodium channel populations are different between MH patients and controls, possibly as a result of chronically elevated intracellular Ca²⁺ levels.⁷⁰

The initial trigger that leads to elevated intracellular calcium concentrations is not well understood. For the inhaled anesthetics, it has been hypothesized that these

agents interact with the ryanodine channel and lower the threshold for release of calcium from the sarcoplasmic reticulum.⁵⁸ For succinylcholine, cellular depolarization from motor end-plate stimulation leads to elevated intracellular calcium concentrations. Phosphodiesterase inhibitors have rarely been reported to cause MH; elevated intracellular calcium concentrations may occur from these agents' effects on cAMP levels and the secondary messenger system.

Several genetic mutations have been found to be associated with MH, but only about half of malignant hyperthermia-sensitive (MHS) families have documented RYR1 mutations.⁷¹ Another gene that has been recently implicated is the dihydropyridine receptor gene; other gene abnormalities have been suggested.⁷² Cases of MH have been associated with various myopathic, metabolic, and mitochondrial genetic disorders.⁷³ Of interest, persistent CPK elevations are frequently found in asymptomatic MH individuals.⁷²

The administration of 5-HT agonists to skeletal muscle from MH patients can trigger contractures.⁷⁴⁻⁷⁷ This suggests a link between MH and serotonin. It is believed, however, that the increase in circulating 5-HT is a secondary response to (like catecholamine increase) and not a primary cause of contractures. The use of 5-HT receptor antagonists has not prevented morbidity from triggered MH in the PSS model.^{78,79} It has been observed that 5-HT₂ antagonists reduce the MH response in human biopsies, possibly by causing hyperpolarization or modifying IP₃ levels.^{33,76,80} Serotonin antagonists (such as cyproheptadine) have not been used in humans for MH.

Although similar to NMS in clinical appearance, MH syndrome has markedly different pathophysiology. Key differences between MH and NMS are the rapid onset of symptoms with MH versus the slower onset with NMS, and the shorter duration of illness in MH. In addition, patients with episodes of NMS have been successfully treated with inhaled anesthetics. Although it has been suggested previously that neuroleptics might be able to trigger MH, subsequent study has shown this not to be true. There is no apparent link between NMS and MH.⁸¹

Clinical Manifestation of Malignant Hyperthermia

MH often begins rapidly after administration of the triggering agent (inhaled anesthetic or succinylcholine). Most of the inhaled anesthetics can trigger MH, including halothane, enflurane, isoflurane, methoxyflurane, desflurane, and sevoflurane.⁸² Synergy between the two classes of agents has been reported. MH has also been reported to be caused by enoximone, a phosphodiesterase inhibitor.⁸³⁻⁸⁵ One should also consider stressors (such as trauma or procedures) as potential triggers for the syndrome. There are "safer" alternative agents that may be used for anesthesia in patients at risk for MH. These agents include propofol, benzodiazepines, nitrous oxide, and narcotics.^{59,86}

The signs and symptoms of MH are reflective of a greatly increased metabolic rate. The earliest, most sensitive, and specific signs of MH are increased rate

of CO₂ production (as either expired CO₂ or partial pressure of CO₂ in arterial blood [Paco₂]). Other early findings include a rapid rise in core temperature (as fast as 1° F every 5 minutes), diffuse muscle rigidity, and acidosis.⁵⁸ Temperature often rapidly increases and may not be initially noticed if the patient began at a subnormal temperature. Tetanic muscle contraction within 20 minutes after the muscle relaxants are administered is often reported. Symptoms of the full syndrome include tachycardia, rigidity, poor chest wall compliance, acidosis, cyanosis, mottling, hypotension, ventricular arrhythmias, increased ventricular rate, and elevated CPK. Hyperkalemia and marked hyperthermia carry a poor prognosis. As for other hyperthermic syndromes, the incidence of secondary complications and mortality is directly correlated with the severity and duration of hyperthermia. Sometimes the initial symptoms are subtle, such as increased masseter muscle tone during intubation; masseter rigidity may make intubation difficult. Generalized rigidity shortly following the administration of inhaled anesthetics or succinylcholine is virtually pathognomonic for MH. Generalized muscle rigidity, however, may not be present. Clinical rigidity may be relatively mild compared with subsequent CPK elevation, lactate, and myoglobinuria. In some patients, particularly those with delayed or atypical cases, the only symptoms might be muscle cramping and urinary color change reflective of ongoing rhabdomyolysis seen postoperatively.^{87,88}

While the majority of cases have rapid onset, there are reports of delayed onset (especially with desflurane). The onset of the signs and symptoms of MH may not occur until the time of paralytic reversal or later in the recovery room.⁸⁹ When succinylcholine is used, it is believed to accelerate the onset of the episode. The use of nondepolarizing paralytics are believed to slow the onset of the MH episode.⁸² Isolated rhabdomyolysis may sometimes occur and is associated with a delayed presentation and diagnosis.⁹⁰ Recurrence of symptoms is not uncommon (see later section on Malignant Hyperthermia Management).

Complications of MH include electrolyte abnormalities (i.e., hyperkalemia, hypercalcemia, hypocalcemia), ventricular fibrillation, DIC, rhabdomyolysis, hypoxia, hyperthermia, pulmonary edema, cerebral edema, and encephalopathy. These complications are ultimately responsible for the mortality and morbidity of MH. Autopsy findings (other than muscle biopsies) are nonspecific. Weakness and fatigue may last for months following an episode.⁶²

DIAGNOSIS OF HYPERTHERMIC SYNDROMES

The initial diagnosis for all three syndromes is made clinically and based on a suggestive history and physical findings. Although confirmatory laboratory tests do not exist for NMS and serotonin syndrome, the diagnosis of MH can be confirmed by the *in vitro* halothane or caffeine contracture test. In general, specific laboratory

and other ancillary tests are obtained to rule out other illnesses that may be confused with these hyperthermic syndromes. For instance, during the initial patient evaluation, a diligent investigation for all sources of infection should be made, including blood, urine, and cerebrospinal fluid cultures. In addition, recommended laboratory tests include CBC, electrolytes, serum creatine phosphokinase (CPK), and urinalysis. An EEG may be obtained to exclude seizure activity.

The gold standard for diagnosis of MH is a muscle biopsy specimen that is then exposed to halothane and caffeine; the basis for this test is that contractions are seen at much lower concentrations of the triggering agents than in normal muscle tissue. There are two significantly different protocols in use for testing the muscle tissue: the North American Malignant Hyperthermia Group Protocol and the European Malignant Hyperthermia Group Protocol. Either of these protocols may be utilized but they have differing reported sensitivities and specificities.^{91,92} Both protocols have a sensitivity close to 100%, whereas the specificity for the European protocol is 82% to 93% but only 78% for the North American protocol.⁹² These protocols will categorize patients into one of three different groups: malignant hyperthermia negative, malignant hyperthermia sensitive (MHS), and malignant hyperthermia equivocal (MHE). Positive *in vitro* muscle contraction to both halothane and caffeine results in an MHS designation, whereas a positive contraction to only one agent results in an MHE designation. For maximum clinical safety, MHE is treated as MHS. The concentration of halothane and caffeine used as well as the strength of contraction should be reported.

There are some significant limitations of the halothane-caffeine contracture test. Caffeine is believed to increase calcium release from the sarcoplasmic reticulum.⁵⁸ The test requires an open biopsy; this combined with its poor specificity makes it ineffective as a screening test. There is a significant difference in outcome between the two protocols,⁹¹ and significant intralaboratory variability as well as variability within the same biopsy.⁹³ False-positive results have been reported in patients with myopathies, but these patients may be at higher risk for developing MH. Abnormal *in vitro* muscle contraction similar to MH has also been observed in some patients that have suffered exertional heat stroke, suggesting a common pathology. The muscle biopsy has no utility in diagnosis of NMS. Although there are reports of abnormal contractions of muscle fibers to fluphenazine, this was performed at very high concentrations and has not been replicated.⁹⁴ In addition, patients who have suffered from NMS have undergone general anesthesia without any problems, and no familial link has been found between the two diseases.

DIFFERENTIAL DIAGNOSIS

Although these three neuromuscular syndromes are all characterized by alterations in mental status, autonomic dysfunction, and neuromuscular hyperactivity, they are

often readily distinguishable by history, temporal profile, and the presence of unique physical findings. The clinical signs and symptoms that can be used to differentiate these syndromes are listed in Table 10A-1. The presence of clonus (myoclonus and ocular clonus), hyperreflexia, and tremors are unique to serotonin syndrome and not present with the other two neuromuscular syndromes. Rigidity is lead pipe type and diffuse with NMS, rigor mortis–like and diffuse with MH, and clasp-knife type and more prominent in the lower extremities with serotonin syndrome.

These three hyperthermic syndromes must be differentiated from other conditions associated with fever and neuromuscular hyperactivity. These include the anticholinergic and sedative-hypnotic withdrawal syndromes; poisoning by hallucinogens, salicylates, and other uncouplers (e.g., dinitrophenol), lithium, MAOIs, strychnine, nicotine, and sympathomimetics; and nontoxic etiologies, such as intracranial hemorrhage, brain tumors, CNS infections (e.g., meningoen- cephalitis, brain abscess), CNS vasculitis, thyrotoxicosis, Addisonian crisis, heat stroke, pheochromocytoma, hypocalcemia, hypomagnesemia, tetanus, and lethal catatonia.

EPS can occasionally look like early NMS, and some clinicians have proposed a spectrum of basal ganglia dopamine dysfunction, with NMS being the extreme manifestation along a continuum. The presence of EPS that are persistent and resistant to or exacerbated by anticholinergic treatment may suggest early NMS.

MANAGEMENT OF HYPERTHERMIC SYNDROMES

Management of NMS, serotonin syndrome, and MH involves immediate termination of any precipitating drugs, the provision of aggressive supportive care, and the administration of adjunctive pharmacotherapies for each syndrome. Aggressive supportive care entails the control of patient agitation and neuromuscular hyperactivity, intravenous rehydration, treatment of hyperthermia, and treatment of associated complications. Gastrointestinal decontamination is not useful for NMS, MH, or serotonin syndrome due to the delay of onset of symptoms and the route of administration of the precipitating agents. The decrease in mortality observed for NMS and serotonin syndrome is most likely due to early recognition and better critical care medicine, not due to specific antidotes. In contrast, the timeliness of initiation of the antidote, dantrolene, is critical to effect a good survival for those with MH.

Complications of these syndromes are similar and can include rhabdomyolysis, renal failure, aspiration pneumonitis, respiratory failure, thromboembolism, deep venous thrombosis, infection, electrolyte imbalance, DIC, hepatic dysfunction, and cardiovascular collapse. Supportive care should be aggressive and directed at preventing or treating these complications. Special attention should be directed to ventilator status (especially if there is chest wall rigidity preventing ventilation),

hydration, temperature, electrolytes, and possible seizures. Aggressive fluid hydration is usually warranted; if comorbidities are present, then central monitoring for fluid status may be required. Hydration and possible alkalinization of the urine will help treat the rhabdomyolysis and myoglobinuria that often results. Vasopressor support should be given as needed for hypotension, assuming that fluid resuscitation is complete.

Many of the complications of these syndromes occur largely as a result of neuromuscular hyperactivity and secondary hyperthermia. Attention should be directed to careful temperature monitoring and should always rely on core temperature readings because peripheral measurements can be erroneous. Cooling measures may initially include intravenous (IV) benzodiazepines (diazepam 0.1 to 0.3 mg/kg or lorazepam 0.05 to 0.1 mg/kg), antipyretics, evaporative cooling, ice packs, cooled IV fluids, and adjunctive pharmacotherapies specific to each syndrome. For those patients with NMS and serotonin syndrome who develop severe or protracted hyperthermia (i.e., temperature greater than 40° C), the use of nondepolarizing paralytics (e.g., pancuronium) is strongly recommended.⁹⁵ Neuromuscular blockade will achieve rapid, predictable, and effective reduction of rigidity and fever. In contrast, for patients with MH, treatment with dantrolene is the key to minimizing mortality from severe hyperthermia. Neuromuscular blockade will not achieve muscle relaxation with MH.

Neuroleptic Malignant Syndrome Management

There are many opinions as to the “correct” treatment for NMS. Most of what we know about treatment for this syndrome is from collections of case reports, case series, or retrospective, noncontrolled studies. There have been no prospective, controlled treatment studies. Immediate discontinuation of the offending agent is central to successful treatment. One should also ensure that other non-neuroleptic dopamine-blocking agents (e.g., metoclopramide) and other syndrome-potentiating medications (e.g., lithium, anticholinergic agents) are stopped as well. Supportive care is often overlooked in a rush to use the most “up to date” treatment. Because the natural course of the illness is often characterized by waxing and waning symptoms, initial improvement may be mistakenly interpreted as a positive response to a specific treatment.

Benzodiazepines and barbiturates have been used successfully in individual cases and retrospective, uncontrolled studies. In one retrospective study of 16 patients with NMS, clinical improvement was noted within 24 to 72 hours of benzodiazepine treatment initiation (e.g., lorazepam).⁹⁶ Regardless, it is uncertain if benzodiazepines hasten the recovery from NMS over supportive care alone. Benzodiazepine therapy has the advantage of being generally safe with minimal side effects. The alternative sedating agents, barbiturates, may lower the blood pressure when administered rapidly, which limit their utility with the unstable patient.

Theoretically there should be some CNS benefit for either drug due to increased γ -aminobutyric acid (GABA) tone limiting central neurologic excitation and possible injury. Standard initial IV doses of benzodiazepines (diazepam 0.1 to 0.3 mg/kg or lorazepam 0.05 to 0.1 mg/kg) should be employed. Additional doses may be administered as needed to achieve the desired level of sedation and sympatholysis. Another GABA agonist, propofol (2,6 diisopropylphenol), might be effective for the short-term treatment of those patients with severe agitation and muscular rigidity. In this setting, propofol should only be administered to patients that are intubated. Propofol is complicated by potential hypotension due to its negative inotropic effects.

Due to the similarity of NMS to MH, dantrolene has been utilized for the treatment of fever and muscle rigidity associated with NMS. Dantrolene is a direct skeletal muscle relaxant; it prevents calcium release from skeletal muscle sarcoplasmic reticulum by acting on the ryanodine receptor. It has very little effect on smooth and cardiac muscle. It is very effective for MH, but its efficacy in NMS has not been firmly established. Anecdotal experience suggests occasional efficacy, but case control studies have had mixed results. Dantrolene will not terminate muscular rigidity and hyperthermia as rapidly as nondepolarizing paralytic therapy. Doses utilized have ranged from 25 mg to more than 300 mg per day. It is available in an oral and IV form; a starting IV dose of 1 to 2.5 mg/kg every 6 to 12 hours is recommended, titrating the dose upward as needed. A maximum dose of 10 mg/kg/day is recommended. Side effects of dantrolene include dizziness, headache, fatigue, drowsiness, and weakness (rarely clinically significant).⁹⁷ Idiosyncratic reactions from chronic use that have been reported include hepatic dysfunction and a pleuropericardial reaction. Dantrolene has not been shown (and would not be expected) to correct a central disorder of thermoregulation.⁹⁸ It should probably be reserved for NMS patients with rigidity who have failed other treatments.

Bromocriptine has been used at a dose of 2.5 to 15 mg given three times a day. Bromocriptine is a partial dopamine agonist/antagonist. In rat studies, it can reverse the catatonia induced by neuroleptics. Data on its efficacy are mixed; studies have been done showing both benefit and lack thereof (see Chapter 38). Some retrospective studies have demonstrated a significant reduction in mortality from NMS in those patients treated with bromocriptine as compared with supportive care alone.^{99,100} In addition, some patients who were treated with bromocriptine for NMS experienced recurrence of NMS symptoms when this therapy was suddenly discontinued. It has some mild side effects, namely nausea, vomiting, limited vasospasm, dyskinesias, hallucinations, and worsening psychosis. Bromocriptine does have a mild stimulatory effect on 5-HT receptors and does reduce brain serotonin turnover.¹⁰¹ Its indiscriminate use should be tempered with the knowledge that it might theoretically worsen serotonin syndrome.⁵³ It should be strongly considered for treatment of unequivocal cases of NMS.

Amantadine is a parkinsonian drug reported to be successfully used for NMS in only a few cases, making firm conclusions about its efficacy impossible.¹⁰² It has minimal dopamine agonistic properties and its benefit may actually arise from its *N*-methyl-D-aspartate, glutamate receptor antagonist properties.¹⁰³ It has been used in divided doses from 200 to 400 mg a day. L-dopa/carbidopa has been tried with mixed success. There is evidence that L-dopa can cause serotonin release, which could worsen serotonin syndrome. In general, other dopaminergic agents should be considered before amantadine or L-dopa are initiated.

For treatment of EPS from neuroleptic use, anticholinergic agents are often employed. The theory is that decreasing cholinergic tone increases dopamine tone, thus alleviating the symptoms of dopamine receptor antagonism. However, in general, anticholinergic agents have not been shown to be of benefit for NMS. They are likely to be detrimental when the dose is increased due to their effect on heat dissipation and CNS effects. They should be stopped or possibly tapered if the patient has been on them for a prolonged period.

Electroconvulsive therapy (ECT) has been reported as effective for the treatment of NMS, although controlled studies are lacking.¹⁰⁴ Some of the early cases had morbidity associated with the procedure, but with closer monitoring these events have not recurred. ECT increases brain catecholamine (i.e., dopamine) levels, which is believed to be the reason for its successful use. The successful use of ECT for NMS utilizing general anesthesia is additional evidence that MH and NMS are different syndromes. One should consider the use of ECT for patients with protracted signs and symptoms of NMS or those with catatonia after the illness has resolved.²⁴

The best treatment for NMS is probably early recognition, immediate discontinuation of the precipitating agent, and vigilant supportive care in an intensive care unit setting. Adjunctive pharmacologic agents may be added.

Once the episode of NMS has resolved, there is often a need to restart medication in patients with mental illness. Ideally, one should wait at least 2 weeks prior to restarting neuroleptics. Doses should be given orally, initiated at the lowest possible dose, and titrated up very slowly. Atypical or low-potency antipsychotics should be utilized. Patients should be in a setting where their temperature and clinical status can be closely monitored. Risk factors such as dehydration and agitation should be addressed and treated with IV fluids and sedation with benzodiazepines.

Serotonin Syndrome Management

Because serotonin toxicity exists as a disease spectrum, it is difficult to give unifying or all-inclusive treatment recommendations. As for NMS, good supportive care and immediate discontinuation of the offending/trigging agent are the most important aspects of treatment and will achieve a good outcome in the vast majority of patients. Depending on the pharmacokinetics and severity of the reaction, treatment decisions

range from outpatient to intensive care unit admission. The severe serotonin reactions are usually due to MAOI interactions with another proserotonergic agent. These patients should probably be admitted to the intensive care unit due to the potential severity of the syndrome.

Serotonin syndrome is due to excessive stimulation at certain CNS 5-HT receptors (most likely 5-HT_{2A} and possibly some 5-HT_{1A}). Treatment with 5-HT_{2A} receptor antagonists have been effective in animal models of serotonin syndrome and in case series of patients with serotonin syndrome. Cyproheptadine, an antihistamine with serotonin antagonist effects, has been effective for the treatment of serotonin syndrome.^{35,105} There are no randomized, controlled trials that have demonstrated the efficacy of cyproheptadine or other 5-HT_{2A} receptor antagonists (e.g., chlorpromazine, olanzapine, risperidone, methysergide) for the treatment of serotonin syndrome. Efficacy for these pharmacotherapies is difficult to establish since serotonin syndrome is often self-limited and has a relatively short duration. Cyproheptadine is only available as an oral formulation; the usual dose in adults is 4 to 8 mg every 1 to 4 hours, up to a maximum of 32 mg/day.⁴⁸ For children, the cyproheptadine dose is 1 to 2 mg every 1 to 4 hours, up to a maximum of 12 mg/day. There often is a positive response after a single dose, but larger doses may be necessary for those with serotonin syndrome as a complication of a serotonin agonist overdose. Cyproheptadine has some sedating and anticholinergic side effects, which may become problematic at the higher recommended doses. Methysergide has blockade at 5-HT₁ and 5-HT₂ receptors and has been infrequently used for serotonin syndrome; it has less 5-HT_{2A} affinity than cyproheptadine.⁵³ The recommended methysergide dose is 2 to 6 mg orally; it is not available for parenteral use. For either agent, if charcoal was given, larger doses may be required or this treatment may need to be abandoned due to adsorption of the antidote to charcoal.

Chlorpromazine has been used as treatment for serotonin syndrome with positive results. In addition to its dopamine receptor antagonist effects, chlorpromazine is a potent 5-HT_{2A} receptor antagonist with similar potency to cyproheptadine. It has the advantage of having a parenteral formulation and can be administered either IV or intramuscularly (IM).¹⁰⁶ A starting dose might be 50 mg IM with a repeat dose in 4 hours if necessary; dosing is usually every 6 hours.²⁹ Hypotension is common following larger doses of chlorpromazine. Thus, intravenous fluid administration should accompany or precede this therapy. Chlorpromazine is associated with numerous side effects (sedation, anticholinergic effects, dopaminergic blockade, potential to induce seizures, cardiac conduction effects). Use of this agent, while potentially effective, may also be associated with adverse effects and complicate patient treatment. Chlorpromazine should not be used if there is any concern for NMS.

Other pharmacologic agents have been used for serotonin syndrome with mixed results. Benzodiazepines have been tried with mixed results. These agents are best reserved for patients with significant muscle rigidity

and hyperthermia. Diazepam or lorazepam may be administered in the same doses as recommended for NMS.¹⁰⁷ The central GABA receptors are believed to have an inhibitory influence on serotonin syndrome.⁴⁶ Very limited data exist for propranolol, which has been used to treat some of the hypertensive symptoms. Propranolol is a 5-HT_{1A} antagonist and, thus, is not expected to reverse all the signs and symptoms of the syndrome.^{46,108} Due to its potential for adverse hemodynamic effects, propranolol must be used with considerable caution and cannot be recommended for first-line use. Mirtazapine has been used for the treatment of serotonin syndrome and theoretically may be efficacious via its 5-HT_{2A} antagonistic properties.^{109,110} Nitroglycerin has been used and has resulted in some clinical improvement anecdotally.¹¹¹ There is the theoretical possibility of exacerbating serotonin syndrome if treated with bromocriptine; this drug can increase brain 5-HT levels.^{53,112} Animal experimental data support the use of memantine (and possibly risperidone) for serotonin syndrome, but no human experience exists.^{113,114} Dantrolene has been used for serotonin syndrome without documented benefit. Dantrolene may cause increased CNS 5-HT tone and, thus, its use is not recommended for treatment of serotonin syndrome.¹¹⁵ Intubation and paralysis should be employed as they are for NMS if muscular rigidity or hyperthermia is severe and not initially responsive to alternative measures.

Restarting medications should be done after a sufficient recovery time has been allowed. Exactly how long depends on the half-life of the drug and its metabolites and the duration of ongoing drug effect. With irreversible MAOI therapy, MAO is permanently inhibited and adequate time should be allowed (3 to 5 weeks) for regeneration of the enzyme prior to reinitiation of another proserotonergic agent.^{48,116} When medications are restarted, they should be restarted one at a time at the lowest effective dose and slowly advanced to the target level. Additional medications can subsequently be added as needed. A reevaluation of the need for MAOI treatment and the most potent serotonin reuptake inhibitors should be performed. Agents with less proserotonergic effect should be tried initially and started at low doses.

Malignant Hyperthermia Management

This syndrome has a radically different pathophysiology from NMS and serotonin syndrome. The pathology is within the skeletal muscle itself and is not secondary to enhanced nerve activity and motor end-plate stimulation. No benefit is derived from benzodiazepines and nondepolarizing paralytics. As for the other hyperthermic syndromes, when MH is suspected, the precipitating agents must be discontinued immediately. For MH, aggressive supportive care includes hyperventilation, IV fluid administration, correction of electrolyte abnormalities (e.g., hyperkalemia, hypocalcemia, hypercalcemia), rapid cooling, and treatment of associated complications as they occur (e.g., rhabdomyolysis, renal failure, respiratory failure). Bicarbonate has been

advocated, and that combined with dextrose should be beneficial to treat associated hyperkalemia.

The treatment of choice is dantrolene. There is a direct correlation between survival and early administration of dantrolene in patients with MH.¹¹⁷ Dantrolene is believed to interact with the ryanodine skeletal muscle receptor, preventing further release of calcium from the sarcoplasmic reticulum, halting the pathologic cascade operative in MH. The starting dose of dantrolene is 2.5 mg/kg IV. This dose can be repeated every 2 to 3 minutes until a maximum of 10 mg/kg has been administered. The IV formulation is preferred in all situations of MH due to uncertain levels achieved with oral dosing. Dantrolene is occasionally used as prophylaxis for patients with a previous history of MH or with a very strong family history of anesthetic-associated deaths. In this situation it is given as a 2.5 mg/kg dose prior to anesthesia; but despite this pretreatment, patients can still develop MH, so there should be strong consideration for using "safer" agents in such patients.

Once a patient has developed MH, dantrolene should be continued every 6 hours until symptoms completely resolve, because dantrolene has a half-life of 12 hours.¹¹⁸ When repeated doses are used, patients are much less likely to have a recurrence of symptoms. Sufficient dosing is recommended because subtherapeutic amounts of dantrolene may paradoxically open the ryanodine channel, possibly exacerbating illness.¹¹⁹ The use of calcium channel blockers (e.g., verapamil) with dantrolene has been associated with hyperkalemia and hypotension. The use of calcium channel antagonists for arrhythmias is thus not recommended, even though this synergistic toxicity has not been demonstrated in a dog model.¹²⁰ Short-term side effects of dantrolene have included weakness, dizziness, and fatigue; clinically significant weakness appears to be rare.⁹⁷

INTRODUCTION AND IMPORTANCE

Many potentially toxic substances enter the body via the gastrointestinal tract. As the blood supply from the gastrointestinal tract (through the portal vein) drains into the liver, the liver comes into contact with them, and this exposure often is at a higher concentration than that received by other tissues. The liver is essential for the metabolic disposal of virtually all xenobiotics. This process is achieved mostly without injury to the liver itself or to other organs.

Some compounds, such as carbon tetrachloride, are toxic themselves and/or produce metabolites that cause liver injury in a dose-dependent fashion. Most agents, however, cause liver injury only under special circumstances when toxins accumulate. Factors contributing to the build-up of such toxic substances include genetic enzyme variants (metabolizing enzymes with altered function due to gene defects), which allow greater formation of the harmful metabolite, and induction (greater production) of an enzyme, which produces more than the usual quantity of toxic substance. There also may be accumulation of toxic substances by interference with regular nontoxic metabolic pathways by substrate competition for enzymes (e.g., ethanol and trichloroethylene) or depletion of substrates used to metabolize the toxins or prevent toxic injury (e.g., glutathione). In addition there are a number of other factors that can potentially increase the risk of drug-related hepatotoxicity. Generally, women are more susceptible to drug-induced hepatotoxicity (with the exception of azathioprine hepatotoxicity, which is more common in men).^{1,2} Being older than 60 years of age is associated with a greater risk of drug-induced hepatotoxicity (particularly with nonsteroidal anti-inflammatory drugs [NSAIDs]), whereas children appear to be more susceptible to salicylate and valproate-related hepatotoxicity.^{1,3,4} Nutritional status also can be important—malnutrition probably is associated with liver glutathione depletion and a greater risk of hepatotoxicity in acetaminophen overdose.^{5,6} Conversely, the risk of halothane hepatotoxicity is greater in obese patients.⁷

Hepatocytes near the portal tract branches (zone 1) receive blood that is rich in oxygen and nutrients, but those near the hepatic vein branches (zone 3) receive blood that has lost much of its nutrients and oxygen (Fig. 11-1). Therefore, zone 3 of the liver is sensitive particularly to damage from toxic compounds. Zone 3 cells also have a higher level of some metabolic enzymes and higher lipid synthesis than zone 1, which may also explain why zone 3 tends to be the most damaged and why lipid accumulation is a common response to this damage (see the carbon tetrachloride example later).

Allyl alcohol (2-propen-1-ol), however, causes zone 1 necrosis partly because this is the first area exposed to

the compound in the blood and partly because of the presence of the enzyme alcohol dehydrogenase in zone 1, which produces reactive toxic metabolites (see Fig. 11-1).

Toxic substances can damage cells in target organs in many ways. The eventual pattern of response may be reversible injury or an irreversible change leading to the death (necrosis) of the cell or perhaps to carcinogenesis (cancer). Molecular mechanisms of liver injury are shown in Box 11-1.⁸

Toxin-induced liver injury is a major challenge, because it is difficult to differentiate from hepatic disease due to other causes, including hepatic drug reactions, which may mimic almost any kind of liver disease.^{9,10} Failure to recognize hepatic injury that is caused by a toxin may lead to worsening of hepatic injury or even hepatic failure.

EPIDEMIOLOGY OF DRUG-RELATED HEPATOTOXICITY

The epidemiology of drug hepatotoxicity is relatively poorly documented.¹¹ There are a number of reasons for this, including the difficulty encountered in making a definitive diagnosis of drug hepatotoxicity.¹² Many cases are subclinical and are never detected or detected only by chance as part of a routine biochemical workup, and many cases are not correctly identified as drug related. Clinical studies during the premarketing phase of drug

FIGURE 11-1 Hepatic zones. ACM, anticentromere; C.V., central vein; CZ, centrilobular zone (zone 3); MZ, midlobular zone (zone 2); PZ, periportal zone (zone 1).

BOX 11-1 MOLECULAR MECHANISMS OF LIVER INJURY

Covalent binding: Free radicals have an unpaired electron centered on a carbon, nitrogen, sulfur, or oxygen atom and hence are extremely reactive, electrophilic species, which can react with a variety of cellular components. Free radicals and other reactive intermediates may be produced by metabolism, which interact with proteins and other macromolecules binding covalently to them. There is a correlation between the amount of binding and tissue damage, though this may reflect production of other damaging species. Binding to critical sites on proteins alters their function by, for example, inhibiting an enzyme or damaging a membrane, but binding could be to noncritical sites, and therefore be of no toxicologic importance.

Lipid peroxidation: Lipid peroxidation is caused by the attack of a free radical on unsaturated lipids (particularly polyunsaturated fatty acids found in cell membranes), the reaction being terminated by the production of lipid alcohols, aldehydes, or malondialdehyde. Therefore, there is a cascade of peroxidative reactions, which leads to the destruction of lipid unless stopped by a protective mechanism or a chemical reaction such as disproportionation, which gives rise to a nonradical product. The structural integrity of membrane lipids is adversely affected, leading to alterations in fluidity or permeability of membranes, destabilization of lysosomes, and altered function of the endoplasmic reticulum and mitochondria. Such mechanisms are thought to be involved in liver damage caused by carbon tetrachloride and white phosphorus.

Thiol group changes: Glutathione is responsible for cellular protection and if depleted, a cell is made more vulnerable to toxic substances. Reactive intermediates of toxic substances can react with glutathione either by a direct chemical reaction or by a glutathione transferase-mediated reaction. If excessive, these reactions can deplete cellular glutathione and leave essential proteins vulnerable to attack by oxidation, cross-linking, formation of disulfides, or covalent adducts.

Enzyme inhibition: Sometimes inhibition of an enzyme may lead to cell death; for example, cyanide inhibits cytochrome aa_3 , leading to blockage of cellular respiration. This results in depletion of intracellular adenosine triphosphate (ATP)—ATP is produced by mitochondria and is the main energy source within the cell—and other vital endogenous molecules.

Ischemia: Reduction of oxygen or nutrients supplied to cells results in cell damage and eventual cell death if prolonged. Ischemia may be a secondary event due to swelling of cells with reduction of

blood flow. As a result changes in subcellular skeleton and organelles may occur. This may result in ATP depletion, changes in Ca^{2+} concentration, damage to intracellular organelles, and DNA damage, and stimulation of apoptosis (programmed cell death) may occur. For example, phalloidin (a toxin from toxic mushrooms) causes centrilobular necrosis (see discussion on toxic mushrooms).

Depletion of ATP: Depletion of ATP may be caused by many toxic substances, usually by the uncoupling of mitochondrial oxidative phosphorylation or by DNA damage that causes activation of poly(ADP-ribose) polymerase. Depletion of ATP in the cell means that active transport in and out of the cell is altered or stopped and changes in electrolytes, particularly Ca^{2+} , lead to changes in biosynthesis within the cell, such as protein synthesis, production of glucose, and lipid synthesis. A very important mechanism of cellular damage is alteration of the intracellular Ca^{2+} concentration. Changes in the intracellular distribution of this ion have been implicated in the cytotoxicity of many toxic substances including carbon tetrachloride. Interference with Ca^{2+} homeostasis may occur as a result of inhibition of Ca^{2+} ATPs, direct damage to the plasma cell membrane allowing leakage of Ca^{2+} , or depletion of intracellular ATP.

Damage to intracellular organelles: Damage to intracellular organelles can result from the above mechanisms of injury; for example, carbon tetrachloride damages both smooth and rough endoplasmic reticulum, leading to disruption of protein synthesis of the whole cell. Mitochondrial damage may occur, for example, after exposure to hydrazine, leading to functional changes and rupture of mitochondria. The mitochondria are crucial to the cell, and inhibition of their electron transport chain leads to rapid cell death.

DNA damage: DNA damage may result from compounds such as alkylating agents; for example, dimethyl sulphate can cause single-strand breaks in DNA, resulting in the activation of poly(ADP-ribose) polymerase, which catalyses post-translational protein modification and is involved in polymerization reactions and DNA repair. Severe DNA damage may result from its activation and be sufficient to lead to cell death or carcinogenesis.

Apoptosis: Apoptosis is programmed cell death. Some foreign compounds may stimulate such cell death by the influx of calcium into a cell. In other cases, cell death may be mediated by cytokines (e.g., interleukin-6), chemicals produced by activated white blood cells capable of mediating tissue injury.

Data from Timbrell JA: Principles of Biochemical Toxicology. London, Taylor & Francis, 1992.

development are likely to identify only agents that commonly cause hepatotoxicity and most information comes from case reports or spontaneous reporting of hepatotoxicity to drug safety authorities such as the U.S. Food and Drug Administration (FDA).¹¹ There have been a number of studies that have attempted to identify the frequency of drug-related hepatotoxicity, but they have not used uniform criteria to define hepatotoxicity and many have not used samples that are representative of the general population. For these reasons it is likely that the true frequency of drug-related hepatotoxicity is greater than the frequency reported in the following studies. It has been estimated that drugs account for 3% to 5% of cases of jaundice admitted to hospitals and 10% of cases of acute liver failure.¹³⁻¹⁶

In a French study, all cases of symptomatic drug-related hepatotoxicity were collected for an area with a population of 81,301 inhabitants.¹ Over the 3 years studied, 34 cases were identified, 82% occurring in outpatients, with the diagnosis being made in primary care in approximately half of the cases. Two deaths were attributed to drug-related acute liver failure, whereas the other 32 patients recovered fully. The most common drugs implicated were antibiotics, psychotropics, hypolipemic agents, and NSAIDs. The crude annual incidence rate was 13.9 ± 2.4 per 100,000 and standardized annual incidence rate 8.1 ± 1.5 , with a female-to-male ratio of 0.86 until 49 years of age and 2.62 at older than 50 years of age.¹ When these figures were compared with spontaneous reporting figures it was estimated that

16 times more cases were identified.¹ In a retrospective cohort study in the United Kingdom, using a primary care database, the incidence rate of drug-related hepatotoxicity varied from greater than 100 per 100,000 users of isoniazid to less than 10 per 100,000 for users of omeprazole, ranitidine, NSAIDs, and amoxicillin; amoxicillin-clavulanic acid and cimetidine were associated with an intermediate risk of between 10 and 100 per 100,000.¹⁷ A further two epidemiologic studies in France suggested that the overall incidence of drug-related hepatotoxicity has not changed significantly in the last 10 years; however, for the reasons discussed previously, these data may not be reliable.^{18,19}

There is relatively little published information on the long-term outcome of drug-induced liver disease.¹² A recent study looked at the natural history of patients with drug-induced liver disease proven through liver biopsy.²⁰ The most common agents involved were antibiotics, NSAIDs, phenytoin, and halothane. At a median follow-up of 5 years (range, 1 to 19 years) 39% of patients had persistent significant abnormalities in liver blood tests and/or scans.²⁰ Factors predicting persistence or development of chronic liver disease were fibrosis at the time of the initial biopsy and continued exposure to the drug.²⁰

DIAGNOSIS OF TOXIN- OR DRUG-INDUCED LIVER INJURY

Determining the Etiological Agent(s)

When assessing a patient with virtually any kind of liver disease, the best policy is to systematically evaluate the possibility of drug- or toxin-induced liver disease. The first step is to establish clearly and meticulously any drugs the patient has been taking, including over-the-counter and herbal or traditional medicine preparations. The patient may not disclose use of certain compounds for fear of admitting to their use or misuse (e.g., Ecstasy [3,4-methylenedioxy-methamphetamine, MDMA], cocaine, hypnotics, antidepressants, anabolic agents, or neuroleptic drugs). It is estimated that greater than 1000 drugs have the potential for hepatotoxicity,²¹ and space limitations here preclude their complete tabulation. Any list of hepatotoxic drugs represents only a soon outdated snapshot, because new drugs are released into the market constantly and the nature of the premarketing studies is that they are small and hence potential for hepatotoxicity is seldom recognized until the postmarketing stage when a larger population is exposed to the drug. The reader is referred to Stricker's book for an exhaustive list.²¹ However, a list of common drugs and toxins in overdose-causing hepatotoxicity is provided below and discussed in more detail later in this chapter.

In addition, poisoning may result from ingestion of natural toxins or synthetic chemicals in food or drink.^{9,22} These also are detailed later in this chapter.

Occupational exposure to hepatotoxic agents also occurs as agents with hepatotoxic potential have been used in various industries (Table 11-1). The number of occupations that give exposure to hepatotoxic agents is

large and includes the manufacture of munitions, rubber, rocket fuels, cosmetics, processed foods, paints, insecticides, herbicides, pharmaceuticals, and chemical products (Box 11-2). The risk, however, is largely hypothetical and a clear history of exposure taking place is required to make the diagnosis. However, many instances of poisoning from exposure to carbon tetrachloride (CCl₄) have resulted from the use of this volatile solvent as a dry-cleaning agent in a poorly ventilated room, particularly by those who drink ethanol to excess.²²

A large number of chemicals are found in the home as components of household products (Table 11-2) or as pesticides (Table 11-3). Household products likely to contain hepatotoxic chemicals are those used for cleaning clothes and furniture and for paint removal. Despite the potential hepatotoxicity of some household products, the number of reported instances is very low. There is little evidence that hepatic injury has occurred as a result of correct use of pesticides.

In contrast, accidental or deliberate overdose of a known drug or chemical (e.g., CCl₄, acetaminophen [paracetamol], iron) is a very common cause of hepatotoxicity. Ingestion of organochlorine insecticides, herbicides, fungicides, copper salts, or compounds of trivalent arsenic also can lead to hepatotoxicity. Ingestion of rodenticides containing phosphorus has led to numerous cases of severe liver injury.²³ Occasionally, liver damage has been caused by ingestion of rodenticides containing thallium or warfarin.⁹ In general, acute hepatic injury due to ingestion of pesticides has been very rare.²²

Evidence must also be gathered that may point to an alternative diagnosis (e.g., alcohol intake, blood transfusions, high-risk sexual activity, intravenous drug misuse, arrhythmias). Viral serology (hepatitis A, B, C, and E, HIV, cytomegalovirus, Epstein-Barr virus) and ultrasonography often are required, particularly in cases in which the liver function tests indicate cholestasis. Other liver disease (autoimmune chronic active hepatitis, hemochromatosis, primary biliary cirrhosis, Wilson's disease) must be excluded.²⁴

Chronology

Once the list of toxins to which the patient has been exposed has been compiled, the chronology of each treatment should be compared with that of the liver disease. As a general rule, toxins or drugs introduced within the last 6 to 12 weeks should be most suspect, although a shorter duration (1 to 7 days) may be observed in patients who have been exposed previously to the drug/chemical and have been sensitized. It is important not to exclude any that have been withdrawn before the onset of the liver injury; for example, with the amoxicillin and clavulanic acid combination, jaundice may not become apparent until 2 weeks after the treatment. Amiodarone may continue to cause liver damage long after it has been stopped. Information that strengthens the case for an iatrogenic reaction includes previous adverse effects with the drug or related analogs and presence of immunoallergic manifestations, such as drug-induced rash.

TABLE 11-1 Partial List of Agents Likely To Be Encountered Occupationally, with Indication of Hepatotoxic Effects in Experimental Animals and Humans

	EXPERIMENTAL ANIMALS	HUMANS	LESION*
Organic, Nonhalogenated			
Alcohols and glycols			
Allyl alcohol	+	?	Necrosis, zone 1
Dioxane	+	+	Necrosis, zone 3

BOX 11-2 SOME OCCUPATIONS THAT ENTAIL EXPOSURE TO HEPATOTOXIC CHEMICALS

Airplane makers	Lacquer makers and lacquerers
Airplane pilots	Leather workers
Airplane hangar employees	Linoleum makers
Artificial pearl makers	Lithographers
Burnishers	Paint remover makers and users
Cement (rubber, plastic) makers	Painters, paint makers
Cementers (rubber)	Paraffin workers
Chemical industry workers	Perfume makers
Chemists	Petroleum refiners
Chlorinated rubber makers	Pharmaceutical workers
Cobblers	Photographic material workers
Color makers	Polish (metal) makers and users
Degreasers	Printers
Dry cleaners	Pyroxylen-plastics workers
Dye makers	Rayon makers
Dyers	Refrigerator workers
Electric transformer and condenser makers	Resins (synthetic) makers
Electroplaters	Rubber workers
Enamel makers and enamellers	Scourers (metal)
Extractors, oil and fats	Shoe factory workers
Fillers (plastics)	Soap makers
Fire extinguisher makers	Spreaders (rubber works)
Galvanizers	Straw hat makers
Garage workers	Tapers (airplanes)
Gardeners (insecticides)	Thermometer makers
Gas (illuminating) workers	Tobacco denicotinizers
Glass (safety) makers	Varnish makers and users
Glue workers	Varnish removers
Ink makers	Waterproofers
Insecticide sprayers/makers	Wax makers
Insulators (wire)

Diversity and Classification of Drug- and Toxin-Induced Liver Disease

The next step in diagnosis relies on comparison of the patient's liver disease with the types of liver disease known to be associated with the drugs or toxins to which he or she has been exposed. Stricker is very useful for identifying likely therapeutic drugs causing hepatotoxicity,²¹ and once suspected they should be withdrawn immediately. The ultimate step in diagnosis of therapeutic drug-induced liver disease is based on the improvement in the liver disease, which usually occurs within a few days or weeks following cessation of exposure to drug.

A differential white count may show eosinophilia and nonspecific autoantibodies (antinuclear, antismooth muscle) at relatively low titers that regress after interruption of the treatment, which may strengthen a diagnosis of immune-mediated drug-induced liver disease. However, specific serologic markers are available for only a minority of drugs (Table 11-4).²⁵⁻²⁹

A liver biopsy is not necessary in most cases of acute liver injury. In rare cases, it is helpful either to eliminate other causes of liver injury or to show lesions suggestive

of drug-induced hepatotoxicity, and it can be carried out even in the presence of significant coagulopathy by the transjugular approach if necessary. The standard transabdominal route is the most common, though it also can be done under laparoscopic control. This has advantages in being able to see the biopsied area and photocoagulate any bleeding points.³⁰

The pattern of liver damage from the mechanisms in Box 11-1 shows that the liver's response to injury is limited and includes fatty liver, necrosis (cell death), cholestasis, cirrhosis, and carcinogenesis.

FATTY LIVER

This is the accumulation of triglycerides (fats) in the liver cells. Fatty liver is a common response to toxicity, often occurring as a result of interference with protein synthesis in hepatocytes, such as after exposure to hydrazine (H_2N-NH_2), for example.³¹ Normally it is a reversible process that does not lead to cell death, although it can occur in combination with liver cell death (necrosis), as is the case with CCl_4 exposure.³² Two types of fatty liver or steatosis can occur. Tetracycline and

Toilet bowl blocks	Paradichlorobenzene

Any unknown product should be considered potentially hepatotoxic, and all halogenated ones should be considered hepatotoxic until otherwise determined.

hypoglycin A produce microvesicular steatosis—the fat droplets are small, there are many in each hepatocyte, and the nucleus is in the center of the cell. Other substances (e.g., ethanol, methotrexate) lead to macrovesicular steatosis. Individual large fat droplets within each cell displace the nucleus to the periphery. See Box 11-3 for examples of drugs and toxins that cause steatosis.³³⁻³⁹ Repeated exposure to compounds that cause fatty liver, such as ethanol, may lead to cirrhosis.

ACUTE HEPATITIS

Acute hepatitis is the most common drug- or toxin-induced lesion. A liver biopsy is rarely necessary for the diagnosis. These cases tend to be diagnosed from the maximal increase in serum alanine aminotransferase (ALT), a marker of hepatocyte damage, and alkaline phosphatase (AP), a marker of "cholestasis," and from the ratio of ALT/AP, with each activity being expressed in multiples of the upper limit of normal (N) (Table 11-5).⁴⁰

Hepatitis may occur by direct cell injury (necrosis), with disruption of intracellular function, or by indirect injury by immune-mediated membrane damage.

TABLE 11-5 Liver Function Test Criteria for Diagnosis of Acute Hepatitis⁴⁰

INJURY TYPE	CRITERIA
Hepatocellular	If only ALT is increased (>2 N) or when both activities are increased, if the ALT/AP ratio is ≥ 5 (reference 6). NB: Many other medical differential diagnoses (e.g., viral hepatitis, Budd-Chiari syndrome, microvesicular steatosis, low output cardiac failure) may also give such a liver test profile.
Mixed	ALT and AP are increased and the ALT/AP ratio is between 2 and 5.
Cholestatic	AP is increased > 2 N or when both ALT and AP are increased, if the ALT/AP ratio is ≤ 2 .

ALT, alanine aminotransferase; AP, alkaline phosphatase; N, normal.

As mentioned previously, allyl alcohol causes periportal (zone 1) necrosis partly because alcohol dehydrogenase is present in zone 1 and partly because this is the first area exposed to the compound in the blood (see Fig. 11-1). Conversely, CCl_4 and bromobenzene cause zone 3 (centrilobular) necrosis as a result of metabolic activation in that region (Fig. 11-2). Mid-zonal (zone 2) necrosis is less common than the other two types of necrosis, but it occurs with beryllium toxicity (see Fig. 11-1). The explosive trinitrotoluene (TNT) can cause massive liver necrosis involving all zones. Ischemia (impaired blood supply to the liver) also may contribute to necrosis; for example, phalloidin, a toxic substance present in poisonous mushrooms, may cause swelling of the cells lining the sinusoids and therefore reduce the oxygen and nutrients supplied to hepatocytes. Hepatitis due to direct toxicity is not associated clinically with hypersensitivity manifestations. The liver injury may have relatively high frequency, consistent with direct toxicity.

Hepatitis due to immune mechanisms has a low frequency, but this may also be true in idiosyncratic hepatitis due to direct toxicity. The frequency of immunologically mediated hepatitis (as that of hepatitis due to direct toxicity) may be influenced by either genetic or acquired metabolic factors (such as microsomal enzyme induction). Immunoallergic hepatitis frequently is associated clinically with hypersensitivity manifestations, such as fever, rash, and blood eosinophilia, and a marked inflammatory infiltrate in the liver with sometime eosinophils, or granulomas. Immunoallergic hepatitis promptly recurs after inadvertent drug rechallenge. In some cases (halothane, tienilic acid, clometacin, α -methyl dopa) the patient's sera have been shown to contain antibodies directed against hepatic neoantigens (see Table 11-4).

DRUGS THAT CAUSE ACUTE HEPATOCELLULAR HEPATITIS AND THEIR MECHANISMS OF HEPATOTOXICITY

Acetaminophen (Paracetamol)

Recent reports have raised the possibility of toxicity from acetaminophen given in therapeutic doses.^{41,42} In most cases of apparent therapeutic toxicity in children, the patterns of liver function tests, clinical course, and plasma concentrations represent those of acetaminophen overdose (see Fig. 11-1).⁴² The confusion often is between therapeutic intent to treat fever or pain and therapeutic dose.⁴² Often parents are tempted to give extra doses of pediatric acetaminophen preparations, and the apparent therapeutic toxicity in children is probably due to overdose.⁴² In adults, unlike the pediatric population, not all the cases are clear-cut overdoses.⁴² Other factors, such as timing, stated dose, stated product, other products/drugs (particularly those that delay gastric emptying), glutathione depletion, and enzyme induction, may be operating, not to mention inadequate treatment with *N*-acetylcysteine.⁴² This causes confusion, but the possibility remains that a few people might be more susceptible to acetaminophen at therapeutic doses.

Acetaminophen overdose is discussed in detail in Chapter 47. Poisoning with acetaminophen is characterized by liver damage, though a variety of less common manifestations, including pancreatitis, renal failure, and thrombocytopenia, also can be seen.⁴³

The mechanism of toxicity in early acetaminophen poisoning (within 15 hours) has been well understood since the 1970s, and it depends on the metabolism of acetaminophen by cytochrome P-450 mixed-function oxidases (CYP2E1 and CYP3A4 in humans) to the active *N*-acetyl-*p*-benzoquinone imine metabolite.^{42,44} This metabolite then causes cell death by covalent binding to hepatic proteins and enzymes once intracellular glutathione is depleted.⁴⁵ Centrilobular necrosis tends to occur first.⁴⁶ The antidote, *N*-acetylcysteine, if given at an early enough stage, particularly within the first 8 to 12 hours of ingestion, prevents hepatic cell damage by production of cysteine, which acts as a glutathione donor.^{45,47} The standard treatment line indicating when *N*-acetylcysteine should be given is lowered by 50% for chronic alcoholics and users of enzyme-inducing drugs (such as phenytoin, carbamazepine, phenobarbital, primidone, and rifampicin) because such patients are at increased risk of toxicity due to increased production of the active metabolite, which is due to CYP enzyme induction.⁴⁸ Alcohol (ethanol) is actually protective if coingested with an acetaminophen overdose, but whether chronic excessive use increases the risk of hepatotoxicity when an acetaminophen overdose is taken remains controversial.^{49,50} In animals chronic ethanol administration causes induction of hepatic microsomal enzymes (especially CYP2E1) and so increases formation of the toxic metabolite and increases acetaminophen hepatotoxicity.⁴⁹ However, because of dose-dependence and species differences in expression, activity, and inducibility of isoenzymes, it is not justifiable to extrapolate these

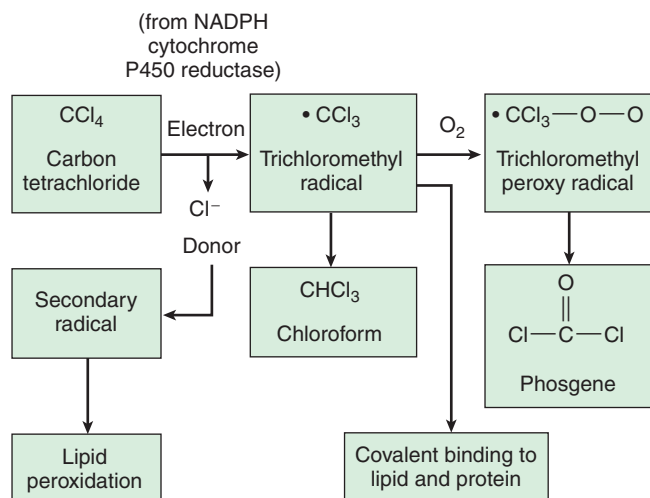

FIGURE 11-2 Metabolic activation of carbon tetrachloride (CCl_4).

results to humans.^{49,50} In a recent series of 553 patients with acetaminophen hepatotoxicity at a regional liver unit, there was no association between chronic alcohol consumption and the severity of hepatotoxicity.⁵¹

Factors that lead to depletion of intrahepatic glutathione probably also potentiate acetaminophen hepatotoxicity in overdose. Fasting decreased glucuronidation of acetaminophen in rats; hence, more active metabolite was present, potentiating acetaminophen-induced hepatic necrosis.⁵² Fasting has been claimed to predispose to toxicity in humans, and a few cases suggest that patients with glutathione depletion are at increased risk of acetaminophen poisoning.^{5,6} The mean half-life of acetaminophen is significantly longer in infants and children with protein-energy malnutrition.⁵³ Patients with HIV and AIDS have been shown to have systemic glutathione deficiency^{54,55} and probably also have hepatic glutathione deficiency. Patients with advanced HIV have been shown to have reduced acetaminophen glucuronidation and increased formation of hepatotoxic oxidative acetaminophen metabolites.⁵⁶ It therefore seems a reasonable precaution to treat malnourished patients and patients who are seropositive for HIV who have taken an overdose with *N*-acetylcysteine at a lower acetaminophen level using the lower treatment line.

In contrast, little is known about the mechanisms of injury in late acetaminophen poisoning. Recently, a significant role of macrophages and Kupffer cells in production of cytokines and chemokines and activation of hepatic sinusoidal cells and neutrophils has been established.^{57,58} In addition, activated macrophages and Kupffer cells produce potentially toxic reactive oxygen species such as superoxide and peroxynitrite, capable of directly mediating tissue injury.^{58,59} Nitric oxide is proposed as a hepatoprotective mechanism against oxidative injury.^{60,61} Many studies have tried to evaluate which of many hundreds of cytokines and chemokines are important in the pathogenesis of liver injury by acetaminophen without a clear result.^{62,63} Such studies are complicated by the fact that the presence of cytokines does not mean they are directly involved in the pathogenesis; they may just be an epiphenomena of injury.⁶³ Nuclear transcription factors NF- κ B and IL-6 are negative regulators of hepatocyte inflammatory cytokines.⁶⁴ The current hypothesis is that toxicity occurs when the tumor necrosis factor pathway is activated but only in the absence of activation of the protective negative modulating NF- κ B pathway.⁶⁴ In addition to their role in the pathogenesis of cell injury, tumor necrosis factor- α and other cytokines facilitate the process of regeneration and repair.^{65,66} Knowledge of the mechanisms of liver injury, at the cellular level, is important in the development of new treatments for acetaminophen overdose, particularly in late presenting patients who are at greatest risk of hepatotoxicity.

Cocaine

It is estimated that 22 million Americans have used cocaine at least once and that 5 million Americans use it regularly.⁶⁷ Fifteen percent of cocaine-use inpatients

(not administered intravenously) have mild elevations of liver enzymes.⁶⁷ Most addicts take cocaine intranasally rather than orally, as it had been assumed that the stomach hydrolyses cocaine. However, oral cocaine produces dose-related hepatotoxicity in male mice.⁶⁸ Acute cocaine hepatotoxicity is caused by hyperpyrexia, hypotension, and direct toxicity of the cocaine and can cause severe hepatic dysfunction.^{69,70} Cocaine is metabolized by cytochrome P-450 to norocaine, which is further oxidized to *N*-hydroxynorocaine, norocaine nitroxide, and norocaine nitrosonium ion.⁷¹ These metabolites cause an oxidant stress and lipid peroxidation in hepatocytes.^{70,72} Mouse studies suggest that a hydroxyl radical produced by the reaction of nitric oxide and superoxide via peroxynitrite may be involved in the pathogenesis of cocaine hepatotoxicity.^{73,74} In animals, toxicity is enhanced by inducers (phenobarbital, ethanol) of cytochrome P-450 and prevented by cytochrome P-450 inhibitors (particularly CYP2A).^{70,71,75,76} The presence of noninjurious doses of lipopolysaccharide (LPS) appears to potentiate the hepatotoxicity of cocaine in mouse models,⁷⁷ and pretreatment with *N*-acetylcysteine prevents this.⁷⁸ Cotreatment with adrenergic antagonist drugs appears to reduce the hepatotoxicity of cocaine.⁷⁹

Cocaine-induced hepatotoxic patients have a huge rise in ALT activity with 48 hours,^{69,80} and liver lesions are in the centrilobular zone, extending into the midlobular zone.^{71,81} Hepatocytes adjacent to the central vein are spared,⁷¹ although hepatic enzyme-inducing and -inhibiting agents affect the site of necrosis.⁸²

Ecstasy (3,4-methylenedioxymethamphetamine)

The social use of Ecstasy and amphetamines is widespread in Europe and the United States.⁸³ Recreational use of this drug presents an important but often concealed cause of hepatitis or acute liver failure, particularly in young people.⁸³ Hepatotoxicity has featured in several hundreds of cases of intoxication with Ecstasy in the literature and it is probable that many are subclinical and go undetected.⁸⁴⁻⁸⁸ The evidence to date suggests there is more than one pattern of hepatotoxicity, in which different mechanisms may be responsible. The clinical pattern varies from asymptomatic hepatic liver function tests to acute hepatic failure due to hepatocellular necrosis, from which some patients recover but others die or require liver transplantation.⁸³⁻⁸⁷ Some present with cholestasis.⁸³ Rarely, accelerated panacinar fibrosis has been observed.⁸⁹ Subacute hepatic toxicity, with cumulative damage on recurrent exposure, has been reported after recurrent ingestions over a period of time.^{87,89,90} Hepatotoxicity may be variously manifest at histological level as a microvesicular fatty change, small foci, or cell necrosis or massive hepatic necrosis,^{84,87,91} but it is most commonly due to necrosis.

In humans, oxidation is the main metabolic pathway for Ecstasy,⁹² and this reaction is catalyzed by cytochrome P-450 CYP2D6 in yeast⁹³ and CYP2D in rats.⁹⁴ Thus, methylenedioxymethamphetamine (MDA) is a main MDMA metabolite.⁹⁵

In humans, the molecular mechanisms involved in the hepatotoxicity of MDMA remain poorly understood. Immune-mediated mechanisms have been hypothesized to play a part in Ecstasy- or amphetamine-induced liver damage, as a result of the observation that rechallenge with ecstasy produced greater liver damage, and this has occurred in some patients in the absence of hyperthermia.^{87,96} Liver biopsy in one patient suggested an autoimmune hepatitis-like injury, which resolved spontaneously on withdrawal of the drug.⁹⁶ However, a dose-dependent effect can be seen.⁹⁷

Many patients with hepatotoxicity have been hyperpyrexia for several hours,^{86,87,98} although this has not occurred in every case. Rat livers perfused by hyperthermic solutions show oxidative stress with superoxide formation.⁹⁹ Animals normally react to hyperthermia by the rapid transcription and translation of heat shock proteins, which help the cell survive thermal stress.¹⁰⁰⁻¹⁰² Administration of amphetamine to rats caused hyperthermia but no induction of heat shock protein in the liver, which suggests the liver may have impaired thermotolerance when amphetamine is present.^{83,103} In mice (and probably in humans), high ambient temperature contributes to hepatotoxicity.^{97,104,105} It is also postulated that apoptosis may occur.¹⁰⁶

Incubation of hepatocytes with d-amphetamine induced a concentration-dependent glutathione depletion, which was prevented by pretreatment with the P-450 enzyme inhibitor metyrapone in rats.⁹⁴ Glutathione depletion most likely contributes to hepatotoxicity of amphetamines and ecstasy.

Hepatic damage has followed the intravenous use of methamphetamine and amphetamine,¹⁰⁷⁻¹⁰⁹ but this is probably a result of viral infection by hepatitis B or C due to contaminated needles.¹⁰⁹

Iron

After overdose of iron, the amount absorbed is probably about 10%.¹¹⁰ All of the absorbed iron goes to the liver via the portal vein and enters cells via a receptor mediated endocytosis of transferrin-bound iron.^{110,111} Acute hepatic necrosis (mid zone necrosis) can result from the ingestion of large amounts of iron,^{23,112} particularly if there is failure to recognize the severity of poisoning and delay in administration of the antidote deferoxamine (see Chapter 72). Shortly after ingestion, evidence of severe gastrointestinal injury is noted, with nausea, vomiting, diarrhea, and melena. Symptoms may abate for a short period followed within 1 to 3 days by the third phase in which evidence of hepatic injury, jaundice, elevated aspartate transaminase (AST) and ALT and striking hypofibrinogenemia appear, with periportal necrosis.^{113,114} Evidence from case reports and animal studies suggests hepatotoxicity occurs early in the clinical course (within the first 24 to 48 hours) and has relatively high mortality.¹¹⁴ The lowest serum iron concentration associated with hepatotoxicity is 304 $\mu\text{M/L}$ (1700 $\mu\text{g/dL}$), although it was not clear at what time post-ingestion this sample was taken.¹¹²

It has long been suspected that free radicals play a part in metal-induced hepatotoxicity because of the

powerful pro-oxidant action of iron and copper salts *in vitro*, which catalyze free radical reactions.¹¹⁵ The resulting oxyradicals have the potential to damage cellular lipids, nucleic acids, proteins, and carbohydrates, and this impairs cellular function and integrity.¹¹⁵ Kupffer cells have enhanced respiratory bursts.^{116,117} Cells have cytoprotective mechanisms (antioxidants, scavenging enzymes, repair processes) that act to counteract free radicals, thus the extent of damage depends on the balance between free radical generation and cytoprotective systems. Iron overload *in vivo* can result in oxidative damage to lipids *in vivo*, once the plasma concentration of metal exceeds a threshold level. In the liver, this lipid peroxidation is associated with impairment of membrane-dependent functions of mitochondria (oxidative metabolism) and lysosomes (membrane integrity, fluidity, pH). Although these findings do not prove causality, lipid peroxidation likely is involved, since similar functional defects are produced by metal-induced lipid peroxidation in these organelles *in vitro*.¹¹⁰ Iron impairs hepatic mitochondrial respiration, primarily through a decrease in cytochrome *c* oxidase activity. In iron overload, hepatocellular calcium homeostasis may be impaired through damage to mitochondrial and microsomal calcium sequestration.¹¹⁰ Reduced cellular adenosine triphosphate (ATP) levels, lysosomal fragility, impaired cellular calcium homeostasis, and damage to DNA all may contribute to hepatocellular injury in iron overload. Deferoxamine is the treatment of choice in significant iron poisoning, in addition to acting as an iron chelating agent it also has antioxidant properties and can reverse or arrest iron-induced lipid peroxidation.^{118,119}

Unlike most other hepatotoxins, the periportal areas of the hepatic lobule are the primary sites of injury. This is the site for hepatic regeneration, which probably accounts for the relatively high mortality.¹¹⁰

Halothane

Halothane is a general anesthetic that causes mild hepatotoxicity in 20% of individuals.^{25,120} In contrast, a very small subset of individuals develops severe halothane hepatitis, which is thought to have an immunologic basis.^{25,120} Halothane is transformed by cytochrome P-450 via both oxidative and reductive pathways to reactive metabolites. The reductive pathway (via CYP2A6 and CYP3A4)¹²¹ forms a radical, CF_3CHCl , which under certain conditions (microsomal enzyme induction and hypoxia) may lead to direct hepatotoxicity in animals. The oxidative pathway (via CYP2E1)¹²¹ forms reactive acyl chloride (CF_3COCl) that binds covalently to hepatic proteins, including plasma membrane proteins. These trifluoroacetylated proteins can lead to immunization and to the severe form of hepatitis seen in rare subjects. This occurs in 1 out of every 10,000 subjects after first anesthesia within 2 weeks of the procedure. In one study, 25 (45%) of 56 patients with halothane hepatitis had autoantibodies against CYP2E1.¹²²

Jaundice is more frequent after repeated exposure and occurs sooner; 12 days after first exposure, 7 days after second exposure, and 5 days after third exposure. Jaundice frequently is associated with fever (75%) and

eosinophilia (40%). Sera from patients with severe halothane hepatitis contain antibodies against trifluoroacetylated plasma membrane proteins such as protein disulfide isomerase, microsomal carboxylesterase, calreticulin, Erp72, GRP 78, and Erp99.^{25,123,124} Halothane hepatitis is hepatocellular. It is best avoided by avoiding repeated exposure, especially over short intervals.¹²⁵ Halothane was the most frequent cause of hepatotoxicity resulting in death over a 21-year period in New Zealand.¹²⁶

Isoniazid (with or without Rifampicin)

Major adverse reactions to antituberculosis drugs can cause significant morbidity and compromise treatment regimens for tuberculosis, and antituberculosis drug-induced hepatitis is one of the most prevalent drug-induced liver injuries.¹²⁷ Most cases of antituberculous drug-induced hepatitis have been attributed to isoniazid. Isoniazid given alone increases serum transaminase activity in 10% of patients and causes clinical hepatotoxicity in 1%.¹²⁸ Peak risk is in the second month of therapy.¹²⁸ Hepatocellular damage without hypersensitivity manifestations take place. Isoniazid is metabolized to a reactive toxic metabolite in the liver.¹²⁹ Isoniazid is first acetylated into acetylisoniazid by hepatic *N*-acetyltransferase, which is hydrolyzed into acetylhydrazine. Acetylhydrazine may be either acetylated again, into the nontoxic diacetylhydrazine, or transformed by cytochrome P-450 CYP2E1¹²⁹ into the reactive acetyl radical that binds covalently to hepatic proteins.¹³⁰ Approximately 40% of Caucasians and blacks, but 90% of Japanese, are rapid acetylators of isoniazid.¹³¹ Rapid acetylators form acetylhydrazine at a faster rate, but at the same time, detoxify it to diacetylhydrazine at a faster rate. Thus, slow acetylators have a higher risk of hepatotoxicity than do rapid acetylators.^{127,131} In addition, slow acetylators are prone to develop more severe hepatotoxicity than rapid acetylators.^{127,132} CYP2E1 genetic polymorphism may be associated with susceptibility to antituberculous drug-induced hepatitis.¹²⁹

Rifampicin in therapeutic doses when given alone is seldom hepatotoxic and mainly produces cholestatic liver injury. However, in patients receiving both isoniazid and rifampicin, the incidence of hepatitis is 5% to 8%, mainly during the first month of therapy.¹³³ Acute hepatic failure due to the combination tends to develop even earlier, after about 1 week of treatment.¹³³ Pessayre and Mazel¹³⁴ suggest that rifampicin, a microsomal enzyme inducer, increases the formation of the reactive isoniazid metabolite.

Liver function tests should be monitored in patients receiving antituberculosis drugs in the first few days, within the first week, and once a month thereafter. Isoniazid should be withdrawn if ALT exceeds three times the upper limit of normal.

Nonsteroidal Anti-inflammatory Drugs

Hepatotoxicity is an uncommon but potentially lethal complication of therapy with nonsteroidal anti-inflammatory drugs (NSAIDs). Clinically apparent liver injury occurs in 1 to 8 cases per 100,000 patient years

of NSAID use.¹³⁵⁻¹³⁸ Hepatotoxicity can occur with all NSAIDs but appears to be more common with diclofenac and sulindac,^{137,139} and most commonly within 6 to 12 weeks of initiation of therapy. Patients who have experienced hepatotoxicity to one NSAID often have the same reaction if the drug is restarted or a sister drug is given. Female patients older than 50 years of age who have autoimmune disease and those on potentially hepatotoxic drugs appear to be particularly susceptible, but whether this merely represents the population taking NSAIDs remains to be established.¹³⁵ Liver function test abnormalities usually settle within 4 to 6 weeks of stopping the causative drug. However, some patients may develop liver failure and require liver transplantation.^{139,140} Several NSAIDs have been withdrawn from clinical use because of associated hepatotoxicity.¹⁴¹⁻¹⁴³ The new more selective cyclooxygenase 2 (COX-2) inhibitors (e.g., celecoxib, rofecoxib) also are associated with hepatotoxicity.¹⁴⁴⁻¹⁴⁷

Two main mechanisms are responsible for injury, hypersensitivity and metabolic aberration. Hypersensitivity reactions often have significant antinuclear factor (ANF) or anti-smooth muscle antibody titers, lymphadenopathy, and eosinophilia. Rechallenge results in an increase in ANF titers.¹⁴⁸ Metabolic aberrations can occur as genetic polymorphisms and alter susceptibility. It may account for the incidence of 1 to 8 in every 100,000 prescriptions. In vitro metabolism of aceclofenac reflects phenotypic variability among donor liver cells.¹⁴⁹

Recent in vitro animal studies have shown that the mechanism of diclofenac toxicity relates both to impairment of ATP synthesis by mitochondria and to production of active metabolites, particularly *n*,5-dihydroxydiclofenac, which causes direct cytotoxicity.^{150,151} Mitochondrial permeability transition also has been shown to be important in diclofenac-induced liver injury, resulting in generation of reactive oxygen species, mitochondrial swelling, and oxidation of nicotinamide adenine dinucleotide phosphate (NADP) and protein thiols.¹⁵² Other studies have shown that ferrous iron release from rat liver microsomes contributes to naproxen-induced microsomal lipid peroxidation.¹⁵³ Toxicity thus relates both to impairment of ATP synthesis by mitochondria and to drug metabolism. Nearly all of the NSAIDs have been implicated in causing liver injury, and they tend to be hepatocellular in nature.^{139,154,155}

Patients who develop NSAID-induced hepatotoxicity must be advised to stop taking NSAIDs permanently. Acetaminophen remains the analgesic of choice for these patients, even if they are jaundiced.^{156,157} They also may safely switch to aspirin use because the toxicity of NSAIDs relates to their diphenylamine ring molecular structure, which aspirin does not have.¹⁴²

Phenytoin

Phenytoin is a microsomal enzyme inducer. Its administration to patients commonly causes a rise in γ -glutamyltransferase and may cause a small rise in ALT and AP in some patients.¹⁵⁸ Clinical hepatitis is much less common (serious idiosyncratic reactions occur in approximately 1% of patients¹⁵⁹) and occurs within 6 weeks of therapy,

usually associated with fever, rash, lymphadenopathy, lymphocytosis, hepatomegaly, splenomegaly, and eosinophilia, suggesting an allergic mechanism. Phenytoin is metabolized to a 3,4-epoxide.¹⁶⁰ An autoantibody against a 53-kD microsomal protein has been reported.¹⁵⁸ Hepatitis is predominantly hepatocellular, but sometimes it is mixed.

Thiazolidinediones

These drugs act as insulin-sensitizing agents and are used in the management of type 2 diabetes mellitus. Troglitazone was the first agent in this class to be used clinically, but it has now been withdrawn after being implicated in more than 100 cases of hepatotoxicity, including a number of deaths and cases of acute liver failure that required liver transplantation.¹⁶¹⁻¹⁷² Significant hepatotoxicity was more common in women and obese patients, but concurrent use of other drugs and pre-existing liver disease did not appear to increase the risk of troglitazone-induced liver disease.¹⁶⁵ The onset of hepatotoxicity often was delayed (mean, 4 months; range, 8 days to 12 months), but progression to acute liver failure once hepatotoxicity developed often was rapid and, in some cases, liver injury continued to progress after discontinuation of troglitazone.^{167-170,173}

Troglitazone is metabolized by CYP3A4 and CYP2C8 to a quinine metabolite, which may cause hepatotoxicity similar to that seen with antimalarials and quinolone antibiotics.¹⁷⁴ The hypotoxicity of troglitazone is predominantly hepatocellular, but in addition, the sulfate metabolite of troglitazone inhibits hepatobiliary transport of bile acids by competing with the bile acid export pump, so there may also be a cholestatic element.¹⁷¹

The other thiazolidinediones (pioglitazone and rosiglitazone) are similar structurally to troglitazone, but their metabolic pathways differ and they do not appear to have the same hepatotoxic potential as troglitazone. In large clinical trials the incidence of liver enzyme elevations with these two drugs did not differ from placebo.^{175,176} There have been two reports of hepatotoxicity with rosiglitazone and one related to pioglitazone; all of these patients recovered.¹⁷⁷⁻¹⁷⁹ In one case of troglitazone-related hepatotoxicity, the patient was successfully treated with rosiglitazone with no recurrence of hepatotoxicity.¹⁸⁰

Many other drugs cause acute hepatocellular hepatitis and some of these are listed in Box 11-4.¹⁸¹⁻²⁰⁵

MUSHROOMS THAT CAUSE ACUTE HEPATOCELLULAR HEPATITIS

Hepatotoxic mushrooms may be mistaken for edible mushrooms. Several hundred deaths per year are attributable to hepatotoxic mushrooms, especially in Europe,²⁰⁶ and the amount ingested need not be great (see Chapter 23). There are more than 21,000 published cases of amatoxin poisoning.^{201,207} Fatal mushroom poisoning is relatively rare in North America. There are many thousands of species of mushrooms, but the number of poisonous species is small. Most fatal poisonings are due to the ingestion of *Amanita phalloides* or the

closely related *A. verna* or *A. virosa*.²⁰⁶ Amatoxins are bicyclic octapeptides that bind eukaryotic DNA-dependent RNA polymerase II and inhibit transcription.^{208,209} A single mushroom has been estimated to contain a fatal dose.²⁰⁶ The toxicity results from thermostabile toxins (amatoxins and phallotoxins) present in the mushroom. They cause a syndrome of hepatorenal failure similar to that caused by CCl₄ and white phosphorus. The lesion produced by mushroom poisoning is steatosis and centrilobular (zone 3) necrosis. Degenerative changes of the gastrointestinal tract, kidneys, heart, and central nervous system also occur.²¹⁰

The syndrome consists of a latent period of 6 to 20 hours after ingestion of poisonous mushrooms followed by extremely severe gastrointestinal symptoms, including abdominal cramps/pain, vomiting, and diarrhea. These symptoms usually are promptly followed by cyanosis and shock. Within 1 to 2 days, hepatocellular jaundice and uremia are noted. Central nervous system abnormalities such as confusion, coma, and convulsions may occur during the first 3 days after ingestion.²⁰⁶ Electrocardiogram evidence of myocardial involvement may include bundle branch block and premature ventricular beats.²⁰⁶ Hemolytic anemia may occur. AST and ALT levels are strikingly elevated, as with those of CCl₄ poisoning.²¹⁰

Mortality rate is 10% to 25%.²¹⁰ Death within 4 to 8 days results from hepatic failure, severe dehydration, and collapse or central nervous system complications. Death also may occur during the first 48 hours from choleraform diarrhea,²¹⁰ of which children are more at risk.

No specific antidote is available, but several agents have been tried, including penicillins, silymarin, thioctic acid, and antioxidants. Benzylpenicillin, *N*-acetylcysteine, and silymarin all are effective in animal models of *Amanita* poisoning.^{207,211-215} However, in a recently published review of 2108 patients treated for *Amanita* poisoning, benzylpenicillin did not appear to offer a significant benefit, whereas *N*-acetylcysteine and silymarin were associated with a modest benefit; these data need to be interpreted with caution as the review was retrospective and uncontrolled.²⁰⁷

CHEMICALS THAT CAUSE ACUTE HEPATOCELLULAR HEPATITIS

Carbon Tetrachloride Poisoning

Careless use or sniffing of the solvent carbon tetrachloride (CCl₄) leads to centrilobular necrosis,²¹⁶⁻²²¹ usually accompanied by renal tubular epithelial necrosis. Alcoholic individuals are particularly susceptible. The syndrome consists of renal and hepatic failure, usually preceded by transient neurological and gastrointestinal symptoms. Immediately after exposure, dizziness, headache, visual disturbances, and confusion occur, reflecting the anesthetic properties of haloalkenes.^{22,216,218} Nausea, vomiting, and abdominal pain with diarrhea occur also during the first 24 hours, especially if ingestion has occurred. Evidence of hepatic disease

BOX 11-4 OTHER COMMON DRUGS THAT CAUSE ACUTE HEPATOCELLULAR HEPATITIS

Amoxicillin-clavulanic acid: Hepatocellular or cholestatic hepatitis.¹⁸¹

Allopurinol: Patients on diuretics or those with compromised renal function are most susceptible. Hepatitis occurs most frequently during the first month of treatment and is hepatocellular.

Granulomas, fever, rashes, and eosinophilia suggest an allergic/hypersensitivity mechanism.¹⁸²

Amodiaquine: Hepatocellular jaundice and even acute liver failure. Amodiaquine undergoes autoxidation into a reactive quinoneimine.^{183,184}

Aspirin: Hepatitis occurs after one to several weeks of treatment. This is a dose-related phenomenon related to intrinsic salicylate hepatotoxicity and generally occurs only when aspirin is used in full anti-inflammatory doses. Plasma salicylate concentrations greater than 25 mg/L are likely to lead to hepatic injury, whereas concentrations less than 15 mg/L rarely do. Hepatic injury often is silent, or, at least, anicteric. However, a few cases with hepatic encephalopathy have been described. Use of aspirin during viral infections favors the secondary development of Reye's syndrome in children.¹⁸⁵

Cyproterone acetate: Often produces mild abnormalities in liver function tests. However, it has also produced acute liver failure in elderly patients. It may also lead to hepatocellular carcinoma.¹⁸⁶

Dantrolene: Prolonged administration of dantrolene increases serum transaminase activity in 1% to 8% of recipients and produces jaundice in 0.6%. Hepatitis usually occurs between month 2 and 5 of treatment, with a fatality rate of 28%. Hypersensitivity is uncommon.¹⁸⁷

Dihydralazine and hydralazine: Hepatitis occurs weeks to months after treatment and is hepatocellular. Some cases of associated fever or blood eosinophilia have been described. Anti-smooth muscle, antimitochondrial, and antimicrosomal antibodies have

been observed. The antimicrosomal antibodies are directed against the cytochrome P-450 1A2 isoenzyme, which transforms dihydralazine into reactive radicals. Slow acetylators are at increased risk of developing hepatitis.^{188,189}

Disulfiram: Disulfiram is converted into reactive metabolites and causes abnormal liver biochemistry in 25% of recipients during the first few weeks of treatment, which represents direct toxicity. However, clinically relevant effects accompanied by hypersensitivity manifestations occur within 2 months of treatment and at least 10 cases of acute liver failure have been reported.^{190,191}

Enflurane: Hepatitis closely resembles halothane hepatitis. Enflurane is transformed into reactive acyl halide metabolites, which cause immune-mediated hepatitis.¹⁹²

Fipexide: Has produced acute liver failure in three patients.¹⁹³

Ketoconazole: Overt hepatitis on rechallenge with drug. May produce cirrhosis.^{194,195}

Lamotrigine: Acute hepatitis has been reported in six patients (acute liver failure in two of these), with onset between 2 and 3 weeks of starting therapy. Liver function tests normalized in five patients when lamotrigine was stopped; the other patient had mildly abnormal liver function tests.¹⁹⁶⁻¹⁹⁸

Methyldopa: Hepatitis seen in pregnancy, sometimes with hemolytic anemia.¹⁹⁹

Nicotinic acid/Niacin: Hepatotoxicity.²⁰⁰

Nifedipine: Acute hepatotoxicity accompanied by eosinophilia.²⁰¹⁻²⁰³

Pyrazinamide: The incidence of pyrazinamide-induced hepatotoxicity is higher than that of other first-line antituberculosis drugs.²⁰⁴

Tacrine: Half of patients treated have abnormal liver functions tests. One case of fatal hepatic necrosis has been documented.²⁰⁵

usually follows the exposure by 2 to 4 days, but it can occur at 24 hours. Jaundice develops in 50% of cases of poisoning; it is hepatocellular and rapid in evolution. Renal failure begins a few days after the liver damage and peaks in the second week. It may be heralded by oliguria between the second and fourth day after exposure. Continued oliguria or anuria beyond day 4 and rising blood urea during the first and second weeks indicates the presence of tubular necrosis. Renal failure is the cause of death in most fatal cases.^{22,216} Pulmonary edema is observed in most patients who survive for longer than 1 week. Laboratory features include a low hemoglobin concentration and a neutrophil leucocytosis. Toward the end of the first week frank uremia secondary to renal tubular necrosis develops. There are striking elevations of AST and ALT^{22,222} and prolongation of the prothrombin ratio. Mortality rate was 25% prior to hemodialysis.²² N-acetylcysteine has been used successfully to treat the hepatotoxicity of CCl₄.²²³ With chronic exposure, like in the case of ethanol, CCl₄ causes micronodular and macronodular cirrhosis.

White Phosphorus Poisoning

Suicide by deliberate ingestion of phosphorus in cockroach powder, rat poison, or firecrackers often takes

place in the developing world. It causes mid-zone necrosis and periportal steatosis.²²⁴ Mortality rate is high (50%), and renal tubular necrosis is common in such cases. Initially, there are severe, irritant effects on the gastrointestinal tract: nausea, vomiting, abdominal pain and diarrhea, and even hematemesis and shock. The vomitus and feces are phosphorescent and have a strong garlic odor, as does the breath. One third of patients die during this 8- to 24-hour stage. One third of patients recover and one third go to the next stage, which is a latent, symptom-free period for 1 to 3 days.²²⁵ The third stage is characterized by hepatic failure, renal failure, and recurrent central nervous system involvement, including restlessness, coma, and toxic psychosis. Jaundice is apparent between days 3 and 5 after poisoning and renal failure is apparent between days 1 and 4. AST and ALT levels are only moderately elevated (compared with CCl₄ poisoning) and coagulopathy occurs.^{22,226-228}

Inorganic Arsenicals, Thallium, and Borates

These compounds can cause neurological, muscular, renal, and gastrointestinal manifestations. Hepatic injury (necrosis and steatosis) is a regular feature of the intoxication, but it has only a contributory role in

determining the outcome. Jaundice and other evidence of hepatic failure are rare, and they can be recognized only in patients who survive for a few days. Prolonged exposure causes cirrhosis.^{22,23,229}

Sniffing of Chloroform, Trichloroethylene, or Perchloroethylene

Often users who develop jaundice have histological features of necrosis and fat deposition in the liver. Features of toxicity include a syndrome usually of lesser severity than that due to CCl₄ poisoning.^{22,230,231}

Copper

Clinical features of copper poisoning are similar to those of iron overdose. Even dermal application has been associated with hepatotoxicity. Copper salt ingestion causes gastrointestinal erosions, centrilobular necrosis, and renal tubular necrosis. The course resembles that of other forms of hepatorenal failure. Severe nausea, vomiting, diarrhea, and abdominal pain, accompanied by metallic taste, are followed by jaundice, high aminotransferase activities, and hepatomegaly by the second or third day after ingestion.^{232,233}

Other chemicals associated with hepatocellular hepatitis are shown in Box 11-5.²³⁴⁻²⁴⁰

DRUGS AND TOXINS THAT CAUSE MIXED HEPATITIS

Mixed hepatitis reflects both hepatocellular necrosis and cholestasis in the same patient from direct necrosis or by adverse immune response against the liver²⁴¹ and causing the liver function tests abnormalities shown in Box 11-6.²⁴²⁻²⁶⁴

HMG-CoA Reductase Inhibitors ("Statins")

Hepatotoxicity from a mixed hepatocellular-cholestatic mechanism has been reported with atorvastatin, fluvastatin, lovastatin, cerivastatin (predominantly hepatocellular mechanism, now removed because of frequent rhabdomyolysis), simvastatin, and pravastatin.²⁵⁶⁻²⁶² Elevation of liver enzymes up to three times the upper limit of normal occurs in up to 3% of patients who take these agents and is usually dose dependent and occurs within 3 months of initiating therapy.²⁵⁶⁻²⁶² The incidence of severe hepatotoxicity is low (0.2 per 100,000), although there are a number of published cases of acute liver failure due to statins.²⁵⁷ There is conflicting evidence on the cross-toxicity of these agents (e.g., in one patient with simvastatin-related toxicity, pravastatin also caused hepatotoxicity but atorvastatin was not associated with hepatotoxicity).²⁶³ Although rhabdomyolysis commonly is associated with statin-fibrate combination therapy, concurrent liver injury with this combination does not appear to be more common than with statin therapy alone.²⁶⁴

BOX 11-5

OTHER CHEMICALS ASSOCIATED WITH HEPATOCELLULAR HEPATITIS

Polychlorinated biphenyls: In 1968, hepatic injury developed in 11% of more than 1000 people in Japan who ate food prepared with cooking oil contaminated with polychlorinated biphenyl.²³⁴⁻²³⁶

Nitrites and nitrates: Caused hepatic necrosis due to reaction of nitrites with secondary amines in the fish to form dimethylnitrosamine. They may be used as food preservatives.⁹

Beryllium: Central zone necrosis.²³⁷

Toluene: Subacute necrosis.²³⁸

Tetrachloroethane: Subacute necrosis in industrially exposed humans. Ingestion or inhalation of high concentration, however, leads to acute disease similar to that induced by CCl₄.²³⁹

Insecticide poisoning (e.g., DDT and paraquat): A number of insecticides are chlorinated hydrocarbons. Ingestion of large amounts of DDT (≈6 g) and paraquat (20 g) has led to zone 3 centrilobular hepatic necrosis. Paraquat also is associated with a later selective destruction of bile ducts and cholestasis.²⁴⁰

BOX 11-6

DRUGS THAT CAUSE MIXED HEPATOCELLULAR AND CHOLESTATIC HEPATITIS IN THERAPEUTIC DOSES

Angiotensin-converting enzyme inhibitors²⁴²

Carbamazepine²⁴³

Chlorpropamide²⁴⁴

Cimetidine²⁴⁵

Clozapine²⁴⁶

Haloperidol²⁴⁷

Methimazole²⁴⁸

Nitrofurantoin²⁴⁹

Dextropropoxyphene²⁵⁰

Quinidine²⁵¹

Ranitidine²⁵²

Sulfonamides^{249,253}

Tamoxifen²⁵⁴

Terbinafine²⁵⁵

HMG-CoA reductase inhibitors (e.g., pravastatin, simvastatin, atorvastatin)²⁵⁶⁻²⁶⁴

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS AND ANGIOTENSIN II RECEPTOR INHIBITORS

There have been a number of reports of pure cholestatic jaundice, hepatocellular hepatitis, and a mixed hepatotoxicity with all of the angiotensin-converting enzyme (ACE) inhibitors and reports of acute liver failure associated with lisinopril and enalapril.²⁶⁵⁻²⁷² Onset of hepatotoxicity can be delayed up to 1 to 3 years, but it generally occurs within the first 3 to 4 months and is more common after a dose increase.^{266,271}

There is little published data on the newer angiotensin II receptor antagonists, but there have been published case reports of hepatotoxicity associated with candesartan (hepatocellular), irbesartan (cholestatic), and losartan (hepatocellular).²⁷³⁻²⁷⁷

DRUGS AND TOXINS THAT CAUSE ACUTE CHOLESTATIC HEPATITIS

Because of the close interrelation between bile ducts and hepatocytes, damage to bile ducts may be accompanied by damage to hepatocytes by the build-up of bile, which damages cell membranes in excess. A list of common agents that cause acute cholestatic hepatitis is shown in Box 11-7.²⁷⁸⁻²⁸⁴ Cholestasis can result from direct bile duct necrosis or by adverse immune response against the liver.²⁴¹ Clinically, cholestasis presents as jaundice, pruritus, and dark urine. Biochemically, in pure cholestasis there is an increase in AP, conjugated bilirubin and γ -glutamyl transpeptidase; in mixed cholestatic-hepatitis the ALT also increases but the ALT/AP ratio is between 2 and 5.

DRUGS AND TOXINS THAT CAUSE PURE CHOLESTASIS WITHOUT HEPATITIS

Bile duct injury may result from exposure to a number of compounds, particularly those that are concentrated in bile. The result of the damage is cholestasis due to debris from necrotic cells blocking the ductules.

Accidental contamination of food by industrial chemicals can lead to domestic hepatotoxicity. Epping jaundice occurred in the United Kingdom after contamination of flour by a leaking container of 4,4'-diaminodiphenylmethane (methylenedianiline).⁹ Similar injuries have been acquired occupationally with this chemical.²⁸⁵

Drugs that cause pure cholestasis are listed in Box 11-8.²⁸⁶⁻²⁹²

CIRRHOSIS

Cirrhosis is characterized by regenerative nodules (clumps of new cells) within fibrotic tissue (amorphous tissue) forming an irregular lobulated (defined) pattern. Any repetitive injury resulting in cell death (necrosis) followed by repair mechanisms may lead to cirrhosis. This happens because the liver has only a limited capacity to regenerate.²⁹³

BOX 11-7 DRUGS THAT CAUSE ACUTE CHOLESTATIC HEPATITIS IN THERAPEUTIC DOSES

Amoxicillin-clavulanic acid (can also get acute hepatocellular hepatitis)^{181,278,279}
 Azathioprine²⁸⁰
 Chlorpromazine²⁸¹
 Erythromycin²⁸²
 Flucloxacillin²⁸²
 Gold salts²⁸³
 Penicillamine²⁸

BOX 11-8 DRUGS AND TOXINS THAT CAUSE PURE CHOLESTASIS WITHOUT HEPATITIS IN THERAPEUTIC DOSES

Estrogens and oral contraceptives²⁸⁶
 Anabolic steroids²⁸⁷
 Cyclosporin²⁸⁸
 4,4'-methylenedianiline (Epping jaundice)^{289,290}
 Rapeseed oil-aniline (Spanish toxic oil syndrome)^{291,292}

The classic and most common agent that causes cirrhosis is ethanol.^{293,294} In addition, compounds that do not appear to cause acute necrosis, such as ethionine, may cause cirrhosis after chronic exposure.²⁹⁵

Other drugs or chemicals that have been reported to cause cirrhosis include ketoconazole, amiodarone, and floxuridine.²⁹⁶⁻²⁹⁹

The main problems with cirrhosis are portal hypertensive complications (i.e., variceal bleeding) and ascites, together with encephalopathy when the liver cell mass becomes insufficient to cope.³⁰⁰⁻³⁰³

VENO-OCCLUSIVE DISEASE

Rarely, a toxin may damage sinusoids and endothelial cells directly; for example, monocrotaline, a plant alkaloid, which is metabolized to a reactive molecule, causes damage and blockage of the venous return to the liver and secondary ischemic death of hepatocytes.³⁰⁴

DRUG- OR TOXIN-INDUCED HEPATIC TUMORS

Liver tumors may be benign³⁰⁵ (grow in situ) or malignant (able to metastasize to other tissues). They may arise from any cell type within the liver (e.g., adenoma,³⁰⁵ hepatocellular carcinoma [aflatoxin,^{306,307} dimethylnitrosamine,³⁰⁸ ethanol,³⁰⁹ hepatitis C³¹⁰], or hemangiosarcoma [vinyl chloride^{311,312}]).

Among the various mycotoxins (toxins produced by molds on nuts, oil seeds, and grains), the aflatoxins have been the subject of intensive research because they are potent carcinogens. Aflatoxin B₁ is a very reactive compound (Fig. 11-3). Its carcinogenicity is associated with its biotransformation to a highly reactive, electrophilic oxide, which forms covalent bonds, adducts with DNA, ribonucleic acid (RNA), and protein (see Fig. 11-3).^{306,307} Damage to DNA is thought to induce tumor growth. There may be species differences due to differences in biotransformation and susceptibility to the initial biochemical lesion.

Dimethylnitrosamine is evenly distributed throughout the body, but exposure to single doses causes centrilobular hepatic necrosis indicating that metabolism is an important factor in its toxicity.³⁰⁸ One metabolite is a highly reactive alkylating agent that methylates nucleic

FIGURE 11-3 Aflatoxin B₁.

acids and proteins. The degree of methylation of DNA *in vivo* correlates with the risk of tumor induction in those tissues.

Vinyl chloride (or vinyl chloride monomer) is the starting point in the manufacture of poly(vinyl chloride). Chronic exposure leads to a “vinyl chloride disease,” which includes skin changes, changes to the bones of the hands, and liver damage. Hemangiosarcoma is a tumor of sinusoidal cells (not hepatocytes) that also may result from chronic exposure to vinyl chloride.^{311,312} This again appears to occur because the epoxide intermediate and fluoroacetaldehyde bind to DNA and proteins respectively within the cell. Hemangiosarcoma has been associated also with arsenite exposure, although the mechanism is still unclear. It should be stressed that the experience in humans with carcinogenicity has not been replicated in animal models.

HERBAL AND PLANT CAUSES OF HEPATOTOXICITY

Hepatic impairment from use of conventional drugs is widely acknowledged but there is less awareness of the potential hepatotoxicity of herbal preparations. Plants and herbs are considered to be harmless and commonly are used for self-medication without supervision. However, many plants and herbs can cause severe hepatotoxicity, including acute and chronic abnormalities and even cirrhotic transformation and acute liver failure (Box 11-9).³¹³⁻³⁵⁶ This list probably represents the tip of an emerging iceberg.

The diagnosis of herbal hepatotoxicity often is delayed because patients may not readily give a history of their use of herbals, so it is important that a detailed history be taken of exposure to drugs (prescribed, over the counter, and illicit/recreational), chemicals, plants, and traditional medicines in all patients with hepatotoxicity. There has been reports of hepatotoxicity related to Chinese herbal medicine (CHM), including at least three cases of acute liver failure.³⁵⁷⁻³⁶⁴ As discussed below,

it can be difficult to identify the specific component of the CHM that is responsible for hepatotoxicity, but the genus *Paeonia* has been present in at least four cases of severe hepatotoxicity.^{357,359,361} Two studies have looked at the incidence of hepatotoxicity in patients taking these agents.^{362,363} In a review of 1265 patients taking CHM, one developed acute hepatitis and 106 (8.4%) developed an increase in ALT up to three times normal, which returned to normal in 95% of patients.³⁶² In a study of 1507 patients using CHM for chronic pain, 14 had a reversible increase in ALT greater than two times normal, the risk being greater with use of *glycyrrhizae radix* and *atractylodis macrophalae*.³⁶⁴ Prescriptions of CHM often contain up to 25 different ingredients, so if hepatotoxicity develops it can be difficult to identify which agent is responsible.

PRINCIPLES OF MANAGEMENT FOR DRUG- OR TOXIN-INDUCED LIVER DISEASE

General Management

Drug- or toxin-induced hepatotoxicity must be considered in the differential diagnosis of all patients presenting with a spectrum of disease that ranges from isolated deranged liver function tests in an otherwise well patient to acute liver failure. The degree and extent of liver injury should be monitored by serial prothrombin time estimations and liver function tests, including bilirubin, aminotransferases, alkaline phosphatase, and albumin. As discussed earlier it is important to exclude all other nondrug causes of liver disease. Liver biopsy should be considered if the extent of liver damage or etiology is in doubt. Accurate clinical assessment of renal function—that is, more than simply monitoring plasma urea and electrolytes—is also required.

Patients who develop hepatotoxicity must be advised to stop taking the drug or stop exposure to the toxin. Acetaminophen is the analgesic of choice for these patients, even if they are jaundiced.^{156,157} Meticulous supportive care is critical to good outcome. Systemic hypotension, which may reduce liver blood flow, should be avoided with judicious fluid and inotropic support.³⁶⁵

Hyperthermia, if present (e.g., MDMA hepatotoxicity), should be treated aggressively with cold fluids, but care should be taken to avoid provocation of hyponatremia due to antidiuretic hormone (ADH) release.^{366,367} The role of dantrolene is controversial.³⁶⁸ It acts to control calcium release at the sarcoplasmic reticulum and thus reduce “muscular” source of heat. However, hyperthermia from amphetamines or Ecstasy also is attributed to a central hyperthermic effect, and there is no evidence that dantrolene has any action on the central nervous system. There may be a role for specific 5-hydroxytryptamine (5-HT) drugs, such as cyproterone, to reduce central nervous system–induced hyperthermia.

The development of acute liver failure is characterized by cerebral edema, circulatory shock, coagu-

BOX 11-9 PLANTS AND HERBALS ASSOCIATED WITH HEPATOTOXICITY

Germander (*Teucrium chamaedrys*): The diterpenoids of the plant are transformed by cytochromes P-450 3A into hepatotoxic epoxide metabolites. Mixed hepatocellular and cholestatic or acute cholestatic hepatitis results. Several cases have occurred, mainly in France, Spain, and Canada.³¹³⁻³¹⁶

Pyrrrolizidine alkaloids: Use of plants that contain unsaturated pyrrrolizidine alkaloids (PAs), such as *Symphytum officinale* (comfrey), *Tussilago farfara*, *Heliotropium*, *Senecio*, and t'u-san-ci' (Compositae), is associated with hepatotoxicity due to veno-occlusive disease. This is due to the conversion of PAs to cytotoxic pyrroles, which damage hepatic sinusoidal and endothelial cells, resulting in ischemic damage and centrilobular necrosis. Liver failure can occur in the acute phase with mortality of 20% to 40%, but complete recovery is also reported. Chronic PA veno-occlusive disease has a poor prognosis.³¹⁴⁻³²³

Pennyroyal oil: Pulegone is the main component that has been shown to deplete hepatic glutathione. It is metabolized to menthofuran, which is directly toxic to hepatocytes. Both pulegone and menthofuran are metabolized via CYP2E1. Administration of N-acetylcysteine is recommended in all cases of ingestion of more than 10 mL of pennyroyal oil.³²⁴⁻³²⁸

Skullcap: Diterpenoid containing metabolite-mediated hepatotoxicity.³²⁹

***Teucrium polium*:** One reported case of acute liver failure requiring liver transplantation.³³⁰

Chaparral leaf (creosote bush, *Larrea tridentata*): Nineteen reported cases of hepatotoxicity (mixed-cholestatic hepatitis), occurring 3 to 52 weeks after ingestion, with resolution over 1 to 17 weeks in most patients. However, there have been two cases of acute liver failure with successful liver transplant and four cases of chronic liver disease progressing to cirrhosis.³³¹⁻³³⁴

Kava (*Piper methysticum*): There have been at least 22 cases of acute hepatitis, including 18 cases of acute liver failure. Generally, the hepatotoxicity settles within 8 weeks, but two patients with ALF have required liver transplantation. Liver histology shows extensive hepatocellular necrosis, and additional cholestasis was identified in two cases. In one report, two patients with kava hepatotoxicity were poor metabolizers of debrisoquine, and so it is possible that CYP2D6 deficiency may increase the risk of kava hepatotoxicity.³³⁵⁻³³⁸

Senna fruit extracts: Commonly used as laxatives and stool softeners. Metabolite rhein anthrane is thought to cause hepatotoxicity.³³⁹

Fruit of the cycad tree: Found on Guam, contains a potent hepatotoxin that can also lead to hepatic injury when eaten.³⁴⁰

***Senecio*, *Heliotropium*, *Crotalaria*:** More than 100 alkaloids have been identified and these cause centrilobular necrosis and veno-occlusive disease. The clinical picture is of relatively acute or subacute hepatic failure, with ascites, jaundice, and a mortality rate of 20%.³⁴¹

Camphor: Hepatitis.^{342,343}

Mediterranean glue thistle (*Atractylis gummifera*): Hepatic necrosis, possibly due to interference with hepatic ADP and ATP transport inhibiting oxidative phosphorylation and induction of the mitochondrial membrane permeability transition pore resulting in apoptosis.³⁴⁴

Impila (*Callilepis laureola*): The carboxyatractyloside component produces an acute illness with abdominal pain, vomiting, convulsions, and acute renal and liver failure (centrilobular necrosis) with profound hypoglycemia. Up to 63% patients die within 24 hours, with an overall mortality rate of 91% at 5 days.³⁴⁵

Cascara sagrada: Cholestatic hepatitis.³⁴⁶

Isabgol: Giant cell hepatitis.³⁴⁷

Venencapsan (horse chestnut leaf): Steatosis.^{348,349}

Prostata: Hepatic fibrosis.³⁵⁰

Ma Huang (*Ephedra* species): There have been two case reports of severe acute hepatitis in patients using ma huang for weight loss. However, the contents of the products were not formally analyzed to confirm botanical identity.^{351,352}

Jin Bu Huan: There have been 10 reported cases of acute hepatitis and one case of chronic hepatitis related to jin bu huang use. Levotetrahydropalmatine is the active agent and probably responsible for the hepatotoxicity, which developed at a mean of 20 weeks (range, 6 days to 52 weeks) in the reported cases. Liver biopsy in one case showed eosinophilic infiltrates and cholestasis.³⁵³⁻³⁵⁵

Greater celandine (*Chelidonium majus*): Ten reported cases of reversible mixed cholestasis-hepatitis within 3 months, one unintentional rechallenge resulting in a recurrence of hepatotoxicity. Commercial extracts of greater celandine contain more than 20 alkaloids and the toxic component has not been identified.³⁵⁶

lopathy, and renal failure, as well as liver failure with encephalopathy.³⁶⁹ Conservative management focuses on invasive hemodynamic monitoring and prevention of complications such as cerebral edema, infection, renal failure, and coagulopathy.³⁶⁹ A common cause of death from acute liver failure is cerebral edema due to raised intracranial pressure.³⁷⁰ Intracranial pressure may increase rapidly and waiting for clinical signs such as pupil abnormalities, bradycardia, or hypertension may result in brain death before treatment can be started. Therefore, intracerebral pressure monitoring ideally should be undertaken in all patients who fulfill liver transplant criteria.³⁶⁹ Controlled hypothermia has been proposed as a treatment for patients with acetaminophen-related acute liver failure.³⁷¹ Jalan and coworkers actively cooled (to 32°C–33°C) seven patients with acetaminophen-related acute liver failure and increased intracranial pressure unresponsive to

treatment with mannitol and ultrafiltration. All seven showed a decrease in intracranial pressure with cooling (from 45 mm Hg [25 to 49] to 16 mm Hg [13 to 17]).³⁷¹ In addition, in some reports, hypothermia associated with acetaminophen overdose appears to have provided additional protection by slowing metabolic activation of acetaminophen.^{372,373}

Specific Therapies

STEROIDS

The role of steroids in cases postulated to have an immune component has not been properly evaluated, although steroids probably have rationale in cases in which rechallenge with the drug produces significant hepatotoxicity.⁸³ Once a viral etiology has been excluded, a therapeutic trial with high-dose steroids (e.g.,

prednisolone 40 mg/day) is worthy of consideration in such patients.

N-ACETYLCYSTEINE

N-acetylcysteine (NAC; see Chapter 47) is used routinely for the management of early and late acetaminophen poisoning. Its mechanism of action is well understood in early poisoning, where it replenishes intracellular glutathione by acting as a cysteine donor.⁴⁵ In late acetaminophen poisoning NAC has been shown to alter cytokine concentrations, such as interleukin-1 and tumor necrosis factor.³⁷⁴⁻³⁷⁶ Chemopreventive properties of NAC include reduction of oxidized thiol groups in key enzymes that permits reestablishment of calcium homeostasis, which plays a key role in apoptosis.³⁷⁷ NAC blocks electrophiles and scavenges reactive oxygen species, and it can restore the capacity of the intracellular proteolytic system to degrade toxic arylated proteins.³⁷⁸ The catheter study by Harrison and coworkers reporting that NAC acts by hemodynamic action together with prostaglandin E₁ (PGE₁) to increase cardiac output, oxygen delivery, and utilization has recently been challenged.^{379,380} Using end-tidal CO₂ as a measure of oxygen uptake, Walsh and colleagues demonstrated that NAC administration alone did not lead to an increase in oxygen utilization.³⁸⁰ The increase in cardiac output seen was transient, lasting, at most, 20 to 30 minutes. Whether regional hyperemia in one or multiple circulations is likely to benefit patients with acute liver failure remains a critical but unanswered question.³⁶⁹

N-acetylcysteine also is used for CCl₄ poisoning,²²³ and it may have a role in amatoxin mushroom poisoning.²⁰⁷

LIVER TRANSPLANTATION

The role of liver transplantation in acute liver failure is controversial and emotive. Orthotopic or auxiliary liver transplantation has been performed successfully in patients with acute liver failure due to acetaminophen,³⁸¹ Ecstasy,^{83,382} NSAIDs (e.g., diclofenac),^{383,384} iron,³⁸⁵ *A. phalloides*,³⁸⁶ isoniazid,³⁸⁷ and many other drugs and chemicals.^{386,387}

In the United Kingdom, the presence of non-acetaminophen drug-induced acute liver failure is considered to be a poor prognostic feature. Association with two of the following four features is considered to be an indicator for emergency liver transplantation³⁸⁸: jaundice to encephalopathy developing over more than 1 week; age younger than 10 years or older than 40 years; serum bilirubin greater than 300 μM/L; prothrombin time greater than 50 seconds. Different criteria are used in the United Kingdom for transplantation for acetaminophen-induced liver failure.³⁸⁹ Ninety-two percent of patients whose peak prothrombin time exceeded 180 seconds died.³⁹⁰ Ninety-three percent of patients with an increasing prothrombin time between day 3 and day 4 died.³⁹⁰ In clinical practice, if a patient's prothrombin time starts to improve, full recovery occurs. The O'Grady criteria (arterial blood pH of less than 7.3 or H⁺ of more than 50 nmol/L or prothrombin time of more than 100 seconds and serum creatinine more than

300 μM/L in patients with grade III or grade IV encephalopathy) currently provides the best guide for when to transplant for acetaminophen poisoning in the United Kingdom.³⁹¹ It therefore follows that in the care of patients prior to transplantation it is important to avoid giving fresh frozen plasma (unless there is life-threatening bleeding), vitamin K, or sedative drugs.³⁹¹ Recently, the O'Grady criteria have been modified to include the post-resuscitation serum lactate concentration, and this has increased the sensitivity from 76% to 91%.³⁹² A threshold value of 3.0 mmol/L after resuscitation even when used alone has a sensitivity of 76% and a specificity of 97% in predicting nonsurvival.³⁹²

Contraindications to transplantation may vary between transplant centers, but in the United Kingdom they include HIV-positive status, acute alcoholism (i.e., delirium tremens), serious sepsis, acute intravenous drug abuse, serious chronic psychiatric illness associated with high risk of repeat suicide attempts, and extrahepatic malignancy.³⁹¹

A report of 7 years' experience of treating acetaminophen-induced liver failure at Kings College, London, found survival rate improved from less than 50% in 1987 to 78% in 1993.³⁹³ Meticulous supportive care and transplants were believed to be responsible, among other factors.

MOLECULAR ADSORBENTS RECIRCULATIONS SYSTEM

Water-soluble drugs can be removed by hemodialysis or hemofiltration. However, kinetically this method of elimination is unsuitable for protein-bound drugs. The molecular adsorbents recirculations system (MARS) offers particular promise in removal of highly protein-bound drugs and in the management of acute liver failure.³⁹⁴ Severe phenytoin toxicity has been successfully treated with the MARS system.³⁹⁵

A Acute Renal Failure

MIGUEL C. FERNÁNDEZ, MD

Acute renal failure (ARF) is one of the most common and serious consequences of poisoning or drug overdose. ARF is a clinical syndrome of diverse causes (Box 12A-1) in which a relatively sudden deterioration of renal function results in the inability of the kidneys to regulate normal homeostasis. Its importance stems from the acuteness and severity of the clinical manifestations that develop and the potential for reversibility of the condition, particularly if it is recognized early and the appropriate preventive and therapeutic measures are instituted promptly. ARF can be a self-limited condition and is one example of organ failure that is totally reversible and for which replacement therapy is available. Nevertheless, ARF is principally associated with a high mortality rate because of the seriousness of the underlying conditions that lead to its onset, which are in turn aggravated by the loss of renal regulatory functions.¹

Much of what we know about ARF was relatively recently elucidated.² Human activity has often led to infection, crush injury, dehydration, massive hemorrhage, and other causes of shock and tissue injury. Historically, acute anuria was attributed to obstruction or associated with edema, earlier known as dropsy. Nonobstructive suppression or retention of urine was termed *ischuria renalis* in the Age of Enlightenment, which came to be attributed to either inflammation or “paralysis of the kidneys.”³ In 1909, Osler classified ARF under the general heading of acute Bright’s disease. He described a broad and vague group of cases of ARF related to burns, other trauma, and the toxicants turpentine, potassium chlorate, and carbolic acid (phenol). Acute renal lesions that affected crushed or wounded soldiers were described in the German literature during and immediately after World War I.⁴ In 1923, Muir used the term *war nephritis* and others used the term *field* or *trench nephritis* in describing variations of ARF.⁵ Sporadic reports of ARF in traumatized civilians began to appear in the literature thereafter and were soon followed by reports of cases of ARF that ensued after prolonged, complicated, and infected surgical procedures.⁶ In 1926, Haas described his poorly accepted hemodialysis invention for treatment of uremia.⁷ In 1941 Bywaters, and Beall reported on four patients who sustained crush injuries during the bombing of London in the Battle of Britain and developed ARF, and although they did not make a clear etiologic connection, they made the first modern description of rhabdomyolysis.⁸ In 1945 nephritis following mite-borne rickettsial scrub typhus

infection was described by several researchers.^{9,10} Detailed studies of ARF developed during efforts to elucidate the mechanism of shock in battle injuries.¹¹ This, coupled with the further development of hemodialysis and renal replacement therapy by Kolff and Beck in 1944, led to a rapid expansion of knowledge about ARF, while hemodialysis became better accepted as further studies led to improvements of outcome in the 1950s.¹²⁻¹⁴ Literature in the 1960s concerning patients whose kidneys had failed because of the acute renal toxicity

BOX 12A-1 MAJOR CAUSES OF ACUTE RENAL FAILURE

Prerenal Failure

Extracellular circulating fluid volume contraction
 Gastrointestinal losses: vomiting, diarrhea
 Fluid sequestration: burns, pancreatitis, peritonitis, crush injury, venous ligation
 Renal losses: diuretics, diabetic ketoacidosis
 Blood loss
 Central or cardiac shock: congestive heart failure, myocardial infarction, tachyarrhythmias, central nervous system injury
 Septicemia: endotoxic shock
 Anoxia (requires salt depletion)

Postrenal Failure

Prostatic hypertrophy, tumors, calculi, blood clots, ureteral edema, retroperitoneal fibrosis, inadvertent ureteral ligation, papillary necrosis

Renal Failure

Primary damage to tubular epithelium
 Ischemia
 Nephrotoxic
 Drugs: aminoglycosides, methoxyflurane, cytolytic agents, phenytoin, cisplatin, bismuth, rifampin
 Radiopaque contrast agents
 Respiratory pigments: hemoglobin, myoglobin
 Poisons: heavy metals, carbon tetrachloride, animal toxins
 Intratubular precipitation: uric acid, myeloma proteins, mucoprotein, sulfas, calcium, xanthine, oxalate
 Primary damage to glomeruli and small renal vasculature
 Acute glomerulonephritis, collagen vascular disease, malignant hypertension, serum sickness, thrombotic microangiopathy
 Primary damage to major renal vessels
 Thrombosis, embolization, atheroembolism
 Parenchymal necrosis
 Cortical, papillary

of drugs and poisons emphasized removal through renal replacement therapy.¹³

Presently, ARF is classified into three general categories: that caused by renal hypoperfusion (prerenal), that caused by intrinsic parenchymal lesions of the kidneys (renal, or intrinsic), and that caused by obstruction of the urinary outflow passages (postrenal, or obstructive uropathy). These categories and their relative prevalence as a cause of ARF are shown in Figure 12A-1.

PATHOPHYSIOLOGY

The hallmarks of ARF are the onset of progressive oliguria and azotemia, typically over a period of hours to days, stemming from a sudden decrease in glomerular filtration rate (GFR) and leading to an acute rise in blood urea nitrogen (BUN) and serum creatinine (Cr) concentrations.¹⁵ Daily urine volume less than the volume necessary to excrete the waste products of the body is termed oliguria. Azotemia exists when the blood contains a higher than normal quantity of urea or other nitrogen-containing substances. Normal human kidneys are able to maximally concentrate the urine to 1200 mOsm/L of water. To maintain normal homeostasis, an adult must excrete about 600 mOsm of solute, with urea constituting 40% to 50% of this obligatory solute load. Therefore, the daily urine excretion necessary to maintain homeostasis is about 400 to 500 mL in an adult with normal renal function who is concentrating the urine maximally and consuming a normal diet, and

oliguria is said to be present if urine production is less than this amount. Normal daily urine output of 1000 to 1500 mL reflects the intake of water in excess of the amount necessary to maintain homeostasis, thus allowing the excretion of less concentrated urine. This is a desirable consequence since concentrating the urine maximally entails added work and energy consumption by the kidneys, rendering them more susceptible to injury.¹⁶

Urea excretion is diminished in individuals with low dietary intake of protein or in those unable to metabolize protein to urea (hepatic cirrhosis). Because urea constitutes half of the normal solute load, the daily urine output to maintain balance in these individuals is reduced to about 300 mL. By the same token, in individuals on restricted salt intake or patients whose kidneys are in a sodium retention state (congestive heart failure, nephrotic syndrome, hepatic cirrhosis), the urine output necessary to maintain balance is also reduced to the extent that the load of sodium excreted and, therefore, the amount of water obligated to it are now reduced. Conversely, in a hypercatabolic state (trauma, burn, or sepsis), when urea production is increased, or in conditions in which diuretics are used to inhibit sodium reabsorption, a proportionately larger urine volume is necessary to clear the solute load.¹⁷

Injured kidneys that are unable to absorb and maximally concentrate urine require a larger volume of water to excrete the daily load of solutes. Thus, in kidneys only able to concentrate urine to 600 mOsm, 1000 mL of urine would have to be excreted to maintain homeostasis, whereas in kidneys only able to concentrate to 300 mOsm, 2000 mL of urine would have to be excreted. This would be the case of chronically diseased kidneys, but much more important for purposes of this chapter is the situation in the early stages of acute renal injury. One of the first structural consequences of injured tubular cells appears to be a loss of the polar distribution of the sodium-potassium-adenosine triphosphatase (Na-K-ATPase) pump, with consequent impairment of the capacity to absorb filtered sodium and, hence, the subsequent natriuresis and inability to achieve medullary hypertonicity necessary to concentrate the urine maximally.^{1,18} The duration of this otherwise invariable phase of early acute renal injury varies, depending on the magnitude and severity of the insult to the kidneys. This stage when the urine output is high at a time that the GFR is declining has been termed nonoliguric ARF (Fig. 12A-2). Its early detection, by noting increasing BUN and Cr concentrations, is important because removal of the insult may prevent progression to oliguric ARF, with its graver prognosis.

In terms of laboratory values, ARF is commonly defined as an increase in Cr concentration of 0.5 mg/dL, an increase in BUN of 10 to 15 mg/dL, or an increase of more than 50% over the baseline levels of either one. The early identification of progressive incremental changes in BUN and Cr concentrations are key to making an early diagnosis of ARF.¹⁹ An acute reduction in the normal regulatory function of the kidneys can occur in the presence of reduced, normal, or high urine

**TABLE 12A-1** Range of Daily Urine Composition

		NORMAL	PRERENAL FAILURE	ACUTE RENAL FAILURE	
				OLIGURIC	NONOLIGURIC
Volume	(mL/24 hr)	300–1500	<400	<400	1500+
Urea	(g/24 hr)	20	15	5	10
	(mM/24 hr)	350	250	85	170
Creatinine	(g/24 hr)	1–1.5	>1.0	<1.0	<1.0
Sodium	(mEq/24 hr)	100	5	25	100
Potassium	(mEq/24 hr)	50–79	10	>50	>50

flow rates (Table 12A-1). The clinical jargon of “good urine output” is a misnomer that provides a false sense of security and should be abandoned.

TOXIC ACUTE RENAL FAILURE

Strictly defined, toxic ARF is acute tubular cell injury and ultimate acute tubular necrosis (ATN) due to dose-dependent direct cell damage caused by a toxic agent that is usually limited to a specific part of the tubule. More broadly defined, in the general context of ARF, the renal injury may be induced by a host of agents that exert a detrimental effect at various sites within the entire nephron by mechanisms other than direct cell injury and that are not necessarily dose dependent (Fig. 12A-3).^{20,21}

Injury due to exogenous poisons, such as mercuric chloride (HgCl_2), formerly the best-characterized form of toxic ATN, is now rare. Much of the ARF currently encountered is due to drugs,²²⁻²⁴ whose increased availability and wider use have been associated with a host of undesirable side effects. The kidneys as the principal organs for the excretion of drugs and their metabolites are particularly prone to their side effects. The renal factors that render the kidneys particularly susceptible to injury are listed in Box 12A-2. Volume depletion is extremely important to recognize and correct early, because the associated increase in renal vascular resistance and consequent ischemia is central to much of the

nephrotoxicity encountered in clinical practice.^{1,18,25} The nonrenal factors that contribute to increased drug-induced injury are listed in Box 12A-3. Clearly, the physician-related factors noted in Box 12A-3 can be circumvented. By the same token, of the patient-related factors, recognition of reduced renal function allows the physician to avert renal hypoperfusion and can prevent renal injury through appropriate adjustments of drug dosage and correction of volume depletion.

Furthermore, although strictly defined acute renal toxicity is a result of toxic effects on the renal parenchyma, several toxic agents exert their effect by causing impaired perfusion of the kidneys (prerenal) or their direct renal toxicity (renal) is magnified in the presence of reduced extracellular circulating fluid volume (ECFV). As such, it is essential to fully appreciate the sequence of events that characterize prerenal ARF.

PRERENAL FAILURE

Prerenal failure is usually present in patients with vascular collapse or circulatory insufficiency (see Box 12A-1). In their attempt to preserve ECFV, the kidneys sustain functional changes without demonstrable organic or structural damage (Fig. 12A-4). The most important of these is severe but reversible renal vasoconstriction with a preferential renal cortical hypoperfusion.²⁶ The resultant reduction in renal blood flow may be associated with reduced glomerular filtration and thus a decreased filtration of solute. In addition, a greater fraction of this filtrate (urea, water, sodium) is reabsorbed under the influence of volume-stimulated factors. Simultaneous stimulation of antidiuretic hormone secretion usually occurs in response to volume changes. Thus, the oliguria that results is associated with urine that is characteristically highly concentrated and low in sodium content. The azotemia that may be present is the result of increased reabsorption of urea and may develop in the absence of an actual decline in GFR. When renal circulation is restored, these patients respond with a prompt diuresis with correction of the azotemia and oliguria.²⁷ An important aspect of prerenal ARF is that it represents an earlier and reversible change in renal circulation that, if left uncorrected, may ultimately lead to organic renal damage (see Fig. 12A-2). At the very

FIGURE 12A-2 Changes in urine osmolality and sodium concentration during the various phases of acute renal failure.

least, it renders the underperfused kidneys much more susceptible to toxic injury.

Although this category of ARF may be identified by the usual accompanying signs of peripheral circulatory failure and low ECFV, the composition of the urine is the main clue to its diagnosis (see Figs. 12A-2 and 12A-4). The urine is characteristically low in sodium content (<10 mEq/L, fractional sodium excretion <1%) and high in concentration (urine osmolarity > 500 mOsm/KgH₂O).

A number of drugs exert their detrimental effects on the kidneys by inducing or aggravating prerenal ARF

(see Fig. 12A-3). Most notable among these are diuretics, whose injudicious and nondiscriminating use accounts for most cases of ARF in the hospital setting.^{27,28} A second and common cause is nonsteroidal inflammatory drugs (NSAIDs).^{28,29} By inhibiting cyclooxygenase, the principal enzyme in prostaglandin synthesis, NSAIDs deprive the kidneys of the protective vasodilatory prostaglandins and thereby aggravate any existing vasoconstriction and initiate a hemodynamically mediated ARF. This is usually a mild and reversible effect but on occasion results in severe oliguric ARF requiring renal replacement therapy.²⁹ Patients with preexisting ineffective ECFV and decreased renal perfusion (congestive cardiomyopathy, cirrhosis, sepsis, or diuretic therapy) or those with preexisting renal disease (nephrotic syndrome, chronic renal failure) are at risk for NSAID-induced ARF. A third group of drugs that inhibit the protective effect of efferent arteriolar vasoconstriction on maintaining GFR in the presence of reduced renal perfusion are the angiotensin-converting enzyme (ACE) inhibitors. The vasodilatory effect of these agents on the afferent arteriole is potentially salutary but essentially modest; by contrast, their effect on the postcapillary efferent arterioles is greater and results in a sudden decline in the glomerular intracapillary hydrostatic pressure (P_{GC}) necessary for filtration. Unless blood flow (Q_a) to the kidneys is increased by the afferent dilatation, the result is a sudden reduction in GFR. As is

the case with NSAIDs, the renal effects of ACE inhibition are usually modest and reversible but on occasion result in severe oliguric ATN necessitating renal replacement therapy.³⁰ The detrimental effect of ACE inhibitors is most evident in patients who have severe congestive cardiomyopathy, renal artery stenosis, or reduced ECFV; they are unable to compensate for the loss of P_{GC} by increasing Q_a . Given the role of diuretics in causing ECFV depletion, it is not unexpected that most cases of ACE inhibitor-induced ARF observed clinically are in patients who have severe congestive cardiomyopathy and who are diuresed aggressively. The combined nephrotoxic effect of NSAIDs and diuretics is associated with a several-fold increase in the development of ARF.³¹ Additionally, the use or abuse of medications and dietary or herbal supplements or drugs that either directly or indirectly lead to increased sympathetic tone, agitation, or muscle activity and heat production can lead to rhabdomyolysis and ARF.³²

Notable among the causes of prerenal ARF are those due to antihypertensive agents, which, even in the absence of decreased ECFV, induce a reduction in renal perfusion pressure that can result in ARF. Not unexpectedly, this is most evident in individuals who have accelerated or malignant hypertension and in whom the endothelial swelling caused by the preexisting severe hypertension results in a narrowed lumen with a high renal vascular resistance that requires high pressure

levels to perfuse the narrowed and constricted renal vasculature.³³ It is in these individuals that the sudden and severe reduction in the mean arterial blood pressure (>25 mm Hg) can result in the onset of progressive ARF, often necessitating renal replacement therapy. Hence, gradual titration of the blood pressure downward in slow increments is important in such cases, while monitoring renal function and maintaining adequate ECFV. Although the inducement of renal hypoperfusion may induce ARF, calcium channel blockers have been shown to protect against acute renal injury at both the vascular and tubular epithelial level in both ARF and chronic renal failure.³⁴

RENAL FAILURE

The broad definition of renal failure includes such diverse entities as acute glomerulonephritis, vasculitis, thrombotic microangiopathy, and papillary necrosis (see Box 12A-1). However, the vast majority of ARF cases encountered clinically are most commonly due to ischemia, nephrotoxic agents, or a combination of both (see Fig. 12A-1).^{24,35} The ultimate picture that results is that of ATN, although strictly defined this term may be a misnomer because the apparently necrotic cells that are excreted have been shown to be viable and to grow in vitro in cultures of tubular epithelial cells isolated from the urine.³⁶ Their shedding into the urine is one of the consequences of cell injury, rather than actual necrosis, which in addition to the loss of their polarity sustain a loss of cell wall integrins and a decomposition of their attachment to the basement membrane and to each other. This accounts for the loss of their anchorage and ultimate shedding into the urine.^{1,25,37} In addition to microscopic examination of the urine for tubular epithelial cells that are shed, analysis of the urine is extremely valuable in the diagnosis (see Figs. 12A-2 and 12A-4), showing a characteristically high sodium (>50 mEq/L, fractional sodium excretion > 1%) and literally isosmotic concentration (320 to 350 mOsm/kg of water).

Should the patient survive, in the absolute majority of cases regeneration of tubular cells sets in and restores renal function. The regenerative and repair process of the injured tubules is an early event that is activated at the very start of injury, culminates during the ensuing days, and results in the ultimate restoration of normal renal structure and function.^{38,39} The clinical course that ATN follows has been divided into four phases that correspond to the various phases of epithelial cell injury, necrosis, and regeneration. They are of variable duration and have considerable overlap.

Initial Phase

The initial phase is the period of ischemia or exposure to the nephrotoxic agent; it continues until oliguria develops (see Fig. 12A-2). The importance of identifying this phase stems from the fact that it represents a potentially reversible stage. Its length varies and depends largely on the causative agent (may last 5 to 7 days). In

general, an abnormal sediment (cylindruria), tubular proteinuria (β_2 -microglobulins), lysozymuria, and a renal concentrating defect precede by several days any decrease in GFR caused by nephrotoxic agents. Other tubular dysfunctions (renal glycosuria, tubular acidosis, sodium loss) may be detectable and should be sought.

The efficacy of prophylactic measures that on occasion are effective during this phase (mannitol, loop diuretics, dopamine) relates to their ability to increase renal blood flow and solute excretion. These measures may also have the capacity to convert oliguric to nonoliguric renal failure (see Fig. 12A-2 and Table 12A-1). As a rule, their efficacy in preventing ARF clinically is questionable.²⁴ On the other hand, prostaglandins have a protective role in the renal autoregulation that is associated with vasoconstricting insults. Inhibitors of prostaglandin synthesis (NSAIDs) or inhibitors of efferent constriction (ACE inhibitors), used during this phase, can accentuate the ischemia and precipitate oliguria.^{28-30,40}

Oliguric Phase

No single pathogenetic sequence appears to account for all the varieties of ATN and the development of oliguria. The balance of evidence favors the view that excessive backleak across the damaged tubular epithelium and tubular obstruction by the sloughed cells are important. Changes in glomerular permeability and filtration rate also appear to be contributing mechanisms.^{1,25} The degree of involvement of any of these potential pathogenetic mechanisms varies and depends on the nature, severity, and duration of the initial nephrotoxic insult.

Oliguria is present in 60% to 70% of cases encountered clinically; another 30% to 40% are diagnosed earlier and are associated with a nonoliguric ARF (see Fig. 12A-2 and Table 12A-1). The average duration of the oliguria is 1 to 2 weeks, and daily urine volume averages 150 mL. Anuria (urine output <50 to 75 mL/day) is uncommon. If oliguria continues for longer than 4 weeks, more likely diagnostic entities to rule out are cortical necrosis, acute glomerulonephritis, and vasculitis. The duration of oliguria is of some prognostic significance, with a longer duration portending a greater likelihood of complications and undesirable outcomes.

Diuretic Phase

The diuretic phase begins when the 24-hour urine volume exceeds 500 mL/day. Classically, at the onset of this phase, urine volume doubles on successive days until a volume of 2000 to 3000 mL is reached. This phase lasts from 7 to 14 days. With the onset of diuresis, the renal blood flow and GFR gradually increase. The urine is at first isosmotic and literally appears to be pure plasma filtrate. As the regenerating tubular cells recover some ability to reabsorb sodium and concentrate urea, the urine gradually contains less sodium and more urea than plasma. Thus, blood chemistry values do not begin to correct with the onset of the diuretic phase, and days may pass before these values begin to normalize. As

diuresis continues, however, the azotemia gradually diminishes. Factors contributing to the diuresis observed in this phase include (1) osmotic diuresis resulting from mobilization of the urea accumulated during the oliguric phase, (2) functional inadequacy of the regenerating tubular cells to reabsorb the glomerular filtrate and concentrate the urine, and (3) pushing intravenous fluids, because overzealous replacement of urine output maintains a patient in a continuous state of volume expansion. Thus, one ends up “chasing” the urine output by infusing gradually larger volumes of fluid.^{25,41}

Although apparently similar to nonoliguric ARF, the diuretic phase of ATN is a totally different entity in that unlike the increasing BUN and Cr of the former, the BUN and Cr levels gradually decline during the diuretic phase. Although the decrement is modest during the first few days, it gradually increases in pace as cellular function matures and the GFR is restored. It is important to remember that many drugs are still poorly excreted during the diuretic phase, and dosage adjustments may be necessary if further drug toxicity is to be avoided.

Convalescent Phase

BUN and Cr levels are usually normal within 5 to 60 days after the onset of the diuretic phase. GFR, however, increases more slowly and may be 70% to 80% of normal within months. The ability to elaborate a maximally concentrated urine will return but may take several months. The principal renal symptoms during this phase are nocturia and polyuria, which gradually subside as the ability to concentrate urine improves. As a rule, there is no convincing evidence of progressive renal disease in recovered patients.

Although urinary tract infection is common during the oliguric phase because of prior urethral catheterization, evidence of persistent chronic infection is rare.

TOXIC ACUTE TUBULAR NECROSIS

The principal agents associated with toxic ATN are listed in Box 12A-4. The exact incidence of nephrotoxicity for

BOX 12A-4	AGENTS ASSOCIATED WITH TOXIC ACUTE TUBULAR NECROSIS
	Antibiotics: Aminoglycosides, cephalosporin, amphotericin, vancomycin, pentamidine, sulfas, acyclovir, foscarnet, penicillin, tetracycline
	Antineoplastic agents
	Alkylating agents: Cisplatin, carboplatin, ifosfamide
	Antimetabolites: Methotrexate, ara-C, 5-fluorouracil, 5-azacitidine, 6-thioguanine
	Metals: Mercury, bismuth, cadmium, chromium, lead, gold, platinum, uranium, lithium
	Organic solvents: Ethylene glycol, diethylene glycol, carbon tetrachloride
	Miscellaneous: Radiocontrast agents, heroin, phencyclidine, cocaine, mannitol

any of these agents is not known, but the sequence in which they are listed parallels that with which they are encountered.^{23,24,28,33,42,43}

Antibiotics

Aminoglycosides are among the most widely prescribed antibiotics. Nephrotoxicity develops in 10% to 15% of persons who use these drugs and depends on the total dose, the duration of treatment, and the frequency of administration. These highly water-soluble agents are freely filtered and absorbed in the proximal tubule. It is their accumulation within the epithelial cells that accounts for their nephrotoxicity. The variations in degree of nephrotoxicity observed remain unexplained but have been attributed to a number of risk factors, such as age, gender, reduced renal function, volume depletion, potassium and magnesium depletion, and hepatic failure. As a rule, toxicity results in nonoliguric ARF, with recovery from mild renal failure if the drug is discontinued, but it can lead to oliguric ARF if the insult remains undetected and drug administration is continued. The role of monitoring drug levels to predict nephrotoxicity is equivocal because the antibiotic levels actually increase when nephrotoxicity is already established.^{42,44,45}

The increased availability of cephalosporins has been associated with an increasing incidence of reported cases of ARF, some of which are due to their nephrotoxic effect, particularly evident with use of cephaloridine, whereas others are a result of a hypersensitivity reaction and are due to acute interstitial nephritis.⁴⁶

The vast number of antibiotics used in the treatment of human immunodeficiency virus (HIV)-infected patients renders this group of patients particularly susceptible to toxic ATN.^{47,48} Incriminated agents include pentamidine, foscarnet, amphotericin, acyclovir, and sulfas. Approximately one third of patients receiving pentamidine and two thirds of those receiving foscarnet have clinical evidence of ARF due to tubular injury. By contrast, the sulfas and acyclovir exert their detrimental effect by intratubular precipitation, and amphotericin exerts its detrimental effect by complexing with the plasma membrane and increasing the cellular aqueous pores (see Fig. 12A-3). The latter accounts for the early polyuria and distal renal tubular acidosis, which with continued therapy result in a dose-dependent toxic ATN.^{24,33,42}

Antineoplastic Agents

The nephrotoxicity associated with antimetabolites is generally cumulative and chronic, although acute injury can result in the presence of severe volume compromise, excessive dosing, and multiple-drug use.⁴⁹ Cancer is the underlying disease in as many as one fifth of cases of ARF in some series, not because of the nephrotoxic effect of antimetabolites alone but rather because of the antimicrobials and analgesics used in their management. Yet another cause of ARF is that of acute massive tumor tissue necrosis, particularly in lymphoproliferative

disorders, with resultant acute urate nephropathy, a potentially preventable lesion with adequate hydration, alkalization of the urine, and inhibition of uric acid synthesis with prophylactic allopurinol.⁴⁹⁻⁵¹ Thrombotic microangiopathy is a rare cause of ARF that has been associated with mithramycin, cyclosporine, and 5-fluorouracil therapy.^{52,53}

Heavy Metals

Exposure to heavy metals is usually chronic in nature and results in various renal abnormalities that are primarily tubular in nature, ranging from proximal tubular dysfunction to oliguric ARF and chronic tubulointerstitial nephritis. Of the metals listed in Box 12A-4, mercuric chloride is the one that is most typically associated with toxic ATN, but this cause of toxicity has literally vanished. Uranium also gives rise to a toxic ATN that closely resembles that of mercuric chloride nephrotoxicity. A similar picture has been reported after excessive doses of bismuth and chromium.^{13,24} Lead exposure, such as lead stabilizers used plastics manufacturing, may lead to reversible azotemia or chronic toxicity,⁵⁴ and chronic environmental lead exposure, even at low levels, is associated with progressively impaired renal function.⁵⁵

Organic Solvents

Cases of accidental ingestion or attempted suicide with the antifreeze solution ethylene glycol are not rare. Oxalate, one of the metabolites of ethylene glycol, accounts for much of its nephrotoxicity owing to the intratubular precipitation of cytotoxic calcium oxalate monohydrate crystals that readily form in the presence of calcium (see Fig. 12A-3).⁵⁶ Diethylene glycol, an organic chemical solvent, causes tubular necrosis and recently was the cause of an epidemic of toxic ATN in children in Haiti. Carbon tetrachloride, another industrial solvent, causes direct, dose-dependent renal and hepatic toxicity, which is much less commonly encountered nowadays.^{13,24}

Biologic Agents

Animal venoms, including those from snakes and arthropods (particularly arachnids and hymenopterans), may cause both obstructive and toxic acute renal failure, in part due to hemolysis and rhabdomyolysis, resulting in the release of myoglobin and hemoglobin from myocytes and erythrocytes, respectively.^{57,58} Additionally, some infectious diseases, such as those caused by *Brucella* species and malaria infection by *Plasmodium* species, may also cause hemolysis and rhabdomyolysis leading to ARF.^{59,60} Myoglobin and hemoglobin dissociate into globin and heme as well as free iron, iron complexes, and reactive oxygen species. Globin can precipitate in the renal tubules, causing obstructive nephropathy, while heme causes direct damage to renal tubular cells, also known as pigment nephropathy. Oxygen radicals, iron, and hemoglobin itself may also play a role in the

cytotoxicity due to venoms or other toxins or toxicants.⁶¹

Many botanical species and some fungus species are associated with acute renal failure. Botanical nephrotoxins are found in medicinal herbs, both identified and misidentified, and in common edible plants such as djenkol beans (*Pithecolobium lobatum*, Southeast Asia) and medicinal herbs such as root of impila (*Callilepis laureola*, South Africa) and *uña de gato*, or cat's claw (*Uncaria* species, South and Central America, Asia).⁶²⁻⁶⁴ One of the most infamous cases of mistaken herbal medicine identification, poorly termed Chinese herbal nephropathy, occurred in Belgium in the 1990s. A weight reduction herbal preparation that was said to contain *Stephania tetrandra* and *Magnolia officinalis* actually contained at least one *Aristolochia* species herb that has been shown to be nephrotoxic and carcinogenic, and its ingestion resulted in an outbreak of rapidly progressive renal fibrosis among over 100 patients.⁶⁵

Mushrooms of several genera are associated with renal failure that may be caused by volume depletion or renal cytotoxicity. Species of *Amanita*, *Galerina*, and *Lepiota* containing the cyclopeptide amatoxin can lead to acute renal failure. Ingestion of *Cortinarius* species containing the toxin orellanine can cause latent toxicity with an onset of symptoms that may be from 2 to 21 days. In cases of amatoxin or orellanine poisoning, renal pathology includes tubular necrosis prominent in the proximal tubules with interstitial edema and no glomerular changes. In severe *Cortinarius* cases, renal tubular necrosis develops that may result in death several weeks after the poisoning in up to 15% of cases. Acute renal failure occurs in 30% to 55% of patients who may go on to develop chronic renal insufficiency and who may end up requiring long-term hemodialysis or renal transplant. Recovery is likely for most patients within a month to several months in less severe cases.⁶⁶

Amatoxin-containing species ingestion involves fulminant hepatic necrosis and carries a higher mortality rate. Whereas hemodialysis may be useful in severe mushroom-induced renal failure cases, plasmapheresis, hemofiltration, venovenous charcoal hemoperfusion, and hemodialysis have not been efficacious in treating cyclopeptide-induced hepatic failure.⁶⁷ Other *Amanita* species that do not contain amatoxin, *Amanita smithiana* (found in the Pacific Northwest), *Amanita proxima* (Europe), and *Amanita pseudoporphyria* Hongo (Japan), are also associated with delayed-onset acute renal failure that may be due to allenic norleucine by an unknown mechanism.⁶⁸ Venovenous charcoal hemoperfusion or hemodialysis may be useful in these cases.

OTHER FORMS OF PARENCHYMAL ACUTE RENAL FAILURE

Of the renal parenchymal forms of ARF, other than ATN, both acute interstitial nephritis (AIN) and acute glomerulonephritis can be a side effect of a number of drugs (see Fig. 12A-3). By far the more common of these two is that of AIN, which although first identified as being due to infection in the preantibiotic era is now

most commonly encountered with the very drugs used to treat infections.^{46,69}

The principal drugs that have been associated with AIN are listed in Box 12A-5. Unlike toxic ATN, AIN is not dose dependent, develops in only some individuals, and is usually associated with the classic findings of a hypersensitivity reaction (fever, eosinophilia, elevated immunoglobulin E levels) that are often transient and on occasion with eosinophiluria. The impairment in renal function begins with discrete abnormalities of tubular function and progresses to ARF. The renal failure is nonoliguric in the early stages of the disease and is usually accompanied by findings of tubular dysfunction (renal glycosuria, hypouricemia, and β_2 -microglobulinuria due to their decreased tubular reabsorption). If renal failure is undetected and administration of the incriminated agent continues, oliguric ARF ensues and is severe enough to require renal replacement therapy. Renal failure is more common in the elderly and more severe in those who become oliguric. In most, the renal failure is reversible and its course can be shortened by brief use (2 to 4 weeks) of steroid therapy. In some (10% to 15%) of those with severe renal failure, irreversible renal failure may persist.

Among the agents that produce AIN, that due to NSAIDs is unique in that it generally presents with renal failure that is accompanied by the nephrotic syndrome.⁷⁰ Oxidative stress and mitochondrial dysfunction occur in the kidney in response to these drugs, and these effects may be mediated by free radicals and activation of phospholipases.⁷¹ The onset after initiation of therapy with NSAIDs is usually longer than that observed with other agents and takes longer (months) to subside after discontinuation. In addition, no beneficial effect of steroids has been noted in cases of AIN due to NSAIDs.^{29,46}

Iodinated radiocontrast agents are a cause of acute renal toxicity. The injury that results ranges from modest tubular dysfunction, which may remain undetected, to severe ARF with ATN, which may require renal replacement therapy. In patients who sustain renal injury, the ARF is generally nonoliguric and develops within 2 to 4 days of the procedure, although a sudden onset of oliguric ARF can ensue on occasion. Proposed mechanisms of radiocontrast-induced ARF include renal ischemia due to intrarenal vasoconstriction, particularly in the presence of volume depletion, tubular obstruction, and oxygen-free-radical-mediated direct tubular

toxicity induced by iodinated contrast. Of the several predisposing factors incriminated, that of decreased ECFV, reduced renal function ($\text{Cr} > 2 \text{ mg/dL}$), diabetes mellitus, and total dose of radiocontrast agent injected are especially important. Adequate volume expansion with a brisk diuresis initiated before and maintained well after the procedure, coupled with use of *N*-acetylcysteine, and limitation of the dose of radiocontrast agents administered, is effective in circumventing the undesirable side effect of these agents.⁷²⁻⁷⁴ *N*-acetylcysteine may provide tissue protection through its antioxidative effects and by increasing intracellular glutathione concentrations.⁷⁵⁻⁷⁷

Rhabdomyolysis consequent to the overuse of many drugs, including sedative hypnotics and opiates and opioids, can result in ARF. Myoglobinuria and hyperuricosuria, due to muscle injury, in a setting of severely compromised ECFV account for the ARF that develops. Prompt recognition, with restoration of intravascular volume and alkalization of urine, can prevent progression to oliguric ARF. A similar picture can occur after overdosage with sympathetic stimulating drugs, such as cocaine, amphetamines, and phencyclidine or therapeutic use of gemfibrozil, particularly when used in combination with statin drugs.^{78,79}

Lithium can induce renal tubular acidosis resulting in polyuria, volume depletion, and water and electrolyte abnormalities. Severe lithium poisoning can lead to acute tubular necrosis and altered renal function, albuminuria, copper metabolism, and urinary enzyme abnormalities.⁸⁰

Other less common forms of ARF are due to glomerular lesions that result from a vasculitis that has been reported in association with the use of allopurinol, hydralazine, procainamide, penicillin, and sulfas. The thrombotic microangiopathy associated with certain antineoplastic agents has been mentioned. Finally, membranous glomerulopathy has been noted with the use of gold, penicillamine, and captopril.^{24,33,42}

TREATMENT

Renal replacement therapy has greatly simplified the management of ARF. Nevertheless, certain principles governing fluid and electrolyte management are important to monitor and correct in order to avoid the invasive nature of dialysis, when possible.^{20,81}

Prerenal Failure

Prompt recognition of the manifestations of prerenal ARF is extremely important.^{38,82} Prerenal ARF represents an early and reversible change in renal hemodynamics that if left uncorrected can lead to ATN. It is characterized by symptoms of peripheral circulatory failure (low blood pressure, rapid pulse, orthostatic hypotension, dry mucous membranes); urine that is low in volume, sodium content (<10 to 20 mEq/L), and fractional sodium excretion ($<1\%$) but highly concentrated (urine osmolarity $>500 \text{ mOsm/kg}$ of water); and rising levels of BUN and Cr (see Figs. 12A-2 and 12A-4).

BOX 12A-5 PRINCIPAL AGENTS ASSOCIATED WITH ACUTE INTERSTITIAL NEPHRITIS

Antimicrobials

Penicillins, cephalosporins, sulfonamides, rifampin

Nonsteroidal Anti-inflammatory Drugs

Propionic acid derivatives, others

Miscellaneous

Phenindione, phenytoin, thiazide diuretics, allopurinol, cimetidine

Apart from discontinuing drugs that aggravate the effects of decreased ECFV discussed previously (diuretics, antihypertensives, ACE inhibitors, NSAIDs), the principal effort should be directed at judiciously restoring ECFV.

If the diagnosis is in doubt in the presence of cardiac disease, direct measurement of pulmonary arterial wedge pressure may be indicated prior to initiating volume replacement. If no response to volume replacement therapy is evident, several therapies may be initiated, either alone or in combination, although each has potential risks and controversial benefits. Low-dose dopamine (0.5–2.0 µg/kg/min) has been advocated to enhance renal perfusion and diuresis. However, several clinical studies have shown questionable benefit and numerous potential deleterious multisystemic effects from dopamine therapy at even low doses despite the theoretical potential benefits in critically ill patients.^{83,84} Therefore, it is recommended that it should be used in this manner only after critical care specialist consultation. Although administration of mannitol (12.5–25 g) or furosemide after volume replacement may induce diuresis, whether or not this effect is renoprotective is controversial, as is their use in conjunction with dopamine. The salutary effect of these pharmacologic maneuvers is, at best, transient and equivocal, particularly once oliguric ARF is established.³⁹ In fact, mannitol itself can induce ARF.⁸⁵ If there is no observed response to their initial administration, their continued use would be contraindicated. Again, it is advised that these therapies be used with caution and in consultation with critical care specialists.

Renal Failure

During the initial phase of ARF, efforts to restore intravascular volume outlined for prerenal ARF should be continued. Appropriate antibiotics for coexistent infection or sepsis should be initiated at the full loading dose, but any subsequent dosing should be modified for a GFR of less than 20 mL/min until this usually reversible phase is actually reversed or its progression to oliguric ARF is ruled out. The use of potentially aggravating and nephrotoxic agents (NSAIDs, ACE inhibitors, antihypertensives, diuretics) should be avoided and the use of radiocontrast agents minimized and restricted to those that are absolutely essential for a definitive diagnosis.

During the oliguric phase of ARF, in well-managed cases without serious complications, the BUN level rises 10 to 20 mg/dL per day and Cr level 0.5 to 1 mg/dL per day. In hypercatabolic patients (trauma, rhabdomyolysis), Cr concentration may increase by more than 2 mg/dL per day. In patients without complications, plasma potassium values can increase by 0.5 mEq/L per day; in catabolic states, it may increase by as much as 1 to 2 mEq/L in hours. Weight losses of 0.2 to 0.5 kg/day are expected because of catabolism; in complicated hypercatabolic states, weight loss may be 1 kg/day. Hypocalcemia (6 to 8 mg/dL) is common, reflecting hypoalbuminemia, hyperphosphatemia, and skeletal resistance to parathyroid hormone.

Water replacement should be restricted to a volume equivalent to urine volume plus extrarenal losses (gastric suction, diarrhea, wound drainage). Insensible losses (800 mL/day) should be restored by 400 to 500 mL of fluid only, because endogenous water production is 300 to 400 mL/day. Water requirements increase in the presence of high ambient temperature, fever, and low relative humidity. Adequate fluid replacement can best be monitored by the following:

1. Daily weight measurement. ARF is a catabolic state, and a daily weight loss of 0.5 kg or 1 pound should be expected. Any weight gain can represent only excess fluid administration.
2. Measuring serum sodium concentration. An increase in serum sodium level (>145 mEq/L) would indicate insufficient water replacement, whereas a decline in serum sodium level (<135 mEq/L) would reflect excess water replacement.

The administration of *sodium chloride* should be restricted once the initial volume replacement during the prerenal ARF or the initial phase of ARF has been accomplished. The guiding principles of sodium chloride replacement are as follows:

1. Body weight losses in excess of 300 g/day in the presence of a normal serum sodium level should be replaced, 1 mL of isotonic saline for each gram of weight loss.
2. Gastrointestinal losses, wound drainage, and estimated sequestered fluid require replacement with isotonic sodium chloride.
3. If acidosis develops, salt losses should be replaced with sodium bicarbonate. Available forms of sodium bicarbonate are concentrated (7.5% NaHCO₃) and hypertonic (890 mOsm). They must not be administered as a bolus or added to isotonic saline solution. They should be restored to isotonicity in glucose or half normal saline solution.

Potassium intake must be restricted. Small deficits need not be replaced. Hypokalemia, unless severe (<3 mEq/L), should not be corrected. Hyperkalemia, if present, can be best treated with correction of acidosis and with sodium polystyrene sulfonate ion exchange resin (Kayexalate, Sanofi-Aventis, Bridgewater, NJ; Kionex, Paddock Labs, Minneapolis, MN; Marlexate, Marlex Pharmaceuticals, Inc., Newcastle, DE). The exchange resins are most effective when used as retention enemas. Hyperkalemia is always an indication to consider dialysis.

Caloric requirements (30 kcal/kg body weight per day) must be met to avoid increased catabolism. In the presence of sepsis, surgery, or burns, the usual caloric requirements are increased by as much as 50%. Caloric intake can be given as glucose (20% to 70%) and fat emulsions (10% to 20%). Any protein given should consist of high-biologic-value essential amino acids and should not exceed 0.5 g/kg of body weight per day.

The potential for upper gastrointestinal bleeding is high in ARF. H₂-receptor blocking agents should be used.

Antacids, if used, represent added loads of aluminum and calcium. The use of magnesium-containing antacids is contraindicated.

Dialysis should be started early and performed daily. Continuous renal replacement seems to have a distinct advantage in the dialysis management of these patients.⁸⁶ The dialysis bath should be adjusted to the level of serum potassium and should be bicarbonate based. Convincing evidence for the advantage of biocompatible membranes in ARF has been presented.⁸⁷ Dialyzers used should have a biocompatible membrane.

The onset of the diuretic phase requires continued vigilance. Dialysis must be continued through this phase until predialysis BUN levels begin to diminish well below 100 mg/dL and patients have no problems with elevated potassium levels. The serum sodium level must be monitored by measurements of body weight and sodium concentration as outlined for the oliguric phase. Although urinary losses must be replaced, pushing fluids must be avoided. This can best be accomplished by replacing urine output no more frequently than every 8 to 12 hours, depending on the previous urine volume, in order to avoid the continued overexpansion of ECFV that is often present. It is unusual for patients to have urine volumes greater than 3 to 4 L/day during this phase unless too much fluid is being administered. It is important to remember that renal function remains compromised, and many drugs are still poorly excreted during the diuretic phase. Dosage adjustment should remain in effect if drug toxicity is to be avoided.

B Chronic Renal Toxicity

MICHAEL W. SHANNON, MD, MPH

Chronic renal toxicity may be defined as a persistent and progressive functional and structural defect in the kidneys. This chapter addresses those drugs and toxins that cause renal injury over a period of months to years. Nephrotoxins that cause acute renal dysfunction are discussed in Chapter 12A; common causes of drug-induced acute renal failure are listed in Box 12A-1. Common causes of chronic renal toxicity are listed in Box 12B-1 and have been reviewed in recent articles.¹⁻³

Chronic renal failure is commonly classified as prerenal, intrinsic, or postrenal, depending on the underlying pathophysiologic etiology.⁴ Prerenal dys-

function is typically the result of renal hypoperfusion, produced by conditions including hypovolemia, low cardiac output, and renal vasoconstriction. Prolonged hypoperfusion can secondarily lead to intrinsic renal injury. Drugs and toxins can produce primary intrinsic injury, for example, by precipitating within renal cells or the tubular lumen. Postrenal dysfunction is commonly the result of obstruction (e.g., myoglobin precipitation) and rarely the primary result of drugs or toxins.

CLINICAL PRESENTATION

The diagnosis of chronic renal toxicity is based almost exclusively on a decrease in renal function. Unlike acute renal failure, in which urine output may abruptly decrease, chronic renal toxicity is by nature insidious and clinically difficult to recognize.

A decrease in renal function is determined by the measurement of serum creatinine concentration. Serum creatinine determination is most informative when considered in the context of total body muscle mass and gender. Serum creatinine is derived from the metabolism of creatinine in muscle and therefore reflects total muscle mass. Dietary meat intake also affects serum creatinine but to a lesser extent. Parenthetically, serum creatinine concentration can be artifactually elevated by acetone, cephalosporins, and other drugs when measured by the Jaffe reaction.⁵⁻⁷ Moreover, drugs can increase serum creatinine concentration without alterations in overall renal function via other means; cimetidine can significantly reduce renal tubular secretion of creatinine, without alterations in glomerular filtration or other aspects of renal function.⁷

Creatinine is eliminated from the body predominantly by glomerular filtration, with a small contribution from renal secretion. Cockcroft and Gault first proposed an empirical formula that uses serum creatinine value (in mg/dL) to assess glomerular filtration rate (GFR) (Equation 12B-1):

$$\text{Creatinine clearance} = (140 - \text{age}) \times \text{Weight in kg} / 72 \times \text{Scr}$$

Their formula is as accurate a determinant of GFR as the more arduous procedure of 24-hour urine collection for creatinine clearance determination.^{1,4,8} Note that this equation for predicting GFR includes a term for age, representing age-associated changes in renal function. For women, the result is multiplied by 0.85. GFR decreases by approximately 1 mL/min per year after the age of 40 years. However, the serum creatinine value does not concomitantly increase with age because of the almost equivalent decrease in muscle mass. Using the Cockcroft-Gault equation yields a more accurate

BOX 12B-1 COMMON CAUSES OF CHRONIC RENAL FAILURE

Nontoxicologic

Chronic interstitial nephritis
 Metabolic (hypercalcemia, hypokalemia)
 Hematologic/oncologic (multiple myeloma)
 Diabetic nephropathy
 Glomerulonephritis
 Hereditary renal disease (polycystic kidney disease)
 Hypertensive nephrosclerosis
 Ischemic nephropathy
 Obstructive, reflux nephropathy

Toxicologic

Analgesics
 Angiotensin-converting enzyme (ACE) inhibitors
 Angiotensin II receptor blockers

Antimicrobials

Acyclovir
 Ceftriaxone

Immunosuppressives

Cyclosporine
 Tacrolimus (FK-506)

Lithium

Chemotherapeutic agents

Cisplatin
 Carboplatin
 Chloroethylnitrosoureas
 Metotrexate
 Interferon- α

Drugs of abuse

Heroin
 Cocaine

Environmental and occupational toxins

Lead
 Cadmium
 Mercury
 Tobacco smoke

estimate of renal function than does serum creatinine determination. Some form of renal disease should therefore be suspected when the GFR is less than the age-appropriate value.

The differential diagnosis of chronic renal failure is extensive (see Box 12B-1). The four most common causes of chronic progressive renal disease are diabetes mellitus, hypertension, glomerulonephritis, and polycystic kidney disease. Therefore, chronic renal disease due to drugs and environmental toxins represents a small subset of the large population of such patients. Patients with chronic renal toxicity generally have the histologic lesion of chronic interstitial nephritis, a description that is also useful as a disease category. Compared with patients having other categories of chronic renal failure, those with chronic interstitial nephritis tend to have low-grade proteinuria (<1.5 g per 24 hours), urinary sediment with few cells or casts, infrequent or mild hypertension, preserved or increased urine volume with a tendency toward sodium wasting, elevated uric acid level, hyperchloremic metabolic acidosis, and anemia disproportionately severe for the degree of renal failure. These abnormalities are a consequence of injury to renal epithelial cells throughout the nephron.

Proximal tubule cells reabsorb filtered sodium, chloride, bicarbonate, glucose, calcium, phosphate, amino acids, and low-molecular-weight proteins, and secrete organic anions. Proximal epithelial cell injury

can therefore result in impaired reabsorption (increased urinary excretion) of these substances. Fanconi's syndrome is the clinical term for defective proximal tubule dysfunction resulting in urinary loss of these substances. Distal tubule epithelial cells secrete hydrogen ions and potassium. Injury to these cells may lead to metabolic acidosis and hyperkalemia. Collecting tubule epithelial cells are responsible for concentrating the urine by water reabsorption. Injury of these cells produces nephrogenic diabetes insipidus, which in minor form may be manifested simply as an increase in urine volume and urinary frequency.

Epithelial cell injury also leads to the appearance in urine of proteins that are normal cellular constituents, mainly brush border membrane and lysosomal proteins. Alanine aminopeptidase, alkaline phosphatase, γ -glutamyl transpeptidase, *N*-acetylglucosaminidase, and β -galactosidase may appear; these have been proposed as markers for identifying early or mild renal injury before the occurrence of a detectable reduction in GFR.

A CLINICAL APPROACH TO PATIENTS WITH CHRONIC RENAL FAILURE

A useful guideline for the clinical approach to patients with increased serum creatinine concentration (or a decrease in GFR) is shown in Figure 12B-1. The presence

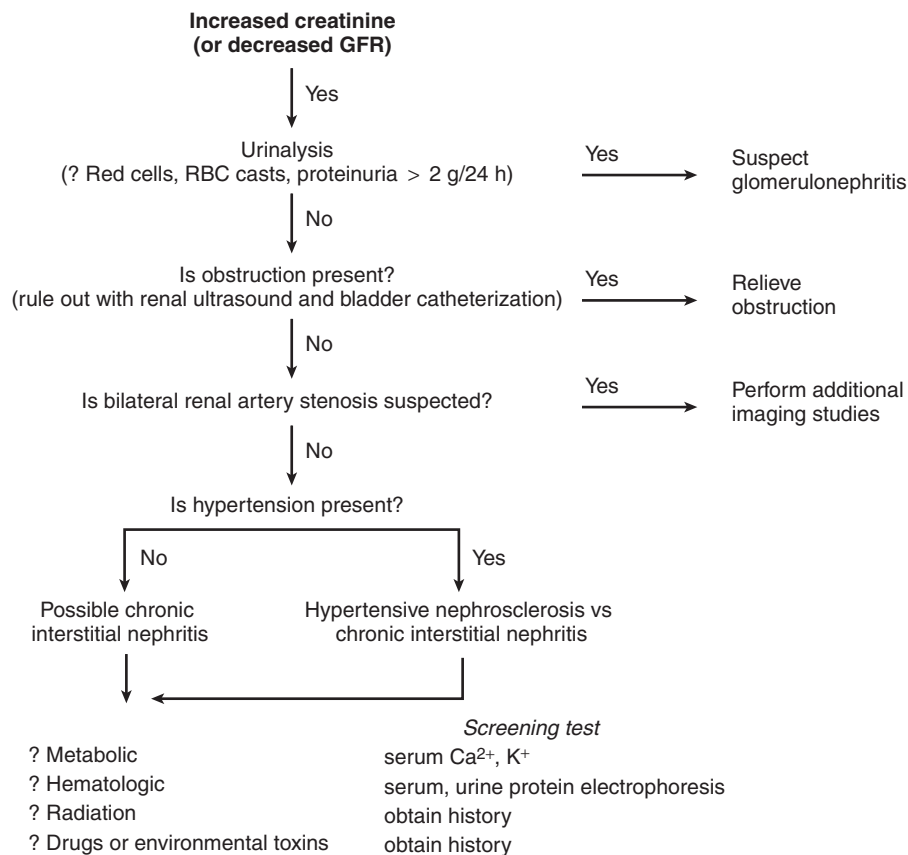

FIGURE 12B-1 Approach to the patient with chronically decreased renal function. GFR, glomerular filtration rate; RBC, red blood cell.

of numerous red blood cells or red blood cell casts should lead one to suspect glomerulonephritis. Similarly, urinary protein in excess of 2 g per 24 hr is more characteristic of glomerular disease than chronic interstitial disease. The possibility that the renal disease is caused by multiple myeloma or another monoclonal gammopathy can be ruled out by serum and urine protein electrophoresis and immunofixation. If a patient has an unremarkable urinalysis result, the possibility of obstruction should be ruled out with bladder catheterization and renal ultrasonography. In patients with diffuse atherosclerosis or risk factors for atherosclerosis, the possibility of bilateral renal artery stenosis should be considered. Metabolic factors should be considered when chronic interstitial nephritis is diagnosed. At a minimum, the serum potassium and calcium levels should be measured.

Investigation for toxicologic causes of chronic interstitial nephritis should be initiated first by careful history taking of drug ingestion (prescription, over-the-counter drugs, and alternative remedies⁹; see Box 12B-1), and assessment for environmental exposure, including occupational and nonoccupational exposures. In many cases of chronic renal toxicity, it is not possible to firmly establish a toxicologic origin, although the circumstantial evidence may be very convincing.

No unique pathophysiologic process is responsible for the development of chronic renal toxicity. Therefore, disease-specific descriptions are most informative.

THERAPEUTIC AGENTS

Nonsteroidal Anti-Inflammatory Agents

EPIDEMIOLOGY

Nonsteroidal anti-inflammatory drugs (NSAIDs) have long been suspected to be a cause of chronic renal disease.⁹⁻¹² The full impact of NSAIDs on renal function is unknown because it is typically difficult to accurately measure their use over long periods.⁹ Most studies have suggested that a cumulative intake of more than 1 to 3 kg of an NSAID is required to produce chronic renal disease. Therefore, clinical disease would not be recognized until a patient had consumed large daily doses of NSAIDs for several years. Conservative estimates are that between 1% and 3% of patients with end-stage renal disease in the United States have “analgesic” nephropathy. Throughout the world, a striking variation is noted in the incidence of analgesic nephropathy, with areas of greater frequency being found in Belgium, Australia, Scotland, and Switzerland.^{9,12}

NSAIDs are commonly divided into conventional agents (e.g., aspirin, acetaminophen, naproxen, and ibuprofen) and cyclooxygenase-2 (COX-2) inhibitors. All NSAIDs inhibit cyclooxygenase. However, conventional NSAIDs possess the theoretical disadvantage of inhibiting both COX-1 and COX-2. COX-1 is generally associated with the production of prostaglandins responsible for beneficial, homeostatic body functions; for example, COX-1 appears to play a key role in maintenance of the

integrity of the gastric mucosa. In contrast, COX-2 produces the prostaglandins that most directly mediate inflammation. NSAIDs and COX-2 inhibitors both markedly decrease production of renal prostaglandin E₂ (PGE₂). PGE₂ has a number of functions, including dilation of the renal bed. Inhibition of PGE₂ is associated with reductions in renal blood flow, along with other adverse effects. Consequently, conditions associated with decreased circulating volume (e.g., congenital heart failure and cirrhosis) can further compromise renal blood flow, placing patients at greater risk for developing NSAID- or COX-2-associated renal failure. COX-2 inhibitors are significantly less likely than NSAIDs to produce renal injury. Moreover, some NSAIDs (e.g., sulindac) are less nephrotoxic than other NSAIDs, presumably because they have less effect on PGE₂ and PGI₂.

Phenacetin was the earliest recognized nephrotoxic NSAID. Because of its association with renal disease, it is no longer marketed. Phenacetin was linked not only to the development of renal disease but also to hypertension, cardiovascular disease, and cancer. In a 20-year prospective study of women who were identified as regular users of phenacetin, the relative risk for death due to urologic or renal disease was 16.1.¹³

Acetaminophen, the major metabolite of phenacetin, is another NSAID associated with the development of chronic interstitial nephritis and renal failure. In a case-control study of subjects hospitalized with a new diagnosis of chronic renal disease, the odds ratio of end-stage renal disease was 3.21 when daily users of acetaminophen were compared with infrequent users.¹⁴ Another case-control study using a similar experimental design found the odds ratio of end-stage renal disease to be 2.1 for subjects who took 366 or more acetaminophen pills for a year, compared with those who consumed fewer than 104 pills per year.¹⁵ This study further estimated that between 8% and 10% of all cases of end-stage renal disease were attributable to acetaminophen use.

PATHOPHYSIOLOGY

NSAIDs can produce chronic interstitial nephritis and papillary necrosis. Although nephritis typically resolves after discontinuation of NSAID use, it occasionally becomes chronic. The precise mechanism of analgesic injury is unclear but probably includes effects produced by the analgesic's toxic metabolite. Acetaminophen accumulates in the renal medulla and papilla, where it is further metabolized by conjugation or oxidation.^{9,12} Conjugation is the usual mechanism of metabolism, although under toxicologic conditions oxidation predominates. Acetaminophen oxidation is catalyzed by cytochrome P-450 and results in generation of the free radical intermediate *N*-acetyl-*p*-benzoquinone imine. Acetaminophen can also be deacetylated to yield *p*-aminophenol, which is then oxidized by cytochrome P-450 to *p*-benzoquinone imine. Glutathione preferentially reacts with these metabolites to protect intrinsic renal macromolecules. When renal glutathione is depleted, renal injury occurs. This proposed mechanism is similar to the mechanism proposed for acetaminophen-induced liver injury.

NSAIDs can also produce important electrolyte disturbances. For example, because NSAIDs both inhibit renin secretion and compete with aldosterone for binding sites, hyperkalemia can occur in those who chronically use NSAIDs. This effect can become life threatening in the elderly or those with preexisting chronic renal disease.

CLINICAL PRESENTATION

Analgesic nephropathy occurs more frequently in women than men. The prototypical patient is one who has suffered chronically from headache or low back pain. Some of these patients also have chronic gastrointestinal symptoms caused by chronic use of NSAIDs. The majority of patients have consumed a mixture of analgesic agents rather than drugs of a single category.

An early sign of analgesic-produced renal insufficiency is impaired renal concentrating ability; patients may also have sterile pyuria. During episodes of papillary necrosis, patients can have flank pain, pyuria, and hematuria. Acute ureteral obstruction may result, and necrotic papillary tissue is often passed in the urine. Intravenous pyelography reveals the characteristic ring sign, which is actually contrast agent surrounding the sloughed papilla. Renal ultrasonography reveals small, irregularly contoured kidneys with irregular thinning of the renal cortex. Past papillary necrosis produces triangular papillary calcifications.¹⁶ The presence of papillary calcification on computed tomography is probably the most sensitive indicator of analgesic nephropathy (Fig. 12B-2).¹⁷ On renal biopsy, the kidneys have interstitial infiltrates and fibrosis.

Long-term use of analgesics also increases the risk for developing transitional cell carcinoma of the urinary collecting system and bladder.^{18,19} This risk may continue

FIGURE 12B-2 Analgesic nephropathy. This computed tomography (CT) scan demonstrates papillary calcification characteristic of analgesic nephropathy. Calcifications appear as triangular, ringlike, or polygonal calcifications on the papillary line. Other CT findings in analgesic nephropathy include a decrease in renal volume and irregular contour. (From Elsevier MM, De Schepper A, Corthouts R, et al: High diagnostic performance of CT scan for analgesic nephropathy in patients with incipient to severe renal failure. *Kidney Int* 1995;48:1316; reprinted with permission of Blackwell Scientific.)

even after cessation of analgesic use. Therefore, hematuria that develops in a patient with a history of chronic analgesic abuse should prompt a thorough search for bladder and collecting system tumors.

OUTCOME AND TREATMENT

The natural history of analgesic nephropathy is often the development of end-stage renal disease. Renal function may stabilize in patients who discontinue analgesic use or switch to a nontoxic drug, even when they already have substantial renal impairment. Once chronic renal insufficiency has developed as a result of analgesic use, any additional NSAID, even one unlikely to cause chronic interstitial nephritis (e.g., aspirin) may impair renal function.

Antimicrobials

Several antimicrobials, particularly antibiotics and antivirals, are associated with both acute and chronic renal injury (see Box 12B-1). What many of these agents have in common is the ability to produce “crystal nephropathy.”^{9,11} The most common members of this group include acyclovir, sulfadiazine, and indinavir. Volume contraction is an important contributor to the development of crystal nephropathy, making conditions such as diarrhea, nausea/vomiting, ascites, or heart failure high-risk preexisting conditions when these drugs are administered. Specific agents are discussed earlier in this chapter.

IMMUNOSUPPRESSIVES

Cyclosporine

EPIDEMIOLOGY

With the widespread use of cyclosporine as an immunosuppressant agent in solid organ transplantation, bone marrow transplantation, and immune-mediated diseases, it has become apparent that chronic renal disease is an unavoidable consequence of long-term cyclosporine use.^{9,20,21} The incidence and severity of cyclosporine-mediated renal disease are debated and depend in large part on the dose of cyclosporine administered and the presence of other risk factors for impaired renal function. However, even in patients without preexisting renal disease, long-term use of cyclosporine results in depressed glomerular filtration and renal blood flow and a high incidence of hypertension. In some patients, these renal effects are reversible as soon as use of the drug is discontinued. In other patients, however, structural injury that is not immediately reversible occurs. Among this latter group of patients, some may develop progressive renal insufficiency; others maintain stable renal function for a number of years.

PATHOPHYSIOLOGY

Acute administration of cyclosporine causes selective renal vasoconstriction in both experimental animals and humans.^{9,22} Renal vasoconstriction causes a decrease in

renal blood flow and a consequent decrease in GFR. While these effects are immediately reversible, they occur repeatedly in patients after administration of each dose of cyclosporine. Multiple mediators for renal vasoconstriction have been proposed and include activation of the sympathetic nervous system, with participation of endothelin as a second messenger, alterations in the balance of vasoconstrictor and vasodilator prostaglandins, and activation of the renin-angiotensin system.

The relationship between acute and chronic nephrotoxicity after cyclosporine use has not been clarified. It is likely that recurrent or persistent vasoconstriction causes chronic ischemic injury of the kidneys; chronic cyclosporine-related nephropathy is characterized by the same physiologic alterations of reduced renal plasma flow and GFR as well as by the development of histologic indicators of chronic renal injury. Both preglomerular and glomerular vessels are involved, as is the renal parenchyma. Cyclosporine arteriopathy is characterized by arterial hyalinosis and, in severe cases, myocyte degeneration and thrombosis of the arteriole (Fig. 12B-3). Glomerular injury is characterized by focal segmental sclerosis. Renal parenchymal disease is characterized by tubular atrophy and interstitial fibrosis, which is often described as patchy or striped in appearance (Fig. 12B-4).²³

Arteriopathy and interstitial fibrosis have been reproduced in rodents after administration of cyclosporine for

2 to 4 or more weeks. In rodents, salt depletion markedly enhances the development of these lesions. The earliest vascular change observed was eosinophilic granular transformation of smooth muscle cells in the glomerular afferent arterioles.²⁴ The renal parenchymal lesion of interstitial fibrosis is preceded by tubular and interstitial cell proliferation and macrophage infiltration.²⁵ Increased accumulation of type I and type IV collagen eventually results in fibrosis.

CLINICAL PRESENTATION

Cyclosporine produces a number of adverse effects, including neurotoxicity, hypertrichosis, and gingival hyperplasia, but its most common and severe complication is chronic nephrotoxicity.^{9,26} Renal dysfunction often appears in the absence of other problems and is recognized only by an increase in serum creatinine values. Cyclosporine toxicity has no other specific renal or clinical markers, although 60% to 100% of patients also develop hypertension. Chronic cyclosporine toxicity is associated with the use of higher doses of cyclosporine (>5 mg/kg per day) and may be more common in patients who have had episodes of acute nephrotoxicity.^{27,28} Attempts to correlate the development of chronic nephrotoxicity with blood levels of cyclosporine or its metabolites have largely been unsuccessful. The diagnosis of chronic cyclosporine nephrotoxicity is usually made when all other potential contributing factors have been

FIGURE 12B-3 Acute cyclosporine arteriopathy is characterized by focal smooth muscle degeneration (*large arrows*) and mucoïd intimal thickening (*short arrows*). Note the loss of smooth muscle cells in the lower right quadrant of the vessel on the left. *Inset*: Chronic cyclosporine arteriopathy. The myocytes are replaced by hyaline deposits that protrude toward the outer aspect of the media.

FIGURE 12B-4 Interstitial fibrosis resulting from cyclosporine toxicity. Bandlike “striped” areas of fibrosis and tubular atrophy are seen between the arrows. This interstitial fibrosis is not fundamentally different from that seen with other causes of chronic nephrotoxicity.

eliminated and renal function remains impaired. Functional and pathologic involvement may be dissociated, and some patients with well-preserved renal function have shown arteriopathy and interstitial fibrosis on renal biopsy.²⁹

OUTCOME AND TREATMENT

The long-term outcome of chronic cyclosporine nephrotoxicity is unclear. Initial reports of cardiac transplant recipients receiving high doses of cyclosporine suggested that long-term administration of cyclosporine resulted in the development of end-stage renal disease that necessitated the use of dialysis in a substantial portion of patients.^{23,30} Many other studies, however, have suggested that after the initial decrease in GFR, renal function stabilizes for many years.^{9,31,32} Some have cautioned that despite stabilization in renal function, progressive glomerulosclerosis and interstitial fibrosis may occur and may ultimately result in further impairment of renal function and possible development of end-stage renal disease.

Most would agree that cessation of cyclosporine use leads to stabilization or improvement in renal function. However, many patients being treated with cyclosporine do not have this option (e.g., heart or liver transplant recipients). Avoiding high doses of cyclosporine is recommended but must be balanced against the possibility that too low a dose may result in ineffective immunosuppression with partial loss of therapeutic efficacy. When cyclosporine use can be discontinued in patients with severe nephrotoxicity, eventual improve-

ment may occur. Even severe cyclosporine arteriopathy has been observed to reverse with discontinuation or lowering of the dose of cyclosporine.³³ Various renal vasodilators have been demonstrated to reduce the acute vasoconstriction induced by cyclosporine; calcium channel blockers improve renal blood flow and GFR in patients receiving long-term cyclosporine therapy.³⁴⁻³⁸ However, it is not known whether these agents can prevent the development of chronic renal disease in patients exposed to cyclosporine for prolonged periods.

Tacrolimus

Tacrolimus produces chronic renal failure via the same mechanism as cyclosporine, that is, by producing renal vasoconstriction.

Lithium

Lithium is an effective and frequently prescribed drug for the treatment of bipolar affective disorders. Unfortunately, lithium has a number of important effects on renal function. These include nephrogenic diabetes insipidus, renal tubular acidosis, and chronic interstitial nephritis.³⁹ Demonstrable defects in the renal concentrating ability occur in more than half of patients taking lithium, with clinically significant polyuria occurring in approximately 20%. Lithium induces nephrogenic diabetes insipidus through several cellular effects. The most important effect of lithium is to impair generation of cyclic adenosine-3',5',-monophosphate in the collecting

tubule of the distal nephron in response to antidiuretic hormone. This defect results in a failure to reabsorb filtered water adequately, and the result is water wasting, hyperosmolality, and secondary polydipsia. Although this defect usually responds to discontinuation of lithium therapy, some patients clearly have persistent nephrogenic diabetes insipidus for months or even years after cessation.⁴⁰

Despite the clinical concern and evidence that long-term administration of lithium leads to interstitial nephritis and decreased GFR, this has been a very difficult subject to rigorously investigate. Early data were retrospective and biased toward patients who came to medical attention because of renal functional abnormalities. Renal biopsies of a number of these patients showed tubular atrophy and interstitial fibrosis.⁴¹ However, the attribution of these lesions to lithium was questioned because similar renal histologic changes have been observed in patients who have never received lithium.⁴² At least one prospective study has demonstrated no difference in renal interstitial fibrosis between psychiatric patients taking lithium for more than 5 years and those who had never received the drug. Nevertheless, prospective studies have suggested an increased incidence of impaired GFR in lithium-treated patients, and a number of well-documented case reports describe patients who had normal baseline renal function yet progressed to end-stage renal disease after long-term therapy with lithium.^{3,11,43,44} The incidence of severely impaired renal function in patients receiving lithium is probably low, and it is reasonable to assume that maintenance of serum lithium levels in the therapeutic range would minimize the risk for progressive renal damage. Patients who demonstrate progressive renal insufficiency while receiving lithium should discontinue the drug.

CHEMOTHERAPEUTIC AGENTS

Chloroethylnitrosoureas

The nitrosoureas, including carmustine and streptozocin, are used against a number of malignancies. Long-term administration of these agents frequently produces renal dysfunction.^{4,9} The risk for renal injury correlates strongly with the cumulative dose. Common signs of nitrosourea-associated nephrotoxicity include increased serum creatinine concentration and proteinuria. Renal dysfunction can progress despite discontinuation of the drug. In addition to causing intrinsic renal injury, some nitrosoureas (e.g., carmustine) can produce (pre)renal injury as a result of systemic hypotension.

Cisplatin

Cisplatin (*cis*-diamminedichloroplatinum) has activity against various solid tumors and is frequently used in combination chemotherapy. Its toxicities include myelosuppression and renal dysfunction. Cisplatin can produce both acute renal failure and chronic interstitial

nephritis; Fanconi-type tubular dysfunction may also occur, producing salt and magnesium wasting.^{4,9,11}

Cisplatin is largely protein bound and is actively taken up by renal cells; it remains in the kidneys for weeks after intravenous administration. Both antitumor and nephrotoxic properties are dependent on the stereoisomer, because *trans*-dichlorodiammineplatinum has no toxicity. Cisplatin produces focal acute tubular necrosis with tubular dilatation and interstitial edema, but spares the glomerulus. Although doses in excess of 100 mg/m² have caused acute renal failure, a more typical presentation with cumulative administration is the slow progressive rise in creatinine levels. Magnesium wasting, a consequence of impaired tubular reabsorption, may be severe, resulting in hypomagnesemia as well as hypokalemia and hypocalcemia.⁴

Vigorous hydration is important in reducing acute and probably chronic nephrotoxicity. Carboplatin has similar nephrotoxicity; however, nephrotoxicity appears less frequently with this drug.

Methotrexate

Methotrexate is a widely used chemotherapeutic agent. Among its adverse effects is renal injury.⁹ Both acute renal failure and chronic insufficiency are associated with methotrexate. Acute renal failure is often the result of tubular necrosis secondary to crystallization of drug and metabolite in the renal tubules (although other mechanisms are suspected).⁴ Because methotrexate solubility in renal tubules is pH dependent, with greater solubility in alkaline urine, urine alkalinization is commonly provided before high-dose methotrexate administration.

ENVIRONMENTAL AND OCCUPATIONAL TOXINS

Lead

Adults may be continually exposed to lead through a number of routes. For example, exposure may occur occupationally, for example, in smelting and refining, casting of battery plates, welding, or petroleum distillation. Painters and plumbers are at particular risk for lead exposure. Although now relatively rare, consumption of moonshine made in improper containers or the use of pottery glazed with lead-containing glazes is another source of lead poisoning.

Acute lead poisoning results in proximal tubular dysfunction or Fanconi's syndrome. Long-term exposure leads to hyperuricemia (saturnine gout), hypertension, and chronic renal failure. The pathologic lesion of lead nephropathy is chronic interstitial nephritis.^{9,45-47} End-stage renal disease may not develop until 20 or 30 years after exposure, and thus it has been difficult to implicate lead in specific cases of renal failure of unclear etiology.⁴⁸ About 5% of patients undergoing hemodialysis have elevated bone lead concentrations.⁴⁹ In a cross-sectional study in Belgium, an inverse correlation was found

between blood lead concentrations and creatinine clearance.⁵⁰

Severe chronic lead intoxication can often be treated by long-term chelation therapy with EDTA. Improvement in GFR has been reported in patients who have minimal reductions in GFR. However, patients with advanced chronic renal failure do not usually demonstrate improvement after chelation.

Lead-poisoned children develop subclinical but important renal disease; they are at six to seven times greater risk for developing hypertension as adults than less exposed children.⁵¹

Cadmium

Cadmium is a potent nephrotoxin. Industrial workers may develop chronic renal disease by inhalation exposure to cadmium. The general population may be exposed to cadmium from prevalent sources such as environmental tobacco smoke. Much like lead, cadmium intoxication results in Fanconi's syndrome and chronic interstitial nephritis.^{9,52} Workers with high-level industrial exposure develop reductions in GFR and increased urinary excretion of various enzymes such as β_2 -microglobulin and *N*-acetyl- β -glucosaminidase.^{9,53} Normally, β_2 -microglobulin undergoes glomerular filtration and is then reabsorbed by proximal tubule epithelial cells. Increased excretion of this protein generally suggests impaired proximal tubule function. *N*-acetyl- β -glucosaminidase is a lysosomal enzyme; increased urinary excretion of this protein suggests chronic cellular injury. Another hallmark of cadmium-induced renal toxicity is the appearance of metallothionein in urine.⁵⁴ Metallothionein is closely linked with cadmium nephrotoxicity; synthesized by the liver in response to cadmium exposure, metallothionein, often referred to as an endogenous chelator, binds to cadmium delivering the heavy metal to the proximal renal tubules. The cadmium-metallothionein complex is nephrotoxic, presumably via deposition in the lysosomes of the proximal renal tubules.⁹

Treatment of cadmium nephropathy consists of elimination of exposure. As is true of all forms of chronic renal disease, however, if renal function is already moderately impaired, progressive dysfunction may continue even when the initiating factor is withdrawn.

Mercury

Mercury is toxic to the proximal tubule. Severe exposure can produce acute, severe tubular necrosis. However, low-dose exposures can also result in injury to the proximal tubules.

INTRODUCTION AND IMPORTANCE

The gastrointestinal (GI) tract provides a key interface between the body and the environment. Symptoms of GI disturbance such as nausea, vomiting, or a change in bowel habits are common complaints, especially in the acute care setting where the diagnosis of “gastroenteritis” is frequently entertained. Of concern, these seemingly benign complaints could either represent acute exposure to life-threatening intoxicants or herald the onset of a serious adverse drug effect. In fact, most drugs have the potential to cause GI tract disturbances at toxic doses or in susceptible individuals. For that reason, it is important to differentiate common medical or surgical conditions from serious intoxicant-induced gastrointestinal disease. In certain ways, the GI tract is uniquely resistant, but in other ways it is extremely vulnerable to certain poisons. A discussion of certain structural and functional aspects of the GI tract will provide a basis for understanding the effects of a wide range of intoxicants on this system and its subsequent response to exposure.

GI TRACT STRUCTURE, FUNCTION, AND REGULATION

The GI tract comprises the mouth, salivary glands, esophagus, stomach, small and large intestines, pancreas, liver, and gallbladder. Functionally, it is characterized by the highly specialized performance and regulation of several critical processes, such as water absorption, nutrient digestion and extraction, and immune surveillance. The GI tract also plays a role in metabolizing and eliminating some xenobiotics through cytochrome P-450, glucuronyl transferases, and sulfotransferases located within small and large intestinal cells.¹ These metabolic processes are discussed in greater detail in Chapter 5. As the largest neuroendocrine organ, the GI tract is directly connected to the vascular and lymphatic systems and indirectly linked with many other systems.

Functional Regulation

PEPTIDES

Gastrointestinal functions are regulated through a complex interplay of neural, hormonal, and paracrine mediators. Five key peptide hormones are responsible for much of this regulatory effect.² They are secretin, gastrin, cholecystokinin (CCK), gastric inhibitory peptide (GIP), and motilin. Secretin stimulates biliary and pancreatic aqueous and bicarbonate secretion. Gastrin stimulates secretion of gastric acid, whereas GIP inhibits gastric acid secretion and stimulates insulin release. Motilin stimulates motility of the upper GI tract. CCK

stimulates pancreatic aqueous, bicarbonate, and enzyme secretion and gallbladder contraction, in addition to inhibiting gastric emptying and signaling the termination of eating.³ These five key hormones are located in endocrine cells scattered throughout the GI tract mucosa and are released into the general circulation in response to chemical triggers in food, neural activity, or physical distention. Somatostatin and histamine have important roles as paracrine agents, that is, once released from endocrine cells they locally diffuse to their target tissue. The former inhibits gastrin release and the latter potentiates parietal cell secretion of gastric acid.

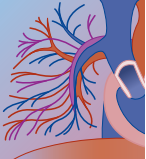

NERVES

Autonomic innervations both intrinsic and extrinsic to the GI tract regulate its functional responses. Input from these systems is further modulated by the central nervous system (CNS). Extrinsic nerves are distributed through both parasympathetic and sympathetic autonomic pathways. The sympathetic nervous system provides for the stimulation (contraction) of sphincteric muscle and relaxation of nonsphincteric muscle. Parasympathetic innervation via the vagus, splanchnic, and pelvic nerves stimulates (contracts) nonsphincteric muscle.⁴ Intrinsic neural pathways comprise the “enteric nervous system” and are grouped into plexuses along the entire length of the GI tract. The myenteric Auerbach’s plexus is located between the longitudinal and circular smooth muscle layers and controls peristalsis. The submucosal plexuses predominantly control secretion and absorption. Within these intrinsic pathways, acetylcholine is the major excitatory neurotransmitter, acting at the M₂ and M₃ muscarinic receptor subtypes.⁵ Other less ubiquitous intrinsic neurotransmitters also mediate important digestive functions. Nitric oxide and vasoactive intestinal peptide (VIP) have major inhibitory roles in this regard.⁶ Other agents function as neurocrines (i.e., they are located in intrinsic neurons, released near target tissue, and diffuse a short distance across synaptic gaps to stimulate or inhibit the release of other hormones or paracrines). Such stimulatory neurocrines are serotonin (5-HT) through 5HT₄ receptors, substance P in the myenteric plexus, and gastrin releasing peptide (GRP), which mediates the vagal release of gastrin. Finally, leu- and met-enkephalins bind to μ opioid receptors on circular smooth muscle and mucosal cells to slow transit and inhibit glandular secretion.^{7,8}

Structure

SALIVARY GLANDS

Functionally, saliva initiates digestion, exhibits antibacterial action, and provides lubrication for food passage. Saliva is produced in large volumes, is hypotonic, and

contains high concentrations of potassium. Digestive enzymes present in saliva include α -amylase and lingual lipase. Interestingly, salivation is triggered by both the sympathetic and parasympathetic branches of the autonomic nervous system and can be a manifestation of either cholinergic or sympathomimetic intoxication. Salivation is inhibited by fatigue, fear, sleep, and dehydration and stimulated by conditioning, smell, taste, and nausea.²

ESOPHAGUS

The function of the esophagus is strictly one of motility—to propel food from the oropharynx to the stomach. The nonkeratinized stratified squamous epithelial cell lining of the esophagus provides a protective coating of cells for the underlying tissue. Mucus secreted from superficial glands at the levels of the cricoid cartilage and the esophagogastric junction provides a protective and lubricant surface to facilitate the passage of food. No digestion or absorption takes place here, since the process of swallowing takes only seconds. The average volume swallowed by a child is 9.3 mL and by an adult 14 to 21 mL.⁹ Swallowing can be initiated voluntarily but proceeds as an involuntary reflex under the control of the brainstem.

STOMACH

The epithelial architecture and cellular makeup of each region of the stomach is distinct. The first portion distal to the gastroesophageal junction, the cardia, is composed of columnar epithelium and mucous cells. The body and fundus have a similar epithelial framework with the addition of parietal cells, chief cells, and endocrine cells. The parietal cells secrete hydrochloric acid and intrinsic factor, necessary for vitamin B₁₂ absorption. The chief cells contain pepsinogen granules, precursors of the proteolytic digestive enzyme pepsin. The endocrine argentaffin cells secrete serotonin and histamine. The pyloric antrum occupies a triangular area in the distal fifth of the stomach where gastrin-secreting (G) cells are found. Gastric contractile activity and emptying are highly regulated processes under the influence of the vagus nerve, motilin, and CCK. Gastric emptying also involves feedback inhibition from small intestinal receptor-mediated responses to osmotic pressure, hydrogen ions, and fatty acids. The stomach is capable of directly absorbing un-ionized lipophilic molecules of moderate size.¹

The H⁺ concentration in gastric juice is 3 million times greater than that in blood or tissue. The toxicologic significance of this fact is that agents which disrupt the integrity of the gastric mucosa (ethanol, caustics) allow for back-diffusion of hydrogen ions, potentiating the initial injury. Hydrochloric acid is secreted into the gastric lumen by parietal cells through an adenosine triphosphate (ATP)-dependent process. This process is blocked by omeprazole, a proton pump inhibitor that concentrates selectively in parietal cells and noncompetitively inhibits the H⁺/K⁺-ATPase. (A related drug, lansoprazole, binds the H⁺/K⁺-ATPase at the parietal cell surface.¹⁰) Acid secretion is regulated by three primary endogenous chemicals: acetylcholine, gastrin, and

histamine.¹⁰ Acetylcholine released from either vagal efferent or intrinsic nerves at the site of the parietal cell causes direct stimulation of acid secretion, an effect that is potentiated by histamine. Gastrin also causes direct stimulation of acid secretion, and its effects are also potentiated by histamine. Gastrin is most highly concentrated in the antrum, although appreciable amounts are also found in the epithelium of the duodenal bulb. Histamine is abundantly present throughout the gastric mucosa, originating from mast cells and basophils. It is hypothesized that histamine constantly sensitizes the parietal cells to other stimuli. The development of histamine-2 (H₂) receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) has clarified this potentiating role of histamine in gastric acid secretion.¹⁰ For example, in the setting of H₂ receptor antagonist use, acid secretion in response to other stimuli, such as gastrin or caffeine, insulin-induced hypoglycemia is inhibited. Of note, proton pump inhibitors are more potent blockers of acid secretion than are H₂ receptor antagonists.

PANCREAS

The exocrine pancreas is a grapelike clustering of acinar glands drained by ductules that ultimately converge to form the pancreatic duct. Through this duct, pancreatic secretions enter the proximal duodenum. Interspersed among the pancreatic acini are islets of Langerhans, or the endocrine pancreas, which produces insulin, glucagon, and somatostatin. Acinar cells manufacture, store (as zymogen granules), and secrete enzymes essential for digestion. These include proteases such as trypsinogen, chymotrypsinogen, proelastase, and carboxypeptidases as well as amylase and lipases. Enzymes are admixed with a large volume of aqueous solution containing sodium and bicarbonate. Pancreatic exocrine secretion is influenced by CCK, secretin, and extrinsic parasympathetic and sympathetic neurons, which are stimulatory and inhibitory, respectively. Specifically, enzymatic secretion from acinar cells is controlled by vagal input and CCK. The primary stimulant of aqueous pancreatic juice secretion is secretin, the effects of which are potentiated by both CCK and acetylcholine. Luminal pH of less than 4.5, dietary fat, and amino acid content are the main triggers of pancreatic exocrine response, stimulating vagal activity, CCK, and secretin release. These triggers potentiate each other through second messengers. Of toxicologic significance, pancreatic injury of sufficient magnitude to decrease enzyme secretion by more than 80% of baseline will result in steatorrhea.

GALLBLADDER

Bile is secreted by the liver as a complex mixture of bile acids, phospholipids, cholesterol, bile pigments, electrolytes, and water. These compounds form mixed micelles that facilitate the digestion of dietary lipids. During fasting, bile is stored and concentrated in the gallbladder. In the fed state, the gallbladder contracts, mostly in response to CCK, expelling bile into the duodenum. Bile acids are then enterohepatically recirculated, with 90% reabsorbed in the small intestine. The remainder reaches the colon, where additional absorption occurs,

but ultimately 0.3 to 0.6 g is lost in the feces daily. The bile acids, chenodeoxycholic acid and deoxycholic acid, have intrinsic cathartic properties. Diarrhea is therefore a serious consequence of bile salt malabsorption from ileal disease and is a potential side effect during chenodeoxycholic acid therapy for the dissolution of cholesterol gallstones.

SMALL INTESTINE

The small intestine comprises the duodenum, jejunum, and ileum. It is highly proliferative, with an abundance of undifferentiated cells, rendering this portion of the GI tract particularly susceptible to toxic exposure, particularly the effects of mitotic inhibitors or irradiation. Its extensive surface area results from an estimated 25 million finger-like projections called *villi*. The surface lining of these villi, the *brush border*, carries out the major function of the small intestine—digestion and absorption of nutrients. Movement of luminal contents is dependent on segmental (mixing) and peristaltic (aboral transit) contraction, both under the coordination of myenteric nerves, motilin, CCK, and gastrin.

Virtually all food enters the GI tract in polymeric form and requires enzymatic hydrolysis to monomers that can be absorbed by specific transport systems. Some key digestive enzymes originating from the salivary glands, gastric chief cells, and pancreas are discussed above. In the small intestine, luminal degradation of food continues primarily through brush border enzyme activity. In humans, these enzymes are all hydrolases, including disaccharidases, peptidases, phosphatases, and others. Substrate is hydrolyzed outside the cell, so at least some part of the protein faces the external surface of the membrane. The surface exposure of these enzymes renders them susceptible to damage not only by ingested drugs and poisons but also by infectious organisms, foreign antigens, and pancreatic proteases. In fact, the proteolytic digestion of these surface enzymes accounts for their rapid turnover and short half-life, in some cases only 4 to 6 hours. Therefore, the maintenance of activity of some brush border enzymes requires several cycles of protein synthesis during the approximately 5-day life span of small intestinal cells.

Absorption of dietary nutrients follows their digestion from polymers to monomers. Complex starches are digested to hexoses, proteins to dipeptides and amino acids, and vitamin complexes to free vitamins. These monomers are then absorbed by specific carrier-mediated mechanisms. Sodium-dependent active transport systems have been described for glucose and galactose, amino acids and peptides, pteroylglutamate, vitamin C, biotin, bile salts, riboflavin, thiamine, and other water-soluble organic substrates. Most mineral absorption occurs in the small intestine, the best studied being calcium and iron. Calcium is absorbed by both active (duodenum) and passive (jejunum and ileum) processes. Iron is absorbed in the proximal duodenum via a divalent metal transporter. Heme iron is readily absorbed by endocytosis. Other metals may also be absorbed by active transport methods in the intestine. While the exact mechanisms for lead absorption are unknown, it is suspected to follow calcium and iron pathways. Lead

absorption is assumed to involve both active and passive transport. Children are known to absorb more lead partly on the basis of their higher calcium absorption efficiency compared with adults, induced by increased calcium demand. Furthermore, iron deficiency will increase lead absorption. It is hypothesized that the sodium gradient across the intestinal absorptive cell membrane is the driving force for active transport. Lithium is a readily absorbed substitute for sodium in the intestinal cells. The carrier systems for these nutrients most likely are integral proteins situated in the lipid membrane of the brush border. As with the surface orientation of brush border digestive enzymes, their external orientation poses susceptibility to toxic injury from ingested poisons.

Lipids do not appear to require a membrane protein for absorption. After dietary neutral fat (triglycerides) is digested to long-chain fatty acids and monoglycerides by pancreatic lipase, the monomers as well as cholesterol are solubilized in bile salts to form micelles. (Orlistat is a synthetic derivative of lipstatin that forms an inactive acyl-enzyme complex with lipase and prevents fat absorption.) Long-chain fatty acids, monoglycerides, and cholesterol are absorbed by diffusion when the molecules by chance collide with the absorptive cell membrane. Fat absorption then is diminished by factors that interrupt the formation of micelles or alter the absorptive membrane.

As described above, the intestinal mucosa is a rapidly proliferating epithelium susceptible to injury by chemicals. Breaks in the mucosal barrier following exposure to intoxicants perturb critical absorptive and secretory transport properties and predispose to infection and systemic illness. Minor mucosal breaches are repaired by “epithelial restitution,” a process independent of cell proliferation. Restitution is regulated by a variety of cytokines and growth factors and is modulated by integrin-dependent interactions with the extracellular matrix. Restitution also involves intracellular signaling pathways that remodel the actin cytoskeleton. Deeper injuries require additional reparative mechanisms involving nonepithelial cells, angiogenesis, and scarring.¹¹

COLON

The colon comprises several anatomically distinct regions: the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. The epithelial lining differs from that of the small bowel in that villi are absent; therefore, the absorptive surface is flat. Like the small intestine, however, the epithelium is highly proliferative, posing susceptibility to toxic insult. Primary colonic functions include (1) absorption of water and electrolytes, (2) secretion of potassium, and (3) storage and discharge of luminal contents. The absorption of metals and toxins from the colon is thought to be minimal.

Each day, the colonic epithelium is confronted by about 1500 mL of water, 200 mEq of sodium, 5 mEq of potassium, 120 mEq of chloride, and 60 mEq of bicarbonate. A normal stool contains about 100 mL water, 5 mEq sodium, 9 to 13 mEq potassium, 2 mEq chloride, and 3 mEq bicarbonate, thus indicating the net

absorption of water, sodium, chloride, and bicarbonate and the net secretion of potassium. Various factors alter colonic fluid and electrolyte movement such as luminal pH, osmolality, and the presence of ions (bile acids, sulfates, hydroxy fatty acids). Additionally, colonic water and electrolyte movement are under the influence of hormones such as aldosterone, 9 α -fluorohydrocortisone, and antidiuretic hormone. The storage and discharge functions of the colon depend on its motor activity, which is regulated by intrinsic and extrinsic nerves, gastrin, and CCK. Aboral movement of contents is a slow process usually taking days.

TOXIC EFFECTS ON THE GI TRACT

Diseases of the Mouth

Excessive salivation can be caused by both cholinergic and sympathomimetic agents. It has been reported as an adverse effect of olanzapine, clozapine, and ketamine therapy. Importantly, drooling can signify exposure to phencyclidine, nicotine, thallium, corrosives, or irritants. In children, drooling is a common manifestation of dystonic reaction, since normal swallowing may be impaired. *Decreased salivation* is seen with exposure to anticholinergics, botulism, and hypovolemia. Drug-induced *stomatitis* can occur in isolation or as part of multisystem illness (e.g., Stevens-Johnson syndrome [SJS]). Many drugs cause SJS, most significantly sulfonamides, anticonvulsants, nonsteroidal anti-inflammatory drugs (NSAIDs), and allopurinol. Of note, reports of stomatitis in association with multiple classes of HIV medications are increasing. Cases of isolated recurrent stomatitis related to fluoxetine use are reported.¹² Latent stomatitis can be caused by epithelial cell cycle inhibitors (chemotherapeutics) or irradiation. (With methotrexate, this recurring toxicity is reduced by supplementation with folic acid, 1 mg/day). Glossitis and stomatitis are significant problems in 11% of persons taking the herbal supplement feverfew. *Gingivitis* can be caused by phenytoin and calcium channel blockers and rarely can stem from the chronic inhalation of elemental mercury vapor or from exposure to other metals such as thallium, nickel, or zinc. Oral mucosal ulcerations have been noted following acute exposure to various corrosive or irritant chemicals and also with the chronic misuse of an undiluted mouthwash containing 70% ethanol.¹³ The chronic use of hydrogen peroxide as a mouthwash can cause hypertrophy of the tongue papillae. *Dysgeusia* can be related to zinc depletion from excessive metal chelation therapy or from chronic cocaine abuse. Metal toxicity, including metal fume fever, can result in a metallic taste. Oral *discoloration* can signify exposure to substances listed in Table 13-1. Finally, *toxic parotitis* has been associated with L-asparaginase, doxycycline, and general anesthesia.

Diseases of the Esophagus

The most common symptoms that relate to esophageal disease are nonspecific and include retrosternal chest

TABLE 13-1 Causes of Oral Discoloration

COLOR	CAUSE
Tongue	
Brown	Bromine, bismuth, arsenic, phenolphthalein, doxorubicin, quinacrine, tobacco
Green	Vanadium
Black, hairy	Cefoxitin, corticosteroids, lansoprazole, penicillin, sodium perborate, sodium peroxide, tetracyclines
White	Chlorhexidine, phenol, caustic acids, hydrogen peroxide (chronic)
Blue	Methylene blue
Gumline	
Blue-gray	Bigmuth, lead, mercury, copper salts, thallium, zinc

pain and dysphagia. Drug-induced esophageal disorders most commonly derive from either change in motility or disrupted mucosal integrity. Motility disorders include esophageal spasm, which can be caused by β blockers, both therapeutically and in overdose. Reflex esophageal spasm is precipitated by local factors such as corrosive injury or Ewald tube insertion during gastric lavage. Mechanical obstruction of the esophagus has occurred following the ingestion of sucralfate or drug packets, or as a late complication of corrosive-induced stricture. Ethanol, caffeine, opioids, and anticholinergic agents decrease lower esophageal sphincter tone and can cause gastroesophageal reflux.

Esophageal disorders that result from changes in mucosal integrity represent a broad spectrum of disease. Drug-induced esophagitis can vary from diffuse mild inflammation to necrotizing ulceration with hemorrhage. Perforation and stricture have occurred as secondary complications. Drugs implicated in esophagitis include antibiotics (tetracycline, doxycycline, clindamycin, lincomycin), 5-fluorouracil, NSAIDs, oral potassium supplements, empronium bromide, iron, quinidine, carbachol, ascorbic acid, cromolyn inhalant, cimetidine, and biphosphonates. The mechanism of injury appears to be direct corrosion based on acid or alkaline pH effect. As examples, tetracycline and doxycycline are known to be highly acidic in solution. Although drug-induced esophageal injury is more likely to occur in individuals with underlying mechanical or peristaltic abnormalities, it can occur in the normal esophagus, especially if the agent is taken with insufficient liquid and upright position is not maintained. Caustic alkali and acid chemically induced injuries to the esophagus are discussed in greater detail in Chapter 98.

Diseases of the Stomach

Slowed gastric emptying results from the ingestion of solids, especially high fat substances, and from metabolic disturbances such as hypokalemia. Drugs can increase or decrease gastric emptying time. Those which delay gastric emptying include anticholinergics and opiates. When the stomach fails to empty normally, symptoms

such as satiety, loss of appetite, and nausea are common, and gastric contents are often vomited. Absorption of concurrently administered therapeutic drugs can thus be impaired. Of toxicologic significance is the common example of acetaminophen overdose in combination with opioids or anticholinergics, where peak levels can be delayed well beyond the expected 4-hour time frame.

Drugs that increase gastric emptying can cause symptoms of diarrhea, sweating, palpitations, and abdominal cramps. These prokinetic agents include metoclopramide, domperidone, and cisapride. Domperidone and metoclopramide block the inhibitory effect of dopamine on gut motility. (Metoclopramide also crosses the blood-brain barrier and exerts central antidopaminergic effects, which can trigger extrapyramidal symptoms in 10% to 30% of patients.) Additional prokinetic actions of metoclopramide include agonism of gut 5-HT₄ receptors and stimulation of acetylcholine release. Cisapride increases acetylcholine release from the myenteric plexus without antidopaminergic effect. Of toxicologic significance, co-ingestion of prokinetic drugs may cause more rapid absorption of CNS depressants such as antihistamines, benzodiazepines, or ethanol with greater than expected sedation.¹⁰

A few miscellaneous toxic scenarios with significant gastric implications deserve mention. Gastric bezoars can form after large ingestions of iron, lithium, calcium channel blockers, sustained-release theophylline, and potassium chloride. Gastric outlet obstruction with stricture formation in the pyloric region is a known late complication of iron toxicity. The distal stomach (antrum and pylorus) is the most frequent site of injury following the ingestion of a liquid strong acid owing to a common pathway (magenstrasse) that directs fluid along the lesser curvature to the pylorus.

Intestinal Disorders

Blood flow to the intestines can be compromised in several ways. Oral contraceptives can cause mesenteric venous or arterial thrombosis.^{14,15} Through unclear mechanisms, mesenteric ischemia with bowel necrosis in the absence of prolonged hypotension has been noted following acute calcium channel blocker overdose.¹⁶ Various other slow-release formulations, iron products, and osmotic pump delivery systems have caused local lesions, strictures, or perforation. Intestinal vasospasm can be caused by vasopressin, T-2 toxin, and cocaine. Cocaine-induced intestinal ischemia with perforation is described following injection or inhalation or with mechanical bowel obstruction from impacted or ruptured cocaine packets.¹⁷⁻¹⁹ Other unusual but presumptively ischemic complications from “crack” include hemorrhagic diarrhea in a child acutely exposed, pneumoperitoneum, and perforation of gastric ulcers.^{20,21} Metformin-associated lactic acidosis can masquerade as mesenteric ischemia.²² Nausea, bloating, vomiting, and diarrhea, common effects noted with both acute overdose and chronic toxicity, must then be cautiously regarded as potential markers of life-threatening metformin-related lactic acidosis.²³⁻²⁵ Additional gastrointestinal compli-

cations due to chronic metformin use include GI bleeding and pancreatitis.²³

Diseases of the Pancreas

Pancreatitis is an acute or chronic inflammatory process characterized by abdominal pain, vomiting, and elevated pancreatic enzymes. The spectrum of severity ranges from mild to rapidly fatal illness. Drug-induced pancreatitis is rare. Most agents, except ethanol, are associated with the acute form of illness with a return to normal pancreatic anatomy and function following withdrawal of the offending agent. Variable mechanisms for drug-induced pancreatitis are proposed, including pancreatic duct constriction, interference with acinar cell protein synthesis/transport/secretion, immunosuppression, direct cytotoxicity from toxic metabolites, elevated triglycerides, arteriolar thrombosis, microcirculatory disruption, and haptene formation. The evidence for a true link between various drugs and human pancreatitis has been evaluated. The strength of association was based on criteria including the absence of other inciting factors, an appropriate temporal sequence, and a positive rechallenge.^{26,27} This information is summarized in Box 13-1.

Isolated hyperamylasemia without clinical evidence of pancreatitis has been described with methanol, lithium, organophosphates, T-2 toxin, and opioid intoxication. (Of note, some of these agents can cause true pancreatitis as well.) Beta cell destruction and diabetes mellitus can occur following exposure to alloxan, streptozocin, vacor, and pentamidine.

Diseases of the Gallbladder

A variety of drugs induce a spectrum of gallbladder diseases. An increase in the relative lithogenicity of bile, from bile and cholesterol hypersecretion, is an adverse effect of oral contraceptive use. Whether this in fact

BOX 13-1

PROPOSED LINKS BETWEEN INTOXICANTS AND HUMAN PANCREATITIS*

Definite: Aminosalicylate, anticholinesterases, didanosine, ethanol, furosemide, methyl dopa, metronidazole, estrogens, scorpion venom, tetracycline, valproic acid

Probable: Hydrochlorothiazide, pentamidine, nitrofurantoin, sulfonamides, olanzapine

Possible: ACE inhibitors, acetaminophen, azathioprine, L-asparaginase, chlorthalidone, cyclosporine, cytosine-ara, corticosteroids, erythromycin, ethacrynic acid, indomethacin, isoniazid, 6-mercaptopurine, metformin, methanol, rifampicin, sulindac, theophylline, vinblastine, zinc chloride

Insufficient evidence: Amphetamines, β blockers, carbamazepine, cimetidine, cholestyramine, clofibrate, clonidine, cyproheptadine, propoxyphene, diazoxide, growth hormone, histamine, isotretinoin, meprobamate, phenformin, procainamide, warfarin

*Modified from Braganza JM, Foster JR: Toxicology of the pancreas. In Ballantyne B, Marro T, Syverson T (eds): General and Applied Toxicology, 4th ed. London, Macmillan Reference, 2004, p 893.

increases the incidence of gallbladder disease is controversial.²⁸ Clofibrate increases the risk of gallstone formation.²⁹ Drugs that induce hemolysis such as dapsone can lead to pigment cholelithiasis. Through its precipitation as a calcium salt, ceftriaxone reversibly induces biliary sludge or “pseudolithiasis” in 25% to 45% of patients.³⁰ Epidemiologic studies conflict regarding the association between acute cholecystitis and thiazide diuretic use. The hepatic artery infusion of chemotherapy agents causes cholecystitis so frequently that prophylactic cholecystectomy is often performed. Finally, hypersensitivity cholecystitis is reported with erythromycin and ampicillin. The role of various opioids in the induction of sphincter of Oddi spasm is controversial.

Malabsorption and Altered GI Tract Flora

Interference with nutrient digestion and absorption results from the toxic effect of a wide variety of exogenous agents. Certain agents can also affect the absorption of therapeutic drugs. The mechanisms leading to maldigestion and malabsorption include (1) alteration of environmental pH (potassium chloride, antacids), (2) chelation (tetracycline, ketoconazole with calcium, cholestyramine with iron), (3) inhibition of digestive enzymes and inhibition of transport processes requiring membrane proteins (drugs that alter mitotic activity such as colchicine and methotrexate), and (4) direct toxic injury to the epithelium (neomycin, mefenamic acid, other caustics). When severe, these toxic effects cause malabsorption of fat, protein, carbohydrate, salt, water, minerals, and water-soluble and fat-soluble vitamins.

Numerous drugs adversely affect the digestion and absorption of nutrients. The absorption of vitamin B₁₂ and folic acid is inhibited by anticonvulsants, neomycin, colchicine, metformin, potassium chloride, and cholestyramine. Chronic ethanol abuse alters the absorption of several nutrients, including vitamin B₁₂, folic acid,

thiamine, amino acids, calcium, and magnesium. Drugs that inhibit digestive absorption are listed in Table 13-2.

Alterations in GI tract flora can be associated with consequences; a few of toxicologic significance are mentioned here. Through mechanisms discussed above, H₂ receptor antagonists and proton pump inhibitors effectively raise gastric pH and can increase the risk of foodborne illness and pulmonary infections. In newborns, immature GI tract flora and relative achlorhydria create a milieu that favors botulinum spore germination and growth and predisposes to infantile botulism. Approximately 30% of an oral digoxin dose is metabolized by normal gut flora (*Eubacterium lentum*). A decrease in this bacterial population can result in a relative digoxin dose increase. Digoxin toxicity from this drug-drug interaction is best described with the concurrent use of erythromycin, clarithromycin, and tetracycline. Broad-spectrum antibiotics can decrease GI tract bacterial synthesis of vitamin K. As a result, coagulopathy and bleeding can occur in patients taking warfarin along with these agents. Similarly, antibiotic reduction of normal gut flora can decrease the enterohepatic recirculation of estrogen metabolites, leading to a reduction in the efficacy of certain oral contraceptives, unwanted pregnancy, or menstrual irregularity. Conversion of ingested nitrates to more potent methemoglobin-inducing nitrites can occur in the gut by coliform bacteria. Because infants possess reduced activity of nicotinamide adenine dinucleotide (NADH) methemoglobin reductase, they are most likely to be affected.

Toxic Disorders That Mimic “Gastritis,” “Gastroenteritis,” or “Enteritis”

Symptoms exhibited during various stages of intoxication caused by myriad drugs or chemicals can mimic those symptoms typical of gastritis, gastroenteritis, or enteritis. Specifically, nausea, vomiting, abdominal cramping, and bloody or nonbloody diarrhea will be

TABLE 13-2 Drugs That Inhibit Digestive-Absorptive Mechanisms

DRUG	NUTRIENT MALABSORBED	PUTATIVE MECHANISMS
Aluminum hydroxide	Phosphate, vitamin A	Intraluminal formation of insoluble complexes
Anion exchange resins (cholestyramine, colestipol)	Water- and fat-soluble vitamins, bile salts, oxalate	Intraluminal binding of nutrient
Biguanides	Glucose, amino acids, folate, B ₁₂	Inhibit oxidative phosphorylation
Cimetidine	B ₁₂ bound to food	Inhibits gastric acid and intrinsic factor
Colchicine	Fat, glucose, B ₁₂	Inhibits mitotic spindle
Dilantin	Folate	Inhibits folate conjugase; alkalinizes intestinal contents
Ethanol	Fat, glucose, amino acids, vitamins, minerals	Alters physical properties of the membrane; inhibits Na ⁺ /K ⁺ -ATPase; stimulates cyclic AMP
Folate antagonists (methotrexate, aminopterin, trimethoprim)	Folate	Inhibit folate transport; inhibit cell proliferation
Neomycin	Fat, cholesterol, fat-soluble vitamins, glucose, amino acids, B ₁₂ , minerals	Precipitates fatty acids and bile acids; causes histologic damage
Oral contraceptives	Folate	Inhibit folate conjugase
p-Aminosalicylic acid	Fat, cholesterol, folate, B ₁₂	Unknown
Somatostatin	Fat	Inhibits pancreatic lipase secretion
Sultasalazine	Folate	Inhibits folate transport
Omeprazole	B ₁₂ bound to protein	Decreases intrinsic factor secretion

discussed. The most common symptom complex, *nausea and vomiting*, can be attributed to most intoxicants under appropriate conditions, and is also a common psychological or vasovagal response. In some situations (cytotoxic drug use), these symptoms are expected. In other situations, nausea and vomiting can signal the onset of unexpected, severe drug toxicity (theophylline and digoxin). Emesis can result from stimulation of serotonin (5-HT₃) receptors, through stimulation of the vomiting center via the chemoreceptor trigger zone (CTZ) or via afferent fibers from the GI tract, the vestibular apparatus, the nucleus of the tractus solitarius, or higher cortical centers. A frequent association is made with drugs that are cholinergic, dopaminergic, or histaminic and with direct GI tract irritation (potassium salts, iron) or pharyngeal irritation (irritant gasses). Drugs such as digoxin, opiates (apomorphine), estrogens, and levodopa have direct action on the CTZ in the floor of the fourth ventricle, outside the blood-brain barrier.¹³ While cocaine likewise directly stimulates medullary centers, nausea and vomiting in the setting of abuse can signify the presence of more ominous conditions such as intestinal or myocardial ischemia.³¹ In the acute overdose setting, the onset and character or color of emesis can occasionally assist in formulating a differential diagnosis (Table 13-3). Hematemesis may result from the ingestion of caustics, iron, concentrated hydrogen peroxide, or mercury salts. Blue-green emesis can be noted following the ingestion of boric acid, methylene blue, or copper sulfate, and luminescence with yellow phosphorus.

Diarrhea is commonly noted both with acute intoxication and as an adverse therapeutic drug effect. Multiple causal mechanisms include mucosal injury with loss of absorptive or digestive capacity, pancreatic

injury, cholinergic excess, or osmotic effect. Some cathartics, for example, increase intestinal motility and decrease transit time based on their osmotic effect. Similarly, antacids such as magnesium hydroxide or aluminum hydroxide can exert osmotic effects within the GI tract that lead to chronic diarrhea and secondary derangements in calcium and phosphorus. Diarrhea caused by antibiotics or high-dose corticosteroids is generally attributed to altered gut flora. An extreme example of this aberration, pseudomembranous colitis, results from antibiotic-related overgrowth of *Clostridium difficile* with toxin elaboration. Erythromycin causes diarrhea through a direct effect on gut motility (through motilin) and has been used in conjunction with metoclopramide to hasten the elimination of ingested drug packets.³² Drugs or conditions associated with increased serotonin activity (serotonin reuptake inhibitor use, serotonin syndrome), excess acetylcholine (organophosphate poisoning), excess catecholamines (methylxanthine toxicity), or excess histamine (scombroid poisoning) cause diarrhea. Diarrhea in these situations is typically only one of a constellation of dramatic clinical features. Metals such as arsenic and iron cause diarrhea, but this rarely occurs in isolation and typically is accompanied by vomiting and, in severe cases, hypotension. Discolored diarrheal stools can occasionally provide clues to the etiologic agent (Table 13-4). Although it is not feasible to present a comprehensive review of the many drugs and chemicals that adversely affect the GI tract, key agents are discussed below—again, with a focus on those that may mimic “gastroenteritis.” Wherever possible, distinguishing features that may point to the diagnosis of poisoning are highlighted.

BIOLOGICALS

Colchicine

Colchicine poisoning can result from pharmaceutical or plant sources (autumn crocus, glory lily). Illness is

TABLE 13-3 Approximate Onset of Gastroenteritis Symptoms by Agent

AGENT	TIME TO ONSET
Arsenic	Early
Caustics	Early
Digoxin (acute)	Early
Iron	Early
Lithium (acute)	Early
Mercury, inorganic	Early
Methylxanthines (acute, non-sustained-release)	Early
Nicotine	Early
Organophosphates	Early
Podophyllum	Early
SSRIs	Early
Abrin/ricin	Delayed 1–3 hours to days
Colchicine	Delayed 2–12 hours
Fluoride	Delayed several hours
<i>Jatropha</i> spp	Delayed 1–2 days
Methotrexate	Delayed 2–4 hours
Methylxanthines (sustained-release)	Delayed for several hours
Opioid withdrawal	Delayed 4–24 hours
<i>Solanum</i> spp	Delayed up to 2 days
Thyroid hormone	Delayed 1–11 days

TABLE 13-4 Agents that Cause Fecal Discoloration

COLOR	AGENT
Black	Acetazolamide, aluminum hydroxide, aminophylline, amphotericin B, barium, benzene, bismuth, bromides, charcoal, chloramphenicol, chlorpropamide, clindamycin, corticosteroids, cyclophosphamide, digitalis, ferrous salts, fluorouracil, formaldehyde, halides (Br, F, I), halothane, heavy metals (Ag, As, Cu, Hg, Mn, Pb, Tl), hydralazine, methotrexate, methylene blue, nitrates, NSAIDs, tetracycline, theophylline, warfarin
Blue	Boric acid, chloramphenicol, manganese dioxide, methylene blue
Yellow-green	Mercurous chloride, yellow phosphorus (stool is luminescent and smoking)
Orange/red	Phenazopyridine, rifampin
Pink	Manganese dioxide, phenolphthalein

characterized by severe hemorrhagic gastroenteritis beginning 2 to 12 hours postingestion. Along with this GI symptom, dehydration, electrolyte disturbances, shock, dysrhythmias, and marked leukocytosis are found in the early phases of toxicity.^{33,34} Later, bone marrow suppression, renal failure, pulmonary edema, alopecia, and neuropathic features develop. Other findings include oral dysesthesias, ileus, colitis, and hepatocellular injury. Colchicine acts through inhibition of the polymerization of tubulin into microtubules, causing mitotic metaphase arrest. As such, gastrointestinal biopsy may be diagnostic, demonstrating numerous metaphases, epithelial pseudostratification, loss of epithelial polarity, and frequent apoptosis.³⁵⁻³⁷

Podophyllum

Poisoning from podophyllum resin (made from the roots of mayapple or “wild mandrake”) occurs following ingestion or dermal application and manifests with nausea, vomiting, abdominal pain, ileus, and severe diarrhea.^{38,39} Symptom onset typically occurs shortly following oral ingestion, although delays of up to 10 hours have been reported.⁴⁰ Other clues to the diagnosis include the presence of a sensorimotor neuropathy, bone marrow suppression, CNS depression, and autonomic instability. Illness is similar to that caused by colchicine, as is the pathophysiology—inhibition of microtubular assembly. Additionally, podophyllum is a direct intestinal mucosal irritant, which accounts for the violent peristalsis and catharsis seen in oral poisoning.

Nicotine

Nicotine ingestion most commonly involves tobacco products and can be life threatening. One of the earliest symptoms is a burning sensation in mouth, throat, esophagus, and stomach. This is commonly followed by increased salivation, nausea, vomiting, abdominal pain, and diarrhea. Early emesis, within minutes, occurs in 16% to 63% of pediatric nicotine exposures but does not correlate with the ultimate severity of illness and therefore has limited usefulness in triage.⁴¹ Diarrhea is delayed for 4 to 24 hours in 14% of patients.³⁷ A diagnostic clue is the constellation of symptoms that includes bronchorrhea, tachycardia, hypertension, pallor, seizures, fasciculations, paralysis, and ultimately hypoventilation, apnea, and cardiovascular collapse. Green tobacco sickness is an occupationally acquired form of nicotine poisoning that typically occurs in teenagers or older males who have been harvesting wet, uncured tobacco leaves. Symptoms begin 3 to 24 hours after a 6-hour exposure period and are mainly gastrointestinal (nausea, vomiting, abdominal cramping).⁴²⁻⁴⁴ Prevention can be accomplished by use of protective clothing.

Abrin/Ricin

Severe toxic gastroenteritis with hemorrhage is a hallmark of toxicity from toxalbumin-containing seeds such as castor oil plant seeds (*Ricinus communis*), *Jatropha* spp seeds, or rosary peas (*Abrus precatorius*). Abdominal pain, vomiting, and frequent heme-positive stools with

tenesmus can occur as early as 1 to 3 hours postingestion or can be delayed for several days.⁴⁵⁻⁴⁸ To some extent, the onset and severity of symptoms are thought to depend on the extent of seed mastication. Gastrointestinal symptoms progress over 4 to 36 hours to dehydration and cardiac, renal, and hepatic toxicity in severe poisoning. Pathophysiology involves toxalbumin inhibition of the 60S ribosomal subunit, which arrests protein synthesis and causes cell death. The reticuloendothelial and highly proliferative intestinal cells are particularly vulnerable to the effects of ricin. While one masticated castor bean or rosary pea (containing up to 10 mg ricin) is potentially fatal to a toddler, the frequently cited human fatal oral dose of 1 mg/kg is unconfirmed.⁴⁹ In one study of *Jatropha* ingestions, most patients exhibited only vomiting and abdominal pain; 98% were discharged 24 to 48 hours postexposure.⁵⁰

Trichothecene Mycotoxins

This family of dermally active toxins is produced by various molds of the genera *Fusarium*, *Stachybotrys*, and others. Anorexia, vomiting, and diarrhea, possibly hemorrhagic, can occur following either ingestion or dermal exposure to some of the more than 150 toxin derivatives. T-2 toxin gained notoriety as a lethal agent after accidental flour contamination caused a Russian civilian endemic illness termed *alimentary toxic aleukia*. In those who consumed contaminated bread, initial GI symptoms, fever, and chills progressed to a protracted illness characterized by bone marrow suppression and secondary sepsis. In another incident, those who consumed moldy rice contaminated with T-2 toxin experienced chills, dizziness, nausea, vomiting, abdominal distention, abdominal pain, and diarrhea.⁵¹ Pancreatitis due to T-2 toxin has been reported. A clue to the diagnosis of T-2 exposure is intense burning, inflammation, and necrosis of dermally exposed skin, mucous membranes, and the respiratory tract. Pathophysiology of the illness involves the inhibition of protein synthesis and a dose-dependent decrease in gastric and intestinal blood flow.⁵² One specific trichothecene mycotoxin—deoxynivalenol, or vomitoxin—consistently causes anorexia and vomiting through unclear mechanisms.⁵³

Other Plants and Mycotoxins

A variety of GI syndromes occur following plant ingestion, many through unidentified mechanisms. Immediate mouth irritation can result from chewing plants with insoluble oxalates (e.g., dieffenbachia and philodendron). Emesis with minimal or absent diarrhea can result from the ingestion of certain bulbs (daffodil, jonquil, and narcissus) or wisteria seeds or flowers, owing to their direct action on the gastric mucosa and the CTZ. Irritation of the intestinal mucosa by pokeweed, holly, elderberry, or baneberry can cause rapid onset of emesis, abdominal pain, and diarrhea. Delayed gastroenteritis (up to 2 days) can be seen following the ingestion of solanine-containing plants (potato sprouts, climbing nightshade, Jerusalem cherry), horsenettle, crocus, castor bean, and rosary pea.

The primary toxic effect of some mushrooms is acute, early-onset gastroenteritis. Members of this “gastrointestinal irritant” class of mushrooms include *Boletus sensibilis*, *Entoloma lividum*, *Leucoagaricus putidus*, *Omphalotus olearius*, *Pholiota squarrosa*, and *Tricholoma pardinum*. Secondary dehydration or electrolyte abnormalities are described, but hepatic injury, renal failure, and neurologic symptoms are absent. (Paresthesias and tetany, when present, are ascribed to fear or hyperventilation and not to primary neurotoxicity.) The onset of symptoms following mushroom ingestion is a valuable diagnostic clue, with the most toxic species causing delayed GI symptom onset. Notable exceptions to this rule, however, are *Gomphus bonari*, *G. floccosus*, and *G. kauffmanii*, all associated with delayed-onset diarrhea (8 to 14 hours).

PESTICIDES/HERBICIDES

Nausea, vomiting, abdominal cramps, diarrhea, and fecal incontinence commonly occur following exposure to acetylcholinesterase inhibitors such as organophosphates, carbamates, or nerve agents.^{54,55} The pattern of illness varies with route and duration of exposure.⁵⁶ In addition, organophosphates cause both pancreatitis and isolated hyperamylasemia, the latter noted in 76% of patients with acute poisoning in one series.⁵⁷ In another series, elevated serum amylase levels correlated with respiratory failure necessitating ventilatory support.⁵⁸ Puzzling gastrointestinal effects described in organophosphate poisoning include intussusception and acute hemorrhagic panesophagitis.^{59,60} A clue to the diagnosis of acetylcholinesterase inhibitor poisoning is the presence of miosis, rhinorrhea, lacrimation, bronchorrhea, bronchoconstriction, CNS depression, seizures, fasciculations, and paralysis. Within the therapeutic arena, the use of reversible cholinesterase inhibitors to treat dementia is consistently associated with nausea, vomiting, and diarrhea in 30% to 50% of patients.⁶¹

Paraquat is a caustic herbicide and frequent suicidal agent in some countries. Ingestion is often associated with immediate mouth and throat irritation, followed by abdominal pain, nausea, vomiting, and diarrhea.^{62,63} Swelling, edema, and ulceration of the mouth, pharynx, esophagus, stomach, and intestines have occurred.^{61,62,64} Patients who develop GI tract injury generally have a poor prognosis.^{63,65,66} Other clues to this diagnosis are severe pulmonary edema with fibrosis; renal, liver, and myocardial injury; and pancreatitis. The pathophysiology of this poisoning stems from paraquat’s potent oxidizing affect and ability to promote free radical formation and redox cycling.

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS/SALICYLATES

An estimated 17,000 deaths per year in the United States are related to nonsteroidal anti-inflammatory medications.⁶⁷ Gastric erosion occurs in 30% and 50% of patients taking one or greater than one NSAID respectively for 12 months, with frank ulceration in 10%.¹³ These agents, including aspirin, cause extensive damage to the GI tract through both topical irritant effect and inhibition of cyclooxygenase (COX-1) in the gastric

mucosa. Injury can occur even at low doses, such as those used for cardioprotection, or with the parenteral route of administration. Gold therapy, used in the treatment of arthritis, can also cause gastric erosions and panenteritis.

ETHANOL AND OTHER ALCOHOLS

Given the per capita annual consumption of 10 L in the United States, it is not surprising that alcohol-induced GI pathology is commonly encountered. Acute ingestions of greater than 8% ethanol or chronic consumption of lower concentrations can result in erosive gastritis, ulceration, and ultimately GI bleeding. (These same complications occur following the acute ingestion of rubbing alcohol, which is typically a concentrated [70%] solution of isopropanol.)⁶⁸ Interestingly, low ethanol concentrations (<5%) stimulate gastrin release and increase gastric acid secretion, as do nondistilled beer and wine.⁶⁹ While these effects are not noted with higher concentrations of ethanol or distilled products, other physiologic effects such as slowed gastric emptying and decreased lower esophageal sphincter tone and esophageal motility occur. These latter effects predispose chronic alcohol users to reflux esophagitis. Other adverse GI effects of chronic alcohol abuse include increased intestinal mucosal permeability to bacterial pathogens and decreased intestinal motility.^{70,71} Despite slowed motility, diarrhea often is seen in persons with alcoholism. Diarrhea stems from alterations in intestinal digestive enzymes, abnormal biliary and pancreatic function, and malabsorption.

The effect of ethanol on the liver and pancreas is even more significant than its effect on the tubular GI tract. Acute and chronic pancreatitis are well-known complications of chronic ethanol abuse.²⁵ Chronic ethanol consumption has also been associated with acute hepatitis; cirrhosis, with portal hypertension and life-threatening esophageal variceal bleeding; inhibition of glycogen storage; and increased risk of hepatotoxicity following exposure to other chemicals.

METALS AND METALLOIDS

Lead

Lead is a significant environmental hazard to children and occupational hazard to adults. GI effects due to lead intoxication are well described and include abdominal colic, vomiting, constipation, diarrhea, anorexia, a metallic taste in the mouth, and weight loss.⁷² Unusual instances of gastrointestinal bleeding following the ingestion of lead bullets, pyloric obstruction following the ingestion of lead glaze frit, and paralytic ileus are reported.⁷³⁻⁷⁵ A clue to the diagnosis is the presence of encephalopathy, anemia, motor neuropathy (adults or children with sickle cell anemia), renal failure, gout, and hypertension. Some of the GI symptoms of lead poisoning may be explained by the ability of lead to induce GI tract smooth muscle spasm.

Iron

Although pediatric mortality due to iron poisoning has declined, accidental ingestion is still a significant

cause of morbidity. Early-onset emesis is common when greater than 20 mg/kg elemental iron is ingested. In fact, protracted vomiting is a useful clinical marker of significant iron toxicity. Gastrointestinal hemorrhage can be seen within the first few hours of severe poisoning. A delayed gastrointestinal effect is pyloric scarring, possibly leading to gastric outlet obstruction 2 to 8 weeks after overdose. Similarly, isolated distal small bowel segmental infarction or stricture following enteric-coated iron tablet ingestion is described.⁷⁶ These effects likely result from the direct corrosive effect of iron on the gastrointestinal mucosa. In fact, hemorrhage, ulceration, and necrosis of the esophagus, stomach, and bowel are common autopsy findings in fatal iron overdosing. Clues to the diagnosis of iron poisoning include hypotension (resulting from GI losses, hemorrhage, vasodilatation), hyperlactemia, metabolic acidosis, lethargy, coagulopathy, hepatic or renal dysfunction, and radio-opacities on abdominal x-ray.

Lithium

Acute lithium intoxication frequently manifests with nausea and vomiting.⁷⁷ Diarrhea can be noted, particularly after overdose with sustained-release preparations.^{78,79} GI effects are reported with chronic therapeutic lithium use in 10% to 20% of patients. As with other metal salts, the mechanism of GI toxicity is one of direct corrosive injury to the intestinal mucosa. Concurrent symptoms that provide diagnostic clues include evidence of dehydration, mental status changes, tremor, neuromuscular hyperexcitability, rigidity, and fever. Hyperamylasemia without clinical evidence of pancreatitis has been reported rarely.⁸⁰

Mercury (Inorganic)

Sources of corrosive inorganic mercury salts include stool fixatives, Chinese herbals, and (historically) disinfectants and teething powders. As with other corrosive metal salts, direct contact between the salt and the gastrointestinal mucosa results in erosion, ulceration, and necrosis. Signs and symptoms include nausea, dysphagia, vomiting, diarrhea, abdominal pain, hematemesis, and hematochezia.^{81,82} Diagnostic clues include concurrent hypovolemic shock, acute renal failure, and radio-opacities on abdominal x-ray.

Arsenic

The gastrointestinal effects of arsenic vary with dose and chronicity of exposure. Within minutes to hours following significant acute arsenic ingestion, abdominal pain, vomiting, profuse watery diarrhea (sometimes described as "rice-water-like"), and GI bleeding are present.^{83,84} In the absence of a history of ingestion, the diagnosis is difficult. Potential clues include multisystem involvement with cardiovascular collapse, prolonged QT interval, encephalopathy, seizures, pulmonary edema, hepatitis, renal failure, anemia, painful sensorimotor neuropathy, alopecia, hyperpigmentation, a desquamating rash, and Mees' lines. Often, burning and dryness of the mouth is reported. Breath, stool, or emesis may have a garlicky odor.⁸⁵

Thallium

Unlike the other metal salts discussed above, GI symptoms due to thallium are generally less dramatic. In fact, constipation unresponsive to laxatives can be a more common manifestation of poisoning than symptoms of toxic gastroenteritis.^{86,87} Nonetheless, nausea, vomiting, paroxysmal abdominal pain, and diarrhea are reported.⁸⁸ Gastrointestinal hemorrhage is rare.^{86,89} The presence of alopecia and a painful ascending neuropathy point to this diagnosis.

Fluoride

Fluoride is present in dental, industrial, and agricultural products. Once ingested, sodium fluoride reacts with gastric acid to produce highly corrosive hydrofluoric acid, which directly injures the GI tract. In most instances, symptomatology is limited to the GI tract. Epigastric pain, nausea, dysphagia, salivation, hematemesis, and diarrhea occur with acute ingestion of greater than 3 mg/kg or with chronic therapeutic use of greater than 30 mg/day sodium fluoride.^{90,91} With acute exposure, symptom onset can be delayed for several hours. The spectrum of GI injury appears to be concentration dependent, with low concentrations of fluoride (1 mg/mL) causing superficial damage to the gastric mucosa, and 13% to 20% bifluoride solutions causing significant burns to the distal esophagus, antrum, and gastric body.⁹² With severe poisoning, other clues to the diagnosis include hypocalcemia, hypomagnesemia, hyperkalemia, hypotension, and dysrhythmias.

METHYLXANTHINES

Fortunately, the incidence of theophylline toxicity is declining, and over-the-counter formulations have been removed from the market. The serious nature of theophylline toxicity, however, coupled with the widespread availability of other methylxanthines (such as caffeine found as guarana in dietary supplements) warrant their discussion. GI symptoms due to methylxanthine toxicity include nausea, protracted vomiting, abdominal cramps, diarrhea, and rarely GI bleeding.⁹³ This symptomatology occurs in more than 80% of patients with acute intoxication compared with only 30% of those with chronic toxicity.⁹⁴⁻⁹⁶ Emesis can be difficult to control and can interfere with attempts to give multiple-dose activated charcoal, a cornerstone of therapy. With acute overdose, sustained-release formulations can form bezoars in the GI tract.⁹⁷ Therapeutic use of theophylline is associated with increased gastric acid secretion and decreased lower esophageal tone due to smooth muscle relaxation. Gastritis or esophagitis can develop as a result. In a retrospective study of low-birth-weight infants, the use of theophylline was associated with feeding intolerance, emesis, GI bleeding, necrotizing enterocolitis, and abdominal radiographic changes (persistently enlarged bowel loops or thickened bowel wall without pneumatosis). These infants also had higher rates of systemic illness, including increased apnea or bradycardia and increased ventilatory support.⁹⁸ Clues to the diagnosis of methylxanthine poisoning include

tachycardia, dysrhythmias, agitation, seizures, respiratory alkalosis, lactic acidosis, sweating, tremor, hypokalemia, hypophosphatemia, hyperglycemia, and widened pulse pressure (decreased systemic vascular resistance).

DIGOXIN

As for theophylline, the incidence of digoxin toxicity is becoming less frequent. Nausea, vomiting, and abdominal pain are some of the earliest manifestations of acute overdose. Complaints related to the GI tract are less common with chronic toxicity but are similar to those listed above, including anorexia and weight loss.⁹⁹ Diagnostic clues of digoxin toxicity include ventricular ectopy, bradydysrhythmias, syncope, hyperkalemia, lethargy, confusion, and visual disturbances.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Because of their improved safety profile relative to cyclic antidepressants, use of selective serotonin reuptake inhibitors (SSRIs) is increasingly widespread. Nausea is a common side effect reported both in the setting of overdose and with therapeutic use.¹⁰⁰ Diarrhea occurred in 38% of patients receiving therapeutic doses of fluoxetine for panic attacks.¹⁰¹ Fluoxetine has been shown to cause anorexia with resultant weight loss in overweight, nondepressed individuals. These effects are not surprising, given the critical role played by serotonin in the GI tract (see above). Although symptoms of acute SSRI poisoning are relatively nonspecific (dizziness, orthostasis, lethargy, and tachycardia), seizures, QRS prolongation, and QT prolongation are more likely to occur with citalopram overdose.

CORROSIVES

Acid and alkaline corrosive injury to the GI tract is covered in detail in Chapter 98. Commonly available household products that cause direct corrosive injury to the GI tract include sodium hydroxide (lye), toilet cleaners, hydrofluoric acid, ammonia, automatic dishwashing detergents, bleach, and phenols. A few agents with unique features relative to their GI tract toxicity are discussed here.

Hydrogen Peroxide

Ingestion of low concentrations of hydrogen peroxide (3% solutions) typically is not associated with symptoms but on occasion results in mild irritation to mucosal tissue and vomiting.¹⁰² Much higher concentrations are sold as “food grade” health and nutrition products, often without child-resistant closures. Ingestion of these concentrated solutions causes oropharyngeal, esophageal, gastric, and intestinal inflammation that may progress to frank ulceration with hemorrhage. Intestinal gangrene has occurred in extreme cases. Unique among corrosives, hydrogen peroxide ingestion can be associated with the liberation of large volumes of oxygen within the GI tract, causing gastric distention, fatal colonic rupture, or systemic gas embolization.¹⁰³⁻¹⁰⁵ Clues to this diagnosis include hematemesis with abdominal distention or the sudden onset of focal neurologic findings.

Boric Acid

Boric acid can be found in homes as an antiseptic, ant killer, roach powder, or homeopathic medication. Most ingestions are typified by early onset of nausea, vomiting, and diarrhea. Hemorrhagic gastroenteritis can occur with the acute ingestion of highly concentrated formulations.^{106,107} A clue to the diagnosis of acute boric acid ingestion is blue-green discoloration of the emesis fluid and feces. Chronic boric acid ingestion can be suspected in patients with renal failure, an erythematous desquamating rash, and seizures.

Batteries

Children with esophageal battery lodgment may exhibit irritability, dysphagia, and refusal of oral intake. These symptoms have been mistaken for nonspecific gastritis or viral syndromes, resulting in diagnostic delays. Batteries can become trapped at anatomic narrowings at the level of the cricoid pharynx, aortic knob, gastroesophageal junction, pylorus, ileocecal junction, and Meckel's diverticulum. Esophageal impaction of a disc battery can result in burns, perforation, and mediastinitis. Such injury begins as early as 4 hours after ingestion.^{108,109} In the absence of esophageal impaction on chest x-ray, most batteries will pass through the GI tract without complication.¹¹⁰ Conversely, abdominal pain or other GI complaints indicate the need for urgent evaluation.

OPIOID WITHDRAWAL STATES

Opioid withdrawal is a common occurrence in the adult emergency department and newborn nursery. Symptoms of nausea, vomiting, increased bowel sounds, abdominal cramps, and dehydration are characteristic.¹¹¹ The onset, duration and severity of symptoms depend on the pharmacologic properties of the withdrawn opioid and on the pattern of its use. Heroin withdrawal, for example, begins within 4 to 24 hours after the last use and generally peaks at 36 to 48 hours.^{112,113} In neonates, failure to thrive, poor suck reflex, and feeding difficulties are noted in about half of those withdrawing from heroin.¹¹⁴ Similarly, poor feeding is seen in infants and young children withdrawing from chronically administered opioid analgesia. The use of opioid antagonists in those with opioid dependence commonly precipitates vomiting and diarrhea. In the setting of acute oral opioid overdose, some propose that this could theoretically restore peristalsis and further the absorption of ingested drugs, but clinical evidence of this phenomenon is lacking. Clues to the diagnosis of opioid withdrawal include dilated pupils, yawning, lacrimation, rhinorrhea, muscle cramping, myalgias, hyperactive bowel sounds, and piloerection.

THYROID HORMONES

The development of thyrotoxicosis is fairly common after chronic hormone overdose but is unusual after acute ingestion. The development of vomiting and diarrhea relate to the adrenergic effects of triiodothyronine (T_3) or levothyroxine (T_4).¹¹⁵ Small or modest ingestions of T_3 usually produce few serious symptoms, whereas

massive overdose can cause symptoms within 12 to 24 hours. Symptoms following T_4 overdose can be delayed up to 11 days as conversion to T_3 takes place. Clinical clues to the diagnosis of thyroid hormone toxicity include palpitations, tachycardia, tremor, anxiety, and behavioral changes.

PROSTAGLANDINS

Misoprostol is a prostaglandin analog used to prevent NSAID-induced GI mucosal toxicity. It is occasionally used as an abortifacient and is contraindicated during pregnancy. In overdose, severe nausea, abdominal cramps, vomiting, induction of labor, and fetal death can result. Other clues to the diagnosis of misoprostol poisoning include hyperthermia, chills, dyspnea, and vaginal bleeding.

METHOTREXATE

Methotrexate is a folate antagonist that is effective in the treatment of various malignancies, ectopic pregnancy, rheumatoid arthritis, psoriasis, inflammatory bowel disease, and other disorders. Intestinal toxicity from methotrexate is a major limitation on its use. Gastrointestinal symptoms of toxicity include nausea, vomiting, abdominal pain, diarrhea, and in severe cases hematemesis and melena with onset 2 to 4 hours postexposure. Mucositis typically begins 7 to 14 days later and persists for 4 to 7 days. It can involve the tongue, buccal mucosa, esophagus, stomach, small intestine, or colon.

Methotrexate is transported into cells by a carrier-mediated system and reaches much higher levels in the intestine than in tumor cells, where it has a substantially longer duration of inhibition of DNA synthesis.¹¹⁶ Intestinal toxicity is dependent both on duration of exposure and supratherapeutic drug levels and occurs after oral or parenteral routes. Toxic methotrexate doses lead to a sustained reduction in mitoses with loss of intestinal surface absorptive cells. This desquamation of the epithelial cell lining is associated with extensive leukocytic infiltration of the lamina propria. Large areas of ulceration develop, and bleeding eventually occurs. These pathologic features are not specific to methotrexate and can be seen with various poisonous or otherwise noxious agents, a fact that contributes to the intestine's vulnerability based on its limited response to injury. Clues to the diagnosis include bone marrow suppression, hepatotoxicity, renal toxicity, seizures, encephalopathy, and focal neurologic deficits.

LAXATIVES (ACUTE TOXICITY)

Acute laxative poisoning is usually accidental, but laxatives are occasionally used in suicide attempts. Most laxatives have a wide margin of safety, and large doses must be consumed to be fatal. A classification of laxatives and representative examples for each group are presented in Box 13-2.

Acute poisoning can lead to abdominal or rectal pain, vomiting, and watery or bloody diarrhea. In extreme cases, fluid and electrolyte abnormalities and respiratory and circulatory failure can occur. The diagnosis is usually

apparent from the history. For laxatives containing magnesium, signs of clinical toxicity are expected at serum magnesium levels of 4 mEq/L and worsen as the concentration rises.

Toxic Disorders Presenting with Constipation

Constipation is commonly associated with drugs that impair GI motility such as opioids and antimuscarinics. An example is severe constipation leading to intestinal perforation in a patient taking amitriptyline therapy.¹¹⁷ Aluminum hydroxide, calcium carbonate antacids, and iron salts are frequent causes of constipation with therapeutic use. Other constipating agents are discussed in greater detail below.

BOX 13-2 TYPES OF LAXATIVES

Stimulant (or Irritant)

Ricinoleic acid (castor oil)
Dehydrocholic acids (Decholin)
Bisacodyl (Dulcolax)
Phenolphthalein (Ex-Lax, Correctol)*
Oxyphenisatin (Lavema)[†]
Aloe
Cascara sagrada
Senna (Senokot)
Danthron (Modane)

Stool Softener (Emollient)

Diocetyl sodium sulfosuccinate (DSS)
Diocetyl calcium sulfosuccinate (Surfak)
Mineral oil (Kondremul)

Saline

Magnesium hydroxide (Milk of Magnesia)
Magnesium sulfate
Sodium sulfate
Sodium phosphate (Fleet Phospho-Soda)
Sodium chloride

Osmotic

Polyethylene glycol (GoLYTELY, Colyte)
Lactulose (Chronulac, Duphalac)

Bulk

Psyllium seed derivatives (Konsyl, Metamucil, LA formula, Effer-Syllium, Serutan, Hydrocil)
Methylcellulose (Citrucel)
Bran products

Lubricant

*Banned for over-the-counter sale by the FDA in 1998 because of its association with tumors in animals.

[†]Withdrawn from distribution by the FDA because of its association with chronic active hepatitis.

CHARCOAL

Albeit chemically inert, the mechanical effects of charcoal can cause serious complications when used to decontaminate the GI tract following drug overdose. The administration of both single- and multiple-dose activated charcoal with or without cathartic has resulted in GI obstruction or charcoal bezoar formation in patients with carbamazepine, amitriptyline, haloperidol/maprotiline, or theophylline poisoning.¹¹⁸⁻¹²¹ Intestinal perforation due to a charcoal stercolith was reported in a patient treated with multiple-dose charcoal after an amitriptyline overdose.¹²² Intestinal pseudo-obstruction (Olgivie's syndrome) has been reported in association with multidose charcoal treatment of theophylline toxicity.¹²³ Inadvertent introduction of charcoal into the peritoneum following gastric lavage resulted in significant morbidity.¹²⁴

OPIOIDS

Most members of the opioid group tend to delay gastric emptying, are antisecretory, and slow intestinal motility. Cramping and constipation are therefore common in chronic opioid users. Diphenoxylate is an opioid antidiarrheal agent that exerts its antimotility effect through gastrointestinal μ receptors and is found in combination with atropine. As such, potentially delayed, prolonged anticholinergic and/or opioid toxicity with respiratory depression have occurred in children following ingestion. Loperamide similarly has antisecretory and antimotility effects through μ receptors in the gastrointestinal tract. Although not a true opiate, gastrointestinal effects from this piperidine drug mimic those observed with opioids in overdose. Specifically, constipation, abdominal pain, and ileus are described.¹²⁵ Neurologic symptoms including miosis, hypotonia, hypopnea, CNS depression, and fatality are primarily described in infants. Rarely, complications include necrotizing enterocolitis in neonates and elevation of pancreatic enzymes with pancreatitis possibly related to spasm of the sphincter of Oddi, an opioid type effect. Body packing means the ingestion or rectal insertion of multiple packets of illicit drugs for the purpose of smuggling. Complications of heroin body packing include mechanical bowel obstruction and perforation.^{126,127}

ANTICHOLINERGICS

Decreased gastric motility and diminished bowel sounds are common with anticholinergic toxicity. Paralytic ileus can occur following oral, intravenous, or nebulized routes of drug administration.¹²⁸ Many psychiatric drugs, particularly the phenothiazines, are antimuscarinic and have been associated with intestinal pseudo-obstruction. The antimuscarinic toxidrome is easily recognized and includes mydriasis, xerostomia, hyperthermia, absence of axillary sweating, delirium, tachycardia, seizures, and urinary retention.

CALCIUM CHANNEL BLOCKERS

Nausea, vomiting, and ileus are common findings with calcium channel blocker overdose.^{129,130} The formation

of large tablet bezoars after the ingestion of sustained-release dose formulations is described. These masses may not be apparent on abdominal films. With therapeutic use, patients taking calcium channel blockers have a twofold increased risk of gastrointestinal bleeding as compared with users of β blockers.¹³¹

THALLIUM

Constipation in the setting of thallium toxicity is discussed above.

BOTULINUM TOXIN

Multiple forms of botulism exist. Abdominal pain, distention, decreased bowel sounds, and constipation are common features among the various types of illness in both adults and infants.¹³²⁻¹³⁴ Nausea and vomiting are more variable, occurring in only 50% of patients. GI symptom onset can occur before or after the onset of paralysis, and abdominal cramping commonly persists throughout the illness. Some have proposed that GI symptoms are rare in type A botulism, occur variably with type B, and are frequent and severe with type E,^{135,136} although reports to the contrary also exist.¹³⁷

CHRONIC LAXATIVE ABUSE

Chronic laxative abuse presents with chronic constipation and occurs in three forms. One is exemplified by constipated patients who therapeutically misuse laxatives, another by bulimic patients who use laxatives for weight loss, and the third by surreptitious laxative abusers.

Cathartic colon is a consequence of prolonged irritant laxative use, typically for 15 or more years. Diarrhea, fever, and blood in the stool are *not* encountered with cathartic colon. The rectal mucosa is not friable, and findings on proctosigmoidoscopy are normal except for the possible presence of melanosis coli, which is discussed below. Clinically, cathartic colon is discovered by barium enema and therefore is primarily a radiologic diagnosis. The earliest radiographic findings are atrophy and shortening of the cecum and ileocecal valve. More extensive changes are a tubular colon with diminished or absent haustrations, which can extend to the distal descending colon. Ulcerations and rigidity are absent. The differential diagnosis of the radiologic findings includes inflammatory bowel disease and amebiasis. Systemic effects of chronic laxative abuse result from the increased fecal loss of sodium and potassium and provide clues to the diagnosis.¹³⁸ Specifically, patients can present with potassium depletion, muscle weakness, metabolic alkalosis, hyperaldosteronism, and chronic thirst. Most of the laxatives in the stimulant category are too irritating for continuous use and should be avoided.

The second group of laxative abusers is composed of patients with eating disorders such as bulimia nervosa, estimated to be present in up to 19% of college-aged women. Bulimia is distinct from anorexia and is characterized by secretive binge eating followed by various methods of purging, including cathartics, diuretics, and self-induced vomiting. These patients can develop severe metabolic disturbances and ventricular

tachydysrhythmias. Sudden death can occur and may be heralded by prolongation of the QT interval.

The third group with chronic laxative abuse includes those who use laxatives surreptitiously and present with diarrhea of unknown cause or with metabolic abnormalities related to long-term laxative misuse. A key feature of the disorder is denial by the patient that he or she takes laxatives. A similar clinical picture may be noted in the setting of Munchausen syndrome by proxy, in which children are given laxatives by adults. Patients often attract at least an initial medical workup designed to rule out infectious, inflammatory, metabolic, and neoplastic diseases before abusive behavior is considered. These studies usually yield normal results. Metabolic abnormalities mentioned above may be present.

A workup for chronic laxative abuse can include blood and urine sampling for laxatives. Clinical laboratories offer a laxative abuse screen of urine for bisacodyl and danthron. Prior to its removal from the market, phenolphthalein abuse was occasionally detected by a pink color change upon alkalinization of stool with sodium hydroxide. Proctosigmoidoscopy itself can be diagnostic by showing the darkened to black mucosa of melanosis coli. Mucosal pigmentation results from melanin accumulation in macrophages in the lamina propria and can begin within 4 months of chronic laxative abuse. Pigmentation is seen most often with use of anthracene derivatives, including cascara, aloes, and senna. When the diagnosis is still suspect in the face of a normal workup, hospital admission is occasionally required, at which point symptoms should improve under direct observation. Meanwhile, stool can be collected while the patient fasts and receives intravenous glucose and fluids. A large stool volume of 500 to 1000 mL or more suggests secretory diarrhea, and the stool is evaluated for sodium, potassium, and osmolality. In secretory diarrhea, the osmolality is accounted for by twice the sodium plus potassium concentration and can be simulated by secretagogue laxatives such as senna, bisacodyl, and phenolphthalein. Osmotic diarrhea is characterized by a wide ion gap that can be caused by magnesium, sulfate, or other laxative ions, and these can be measured in the stool. Since laxatives are not addictive, persons who use them surreptitiously have a serious psychological condition, usually anxiety, depression, or chronic factitious disease with physical symptoms, also known as Munchausen syndrome.

Proctitis

Proctitis can be associated with the local application of nonsteroidal anti-inflammatory agents, ergot suppositories, and lithium, which in addition is associated with painful diarrhea.¹³⁹ Severe cases of drug-induced proctitis have been associated with rectovaginal fistulae. Rectal inflammation and hemorrhage can also result from the administration of a 95% ethanol enema.¹⁴⁰ Hydrogen peroxide enemas, as 3% or even more dilute solutions, have caused inflammation and, in some cases, ulceration.¹⁴¹ Irrigation of endoscopes prior to sigmoidoscopy or

colonoscopy with hydrogen peroxide or glutaraldehyde was associated with white rectal plaques, occasional rectal bleeding, tenesmus, and increased stool frequency.¹⁴² Finally, through unclear mechanisms, perineal burning and irritation is well documented after the intravenous administration of dexamethasone.¹⁴³

MECHANICAL INJURY TO THE GI TRACT

Complications occur during gastric decontamination procedures. Orogastric lavage has been associated with esophageal tears, esophageal perforation, and gastric perforation or hemorrhage. Similarly, emesis induced by syrup of ipecac has resulted in esophageal tears and gastric rupture or herniation. Whole-bowel irrigation has been associated with colonic perforation, but this was in the setting of severe underlying diverticulitis.

GASTROINTESTINAL CANCER

Several chemicals have been linked to human gastrointestinal tract malignancy. Gastric cancer can be caused by chronic exposure to asbestos, chromates, coal tar pitch volatiles, nickel compounds, and nitrosamines. Esophageal cancer is associated with asbestos exposure and is also described several years following acid and alkaline corrosive esophageal injury with stricture. Pancreatic cancer has been associated with petroleum refining, coke oven by-products, and rubber and furniture manufacturing. The development of peritoneal mesothelioma has been linked to asbestos exposure.

Ethanol consumption is linked to an increased risk of cancer of the oropharynx, esophagus, stomach, and colon, suggesting possible roles for ethanol (or its metabolites) as either tumor promoters or carcinogens. Other factors associated with chronic alcoholism confound these analyses, however. These include diminished host defenses, hormonal alterations, depletion of vitamin stores, and the occasional presence of nitrosamines, urethanes, microtoxins, inorganic arsenic, pesticides, preservatives, or antifoaming agents in some alcoholic beverages.^{68,70}

TREATMENT

Specific treatments, antidotes, and indications for treatment of the many toxicities discussed above are covered in other chapters of this text. Only a few basic management points are discussed here. First, patients with chemical injury of the oropharynx, stomatitis, or angioedema must be monitored for impending airway compromise, systemic allergic reaction, or evidence of Stevens-Johnson syndrome. Those with drug-induced esophagitis generally respond to cessation of the offending drug and management of the complications. Further episodes may be prevented by ensuring that the drug is taken with sufficient liquid and upright position is maintained. Recognition of this disorder is critical

because the disease is usually reversible if discovered early. Malabsorption is usually sufficiently treated by removal of the drug from a patient's regimen and restoration of nutrient deficiencies. Cessation of excessive laxative use and correction of fluid and electrolyte disturbances is usually satisfactory treatment for cathartic colon. Bulimia nervosa and Munchausen syndrome require long-term therapy with medical, psychological, and nutritional professionals. Several investigational therapeutic strategies may someday enhance GI tract wound healing following toxic insult. These include trefoil factors, transforming growth factor β , and the manipulation of the luminal environment with supplemental polyamines or lipid mediators to accelerate mucosal repair.¹⁰ Novel therapeutic neuronal options (e.g., substance P receptor antagonists, somatostatin analogs, and enkephalinase inhibitors) for the treatment of secretory diarrhea are under investigation.⁷

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of William B. Strum, MD, who wrote this chapter for a previous edition, and Deborah Mouzon for her technical assistance.

Hematologic Consequences of Poisoning

STEVEN C. CURRY, MD

This chapter provides an overview of hematologic issues confronted by toxicologists caring for patients who are suffering from acute or chronic poisoning. The thousands of pharmaceutical agents that produce adverse hematologic effects when given at therapeutic doses (e.g., agranulocytosis, aplastic anemia, and thrombocytopenia) or at intentionally toxic doses (e.g., chemotherapy) are not the subject of this chapter. Details concerning specific agents are found in other chapters of this text. The reader is also referred to Chapter 66 for a discussion of thrombolytic agents and anticoagulants.

ERYTHROCYTES

Oxidant Stress

Oxidant stress, or the removal of electrons from molecules, results in three major disorders of toxicologic interest. The removal of electrons from the protein portion of hemoglobin produces *Heinz body hemolytic anemia*. The removal of electrons from iron found in hemoglobin produces *methemoglobinemia*. The oxidation of hemoglobin's porphyrin ring by sulfur produces *sulfhemoglobinemia*. These three disorders are intertwined with respect to the pathophysiology, occurrence,¹ diagnosis, and treatment of poisonings with oxidizing agents (Fig. 14-1).

In many instances, the parent drug or toxin producing hemolysis, methemoglobinemia, or sulfhemoglobinemia possesses no significant oxidizing potential in vivo. Oxidant stress in this setting is caused by electrophilic metabolites, which are frequently generated from metabolism by cytochrome P-450 enzymes. For example, dapson and sulfonamides are metabolized to hydroxylamines that are responsible for the consequences of oxidant stress.

The mature erythrocyte lacks mitochondria and depends on glycolysis and the hexose monophosphate

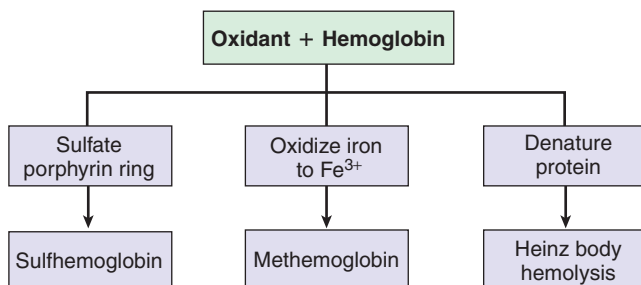

FIGURE 14-1 Results of oxidation of hemoglobin.

shunt for energy production (Fig. 14-2). Glycolysis fulfills the cell's adenosine triphosphate and NADH (nicotinamide adenine dinucleotide, reduced form) requirements, the latter being essential to the maintenance of low fractions of methemoglobin. In contrast, the hexose monophosphate shunt mainly serves to facilitate the formation of NADPH (reduced NAD phosphate), which protects against oxidant-induced hemolysis.²

Hemolysis

The mature erythrocyte continually undergoes oxidant stress from various sources, including food, infection, oxygen, drugs, and chemicals. Oxidation of the protein portion of hemoglobin (i.e., the removal of an electron from globin) results in denaturation of hemoglobin and attachment of damaged protein to the internal cell membrane. This denatured hemoglobin is visible as Heinz bodies on histologic examination of blood smears with special staining. Red cells containing denatured hemoglobin are removed from the circulation primarily by the spleen. The cells are trapped in the spleen's microcirculation, where they are destroyed; this produces

FIGURE 14-2 Metabolism in the erythrocyte. mainly an extravascular hemolysis (nonspherocytic).³ Oxidant stress may produce hemolysis by several additional mechanisms as well, including the depletion of intracellular glutathione stores with direct damage to the erythrocytic membrane, and the inactivation of several enzymes needed for erythrocyte integrity. In the face of tremendous oxidant stress (e.g., arsine), hemolysis may occur intravascularly as well.

The main mechanism by which the erythrocyte protects itself against oxidant-induced hemolysis is to reduce oxidants before they have a chance to denature

hemoglobin.² Reduced glutathione, both nonenzymatically and enzymatically with glutathione peroxidase, is responsible for most reducing capacity in this regard. Catalase reduces hydrogen peroxide, and ascorbate is a mild reducing agent (Fig. 14-3).

Adequate stores of reduced glutathione are maintained within the erythrocyte through conversion of NADPH to NADP (see Fig. 14-2). In turn, NADPH formation requires a properly functioning hexose monophosphate shunt. Patients with the various forms of congenital deficiency of glucose-6-phosphate dehydrogenase (G6PD), the first enzyme in the hexose monophosphate shunt, can be predisposed to hemolysis by sources of oxidant stress that would not affect the ordinary phenotype. The most common sources of oxidant stress in these patients are infection, drugs, and food. However, *Heinz body hemolysis can be produced in anyone* (i.e., normal phenotypes) *if oxidant stress is sufficiently severe* (i.e., after ingestion of dapsone or aniline).

Not surprisingly, substances capable of causing oxidant-induced hemolysis (Box 14-1) share the ability to produce methemoglobinemia and sulfhemoglobinemia. However, some agents are better known for the hemolytic activity they induce than for accompanying dysmethemoglobinemias. As examples, arsine and stibine cause massive hemolysis and death following inhalation. Ingestion of naphthalene results in the formation of α -naphthol, a metabolite that is responsible for hemolysis. Patients ingesting, aspirating, or inhaling large amounts of gasoline also can experience significant hemolysis,

*Poisoning by these agents variously produces Heinz body hemolytic anemia, methemoglobinemia, sulfhemoglobinemia, or any combination of these. Agents best known for causing sulfhemoglobinemia are listed in Box 14-4.

[†]Children's crayons made in the United States are safe.

although the exact cause of this outcome is not clear. Perhaps naphthalene, a component of gasoline, is also responsible for hemolysis in gasoline poisoning. Chlorates and chromates produce both severe hemolysis and methemoglobinemia.

The diagnosis of hemolysis is based on the demonstration of a decrease in blood hemoglobin concentration, an increase in plasma free hemoglobin concentration, and a decrease in serum haptoglobin concentration. Other diagnostic clues include hemoglobinuria (after plasma concentrations of hemoglobin have become sufficiently elevated) and the presence of Heinz bodies (confirmed by special staining technique). Heinz bodies are not detectable on a routine Wright stain of blood, but “bite cells” or other abnormally shaped cells may be noted.⁴ Spherocytes are typically absent or only mildly increased in number. Reticulocytosis is delayed for several days after onset of hemolysis. Although hemolysis may occur early after poisoning (e.g., with chlorate toxicity), it may not become clinically apparent until several days after ingestion. Other complications of hemolysis include hyperkalemia, pigment nephropathy, and jaundice. In severe cases, impaired oxygen-carrying capacity results in metabolic acidosis, brain failure, and cardiovascular collapse. Methemoglobinemia and, occasionally, sulfhemoglobinemia may accompany Heinz body hemolytic anemia, and evidence of such a combination should be sought.

In general, treatment is supportive and includes giving blood transfusions, ensuring a brisk urine output, and monitoring for hyperkalemia. Specific therapies may be indicated in poisonings with specific toxins (e.g., exchange transfusions for arsine; D-penicillamine therapy for copper). Intravenous administration of *N*-acetylcysteine prevents severe decreases in whole blood glutathione concentration in cats suffering from acetaminophen-induced methemoglobinemia (this is not a problem in humans).⁵ This finding suggests that *N*-acetylcysteine might be effective in preventing or lessening oxidant-induced hemolysis in humans with acute poisonings, but this conjecture has not been proved.

METHEMOGLOBINEMIA

Pathophysiology

Reduced hemoglobin (deoxyhemoglobin) contains four heme groups, each with a ferrous (Fe^{2+}) ion capable of binding and transporting oxygen. Oxidation (removal of an electron) of iron to the ferric (Fe^{3+}) state produces *methemoglobin*. The fact that oxidant stress produces both denaturation of hemoglobin (Heinz body hemolytic anemia) and methemoglobin explains the common coexistence of hemolysis and methemoglobinemia (see Fig. 14-1).

Methemoglobin continually forms in erythrocytes, to a large extent from the oxidizing power of oxygen. Methemoglobin fractions are most commonly reported in percentages. These values represent the total

percentage of hemoglobin pigments present as methemoglobin. Normally, methemoglobin fractions in circulating whole blood are less than 1% to 2%. When fractions exceed this value, methemoglobinemia is said to be present. Although the term *hemoglobinemia* means the presence of excess hemoglobin in plasma, the term *methemoglobinemia* means the presence of elevated circulating fractions of methemoglobin within erythrocytes.

Methemoglobin cannot transport oxygen and thus produces a functional anemia. Furthermore, ferric heme groups impair unloading of oxygen by ferrous heme on the same hemoglobin tetramer, shifting the oxyhemoglobin dissociation curve to the left and thereby further impeding oxygen delivery.² Thus, the signs and symptoms of methemoglobinemia result from the impairment of oxygen delivery to tissues.

Unlike hemoglobin, methemoglobin is dark brown. Five grams of normal reduced hemoglobin per deciliter of capillary blood produces visible cyanosis. However, only 1.5 g of methemoglobin per deciliter of blood produces noticeable discoloration. In a patient without anemia, methemoglobin fractions of approximately 10% to 15% produce cyanosis, even before the impairment of oxygen delivery becomes significant. As methemoglobin fractions increase to more than 20% in the nonanemic patient, cardiovascular and central nervous system signs develop and include headache, dyspnea, tachypnea, tachycardia, and mild hypertension. Further increases in methemoglobin fractions into the 40% to 50% range (without anemia) produce confusion, lethargy, and metabolic acidosis. Additional elevation results in coma, seizures, bradyrhythmias, ventricular dysrhythmias, and hypotension; when methemoglobin fractions approach 70%, death ensues. The anemic patient suffers more severe symptoms at given methemoglobin fractions than does the nonanemic patient. In addition, anemic patients exhibit less profound cyanosis at given methemoglobin fractions.

The inactivation of oxidants is relatively unimportant in maintaining methemoglobin fractions within the normal range. For example, patients with congenital glutathione deficiency, G6PD deficiency, catalase deficiency, and scurvy do not have elevated methemoglobin fractions. Rather, methemoglobin fractions are maintained within the normal range by immediate reduction back to ferrous hemoglobin after spontaneous formation.

Cytochrome- b_5 reductase is responsible for essentially all methemoglobin reduction in vivo (Fig. 14-4).⁶ In the step mediated by this enzyme, electrons are transferred from NADH (from glycolysis) to cytochrome b_5 and then to methemoglobin to form deoxyhemoglobin. Thus, the normal functioning of this enzymatic reduction requires an intact glycolytic pathway, cytochrome b_5 , and adequate activity of the reductase enzyme. Usually, the rate of the enzymatic reduction of methemoglobin exceeds the rate of spontaneous background methemoglobin formation by several hundred-fold. Patients who are heterozygous for this enzyme deficiency normally do not have elevated methemoglobin fractions but are

FIGURE 14-4 Reduction of methemoglobin. Essentially all methemoglobin reduction in vivo is catalyzed by cytochrome- b_5 reductase. Methylene blue markedly enhances methemoglobin reduction by acting as a cofactor for NADPH methemoglobin reductase. HbFe^{2+} , normal ferrous hemoglobin; NADPH, reduced nicotine adenine dinucleotide phosphate; METHbFe^{3+} , methemoglobin.

predisposed to suffering methemoglobinemia in response to oxidant stress that would not affect a patient with a normal phenotype. Patients homozygous for this deficiency have congenital methemoglobinemia.

A second enzyme, *NADPH methemoglobin reductase*, normally remains inactive. However, the addition of a cofactor such as methylene blue markedly accelerates NADPH methemoglobin reductase activity and serves as the basis for treating methemoglobinemia with methylene blue.² In this pathway (see Fig. 14-4), electrons are transferred from NADPH (from the hexose monophosphate shunt) to methylene blue and then to methemoglobin to produce deoxyhemoglobin. Thus, reduction of methemoglobin by this pathway requires an intact hexose monophosphate shunt, a cofactor such as methylene blue, and normal activity of the NADPH methemoglobin reductase enzyme. In vitro, some methemoglobin reduction can be demonstrated by glutathione and ascorbate; however, this activity is thought to be insignificant in vivo. Ascorbate generally is not considered an effective agent for the treatment of acute methemoglobinemia because of its slow action.

Infants are predisposed to methemoglobinemia because of their limited cytochrome- b_5 reductase activity and the low cytochrome- b_5 concentrations in their erythrocytes. Oxidant stress resulting from infections such as gastroenteritis or urinary tract infections are by far the most common cause of acquired methemoglobinemia in patients of this age group.^{7,8}

Etiology

CONGENITAL CAUSES^{3,6}

Homozygous deficiency of cytochrome- b_5 reductase produces congenital methemoglobinemia, which responds to oral methylene blue therapy. Several mutant hemoglobin species collectively termed *hemoglobin M* have been described in which the iron remains in the ferric form. Most patients with hemoglobin M suffer from congenital methemoglobinemia that is unresponsive to methylene blue therapy. Finally, there exist mutant unstable hemoglobins that undergo denaturation to produce congenital Heinz body hemolytic anemias; some of these also oxidize to methemoglobin.

ACQUIRED CAUSES

Most cases of methemoglobinemia are acquired and, except in neonates with infections, result from exposure to drugs or toxic agents (see Box 14-1). Oral overdoses of nitroglycerin and organic nitrates (which are esters of nitrite), as well as therapeutic doses of intravenous nitroglycerin are well known to produce methemoglobinemia.⁹ The topical use of benzocaine spray, teething ointments, and hemorrhoidal creams, along with therapeutic doses of most other local anesthetics administered by injection or topical application (e.g., lidocaine spray for bronchoscopy) have produced this disorder. Methemoglobinemia is the rule following overdoses of phenazopyridine (Pyridium) or dapsone, and it occasionally results from the administration of therapeutic doses of the latter. The conversion of nitrates to nitrites by bacteria in the upper gastrointestinal tract has produced fatal methemoglobinemia in infants who ingested well water with high nitrate concentrations.¹⁰ The recreational use of inhalable nitrites such as isobutyl nitrite has resulted in death. Aniline dyes are potent inducers of methemoglobinemia, and topical contact with these agents, which include components of printing ink on diapers, leather dyes in new shoes, and commercial marking crayons, has resulted in significant methemoglobinemia and death.² A multitude of prescription drugs have been less frequently associated with methemoglobinemia, including valproic acid, ifosfamide, and flutamide.

As expected, many agents producing methemoglobinemia also produce oxidant-induced hemolysis. For example, profound hemolysis may accompany poisonings with chlorates, arsine, stibine, chromates, and dapsone.

Diagnosis

The diagnosis of methemoglobinemia is confirmed by multiple-wave-length co-oximetry. Other diagnostic clues, however, may be either helpful or misleading. Generalized cyanosis in the presence of a normal arterial oxygen tension almost always represents methemoglobinemia. Failure of cyanosis to resolve with oxygen therapy also is an important diagnostic clue. Many blood gas instruments do not actually measure percent

saturation, although they do report a value for saturation. This value is usually calculated from the oxygen tension and pH, and it represents what the saturation should be, assuming a lack of abnormal hemoglobin pigments. Therefore, in methemoglobinemia, the true percent saturation as determined by co-oximetry is much lower than the calculated percent saturation as reported by many blood gas instruments. The difference between these two values, or the *saturation gap*, should be less than 3% to 5% in arterial blood. Large saturation gaps in arterial blood are almost always due to methemoglobinemia or carboxyhemoglobinemia and less commonly to sulfhemoglobinemia.

In the past, most co-oximeters did not differentiate between methemoglobin and sulfhemoglobin and thus reported elevated methemoglobin fractions in the presence of sulfhemoglobinemia. While some of these instruments remain in use, many more recent co-oximeters will not report a falsely elevated methemoglobin fraction in the face of isolated sulfhemoglobinemia (see later section Sulfhemoglobinemia).

Pulse oximetry neither accurately nor reliably measures percent saturation in the presence of methemoglobinemia.¹¹ Depending on the true oxygen saturation, pulse oximetry may yield falsely low or falsely high values. In an otherwise healthy patient with a normal baseline oxygen saturation, pulse oximetry will read falsely elevated saturations, although they can decline below baseline values. For example, with methemoglobin fractions of 60% and a true oxygen saturation of 40%, a pulse oximeter may report a saturation of 85%. Once the diagnosis of methemoglobinemia has been made, the pulse oximeter should be disconnected from the patient so that medical personnel are not misled by unreliable readings.

Patients with significant methemoglobinemia may be observed to have chocolate-colored blood during blood sampling. A drop of this blood allowed to dry on filter paper appears noticeably brown when compared with venous blood from an asymptomatic patient when methemoglobinemia fractions exceed 10% to 15% in the nonanemic patient.¹² The presence of methemoglobinemia does not alter measurements of total hemoglobin concentration provided by the hematology laboratory. Because co-oximetry determines methemoglobin concentrations by measuring the absorption of light, substances that interfere with light absorption can produce false results on co-oximetry. Hyperlipidemia, such as that seen after the infusion of lipid emulsions or in patients with diabetes mellitus, interferes with the measurement of hemoglobin pigments by some co-oximeters and results in the reporting of a falsely elevated fraction of methemoglobin.¹³ Total blood and plasma free hemoglobin concentrations may also be falsely elevated in this situation. Immediately after a dose of methylene blue has been administered, co-oximetry may be unreliable for several minutes.¹⁴ In the foregoing instances, it should be remembered that significant methemoglobinemia is not present in a patient with a normal hemoglobin concentration if he or she does not appear cyanotic.

Methemoglobin fractions increase after death. Therefore, postmortem methemoglobin concentrations are not valid indicators of antemortem methemoglobinemia.¹⁵

DIFFERENTIAL DIAGNOSIS

Cyanosis caused by methemoglobinemia is most commonly confused with that from hypoxia. However, in cases of isolated methemoglobinemia with or without hemolysis, the arterial oxygen tension remains unchanged from baseline values and, in the absence of other causes, is normal. Furthermore, the cyanosis from methemoglobinemia does not respond to oxygen therapy. An unusual and poorly characterized discoloration of skin and other organs has been reported in patients suffering from hydrogen sulfide poisoning. Rare cases of tellurium exposure are characterized by blue discoloration. Many patients with severe cyanide poisoning experience cyanosis, and many other signs and symptoms of cyanide poisoning are similar to those of methemoglobinemia. Both carbon monoxide poisoning and sulfhemoglobinemia (described later in this chapter) produce saturation gaps in the presence of normal arterial oxygen tensions. Skin contact with new clothing or towels that contain blue dyes may cause discoloration of the skin, but this discoloration is removed by washing or wiping the skin. Excessive administration of methylene blue may also produce cyanosis that can be confused with continuing methemoglobinemia or cyanosis from other causes.

TREATMENT

Patients suffering from methemoglobinemia should receive oxygen to maximize the oxygen-carrying capacity of their remaining normal hemoglobin. Blood should be drawn and analyzed for evidence of hemolysis (hemoglobin measurement, blood smear, Heinz body staining, plasma free hemoglobin determination, and serum haptoglobin measurement). Patients should undergo arterial blood gas analysis and co-oximetry, and routine laboratory studies should be performed. An electrocardiogram should be obtained for ruling out myocardial ischemia.

ASYMPTOMATIC PATIENTS

Many patients suffering from methemoglobinemia exhibit cyanosis but lack signs and symptoms and do not require specific treatment. Once exposure to the offending agent ends, methemoglobin levels usually return to normal within 36 hours. Most of these patients require admission to a hospital for clinical follow-up for worsening of signs and symptoms, monitoring for onset of hemolysis, and serial determination of methemoglobin levels. Assuming normal hemoglobin concentrations, asymptomatic patients usually have methemoglobin fractions between 10% and 15%.

SYMPTOMATIC PATIENTS

Symptomatic patients suffering from methemoglobinemia (e.g., tachycardia, dyspnea, headache) are candidates for antidotal therapy with methylene blue, in the absence of a history of G6PD deficiency. Parenteral

methylene blue is available as a 1% solution (10 mg/mL); it should be administered intravenously over 3 to 5 minutes at an initial dose of 2 mg/kg (0.2 mL/kg of a 1% solution). Resolution of cyanosis usually occurs within 15 to 20 minutes; more time may be required in some instances. If the patient is seriously symptomatic and no response occurs within 15 minutes, or if the patient remains moderately symptomatic without any improvement after 30 minutes, then repeat doses of 1 mg/kg (0.1 mL/kg of a 1% solution) may be given. If methemoglobin levels are readily available, repeat determinations of methemoglobin fractions should be performed before repeat dosing of methylene blue because large doses of methylene blue themselves produce discoloration of the skin. The total dose of methylene blue administered during the first few hours should not exceed 5 to 7 mg/kg.

Some methemoglobin-producing toxins have long half-lives. The classic example is dapsone, which may produce methemoglobinemia and hemolysis that last for days. In this situation, it may be necessary to administer methylene blue as a continuous infusion. Methylene blue may be dissolved in the crystalloid solution of choice and administered, on the basis of case reports in the literature, starting at 0.1 mg/kg per hour (0.01 mL/kg per hour of a 1% solution).¹⁶ However, in the author's experience, higher rates may be required on occasion. Serial methemoglobin fractions are followed to monitor therapy.

Methylene blue largely undergoes renal excretion unchanged (about 75%). Therefore, patients with renal insufficiency do not require changes in initial doses for the treatment of methemoglobinemia but should receive lower continuous infusion doses of the drug determined on the basis of their creatinine clearance.

Adverse effects associated with large or rapidly administered doses of methylene blue in normal volunteers include dysuria, substernal chest pain, nausea, tachycardia, hypertension, and anxiety. Urine initially turns blue and then green as the drug undergoes excretion. Although the literature cautions that methylene blue may produce transient methemoglobinemia when given in large doses (e.g., 5 mg/kg over 35 to 70 minutes),¹⁷ this has not been thought to be a significant problem in humans receiving recommended doses and has been ascribed largely to an *in vitro* effect occurring in the presence of hypoxic conditions.^{18,19} Worsening hemolysis in methemoglobinemia patients has been ascribed to methylene blue therapy, even in those with normal G6PD activity. However, this finding has primarily been noted in case reports of patients in whom hemolysis was not unexpected from the agent producing methemoglobinemia, making causal relationships unclear. Importantly, neonates do seem sensitive to hemolytic actions of methylene blue.²⁰⁻²² Regardless of these concerns, the administration of methylene blue to a symptomatic patient with methemoglobinemia (without G6PD deficiency) has never been proved to worsen methemoglobinemia, and so methylene blue continues to be the drug of choice for treating symptomatic patients.

Furthermore, patients with methemoglobinemia should always be closely followed for evidence of hemolysis because hemolysis is common whether or not methylene blue is given.

Methylene blue should never be administered to someone with known G6PD deficiency. Such patients have low red cell NADPH concentrations, which limit augmentation of NADPH methemoglobin reductase by methylene blue. Importantly, methylene blue triggers hemolysis in such patients, which further impairs oxygen delivery to tissues.^{2,23} Methylene blue should never be withheld from a symptomatic patient simply because a history concerning the presence or absence of G6PD deficiency cannot be obtained.

Cimetidine has been used to help control methemoglobinemia secondary to dapsone. By inhibiting cytochrome P-450 conversion to the oxidizing metabolite responsible for methemoglobinemia (dapsone hydroxylamine), oral administration of 1200 mg/day cimetidine to patients taking therapeutic doses of dapsone decreased circulating methemoglobin fractions by an average of 25%.²⁴

In a manner similar to methylene blue, riboflavin also acts as an electron transfer agent and reduces methemoglobin in the presence of NADPH methemoglobin reductase. While endogenous riboflavin concentrations are not high enough to provide for significant methemoglobin reduction, oral doses of 60 to 100 mg per day have been used with success in patients with congenital methemoglobinemia.^{25,26} The safety and efficacy of IV or oral riboflavin for the treatment of acquired, acute methemoglobinemia has not been described.

Incubation of erythrocytes in very high concentrations of *N*-acetylcysteine appears to enhance methemoglobin reduction *in vitro*.²⁷ However, these concentrations of *N*-acetylcysteine cannot be safely achieved in human beings, and a randomized controlled trial found that conventional doses of IV *N*-acetylcysteine were ineffective in reducing nitrite-induced methemoglobin fractions in human volunteers.²⁸

During the care of patients with methemoglobinemia, care should always be taken to monitor total oxygen-carrying capacity by following both hemoglobin concentrations and methemoglobin fractions. For example, a decrease in the methemoglobin fraction from 30% to 15% will not result in improved oxygen delivery if accompanying hemolysis has resulted in a decrease of hemoglobin concentration from 15 to 5 g/dL. In fact, in this example, oxygen-carrying capacity has worsened. Furthermore, the onset of anemia alone may result in the disappearance of cyanosis if total hemoglobin concentrations decrease to the point where significant amounts of methemoglobinemia do not produce discoloration. For example, a 10% methemoglobin fraction in combination with a hemoglobin concentration of 15 g/dL produces visible cyanosis in most persons. However, a 20% methemoglobin fraction in a patient with a hemoglobin level of 5 g/dL produces no visible discoloration, yet may be lethal. Therefore, caution must be taken in interpreting the disappearance

of cyanosis to mean that methemoglobinemia has not worsened or that the patient's status has improved.

After initial signs and symptoms of methemoglobinemia have been addressed, then routine gastrointestinal and skin decontamination should be performed as indicated. If ascorbic acid is used to treat methemoglobinemia, a recommended dose is 0.5 to 1 g intravenously or orally every 6 hours. Again, ascorbic acid works slowly and generally is considered ineffective for the treatment of acute acquired methemoglobinemia.

FAILURE TO RESPOND TO METHYLENE BLUE THERAPY

When patients with methemoglobinemia do not improve with methylene blue therapy, several possibilities should be considered (Box 14-2). They may have been exposed to large amounts of drugs or chemicals that, even with methylene blue therapy, produce methemoglobin at rates greater than the rate of reducing capacity. However, this possibility remains the exception. Although there are certainly times when methemoglobin fractions do not return to normal because of continued methemoglobin formation, methylene blue therapy almost always results in at least a transient decrease in methemoglobin fractions.

The patient who does not respond to methylene blue may also have an unrecognized G6PD deficiency. The rare patient with congenital lack of NADPH methemoglobin reductase also fails to respond to methylene blue treatment. Sulfhemoglobinemia can be mistaken for methemoglobinemia (see later in this chapter). Finally, repeated doses of methylene blue may result in blue discoloration of skin that is mistaken for methemoglobinemia.²⁹

Treatment options for the patient who cannot receive or who fails to respond to methylene blue therapy are somewhat limited. Blood transfusions and exchange

transfusions may be life saving³⁰ and are recommended whenever refractory methemoglobin fractions approach 70% in the nonanemic patient. Hyperbaric oxygenation can be a temporizing measure that provides adequate oxygen delivery during preparation for blood transfusion. However, a patient can stay in a hyperbaric chamber only for a relatively limited period of time without suffering from consequences of oxygen toxicity. Although not known to be effective, administration of large doses of ascorbic acid may also be indicated in this situation.

SULFHEMOGLOBINEMIA

Background and Characteristics

Sulfhemoglobin is a green molecule resulting from the incorporation of a sulfur atom into the porphyrin ring of hemoglobin by oxidant stress. Like methemoglobin, sulfhemoglobin cannot transport oxygen (Table 14-1). *Sulfmyoglobin*, a surrogate for one sulfhemoglobin tetramer, has a 2500-fold lower affinity for oxygen than myoglobin does.³¹ Although small amounts of methemoglobin normally exist in vivo, no circulating sulfhemoglobin usually occurs. Unlike methemoglobin, sulfhemoglobin persists for the life of the erythrocyte and does not undergo conversion back to hemoglobin. Very little sulfhemoglobin causes typical slate-gray cyanosis. Only 0.5 g/dL of sulfhemoglobin produces noticeable skin discoloration (as compared with 1.5 g/dL of methemoglobin and 5 g/dL of deoxyhemoglobin).

In sulfhemoglobinemia (i.e., in vivo), hemoglobin tetramers usually contain only one or two sulfated heme isomers. The affected molecules shift unaffected heme moieties toward the unliganded conformation. This reduces the oxygen affinity of the unmodified subunits and shifts the oxyhemoglobin dissociation curve to the right, enhancing oxygen delivery to tissues and partially ameliorating the effects of reduced oxygen-binding capacity.³² In contrast, methemoglobin and carboxyhemoglobin shift the dissociation curve to the left, worsening the impairment of oxygen delivery to tissues.

Sulfhemoglobin, methemoglobin, and hemoglobin M possess similar light absorption spectra, and many early authors failed to distinguish among these three abnormal pigments. Some multiple-wave-length co-oximeters still in use today report sulfhemoglobin as methemoglobin. Furthermore, early studies of "sulfhemoglobinemia" from hydrogen sulfide mixed with blood

BOX 14-2 POSSIBLE CAUSES OF FAILURE OF METHYLENE BLUE THERAPY IN METHEMOGLOBINEMIA

Response to methylene blue treatment	None	Decreases	None	None

in vitro may have represented nothing more than a mixture of oxidized and denatured hemoglobin pigments that were unrelated to what is termed *sulfhemoglobin* today.³³ Readers interpreting the confusing medical literature on sulfhemoglobinemia must be aware that older literature describing sulfhemoglobin, probably better termed *pseudo-sulfhemoglobin*,³⁴ might represent true reports of sulfhemoglobinemia, methemoglobinemia, hemoglobin M disease; various species of denatured hemoglobin from hydrogen sulfide mixed with blood in vitro; or perhaps of other chemical compounds.

Etiology

Sulfhemoglobinemia is always acquired (Box 14-3), and chemicals capable of producing sulfhemoglobinemia³⁵ usually are better known for their ability to produce methemoglobinemia and hemolysis. Thus, methemoglobinemia, sulfhemoglobinemia, and hemolysis may coexist. Why some patients develop sulfhemoglobinemia and others methemoglobinemia after exposure to the same agent remains a mystery.

Sulfhemoglobin forms when sulfur binds to the β -pyrrole ring of the heme moiety (Fig. 14-5A). Based on studies of sulfmyoglobin, it has been suggested that an unstable episulfide bond forms (Fig. 14-5B) that

spontaneously converts to the stable conformation (Fig. 14-5C), which persists for the life of the red blood cell.³⁶ In the past, authors suggested that the source of sulfur responsible for the oxidation of hemoglobin to sulfhemoglobin was the offending chemical producing the oxidant stress. However, many drugs associated with sulfhemoglobinemia do not contain sulfur. Another older belief was that an abnormally functioning gastrointestinal tract alone could produce hemolytic anemia, sulfhemoglobinemia, and methemoglobinemia ("enterogenous cyanosis") from the purported absorption of endogenously produced nitrites and sulfides. However, it appears that such patients were unknowingly ingesting analgesics known to cause such disorders.³⁷

In an attempt to identify the source of the sulfur atom when exogenous sulfur was not supplied, Westphal and Azen³⁸ studied rats with jejunal pouches in which bacterial overgrowth occurred. Rats with jejunal pouches exposed to phenacetin were more likely to develop sulfhemoglobinemia than were the controls. In addition, erythrocytes from both control animals and those with pouches were more likely to become sulfurated when incubated in the urine of pouched rats than when incubated in the urine of controls. Finally, pouched rats were less likely to develop sulfurated hemoglobin when they were treated with neomycin. This suggests that bacterial metabolism in the gastrointestinal tract may

serve as a source for sulfur found in sulfhemoglobin during times of oxidant stress induced by various chemicals. Endogenous sulfhydryl groups may act as sulfur donors during the production of sulfhemoglobin.

Laboratory Diagnosis

In an early attempt to discern what was being measured when “sulfhemoglobin” was reported to be present, Michel and Harris³⁹ reported that the addition of cyanide or dithionite (hydrosulfite) to blood bound methemoglobin eliminated its spectral absorption immediately, while that of sulfhemoglobin remained. However, this simple test did not exclude hemoglobin M (or perhaps other oxidation products of hemoglobin), which also remains after addition of these compounds. Carrico and colleagues⁴⁰ later demonstrated that carbon monoxide bound sulfhemoglobin to produce carbonmonoxy-sulfhemoglobin, a compound with enhanced spectral absorption and a down-field shift, whereas neither methemoglobin nor hemoglobin M bound carbon monoxide. Therefore, light absorption in the presence of cyanide (or dithionite) and carbon monoxide served for several years as laboratory tools to measure “sulfhemoglobin” fractions and concentrations, although it is not known that what we know today as sulfhemoglobin was always the species being measured. Park and Nagel³² reported that isoelectric focusing (a form of electrophoresis) reliably delineates the three pigments. Although this test is not widely available, it is the most reliable way of distinguishing sulfhemoglobin from methemoglobin and generally serves as the gold standard, although other methods may be used in some reference laboratories.

Various brands and models of co-oximeters detect and report sulfhemoglobin differently. As examples, Instrumentation Laboratory Inc.’s IL282 and IL482 (Lexington, MA) both report sulfhemoglobin as methemoglobin. However, the IL682 by the same manufacturer is reported to indicate the presence of sulfhemoglobin fractions greater than 1.5%.⁴¹ The Radiometer OSM3 (Westlake, OH) has been noted to report falsely elevated oxygen saturations in the presence of sulfhemoglobinemia unless a service program configuration used by factory representatives is used.⁴² It is essential that physicians know how the co-oximeter their laboratory uses detects and reports sulfhemoglobinemia. It is wise to remain skeptical about the reliability of some manufacturers’ claims and to always use a reference laboratory to quantify sulfhemoglobin if there is any question about the diagnosis.

The exact behavior of pulse oximetry in the face of sulfhemoglobinemia remains unresolved, although reports document that pulse oximeters will not provide reliable estimates of true saturation. This author has seen pulse oximeters read falsely low saturations in the face of sulfhemoglobinemia in two patients. Other authors^{43,44} have described falsely elevated saturation reports by pulse oximetry in the face of sulfhemoglobinemia. At present, pulse oximetry should not be used to estimate true saturation when sulfhemoglobinemia is suspected.

Clinical Presentation

Sulfhemoglobinemia enters the differential diagnosis with a cyanotic or gray patient who has a normal oxygen tension, who may or may not have what the laboratory reports to be elevated methemoglobin fractions, and who has failed to respond to methylene blue therapy. Except for cyanosis, most patients with sulfhemoglobinemia are not symptomatic unless other abnormal hemoglobins are present (e.g., methemoglobin) or there is accompanying anemia from hemolysis. The discoloration of skin most often appears slate gray and may persist for weeks or even months owing to the irreversible nature of sulfhemoglobin. Only rarely is sulfhemoglobinemia severe enough to produce tachycardia, tachypnea, dyspnea, and altered level of consciousness due to impairment of oxygen delivery. The coexistence of methemoglobinemia and anemia, of course, may alter the discoloration of cyanosis and clinical symptoms. As with other hemoglobinopathies, arterial oxygen tension is normal unless coexisting disease is present.

Numerous cases of “sulfhemoglobinemia” have been reported in the English literature, and the frequency of reports may be increasing with the use of more modern co-oximeters. However, only rarely has the diagnosis been confirmed with isoelectric focusing. In the past, the drugs most commonly causing sulfhemoglobinemia were acetanilide, phenacetin, and sulfonamides. Use of Bromo-Seltzer was the single most common cause, but acetanilide, the offending ingredient, has since been removed from this product’s contents. Over the last several years, reports of sulfhemoglobinemia attributable to flutamide, metoclopramide, phenazopyridine, and dapsone have appeared. Again, these same agents are known to produce methemoglobinemia as well.

Three examples of typical cases follow. Halvorsen⁴⁵ reported the case of an 85-year-old woman who received nitrofurantoin and phenazopyridine for a urinary tract infection. She was subsequently hospitalized when she complained of dizziness and was noted to exhibit cyanosis. Co-oximetry reported a methemoglobin fraction of 50.3%. The addition of cyanide to blood produced no change in the methemoglobin fraction. Methylene blue was administered and repeated 1 hour later without effect. On the ninth day of hospitalization, co-oximetry reported a methemoglobin fraction of 26.5%. Her symptoms gradually resolved, but 9 months later she was inadvertently rechallenged with phenazopyridine in combination with cotrimoxazole. She was admitted to the hospital on the seventh day of therapy for cyanosis and what was reported to be a 30% methemoglobin fraction by co-oximetry. Again, methylene blue was given without effect, and cyanosis and reported methemoglobin fractions decreased over several weeks to months.

Basset and associates⁴⁶ reported the case of a 37-year-old man who was admitted with chronic anemia and cyanosis. For two weeks he had been taking an average of 100 tablets per week of aspirin, codeine, and phenacetin for headaches. Total hemoglobin concentration was 9 g/dL, the reticulocyte count was 12%, and Heinz body

formation was observed. Diagnosis of sulfhemoglobinemia was made after identification of absorption spectra at 620 nm without change after addition of cyanide. Confirmation was performed with isoelectric focusing.

Chawla and coworkers⁴⁷ described a patient who ingested 3 g of dapsone in a suicide attempt and had cyanosis, tachycardia, and tachypnea. Laboratory studies revealed both methemoglobinemia (4.3 g/dL) and sulfhemoglobinemia (0.25 g/dL). Methylene blue therapy produced a resolution in cyanosis and methemoglobinemia and thus was continued for a total of 36 hours. Forty-eight hours later, the patient again became cyanotic, and repeat studies revealed that the methemoglobin concentration had decreased to 0.7 g/dL while the sulfhemoglobin level had risen to 0.39 g/dL.

Treatment

There is no specific antidote for sulfhemoglobinemia. Methylene blue does not confer any beneficial effect. Treatment centers on ensuring adequate oxygen delivery to tissues through the correction of coexistent methemoglobinemia and anemia (frequently from hemolysis) and on promoting maximal oxygen-carrying capacity with administration of oxygen when the patient is symptomatic. In the rare severe case, transfusions have been performed, with a resultant increase in total hemoglobin concentration and a decrease in sulfhemoglobin fraction and concentration.

OTHER ERYTHROCYTE DISORDERS

In addition to oxidant stress, anemia from other or unclear causes may occur in various acute and chronic poisonings (Box 14-4). Hemolysis from damaged red cell membranes may follow some poisonous snake bites or *Loxosceles* envenomation. Impaired heme or erythrocytic synthesis explains at least some of the anemias seen in those with toxicity produced by arsenic, lead, aluminum, colchicine, podophyllum, and nitrous oxide. Acute lead poisoning (from an acute single ingestion of a large amount of lead) may be accompanied by profound hemolysis. The ingestion of zinc supplements prevents

the absorption of copper and may lead to a sideroblastic anemia.⁴⁸

Elevated values for mean erythrocytic cell volumes suggest the presence of several different toxins (Box 14-5). Refractory anemia seen in benzene-induced myelodysplastic syndromes may also be accompanied by an increased mean cell volume.

Carboxyhemoglobin is covered in Chapter 87. Like other dyshemoglobinemias, carboxyhemoglobin produces a percent saturation gap. Like methemoglobin, carboxyhemoglobin does not carry oxygen and shifts the oxyhemoglobin dissociation curve to the left, further impairing oxygen delivery. Pulse oximetry does not detect low oxygen saturations that result from carboxyhemoglobin. Accurate diagnosis is made with the use of co-oximetry.

Porphyrias are diseases resulting from deficiencies of various enzymes involved in heme synthesis. Although a multitude of agents given at therapeutic doses have exacerbated or triggered crises in patients with porphyrias, the chronic ingestion of grain treated with hexachlorobenzene (a fungicide) serves as the main example of a toxin's being primarily responsible for an outbreak of porphyria (porphyria cutanea tarda).⁴⁹ It is now recognized that most patients with idiopathic porphyria cutanea suffer from hepatitis C, and it is unclear whether hepatitis C played an important predisposing role in hexachlorobenzene-induced porphyria.

Leukocytes

Although hundreds of pharmaceutical agents given at therapeutic doses produce leukopenia as an adverse effect, the presence of leukopenia in acute or chronic poisoning suggests only a few causes (Box 14-6). Leukopenia following acute overdoses of chemotherapeutic drugs may not appear for several days and commonly reaches a nadir in 1 to 3 weeks. In contrast, the leukopenia following colchicine poisoning is frequently severe and of rapid onset, appearing within 48 hours after an initial leukocytosis.⁵⁰ Leukopenia commonly accompanies the sideroblastic anemia seen in copper deficiency from the ingestion of excessive zinc supplements.⁴⁸ Some types of nonlymphocytic leukemias might result as part of a benzene-induced myelodysplastic syndrome after chronic exposure.

Platelets

Thrombocytopenia may result from bone marrow suppression (e.g., by chemotherapeutic drugs, colchicine, or arsenic), increased destruction by enzymes (e.g., after snake bite), or an intoxication complicated by disseminated intravascular coagulation. Severe acetaminophen toxicity (with hepatic failure) may be accompanied by profound thrombocytopenia.⁵¹ Thrombocytopenia has been reported on several occasions complicating valproic acid overdoses.⁵² Most thrombocytopenia seen in patients who have received therapeutic doses of drugs is immune mediated.

Numerous pharmaceutical agents impair platelet function at therapeutic doses and, of course, at toxic doses. Examples include aspirin, nonsteroidal anti-inflammatory drugs, ticlopidine, dipyridamole, and nitroglycerin. Despite inhibition of platelet function, bleeding is a rare cause of serious morbidity or mortality after acute poisonings by these agents.

15 *Ocular Toxicology*

ANGELA C. ANDERSON, MD

At a Glance...

- All chemical exposures to the eye require immediate decontamination by copious irrigation with an aqueous solution.
- Rapid irrigation optimizes the chances for full recovery after chemical eye injuries; conversely, a delay in decontamination can negatively affect outcome.
- Tap water is readily available, safe, and effective and, thus, the preferred irrigation fluid.
- Lactated Ringer's solution is theoretically preferable to normal saline as an ocular irrigant because it has a more physiologic pH and osmolarity.
- Newer, specialized irrigation solutions (e.g., hexafluorine or Diphoterine, Previor Laboratories, France) may become the ideal methods of ocular decontamination, particularly following exposure to chemical warfare agents.
- Some ocular toxins have delayed effects (e.g., mustard agents and hydrofluoric acid).
- Immediate ophthalmologic referral is recommended for all but the most trivial chemical burns to the eye.

In 2005, 133,270 ocular toxic exposures were reported to national poison centers.¹ These exposures accounted for 5.2% of all poison center calls. Toxic injuries to the eye result predominantly from direct, local contact with caustic substances. Some toxins, however, may produce ocular toxicity following systemic absorption, and certain toxins may produce systemic effects following ocular exposure. This chapter reviews the more common and devastating caustic eye injuries and potential abnormalities caused by toxins absorbed systemically.

Consequences of toxic eye injuries may range from minor eye irritation to total loss of vision. Understanding the mechanisms of ocular injury produced by toxic substances requires an understanding of the anatomy, physiology, and repair mechanisms of the eye.

Anatomy of the Eye

The anatomy of the eye is illustrated in Figures 15-1 and 15-2.^{2,3} The conjunctiva is the outermost layer of the globe. The portion that overlies the globe itself is called the bulbar conjunctiva, while that which lines the inner surfaces of the eyelids is the palpebral conjunctiva. The next layer is the cornea, which overlies the iris and the anterior chamber of the eye. It is continuous with the sclera, the white part of the eye. The bulbar conjunctiva

covers both the cornea and the sclera. The cornea and sclera meet at the limbus (see Figs. 15-1 and 15-2). This area is also the location of the canal of Schlemm, which is the drainage system for aqueous fluid. The space posterior to the cornea and anterior to the iris is the anterior chamber. Behind the iris are the posterior chamber and the lens. Aqueous humor is secreted by the ciliary process into the posterior chamber, travels through the pupil into the anterior chamber, and drains into the canal of Schlemm. The vitreous and the retina are posterior to the lens.

Eye Physiology and Toxin-Induced Physiologic Disturbances

The cornea is normally transparent because it is avascular. It derives nutrition from the aqueous humor and oxygen from that which is dissolved in tears. The cornea comprises five layers. The outermost layer is the epithelium, which has three major purposes: (1) it provides a barrier to microbial pathogens, (2) it produces cytokines that inhibit collagenase production from fibroblasts, and (3) it produces superoxide dismutase, which scavenges free radicals.^{4,5} Alkali, acids, and other eye toxins can damage the epithelium and impair these functions.

The next layer is Bowman's membrane. It is not capable of regeneration if damaged. Injuries that extend through this layer always result in scar formation.⁶

The stroma is the third layer and makes up 90% of the cornea. It consists mostly of collagen. Binding of alkali cations to collagen causes stromal hydration; thickening and shortening of collagen meshwork occurs as well. Stromal hydration results in loss of corneal clarity, and contracted meshwork results in an increase in intraocular pressure (glaucoma).⁴ The cellular components of the stroma are keratocytes, which are responsible for remodeling damaged stroma. Sensory nerve endings are located in the stroma as well. Consequently, damage to the stromal layer may result in anesthesia of the eye.

The fourth layer of the cornea is Descemet's membrane. Injury to this layer produces corneal hydrops, a condition in which aqueous leaks from the anterior chamber into the stroma and causes corneal clouding.

The endothelium is the innermost layer of the cornea. It is responsible for transporting aqueous back and forth between the anterior chamber and the cornea. Damage to this layer may result in permanent corneal edema.

Damage to the iris and ciliary body may cause either increased intraocular pressure secondary to impaired outflow of aqueous, or hypotony from decreased aqueous production or aqueous leakage. Lens injuries may result in cataract formation.

FIGURE 15-2 Anatomy of the anterior eye: surface view.

Mechanisms of Repair

EPITHELIUM

Repair of the epithelium is a two-step process. Reepithelialization is the first step: it involves replacement of lost or damaged epithelium. This is followed by differentiation, in which the newly formed epithelium undergoes further morphologic development. Small defects in the epithelium will be repaired in 1 to 3 days; large defects may take up to 2 weeks.⁶ The rate of this process, and the ultimate morphology and physiology of the new epithelial layer, depends on the source of the migrating epithelium.⁴ If portions of the corneal or limbal epithelium have remained intact after chemical injury, reepithelialization is rapid and differentiation results in a normal, clear, and stable corneal epithelium. If the corneal and limbal epithelia have both been destroyed, resurfacing must depend on the conjunctival epithelium as a source for the new layer. This is a slower process, which may result in a normal epithelium if the injury was not severe. However, if damage was extensive, the new corneal surface will retain the characteristics of conjunctival epithelium, which will result in vascularization, fibrovascular pannus formation, and loss of clarity. This may cause significant vision loss. Additionally, severe damage to goblet cells may cause abnormal tear film

production, leading to chronic ocular surface irritation. This may result in the formation of a symblepharon, an adhesion between the palpebral and bulbar conjunctiva.

STROMA

Stromal keratocytes secrete collagen, collagenase, and matrix mucopolysaccharides. If these cells are injured, balanced regulation of the healing cornea may be disturbed and collagen breakdown may exceed collagen synthesis. This causes sterile ulcerations of the cornea, which may progress to perforation.

SPECIFIC AGENTS AND THEIR MECHANISM OF TOXICITY

Caustic (Corrosive) Chemicals

CHEMICAL IDENTIFICATION AND STRUCTURE OF ALKALIS

The most common and severely damaging alkalis are ammonium hydroxide (NH_4OH), sodium hydroxide (NaOH), potassium hydroxide (KOH), and calcium hydroxide ($\text{Ca}(\text{OH})_2$) (see Table 15-1 and Chapter 98).

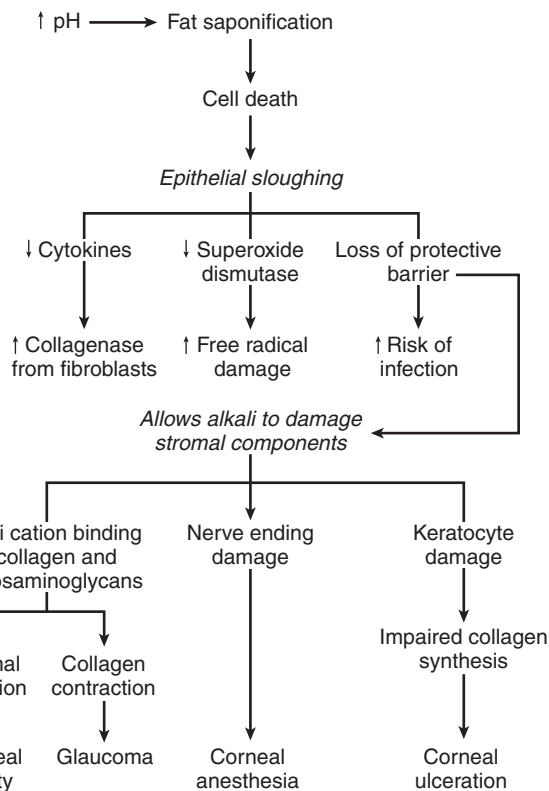

PHARMACODYNAMICS/MECHANISM OF ACTION AND TOXICITY

Alkali burns commonly cause the most severe chemical injuries. The severity of tissue injury is proportional to the degree of increase in tissue pH. The hydroxyl ion saponifies fatty acids (lipids) in cell membranes (Fig. 15-3). This causes cell destruction and allows for further penetration of the substance into the deeper structures of the eye. The depth of destruction influences the potential complications caused by the exposure. Alkali cations react with and hydrate tissue stromal contents (e.g., collagen), which leads to loss of ocular tissue clarity.

In animal studies in which rabbit corneas are removed, the degree of damage caused by various alkalis is directly correlated to the magnitude of the solution's pH, with irreversible damage occurring at a pH greater than 11.0.⁷ However, when the corneal epithelium is intact, the extent of damage becomes dependent on the

**TABLE 15-1** Alkalis: Characteristics, Uses, and Ocular Toxic Effects

ALKALI	CHEMICAL COMPOSITION	DOMESTIC AND INDUSTRIAL USES	COMMENTS	POTENTIAL COMPLICATIONS
Ammonium hydroxide	NH ₄ OH	Fertilizer, refrigerant, cleaning agents	Highly soluble Extremely rapid penetration	Corneal anesthesia Cataract formation Glaucoma Permanent blindness
Sodium hydroxide	NaOH	Drain and oven cleaner Car airbags Acid neutralization Petroleum refining Treatment of cellulose, plastics, and rubber	Second to NH ₄ OH in rate of penetration	Same as those of NH ₄ OH
Potassium hydroxide	KOH	Common laboratory reagent	Third highest rate of penetration of the alkalis	Similar to those of NaOH
Calcium hydroxide	CaOH	Mortar, plaster, cement, whitewash	Calcium soaps cause slower penetration than other alkali Particulate matter may provide reservoir for continued exposure	Superficial ground glass opacification

**FIGURE 15-3** Alkali: mechanisms of action and toxicity.

rate and manner of penetration through the epithelial barrier. The rate of epithelial penetration is highest for substances with the greatest fat solubility. Penetration rates of various alkalis (controlled for pH), listed from slowest to fastest, are as follows: calcium hydroxide, potassium hydroxide, sodium hydroxide, and ammonium hydroxide.⁸

Other factors important to the injury process include the concentration and amount of the chemical, duration

of exposure, and binding of alkali cations (e.g., sodium, calcium) to corneal membranes.⁸

CLINICAL PRESENTATION

Pain is the most common symptom associated with ocular injuries. Ironically, the absence of pain experienced in some exposures may be indicative of a greater severity of injury and poorer prognosis since some injuries destroy sensory nerves of the cornea, causing anesthesia. Injuries in which ocular sensation remains intact are more superficial and more painful. The patient may also complain of decreased visual acuity.

SPECIFIC ALKALIS

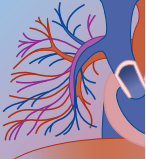

Ammonia

Ammonia (NH₃) is a colorless gas used as a fertilizer, a refrigerant, and in the production of other chemicals. It is found most commonly in the household as a 7% solution used for cleaning. Available industrial solutions contain concentrations of ammonia as high as 29% (see Chapter 97).

Fumes of ammonia gas stimulate tearing, which dilutes the chemical and decreases its potential for injury. Consequently, ammonia gas is irritating to the eye, but rarely causes significant damage without prolonged contact.

Ammonia liquefies under pressure to form ammonium hydroxide (NH₄OH). Aqueous ammonium hydroxide and liquid ammonia cause the most devastating eye injuries. These solutions are highly soluble in tissue water. High lipid solubility allows rapid penetration of ammonia into the deeper structures of the eye. The pH of the aqueous humor rises within seconds of exposure to ammonia, while similar increases from sodium hydroxide take 3 to 5 minutes.^{4,9} Aqueous pH returns to normal in 30 minutes to 3 hours, with or without irrigation.¹⁰

Because of its extremely rapid penetration, ammonia exposures are very difficult to ameliorate by rapid

irrigation. As a result, ammonia exposures to the eye may produce serious complications, such as corneal opacification, corneal anesthesia, stromal edema, atrophy of the iris, dense cataract formation, persistent and recurrent glaucoma, and permanent blindness.⁸

Sodium Hydroxide

Sodium hydroxide (also termed *lye*, *caustic soda*, and *sodium hydrate*) is a white solid that dissolves in water to produce a strongly alkaline solution. Both the solid and liquid forms can cause severe injury to all tissues. It is most commonly found in the home as drain and oven cleaners in concentrations between 0.5% and 54%. Industrial uses include acid neutralization, petroleum refining, and treatment of cellulose, plastics, and rubber. Another potential source of exposure is associated with automobile airbag deployment.¹¹ Sodium hydroxide and talc powder liberated during airbag deployment have resulted in corneal keratitis, abrasions, and chemical burns.¹¹

The penetration rate of sodium hydroxide is second only to that of ammonium hydroxide; consequently, eye damage can be similarly devastating (see discussion of ammonium hydroxide in the earlier section on Ammonia). Studies performed on rabbit eyes demonstrated severe injury and perforation following a 30-second exposure to a drop of 1-N (4%) sodium hydroxide; both mild and severe injury following 15 to 20 seconds of exposure to a 2-N solution; and mild burns from a 0.5-N solution for 30 seconds.⁸

Potassium Hydroxide

Potassium hydroxide (caustic potash) causes the same degree of injury as sodium hydroxide.⁸

Calcium Hydroxide

Calcium hydroxide, or lime, is a common cause of alkali injury in the construction workplace. It is a white powdered or granular solid that is used to make plaster, cement, mortar, and whitewash. Since calcium hydroxide exists in a particulate form, it is commonly retained in the eye (particularly beneath the upper eyelid) and provides a continuous source of exposure. Fortunately, it penetrates the eye much more slowly than ammonium hydroxide or sodium hydroxide, forming insoluble calcium soaps during saponification of cell membrane fatty acids. The calcium soaps precipitate and make penetration of the cornea more difficult. Consequently, lime causes many of the superficial complications seen following other strong alkali injuries, but deeper structures, such as the iris and lens, are routinely spared.⁸

Although calcium hydroxide causes eye injuries that tend to be less severe than those of ammonium or sodium hydroxide, it promotes corneal opacification more quickly than other alkalis.⁷ Mild lime burns typically cause a frosted or ground-glass opacity superficially at the level of Bowman's membrane. They usually result in a significant loss of epithelium, but rarely affect the underlying stroma. The opacification of Bowman's membrane observed in mild exposures is secondary to precipitations of calcific material. Therefore, part of the

management of these injuries involves the use of disodium edetate (EDTA) to extract the entrapped calcium (see section on Special Management Considerations).¹² More severe injuries occur when the pH is 12 or higher and are often associated with stromal opacification and corneal anesthesia.⁸ Stromal opacification is a result of damage to stromal components and is not responsive to EDTA treatment.

CHEMICAL IDENTIFICATION AND STRUCTURE OF ACIDS

Acids can be classified as inorganic or organic. Inorganic or mineral acids, unlike their organic counterparts, lack carbon atoms (see Table 15-2 and Chapter 98). Strong inorganic acids include sulfuric, hydrochloric, hydrofluoric, and nitric acids, and liquid sulfur dioxide.^{3,13} These acids can cause significant ocular damage similar to that of alkalis. Common organic acids include acetic acid, formic acid, and phenol. Acids may also exist as an anhydride, which is the oxide of a metalloid or metal. When combined with water, the anhydride forms its acid. Common organic anhydrides include acetic anhydride and maleic anhydride. Typically, organic acids destroy the conjunctiva and cause little damage to the cornea. Corneal opacification and complete vision loss, however, have been occasionally described with these compounds.¹⁴ Acid anhydrides usually cause more severe damage than their corresponding acids, because of their ability to penetrate the cornea more quickly.¹⁴

PHARMACODYNAMICS/MECHANISM OF ACTION AND TOXICITY

In acid burns to the eye, the hydrogen ion causes tissue damage by lowering pH, whereas the anion component precipitates and coagulates proteins of the corneal epithelium, forming a relative barrier to further penetration of the acid. Consequently, acids cause fewer stromal and intraocular complications and have a reputation for causing less severe eye injuries than alkalis. However, this is primarily true of weak or dilute mineral acids with concentrations of 10% or less. Although acids tend to be less penetrating and may require a few hours of contact to cause ocular injury, the surface injuries (vascularization and corneal scarring) can be as severe as those of alkali exposures.

Various factors enhance the severity of acid burns. Significant ocular injury does not occur unless the pH of the solution is 2.5 or less. If the protective epithelium of the cornea is removed or compromised, damage can occur with weaker or higher pH substances. Some acids react with water to produce an exothermic reaction. The heat liberated from this reaction damages the corneal epithelium and allows increased tissue penetration. Acids with strong solvent or lipophilic properties destroy cell membranes and penetrate the eye rapidly. Finally, prolonged contact with any acid increases the likelihood of significant ocular injury.

CLINICAL PRESENTATION

As with most chemical eye injuries, pain and irritation are the most common presenting symptoms. Initial

**TABLE 15-2** Acids: Characteristics, Uses, and Ocular Toxic Effects

ACID	CHEMICAL COMPOSITION	DOMESTIC AND INDUSTRIAL USES	COMMENTS	POTENTIAL COMPLICATIONS
Inorganic Acids				
Sulfuric acid	H ₂ SO ₄	Automobile batteries Metal, chemical, fertilizer	Causes thermal and chemical injury	Globe perforation Corneal opacification
Hydrochloric acid	HCl	Metal refining, bleach, plumbing	Strong solvent properties promote cell membrane destruction	Corneal opacification
Hydrofluoric acid	HF	See Table 15-3	Free fluoride ion binds Ca ⁺ and Mg ⁺ to cause liquefaction necrosis	Globe perforation Total globe destruction
Nitric acid	HNO ₃	Soda, engraving, metal, fertilizer	Possible delayed toxicity	Corneal opacification Symbblepharon formation
Sulfur dioxide	SO ₂	Refrigerant, bleach, fruit and vegetable preservative	Causes eye anesthesia Possible delayed toxicity	Symbblepharon formation Conjunctival overgrowth of cornea
Organic Acids				
Acetic acid	CH ₃ OOH	Vinegar (10%) Essence of vinegar (80%) Glacial acetic acid (90%)	>10% needed to cause damage if exposure brief Severity of damage may be delayed	Minor injury unless concentrated solution or prolonged exposure
Formic acid	HCOOH	Airplane glue Cellulose, tanning, formate	Rapidly penetrating	Minor to severe damage
Phenol	C ₆ H ₅ O	Antiseptic, disinfectant, barn deodorant	Caustic to skin and eyes	Corneal hypesthesia and opacification Complete vision loss
Organic Anhydrides				
Acetic anhydride	CH ₃ COOH	Manufacture of acetyl compounds, cellulose acetates, glycerol Dehydrating agent	Severity of damage may be delayed More damaging than dilute acetic acid	Permanent opacification if delayed decontamination
Maleic anhydride	C ₄ H ₂ O ₃	Manufacture of alkyd resins, pharmaceuticals Dye intermediate Agricultural chemicals	More damaging than maleic acid	Produces damage similar to that of alkali

examination of patients with severe damage may reveal iritis, corneal opacification, or corneal anesthesia. Evidence of these abnormalities usually occurs within hours of acid contact, but they may be delayed, particularly following sulfuric acid and hydrogen fluoride exposures.

SPECIFIC ACIDS

Inorganic Acids

SULFURIC ACID

Sulfuric acid is used in fertilizing, metal, and chemical industries. It can be found in household drain cleaners in concentrations as high as 99.5%. However, most sulfuric acid burns to the eye result from exploding automobile batteries. The most common causes of battery explosions include improper use of battery cables, using a match to read the directions on the battery, smoking while working, and improperly connecting battery chargers.¹⁴ When concentrated sulfuric acid reacts with water in the tear film of the cornea, heat is released, causing both thermal and chemical burns to the eye. Very severe burns may cause complete opacification of the cornea or perforation of the globe with loss of significant ocular

fluid.⁸ Complications include glaucoma and cataract formation.

Although the ocular damage caused by concentrated sulfuric acid may be devastating, diluted sulfuric acid causes much less damage because the oxygen and hydrogen molecules in the water that dilute the acid partially satiate the acid's avidity for the same molecules in the eye. Consequently, diluted sulfuric acid produces less of an exothermic reaction on contact with the eye and behaves more like simpler acids, such as hydrochloric acid.⁸

SULFUR DIOXIDE

Sulfur dioxide exists in both gas and liquid forms. Sulfur dioxide gas is a common component of smog, but in concentrations likely too low to cause significant eye irritation.⁸ Sulfur dioxide gas has a pungent smell and is irritating to the respiratory tract at concentrations lower than those that cause eye irritation. Exposure to sulfur dioxide gas does not cause significant eye injury because of the body's protective mechanisms.

The most damaging form of sulfur dioxide is sulfurous acid, which is formed when sulfur dioxide is combined with water. Sulfurous acid is considered more

toxic than sulfuric, hydrochloric, or phosphoric acids, because it is highly lipid soluble and, therefore, penetrates the corneal epithelium quickly.^{8,15}

Liquid sulfur dioxide is responsible for all significant eye burns. It is used in fruit and vegetable preservatives, bleach, and domestic refrigerators. Eye damage from the refrigerant is attributable to the direct action of the acid itself and not to freezing.¹⁵ The solution is often combined with oil, which facilitates prolonged contact with the eye.

Although damage occurs rapidly, symptoms may be minimal following liquid sulfur dioxide exposure since the acid damages corneal nerves with resultant anesthesia of the eye.¹⁵ The patient may not become aware of eye injury until vision becomes impaired hours to days after the initial contact. Following sulfur dioxide exposure, the corneal epithelium initially becomes opacified but remains adherent to the stroma, similar to acid burns. Later, the opaque corneal epithelium sloughs, which may transiently afford the patient improved vision and allows for a better examination of deeper injury. Slit-lamp evaluation may then reveal stromal edema, corneal opacity, interstitial vascularization, and damage to the endothelium. This deeper damage is similar to that encountered in alkali burns. Vascularization and opacification may continue for months, causing severe vision impairment. Frequent complications include symblepharon formation and conjunctival overgrowth of the cornea.

HYDROCHLORIC ACID (MURIATIC ACID)

Hydrochloric acid is a weak acid but it has strong solvent properties that promote cell membrane destruction. Concentrated solutions of hydrochloric acid (36%) are used primarily in the metal refining, chemical manufacturing, and plumbing industries. More dilute concentrations (8.5% to 15%) are found in bleaching agents and toilet bowl cleaners.

Exposure to hydrochloric acid vapors in concentrations greater than 10 ppm causes immediate eye and mucous membrane irritation.¹⁶ A concentration of 1350 ppm for 1.5 hours causes corneal clouding in animals.⁸ Strong protective responses in humans usually limit the degree of exposure so that serious injury from hydrochloric acid gas is rare.

Damage to the eye from hydrochloric acid solutions only occurs when the pH is below 3.⁸ The severity of the injury can range from conjunctival irritation to total opacification of the cornea. A 2% solution of hydrochloric acid applied to human eyes for a few seconds does not produce significant injury.⁸ Application of a 10% solution to rabbit corneas results in corneal scarring 2 weeks following exposure.⁸

NITRIC ACID

Nitric acid is one of the most commonly used industrial chemicals. It is found in the soda making, engraving, metal refining, electroplating, and fertilizer manufacturing industries. It is also a common laboratory reagent. Nitric acid exists as a colorless liquid that can cause yellow opacification of the corneal epithelium. It causes tissue damage by binding to complex proteins to form a yellow substance called xanthoproteic acid.¹⁷

Accidental applications of nitric acid to the eyes of newborn babies, given in lieu of dilute silver nitrate, has caused corneal opacification, symblepharon formation, and globe shrinkage.⁸ In less severe cases, the opacified corneal epithelium may slough off in 1 or 2 days, and the eye returns to normal as the epithelium regenerates. Nitric acid causes eye injuries similar to those caused by hydrochloric acid burns and is less corrosive than sulfuric acid.

HYDROFLUORIC ACID

Hydrofluoric acid (HF) is formed when hydrogen fluoride is combined with water. Hydrogen fluoride can be a devastating eye, skin, and systemic toxin in both gaseous and liquid states (see Chapter 90). It has multiple industrial and household uses (Box 15-1).

The damage caused by HF is concentration dependent and largely related to the fluoride component rather than its corrosive hydrogen ion. Because HF is a relatively weak acid (pKa 3.8), it is largely nonionized and can penetrate cell membranes easily. During deep tissue penetration, the fluoride ion is released, and subsequently binds avidly to divalent cations to form insoluble salts (predominantly calcium and magnesium fluoride). This results in liquefaction necrosis and significantly decreased tissue concentrations of ionized calcium and magnesium concentrations. Alterations in calcium and magnesium concentrations result in an increase in cellular potassium permeability, which causes spontaneous neuronal depolarization and pain. The onset of pain is immediate following exposure to high-concentration liquids but may be delayed for several hours to days for less concentrated solutions.¹⁸ Despite its deep tissue penetration, systemic fluoride toxicity is highly unlikely following ocular exposure to HF-containing products.

BOX 15-1

USES OF HYDROFLUORIC ACID

Industrial Uses

- Semiconductor production
- Aluminum manufacturing
- Glass polishing and etching
- Electropolishing of metals
- Ceramic glazing and etching
- High-test gasoline production
- Manufacture of refrigerants
- Fertilizer production
- Leather tanning
- Control of fermentation in breweries
- Plastic production
- Germicide production
- Rust removal in commercial laundries
- Photographic etching
- Dispensing agents for insecticides
- Dispensing agents for aerosol propellants

Household Uses

- Rust remover
- Wire cleaner

Local ocular penetration of the fluoride ion may continue for 24 hours, causing progressive damage to the corneal epithelium and underlying structures.¹⁹ Reported ocular complications include tearing, conjunctival irritation and scarring, corneal opacification, uveitis, glaucoma, lid deformities, keratitis sicca, blindness, and globe perforation.²⁰ Anhydrous hydrogen fluoride has caused total eye destruction that necessitated enucleation.⁸

Animal studies have demonstrated complete recovery 10 days after ocular exposure to 0.5% HF solutions, and mild persistent stromal edema and vascularization 40 days following exposure to 2% HF solutions.²¹ Instillation of 20% HF caused total corneal opacification, conjunctival ischemia, corneal stroma edema, and necrosis of anterior ocular structures.⁸

Organic Acids

FORMIC ACID

Formic acid is found in the airplane glue, cellulose formate, and tanning industries in concentrations of about 60%. It is one of the most rapidly penetrating acids; consequently, immediate and thorough irrigation is tremendously important. In one case of eye exposure to 90% formic acid, immediate irrigation was associated with complete recovery in 36 to 60 hours (initial examination had revealed loss of epithelium and cells in the anterior chamber).²² In addition, copious irrigation was associated with complete recovery (initial examination revealed chemosis and epithelial damage) following eye exposure to a solution of 80% formic acid and 2% orthophosphoric acid. Conversely, ocular exposure to the same concentrated formic acid solution resulted in eye perforation and necessitated enucleation in a patient whose eye was less well irrigated.^{23,24}

PHENOL

Phenol, also known as carbolic acid, is used primarily as an antiseptic, disinfectant, or barn deodorant. It is available as a pure crystal and in liquid forms in concentrations that range from 1% to 88%.²⁵ Ocular exposure to 12.5% phenol in 25% glycerol has been reported to cause minor corneal opacification and a temporary decrease in visual acuity; these effects fully resolved in 4 days.⁸ Exposure to concentrated phenol, however, can cause conjunctival chemosis, corneal hypesthesia and opacification, and complete vision loss. Phenol is also very caustic to the skin and has damaged eyelids so severely that plastic surgery was required.⁸

ACETIC ACIDS

Acetic acid (CH_3COOH) is an organic acid that is found in the household as common vinegar. Other names include ethanoic acid, ethylic acid, methane carboxylic acid, and glacial acetic acid. Vinegar and most other commercial products contain 4% to 10% acetic acid. "Essence of vinegar" is 80% acetic acid; glacial acetic acid contains 90% acetic acid.

Vinegar routinely produces only minor ocular damage unless contact is prolonged. Consequences of typical exposures include immediate pain, conjunctival hyperemia, and mild, reversible injury to the cornea. Acetic acid typically requires concentrations greater than 10% to cause severe injury.²⁶ More dilute acetic acid concen-

trations, however, may produce significant ocular injury after very prolonged contact. Permanent corneal opacification was described in a woman who fainted after having vinegar thrown in her face.⁸ Severe, irreversible damage may result from essence of vinegar and glacial acetic acid.⁸

Trichloroacetic acid causes injury similar to that of low-concentration acetic acid.^{3,8}

Organic Anhydrides

ACETIC ANHYDRIDE

Acetic anhydride, in both liquid and gaseous forms, is necrotizing to tissues and is more damaging than dilute acetic acid. In its liquid form, acetic anhydride causes immediate burning of the eye, followed hours or days later by increasing corneal and conjunctival edema.⁸ Permanent opacification can occur if decontamination is delayed. Acetic anhydride reacts with water to form acetic acid. The severity of injury of both acetic anhydride and acetic acid may not be evident until a few days after exposure.

MALEIC ANHYDRIDE

Maleic acid is a crystalline substance that has the potential to cause severe ocular damage similar to that caused by alkalis. It has a very reactive double bond and may cause protein denaturation.⁸

Solvents

Organic solvents are routinely found in laboratories and in industry. Common solvents include ethyl alcohol, methyl alcohol, toluene, acetone, and butanol. Fortunately, they have no strong alkaline or acidic properties and cause almost no reaction with tissues; therefore, they rarely cause significant eye injury.⁸ On contact, solvents cause immediate pain from nonspecific dissolution of superficial lipid membranes; exposure may result in partial or complete loss of the corneal epithelium. Fortunately, these substances do not penetrate deeply and cause little or no damage to the underlying stroma.²⁶ The epithelium commonly regenerates in a few days without permanent sequelae.

Detergents and Surfactants

Detergents and surfactants cause injury that ranges from minor irritation to extensive injury. Detergents are divided into four categories: inorganic, organic, combination, and oil-soluble agents (see Chapter 102).

Inorganic detergents (sodium carbonate, sodium silicates, sodium metasilicate, and sodium phosphates) are used for laundering and dishwashing. Liquid and granular automatic dishwashing detergents contain combinations of these agents and have pH values that range from 9.7 to 12.7.^{27,28} The phosphate detergents (e.g., sodium tripolyphosphate) routinely cause only transient irritation. The non-phosphate-containing detergents (sodium carbonate, sodium silicate, sodium metasilicate) are much more alkaline than phosphate-containing agents. Consequently, sodium carbonate, sodium silicates, and sodium metasilicate have caused significantly more

corrosive damage, including total and permanent opacity and corrosion to the cornea.²⁹ In general, liquid dishwashing and laundry detergents are less corrosive than automatic, granular dishwashing detergents.³⁰

Organic detergents are composed of soaps and surfactants. Soaps cause tearing and pain, but they very rarely cause significant eye injury. The exception is commercial laundry soap that contains free alkali and has a pH of 12 or higher. These agents have caused permanent corneal opacification.⁸

Combination detergents are compounds that contain both organic and inorganic detergents. They include sodium dodecylbenzene sulfonate, sodium tripolyphosphate, sodium silicate, and sodium sulfate. These agents have caused corneal opacification in animals that have taken weeks or months to resolve.⁸

Oil-soluble detergents are additives to lubricating oils and produce no known eye hazard.

Surfactants are synthetic organic compounds that have hydrophilic properties at one end and lipophilic properties at the other end. They are used industrially for cleaning and are found in household cosmetics, ophthalmic solutions, shampoos, and detergents.

Surfactants can be classified as cationic, anionic, and nonionic. Cationic surfactants are usually quaternary ammonium compounds (e.g., benzalkonium chloride and benzethonium chloride). They precipitate proteins and routinely cause more damage than either anionic or nonionic agents. Anionic surfactants cause cell lysis. Soaps are included in this category. They tend to cause less damage but produce more pain and irritation than cationic agents. However, irreversible damage has occurred from 10% docusate and 40% dodecyl sodium sulfate.⁸ Nonionic surfactants usually cause little or no damage other than local anesthesia of the cornea. However, full-strength tetradecylheptaethoxylate and tridecylhexaethoxylate caused permanent damage in rabbits, and G1690 in concentrations of less than 10% has caused severe irritation and corneal opacity.⁸

Cyanoacrylates

Cyanoacrylate adhesives are the components of common household glues (e.g., Krazy Glue [Elmers Products, Inc., Columbus, OH] and Super Glue [Super Glue, Inc., Rancho Cucamonga, CA]) and commercially available tissue adhesives for laceration repair (e.g., Dermabond [Ethicon, Inc., Somerville, NJ]). A number of accidental applications to the eye have occurred because the bottle was mistaken for an ophthalmic solution.^{31,32} Childhood curiosity and ingenuity have resulted in a number of pediatric exposures. Applications to the eye have resulted in focal destruction of the epithelium and mild superficial stromal edema that resolved without sequelae.³¹ Use of octylcyanoacrylate for facial laceration repair could also result in inadvertent adhesive application to the eye.

Mustard

Mustard agents are potent alkylating liquid substances that cause severe vesication (blistering) of the mucous

membranes and skin (see Chapter 105B). There are two forms of mustard: (1) sulfur mustard (2,2-dichloroethyl sulfide, HD), used as a chemical warfare agent, and (2) nitrogen mustard (usually *N*-methyl-2,2-dichlorodiethylamine HN₂), a chemotherapeutic agent. Although routinely termed a *gas*, mustard exists as a straw-colored aerosol of oily droplets.³³

The eye is the organ most susceptible to injury upon exposure to mustard agents delivered via aerosol. In fact, 75% to 90% of mustard casualties in World War I experienced some degree of eye pathology.³⁴ Ninety percent of those with ocular injury were visually incapacitated for approximately 10 days.³⁵ In the Iran-Iraq War, the majority of sulfur mustard casualties experienced some degree of ocular injury and 10% developed severe damage with corneal ulceration; 2% of these patients had anterior chamber scarring and neovascularization that caused prolonged disability.

Mustard's lipophilic nature causes it to concentrate in the oily milieu of tears. As an alkylator, mustard interferes with nucleic acid function and protein synthesis. Mustard affects rapidly dividing cells most readily, making the rapidly dividing corneal epithelium a prime target. Mustard agent-induced tissue injury necessitates extensive DNA repair, which leads to depletion of cellular NAD⁺, which is required for glycolysis. Impaired glycolysis promotes release of tissue proteases, which, in turn, cause cellular necrosis.³³ Oxidative stress also results in free radical formation. Rabbit studies demonstrate that glutathione and ascorbic acid concentrations in the aqueous humor decline 4 hours following sulfur mustard exposure.³⁶

Sulfur mustard also has direct effects on cells to induce an inflammatory response that is active even before cell death has occurred; it stimulates the release of cytokines (interleukin-6 [IL-6], IL-8, IL-1 β , and tumor necrosis factor- α).³⁷ This observation has stimulated study of anti-inflammatory agents to treat mustard exposures (see section on Special Management Considerations).

Mustard agents are highly reactive and bind to cellular components within minutes of exposure. Clinical evidence of ocular injury develops gradually over 4 to 12 hours in humans.³³ Symptoms range from mild stinging and dryness, to severe pain, photophobia, blurred vision, and temporary or permanent blindness. Physical findings include blepharospasm, conjunctival injection and edema, chemosis, anterior chamber cellular infiltrates, and decreased visual acuity. Corneal edema begins within 1 hour after exposure, and the corneal epithelium vesicates and sloughs within 4 to 36 hours. The extent of ocular damage is dependent on the concentration and duration of mustard exposure. Resolution of ocular injury occurs over 1 to 2 weeks.

A small percentage (0.5%) of severely injured victims will develop delayed ulcerative keratitis as late as 40 years after the original exposure. These patients undergo a long asymptomatic period followed by recurrent keratitis and areas of porcelain white episcleral tissue that later cause opacification, recurrent ulceration, pain and blindness.³³ Corneal opacification primarily occurs in the lower and central portions of the cornea; the upper

aspect of the cornea is protected during the exposure by the upper eyelid.³⁸

Systemic Eye Toxins

Multiple agents taken systemically cause a variety of eye and vision abnormalities. A detailed description of these substances is beyond the scope of this chapter. A partial list of various agents and their effects (noted in humans) is depicted in Box 15-2. Methanol and quinine are two substances whose importance in toxicology requires special mention.

Systemic methanol toxicity is heralded by metabolic acidosis and visual disturbances (see Chapter 32A). Both formaldehyde and formic acid, the metabolites of methanol, are capable of causing ocular injury. However, the metabolite primarily responsible for the ocular damage that occurs following methanol ingestions has

been the subject of controversy. Rabbit studies suggest that direct instillation of formaldehyde into the eye causes injury to the retina and optic nerve, while direct instillation of formate causes little or no damage.³⁹ The potential reasons for this observation are twofold: (1) formaldehyde is rapidly converted in vivo to formic acid (within 1 to 2 minutes),⁴⁰ thereby providing little time to cause significant damage, and (2) in order for formic acid to cause damage, it must be metabolized from methanol within the retina itself.⁴¹ Most investigators believe that formic acid is primarily responsible for methanol-associated blindness.

Formic acid inhibits cytochrome oxidase *c* in the mitochondria of optic nerve and retinal cells.⁴² The resultant disruption of oxidative phosphorylation impairs the ability of the retina and optic nerve to produce adenosine triphosphate (ATP) and inhibits local aerobic metabolism. This inhibition of the electron transport

BOX 15-2 EYE AND VISION ABNORMALITIES FROM SYSTEMIC AGENTS

Substances Reported to Cause Papilledema When Taken Systemically

Aspirin	Dynamite	Lead	DL-Penicillamine
Bee sting (venom)	Ergotamine	Levothyroxine	Penicillin
Chloramphenicol	Ethylene glycol	Minocycline	Phosphorus
Chloedecone	Isoniazid	Minoxidil	Sulfonamides
Cisplatin	Isotretinoin	Nalidixic acid	Tetracycline
Contraceptive hormones	Ketoprofen	Nitrofurantoin	Vitamin A
Corticosteroids			

Substances Reported to Cause Nysagmus When Taken Systemically

Barbiturates	Ergot	Methocarbamol	Phenytoin
Carbamazepine	Ethchlorvynol	Methyl bromide	Primidone
Carbon disulfide	Ethyl alcohol	Methyl chloride	Streptomycin
Diazepam	Glutethimide	Methyl iodide	Toluene
Dieldrin			

Substances Reported to Cause Central Scotomas When Taken Systemically

Carbon disulfide*	Digoxin	Ethchlorvynol	Minoxidil
Cassava*	Dinitrochlorobenzene*	Ethyl alcohol	Streptomycin
Chloramphenicol*	Dinitrotoluene*	Ethylene glycol	Sulfonamides
Chloroquine	Disulfiram*	Ibuprofen	Tetraethyl lead*
Chlorpropamide*	Ergotamine	Isoniazid*	Thallium*
Digitalis*	Emetine	Lead*	Wasp sting* (venom)
Digitoxin*	Ethambutol*	Methanol	

Substances Reported to Cause Peripheral Visual Field Constriction When Taken Systemically

Bee sting (venom)	Carbon tetrachloride	Ethambutol	Oxygen
Botulism toxin	Castor beans	Methylmercury compounds	Pheniprazine
Carbon dioxide	Chloramphenicol	Methanol	Quinine
Carbon monoxide	Emitine	Naphthalene	

Substances Reported to Cause Cataracts When Taken Systemically

Acetaminophen†	Busulfan	Deferoxamine	Lead
Allopurinol	Corticosteroids	Ergot	Trinitrotoluene

Substances Reported to Cause Alopecia of the Eyebrows and Eyelids

Dactinomycin	Thallium	Triparanol	Vitamin A
--------------	----------	------------	-----------

*Also reported to cause bulbar neuritis.

†Has been described in animals, not humans.

chain promotes the formation of oxidative radicals such as superoxide and hydrogen peroxide. Antioxidant protection is particularly important for the retina because of its frequent exposure to radiation and high metabolic rate. Additional insult to the retina may be caused by a reduction in retinal glutathione concentrations, which has been observed in methanol poisoned rats.⁴²

Visual disturbances from methanol intoxication typically occur between 12 and 48 hours postingestion and range from reversible blurred vision and scotomas to permanent blindness. Fundoscopic examination reveals optic disc hyperemia, as well as retinal and disc edema. Macular edema is rare but has been described.⁴³

Systemic quinine poisoning may result in significant ocular pathology as well (see Chapter 54). The mechanism by which quinine causes ocular damage remains controversial. Two plausible theories have been promulgated and include: (1) quinine causes vasoconstriction of the retinal artery, leading to retinal ischemic damage or (2) quinine is directly toxic to the retina, which leads to subsequent attenuation of the retinal vessels. Electroretinographic studies indicate that retinal damage precedes vessel narrowing,⁴⁴ supporting the later theory. Quinine may additionally exert its retinotoxic effects by blocking acetylcholine neurotransmission in the inner synaptic layer of the retina.⁴⁵

Signs of quinine toxicity usually develop within 1 to 7 hours of an acute ingestion, but can be delayed more than 24 hours. Visual symptoms range from mild deficits in visual acuity to visual field cuts, disturbances in color and light perception, and complete blindness. Most patients recover at least some vision from several days to weeks after acute poisoning, although permanent visual defects may remain.

Fundoscopy evaluation is usually normal early in the course of quinine poisoning. Interestingly, abnormalities are often absent until symptoms begin to improve.^{45,46} Findings may include dilated pupils (possibly secondary to the anticholinergic effects of quinine), loss of papillary light reflexes, retinal arteriolar vasoconstriction, a cherry red spot, and macular edema. Optic atrophy may appear days to weeks following exposure.⁴⁶

Patient Examination

A detailed eye examination should not occur until copious irrigation has been performed. Ocular examination should include an assessment of visual acuity, intraocular pressure, tear pH, and corneal debris. The lids should be everted and examined for the presence of debris, particularly in the fornices. Irrigation should be resumed for persistent abnormalities in tear pH (i.e., pH less than 5 or greater than 8). A sterile fluorescein examination (using sterile, single-use strips) should be performed since it will allow evaluation of corneal epithelial defects; however, fluorescein examination alone will not provide adequate information about deeper damage. A slit-lamp examination is essential to assess the depth of the burn, degree of anterior chamber involvement, and potential presence of corneal edema.

Prognosis

The severity of injury at initial presentation correlates with long-term prognosis, such that preserved early vision predicts a preserved long-term visual acuity.^{4,47} The most widely used grading system for ocular alkali injuries is the Hughes classification.^{4,48} It is based on the degree of corneal epithelial damage and the extent of limbal ischemia. Damage to conjunctival and episcleral blood vessels will cause ischemia and pallor in the area of the limbus.^{8,13,49} The degree of ischemia in this area is the most important prognostic sign following alkali injury. The Hughes classification divides injuries into four groups as listed in Table 15-3.

TREATMENT PRINCIPLES

Immediate Management

The initial management of all chemical ocular injuries requires immediate decontamination by irrigation. Early application of a topical anesthetic (e.g., 0.5% to 1.0% proparacaine or tetracaine) is recommended to facilitate irrigation and enhance patient comfort. Occasionally, a lid block may be necessary to relieve severe orbicularis spasm and allow irrigation to proceed.⁵⁰ The upper and lower eyelids should be retracted, inspected for retained solid material and injury, and irrigated. Immediate referral to an ophthalmologist is necessary for all significant burns.

TYPE OF IRRIGATION SOLUTION

Any, readily available, sterile, nonirritating solution is appropriate for irrigation. The choice of irrigant is not likely to affect outcome, whereas a delay of seconds to minutes to initiate irrigation could greatly affect outcome. Thus, the most readily available irrigant is what should be used. The most commonly available solutions include sterile water, normal saline, balanced saline solution, and lactated Ringer's. Diphoterine is a newer decontamination solution that may be available at some institutions.

Ordinary tap water is readily available, safe, and effective, and is thus often the initial irrigation fluid

TABLE 15-3 The Hughes Classification System

GRADE	DESCRIPTION	PROGNOSIS
I	Corneal epithelial damage	Good
II	Cornea hazy Iris details seen Less than a third of limbus ischemic	Good
III	Total loss of corneal epithelium Stromal haze blurring iris details A third to half of limbus ischemic	Guarded
IV	Cornea opaque, obscures iris or pupil More than half of limbus ischemic	Poor

used, particularly in the prehospital environment. Although effective, tap water is hypotonic relative to the cornea. The osmolarity of the corneal stroma is 420 mOsm/L.⁵¹ On theoretical grounds, the osmolarity gradient will promote water flow into the cornea, which will facilitate corneal swelling and toxin entry into ocular tissue. These theoretic concerns should not preclude the use of tap water if it is the most readily available solution.

Normal saline (pH 4.5 to 6.0) has a higher osmolarity than water but is still hypotonic with respect to the cornea. In addition, normal saline is slightly acidic and will not normalize the pH of the anterior chamber even following prolonged irrigation.^{51,52}

Balanced saline solution plus (BSS Plus, Alcon Laboratories, Fort Worth, TX) is a pH-neutral solution (pH 7.2) with an osmolarity similar to aqueous humor. In theory, BSS does not cause corneal swelling and has enhanced buffering capabilities.⁵³ BSS Plus, however, costs more than \$100 per bottle, and must be reconstituted prior to use, which will delay initial treatment.

Normal saline buffered with sodium bicarbonate to achieve a pH near 7.4 is attractive because it is inexpensive and causes less discomfort than nonbuffered solutions.⁵⁰ It can be made by adding 0.2 mL of bicarbonate (1 mEq/mL) to 500 mL of normal saline.⁵⁴ However, initiating immediate irrigation is again paramount; therefore, the use of special solutions is not appropriate unless they are readily available.

Lactated Ringer's solution (pH 6 to 7.5) is a buffered, inexpensive solution available in the hospital setting, and is potentially more effective and better tolerated than nonbuffered normal saline. Warmed solutions and the application of topical anesthesia prior to irrigation may also obviate the need for special formulations.

Diphoterine or hexafluorine is an amphoteric, hypertonic, polyvalent, chelating solution that is currently available in the United States (JR Enterprises, Goldendale, WA). Diphoterine's amphoteric properties allow it to bind and neutralize both acidic and basic compounds; it corrects corneal and aqueous humor pH.⁵⁵ Its hypertonicity (820 mOsm/L) attracts substances that have already penetrated tissues. In addition to binding acids and bases, Diphoterine is capable of binding oxidizing, reducing, and alkylating agents, solvents, irritants, and radionuclides.⁵⁶ These characteristics make it an appealing choice for decontamination of most ocular toxins, particularly chemical warfare agents (e.g., lacrimating agents and vesicants). Diphoterine is nontoxic (median lethal dose in rats greater than 2000 mg/kg orally and dermally) and nonirritating. The preparation available in the United States is an aerosol that is contained inside a plastic bag and housed within a pressurized can; as a result, no propellant comes in contact with the eye.

DURATION OF IRRIGATION

Prolonged irrigation appears to improve outcome. Thus, irrigation should be performed for at least 30 minutes, 2 L per eye, or until the pH of the eye returns to normal (7.3 to 7.7).^{23,53} Severe acid and alkali burns require at least 1 to 2 hours of irrigation regardless of normal ocular pH.⁵⁷ A brief irrigation period (1 to 2 minutes) is

needed for most solvent injuries.⁸ An irrigation device may facilitate irrigation but is not required.⁵⁸

Special Management Considerations

A few substances deserve special management considerations. Table 15-4 includes a summary of the potential treatments for these compounds.

OCULAR CALCIUM HYDROXIDE BURNS

Irrigation should begin promptly. Following irrigation, a careful search for particulate matter should be performed; attention must be directed to identification and removal of solid material, because particulate matter usually accompanies calcium hydroxide ocular burns. It may be necessary to double-evert the upper eyelid and swab or brush away lodged material, looking especially in the fornices, where particles are frequently hidden. Application of a topical anesthetic followed by a 15-minute irrigation with a 0.01 to 0.05 mol/L (0.3% to 1.86%) solution of EDTA (at a pH between 4.6 and 7.0) may help loosen and dissolve solid matter.⁸ A cotton-tipped applicator soaked in EDTA may also facilitate particle removal. To prepare a 0.05 mol/L neutral

TABLE 15-4 Special Management Considerations

CHEMICAL	CONCERNS	MANAGEMENT
Calcium hydroxide	Embedded particulate matter Opacification secondary to calcium binding to Bowman's membrane	Swab soaked in 0.3%–1.86% disodium edetate or 15-minute irrigation with 0.3%–1.86% disodium edetate
Hydrofluoric acid	Binding of free fluoride ions Do not irrigate with benzethonium chloride or benzalkonium chloride Do not use subconjunctival injections of CaCl ₂ , MgCl ₂ , or calcium gluconate	Irrigate with water, normal saline, lactated Ringer's solution, or isotonic magnesium chloride Consider 1% calcium gluconate drops
Phenol	Decontamination may be difficult	Consider irrigation with 1% diethylenetriamine or 30%–50% polyethylene glycol
Cyanoacrylates	Eyelid adhesions	Consider mineral oil or wet compress applied overnight Antibiotic ointment applied overnight may be somewhat helpful Acetone is effective but may cause transient corneal abrasions

solution of EDTA, dilute 20 mL of Endrate disodium (150 mg/mL) (Abbott Laboratories, North Chicago, IL) with 180 mL of sterile 0.9% sodium chloride.⁸ Disodium edetate may also clear the corneal opacification caused by the binding of calcium to Bowman's membrane (see earlier section on Calcium Hydroxide).¹²

OCULAR HYDROFLUORIC ACID BURNS

Management of ocular HF burns deserves special attention for two reasons. First, in addition to simple decontamination measures, treatment of HF burns is targeted at prevention of further penetration of the fluoride ion. Second, application of substances used to treat cutaneous hydrochloric acid burns may cause damage to the eye.

Because the onset of severe symptoms may be delayed, patients with even minor symptoms following hydrogen fluoride exposure may develop significant pain and damage later. Immediate and copious irrigation is imperative, as with all chemical injuries to the eye. Irrigation with benzethonium chloride solutions (0.2% or 0.5%) or benzalkonium chloride solution (0.05%) has been recommended for treatment of HF skin burns, because these compounds deactivate the free fluoride ion. However, these solutions are potentially damaging to the corneal epithelium of the normal eye and provide no benefit for patients with ocular HF burns.^{8,20} Multiple irrigations also appear to be deleterious. For ocular HF burns, a single, thorough irrigation with 2 L of sterile lactated Ringer's, saline, water, or isotonic magnesium chloride is recommended.²¹ The use of isotonic magnesium chloride solutions have been effective and not irritating.⁵⁹

Injection of divalent cations (e.g., calcium or magnesium salts) binds free fluoride and is also commonly recommended for HF skin burns. Subconjunctival injections with CaCl_2 , MgCl_2 , and 10% calcium gluconate can induce significant eye damage and are contraindicated for the treatment of ocular hydrogen fluoride injuries.²⁰

The instillation of two to three drops of 1% calcium gluconate solution every 3 hours may be effective in ocular HF burns. This solution, when used with topical cycloplegia and antimicrobial agents, provided complete resolution of signs and symptoms in a patient with ocular burns from 49% HF seen at a 3-month follow-up visit.²⁰ Further controlled study is necessary prior to formal recommendation of calcium gluconate drops.

Hexafluorine is an amphoteric hypertonic polyvalent compound designed specifically to decontaminate HF eye and skin exposures. It has been shown to prevent chemical burns in workers exposed to 40% HF.⁶⁰ However, one study suggests that animals decontaminated with Hexafluorine had a worse outcome than those treated with topical calcium or water irrigation.⁶¹ Further study is warranted.

OCULAR PHENOL BURNS

Although isopropyl alcohol is commonly recommended for skin decontamination of phenol, water remains the

solution of choice for eye irrigation. The use of 1% diethylenetriamine or 30% to 50% polyethylene glycol (e.g., PEG 400) has been recommended for eye irrigation, but further investigation is necessary.^{8,62}

OCULAR CYANOACRYLATE EXPOSURE

When faced with the task of managing ocular cyanoacrylate exposure, eyelid adhesions are usually the greatest source of aggravation for both the patient and the health care provider. The initial management should include warm fluid irrigation through any available eye opening, as this may decrease the likelihood of corneal abrasions (especially if performed within 15 minutes of exposure).⁶³

Acetone has been successfully utilized to loosen glue from the lashes as well as the cornea itself.⁶⁴ However, acetone is irritating to the eye and may cause temporary loss of corneal epithelium.⁸

The application of mineral oil has resulted in immediate softening of adhesions.^{63,65} Application of a mineral oil compress applied overnight may be necessary to separate eyelids.

OCULAR MUSTARD EXPOSURE

Initial management of mustard eye exposures begins, as always, with irrigation for 10 to 15 minutes; although damage may have already occurred, irrigation may remove potential foreign bodies and debris. Systemic analgesics are usually required. Following irrigation, one should perform a fluorescein examination to initially assess corneal involvement. In mass casualty situations, patients may be divided into two groups: (1) those with conjunctival involvement only; and (2) those with corneal injury evidenced by areas of fluorescein uptake.³³ If injury is confined to the conjunctiva, patients may be discharged with symptomatic therapy, reassurance that vision will return to normal in a few days, and psychological support. Patients with corneal involvement should be referred to an ophthalmologist immediately for further evaluation and care.

A number of therapies specific to management of ocular mustard injuries have been evaluated. Anti-inflammatory agents appear to be promising: dexamethasone eye drops (one drop [50 μL] 4 times daily applied 1 hour postexposure) attenuated the inflammatory response in sulfur mustard exposed rabbits.⁶⁶ Diclofenac, a non-steroidal anti-inflammatory agent, applied in the same manner, gave similar but less notable results.⁶⁶

Topical diltiazem (30 μL of a 10 mmol/L solution) applied prior to nitrogen mustard application, reduced eye irritation and attenuated intraocular pressure elevation in rabbits.⁶⁷ Zinc-desferrioxamine or gallium-desferrioxamine (two drops each hour for 12 hours instilled immediately after nitrogen mustard application) significantly reduced conjunctival, corneal, iris, and anterior chamber injury by inhibiting free radical formation.⁶⁸ Finally, lowering the incubation temperature of sulfur mustard-exposed cells from 37°C to 31°C transiently decreased apoptotic cell death.⁶⁹

SYSTEMIC METHANOL-INDUCED RETINAL INJURY

Eels and colleagues described the successful use of photobiomodulation to promote recovery of retinal function following methanol-derived formate exposure.⁷⁰ Photobiomodulation is a process that uses low-energy lasers or light-emitting diode (LED) rays to accelerate wound healing. LEDs work by up-regulating cytochrome oxidase activity and mitochondrial ATP synthesis. Unlike most lasers, negligible amounts of heat are generated; therefore, thermal damage to biologic tissues does not occur. The Food and Drug Administration has deemed LED technology safe in human trials.⁷⁰ Further investigation for the use of LEDs in methanol-poisoned humans is required. See Chapter 32A for a more detailed description of the management of methanol poisoning.

SYSTEMIC QUININE-INDUCED RETINAL INJURY

Specific therapies for quinine-induced ocular injury are limited to isolated case reports and include therapies such as hyperbaric oxygen⁷¹ and intravenous nimodipine.⁷² To date, there have been no significant clinical trials in humans or animals. Refer to Chapter 54 for a more detailed description of the management of quinine poisoning.

Special Agents

Many other agents have been found to aid in the healing process following chemical injuries. These therapies are geared toward correcting impediments to reepithelialization and improving transdifferentiation (see earlier section on Mechanisms of Repair). Factors that impair reepithelialization include damage to the basement membrane, abnormal tear production, and infiltration by polymorphonuclear neutrophils.

Toxin-induced damage to the epithelial basement membrane may cause a decrease in fibronectin, which is needed to help the adherence of the advancing epithelium. If fibronectin is decreased, recurrent epithelial erosions can occur. Unfortunately, clinical trials evaluating the efficacy of fibronectin have failed to reveal a benefit.^{73,74} Abnormal tear film production may lead to chronic ocular surface irritation, making reepithelialization difficult. Finally, polymorphonuclear neutrophil infiltration will slow the epithelial migration process. Polymorphonuclear neutrophils also produce collagenase and other enzymes that interfere with corneal differentiation. Substances known or currently used to improve corneal healing are listed in Table 15-5.

Final Considerations

After irrigation, the eye should be reinspected for particulate matter and other injuries. The ocular pH should be checked intermittently over the following hour to ensure that the pH remains neutral. An ophthalmic antimicrobial agent should be applied to prevent secondary infection, and a cycloplegic drug may be added to prevent painful ciliary spasms and the development of posterior synechiae. Application of a pressure patch may improve patient comfort. Systemic analgesics rather than topical anesthetics should be administered for additional pain control. Immediate consultation with an ophthalmologist is required for all but the most trivial burns; formal ophthalmologic evaluation is recommended for most patients within 24 hours of exposure. Finally, tetanus prophylaxis should be administered as necessary.

TABLE 15-5 Medical Therapy for Chemical Injuries to the Eye

AGENT	MECHANISM OF ACTION	COMMENTS
Tear substitutes and lubricating ointments	Lubricant	Use only nonpreserved medications
Topical corticosteroids	Minimizes trauma of eyelid movement Reduces inflammation Anticollagenolytic effects	Impairs the stromal repair process that occurs ~14 days after alkali injuries; should not be continued beyond 10–14 days Can be used after 10–14 days
Medroxyprogesterone (Provera 1%)	Reduces inflammation without affecting corneal wound repair	
Ascorbate (topical and systemic)	Necessary for collagen synthesis Replaces ascorbate depletion that accompanies keratocyte damage	Reduces incidence of ulcer formation following alkali injury
Citrate	Decreases polymorphonuclear neutrophils infiltration	
Retinoic acid (vitamin A analog)	Promotes corneal epithelial differentiation	Requires further investigation
Fibronectin	Facilitates adhesion of migrating epithelium	Not currently available for clinical use
Epidermal growth factor	Promotes epithelial mitosis	Not currently available for clinical use

GLUCOREGULATORY SYSTEM

Glucose is an important source of energy for cellular function. This is especially true of the brain, which is incapable of using free fatty acids. The regulation of blood sugar is accomplished by a complex interplay of systems. Alterations in glucose level can be caused by a variety of agents with endocrine system actions. Hypoglycemia is the most common endocrine emergency, and can be life threatening in certain cases.¹ According to the National Institutes of Health, 6.3% of the U.S. population was afflicted with diabetes in 2002. A correspondingly large number of prescriptions for antidiabetic agents were written as a consequence.

GLUCOSE METABOLISM

Glucose enters the body through the intestinal wall, in some cases after its production in a catabolic reaction involving amylase or a glucosidase. It is then taken up by body tissues with the help of insulin. This hormone, secreted by the β islet cells of the pancreas, facilitates glucose uptake across cell membranes. In adipose tissues, insulin promotes glycogen formation and fatty acid synthesis. Insulin is degraded by insulinase, with a half-life of 5 minutes. In response to hypoglycemia, epinephrine release, or norepinephrine release, glucagon is secreted by the α cells of the pancreas. This hormone, a 29-unit polypeptide, works in the liver through a cyclic adenosine monophosphate pathway to activate phosphorylase. As its name suggests, this enzyme dephosphorylates glucose-1-phosphate to glucose. This reaction is the rate-limiting step in conversion of glycogen to glucose. Glucagon also induces gluconeogenesis. Both of these effects serve to increase glucose levels in the blood. A number of xenobiotics cause hypoglycemia or hyperglycemia through effects on this system.

SPECIFIC AGENTS AND THEIR MECHANISMS OF TOXICITY

Hypoglycemic and Antihyperglycemic Agents

Insulin of various types can be injected intravenously or subcutaneously. Depending on the formulation, dose, and route of administration, the level of hypoglycemia and duration of action are quite variable (Table 16-1). Excess insulin can be the result of greater than necessary insulin administration, decreased caloric intake, or an insulinoma. Once in the bloodstream, exogenous insulin has effects identical to those of the endogenously

produced substance. As the kidneys metabolize insulin, patients in renal failure will require decreased doses to avoid hypoglycemic events. Orally, insulin is not bioavailable at all and therefore represents no risk for hypoglycemia when taken in this manner.

Oral antihyperglycemic agents have a variety of mechanisms of action. The α -glucosidase inhibitors prevent the breakdown of oligosaccharides and polysaccharides into simple sugars. Hyperglycemia after meals is prevented, and the delivery of glucose into the bloodstream is delayed. There are few reports of overdose of α -glucosidase inhibitors. Their mechanism of action and the existing animal studies would suggest there are no significant effects in overdose.^{2,3} Among the oral antihyperglycemic agents, the sulfonylureas stand out as being able to produce a significant hypoglycemia.⁴ They accomplish this by acting on the pancreatic β islet cell to cause it to secrete insulin. Additionally, these drugs increase insulin sensitivity in peripheral tissues. In overdose, approximately one third of children ingesting a sulfonylurea became hypoglycemic; in a case series largely of adults, three fourths developed hypoglycemia.^{5,6} Sulfonylureas may result in hypoglycemia many hours after ingestion. Although approximately 90% of patients in several pediatric studies developed hypoglycemia within 8 hours of ingestion, there has been at least one case report of 24 hours' delay in developing significant hypoglycemia following chlorpropamide ingestion.^{5,7,8} Between one third and three fourths of pediatric patients had blood glucose measurements below 60 mg/dL.^{5,8} There is also a significant risk for prolonged or recurrent hypoglycemic episodes.^{9,10}

The thiazolidinedione class exerts its effect by decreasing insulin resistance at peripheral and hepatic sites. These drugs bind selectively to the peroxisome proliferator-activated receptor- γ (PPAR- γ), which is found in fat, liver tissue, and skeletal muscle.¹¹ Little is known about adverse effects in overdose. In therapeutic doses, hypoglycemia has occurred in conjunction with insulin use, and liver abnormalities have also been noted.²

TABLE 16-1 Insulins

INSULIN	ONSET	PEAK	DURATION
Humalog	15–20 min	30–90 min	3–4 hr
Novolog	15–20 min	40–50 min	3–4 hr
Regular	30–60 min	80–120 min	4–6 hr
NPH	2–4 hr	6–10 hr	14–16 hr
Lente	3–4 hr	6–12 hr	16–18 hr
Ultralente	4–6 hr	10–16 hr	18–20 hr
Lantus	2–3 hr	None	18–26 hr

Biguanide oral diabetic agents work by three mechanisms: (1) reduction in intestinal glucose absorption, (2) reduction in hepatic glucose production, and (3) increase in peripheral insulin sensitivity. In overdose, nausea, vomiting, and diarrhea are common. Metabolic acidosis, tachypnea, hypotension, hypoglycemia, and pancreatitis have also been reported. In therapeutic administration, lactic acidosis is the most worrisome adverse effect, but this is relatively rare. In one study, the incidence was only nine cases per 100,000 patient years.¹² Additionally, patients found to be at greater risk are those with underlying chronic or acute renal insufficiency, those with hepatic dysfunction, or those who have a concurrent severe illness.¹³⁻²⁰ There does not seem to be a relationship between serum lactic acid level and outcome.²¹ This suggests that biguanide-induced lactic acidosis is of the type B variety.

Meglitinides are among the newest agents available. They stimulate insulin secretion by closing adenosine triphosphate (ATP)-sensitive potassium channels in β cells, with a resultant rise in intracellular calcium and secretion of insulin.²²⁻²⁷ According to one study, the duration of effect is similar to glyburide.²³ Although data on adverse effects following overdose are scarce, the mechanism of action suggests that hypoglycemia is likely (Table 16-2).

Ethanol can also cause significant hypoglycemia, notably during binge drinking. This generally occurs to those who do not consume enough calories during the event, those with poor glycogen stores, and those in whom nicotinamide adenine dinucleotide (NAD) has been depleted by the metabolism of ethanol. Chronic alcoholics, those who are malnourished, and children are particularly at risk.^{28,29}

TABLE 16-2 Oral Antihyperglycemic Agents

CLASS	GENERIC NAME	DURATION OF ACTION (hr)
First-generation sulfonylurea	Chlorpropamide	24-72
First-generation sulfonylurea	Tolazamide	
First-generation sulfonylurea	Tolbutamide	6-10
First-generation sulfonylurea	Glucotrol	12
Second-generation sulfonylurea	Glucotrol XL	24
Second-generation sulfonylurea	Glyburide	18-24
Second-generation sulfonylurea	Glyburide micronized	24
Third-generation sulfonylurea	Glimepiride	24
Biguanide	Metformin	8-12
Biguanide	Metformin XR	24
Meglitinide	Repaglinide	3
Meglitinide	Nateglinide	3
α -Glucosidase inhibitor	Acarbose	4
α -Glucosidase inhibitor	Miglitol	4
Thiazolidinedione	Rosiglitazone	
Thiazolidinedione	Pioglitazone	

Vacor, a rodenticide, has particular toxicity to the β islet cells of the pancreas. A massive release of insulin ensues, with resulting hypoglycemia. After the destruction of the β islet cells is complete, type 1 diabetes ensues. Pentamidine poisoning has the same pathophysiology.

Ackee is the national fruit of Jamaica. It is the product of the *Blighia sapida* tree, indigenous to West Africa but carried to Jamaica in the latter part of the 18th century. Two compounds have been isolated in the flesh and seeds. Hypoglycin, also known as hypoglycin A, is the more toxic of the two and is present in much higher concentration in the unripe fruit. When hypoglycin is ingested, it is transaminated and decarboxylated to methylene cyclopropyl acetic acid (MCPA). This metabolite interferes with the process of gluconeogenesis.

Other xenobiotics such as salicylates, β -adrenergic blockers, disopyramide, ritodrine, haloperidol, and quinine have been associated with hypoglycemia. In renal failure, trimethoprim-sulfamethoxazole and propoxyphene have been noted to cause hypoglycemia.^{1,4}

Hyperglycemic Agents

Glucagon is used as a hyperglycemic agent in insulin-treated patients who become hypoglycemic and are too obtunded to take oral carbohydrates; nonendocrine uses have included therapy of β -blocker overdose, cardiovascular emergencies, and relaxation of the gastrointestinal (GI) tract for diagnostic procedures. Its toxicity is limited; nausea and vomiting are frequent consequences of its use. The expected increase in glucose does not occur in patients who are depleted of glycogen stores; for example, patients with alcohol-related hypoglycemia show no response, and delaying more effective therapy (such as glucose administration) poses a risk in such a setting. In a patient with an insulinoma, the initial beneficial increase in glucose levels may be followed by a subsequent precipitous glucose drop due to stimulation of further insulin production by the glucagon.

Diazoxide, used infrequently as a parenteral agent in hypertensive crisis, is an inhibitor of insulin secretion and can be used as an oral agent in the therapy of patients with insulinomas. It causes sodium and fluid retention, with associated edema, and simultaneous use of a loop diuretic is a frequent need. In addition to being monitored for development of hyperglycemia related to excessive insulin suppression, patients should be monitored for complications that include GI distress, pancreatitis, thrombocytopenia or leukopenia, impairment of renal function, and proteinuria.

TREATMENT PRINCIPLES

Hypoglycemic Agents

Glucose can be used to rapidly increase blood glucose for use by the target tissues. In most circumstances, it should be the first agent used to counter hypoglycemia. Glucagon can be used to stimulate glycogenolysis and

gluconeogenesis, thereby increasing available glucose. One advantage is that it can be administered subcutaneously or intramuscularly. Another advantage is its longer duration of effect. However, patients with poor glycogen stores will not develop an adequate response. Patients with insulinoma should not receive glucagon due to the risk for insulin release and resultant hypoglycemia. Patients with pheochromocytoma should not receive glucagon because it may trigger catecholamine release from the tumor and subsequent hypertension.

Octreotide is a long-acting synthetic somatostatin analog. It acts at somatostatin receptors and inhibits release of a number of pituitary and GI hormones, including insulin and glucagon. It can be used to provide protection against hypoglycemic events due to xenobiotic agents which promote release of insulin by the pancreas. Hypoglycemia caused by sulfonylureas, meglitinides, and perhaps by Ackee fruit, can be treated by its use.

The decision to admit a patient should be based on the nature of the poisoning as well as the clinical picture. It is worth noting that sulfonylurea overdoses in particular benefit from long-term glucose monitoring. Although one study suggests that 8 hours may be sufficient for most cases, many clinicians prefer a period of 24 hours.^{8,30}

Hyperglycemic Agents

The hyperglycemia from glucagon is generally transient and does not require any treatment other than stopping the drug. If the patient develops hypertension requiring control, phentolamine mesylate 5 to 10 mg intravenously may be used. Treatment of adverse effects from diazoxide must be tailored to the particular pathology (Table 16-3).

HYPOTHALAMIC AGENTS

Introduction and Importance

The hypothalamus-pituitary axis is the primary interface between the brain and the endocrine system. The

circumventricular organs of the hypothalamus play a key role, because their endothelium lacks tight junctions. They are therefore effectively on the outside of the blood-brain barrier, and able to sense levels of various factors and release others.

A number of hormones are secreted by the hypothalamus, with varied target organs. Some of these have been purified or synthesized for medical use. Two hormones secreted by the hypothalamic neurohypophyseal tract have important clinical uses. Oxytocin has a number of functions, but is primarily administered to induce labor and cause postpartum uterine contraction. Vasopressin and its analogs (desmopressin, lypressin) are used primarily for hormone replacement therapy in patients with central diabetes insipidus. Two of the hypothalamic agents, growth hormone-releasing hormone (GHRH) and gonadotropin-releasing hormone (GnRH) are used therapeutically as well.

Specific Agents and Their Mechanisms of Toxicity

Oxytocin is an octapeptide produced in the hypothalamus and stored in the posterior pituitary. It has uterine-stimulatory action, a vasopressive effect, and an antidiuretic effect. It also stimulates the milk letdown reflex. Adverse actions from oxytocin use include overstimulation of the uterus, with potential for fetal distress or uterine rupture, hypertension, or water intoxication. Hyponatremia, resulting from the intrinsic antidiuretic action of the molecule, can lead to various neurologic consequences, including convulsions.

Toxic effects of vasopressin are uncommon if the agent is used in appropriate dosage, and the major adverse effects are related to the expected physiologic action of the molecule in question. Desmopressin (DDAVP) has emerged as the most commonly used vasopressin analog for several reasons, including its convenient forms of administration and its prolonged half-life with enhanced antidiuretic and decreased vasopressor effects compared with the parent arginine vasopressin molecule.³¹ Because of the drug's physiologic action, hypertension might also be anticipated as a possible adverse effect of vasopressin administration, but this is also very uncommon, particularly with desmopressin. Hyponatremia is the most likely adverse result of vasopressin administration but is a relatively uncommon problem, because hyponatremia cannot develop unless the vasopressin-stimulated decrease in renal tubular free water clearance is combined with an increase in free water intake.

The hypothalamic-releasing hormones include thyrotropin-releasing hormone (TRH, or protirelin), GnRH (or gonadorelin), GHRH, and corticotropin-releasing hormone. For the most part, these drugs are used as investigative or diagnostic agents, and toxic effects are limited and transient, including flushing, nausea, vomiting, brief abdominal discomfort, and hypotension. In addition to their diagnostic use, two of the releasing hormones, GHRH and GnRH, have potential therapeutic uses.

TABLE 16-3 Treatment of Hypoglycemia

AGENT	ADULT DOSE	PEDIATRIC DOSE
Glucose (bolus)	50 mL of 50% dextrose IV	0.5–1 g/kg of 25% dextrose IV
Glucose (infusion)	10%–20% dextrose in water IV	10%–20% dextrose in 0.2% normal saline
Glucagon	1–2 mg IV/IM/SC	0.03–0.1 mg/kg IV/IM/SC
Octreotide	50–100 µg SC/IV q 6–12 hr	4–5 µg/kg/day SC/IV divided into q 6 hr doses

IM, intramuscularly; IV, intravenously; SC, subcutaneously.

GnRH is used for treatment of infertility in women who have hypothalamic disease with intact pituitary function, enabling them to respond to the hypothalamic agent. Treatment involves episodic pulsatile delivery of the peptide by an infusion pump.³² Side effects include a potential for ovarian hyperstimulation; because of this potential, this agent should be used only by reproductive endocrinologists who are well trained in its application. Sustained delivery of GnRH analogs suppresses gonadotropin production through down-regulation of the GnRH receptor. These agents are used when inhibition of gonadal function is desired, such as in patients with precocious puberty or carcinoma of the prostate or endometrium. Side effects are minor, with the major effects due to the expected suppression of gonadal function.

GHRH is an investigational agent that may eventually have utility in therapy of individuals who have growth failure due to hypothalamic dysfunction but who maintain normal pituitary function. No significant toxicity has been described.

Treatment Principles

Management of oxytocin toxicity is the same as that for vasopressin toxicity. Careful monitoring during intravenous infusion is essential for prevention of these problems, and the infusion must be discontinued immediately at the first evidence of adverse effect on the mother or her fetus.

Hyponatremia caused by vasopressin or DDAVP is effectively treated by restriction of free water intake and a decrease in, or discontinuation of, vasopressin administration. As with any state of severe hyponatremia or hypo-osmolality, the use of hypertonic saline may be a consideration if the decrease in sodium concentration has been abrupt, is associated with neurologic abnormalities, and has not responded promptly to removal of the precipitating causes.

No therapy is usually required to treat adverse effects of hypothalamic-releasing hormone in view of their brief duration. If hypotension persists, administration of intravenous fluids usually corrects the problem.

PITUITARY AGENTS

Introduction and Importance

Growth hormone (GH) is administered to children who are of short stature due to its deficiency. Gonadotropins are used mostly to treat infertility due to secondary gonadal dysfunction. Adrenocorticotrophic hormone (ACTH) stimulates the adrenal cortex and is therefore sometimes used in disorders that respond to glucocorticoid (GC) therapy.

Octreotide is used to treat acromegaly by lowering GH levels, and may be helpful in shrinking pituitary adenomas. Because it has a suppressive effect on many

other hormone systems, it can be used in the treatment of other hormone-producing tumors. As has been discussed in the section on glucose metabolism, it can prevent the release of insulin from the pancreas due to sulfonyleurea ingestion. Octreotide has a role in the treatment of upper GI hemorrhage due to its inhibition of hormones, which cause vasodilation. Bromocriptine is an ergot alkaloid that has dopaminergic properties useful in treating hyperprolactinemic states, acromegaly, and some nonendocrine disorders.

Specific Agents and Their Mechanisms of Toxicity

The toxicity of GH can be related to two different factors: (1) contaminants that might be inadvertently administered with the hormone, and (2) the metabolic and physiologic effects of the hormone per se. With recombinant DNA-produced GH, the former consideration is not a current concern. However, before the advent of the technology that led to biosynthetic GH production, the only available GH into the mid-1980s was derived from human cadavers, and cases of transmission of the devastating Creutzfeldt-Jakob infection have been described.³³ Because of the long incubation period for this slow virus, it is possible that more cases will develop in the future in patients who previously received virus-contaminated hormone preparations. Patients who have received these human cadaver-based GH injections are at continued risk and should be monitored for neurologic problems; unfortunately, no effective treatment is currently available.

Otherwise, problems with GH occur predominantly in situations in which the agent is used in excessive doses, thereby causing medical problems that are similar to the problems encountered in acromegaly.³⁴ Long-term administration can cause edema, hypertension, carpal tunnel syndrome, and arthralgias. Insulin resistance and impaired glucose tolerance are also metabolic consequences of GH administration, especially when the drug is used at supraphysiologic doses. Whether GH administration to adults might increase the risk for cardiovascular disease is a concern, based on the observation that acromegalic patients are at increased risk for hypertension and cardiomyopathy. It is not totally clear whether the cardiomyopathy reflects the cardiac response to acromegaly-associated hypertension or is instead evidence of an anabolic effect of GH on cardiac tissue. Whether GH might be a promoter of tumor growth is also speculated, because GH has been shown to exert mitogenic effects in some animal systems, and acromegaly has been associated with an increased risk for premalignant colonic polyps and colon cancer. It has also been suggested that GH therapy in children may be associated with increased risk for leukemia. Despite this speculation, GH therapy has no established association with any malignancy at this time.

Gonadotropin therapy is used in individuals with secondary gonadal dysfunction, primarily as treatment for infertility. Human chorionic gonadotropin (HCG)

binds to luteinizing hormone receptors and thereby stimulates gonadal function. HCG promotes gonadal steroidogenesis and stimulates the aromatase enzyme that converts testosterone to estradiol; as a result, males have a disproportionate increase in estradiol compared with the increase in testosterone, and gynecomastia may develop. Acne, weight gain, and fluid retention can also occur. In order to achieve fertility in males with secondary hypogonadism, simply stimulating testosterone production with HCG is not sufficient; stimulation of spermatogenesis is also needed, and this requires the use of an agent with follicle-stimulating hormone effect; human menopausal gonadotropin (HMG) is used for this purpose. Because this product contains both follicle-stimulating hormone and luteinizing hormone, the same side effects of weight gain, edema, acne, and gynecomastia are noted.³² Women who are treated with gonadotropins for infertility can also develop weight gain, edema, and acne. However, a greater clinical concern is the risk for developing ovarian hyperstimulation. This syndrome, which can occur in as many as 15% of HMG-treated patients, consists of cystic ovarian enlargement and fluid shifts (including ascites and pleural effusions), with more severe cases characterized by severe hemoconcentration, electrolyte imbalance, thromboembolism, and even death. The basis of the disorder appears to be increased capillary permeability with major fluid shifts that lead to hemoconcentration, prerenal azotemia, and development of a hypercoagulable state. The likelihood of hyperstimulation syndrome can be minimized by careful monitoring of serum estradiol levels; if the estradiol level becomes excessively elevated during HMG stimulation, subsequent HCG administration should be postponed for that cycle.³⁵

ACTH is used for its action of stimulating the adrenal cortex. It is used in disorders that respond to GC treatment. ACTH is used infrequently because of its undesirable properties, which include the need for parenteral administration and an inability to titrate dosage to a specific GC level. The unwanted simultaneous stimulation of mineralocorticoid and androgen activity also complicates its use. In patients with disorders that respond to GC effect, it is preferable to administer a known amount of GC directly rather than to stimulate uncertain GC levels through ACTH administration. Furthermore, the ACTH used for therapeutic purposes is derived from bovine pituitary glands and can produce allergic reactions. ACTH is also used for diagnostic evaluation of adrenal gland function; for this short-term purpose, a synthetic but fully bioactive analog, composed of the first 24 amino acids of the 39-amino acid human ACTH molecule (cosyntropin), is commonly used; this analog is devoid of adverse effects.

Treatment Principles

Mild or moderate ovarian hyperstimulation can be monitored conservatively, with discontinuation of gonadotropin therapy. More severe cases require

hospitalization with monitoring of fluid and electrolyte status, weight, fluid intake and output, hematocrit, and renal function. Sodium restriction may also be required, as well as cautious use of plasma expanders or albumin to maintain urine output.

Treatment of other conditions caused by pituitary agents is supportive and should be tailored to the particular pathology encountered.

THYROID

Introduction and Importance

The thyroid is principally responsible for the regulation of the basal metabolic rate. Thyroid hormones act within cells to regulate gene transcription and protein synthesis. Increase in consumption of ATP results in an increase in metabolism of carbohydrates, proteins, and lipids. Thyroid dysfunction falls into two categories. Decreased function of the thyroid gland, or hypothyroidism, is a fairly common disease. Estimates of its prevalence in the United States range from 2% to 10%, and thyroid hormone is therefore one of the most commonly prescribed medications. Thyrotoxicosis, a surfeit of active thyroid hormone, occurs most often as the result of Graves' disease, an autoimmune disease that increases the mass of the gland. This endogenous overproduction of thyroid hormone can be termed *hyperthyroidism*. Alternatively, an excess of thyroid hormone can result from ingestion of xenobiotics. Thyroid tissue is sometimes present in meat from animals' necks, and can be inadvertently consumed. Some people abuse thyroid medications, usually in an attempt to lose weight, but also in intentional overdoses.

Secretion of thyroid hormone results from a complex interplay among the hypothalamus, anterior pituitary, and thyroid. Circulating levels of thyroxine (T_4) and triiodothyronine (T_3) are sensed by the hypothalamus, which secretes TRH or somatostatin (SRIH). TRH has a releasing effect on the anterior pituitary, and SRIH has an inhibiting effect. These signals cause the anterior pituitary to release thyroid-stimulating hormone (TSH, or thyrotropin), which stimulates the thyroid to release both T_3 and T_4 . Iodide and, to a much lesser extent, lithium ion have a suppressive effect on the thyroid³⁶ (Fig. 16-1).

T_4 , which has a half-life of about a week, is slowly converted to T_3 in various body tissues. Two enzymes catalyze this process: D1, present in the thyroid, liver, and kidney; and D2, present in the thyroid, smooth muscle, and cardiac muscle. Of the total T_3 in circulation, 80% is formed from T_4 in the periphery, and 20% is released directly from the thyroid.

Toxin-Induced Physiologic Disturbances

NATURAL AND SYNTHETIC T_3 AND T_4/T_3 PRODUCTS

Because of its short half-life, considerable elevation and fluctuation in T_3 levels can occur in patients who

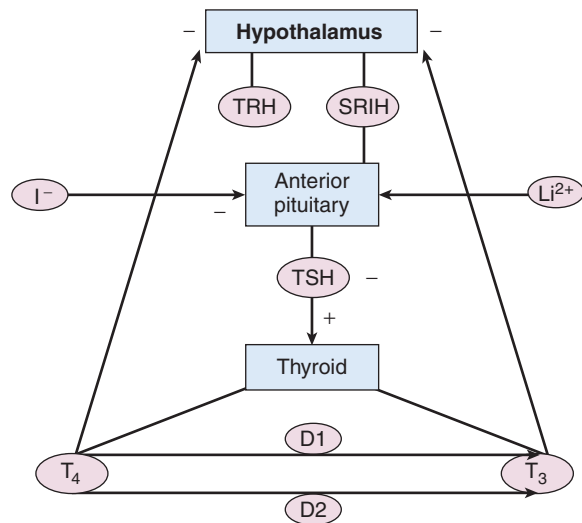

FIGURE 16-1 Hypothalamus-pituitary-thyroid axis.

are treated with pure T_3 or combined T_4/T_3 products. Intermittent peaking to supraphysiologic levels can have adverse effects, especially in older patients with cardiovascular disease. As a result, a number of combined T_4/T_3 preparations have been taken off the market in recent years. Nonetheless, the traditional but outdated standard of an earlier era, desiccated thyroid hormone, is still available and used with surprising frequency. Problems with this preparation include inconsistent absorption and bioavailability, as well as its content of potentially cardiotoxic T_3 .³⁷ Liothyronine (synthetic T_3) has problems similar to those of the animal-derived T_3 and is not in common use.

LEVOTHYROXINE

Levothyroxine is synthetic T_4 , which is converted to T_3 by the same enzymatic systems that handle endogenous T_4 . Long-term physiologic effects of excessive levothyroxine administration include cardiac changes (shortening of systolic time intervals and increased nocturnal heart rate), elevated levels of liver enzymes, and increased bone resorption; the last is of particular concern in postmenopausal women who already have a high risk for osteoporosis.^{36,38} The hypermetabolic consequences of thyrotoxicosis can include weight loss, tremor, heat intolerance, loss of muscle mass and muscle strength, palpitation, and cardiac rhythm disorders, especially supraventricular dysrhythmias. Cases of true thyrotoxicosis are usually encountered in paramedical personnel, although anyone who has access to thyroid medications can potentially be at risk.

Acute overdose of thyroid hormone may cause symptoms in as few as 12 hours in the case of products containing T_3 . If levothyroxine is ingested without T_3 , a period of 5 to 11 days without symptoms may be followed by the development of illness. Thyrotoxicosis is much more common in chronic overdose than in acute overdose. However, massive acute ingestions may cause profound

TABLE 16-4 Signs and Symptoms of Acute Thyroid Hormone Overdose

SYSTEM	FINDING
Cardiovascular	Tachycardia, hypertension, dysrhythmia
Neurologic	Mydriasis, tremor, hyperreflexia, agitation, seizure, coma, psychosis
Skin	Flushing, diaphoresis, dermatitis, rash
Gastrointestinal	Nausea, vomiting, diarrhea
Metabolic	Fever, weight loss

illness. The spectrum of signs and symptoms of acute overdose encompass many organ systems (Table 16-4).

Specific Agents and Their Mechanisms of Toxicity

For a discussion of thyroid hormone–induced physiologic disturbances, see Natural and Synthetic T_3 and T_3/T_4 Products. It is important to note that some xenobiotics have significant effects on the hypothalamus-pituitary-thyroid axis. Thyrotoxicosis due to amiodarone is divided into two varieties. Type 1 occurs mostly in patients with underlying thyroid disease and is characterized by excessive thyroid hormone synthesis due to iodine present in the compound. Type 2 is a destructive thyroiditis that can affect previously euthyroid patients. Differentiation of these two types can be made on the basis of a fine-needle aspiration, which will show evidence of thyroiditis in type 2 disease. Conversely, amiodarone can also cause hypothyroidism via blockade of peripheral conversion of thyroxin to triiodothyronine. Chronic lithium therapy can cause hypothyroidism and goiter. GCs cause a decrease in T_3 production by inhibiting D1 and D2 enzymes. TSH secretion is suppressed by a number of compounds (Table 16-5). A few agents can also cause thyroid storm (Box 16-1).

Radioactive iodine is a frequently used first-line agent in the treatment of Graves' disease and toxic nodular

thyroid disease.³⁹ There has been long experience with this agent, which is extremely safe. The eventual development of hypothyroidism is an expected outcome of the agent, although not universal. Whether radioactive iodine can provoke or worsen the ophthalmopathy of Graves' disease is debated. Radioactive iodine has not been associated with increased risk for malignancy, nor is there evidence for any teratogenic effect in offspring of mothers who were previously treated with radioactive iodine. Pregnancy is an absolute contraindication to the use of radioactive iodine because of the risk for ablation of the fetal thyroid and subsequent congenital hypothyroidism. Because thyroid destruction becomes a risk only after the fetal thyroid has developed, which occurs at 10 weeks of gestation, radioactive iodine is safe and appropriate therapy for women of childbearing age after a negative pregnancy test result has been documented; advice to avoid pregnancy for the following 4 to 6 months is typically given.

Thyroiditis can occur within the first 2 weeks of radiation treatment for hyperthyroidism, with neck pain, swelling, and transient worsening of the hyperthyroidism.

The thionamide derivatives propylthiouracil (PTU) and methimazole are commonly used to treat hyperthyroidism, and they have a generally good track record of limited toxicity.³⁹ These agents are thought to work by inhibiting human thyroid peroxidase, which catalyzes both incorporation of iodide into tyrosyl residues and the subsequent coupling of iodotyrosyl into T_4 and T_3 . Propylthiouracil also inhibits the peripheral deiodination of T_4 to T_3 . PTU crosses the placenta to a lesser degree than methimazole and can be used safely during pregnancy and by breast-feeding patients. In pregnancy, fetal exposure should be limited by using the lowest necessary dose to keep the free T_4 index in the high-normal range, and monitoring of thyroid hormone levels in the infant of a breast-feeding woman is advocated to ensure that no effect of drug exposure occurs through the mother's milk.⁴⁰

By far the most serious side effect of these drugs is agranulocytosis, which occurs in about 3 of every 1000 treated patients. This is an idiosyncratic reaction that is more common in patients older than 40 years but can occur regardless of a patient's age, the duration of therapy, or the drug dose.⁴¹ The fall in granulocyte count is abrupt and precipitous, and thus no benefit is derived from periodic monitoring of blood counts. Most patients with drug-induced agranulocytosis present with fever, sore throat, or other features of infection.

Liver disease is also a major potential toxic effect of the thionamides.⁴¹ Drug-related hepatotoxicity seems to be a problem predominantly with PTU, whereas cholestatic jaundice has been associated with methimazole.⁴² PTU-related hepatic injury has been fatal in some cases.⁴³ The presentation is similar to that of viral hepatitis. Mild abnormalities in liver function tests are common in patients who are treated with PTU,⁴⁴ and mild abnormalities on liver biopsy have also been demonstrated.

Acute overdoses of methimazole and PTU are rare. Because the duration of effect of these medications is fairly short, the decrease in T_3 levels can be expected to have few significant effects. In one case, between 5 and 13 g of PTU was ingested. An increase in alkaline phosphatase and decrease in T_3 were noted, and the patient recovered fully.⁴⁵

Treatment Principles

THYROID HORMONES AND OTHER MEDICATIONS CAUSING THYROTOXICOSIS

Activated charcoal absorbs thyroid medications and should be given to patients with a recent acute overdose. The onset of any thyrotoxicosis will likely be delayed for hours to days. Sodium ipodate or iopanoic acid has been used in ingestions of levothyroxine and amiodarone thyrotoxicosis to inhibit conversion of T_4 to T_3 . In the few patients in whom its use has been documented in case reports, significant improvement has been noted.⁴⁶⁻⁵⁰ The dose to be used in treatment should likely be determined in consultation with an endocrinologist, because dosing information is limited. Cholestyramine has been used in numerous cases and recommended in a review article for its ability to interrupt enterohepatic recirculation of iodothyronines.⁵¹ In the short term, its only significant side effect is constipation. It is worth consideration in this case.

Adrenergic effects can be rapidly treated by an agent with β_1 - and β_2 -adrenergic antagonism. The typical agent is propranolol, although labetalol or sotalol might also be used. Fever should be treated aggressively with acetaminophen and external cooling; aspirin should not be used because it displaces T_3 from thyroglobulin, which may worsen the condition. Benzodiazepines are the first-line agents of choice for treatment of agitation and seizure. Congestive heart failure should be managed with diuretics and digoxin, and may not resolve rapidly. There are no data on which antiemetic is best for treating the nausea and vomiting. Supportive care, including airway protection, ventilatory support, and hydration, is also important. Cardiac and hemodynamic monitoring is necessary. Laboratory analysis should include a basic metabolic panel. There is no role for the measurement of T_3 and T_4 levels unless the diagnosis is in doubt.

THIONAMIDES

Patients taking thionamides should be advised to discontinue their medication immediately and arrange for blood count measurements at the first evidence of an infectious process. The hematologic abnormalities

usually resolve within 7 to 10 days; in the meantime, in-patient hospitalization with intravenous antibiotics is usually recommended.⁴⁰ The simultaneous use of corticosteroids or granulocyte-stimulating factors has been suggested, but these are not proven interventions and thus are not recommended at this time.⁴⁰ Further thionamide therapy should be avoided in patients who have experienced agranulocytosis from one of these drugs. Hepatotoxicity due to PTU generally resolves on withdrawal of the drug. Mild elevations of the transaminases are considered to be transient and asymptomatic. It has been suggested that therapy can be cautiously continued in patients who are symptom free and not jaundiced.⁴⁴ Acute overdoses of these medications can generally be managed with supportive care.

OTHER TREATMENTS AFFECTING THE THYROID

Radiation thyroiditis can be effectively treated with analgesic agents and β -adrenergic blockers, as would be used in other types of painful thyroiditis.

Type 2 amiodarone thyrotoxicosis can be treated with steroids, nonsteroidal anti-inflammatories, and antithyroid medications.

PARATHYROID SYSTEM

Introduction and Importance

Calcium plays a number of critical roles in the body. It is essential in the functioning of skeletal, smooth, and cardiac muscle. Its flux through nerve cells results in transmission of neural impulses. Calcium mediates changes in vascular tone. Its presence is essential for the functioning of numerous protein and enzyme systems, including the vitamin K-dependent factors in the clotting cascade. Calcium helps to modulate neurotransmitter release and affects many endocrine and exocrine systems.

Ninety-nine percent of the body's stores of calcium reside in bone, in its mineralized phase. The remaining 1% moves between bone and the intra- and extracellular compartments. In the vascular compartment, 50% is protein bound. In the intracellular compartment, only 1% is free. The rest is bound to the cell membrane or the endoplasmic reticulum, or is within the mitochondrion.

The parathyroid glands are dedicated to the homeostasis of this mobile 1% of body calcium mentioned above. In response to a decrease of the ionized calcium level in the vascular compartment, chief cells of the parathyroids increase their secretion of parathyroid hormone (PTH). This hormone triggers responses in bone and kidney that increase the blood calcium level. In bone, the effects of PTH are complex, but the net effect is to increase bone resorption and thus increase the amount of available calcium. PTH increases reabsorption of calcium at the renal distal tubule by increasing the opening of calcium channels in the membrane. In addition, the kidney secretes 1,25-dihydroxyvitamin D, which stimulates the intestine to increase absorption of dietary calcium (Fig. 16-2).

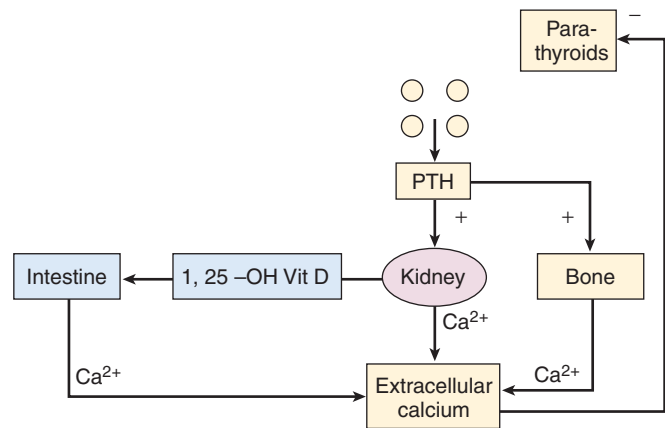

FIGURE 16-2 Parathyroid system.

Disequilibrium of normal calcium homeostasis is a feature of many diseases, including Paget's disease, multiple myeloma, primary hyperparathyroidism, osteoporosis, and hypercalcemia of malignancy. Medications that are intended to treat alterations in calcium metabolism can have significant undesired effects.

Toxin-Induced Physiologic Disturbances

Vitamin D, its metabolites, and its analogs are used to treat osteoporosis (Box 16-2). These medications have a number of effects, because vitamin D receptors exist throughout the body. The receptor then up-regulates transcription of DNA into RNA, bringing about the desired biologic effect. Some actions of vitamin D are thought to occur independently of gene transcription, such as intracellular hypercalcemia, activation of phospholipase C, and opening of calcium channels. The most significant effect, however, is to increase the proportion of dietary calcium that is absorbed. In overdose, nausea, vomiting, diarrhea, and GI bleeding may be seen. The effects of the provoked hypercalcemia include headache, itching, weakness, neuropathy, stupor, and coma; cardiac arrhythmias and hypertension; renal calcium deposits and nephritis; and depression and apathy in chronic overdose.^{2,52-54}

Bisphosphonates are synthetic pyrophosphate analogs that inhibit osteoclast-mediated bone resorption (Table 16-6). They are used to treat primary hyperparathyroidism, hypercalcemia, osteoporosis, Paget's disease, and multiple

myeloma. Three generations of these medications have been developed, with the newer compounds having significantly more potency. Adverse effect data are limited, but hypocalcemia is both a theoretical and practical concern. Additional effects include nausea, diarrhea, and GI bleeding; fluid retention, hypokalemia, hypomagnesemia, and hypophosphatemia; nephrotoxicity; muscle and bone pain; avascular necrosis of the jaw; and headaches, paresthesias, malaise, dizziness, and seizure. Other uncommon reactions include a self-limited acute-phase response with fever and myalgia, inflammatory eye reactions or scleritis, skin lesions, erythroderma, and bronchospasm.^{2,55-66}

Specific Agents and Their Mechanisms of Toxicity

Calcitonin, an inhibitor of bone resorption, is used in the treatment of Paget's disease, osteoporosis, and hypercalcemia. Both salmon calcitonin and human calcitonin are available, and administration is by injection or nasal spray. Local effects are common, including itching and irritation at the injection site. Systemic symptoms are also frequent, including flushing, nausea, vomiting, and anorexia. Hyperglycemia, hypokalemia, and renal lesions or insufficiency have been reported. There is a case report of anaphylactic shock in response to intramuscular calcitonin injection.⁶⁷⁻⁸¹ A slight but asymptomatic decrease in serum calcium levels may occur after injection of calcitonin in patients with Paget's disease. Loss of efficacy is common; this may be related to down-regulation of calcitonin receptors or perhaps development of neutralizing antibodies to the salmon form of this peptide. The use of calcitonin has been limited by the availability of the bisphosphonates, which have similar actions with fewer undesirable effects.

In addition to inhibition of bone resorption, etidronate (but not the other bisphosphonates) can impair bone mineralization, and patients are at risk for developing osteomalacia with chronic etidronate use. As a result, the agent is usually prescribed in a cyclic regimen.⁸²⁻⁸⁶

Although not approved for use in treatment of metabolic bone disease, sodium fluoride is undergoing investigation as a therapeutic agent for osteoporosis because of its ability to stimulate osteoblast activity and

promote new bone formation.^{41,87-91} Concerns about its use have centered around the potential for abnormal bone formation with increased fracture risk, as well as other adverse effects such as gastric irritation. In massive overdose, with ingestions of greater than 5 mg/kg of fluoride, adverse effects can occur. These include nausea, vomiting, GI hemorrhage, hypocalcemia, hyperkalemia, hypomagnesemia, and cardiac dysrhythmias.^{2,92-94}

Treatment Principles: Vitamin D Agents

Activated charcoal is only needed in massive ingestions, where greater than 100 times the U.S. recommended daily allowance has been ingested.² Multiple-dose activated charcoal and dialysis are not helpful in removing vitamin D from the body. Potassium, calcium, magnesium, and phosphate, as well as renal function, should be checked. The patient should have an electrocardiogram and be put on a cardiac monitor. Hypercalcemia above 14 mg/dL or with significant symptoms should be treated initially with normal saline diuresis. This may be followed by furosemide, especially in patients likely to develop fluid overload. Calcitonin can be given in a dose of 4 to 8 IU/kg intramuscularly. Critical hypercalcemia should be treated with hemodialysis. Since the advent of bisphosphonates, mithramycin has fallen out of favor as a treatment. With parent vitamin D (ergocalciferol, or vitamin D₂), the hypercalcemia may persist for many weeks owing to the accumulation of this fat-soluble substance in adipose stores. Additional therapy might include reduction of dietary calcium intake and prescription of a bisphosphonate. Prednisone also may be helpful, because it decreases absorption of dietary calcium; oral hydration and oral phosphate therapy will also decrease the serum calcium level.^{2,95}

Bisphosphonate toxicity should be managed mainly with supportive care. Activated charcoal can be given in acute overdoses. Methods of enhanced elimination such as multiple-dose activated charcoal or hemodialysis are not effective. A serum ionized calcium level, as well as potassium, magnesium, and phosphate levels, should be obtained. Renal function tests should be performed. An electrocardiogram and cardiac monitoring are important, because QT prolongation and dysrhythmias can result from hypocalcemia. Severe or symptomatic hypocalcemia can be managed with an intravenous infusion of 10 to 30 mL of 10% calcium gluconate solution. Pediatric dosing of calcium gluconate is 200 to 500 mg/kg/24 hours, divided in every-6-hour doses.²

Calcitonin and sodium fluoride toxicities can be managed supportively. Withdrawal of the agent will aid in resolution of the symptoms and signs.

ADRENAL CORTEX

Introduction and Importance

Essential for life, the adrenal gland was first described by Eustachius in 1563. This highly vascular endocrine organ is divided into the medulla, which is a neurosecretory

organ dispensing catecholamines; and the cortex, which secretes derivatives of cholesterol. The adrenal cortex is critical to the body's function. Steroids secreted by the adrenal cortex fall into three categories: GCs, which have effects on carbohydrate and protein metabolism; mineralocorticoids, which regulate sodium and extracellular fluid balance; and androgens, which have effects on reproductive function. The latter will be discussed later in this chapter, in the section on gonadal agents.

GC medications (Table 16-7) are commonly used in the treatment of various medical disorders associated with an immunologic or inflammatory component. GC antagonists (Table 16-8) are used in the therapy of Cushing's syndrome and adrenocortical carcinoma. These are not definitive treatments but are instead used for reversal of some of the severe consequences of Cushing's syndrome in preparation for surgery, while

awaiting the effects of radiation therapy, or in ameliorating the more devastating effects of Cushing's syndrome in patients with malignancy. Mineralocorticoids are typically used for patients with aldosterone deficiency, such as Addison's disease or other hypoaldosterone states, or for situations in which volume expansion may be desirable, as in patients with idiopathic orthostatic hypotension. Mineralocorticoid antagonists are very useful endocrine agents. Classically used for their action as a competitive inhibitor at the aldosterone receptor, they are also fairly potent antiandrogens. They also possess progestin action.

Toxin-Induced Physiologic Disturbances

GLUCOCORTICOIDS

GCs bind to both the glucocorticoid receptor (GR) and the mineralocorticoid receptor (MR), although more recently synthesized agents have selectivity for the GR alone. Use of GCs causes an increase in expression of anti-inflammatory proteins and a decrease in expression of proinflammatory proteins. This occurs through GR-DNA interactions, which activate certain gene transcriptions and repress others. There may also be direct GR-protein interactions.⁹⁶ The resulting suppression of the inflammatory and immune systems represents both the desired clinical effect and a prime adverse effect. A meta-analysis of a number of studies concluded that a relative risk of 1.6 exists for infectious events in patients on moderate chronic doses of systemic corticosteroids.⁹⁷ While this may not appear consequential, many of these infections are complicated or opportunistic.

One of the most worrisome consequences of long-term use of GCs is their effect on the musculoskeletal system. Significant bone loss can occur in weeks to months, even with low-dose therapy. Risk factors include age, female gender, body mass, and level and length of steroid therapy.⁹⁸ This process occurs through a number of mechanisms, including suppression of osteoblasts; decrease in calcium absorption with an increase in calcium excretion; and suppression of factors important for bone homeostasis, including GH. The effects are most pronounced on cancellous bone: over one third of patients on GCs have evidence of vertebral fractures after 5 years of treatment. In muscle, catabolic effects may lead to myopathy and atrophy. GCs inhibit the uptake of glucose into myocytes, which encourages muscle breakdown. They also up-regulate protein degradation and down-regulate protein synthesis through effects on gene transcription.⁹⁷ Muscle enzyme levels will be normal. A biopsy will show type II muscle fiber damage. Longer-acting or halogenated compounds may be more likely to produce this effect. An association between muscle injury and GC therapy with concurrent use of nondepolarizing paralytics has been reported frequently.⁹⁹

In the skin, atrophy of the epidermis and dermis can lead to thinning of the skin as well as the permanent and disfiguring striae rubrae distensae. This results from a decrease in the proliferation of cutaneous cells and protein synthesis, probably from a direct down-regulation of gene expression.¹⁰⁰ These effects can be seen both with

TABLE 16-7 Adrenal Agents

AGENT	CLASS
Betamethasone	Glucocorticoid
Dexamethasone	Glucocorticoid
Methylprednisolone	Glucocorticoid
Prednisone	Glucocorticoid
Triamcinolone	Glucocorticoid
Desoxycorticosterone	Mineralocorticoid
Fludrocortisone	Mineralocorticoid
Aminoglutethimide	Glucocorticoid antagonist
Ketoconazole	Glucocorticoid antagonist
Metyrapone	Glucocorticoid antagonist
Mitotane	Glucocorticoid antagonist
Trilostane	Glucocorticoid antagonist
Mifepristone	Glucocorticoid antagonist
Spirolonactone	Mineralocorticoid antagonist
Eplerenone	Mineralocorticoid antagonist

AGENT	CLASS
Cholestyramine	Bile acid sequestrant
Colesevelam	Bile acid sequestrant
Colestipol	Bile acid sequestrant
Bezafibrate	Fibric acid derivative
Ciprofibrate	Fibric acid derivative
Clofibrate	Fibric acid derivative
Fenofibrate	Fibric acid derivative
Gemfibrozil	Fibric acid derivative
Atorvastatin	HMG-CoA reductase inhibitor
Fluvastatin	HMG-CoA reductase inhibitor
Lovastatin	HMG-CoA reductase inhibitor
Pitavastatin	HMG-CoA reductase inhibitor
Pravastatin	HMG-CoA reductase inhibitor
Rosuvastatin	HMG-CoA reductase inhibitor
Simvastatin	HMG-CoA reductase inhibitor
Niacin	Nicotinic acid
Ezetimibe	Selective cholesterol absorption inhibitor

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

systemic and inhaled GC use. Poor wound healing also represents a significant pathologic effect. It results from suppression of the early inflammatory response and the inhibition of gene expression, which synthesizes matrix protein and collagen.^{101,102} Reversible side effects such as hypertrichosis and steroid acne can also be seen.⁹⁷

Effects on the eye from chronic systemic or inhaled GC use include cataract formation and development of glaucoma. These conditions are more likely in middle-aged or elderly patients.¹⁰³ One in three patients is susceptible to steroid-induced elevations in intraocular pressure. This risk rises with a personal or family history of primary open-angle glaucoma.¹⁰⁴ Mechanisms for the formation of cataracts include elevation of glucose levels, inhibition of RNA synthesis, and formation of covalent bonds between GC and lysine amino acids present in lens proteins. In the case of glaucoma, increased ocular pressures are commonly seen, the result of GC-induced changes in the trabecular meshwork.⁹⁷ Rare complications include retinal emboli and ocular infection.¹⁰⁵

Central nervous system (CNS) effects of GC range from euphoria to mood swings to suicidal depression and psychosis.¹⁰⁶ The aggregate incidence of these findings, in a meta-analysis of data from several decades, is 5.7%. At least 2 weeks of treatment is usually required before these psychopathologies are manifested. They may be more likely to occur in a patient with a previously existing psychiatric condition, although this point is debated.¹⁰⁷ Some patients suffer depression after the withdrawal of GC. Although it is incompletely understood, repression of the 5-HT_{1A} receptor plays a key role in the pathophysiology of GC induced psychiatric disorders.¹⁰⁸ Memory and cognitive function mediated by the hippocampus can also be affected.¹⁰⁹ This organ appears to be directly injured by GCs. In addition, decreased dendritic branching, loss of neurons, inhibition of neuronal regeneration, and other effects have been noted in the brain.⁹⁷ Cases of elevated intracranial pressure (ICP) have been reported, the majority of which occur in boys. The typical case is that of a patient whose long-term GC was stopped, tapered, or changed to another agent. The pathophysiology of this increase in ICP is not clear.¹¹⁰⁻¹¹³

Alterations in metabolism and effects on many endocrine organs occur with high frequency in the patient receiving chronic GC therapy. In response to corticosteroids, the pancreas secretes less insulin, and insulin resistance rises.¹¹⁴ GR-mediated transcription up-regulation increases glucose production. There is evidence to suggest that patients who develop steroid-induced diabetes have a preexisting decrease in insulin secretory reserve. Risk factors include a personal or family history of diabetes. A few patients who develop frank type 2 diabetes may remain diabetic after GC therapy ceases.¹¹⁵ Most cases of simple hyperglycemia resolve a few days after GC therapy ends. Some of the most common effects of chronic GC therapy result from their influence on the hypothalamic-pituitary-adrenal axis. These include Cushing's syndrome of moon face, buffalo hump, and central obesity; growth inhibition; and adrenal insufficiency.⁹⁷ Activation of GRs in the hypothalamus causes

a decrease in the secretion of ACTH and corticotropin-releasing hormone, with subsequent downstream effects. There is no clear consensus on how long GC therapy must continue in order to reliably provoke adrenal insufficiency, but even periods of 1 week may be sufficient.¹¹⁶

Hypertension, hyperlipidemia, and reduced fibrinolytic potential are the main adverse cardiovascular effects.¹¹⁷ Although elevated blood pressure is more common in the elderly and those with preexisting hypertension, this adverse event also commonly occurs in children, both with oral and inhaled GC use. This hypertension is the result of increases in systemic vascular resistance, extracellular volume, and cardiac contractility. These effects are mediated by activation of the GR and MR.⁹⁷

In the GI system, the chronic use of GC can lead to peptic ulcers. The relative risk associated with GC use alone ranges from 1.1 to 2.7, but increased to 14.6 when nonsteroidal anti-inflammatory drugs (NSAIDs) are used concurrently.¹¹⁸ In experimental animals, GCs increase gastric acid secretion, thin gastric mucus, cause gastrin and parietal cell hyperplasia, and slow ulcer healing.¹¹⁹ It is thought that these effects lead to peptic ulcer disease in humans. Upper GI bleeding and pancreatitis are known adverse effects, as is oral candidiasis with inhaled corticosteroids.^{97,120}

MINERALOCORTICOIDS

At therapeutic doses, the toxic effects of these agents are the same as the expected physiologic effects of a mineralocorticoid and tend to be dose related. Mineralocorticoids act at the distal tubule of the kidney to promote the excretion of potassium and reabsorption of sodium. Thus, intravascular volume expansion, hypertension, and hypokalemia are the most likely problems. In suprathreshold doses, they can inhibit the adrenal cortex and the thymus, and act on the pituitary to decrease corticotropin excretion. They may also stimulate an inappropriate wound healing response in uninjured vascular tissues.^{2,121-124}

MINERALOCORTICOID ANTAGONISTS

Toxicity of these agents can be divided into three categories. Classic effects occur at the distal convoluted tubule of the kidney. Because of poor specificity to the MR, antiandrogenic and progestational effects can also be seen. Lastly, pathologic cardiovascular remodeling can also occur. Thus, hyperkalemia is a risk in predisposed patients, such as those with renal insufficiency or long-standing diabetic patients who may have hypoaldosteronism; men can experience impaired libido, impotence, and gynecomastia due to the antiandrogen effects; and women frequently experience menometrorrhagia and mastodynia.¹²⁵⁻¹²⁷

Specific Agents and Their Mechanisms of Toxicity

GLUCOCORTICOIDS

In rare cases, methylprednisolone administration has been associated with seizures. Intrathecal infusions of methylprednisolone acetate have caused aseptic meningitis, thought to be due to the polyethylene glycol excipient.²

GLUCOCORTICOID ANTAGONISTS

Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone, the first step in steroid synthesis. Thus, in addition to lowering cortisol levels, it also inhibits production of other steroids, including aldosterone and estrogen. Iodine-concentrating abilities of the thyroid are also impaired. Adverse effects can therefore include hypoaldosteronism and hypothyroidism in addition to cortisol deficiency. Common nonendocrine toxic effects include lethargy, somnolence, and a fairly common maculopapular rash. The latter is often associated with fever, occurring within 2 weeks of initiation of therapy, and frequently self-resolving. Patients develop neutropenia, pancytopenia, leukopenia, or agranulocytosis; the incidence of each of these conditions is an estimated 4%.²

Ketoconazole is an imidazole antifungal agent. Used primarily as an antimycotic agent, it is a potent inhibitor of enzymes involved in the synthesis of steroids. It is thought to inhibit C-17, 29-desmolase, the enzyme responsible for androstenedione biosynthesis.¹²⁸ Ketoconazole has therefore been used effectively to normalize cortisol production in patients with Cushing's syndrome, as well as to treat prostate cancer. Adrenal insufficiency has been reported with its use.¹²⁹ It also lowers testosterone production, potentially leading to gynecomastia and reversible loss of libido and impotence in men, as well as a teratogenic effect in male fetuses.¹³⁰ Hepatotoxicity is the most significant toxic action of ketoconazole. The injury pattern is usually hepatocellular, although it may be cholestatic.¹³¹⁻¹³³ Reversible transient abnormalities in liver function seem to occur in about 5% of patients.¹³⁴ However, a prospective trial showed some degree of transaminase elevation in 17.5% of patients taking ketoconazole.¹³⁵ In a large cohort study, a relative risk of 228, with confidence intervals from 34 to 933, was calculated for development of acute liver injury when taking ketoconazole.¹³⁶ Occasional fatal hepatotoxicity is reported.^{132,137-140} A case of massive enlargement of the liver, with fatty infiltrate, has been reported.¹⁴¹ The most common side effect is nausea and vomiting. Fatigue is also a frequent complaint.¹³⁴ Skin eruptions are seen in some patients.¹⁴² In the eye, ketoconazole has been associated with papilledema.^{143,144} Other rare side effects include weakness and tremor, psychiatric disturbances, and aplastic anemia.¹⁴⁵⁻¹⁴⁸ Ketoconazole strongly inhibits CYP3A4, so potential interactions exist with medications metabolized by this enzyme.^{149,150} A disulfiram-like reaction with ethanol ingestion has also been reported.² Limited data exist for acute overdose, but headache, fatigue, and tinnitus have been reported.²

Metyrapone reduces cortisol and corticosterone production by blocking 11 β -hydroxylation of precursor molecules in the adrenal cortex. To a lesser extent, it inhibits 18-hydroxylation and side chain cleavage. In addition to lowering cortisol levels, metyrapone also causes steroidogenesis to be shifted toward increased androgen production. It may also reduce production of aldosterone.² Adrenal insufficiency is the most serious

adverse effect of metyrapone. It occurs predominantly in patients with diminished adrenal secretory capacity. Monitoring is problematic and potentially misleading because the immediate precursor to cortisol, 11-deoxycortisol, accumulates to high levels with the use of metyrapone. This precursor also cross-reacts to various extents with most cortisol assays, which can give a false sense of security about the appropriateness of cortisol levels. Chronic metyrapone use can cause hirsutism and mild acne in women, although long-term use has also been associated with alopecia.^{151,152} Hypertension is a side effect seen in patients as well as in animal studies.^{153,154} Metabolic derangements consistent with alteration in mineralocorticoid production occur. Rarely, bone marrow depression or leukopenia have been noted. GI symptoms occur with use of the drug but predominantly when adrenal insufficiency occurs as a result of overtreatment.² Rare instances of dissociative psychiatric disturbances have been observed.¹⁵⁵ In overdose, patients may have hypotension and dysrhythmias; nausea, vomiting, diarrhea, and abdominal pain; electrolyte derangements; and adrenal insufficiency.²

Mitotane, also known as o,p'-DDD, is a congener of the notorious insecticide DDT (dichlorodiphenyltrichloroethane) and an isomer of another insecticide, p,p'-DDD. Its primary effect is to produce selective atrophic damage to the adrenal cortex. It also reduces the excretion of 17-hydroxycorticosteroids without altering plasma cortisol levels. The mechanisms of action of these effects are not known. Mitotane is used to treat inoperable adrenocortical carcinoma.¹⁵⁶ CNS adverse effects occur in up to 40% of patients, and include depression, lethargy, and vertigo. Long-term use may cause permanent brain damage. GI side effects are frequent and include anorexia, nausea, and vomiting.¹⁵⁷ Elevations of hepatic transaminases are common, and elevated lipid levels have also been seen.^{158,159} In one study, all patients developed low serum T₄ levels while being treated with mitotane for Cushing's syndrome.¹⁵⁷ Up to 15% of patients developed skin toxicity. Renal insufficiency and hemorrhagic cystitis, as well as retinopathy and opacification of the lens, have been reported.^{2,160-162} Acute overdose information is limited, but effects similar to the above are hypothesized.

Trilostane is a competitive inhibitor of 3- β -hydroxysteroid dehydrogenase. This action slows conversion of biologically inactive δ -5 steroids to their δ -4 derivatives.¹⁶³ Trilostane also inhibits testicular 3- β -hydroxysteroid dehydrogenase, resulting in a fall in testosterone levels and elevation of luteinizing hormone levels.¹⁶⁴ Adverse effects in therapeutic doses include hypotension; low testosterone levels; adrenal insufficiency; nausea, vomiting, and diarrhea; palatal edema; rhinorrhea; and flushing.^{2,165,166}

Mifepristone (RU 486) is the first synthetic GC and progesterone receptor antagonist.¹⁶⁷ Its only Food and Drug Administration (FDA)-approved use is for the termination of early pregnancy, but it has been used to treat a number of diseases, including Cushing's syndrome. Not surprisingly, uterine pain, cramping, and

vaginal bleeding are common adverse effects. Headaches, nausea, vomiting, and diarrhea are also seen with regularity. Rash, adrenal insufficiency, elevation of liver transaminases, uterine rupture, hypotension, and myocardial infarction have also been reported.^{2,168-176}

MINERALOCORTICOIDS

Fludrocortisone is a halogenated hydrocortisone derivative with a high degree of GC and mineralocorticoid activity. Its action in the distal tubule of the kidney to increase sodium resorption and the subsequent fluid retention make it a useful agent for treatment of orthostatic hypotension. Potassium and hydrogen ions are excreted via the same mechanism. Fludrocortisone is also used for adrenocortical insufficiency as well as adrenogenital syndrome. As expected, common adverse effects include hypertension, peripheral edema, and hypokalemia.^{177,178} Adrenal suppression and severe metabolic alkalosis have also been reported.¹⁷⁹⁻¹⁸¹ Cardiac hypertrophy and heart failure have been described after long-term therapy.¹⁸²⁻¹⁸⁴ Topical and inhaled nasal forms of this medication exist, and excess mineralocorticoid activity as well as hypertension have been described with their use.^{185,186}

Desoxycorticosterone toxicity is not well described in the literature. In the United States, it is available for veterinary use only. Animal studies have demonstrated hypertension as well as hypernatremia and hypokalemia as adverse effects associated with its use.¹⁸⁷⁻¹⁸⁹ Hypertension has also been documented in humans, in some cases lasting long after the cessation of treatment.¹⁹⁰

MINERALOCORTICOID ANTAGONISTS

Spironolactone is a competitive inhibitor of aldosterone at the MR. Renally mediated hyponatremia and hyperkalemia are the expected primary effects.¹⁹¹ It also appears to have effects on the systemic vascular resistance and the cardiac response to adrenergic signaling, which are independent of its mineralocorticoid antagonism.¹⁹² Spironolactone also decreases 17-hydroxylase activity, which explains its effectiveness in the treatment of hirsutism.¹⁹³ It has been used to treat a wide array of diseases, with the most common being hyperaldosteronism, hypertension, hypernatremia, and hypokalemia.

Eplerenone is an aldosterone receptor antagonist with high specificity for the MR. This leads to fewer cardiovascular and nonmineralocorticoid effects, although it has less affinity for the MR than does spironolactone. It is used after myocardial infarction to prevent pathologic cardiac remodeling and for the treatment of some types of hypertension.^{2,125} The most common and serious effect is hyperkalemia.¹⁹⁴ The manufacturer's experience suggests that gynecomastia and vaginal bleeding are infrequent, and placebo-controlled trials show no difference in incidence. Some patients were noted to have elevations of TSH.¹⁹⁵ Dose-related elevations in transaminases, as well as elevated lipid levels, occurred. No cases of hepatotoxicity were described.² There are currently no data on toxicity after acute overdose.

Treatment Principles

For many of the steroid-related complications, there are no specific antidotes. The general recommendation of limiting steroid use to the lowest possible effective dose for the shortest possible interval is a logical maneuver to prevent complications. Withdrawal of the offending agent is suggested as a first step in reversing toxicity. However, this advice may not be practical in the management of a specific patient who has a clearcut need for long-term steroid therapy at high doses. In some situations, other options are available to limit or treat adverse effects. Consultation with a specialist may be helpful.

GLUCOCORTICOIDS

Suppression of the hypothalamic-pituitary-adrenal axis as a result of high-dose GC treatment for greater than 1 month requires that doses be tapered. One recommendation for a prednisone taper is to decrease the dose by 1.0 to 2.5 mg per week, and to assess the adrenal reserve with a cortisol stimulation test when a daily dose of 5 mg has been reached.¹¹⁵ Stress level steroid coverage is mandatory in acutely ill patients if there is any question of possible adrenal suppression.¹⁹⁶ With severe stress, it is estimated that approximately 200 to 300 mg of hydrocortisone daily, in divided doses, reasonably mimics the response of normally functioning adrenals to a major illness. This stands in contrast to the basal physiologic production of no more than 12 to 15 mg/m² per day for nonstressed individuals.

It is best to prevent development of steroid-induced osteoporosis rather than to treat its sequelae. The 2001 American College of Rheumatology guidelines recommend calcium and vitamin D supplementation as well as the use of bisphosphonates in all men and postmenopausal women.^{197,198} Bisphosphonates are well tolerated, and robust data exist to demonstrate their effectiveness.¹⁹⁸⁻²⁰⁰ It is reasonable to use these agents for all patients who are going to be treated with GC for an extended interval.²⁰¹ A cyclic regimen of etidronate, 400 mg per day for 2 weeks every 3 months, has been effective and well tolerated.²⁰² Loading of the skeleton through exercise is also recommended. Monitoring of bone mineral density on a regular basis is a reasonable way of assessing the effectiveness of prophylaxis. Dual-energy x-ray absorptiometry is a sensitive method of accurately assessing skeletal status. The spine and proximal femur, with a high percentage of trabecular bone, are particularly affected by steroids.¹⁹⁷

Treatment of steroid myopathy consists of tapering and discontinuing the steroid. In cases where a nondepolarizing paralytic has been used, that agent should be stopped if possible. Clinical recovery may take many weeks. Physical therapy is helpful in prevention as well as recovery.⁹⁹

Diabetes as a complication of GC therapy generally requires administration of insulin at mealtimes to achieve adequate glucose control.²⁰³ Diet control and oral medications have been attempted with some success.²⁰⁴

Blood glucose levels only rise significantly after eating. For this reason, regular checks of postprandial glucose are important for the patient receiving long-term corticosteroids.¹¹⁵

Increases in intraocular pressure as a result of GC treatment are generally reversible if the treatment duration is under 1 year.²⁰⁵ Treatment includes stopping the corticosteroid and administration of topical agents for open-angle glaucoma.²⁰⁶ If cataracts develop, they must be treated in the standard fashion.²⁰⁷ Regular ophthalmologic examinations, including tonometry, are essential in early detection of ocular side effects.²⁰⁸

Standard treatment of corticosteroid-induced psychosis consists of tapering the steroids and treatment with a neuroleptic. Lithium has been used prophylactically with success, but has not been reported as a treatment. Atypical antipsychotics are recommended as treatment for subacute cases.¹⁰⁷ The treatment for elevated ICP is as unclear as its etiology. Changing the corticosteroid, or increasing or decreasing the dose, have been attempted. Therapeutic lumbar puncture has also improved the clinical picture in some patients.²⁰⁹

Elevation of low-density lipoprotein (LDL) cholesterol due to GC can be effectively treated with a statin. To lower triglycerides, omega-3 fatty acids or fibrates may be used. Omega-3 agents appear to have fewer interactions with statins than do fibrates. Nicotinic acid may potentiate glucose intolerance and thus may not be ideal for the patient already taking GC.²¹⁰

Treatment of GC-induced hypertension includes stopping the agent, lowering the dose, or moving to an every-other-day dosing regimen.^{211,212} Sodium restriction or initiation of a thiazide diuretic may be necessary.²¹³

Peptic ulcers seen in association with steroid use are better prevented than treated. Elimination of risks such as NSAID use, smoking, and alcohol may help.¹¹⁸ Although no data exist on their efficacy, it would be reasonable to treat GC-related ulcers with antacids, H₂ blockers, or proton pump inhibitors, or to initiate this treatment prophylactically.²¹³

Acute overdose of GCs generally does not produce significant toxicity. However, in one case Cushing's syndrome was caused in a patient who received a large inadvertent overdose of triamcinolone. Experimentally, a GC antagonist was given and clinical improvement was noted. The dosing regimen was as follows: mifepristone 200 mg daily for 11 days, followed by 600 mg on days 12 and 13, and 200 mg daily for 5 more days.²¹⁴ On a theoretical and clinical basis, this therapy is logical and appears to work. However, this is a single experience and cannot be unreservedly recommended.

GLUCOCORTICOID ANTAGONISTS

All GC antagonists may produce adrenocortical insufficiency, which can be treated with exogenous corticosteroids such as hydrocortisone or dexamethasone. Hyperkalemia and hyponatremia should be identified and treated if necessary. In acute ketoconazole overdose, administration of an oral antacid may prevent the absorption of ketoconazole by preventing the tablets from dissolving.²¹⁵ Adrenal insufficiency caused by

metyrapone overdose can be treated by administering stress dose GCs. Cardiac monitoring should be implemented, and patients should have fluid and electrolyte replacement. Vasopressor agents may be necessary to reverse hypotension.^{2,3} Patients on mitotane treatment should receive GC and mineralocorticoid replacement if necessary.²¹⁶ Thyroid function should be tested and levothyroxine administered if necessary. Because of the bleeding complications associated with mifepristone, a complete blood count should be checked and blood products transfused if necessary.

MINERALOCORTICIDS

Hypertension can be treated by stopping the drug. If this is not possible, sodium restriction to less than 2 g per day may be helpful. Pharmacologic treatment may include amiloride, which blocks the sodium channel in the distal renal tubule. Spironolactone or eplerenone may be used, but these agents will counter the desired effect of the mineralocorticoid. Hypokalemia should be identified and treated by potassium replacement, if necessary.²¹⁷

MINERALOCORTICOID ANTAGONISTS

The serum potassium level should be monitored, and an electrocardiogram obtained. Treatment of hyperkalemia caused by mineralocorticoid antagonists is the same as that caused by other factors. Sodium bicarbonate, sodium polystyrene sulfonate, and insulin/glucose will be effective. Intravenous calcium should be used in severe cases as the first agent. Hypotension can be treated with intravenous crystalloid volume replacement. Vasopressors should be used if the patient remains hypotensive despite adequate fluid resuscitation.³

GONADAL

Introduction and Importance

Androgens are endocrine agents commonly used for legitimate purposes such as the treatment of male hypogonadism but are also used illegally in attempts to improve sex drive and athletic performance.^{218,219} Androgen replacement for elderly men and postmenopausal women is advocated, although controversial.^{220,221} Antiandrogens are primarily used to treat prostate cancer.³¹

Clinical indications for use of estrogen as medical treatment can be divided into at least three categories. Estrogen finds use as a physiologic hormone replacement therapy in estrogen-deficient women. It is also used in premenopausal women for contraceptive purposes. Controversial situations occur when it is used for other purposes, for example, the use of diethylstilbestrol (DES) in years past, for the purposes of improving pregnancy outcome.

Antiestrogens are used for therapy of reproductive disorders and for treatment of estrogen-dependent malignancies. These agents are not pure antagonists but have both estrogen antagonist and estrogen agonist effects, a situation that complicates understanding of

their action and controversy about their toxicity. Tamoxifen's estrogen antagonist action is reflected by improved survival of tamoxifen-treated patients with breast cancer and lowered risk for contralateral breast cancer.

Progestins are at times used as single agents for contraceptive purposes, although they are generally used in conjunction with an estrogen. Megestrol is a progestational agent that suppresses gonadotropin production, lowers testosterone levels, and thus functions as an antiandrogen. It has been used in the treatment of prostate carcinoma, and its antigonadotropic activity has also led to its use in the treatment of breast carcinoma and endometrial carcinoma. It has been observed that cancer victims who are treated with megestrol acetate tend to gain weight, leading to its use for the cachexia associated with malignancy and acquired immunodeficiency syndrome (AIDS).

Toxin-Induced Physiologic Disturbances

ANDROGENS

Many of the androgens that are clinically available are chemically altered versions of the testosterone molecule; without these modifications, effective androgen replacement would be difficult. Unmodified testosterone is quickly absorbed and very quickly metabolized by the liver; oral administration of testosterone is therefore not a useful therapeutic approach. It is now possible to administer unmodified testosterone transdermally. Outside the United States, testosterone implants are also available as a method for delivery of unmodified testosterone. Otherwise, the androgens that are available for administration can be divided into two major categories, based on the way in which the testosterone molecule has been modified for clinical use. Esterification of the 17α -hydroxyl group decreases the molecule's polarity and increases fat solubility. These testosterone esters, testosterone enanthate and testosterone cypionate, are administered in oily injection vehicles and function as depot agents with long half-lives; once absorbed, the esters are hydrolyzed to free testosterone, with subsequent physiologic actions that are no different from those of endogenously produced testosterone.

Acute overdose of androgens is not particularly toxic. Chronic misuse, however, results in significant pathology. The adverse effects of androgens tend to be related to the physiologic effects that result from the interaction of the hormone molecule with the hormone receptor. In the case of the androgens, the prostate gland is a major target organ for androgen action, with prostate cancer and benign prostatic hyperplasia being disorders of particular concern in patients who are treated with androgens.²²² Neither prostate cancer nor benign prostatic hyperplasia develops in the absence of testosterone exposure.²²³ Prostatic cancer arises by a two-step process. The first component is the development of microscopic disease, and animal studies suggest that androgens are promoters of this step. The second step is the progression to clinical cancer, and it is not known whether

androgens promote this phase of the disease.²²⁴ The androgenic effect on benign prostatic hyperplasia is clearly demonstrated by the finding that prostate size can be reduced, and urinary obstructive symptoms improved, by agents that decrease androgen levels or androgen effect. Testosterone replacement in elderly men is associated with an increase in prostate-specific antigen.²²³

The effects of androgens on classic androgen-sensitive tissues are particularly of concern in athletes who take large and supraphysiologic doses of androgens. In male athletes, suppression of spermatogenesis, subsequent infertility, and testicular atrophy can occur.²²⁵ Female athletes can become virilized, and some of these changes, such as effects on deepening of the voice caused by androgen action on the larynx, can be irreversible. Children and adolescents can experience accelerated skeletal maturation and early epiphyseal closure, which ultimately inhibits their final height.²²⁶ Testosterone administration does not cause excessive stimulation of libido or potency, except in prepubertal boys and young men with long-standing androgen deficiency; in such patients, the possibility of severe and prolonged episodes of priapism dictates that very small initial doses of testosterone be used.

In what may seem to be a paradoxical side effect, administration of testosterone can at times cause gynecomastia. This is related to the conversion of testosterone to estradiol in peripheral tissues by aromatase enzymes and appears to be more common in young boys who are treated with testosterone for induction of puberty and in men with underlying disorders such as hepatic cirrhosis; in these situations, an elevation of the ratio of estradiol to testosterone is the likely mechanism. Testicular shrinkage is noted by chronic users and has been seen at autopsy of such patients.²²⁷

Androgen effects on nonreproductive tissues include androgen-dependent changes in serum lipoproteins. Men have lower levels than women of the protective high-density lipoprotein (HDL) cholesterol, with the disparity in HDL cholesterol level developing at the time of puberty. A 10% to 15% drop in HDL cholesterol level occurs during testosterone therapy. This androgen-driven decrement in HDL cholesterol may be a major contributor to the increased male risk for cardiovascular disease, although other factors such as a direct protective effect of estrogen on vascular tissue may also be important. Anabolic steroid use has been associated with myocardial infarction in otherwise healthy young athletes with normal coronary anatomy.²²⁸ The cardiovascular risk of androgens may depend on the particular type of androgen used. Orally administered 17α -alkylated steroids cause a much more pronounced lowering of HDL cholesterol level than the testosterone esters, as well as an elevation of LDL cholesterol level that is not noted with the parenteral testosterone products.^{222,229} The oral agents may have a greater effect on lipids because of the first-pass effect through the liver; furthermore, the effect of testosterone may be attenuated by its conversion to estrogen, which cannot occur with the 17α -alkylated agents. Although previous work showed an adverse effect of androgens on the cardiovascular system,

more recent studies suggest that testosterone may protect the arterial vascular system.²³⁰ The musculoskeletal system is also at risk: one study reported unusual cases of tendon rupture among steroid-using bodybuilders. Dysplasia of collagen fibrils was the postulated mechanism.²³¹

The initiation of androgen therapy can be associated with modest weight gain, which reflects the anabolic effects of testosterone and a component of sodium retention. Patients with disorders such as congestive heart failure and cirrhosis can have worsening of their edema with testosterone treatment. In combination with other risk factors such as obesity, chronic obstructive lung disease, and advancing age, testosterone administration to hypogonadal men appears to increase the incidence of sleep-related breathing disorders.³²

Androgens have a number of effects on the body's hematopoietic system. Erythropoiesis increases, especially in the elderly. Cases of thrombosis in the extremities and in the CNS have been described, and it has been suggested that increased platelet aggregation may be the cause.²³²⁻²³⁵ Conversely, androgens potentiate the effect of warfarin; a dose reduction up to 25% of this anticoagulant may be necessary.^{236,237}

An ongoing controversy is whether or not androgens, when used in high doses, can induce pathologically aggressive and violent behavior or even psychotic symptoms. It is difficult to separate fact from conjecture, because most reports are anecdotal and do not take into account the pretreatment characteristics of the androgen user or consider possible concurrent use of other substances of abuse.²³⁸ However, psychologic effects are suggested by the findings of a full affective disorder in more than 20% of athletes who used 10 to 100 times the usual therapeutic doses of these drugs, with psychotic symptoms appearing in 12%. This is consistent with the concept of androgen-related fluctuations in mood and increased levels of aggressiveness, which have been termed '*roid rage*.'^{227,239} At testosterone doses double the physiologic replacement dose, little change in sexual and aggressive behaviors occurs, and the suggested concerns of adverse effects of exogenous testosterone on male sexual and aggressive behavior thus may be overstated.²⁴⁰

The question has also arisen about whether androgens can produce a psychological dependence syndrome. Evidence shows that in some individuals, androgen abuse can develop into a psychoactive substance dependence disorder with features that are similar to those seen with cocaine, alcohol, or opioid abuse. The features of psychological dependence include a preoccupation with the use of androgens, drug craving, and difficulty in discontinuing the agent despite psychological side effects; withdrawal effects are said to include mood swings, violent behavior, and profound depression.²⁴¹ In an effort to produce an androgen that can be given by the oral route, testosterone derivatives have been developed in which the molecule has been alkylated at the 17 α position, sometimes in association with modification of the ring structure. These changes lead to a slowing of hepatic metabolism, which results in

effective drug levels after oral administration. These 17 α -alkylated androgens have been associated with severe hepatic toxicity, including cholestasis, liver tumors, and peliosis hepatis.²⁴²⁻²⁴⁴ Because of these problems, it is generally recommended that these oral androgens should not be used for therapy of male hypogonadism; nonetheless, they can still be prescribed, and their illicit use continues.

Oxymetholone has been associated with development of leukemia in patients being treated for aplastic anemia and Fanconi's anemia. There is no clear causative relationship.²⁴⁵

Diabetic patients taking stanozolol may have decreases in glucose tolerance requiring a change in their diabetic medication.²

ANTIANDROGENS

Antiandrogens, used for therapy of benign prostatic hyperplasia, inhibit the 5 α -reductase enzyme that converts testosterone into the active metabolite dihydrotestosterone. Although testosterone has a direct action in some tissues, it must be converted to dihydrotestosterone to exert an effect on the prostate and skin. No data on acute overdose are available, and adverse effects are rare. The most clinically important chronic toxicity is hepatic, and this effect is noted principally with the agents cyproterone and flutamide. Jaundice and hepatitis occur in 1% to 5% of patients taking these agents, and a few deaths due to liver failure have occurred.² Fluid retention, congestive heart failure, and hypertension have been noted.²⁴⁶ Gynecomastia has been observed.²⁴⁷ The drug is not approved for use in treatment of hirsutism, because its use in women would be associated with a theoretic risk of impaired virilization of the genitalia of male offspring.

In acute overdose, flutamide can cause CNS depression and decreased respirations.² Some cases of methemoglobinemia have been reported following chronic administration of flutamide, both in animals and humans. Methemoglobin levels as high as 32% were measured in one case.²⁴⁸⁻²⁵⁰

Nilutamide has been strongly associated with development of interstitial pneumonitis, with incidence ranging from less than 1% in the general population to 17% in Asians. Oxidative stress resulting from the redox cycling of the drug has been proposed as a mechanism.²⁵¹

ESTROGENS

Acute overdose of oral contraceptive pills is considered a low-toxicity ingestion. GI upset the following day is common, and vaginal bleeding in girls or women in the few days following ingestion may occur.²⁵²

The use of estrogen replacement in postmenopausal women has risks. An increased risk for endometrial cancer was one of the first described complications of long-term estrogen therapy, with a 2- to 10-fold increase in disease among untreated women. This risk is present only in women who are treated without concurrent use of a progestational agent. The question of whether postmenopausal estrogen therapy leads to an increased risk for breast carcinoma continues to be one of the most

controversial concerns with estrogen treatment. Some studies have not shown any increase in risk, others have demonstrated some risk increase, and some have shown even a decreased risk.²⁵³ When increased risk has been demonstrated, it appears that survival from breast cancer in estrogen-treated patients may be better than that in non-estrogen-treated women; whether this is related to closer medical supervision and monitoring in estrogen-treated women, biologic differences in the cancers, or other unidentified factors is uncertain. The risk question is further complicated by a large number of other variables, including the variety of estrogen products that have been used and the possibility of bias in the selection of patients who take estrogen. Even though at least one meta-analysis has concluded that postmenopausal estrogen therapy does not increase the risk for breast cancer, it is premature to conclude that this issue is settled. In particular, the contemporary tendency to combine estrogen and progestin may negate strict interpretation of earlier studies that evaluated estrogen-only therapy. Further studies will undoubtedly continue to provide more data on this topic; in light of the many conflicting results that have been reported thus far, no conclusive or final answer can be given to the breast cancer question at this time, and this will continue to be a topic of concern.²⁵⁴

The risk for gallbladder disease, however, is approximately doubled with estrogen treatment related to changes in the composition of bile.²⁵⁵ In addition, estrogen can trigger migraine headaches in susceptible women.²⁵³

Postmenopausal estrogen replacement is usually administered as oral conjugated equine estrogens, oral estradiol, or transdermal estradiol. Transdermal therapy results in direct absorption of the estrogen into the systemic circulation and avoids the first pass effect of estrogen on the liver. The physiologic relevance of this is uncertain; however, in some cases, such as patients with a prior history of thromboembolic disease, the use of transdermal estrogen should minimize risks related to stimulation of clotting cascade protein production. Otherwise, the choice between oral and transdermal estrogen is an issue of individual patient preference.

The current oral contraceptive agents used in the United States are combination pills that contain ethinyl estradiol and one of five possible progestational agents, all of which are 19-nortestosterone derivatives.²⁵⁶ The risks of estrogen use in these products are a complex issue because of the varying doses of estrogen and the combinations with various progestational agents. All of the data on oral contraceptive risks should be considered to be a moving target, because the earlier agents were relatively rich in estrogen content compared with contemporary agents. Although increased cardiovascular risk was a concern with the initial oral contraceptives, the risk for death due to coronary artery disease does not appear to be increased in present or past birth control pill users in the absence of other cardiovascular risk factors. However, additional risk factors such as hypertension, diabetes, and hypercholesterolemia are synergistic with birth control pills as risk factors for myocardial

infarction, and cigarette smoking in particular is the greatest single factor.

Birth control pills might influence cardiovascular risk factors in a number of ways. All estrogen-containing pills increase fasting triglyceride levels, and patients with underlying hypertriglyceridemia have an increased risk for pancreatitis if the triglyceride level exceeds the 800 to 1000 mg/dL range. Various effects on cholesterol metabolism are noted, depending on the dose of the estrogen and the particular progestin that is used. The addition of progestin may tend to attenuate mildly the generally favorable effects of estrogen on lipoprotein levels. In the various formulations of triphasic pills, changes in total cholesterol, LDL, and HDL are generally very slight. Pills containing only progestin seem to have the least effect on lipids, and it has been suggested that progestin-only pills, implantable levonorgestrel, or pills containing newer progestins such as desogestrel may be the best choice for patients who have a higher than usual risk for coronary artery disease but who would benefit from an effective contraceptive agent.²⁵⁶

Before the 1990s, virtually all oral contraceptive pills caused some degree of insulin resistance, with some increase in serum glucose and insulin levels. Both the estrogenic and progestational agents are responsible for the insulin resistance in a dose-dependent manner, and the same effects are less apparent with current oral contraceptives. In a practical sense, the changes in insulin and glucose metabolism are so small that they have no significance for normal women.²⁵⁶

Of all the metabolic changes that are related to oral contraceptive use, the changes in liver protein metabolism are the most important, particularly the hepatic proteins associated with coagulation, which increase in proportion to the estrogen content of the oral contraceptive. Oral contraceptive or postmenopausal combination estrogen-progestin therapy is associated with increased risk of thrombosis. This is not the case for low-dose estrogen-only therapy.^{257,258}

Venous thromboembolism is the most serious complication related to the use of birth control pills. Its occurrence does not seem to be related to age, parity, obesity, smoking, or other apparent factors. Levels of these serum proteins return to normal within 2 months or so of discontinuation of the pills; the increased risk for thrombophlebitis decreases sooner. A case report describes an ischemic stroke in a young female smoker shortly after inadvertently taking a fourfold overdose of emergency contraception.²⁵⁹

Postmenopausal estrogen therapy usually does not affect blood pressure. If it has any effect, it may cause somewhat of a reduction in blood pressure in both normotensive and hypertensive women, with blood pressure elevation being an unusual finding.²⁵⁴ Blood pressure elevation has been linked to oral contraceptive use, however. Combined oral contraceptives cause hypertension in 4% to 5% of women with normal blood pressure and an increase in blood pressure in 9% to 16% of women with previously established hypertension.²⁶⁰ An estrogen-related effect on hepatic production of angiotensinogen has been invoked as a possible

mechanism. In most patients, a compensatory decrease in renin levels seems to prevent the development of hypertension. Ethinyl estrogen at the typical doses of 30 or 35 μg has minimal effects on blood pressure, even in those individuals who may be predisposed to hypertension. Blood pressure is not influenced by progestin-only preparations, and some of the new third-generation progestins may even have an antimineralocorticoid effect that lowers the risk for hypertension.²⁶¹ With the triphasic pills, mean blood pressure in groups of patients does not change, although individual patients may have some increase.

DES is a synthesized stilbene with the estrogenic properties of naturally occurring estrogens. It was used for many years because of its effectiveness with oral administration and its low cost of production. DES was eventually banned from use in pregnancy in 1971 because of associated adverse medical effects.²⁶¹ The drug was commonly used in pregnancy because of its purported effectiveness in preventing miscarriages and premature births. In the early 1970s, a clear association with clear cell vaginal carcinoma was observed in young women who had been exposed to DES in utero. These women also seem to be at greater risk for anatomic anomalies of the reproductive tract. It is not clear whether males exposed in utero have any increased risk for comparable problems. Men being treated with DES for prostatic cancer have an increased risk for arterial thrombosis.²⁶² It has also been associated with a case of fatal hemolytic anemia as well as with a number of cases of fluid overload.^{263,264} A number of cases of porphyria cutanea tarda have been reported in the literature after DES administration over a period of 1 to 3 years.²⁶⁵⁻²⁶⁹

An industrial exposure to norethindrone and mestranol caused a prolactinoma in a 61-year-old man, with gynecomastia, galactorrhea, and impotence.²⁷⁰

ANTIESTROGENS

Although little data exist on acute toxicity, sixfold overdoses in humans have been shown to cause neurotoxicity, including dizziness, ataxia, tremor, hyperreflexia, and seizure, as well as QT prolongation. In animals, respiratory distress and seizures have been generated.³

In chronic use, adverse effects include reversible hepatitis, which is thought to be a hypersensitivity reaction, and fatigue, headache, depression, and dizziness.^{271,272} The expected estrogen deficiency symptoms of vasomotor instability and vaginal dryness are common. Clomiphene has traditionally been used to induce ovulation in anovulatory women; by masking the estrogen receptor at the hypothalamic-pituitary level, gonadotropin secretion is augmented, with subsequent stimulation of ovarian function. Side effects are infrequent and fairly mild and include occasional pelvic cramping, hot flashes, nausea, and breast tenderness, as well as some visual symptoms. The most significant side effect is ovarian hyperstimulation, with formation of luteinized ovarian cysts.

The estrogen agonist effects of tamoxifen seem to predominate over antagonistic action at the skeleton, where the drug increases bone density; in the metab-

olism of lipoproteins, where it has an estrogen-like action in increasing triglycerides and lowering LDL cholesterol; and at the endometrium, where an increased incidence of endometrial carcinoma has been noted.

PROGESTINS

Many of the effects of progestin therapy were reviewed in the earlier section on oral contraceptives under Estrogens. Because progestins are commonly used in conjunction with estrogens, distinguishing the effects of progestins from those of estrogen has been difficult. It is clear that more information is needed about the consequences, positive and negative, of combining estrogen with progesterone.

Implantable levonorgestrel may not completely suppress gonadotropins, and the subsequent irregularity of estrogen secretion can result in irregular bleeding, which may necessitate removal. No consistent effects on blood pressure, lipoproteins, or coagulation have been noted with this agent. Injectable depot medroxyprogesterone acetate has also been associated with irregular bleeding. Infertility may persist for months after its use. Despite gonadotropin suppression, bone density does not seem to be affected. Decreases in triglycerides and HDL cholesterol may occur without a change in total cholesterol or LDL cholesterol.

At high doses, progestins appear to cross-react with receptors for other steroids, and thus these agents may also have a GC effect. Cushingoid features and hypoadrenalism have been noted in patients taking medroxyprogesterone.²⁷³ Five cases of Cushing's syndrome associated with megestrol therapy have been identified.²⁷⁴ In one study, 16% of patients receiving high-dose progestins for breast cancer developed hyperglycemia.²⁷⁵ Adrenal suppression due to ACTH inhibition after abrupt discontinuation of megestrol in a patient with AIDS has been described.²⁷⁶

Specific progestin side effects, which are dose dependent, can include breast tenderness, bloating, irritability, and depression.²⁷⁷ However, a double-blind, placebo-controlled, crossover trial found no significant mood change.²⁷⁸ Common skin side effects include acne, dermatitis, darkened skin, and hirsutism.²⁷⁹ There have been 56 cases of intracranial hypertension associated with levonorgestrel use worldwide. Signs and symptoms included headache, nausea, and papilledema.²⁸⁰ Intrathecal administration of medroxyprogesterone has been linked with the development of arachnoiditis in 17 cases. The mechanism is unclear.²⁸¹ However, the agents are generally considered so safe in terms of acute overdose that they have been exempted from poison prevention packaging requirements.²⁸²

ANTIPROGESTIN

Mifepristone is discussed in this chapter, in the section on the adrenal system.

Treatment Principles

Generally, withdrawal of the agent and supportive care are the mainstays of treatment. Most gonadal agents,

with a few exceptions, are fairly benign in acute overdose (Table 16-9). Laboratory studies should include complete blood count, basic metabolic panel, liver function tests, and coagulation tests.

ANTIANDROGENS

If there is clinical concern, chest radiography should be done to look for pneumonitis. Methemoglobin and sulfhemoglobin levels should be obtained. Methemoglobinemia caused by antiandrogens can be treated with methylene blue, although treatment failures have been described.

ESTROGENS

It is generally recommended that all women who are taking estrogen and who have not had a hysterectomy should also be treated with a progestational agent. Options include the use of medroxyprogesterone acetate, 10 mg for 12 to 14 days monthly, in addition to daily estrogen, with resultant withdrawal bleeding from endometrial sloughing and complete abrogation of the

risk from estrogen treatment. An alternate approach, which avoids menstrual bleeding, is to add medroxyprogesterone, 2.5 mg daily, to the daily estrogen therapy. The progestin reduces the nuclear concentration of estrogen receptors, causing involution of the endometrium; breakthrough bleeding may occur in the first several months.

In women with latent diabetes, such as normoglycemic patients with a history of gestational diabetes, periodic glucose monitoring is reasonable.

Daughters exposed to DES in utero should have careful cervical and vaginal examinations, using half-strength Lugol's solution to stain the entire vaginal wall. If annual Papanicolaou's test results are suspicious, vaginal cytologic tests and colposcopy are recommended. When pregnant, these DES-exposed daughters should be followed as high-risk obstetric patients because of their increased risk for spontaneous abortions, ectopic pregnancies, and premature labor. Although no clear association with testicular cancer has been noted, routine genital examination is also suggested for DES-exposed sons. This is especially true for those with the risk factor of cryptorchidism, which appears to be more prevalent with a DES exposure history.²⁶¹

TABLE 16-9 Gonadal Agents

AGENT	CLASS
Calusterone	Androgen
Danazol	Androgen
Fluoxymesterone	Androgen, 17 α -alkylated
Methandrostenolone	Androgen
Methenolone	Androgen
Methyltestosterone	Androgen, 17 α -alkylated
Nandrolone	Androgen
Oxandrolone	Androgen, 17 α -alkylated
Oxymetholone	Androgen, 17 α -alkylated
Stanozolol	Androgen, 17 α -alkylated
Testosterone	Androgen
Chlorotrianisine	Estrogen
Dienestrol	Estrogen
Diethylstilbestrol	Estrogen
Estrogen	Estrogen
Promestriene	Estrogen
Quinestrol	Estrogen
Tibolone	Estrogen
Hydroxyprogesterone	Progestin
Levonorgestrel	Progestin
Medroxyprogesterone	Progestin
Megestrol	Progestin
Nomegestrol	Progestin
Norethindrone	Progestin
Progesterone	Progestin
Bicalutamide	Antiandrogen
Cyproterone	Antiandrogen
Dutasteride	Antiandrogen
Finasteride	Antiandrogen
Flutamide	Antiandrogen
Nilutamide	Antiandrogen
Cyclofenil	Antiandrogen
Droloxifene	Antiandrogen
Fulvestrant	Antiandrogen
Levomeloxifene	Antiandrogen
Reloxifene	Antiandrogen
Tamoxifen	Antiandrogen
Testolactone	Antiandrogen
Toremifene	Antiandrogen
Aglepristone	Antiprogestin (not available in USA)
Mifepristone	Antiprogestin

ANTIESTROGENS

Patients with severe periovulatory or postovulatory pain should undergo pelvic examination or ultrasound evaluation to confirm that the ovaries are of normal size before proceeding with further therapy.

An electrocardiogram should be obtained to evaluate the QT interval. Standard therapy should be used for treatment of seizures or torsades de pointes.

LIPID METABOLISM

Introduction and Importance

Lipids are essential for multiple body functions. Triglycerides are used as fuel stores for the body; cholesterol is a precursor for steroids and bile acids; and other lipids function as cellular signalers. One source of cholesterol is ingestion of cholesterol-containing foods, which are exclusively animal derived. The other source is synthesis of cholesterol within the body. Three molecules of acetate link to form 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA). This compound is metabolized to mevalonic acid via the enzyme HMG-CoA reductase. Cholesterol is either excreted unchanged in the stool or converted to bile acids. Half of the cholesterol and almost all of the bile acids are excreted and then reabsorbed in the small bowel.

Control of plasma lipid levels has been proven in multiple large clinical trials to reduce the incidence of symptomatic coronary artery disease in at-risk patients. Prescription of lipid-lowering agents has therefore become ubiquitous, with global sales reaching 15.5 billion dollars in the year 2001.²⁸³ Although many of these agents have excellent safety records, they are not without toxicity and adverse effects.

Toxin-Induced Physiologic Disturbances

Bile acid sequestrants lower cholesterol by binding bile acids in the stool and preventing their reabsorption. Subsequently, more bile acid is synthesized through cholesterol-7- α -hydroxylase, decreasing cholesterol stores.²⁸⁴ This results in an increase in the number of hepatic LDL cholesterol receptors, which remove cholesterol from the circulation.²⁸⁵ Fat-soluble vitamins A, D, E, and K, as well as vitamin B₁₂ and folic acid can be trapped with the bile acids and excreted as well. Depletion of vitamin K-dependent clotting factors and bleeding can occur, as can other conditions related to low levels of these vitamins.²⁸⁶⁻²⁹⁰ Patients taking cholestyramine and colestipol at high doses can develop severe hyperchloremic acidosis. This occurs because the chloride ion in the resin is exchanged for HCO₃, depleting the body of this buffer.²⁹¹ In some cases this has been related to a predisposition to renal tubular acidosis, such as dehydration, renal insufficiency, or concomitant spironolactone administration.²⁹²⁻²⁹⁷ Bile acid sequestrants also commonly cause constipation; they have been associated with vomiting or diarrhea to a lesser degree. Although no data exist about acute overdose of bile acid sequestrants, it is thought that bowel obstruction from inspissation would be a likely result.²

The same binding that seizes bile acids results in another of the adverse effects of this class of lipid-lowering agent. Taking a bile acid sequestrant at the same time as another drug may result in binding of the other medication and a decrease in its absorption.²⁹⁸ In one study, a group of hypothyroid patients receiving cholestyramine and levothyroxine had a decrease in free T₄ levels.² It has also been documented that bile acid sequestrants bind endogenous iodothyronines and increase their fecal excretion.²⁹⁹ This property may be useful in GI decontamination and enhanced elimination of other xenobiotics after toxic ingestions. Reports in the literature abound of cholestyramine being used to enhance elimination of levothyroxine, amiodarone, ochratoxin A, cardiac glycosides, methotrexate, chlordane, and chlordecone.^{51,300-310} It is logical that lipid-soluble compounds, especially those that undergo enterohepatic recirculation, could be removed in this way. In one study, cholestyramine was found to be more effective than activated charcoal in absorbing lindane.³¹¹

Fibric acid derivatives reduce triglycerides and LDL cholesterol, and increase HDL cholesterol. They do this via activation of PPAR- γ . This nuclear hormone receptor exists in peripheral tissues as well as in the liver. Downstream effects include oxidation of fatty acids, increased synthesis of lipoprotein lipase, and reduced expression of apo-CIII.³¹²

Gemfibrozil, and potentially other fibric acid derivatives, are likely metabolized by CYP3A4.³¹³ At least one, gemfibrozil, inhibits CYP2C8. This property has been experimentally shown to significantly raise the concentration of rosiglitazone when the two are administered together.³¹⁴ This inhibition may be the mechanism of other interactions between fibrates and oral hypoglycemic agents. In addition, a known interaction between fibric

acid derivatives and warfarin results in increased International Normalized Ratio. This may be the result of enzyme inhibition as well as displacement of warfarin from protein binding sites. An interaction with furosemide is also postulated.³¹⁵

A particularly feared complication of fibrate and statin-fibrate combination therapy is the possibility of rhabdomyolysis. Myopathy, which is much more common than frank rhabdomyolysis, has an incidence of 0.1% to 0.5% with monotherapy and 0.5% to 2.5% with combination therapy. Endocrine, metabolic, or genetic factors may play a role.³¹⁶ Reports have been published of autoimmune diseases potentiated by statin or fibrate therapy. It has been suggested that myositis is a manifestation of this synergy.³¹⁷ Some research suggests that rhabdomyolysis in this case is caused by two elements. First, fibrates strongly induce pyruvate dehydrogenase kinase 4 (PDK4) messenger RNA in muscle. Second, there is a reduction in serum triglyceride and fatty acid levels, which myocytes rely on for energy.³¹⁸ Another theory relates the adverse myotonic effects to inhibition of chloride ion channels in muscle.³¹⁹ Rhabdomyolysis has been seen to occur in acute overdose as well as chronic therapeutic dosing.³²⁰

Elevations in liver function tests have been seen in patients on fibrate therapy. Clofibrate has been found to induce peroxisomal enzymes and glutathione peroxidase activity. Reactive oxygen species are thus generated. It is unclear whether this is the pathophysiology which causes liver function test elevation.³²¹

Mild creatinine elevations occur in about 10% of patients on fibrates.³²² This increase is on the order of 40%.³²³ One study suggests that this is the result of increased creatinine production rather than development of renal insufficiency.³²⁴

Elevated homocysteine levels are well known to be caused by statin therapy, with the possible exception of gemfibrozil. Hyperhomocysteinemia is an independent risk factor for cardiovascular disease.³²⁵ Elevations range from 20% to 50%.³²⁶ The mechanism by which this occurs is not known.

White blood cell counts may drop in patients on fibric acid derivative medications. Using a chemoluminescence assay, one group of researchers determined that a single therapeutic dose of gemfibrozil strongly increases the production of reactive oxygen species in blood phagocytes. This may explain the leukopenia phenomenon.³²⁷

Other adverse effects common to the fibric acid derivatives include fatigue, dizziness, headache, nausea, vomiting, diarrhea, and constipation.

HMG-CoA reductase inhibitors, as their name implies, impede the enzyme involved in the rate-limiting step in cholesterol synthesis. Differences in the side chains of these otherwise similar molecules affects their lipophilicity. They are metabolized by CYP3A4, and primarily excreted in the bile. Total serum cholesterol and LDL cholesterol are both reduced. In some studies, but not in others, serum ubiquinone levels have been shown to decrease significantly.^{328,329} Ubiquinone, also known as coenzyme Q₁₀, is an antioxidant and membrane stabilizer necessary for mitochondrial respiration. Mevalonic acid

is a precursor for ubiquinone as well as for cholesterol.³³⁰ Treatment with an HMG-CoA reductase inhibitor would therefore theoretically inhibit the production of ubiquinone as well as cholesterol. Its deficiency has been proposed as a cause for the adverse effects of the statins.³³¹ However, muscle ubiquinone levels were actually elevated.³³² Another proposed mechanism for the adverse effects of the statins is the reduction in cholesterol, which is itself necessary for many biochemical functions.³³³

Myalgias, myopathy, and rhabdomyolysis, with the possibility of renal failure and hyperkalemia, are the most significant adverse effects. The risk for this occurring is greater if the patient is taking a fibric acid derivative or nicotinic acid, which can also have this effect. One medication in this class, cerivastatin, was withdrawn from the market due to concerns about a high incidence of rhabdomyolysis. However, the overall incidence of myopathy is only 1.2 per 10,000 patient-years.³³⁴ Elevations in liver function tests occur in a minority of patients. The incidence is approximately 2% to 3%, and may be dose dependent. Hepatotoxicity is extremely rare.³³⁵ Nervous system changes, including stocking-glove neuropathy, confusion, memory impairment, and headache, have been reported.³³⁶ The relative risk for definite cases of polyneuropathy has been estimated at 14.2 in a case control study. For patients on a statin for more than 2 years, the relative risk rises to 26.2.³³⁷ The cause of these effects has not been elucidated, although some *in vitro* research suggests that simvastatin is neurotoxic.³³⁸ Colitis has been associated with HMG-CoA reductase inhibitors in extremely rare cases. It is thought that up-regulation of nitric oxide synthase and cytokine production may be the cause, but further study is necessary to establish a causal link.³³⁹ In acute overdose, up to 6 g has been taken without adverse effect.³ No toxic overdoses have been reported in the literature.

Nicotinic acid therapy lowers the level of triglycerides, LDL and total cholesterol, and increases the HDL cholesterol level. The mechanism of action has not been completely elucidated. Proposed modes of action include inhibition of synthesis of apolipoprotein B-100,³⁴⁰ up-regulation of lipoprotein lipase activity,³⁴¹ and reduction of free fatty acid release.³⁴² Niacin is a component of coenzymes NAD and nicotinamide-adenine dinucleotide phosphate (NADP) which are essential for redox reactions in numerous tissues.³⁴³

Adverse effects include atrial arrhythmia, with an incidence of 4.7%, compared with 2.9% in a group receiving placebo.^{2,344} Glucose control becomes more difficult in diabetics.³⁴⁵ Niacin also causes flushing of the skin through vasodilation (niacin flush), especially when the patient is exposed to large initial doses, until plateau serum levels are reached.³⁴⁶ Nausea, vomiting, diarrhea, and peptic ulcer disease are fairly common. Pruritus can be disabling. Elevations of liver function tests, including some cases of fulminant hepatic necrosis, have been documented.³⁴⁷ Three preparations are currently available: immediate release (IR), extended release (ER), and sustained release (SR). Hepatotoxicity is more

common with the SR preparation, while flushing symptoms and GI distress are less frequent.³⁴⁸ ER preparations offer less flushing than the IR and fewer hepatic complications than the SR preparations.³⁴⁹ The differences in adverse effects among the preparations are a function of the drug metabolism. The IR preparation is primarily conjugated; the SR is mostly metabolized through the nicotinamide pathway; the ER is a balance between the two.³⁵⁰ The presentation of hepatotoxicity is one of hepatocellular death, and can even mimic hepatobiliary neoplasia.³⁵¹ Dose-related and reversible visual changes, such as decreased vision or paracentral scotoma, have been noted in a few cases. Cystoid macular edema can be seen on examination.^{352,353} In the SR formulation, niacin administration has been associated with a small decrease in platelet count and increase in prothrombin time.²

Acute overdose data are limited, but toxicity includes flushing, rash, pruritus, hepatotoxicity, and lactic and anion-gap acidoses.^{3,354,355}

Ezetimibe is a novel lipid-lowering agent known as a selective cholesterol absorption inhibitor. It impedes the absorption of dietary and biliary cholesterol across the brush border of the intestine.³⁵⁶ It appears to have no significant effect on the absorption of nutrients or vitamins. It is glucuronidated in the intestinal wall, and the parent and metabolite undergo enterohepatic recirculation.³⁵⁷ Varied adverse effects, such as fatigue, headache, sinusitis, diarrhea, viral infections, variations in taste, and elevations in transaminases have been reported in clinical trials. However, the frequency of these effects in the placebo group was almost identical.³⁵⁸ No data on acute overdose are available. The expected toxicity is low, based on the mechanism of action and metabolism.

Specific Agents and Their Mechanisms of Toxicity

Cholestyramine is a quaternary ammonium anion exchange resin with a high molecular weight. In case reports, it has been associated with platelet gigantism in a 9-year-old boy with hypercholesterolemia. The drug was given on three separate occasions, with recurrence of the finding each time.³⁵⁹

Colesevelam is a cross-linked hydrogel polymer bile acid sequestrant. It has been associated with asthenia and myalgias in small numbers of patients.² Incidence of adverse GI side effects appears lower. Serum levels of fat soluble vitamins were unaffected by colesevelam administration, and coadministration with a variety of other medications showed no significant impairment of absorption.³⁶⁰⁻³⁶²

Colestipol is a basic anion exchange resin, which is composed of amine groups. Occasional reports of chest pain and shortness of breath have been made by patients taking this medication.² Reversible elevations in liver function tests have been seen.³⁶³ Some patients reported a decrease in visual acuity, but ocular examination of 10 patients who had been taking colestipol for 1 year showed no changes.^{364,365}

Fenofibrate has been associated with one case report of allergic reaction characterized by asthemia, hyperthermia, and muscular pain. Laboratory abnormalities included pancytopenia and elevated creatine kinase. The patient survived.³⁶⁶

Treatment Principles

GENERAL PRINCIPLES

Activated charcoal will bind these agents if administered promptly. Either because of large volume of distribution or high protein binding, hemodialysis is not thought to be helpful in enhancing elimination. Laboratory studies should include a metabolic panel, liver and renal function tests, urinalysis, and creatine kinase or myoglobin to assess for rhabdomyolysis. Care should be supportive and tailored to the toxic manifestations.

BILE ACID SEQUESTRANTS

An agent should be given to prevent constipation. Psyllium has been studied and found to provide significant relief.³⁶⁷ Fat-soluble vitamins should be replenished. If hyperchloremic acidosis occurs, treatment should include intravenous sodium bicarbonate and replenishment of potassium, if it is low.²⁹¹

FIBRIC ACID DERIVATIVES

Treatment with folic acid and vitamins B₆ and B₁₂ significantly limit the hyperhomocysteinemia seen with fibrate therapy.^{325,326} Care should be taken to identify drug interactions as described above. Fibrin acid–statin combination therapy should be avoided if possible.

HMG-CoA REDUCTASE INHIBITORS

Most of these medications are extensively metabolized by CYP3A4. Xenobiotics that inhibit this liver enzyme should therefore not be used in patients on a statin.

NICOTINIC ACID

Administration of 325 mg of aspirin 1 hour prior to the dose of niacin may help lessen the degree of skin flushing. In cases of acute overdose, the same treatment may be given postingestion.

SELECTIVE CHOLESTEROL ABSORPTION INHIBITOR

Provide supportive care.

SECTION C

POISONING IN SPECIAL POPULATIONS

17 Management Principles of Overdose in Pregnancy

TIMOTHY B. ERICKSON, MD ■ KIRK CUMPSTON, DO ■ VALERIE A. DOBIESZ, MD

INTRODUCTION AND EPIDEMIOLOGY

The obstetric patient can suffer from various toxicities presenting as acute intentional drug overdose, recreational drug abuse, unintentional exposure from industrial or environmental toxins, and, finally, through iatrogenic causes. Suicide attempts during pregnancy frequently present as intentional drug overdoses, representing a more common means than self-mutilation, gunshot wounds, or jumping from high places.¹ Although an uncommon cause of maternal mortality as a whole (1% to 5%), suicide attempts and gestures can account for significant obstetric morbidity. According to one study, the incidence of attempted suicide for pregnant women ranged from 1% to 22%. Of women who actually committed suicide, 2% to 12% were pregnant.² The suicide rate was reported as 1 for every 88,000 to 400,000 live births before abortion became legalized, and is now felt to be much less common.¹ Suicidal gestures are typically impulsive, as a result of untimely pregnancies, interpersonal conflicts, or broken homes. In addition, pregnant women may take overdoses of an abortifacient with no intent of self-harm. Attempts are most common during the early stages of pregnancy and during the early third trimester, and half are by primigravid mothers. Personality disorders are often present, but true mental illness is infrequent, with neurotic depression being the most common psychiatric disorder diagnosed.¹

Unless routinely screened or tested, early stages of pregnancy can go unrecognized in the overdose patient.³ Pregnant women also have significant access to multiple medications. According to one study of prescription use in a Medicaid population, pregnant women received an average of 3.1 prescriptions, excluding vitamins.⁴ Another study of drug utilization found a median of 4.7 drugs taken by pregnant females, most commonly vitamins, iron preparations, analgesics, antipyretics, anti-inflammatory agents, antiemetics, antacids, and antibiotics.⁵

Illicit drug use is also reported to have an incidence from 10% to 25% among pregnant patients. The rate of herbals/alternative remedy use among pregnant women is unestablished. It is the opinion of some that substance abuse during pregnancy is the most frequently missed diagnosis in perinatal medicine.⁶

The obstetric patient risks toxic exposure from an unprecedented number of chemicals and drugs. The Food and Drug Administration has assigned a risk classification (A, B, C, D, X) for all drugs based on the level of potential risk to the fetus (Table 17-1). These classifications must be interpreted with caution. Category A simply means that controlled studies in women fail to demonstrate a risk to the fetus. Category B means either animal studies have or have not demon-

TABLE 17-1 FDA Fetal Risk Classification

CATEGORIES

- A Controlled studies in pregnant women fail to demonstrate a risk to the fetus in the first trimester with no evidence of risk in later trimesters. The possibility of fetal harm appears remote.
- B Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester and there is no evidence of a risk in later trimesters.
- C Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal effects or other) and only if the potential benefits justify the potential risk to the fetus.
- D There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the potential risk to the patient.
- X Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk.

strated a risk to the fetus, and there are no controlled studies in women. Category C means either adverse effects have been discovered in animals and there are no controlled studies in humans, or there are no studies in women or animals. A majority of pharmaceuticals fall into this classification. The “safety” of category C may be based more on the absence of data, rather than the absence of proven teratogenic effects. Category D states there is a risk for teratogenicity to the human fetus, but if the therapeutic benefits of the drug to the pregnant woman outweigh the risks for teratogenicity to the fetus, its use is acceptable. Category X clearly states these drugs are contraindicated in pregnancy due to demonstrated fetal abnormalities in humans.

The potential for teratogenicity is often a concern even in a one-time exposure to a drug. When 1400 acute overdoses in pregnant women were followed over 30 years, there was no increase in congenital abnormalities when compared with women who did not overdose. If the fetus is exposed at 18 to 60 days of gestation, it will either spontaneously abort or survive without abnormalities.⁷⁻¹⁰ Therefore, an acute insult by a toxin to the fetus will most likely result in demise of the fetus or survival without congenital malformations.

It is beyond the scope of this text to cover all poisonings and their teratogenicity. Instead, this chapter will focus on the more common toxins pregnant patients may be exposed to and those that have special considerations in the obstetric setting. Additionally, altered physiology, pharmacokinetics, and general management issues regarding poisoning in pregnancy will be discussed.

As with obstetric care in general, the same holds true for the poisoned patient: if you optimally treat the mother, you will also be treating the fetus. Conversely, if treatment is delayed or withheld over concern of inducing fetal harm, and the mother’s care is compromised, both maternal and fetal outcome can be jeopardized. Therefore, the well-being of the mother should be of foremost concern in the treatment of a toxic exposure in a pregnant patient.

RELEVANT ANATOMY, PHYSIOLOGY, AND PHARMACOLOGY OF PREGNANCY

There are many physical and physiologic changes that occur during pregnancy that alter the pharmacokinetics of drugs and therefore affect the maternal exposure and toxic response.^{11,12} These physiologic changes of pregnancy are summarized by organ system in Box 17-1.

Absorption

Gastrointestinal (GI) absorption is altered secondary to delayed gastric emptying, decreased GI motility, and prolonged transit time through the GI tract. During pregnancy, there is delayed but more complete GI absorption of drugs. Pulmonary changes may increase absorption of inhaled substances because of increased minute ventilation, increased tidal volume, and decreased residual lung volume. Dermal absorption may

be enhanced because of increased total surface area and increased blood flow to the skin.

Distribution

The apparent volume of distribution (Vd) of drugs may be increased because of increases in mean plasma volume, extracellular fluid volume, and body fat stores. This Vd is variable in pregnancy because these physiologic changes are dynamic throughout the gestational period. An increase in serum concentrations of many drugs has been documented. Decreases in plasma albumin, protein binding, increased binding competition, and decreased hepatic biotransformation may all increase free drug concentration. This increased unbound or free drug results in larger volumes of distribution as the unbound drug is free to move into tissues. Free fractions of drug may also account for increased clearance rates as it is available for metabolism or elimination.

Metabolism

Hepatic alterations during pregnancy may include hepatic blood flow, bile excretion, and enzyme induction. There appears to be no clinically significant change in hepatic blood flow or bile excretion. Enzyme induction can be variable. Overall hepatic elimination patterns are inconsistent and difficult to predict in the pregnant woman.

Renal Excretion

Increased renal blood flow and glomerular filtration may result in increased renal elimination. Drugs excreted by the kidney are more rapidly excreted during pregnancy.

Placental-Fetal Blood Flow

The maternal-fetal unit is complex in terms of drug disposition and pharmacokinetics.

Increased lipid solubility and low molecular weight promote the transplacental passage of specific compounds. Additionally, drugs that are highly ionized tend to be more protein bound, limiting their transport across the placenta. As a result, with certain drugs, the placenta can act as a barrier protecting the fetus from a toxic insult. Conversely, it may prevent the passage of a beneficial antidote in an overdose setting. For certain toxins (e.g., lead), the placenta seems to provide no barrier to its free transmission to the fetus.

TREATMENT PRINCIPLES

Supportive Measures

The general management principles for a poisoned pregnant patient are the same as for a nonpregnant patient, with the exception of concern for fetal well-being. As with all overdose patients, initial stabilization measures should be addressed regarding ventilatory and hemodynamic status. If the patient is hypotensive, as with

BOX 17-1 Physiologic Changes of Pregnancy by Organ System (Time of Detected Change)
Overall Physiologic Changes

- ↑ body mass 25% by term
- ↑ body water 7–8 L
- ↑ body fat 3–4 kg; 21%
- ↑ body temperature 0.5°C

Specific Organ Physiologic Changes
Renal

- ↓ Urine concentration (5 days)
- Ureteral dilation due to hormonal relaxation, mechanical compression
- ↑ Aldosterone secretion
- ↑ Antidiuretic hormone secretion
- ↑ Plasma volume 45%–50% with 70% increase in volume of extracellular fluid space
- ↑ Renal plasma flow 25%–85%
- ↓ Serum creatinine; blood urea nitrogen

Gastrointestinal

- ↑ Nausea and vomiting
- Relaxed cardiac sphincter
- ↑ Gastrointestinal reflux
- ↓ Gastric acidity 30%–50% (0–4 mo)
- ↓ Mucus secretion
- ↓ Gastric motility
- ↓ Small bowel motility
- ↑ Stomach emptying time 0–160%
- Hepatic metabolism ↑ or ↓

Neurologic

- ↓ Plasma cholinesterases 20%

Cardiovascular

- ↑ Cardiac output (6 wk)
- 35% by 10 wk
- 48% by 25 wk
- ↑ Heart rate 20% or 15 bpm
- ↑ Stroke volume 10%–32% or 17 mL
- ↓ Peripheral vascular resistance due to low resistance placental circulatory shunt
- ↑ Peripheral blood flow
- ↑ Perfusion of skin, mucosa, epidural space
- ↓ Oxygen extraction
- ↑ Oxygen consumption 15%–20%

Urogenital

- ↑ Weight of uterus
- 400% by 10 wk
- 2000% by term

Pulmonary

- ↑ Ventilatory response to CO₂
- ↑ Arterial Po₂ 10 mm Hg
- ↓ Arterial Pco₂ 10 mm Hg
- ↑ Minute ventilation 40%–50%
- ↑ Alveolar ventilation
- ↓ Vital capacity
- ↑ Respiratory rate 0–15%
- ↑ Tidal volume 40%
- ↓ Functional residual capacity 20%
- ↓ Expiratory reserve volume 20%
- ↓ Residual volume 20%
- ↓ Subjective dyspnea
- ↓ Airway resistance 36%
- Pulmonary blood flow

Blood

- ↑ Blood volume 35%–40%
- ↑ Plasma volume 50%
- ↑ Red blood cell volume 18%–20% 300–400 mL
- ↓ Hematocrit 15%
- ↓ Serum hemoglobin
- ↓ Serum iron
- ↑ White blood count 66%
- ↓ Total serum proteins 18% (3rd trimester)
- ↓ Serum albumin 14%–30%
- ↑ α₁ α₂ globulins 0–20%
- ↑ Serum fibrinogen 40%–200%
- ↑ Phospholipids
- ↑ Cholesterol
- ↑ Free fatty acids

↑, increase; ↓, decrease.

traumatic injury, the patient should be placed in the left lateral decubitus position with aggressive intravenous fluid administration. A thorough history and physical examination should be performed addressing the time of and reason for exposure, type and quantity of the toxin, stage of pregnancy, and symptomatology. The physical examination should include fetal monitoring if gestation is at an appropriate level of development. If the mother is experiencing altered mental status, assessment of her glucose status is indicated, and if hypoglycemic, 50% dextrose solution should be administered. In the setting of coma, the benefit of giving naloxone to a suspected opioid-intoxicated mother with respiratory compromise outweighs the potential risks of inducing narcotic withdrawal in mother and fetus.¹³

Decontamination Principles

Decontamination principles in the pregnant patient should be practiced in a similar fashion to those used in general overdosed patients, with a few caveats. The emetic agent syrup of ipecac is strongly discouraged from use in pregnancy, keeping with the most recent trends in the poison decontamination literature.¹⁴⁻¹⁷ Syrup of ipecac can induce protracted emesis, resulting in increased abdominal and thoracic pressure. This agent is absolutely contraindicated if the patient has altered mental status, seizures, and toxin-induced vomiting. Additionally, there are potential teratogenic concerns over the chronic use of ipecac.¹⁸ Although there are currently no studies addressing the utility and

safety of gastric lavage in the pregnant patient, it may be indicated following a very recent ingestion of a potentially life-threatening or fetal toxic drug.¹⁴ Additionally, since the pregnant patient has physiologic delayed gastric emptying and decreased gut motility, delayed lavage may be considered following massive ingestions. The literature is unclear as to the timing and indications for evacuation of drugs that slow gut motility (anticholinergics and opioids), or those toxins that are known to form concretions (salicylates and iron). Activated charcoal, the most efficacious and safe gastric decontamination modality, is not systemically absorbed from the GI tract and is considered safe (low risk of adverse side effects) in the pregnant patient, with no reports of fetal toxicity.

The usefulness of cathartics for GI decontamination has never been well documented; therefore, their addition to general decontamination measures in the pregnant patient is not mandatory. The general use of cathartic agents such as magnesium citrate or sorbitol in the pregnant patient should be used with extreme caution, particularly in later stages of pregnancy. Overzealous use of these agents may stimulate preterm labor, cause dehydration, or produce electrolyte imbalance.¹⁹ Whole bowel irrigation is an osmotically safe, high-molecular-weight, polyethylene glycol solution. This decontamination modality has been shown to be efficacious and safely administered in iron, cocaine packet, lead, and sustained-released product ingestions.²⁰ Although reported cases are anecdotal, it has been safely used in overdosed pregnant patients.^{21,22}

Multiple-dose activated charcoal is indicated for the same toxic overdoses as in the nonpregnant patient: theophylline, phenobarbital, carbamazepine, dapsone, and quinine. Enhanced elimination of these drugs occurs because their physical properties or enterohepatic circulation allow for gut dialysis of the drug from the circulatory system into the GI tract, where it is adsorbed to the charcoal.

Antidotes

Literature on the use of antidotes in the pregnant overdosed patient is limited largely to animal studies and isolated case reports or retrospective case series. There have been no adequate or well-controlled clinical trials. Thus, definitive conclusions regarding their use with obstetric patients are inconclusive.¹¹ In general, the use of antidote therapy in pregnancy is indicated if needed to reverse the toxic manifestations in the mother. Several cases in the literature have reported both maternal and fetal death when a potentially life-saving antidote was withheld because of fear of harming the fetus.^{23,24} As with general poison management, if you appropriately treat the mother, you will be treating the fetus (Table 17-2).

Enhanced Elimination

Literature regarding the use of hemodialysis and hemoperfusion in poisoned pregnant patients is limited. However, if indicated, their implementation is recom-

TABLE 17-2 Placental Permeability of Toxins and Antidotes

mended as there have been few adverse effects reported in women who required these treatments in the acute overdose setting.^{25,26} In addition, routine use of hemodialysis in pregnant patients with chronic renal failure is reported as relatively safe. However, premature labor and growth retardation have been described but have been attributed to the chronic disease state and not a consequence of dialysis.^{27,28}

Disposition

Specific disposition of the poisoned pregnant patient depends on the type of toxin, symptomatology, stage of pregnancy, and intent of exposure. Unstable overdosed patients should be closely monitored in an intensive care setting. There are reports of complete maternal and fetal recovery after maternal cardiac arrest justifying aggressive, prolonged resuscitation attempts.²⁹ Under certain circumstances, emergent delivery of a mature or full-term fetus may prove beneficial for the specific treatment of both mother and newborn. When the toxic mother is deemed stable, admission to a general obstetric, labor and delivery, or medical ward is appropriate with close fetal monitoring. If the toxic exposure is intentional, once medically stabilized, a psychiatric consultation should be obtained. If the patient is medically stable and not psychiatrically impaired, she may be discharged home with close outpatient prenatal care.

ABORTIFACIENTS

An abortifacient is any substance that is used to terminate a pregnancy (Box 17-2). Historically, lead and quinine have been used as abortifacients, but now over-the-counter preparations such as acetaminophen, aspirin, iron, and herbal preparations are more commonly used to induce abortion. The greatest dangers of abortifacients are the effect of the toxin on the mother and the potential teratogenic effect on the fetus. Most attempts to chemically abort a fetus are made in the first trimester. Acetaminophen and multivitamin ingestions

**BOX 17-2 ABORTIFACIENTS**

Angelica root (*Angelica archangelica*)
 Black cohosh (*Cimicifuga racemosa*)
 Blue cohosh (*Caulophyllum thalictroides*)
 Buckthorn bark (*Rhamnus cathartica, frangula, alnifolia*)
 Diethylcarbamazine
 Ergotamine
 Mandrake (*Podophyllum peltatum*)
 Mifepristone (approved in France as an abortifacient in 1988)
 Misoprostol
 Mistletoe (*Phoradendron falvescens, macrophyllum rubrum, serotinum, tomentosum; Viscum album*)
 Pennyroyal (*Mentha pulegium/Hedeoma pulegioides*)
 Poison hemlock (*Conium maculatum*)
 Quinine
 Rue (*Ruta graveolens*)
 Savun/juniper (*Juniperus sabina*)
 Sodium chloride 20% by transabdominal intra-amniotic injection
 Tansy (*Tanacetum/Chrysanthemum vulgare*)
 Windflower (*Anemone pulsatilla*)

are the most common exposures, with minor maternal toxicity reported in most cases.

As a result of the serious nature of an abortion attempt and the often nonspecific clinical manifestation of the ingestion, a high index of suspicion is required to discover if this has occurred in gravid patients. Therefore, every female overdose patient of childbearing age should have a pregnancy test performed. In addition, women who present with significant vaginal bleeding should be questioned about possible abortifacient use.^{30,31}

ACETAMINOPHEN

Acetaminophen or paracetamol is readily available to pregnant patients since numerous over-the-counter preparations such as cold remedies, antipyretics, and analgesics contain this compound. It has been cited as the drug most frequently taken in an acute overdose by pregnant patients.¹

In an acute overdose, sulfonation and glucuronidation metabolic pathways become saturated, causing an increased shift to the cytochrome P-450 pathway. As a result, glutathione stores are depleted, leading to hepatotoxicity via central lobular necrosis. Since acetaminophen crosses the placental barrier, the fetus is at risk for poisoning.^{32,33} Evidence of placental transfer has been documented in both animals³⁴ and humans.³³ The cytochrome P-450 system is present in the fetus by 14 weeks' gestation.³⁵ Early in fetal development, the cytochrome P-450 activity is only 10% of adult activity and develops in a linear fashion throughout gestation.¹⁸ As a result, in later stages of pregnancy, the fetus is more susceptible to toxicity since it is able to form the toxic metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone imine. This finding has been observed clinically in selected studies in which the fetal outcome was worse if the overdose occurred during the third trimester,

particularly if the mother demonstrated concomitant signs of hepatotoxicity.^{18,35-38}

In an acute ingestion, an acetaminophen level should be drawn and plotted on the Rumack-Matthew nomogram to assess the risk for hepatotoxicity. Peak serum levels and pharmacokinetics of acetaminophen in the pregnant patient are unchanged in standard doses but are as yet undetermined in the overdose setting.³⁹ In addition, baseline liver function tests and coagulation profiles should be drawn and followed in a serial manner as indicated.

If the time of ingestion is unknown, or is chronic in nature, a serum level is still recommended in order to document the exposure. Subsequent levels should be followed as hepatic damage will prolong the half-life of the drug. The mean half-life of acetaminophen during pregnancy in therapeutic doses has been shown to be 3.7 hours versus 3.1 hours in the nonpregnant patient.³⁹

In the acute acetaminophen overdose, general stabilization and decontamination measures should be implemented. If the acetaminophen level is hepatotoxic on the nomogram or if over 140 mg/kg is acutely ingested, administration of the antidote *N*-acetylcysteine is indicated. *N*-acetylcysteine (NAC) acts by replenishing hepatic glutathione stores and is most effective if given within 8 hours postingestion.⁴⁰

Whether NAC administration is protective or toxic to the fetus is unknown. However, Riggs and colleagues, in a study of 60 pregnant patients, demonstrated a significant positive correlation between the time to initial administration of NAC and pregnancy outcome. There was an increase in the incidence of spontaneous abortion or fetal demise when the treatment was delayed.³⁵ In a large series describing 48 cases, the researchers observed no birth defects associated with first-trimester NAC therapy.⁴¹

There has been controversy over the ability of NAC to cross the placenta in humans. One ovine study examining whether NAC crossed the placenta documented negligible transfer.⁴² Another study in a rodent model clearly demonstrated placental transfer of NAC.⁴³ NAC has been measured in fetal cord blood from human neonates born to mothers who received NAC as treatment for acetaminophen overdose. The level found in the cord blood was in the therapeutic range.⁴⁴ A possible explanation for the discrepancy between animal species could be the number of layers present in the different placentas. The human and rat placenta are composed of three layers while the ewe placenta is made up of five layers.

If deemed hepatotoxic by history, the nomogram, or liver function tests, the standard oral loading dose of 140 mg/kg followed by 70 mg/kg every 4 hours for 17 doses should be administered. Some sources advocate the recently approved intravenous form of NAC in pregnant patients since the oral form produces lower plasma levels, may induce vomiting, and undergoes maternal first-pass hepatic metabolism, lessening its availability to the fetus.^{15,18,42,44} The latest literature also supports treatment with NAC in chronic or delayed acetaminophen-induced hepatotoxicity because it may

rescue the hepatocytes by acting as a free radical scavenger or through other hepatoprotective mechanisms.^{45,46}

Any pregnant patient presenting with a potentially hepatotoxic ingestion of acetaminophen should be admitted for both maternal observation and fetal monitoring. In general, the maternal-fetal outcome is good following an acetaminophen overdose.^{35,41,47-49} Thus, acetaminophen poisoning in and of itself should not be an indication for termination of a pregnancy.^{50,51} In third-trimester acetaminophen toxicity, a greater risk for intratentorial hemorrhage, fetal demise, and maternal death has been reported when compared with other stages of pregnancy. For this reason, emergent delivery of the fetus by vaginal or cesarean section for extrauterine NAC therapy has been advocated in the third trimester in mothers suffering from fulminant hepatic failure secondary to acetaminophen overdose.¹⁸ If the mother demonstrates signs of hepatic failure or hepatic encephalopathy, she should be admitted to an intensive care unit. In this setting, consultation with a gastroenterologist or hepatologist is recommended for potential maternal liver transplantation.

IRON

As a result of their widely prescribed use in prenatal care, iron preparations are readily available to the obstetric patient and are documented as the second most common drug overdose during pregnancy.¹ Iron normally does not diffuse through the placenta but is actively transported against a gradient into the fetal circulation.^{18,51} Iron apparently crosses the placenta by receptor-mediated endocytosis. However, these receptors can become saturated, limiting the rate of transport. As a result, the placenta acts as a barrier to protect the fetus from iron toxicity. Animal studies have demonstrated that acutely elevated maternal serum iron concentrations are not accompanied by significant elevations in fetal serum iron levels.⁵¹ In general, the mother suffers more from the insult of iron than does the fetus. Fetal compromise probably results from maternal instability rather than the direct toxic effects of iron. Although elevated iron levels in the fetus may be detrimental, there are no known reports of anomalies or adverse outcomes in the neonate in cases of maternal toxicity if the mother survives the overdose.⁵² However, an increased risk for neonatal infection by bacteria from the *Yersinia* or *Listeria* species (both of which have fastidious iron requirements) has been reported.

In pregnancy, peak serum iron levels have been reported to appear within 2 to 4 hours after ingestion, similar to nonpregnant patients.⁵³ Historically, the laboratory hallmark of toxicity was when the serum iron levels exceeded the measured total iron-binding capacity (TIBC) of serum. However, these laboratory findings have been inconsistently observed in the poisoned pregnant patient. In one reported case, iron levels in a toxic third-trimester patient did not exceed the TIBC, nor did they correlate with the severity of the poisoning.^{15,54} As a result, TIBC measurement should not be used to assess iron toxicity in the pregnant patient.

Therapeutic interventions in iron toxicity begin with general decontamination principles. Specifically, gastric decontamination with lavage may be indicated in any potentially toxic overdose presenting with a very recent ingestion. Syrup of ipecac use is discouraged and absolutely contraindicated if the patient has already vomited or has altered mental status. Activated charcoal, although considered safe in the pregnant patient, is not efficacious in iron poisoning due to the drug's small ionic size.¹⁵ However, charcoal may be administered if multiple drugs were ingested or the history is unclear. Whole bowel irrigation may be indicated in the setting of an iron overdose, particularly if multiple radio-dense pills are noted on an abdominal flat plate radiograph²² (Fig. 17-1). The amount of radiation risk the fetus is exposed to from a single radiograph to document the presence of iron tablets is minimal compared with the potential toxicity of a maternal iron overdose. Alternatively, ultrasonography can be utilized to detect the presence of pill fragments in the GI tract while additionally assessing the status of the fetus.⁵⁵

Deferoxamine (DFO) is the specific chelating antidote for iron poisoning, capable of binding the free circulating iron. Unlike elemental iron, the DFO-iron complex can be excreted through the kidneys. Hypotension, metabolic acidosis, GI bleeding, shock, and an iron level of more than 500 $\mu\text{g}/\text{dL}$ are all signs of severe iron poisoning and are indications for DFO administration. Some believe that the threshold for treatment with DFO in the pregnant patient should be lowered to an iron level of 350 $\mu\text{g}/\text{dL}$ or with ingestions greater than 30 mg/kg of elemental iron.⁵² As with the

FIGURE 17-1 Radiograph demonstrating radiopaque iron tablets following an overdose in a third-trimester pregnant patient.

nonpregnant patient, the traditional dose of DFO is 15 mg/kg/hr intravenously, not to exceed a daily dose of 6 g.^{52,56} Although some sources have historically recommended chelation therapy until after the urine clears of its “vin rosé” color, more recent literature suggests continued therapy until the acidosis and symptoms resolve. At present, a specific end point of therapy remains controversial.

Chelation is critical in significant maternal iron toxicity and should always override theoretical concerns of fetal teratogenicity.^{23,57-59} Cases of maternal death have been reported when DFO was withheld over this concern.^{23,24} Two animal studies documented skeletal abnormalities during exposure to high-dose DFO during early gestation.^{56,57} However, limited case reports suggest that DFO can be administered to a pregnant patient suffering from iron toxicity without concern for producing adverse fetal effects.^{52,54,60} A more recent animal study in an ovine model demonstrated that maternal infusion of DFO resulted in a rapid decrease in maternal serum iron concentrations but had minimal effect on fetal serum iron levels, supporting the theory that DFO does not cross the placenta.⁵¹ To date, infants delivered after DFO therapy appear to have tolerated this antidote well.^{54,57} Therefore, pregnancy should not be considered a contraindication to the use of DFO if its administration is indicated in the mother.^{24,60-62}

The largest known study to address the effect on the outcome of pregnancy in iron overdose was a retrospective investigation involving 49 pregnant patients with mild to moderate iron overdoses.⁶³ Twenty-five of these patients (51%) were treated with DFO. Of these, 21 had normal outcomes, and the investigators found no evidence to suggest that DFO given for iron overdose caused toxicity in either the mother or the baby. Any malformations were not considered by the researchers to be directly related to the DFO administration since all were treated after their first trimester.

Any pregnant patient who presents following a serious acute iron ingestion should be aggressively treated, chelated with DFO, and admitted to the intensive care unit for both maternal and fetal monitoring. If the patient is medically stable and only has a potentially toxic ingestion, admission to a general medical or obstetric ward is appropriate with close observation of serial iron levels and possible chelation. If the mother receives chelation therapy with DFO, particularly in later stages of pregnancy, pediatric postpartum monitoring of the infant's serum iron levels is recommended.^{52,56,57} Finally, when the mother recovers from a significant iron ingestion, gastroenterology consultation is recommended to diagnose any subsequent GI scarring weeks after ingestion.

SALICYLATES

Salicylate usage is extremely common in pregnancy due to the ubiquitous nature of the drug in over-the-counter preparations. It has been reported in numerous studies as one of the most common drugs taken during pregnancy.^{2,5,64} Many of the mothers took these

medications both with and without medical supervision.⁶⁵ In therapeutic doses, salicylates appear to be safe in early pregnancy but should be avoided in the third trimester because they may affect neonatal coagulation and cause premature closure of the ductus arteriosus.¹¹

Maternally ingested salicylates freely cross the placenta and can be detected in fetal serum. The toxicity of salicylates stems from the parent compound and not its toxic metabolites, unlike acetaminophen.¹⁸ Particularly in later stages of pregnancy, the fetus appears to be at greater risk of toxicity than the mother for several reasons. Salicylate concentrations at a given maternal level are higher in the fetus.⁶⁶ There is a greater proportion of salicylates that enters the fetal central nervous system (CNS). The fetus has less buffering capacity for the ensuing acidosis. Finally, the fetus has reduced metabolism and excretion as compared with the mother.^{18,67} Several studies have documented the characteristic platelet abnormality caused by salicylates, namely, a loss of the secondary phase of platelet aggregation in babies born to mothers ingesting salicylates just prior to delivery.⁶⁸ There have been several reports of petechiae, purpura, cephalhematoma, and severe GI and intracranial bleeding in infants whose mothers had taken salicylates late in the third trimester.^{68,69} Salicylates also have been found to displace bilirubin from albumin-binding sites and may lead to hyperbilirubinemia in the neonatal period. One study of 144 infants chronically exposed to salicylates in utero found significantly lower birth weights and increased perinatal mortality but no significant difference in rate of congenital anomalies.⁷⁰ These infants were found to have elevated cord-blood salicylate levels, but they had no clinical evidence of bleeding or hypoglycemia. In comparison with children, neonatal hypoglycemia has not been commonly observed.^{66,71} Pregnant women who ingest salicylates on a frequent basis are reported to have longer gestational periods, prolonged labor, more hemorrhage, and a higher frequency of cesarean section.⁶⁶ All of these are believed to be attributed to the antiprostaglandin properties of salicylates.⁷¹

Treatment guidelines for salicylate poisoning in the pregnant mother are deficient in the literature. Current recommendations are to treat the mother in the same fashion as the nonpregnant patient. Initial stabilization, supportive care, fluid management, and electrolyte and glucose monitoring are essential. Gastric lavage and activated charcoal should be administered when indicated. Although unproven, since salicylates may form gastric concretions, late GI decontamination may prove beneficial. Additionally, because of delayed absorption, serial serum salicylate levels are essential until peak and declining levels have been documented. Enhanced elimination with sodium bicarbonate alkalization appears to be safe and efficacious in the pregnant patient, particularly if the mother is acidotic. As with any salicylate overdose, the effectiveness of alkalization is dependent on an adequate potassium supplementation. Hemodialysis is indicated in the toxic mother using the same inclusion criteria as in the nonpregnant patient. However, these treatment methods may not be as effective in the fetus as the mother. As a result, prompt

delivery of a mature fetus should be considered for its optimal treatment.¹⁸

The obstetric patient manifesting signs of severe salicylism (metabolic acidosis, altered mental status, pulmonary edema, or seizures) should be admitted to the intensive care unit with close maternal and fetal monitoring. In this setting, the nephrologist should be consulted for emergent hemodialysis. In the stable maternal patient with a potentially toxic ingestion, admission to an obstetric or medical ward is recommended for serial salicylate levels. If the overdose occurs in later stages of gestation, the pediatrician should be alerted regarding potential bleeding complications in the newborn.

COCAINE

Cocaine use is reported to be increasing in women of all socioeconomic levels in the United States. Cocaine abuse by women is most widespread during the childbearing years, and this age group has shown the greatest increase in recreational use over the past decade.^{11,72} In fact, 20% of all women between the ages of 26 and 34 have used cocaine at least once.⁷³ Additionally, cocaine use is on the increase among pregnant women. In one study, 17% of urban women enrolled in prenatal care were found to have used cocaine at least once during pregnancy.⁷⁴ It is estimated that as many as 1 fetus out of every 10 is exposed to cocaine via maternal use.⁷⁵ Smoking of crack cocaine has become the predominant route of exposure in pregnant women.⁷⁶ Unfortunately, an estimated 60% of pregnant women who use crack cocaine receive no prenatal care.⁷⁷ Many addicted women do not discover they are pregnant until well into gestation. Although some seek treatment, others assume that the fetus has already been harmed and therefore continue to abuse.⁷⁸ There also exists a false perception in the lay population that cocaine speeds up the labor and delivery process, when in fact it may actually intensify the awareness of pain and prolong delivery time.⁷⁹ Finally, one recent study showed that infants of 66 mothers who reported heavy cocaine use during pregnancy already had evidence of delays in auditory comprehension and language development by 1 year of age.⁸⁰

Symptoms and adverse effects of cocaine toxicity in the mother can include agitation, tachycardia, hyperthermia, hypertension, seizures, myocardial ischemia, cerebral vascular accidents, and intracranial bleeds resulting in significant morbidity and mortality.⁷⁶ Maternal concentrations of serum cholinesterases are diminished during pregnancy, resulting in more sustained cocaine blood levels than in nonpregnant users.⁶³ Fetal cholinesterase is relatively deficient compared with adult levels. Cocaine readily crosses the placental barrier, placing the fetus at risk following maternal use of cocaine by any route. Cocaine is biotransformed by the human placenta, presumably by cholinesterase activity. Therefore, the placenta may provide a moderate degree of protection from cocaine-induced morbidity by converting the cocaine into less active metabolites.⁷⁵ Cocaine administration in a pregnant ovine model

increased uterine vascular resistance, decreased uterine blood flow, increased fetal heart rate and arterial blood pressure, and decreased fetal oxygen content.⁸¹⁻⁸³ This animal study also showed that pregnancy in and of itself increased the cardiovascular toxicity to cocaine, thought to be mediated by progesterone.⁸³ Maternal exposure can cause preterm labor, placenta abruptio, decreased fetal growth, prematurity, urinary congenital anomalies, neonatal neurobehavioral deficits, and fetal death.⁸⁴⁻⁸⁶ However, assessing maternal and fetal risks of cocaine use is difficult because this patient population may abuse other illicit drugs, alcohol, and cigarettes. In addition, these studies are limited by inconsistent cocaine detection methods, confounding socioeconomic factors, and reporting bias.⁸⁵

Any pregnant patient with suspicion for cocaine toxicity should have a toxicology screen sent for confirmation. Urinary toxicology screens detect cocaine metabolites for only 48 to 72 hours; therefore, an accurate prenatal history may prove more reliable. However, in one urban-based study, 24% of pregnant women denied use of cocaine at the time of their interview but were identified as positive by urinary screens.⁷⁴ More recent studies have advocated the use of neonatal hair⁸⁷ or meconium tests to measure cumulative intrauterine exposure.⁸⁸

Numerous studies exist in the medical literature addressing the epidemiology, maternal-neonatal outcome, and detoxification efforts of the cocaine-abusing pregnant patient. However, specific treatment recommendations in the acutely intoxicated pregnant patient are lacking. As with other poisonings, optimal treatment of the mother will ultimately benefit the fetus. Agitation, hypertension, tachycardia, and myocardial ischemia experienced by the acutely cocaine-intoxicated mother can often be controlled by the administration of benzodiazepines alone. Clinical experience supports their use as a first-line treatment for cocaine-intoxicated patients. Benzodiazepines have effective anxiolytic properties; they also reduce blood pressure, heart rate, and myocardial oxygen demand in the face of myocardial ischemia.⁷³ Although controversial, according to one authority, no specific fetal malformations have been attributed to benzodiazepines administered during pregnancy.¹¹ However, late in gestation or soon after delivery, the newborn can have transient CNS and respiratory sedation. In this setting, the benefit of giving benzodiazepines to a pregnant patient with acute cocaine toxicity may outweigh the potential fetal risks. When presenting with chest pain, the mother should have a baseline electrocardiogram with continuous maternal and fetal monitoring. Cardiac ischemia may also require the administration of nitroglycerin.⁷³ Cocaine-induced seizures should be treated with intravenous benzodiazepines. If seizure activity is refractory, phenobarbital loading may be an alternative therapy.¹¹ Phenytoin should be avoided due to its well-documented fetal neurotoxicity.¹¹ With seizures occurring during the third trimester of pregnancy, the diagnosis of eclampsia should also be entertained and traditional doses of intravenous magnesium administered as indicated. One of the most critical treatment interventions is the rapid

cooling of the acutely hyperthermic patient, because temperature duration and level can have a negative effect on both maternal and fetal mortality.⁸⁹ Finally, in a patient presenting with ingestion of cocaine packets (i.e., body packers and stuffers), activated charcoal administration and whole bowel irrigation are recommended. In general, both modalities have been shown to be safe and efficacious in the pregnant patient.

Any pregnant patient presenting with severe cocaine toxicity should be monitored in the intensive care setting. If manifesting cardiotoxicity, a cardiologist should be consulted. If the mother and fetus survive the acute intoxication, prenatal care should be focused on drug rehabilitation and education. If the cocaine exposure occurred throughout the prenatal period, the pediatrician should be aware that the newborn may manifest signs of cocaine withdrawal.

HEROIN

Heroin overdose presents with the triad of respiratory depression, CNS depression, and miosis.⁹⁰ Neonates can experience lethargy at birth if there was recent maternal opioid use, or if large doses of an opioid agent were therapeutically administered to the mother during labor. The specific antidote naloxone can be administered to the pregnant patient with an opioid overdose in standard 2-mg doses.⁹¹ Concern over the possibility of fetal and neonatal withdrawal syndrome in heroin-dependent mothers given naloxone is outweighed by the benefit from reversing maternal and fetal hypoxia. The neonate is prone to withdrawal symptoms if the mother had chronic dependency during her later prenatal stages. If acute maternal withdrawal is a concern, smaller doses of naloxone can be administered to lessen the severity of maternal and fetal withdrawal. Withdrawal seizures have been documented in neonates born to opioid-dependent mothers.^{92,93}

CARBON MONOXIDE

Carbon monoxide (CO) is a leading cause of poison-induced deaths in the United States.⁹⁴ The clinical presentation of CO poisoning can be subtle in pregnant patients, resulting in misdiagnosis and significant maternal-fetal morbidity if not approached with a high index of suspicion. During pregnancy, endogenous CO levels increase about 20% above normal nonpregnant values secondary to increased fetal production and an increase in maternal red cell mass, and from the action of progesterone on hepatic microsomal enzymes.⁹⁵ In addition, at a given CO exposure, pregnant patients are more susceptible to toxicity because of her increased minute ventilation. Cigarette smoking also results in higher than normal maternal and fetal CO levels.

In the mother, CO possesses 240 times the binding affinity to hemoglobin than oxygen, resulting in cellular hypoxia. CO decreases the capacity of blood to transport oxygen. CO shifts the oxyhemoglobin saturation curve

to the left and alters the shape of the curve to a more hyperbolic form (Fig. 17-2).⁹⁵ Fetal carboxyhemoglobin (COHb) is associated with an exaggerated shift to the left, impairing the release of oxygen to the tissues. Under normal circumstances, the fetal COHb is approximately 10% to 15% greater than that of the mother.⁹⁵ With maternal exposure, the fetal COHb level rises more slowly than the maternal COHb level but will continue to rise for several hours after acute exposure until it reaches an equilibrium.⁹⁴ Fetal hemoglobin appears to falsely elevate COHb concentration.⁹⁶

CO readily crosses the placenta by simple diffusion, and fetal hemoglobin has a higher affinity for CO than adult hemoglobin.⁹⁷ As a result, unlike the majority of poisonings, the fetus is at greater risk for toxicity and mortality than the mother.⁹⁸ This has been documented in several case reports where the mother has survived a significant CO exposure but fetal demise ensued.^{94,99,100} As with the general population, maternal blood CO levels often do not correlate with the severity of symptoms. Maternal symptoms at the scene of exposure are a better predictor of fetal toxicity than CO levels.^{94,97,101} These symptoms may include altered mental status, neurologic deficits, seizures, and coma.

The result of fetal CO exposure can lead to different effects on the fetus depending on the stage at which it is exposed. In the embryonic stage, neurologic, skeletal, and cleft palate deformities can be seen. In the fetal stage, anoxic encephalopathy and growth restriction may result. In the third trimester, premature delivery, decreased immunity, right-sided cardiomegaly, sodium channel, and myelin defects have been reported.¹⁰²

Apart from removing the patient from the site of exposure, oxygen therapy is paramount. Oxygen acts by competing with the CO for hemoglobin binding sites.

FIGURE 17-2 Oxygen dissociation curve of maternal and fetal hemoglobin demonstrating effects of carbon monoxide exposure.

On room air, the half-life of CO is 5 to 6 hours; on 100% oxygen, the half-life is 90 minutes; and with hyperbaric oxygenation (HBO), the half-life falls to 20 minutes. Because the fetal hemoglobin binds CO much more readily than maternal hemoglobin, it is recommended that pregnant patients receive 100% oxygen five times longer than do normal adults to ensure adequate reduction of CO in the fetus.^{94,97,101} In the past, controversy existed in treating the pregnant patient with HBO because of adverse effects of high partial pressures of oxygen on the fetus observed in animal investigations.¹⁰³ However, several human studies, the majority of which are case reports,^{96,101,103,104} advocate the use of HBO in pregnant patients exposed to CO.^{15,103,105,106} Although no definitive guidelines have been established, it has been recommended that more liberal HBO treatment be initiated in pregnant patients because of the enhanced vulnerability of the fetus to CO, hypoxia, and permanent brain damage. Additional HBO therapy may also be needed if fetal signs of distress are demonstrated after initial HBO therapy. One source suggests that if cesarean delivery of the fetus is being considered, delivery of the fetus before HBO therapy can lead to a greater probability of fetal death. This opinion is not a result of clinical trials. Despite studies in animals linking HBO therapy with retinopathy, cardiovascular defects, and premature closure of the ductus arteriosus, human case reports and a prospective study have not shown morbidity or mortality in the mother or the fetus after HBO therapy.

The safety of HBO was documented in a prospective study where 44 pregnant patients with CO poisoning tolerated HBO without any fetal or obstetric morbidity.¹⁰⁷ Human clinical experience indicates that the short duration of high-dose oxygen attained during HBO therapy can be tolerated by the fetus in all stages of pregnancy and can reduce the risk for death or deformity to the mother and fetus.¹⁰³ Indications for HBO in pregnancy are indicated in (Box 17-2).

All pregnant patients with suspected CO poisoning should be removed from the source of exposure and transported to an emergency facility for evaluation, fetal monitoring, CO level measurement, and oxygen therapy. If symptoms or levels indicate the need for HBO, the patient should be transported to a facility with hyperbaric capabilities.¹⁰⁹ With exposures occurring in early stages of pregnancy, consultation should be obtained regarding potential fetal neurotoxicity. However, one case showed significant first-trimester CO exposure with subsequent normal outcome in the newborn.¹¹⁰ If the mother presents in late stage pregnancy and delivery is eminent, the pediatric intensivist should be advised of the need for aggressive oxygen delivery to the neonate.

LEAD

Lead poisoning is a major public health problem and a significant paradigm of maternal-fetal toxicity. It is well documented that the fetus is at risk from maternal lead exposure. In fact, lead has been used historically as an

BOX 17-2

INDICATIONS FOR HYPERBARIC OXYGEN THERAPY IN THE PREGNANT PATIENT

Metabolic acidosis
Fetal distress
Cardiotoxicity
Any neurologic findings in the mother

abortifacient.¹¹¹ Pregnant women can suffer from environmental¹¹² or occupational lead exposure.^{113,114}

Removal of lead from gasoline has caused a dramatic reduction in the average blood lead level of children in the United States, from 15 $\mu\text{g}/\text{dL}$ in 1978 to 2 $\mu\text{g}/\text{dL}$ in 2004. Despite this advancement, lead poisoning is still a major health concern for children. The mother also may unknowingly ingest lead from containers coated with lead glaze¹¹⁵ or herbal products,¹¹⁶ or may demonstrate increased pica behavior during the prenatal period.¹¹⁷⁻¹²⁰

There are limited case reports that describe lead poisoning in the pregnant patient. Most involve the mother exhibiting pica behavior.^{119,120} A study of lead exposure of pregnant women in their first trimester in New York City found that blood lead levels were inversely related to maternal age and length of time in the United States, and directly related to gestational age and pica behavior.¹²¹ Another study found that endogenous lead sources in bone continues to influence blood lead levels of immigrants in the United States during and after pregnancy. Due to hormonal changes during pregnancy, chronic maternal lead stores may be mobilized from the bone and transferred to the fetus.¹²²⁻¹²⁴

Placental transfer of lead has been demonstrated in the human fetus at 12 to 14 weeks' gestation along with increasing fetal tissue lead stores with advancing gestational age.¹¹² This heavy metal has been shown to induce spontaneous abortion, teratogenesis, and neurodevelopmental delays in the newborn.^{25,125} One study measured umbilical cord blood lead levels in over 5000 consecutive deliveries of over 20 weeks' gestation. Lead was found to be associated in a dose-related fashion with an increased risk for minor congenital anomalies such as hemangiomas, lymphangiomas, hydrocele, skin tags, and undescended testicles. This study controlled for other covariables and found no characteristic anatomic defect.¹²⁶ An epidemiologic study performed in Turkey found that umbilical cord lead levels that correlated significantly with maternal levels were approximately 70% of the latter.¹²⁷ A case report describing the radiographic findings seen in congenital lead poisoning described a dense cranial vault, lead lines in the distal ends of long bones, and delayed emergence of dentition. The investigators recommend using these findings as a screen for subtle presentations of congenital lead poisoning.¹²⁸

Although currently under debate, the highest acceptable lead level in young children is 10 $\mu\text{g}/\text{dL}$.¹²⁹ How-

ever, according to one investigation, the fetus appears to be adversely affected at low blood lead concentrations, cautioning against the application of this level toward the fetus.¹³⁰ The primary treatment of maternal and congenital lead poisoning is discovery and removal of the mother from the source of exposure.

Data on chelating obstetric patients with elevated blood lead levels are limited. As a result of their nonspecific action on metal binding and subsequent excretion, prior concern existed that chelating agents may be teratogenic or toxic to the fetus.⁹² According to one leading authority, maternal toxicity should be the primary reason for initiating lead chelation during pregnancy.¹⁸ Calcium ethylenediaminetetraacetic acid (EDTA) has been used with some success in the later stages of third-trimester pregnancy.^{114,117} In one case, a maternal blood level of 86 µg/dL was documented and the mother was given a 3-day chelation course of calcium EDTA. Eight days later, at delivery, her level had fallen to 26 µg/dL, but the cord blood level remained elevated at 79 µg/dL.¹¹⁷ Based on this and other studies, it is unlikely that EDTA crosses the placenta and would therefore be an ineffective fetal chelator.¹⁸ EDTA chelates calcium and zinc and is a known teratogenic agent when administered in pregnant rats. In two case reports, pregnant women received EDTA, 2 g/day intravenously and 75 mg/kg/day intravenously, respectively. Both mothers delivered a normal fetus post-therapy.¹³¹

Since intramuscular dimercaprol or bronchoalveolar lavage (BAL) penetrates into the central nervous system tissues, it theoretically should cross into fetal tissues, although little data exist describing its use in pregnant humans with lead poisoning. However, this drug may be of limited value in the pregnant patient due to its known adverse side effects such as hypertension, febrile reactions, tachycardia, and nephrotoxicity. BAL is known to cause skeletal abnormalities in mice at doses greater than 125 mg/kg/day when given subcutaneously. Newborn infants have required continued chelation therapy with calcium EDTA or dimercaprol weeks after delivery since lead levels have been noted to rebound.^{115,117} This demonstrates that a short intrauterine course of chelation therapy with these agents may not be adequate to fully treat congenital lead toxicity.

The newer oral lead chelator, dimercaptosuccinic acid (DMSA, succimer), is structurally related to BAL with less severe side effects and may be the treatment of choice for maternal lead toxicity.¹⁸ Animal studies have documented that DMSA is not toxic to fetal development.¹³² In one investigation, DMSA was administered to pregnant rodents. On day 20 of gestation, no gross external abnormalities, visceral/skeletal abnormalities, or teratogenicity at any dosage level was noted in the fetal rats.¹³³

DMSA has been shown to cause prenatal deaths, reduction in body weight, soft tissue abnormalities, and skeletal anomalies in mice when administered subcutaneously at dosages greater than 410 mg/kg/day. The no observed effect level of fetal-maternal toxicity after oral DMSA is less than 100 mg/kg/day, and no teratogenicity has been seen at levels greater than 1000 mg/kg/day.¹³⁴ Because DMSA has not been studied

in humans in controlled trials, it is category C in pregnancy. It has been used during pregnancy at the maximum human dose of 30 mg/kg/day without fetal abnormalities. Nevertheless, in one case report the blood lead level remained essentially unchanged from 44.0 µg/dL to 43.9 µg/dL after 18 days of chelation.¹³⁴

Penicillamine has been found to be a teratogen in both humans and animals. It has been implicated as the cause of congenital connective tissue and other abnormalities in neonates born from women chelated during pregnancy for cystinuria, rheumatoid arthritis, and Wilson's disease. The dosage used in pregnant women is 0.25 to 0.50 g/day. Because safer chelators such as DMSA are available, penicillamine should be avoided when chelating the pregnant patient.¹³⁵

It is unknown if chelation during pregnancy is effective at decreasing the fetal or maternal body lead burden, or improving the outcome of the fetus exposed to lead. The small amount of data on the risk of chelators to the fetus and the mother is provided in animal studies and human case reports.¹³⁶ In the literature, a few case reports have documented maternal chelation therapy for lead poisoning during pregnancy. The chelators used were EDTA, BAL, and DMSA. After birth, the blood lead levels were consistently higher in the neonate than the mother. None of these children were born with birth defects.¹²⁰ At this time, nutritional supplementation along with analysis of the risk versus benefit of a chelation agent appears to be a sound approach for treatment of gestational lead poisoning.

Nutritional supplementation is a safe adjunct for treatment of lead toxicity. Many lead-toxic patients are deficient in iron, zinc, and calcium. Women taking iron and folic acid have been found to have lower lead levels than matched cohorts.¹³⁶ Alcohol and tobacco use have been found to correlate with higher lead levels, so abstinence from their use has multiple benefits.

In a pregnant patient exhibiting signs of acute lead intoxication with encephalopathy, admission is recommended with institution of chelation therapy and close fetal monitoring. When the blood lead levels are elevated yet the mother is asymptomatic, removal from the source is essential with monitoring of serial levels and possible institution of outpatient chelation therapy. If maternal toxicity is documented at any time during the prenatal period, the newborn should be monitored for initial and rebounding lead levels.

ORGANOPHOSPHATES

Insecticide ingestions are uncommon in pregnancy per se, but these chemicals are widely available to an expectant mother with suicidal intentions. Pregnant women may also be occupationally or environmentally exposed to pesticides (organophosphate, carbamates, and pyrethrins). A study of an Ontario farm population¹³⁷ exposed to a variety of pesticides found that the timing of the exposure during gestation could predict the toxicity of a pesticide, including organophosphates. There is a significant risk for morbidity and mortality in

the mother and the fetus exposed to organophosphates, but the relationship between chronic exposure and risk for effects is still uncertain.

A case report documented the use of an organophosphate in conjunction with substance abuse. Because of "street knowledge" that lowering one's cholinesterase activity may prolong the euphoric effects of cocaine, a nearly full-term pregnant woman took an organophosphate with her cocaine and presented in both cholinergic and sympathomimetic crisis.¹³⁸ In general, acute organophosphate poisoning can present with maternal cholinergic crisis (diarrhea, urination, miosis, bradycardia, bronchosecretions, emesis, lacrimation, and salivation) along with nicotinic symptoms of central nervous system depression and muscle fasciculations.¹³⁹

Access of terrorists to chemical weapons opens the possibility of pregnant women being exposed to "nerve gas" agents like sarin, soman, tabun, and VX. All of these agents inhibit acetylcholinesterase, causing cholinergic signs of toxicity such as bronchospasm, bradycardia, bronchorrhoea, salivation, lacrimation, urinary and fecal incontinence, abdominal pain, and miosis. They may also cause nicotinic signs because of inhibition of the metabolism of acetylcholine at these receptors. Nicotinic symptoms include tachycardia, hypertension, muscle fasciculations, weakness, and mydriasis. In 1995 a Japanese terrorist group released sarin gas into a subway system. Five toxic pregnant women were treated with atropine only. No fetal malformations were reported 1 month and 1 year after the attack.^{140,141}

There exist little data accounting for the transplacental passage of specific organophosphate compounds.^{18,142} Fetal organophosphate levels have been detected on autopsy of fatalities from organophosphate poisoning.¹⁴⁰ In a case report describing both maternal and fetal fatalities from an organophosphate ingestion, the investigators documented fetal levels of the insecticide on autopsy, indicating that these agents cross the placental barrier.¹⁴³ Regarding cholinesterase enzyme levels, studies have noted 50% to 70% decreases in activity of red blood cell cholinesterase in normal neonatal plasma.^{144,145} This would intuitively make the fetus more susceptible to the effects of anticholinesterase insecticides.¹⁸

As with any organophosphate poisoning, the mother should be managed with gastric and skin decontamination when indicated, along with aggressive airway control to maintain adequate maternal and fetal oxygenation. There have been cases where organophosphate poisonings in second- and third-trimester pregnancy have been successfully treated with appropriate doses of atropine for the cholinergic effects and pralidoxime (2-PAM) for the nicotinic manifestations.¹⁴⁶ In two of the cases, both women delivered normal, full-term infants. In one investigation using a chick embryo model, supplemental use of oxime cholinesterase reactivators such as 2-PAM reduced the incidence and severity of developmental defects to specific organophosphate teratogens such as parathion and dicrotophos (bidrin). The protective effect noted was dose related.¹⁴⁷

Another case report described a woman at 35 weeks' gestation who presented with an unknown overdose in

cholinergic crisis.¹⁴⁸ Organophosphate toxicity was presumed and confirmed by markedly depressed serum and erythrocyte cholinesterase levels. Moderate doses of atropine in the mother demonstrated maternal improvement, but profound fetal tachycardia forced the treating physicians to stop the infusion, resulting in worsening of the mother's condition. An emergent cesarean section was performed, with the delivery of a hypotonic infant with low Apgar scores. The mother went on to require 8 days of assisted ventilation and 11 days of atropine infusion. The newborn required mechanical ventilation for 2 days and atropine therapy for 8 days. Neither patient received 2-PAM. Compared with the baby, it took longer for the mother's cholinesterase activity to recover to normal. Interestingly, the mother presented with more serious symptoms of poisoning requiring doses of atropine that proved toxic or intolerable to the fetus. However, it is difficult to ascribe the cause of the fetal distress based on this one case. Several factors may have contributed to both maternal and fetal distress, such as fetal hypoxia secondary to maternal respiratory distress or the direct transplacental fetal action of the atropine. The atropine serum level in the fetus is half the maternal level in 20 minutes in early pregnancy. In late pregnancy, fetal serum atropine reaches 93% of the maternal level in 5 minutes.¹⁴⁰

Any pregnant patient with an organophosphate poisoning manifesting acute cholinergic or nicotinic manifestations should be managed in an intensive care setting with close maternal-fetal monitoring and appropriate doses of atropine and 2-PAM.¹³⁹ Additionally, it may prove efficacious to deliver a mature or full-term fetus in distress for initiation of extrauterine therapy.¹⁸

CONCLUSION

Pregnant women have significant risk for toxic exposures and may present as a diagnostic and therapeutic dilemma. Unfortunately, few adequate or well-controlled studies are available in the medical literature regarding treatment guidelines for the poisoned obstetric patient. The most critical issue in managing the pregnant patient suffering from any toxin is the stabilization and treatment of the mother, since this will have a beneficial effect on maternal and fetal outcome. If questions arise concerning potential toxins and exposure to the pregnant patient, regional poison control centers and teratogen resources are available.

INTRODUCTION AND EPIDEMIOLOGY

In the past few decades, technology has advanced to such a degree that premature and critically ill neonates, who would have previously had no hope for survival, can be saved, often with remarkably good outcomes. With the advent of neonatal intensive care facilities, aggressive pharmacologic intervention has become the norm. Not surprisingly, the increasing use of potent pharmaceuticals in neonates has increased the likelihood of adverse drug reactions occurring in this age group. During the past 50 years, this has been demonstrated on several occasions. In 1956, an increased incidence of kernicterus and associated mortality were reported in premature infants receiving a sulfonamide antibiotic.¹ In 1959, high-dose chloramphenicol was implicated in the cardiovascular collapse of three neonates.² Similar outbreaks have been associated with the use of benzyl alcohol as a preservative in bacteriostatic saline³ and intravenous α -tocopherol^{4,5} in newborns. In addition, the escalating ubiquity of toxins in everyday life has also placed the neonate at risk for inadvertent exposure to environmental toxins.

This chapter reviews the current understanding of the pathophysiology of certain toxic reactions in the neonate and discusses those toxins that are most commonly responsible for neonatal toxic emergencies. It is not a comprehensive summary of all the toxic drug reactions reported in neonates. A more complete listing of neonatal drug toxicity is shown in Table 18-1.

Neonatal toxicology is not a simple extension of the established knowledge of clinical toxicology as it pertains to other patient groups. The physiology of the newborn is unique, and organs that play an important role in susceptibility to and moderation of toxic reactions, such as the liver and kidney, are immature in their function. As a result, the manner in which the neonate handles a toxic exposure is frequently quite different from the response of an older child or adult. A working knowledge of neonatal physiology and pharmacokinetic differences from older children and adults is essential for understanding neonatal drug toxicity.

RELEVANT ANATOMY, PHYSIOLOGY, AND PHARMACOLOGY

Neonatal Pharmacokinetics

Pharmacokinetics describes the various processes through which drugs are absorbed, distributed, metabolized, and/or excreted. Several of these processes are markedly different in the neonate than in the adult or even the older child (Table 18-2). In many cases, the peculiarity of

these processes in the neonate predisposes to the development of toxicity. This, combined with the fact that many infants in the neonatal intensive care unit suffer from diseases that may also alter the disposition of medications, places these infants at high risk for drug toxicity.⁶

ABSORPTION

Drug absorption differences in the neonate enhance neonates' susceptibility to toxicity. The neonate has a higher gastric pH due to decreased gastric acid secretion. Since gastrointestinal absorption of many drugs is pH dependent, the continuous changes that occur in gastric pH from birth through the second year of life complicate predictions of drug absorption.^{7,8} In addition, the more alkaline gastric environment of infants coupled with their lack of mature mucosal immunologic defenses allows growth of *Clostridium botulinum* and makes them susceptible to botulism (see Chapter 26). As compared with older patient groups, gastric emptying is slower in the neonate and infant. Thus, absorption of drugs may be delayed considerably, leading to a delay in the time to peak serum concentration and a decrease in peak serum concentration. If these factors are not taken into account when initially dosing medications in the neonate, supplemental dosing may be necessary with the consequent increase in potential toxicity.

Absorption of drugs administered by the intramuscular route is also altered in the neonate. Since the relative blood flow of the various muscle groups changes dramatically, particularly in the first 2 weeks of postnatal life, and muscle activity may also undergo alterations, intramuscular administration of medications may produce inconsistent and unreliable absorption in both premature and full-term infants.^{7,9}

Transdermal absorption of drugs may also lead to toxicity in the neonate. The comparatively reduced thickness of the stratum corneum, particularly in the premature infant, permits more effective absorption by the cutaneous route.^{8,9} Indeed, the literature contains several reports of toxicity in neonates resulting from percutaneous absorption (see Dermatologic Exposures below).¹⁰⁻¹³

DISTRIBUTION

Drug distribution varies considerably in the neonatal period from that which occurs in later life. The differences are due largely to age-related variations in protein binding, body fat, and total body water.^{8,9} Overall, protein binding of drugs is reduced and body fat and total body water are increased in the neonate. This may result in an increase in the apparent volume of distribution of drug and consequent increase in the elimination half-life of the drug. Furthermore, the

TABLE 18-1 Commonly Used Drugs and Their Potential Toxicity in Neonates

DRUG	TOXICITY
Amikacin	Nephrotoxicity, ototoxicity
Aminophylline	Tachycardia, abdominal distention, GI hemorrhage, jitteriness, or seizures
Amoxicillin	Nephrotoxicity, vitamin K depletion, distal renal tubular acidosis
Ampicillin	Rare; increased, transaminase; eosinophilia; irritability
Atropine sulfate	Tachycardia, urine retention, hyperthermia
Belladonna, tincture of	Hyperthermia, dry secretions, flushing
Bicarbonate	Transient hyperosmolarity, alkalosis, hypernatremia
Caffeine citrate	Tachycardia, seizures, abdominal distention
Calcium gluconate	Bradycardia, sloughing and calcification with IV infiltration; potentiates digitalis effect
Carbenicillin	Hypernatremia, sloughing with IV infiltration; transaminase elevation, platelet dysfunction
Cephalothin	Nephrotoxicity, neutropenia, false-positive Coombs' test results, allergic rash, poor passage through blood-brain barrier
Cefazolin	Neutropenia, thrombocytopenia, false-positive Coombs' test results, transient transaminase elevation
Chloral hydrate	Gastric irritation, paradoxical excitement
Chloramphenicol	May cause "gray baby syndrome" with toxic level; potentiates phenytoin effect, reversible bone marrow depression
Chlorothiazide	Hyperglycemia, hypokalemia, hyponatremia, alkalosis
Cholestyramine	Steatorrhea, GI dysfunction, malabsorption of fat-soluble vitamins; metabolic acidosis
Diazepam	Sodium benzoate diluent, competes with bilirubin for albumin binding sites; respiratory depression, hypotension
Diazoxide	Hypotension, hyperglycemia, sodium and water retention
Digoxin	Bradycardia, vomiting, arrhythmias, poor feeding
Epinephrine	Tachycardia, arrhythmia
Furosemide	Hypokalemia, hyponatremia, hypochloremia, alkalosis, dehydration, ototoxicity with aminoglycosides, renal calcifications; enhances nephrotoxicity of cephaloridine
Gentamicin	Nephrotoxicity, ototoxicity
Glucagon	Rebound hyperglycemia
Hydralazine HCl	May cause hypotension or tachycardia
Indomethacin	Transient renal and liver dysfunction, decreased platelet aggregation, hyponatremia, hypoglycemia
Isoproterenol	Marked inotropic effect, hypotension, arrhythmia
Kanamycin	Nephrotoxicity, ototoxicity
Lidocaine HCl	Hypotension, seizures, respiratory arrest, asystole
Magnesium sulfate	Hypotension, CNS depression
Mannitol	Rebound edema and/or circulatory overload
Moxalactam	Thrombocytopenia, platelet dysfunction, hypofibrinogenemia
Naloxone HCl	Tachycardia, hypertension, tremors, seizures
Nitroprusside	Hypotension, tachyphylaxis, thiocyanate toxicity with long-term use
Oxacillin	Penicillin sensitivity, nephrotoxicity
Paraldehyde	Cardiopulmonary depression, CNS depression, pulmonary edema
Phenobarbital	CNS depression with respiratory arrest with overdose
Phenytoin	Bone marrow depression, nystagmus
Prostigmine	Respiratory failure, cardiovascular collapse
Streptomycin sulfate	Nephrotoxicity, ototoxicity, cardiovascular collapse
Thorazine	Hypotension, hypothermia rare, liver disease and bone marrow depression
Ticarcillin	Bleeding problems, hypernatremia
Tobramycin sulfate	Nephrotoxicity, ototoxicity
Vancomycin	Nephrotoxicity, ototoxicity, histamine-like response

GI, gastrointestinal; IV, intravenous; CNS, central nervous system.

Modified from Harper RG, Jing JY: Handbook of Neonatology, 2nd ed. Chicago, Year Book Medical Publishers, 1987.

reduction in protein binding may result in an increased concentration of free (unbound, and therefore, active) drug with a potentially augmented pharmacologic response for a given drug concentration in the plasma. For a premature infant, the body fat may be much lower, complicating the pharmacokinetic estimates further.

METABOLISM

Neonates have a decreased capacity to metabolize drugs in the liver. The activity of the enzymes that catalyze the nonsynthetic, phase I metabolic functions of the liver

(e.g., cytochrome P-450–dependent mixed-function oxidases) is markedly lower than that of adults. Postnatally, these systems appear to mature at varying rates, and several may increase to levels greater than those observed in adults by a few months of age. The synthetic, phase II reactions are also thought to be reduced at birth and to evolve more slowly (often over several years) postnatally.

Renal clearance of drugs is also reduced in the neonate. Consequently, renally excreted drugs such as the aminoglycoside antibiotics will have significantly

**TABLE 18-2** Differences in Specific Pharmacokinetic Processes Between the Neonate and Adult

VARIABLE	NEONATE	ADULT
Absorption		
Stomach acidity	Premature: pH, 4.7; Full-term: pH, 2.3–3.6	pH, 1.4–2.0
Gastric emptying time	Prolonged; depends on maturity and gestational age	Adult levels at about 6 mo
Gastrointestinal motility	Irregular and unpredictable	
Percutaneous absorption	Increased in neonate	
Distribution		
Fat content	Premature: 3%–12%; Full-term: 12%	18%
Skeletal muscle content	25%	43%
Extracellular water	60%	20%
Total body water	75%	50%
Plasma protein binding	Decreased binding due to decreased plasma proteins	Adult levels at about 1 yr
Metabolism		
Microsomal tissue	26 mg/g of liver	35 mg/g of liver
NADPH-cytochrome c reductase	49% of adult activity	
Cytochrome P-450	25%–50% of adult activity	
Glucuronidation	Low at birth	Adult level at 3 yr
Excretion		
Glomerular filtration rate	Premature: 0.7–2 mL/min Full-term: 2–4 mL/min	130 mL/min
Tubular secretion	20%–30% of adult function	Adult level at 5–7 mo

From Warner A: Drug use in the neonate: interrelationships of pharmacokinetics, toxicity, and biochemical maturity. Clin Chem 1986;32:722.

prolonged elimination and greater potential for producing toxicity. Furthermore, the various renal functions (e.g., glomerular filtration, tubular secretion, etc.) appear to develop at different rates.^{9,14}

TREATMENT PRINCIPLES

Toxic Exposures through Breast Milk

Although breast milk offers a nearly ideal source of nutrients for the newborn, there is now considerable evidence that, under certain circumstances, human milk may also become a route of exposure to potentially toxic substances.¹⁵ Neubert has listed three circumstances by which “undesired chemicals” might be transferred to a neonate via the mother’s milk: (1) when the nursing mother uses particular medications, (2) when the nursing mother uses “recreational” drugs or drugs of abuse, and (3) when certain environmental toxins have been stored within maternal adipose tissue.¹⁶

There are a number of routes by which toxins might be transported into breast milk from maternal tissues. According to Berlin, the most probable of these are transcellular diffusion, intercellular diffusion, passive diffusion, and ionophore diffusion.¹⁷ Because diffusion represents the primary mechanism by which drugs enter breast milk, factors such as pH, pK_a , protein binding, and lipid solubility of the substance will play an important role in the final concentration of the drug or toxin in breast milk.

For most substances, the concentration of the drug or toxin in breast milk is considerably lower than in the

maternal serum¹⁸ (Table 18-3). However, some medications have been shown to be concentrated in breast milk above the concentration in maternal serum. These include iodine 131, propylthiouracil, erythromycin, and gentamicin.¹⁶

In addition to medications, several environmental substances have been found to accumulate in breast milk. Indeed, there has been increasing concern that for lipophilic toxins such as the organochlorine insecticides, polychlorinated biphenyls, and polybrominated biphenyls, milk may be the only significant path of elimination from the human body.¹⁷ Due to significant exposure variability and uncertainty about the the degree of toxicity produced by these substances, it has been suggested that breast milk should be tested prior to the initiation of breast-feeding for women exposed to these substances.¹⁹

Box 18-1 lists a number of maternal drug and environmental agent exposures that are thought to be contraindications to breast-feeding.

Toxic Effects of Maternal Drug Dependence

The maternal use and abuse of drugs during pregnancy may have lasting implications for the neonate. For instance, the fetal alcohol syndrome that results from maternal prenatal alcohol abuse has been well documented.²⁰ The fetal alcohol syndrome is characterized by growth retardation, mental retardation, and facial dysmorphogenesis (i.e., microcephaly, short palpebral fissures, epicanthal folds, maxillary hypoplasia, cleft palate, hypoplastic philtrum, and micrognathia). In addition to teratogenic effects, the maternal use of

*Although use of these agents during nursing should not result in excessive infant exposure (at usual doses), alternative therapeutic agents exist that do not share the same risk of serious adverse effects or case reports of adverse occurrences.

[†]May suppress lactation.

[‡]Use of these substances as drugs of abuse results in uncontrolled infant exposure because of unknown quality and purity of street drugs. Abstinence should be encouraged.

[§]Testing of milk indicated if mother is known to be exposed in excess to environmental chemicals for which infant sensitivity is not defined.

numerous drugs during pregnancy has been found to result in neonatal abstinence syndromes, and, occasionally, to long-term neurodevelopmental effects. Opiates, cocaine, barbiturates, benzodiazepines, phencyclidine, and selective serotonin reuptake inhibitors (SSRIs) have all been associated with neonatal withdrawal symptoms. Because of the large number of users, opiates and cocaine represent the largest contributors to neonatal toxicity resulting from in utero exposure.

OPIOIDS

An estimated 10,000 women who are addicted to opioids give birth each year.²¹ Of these neonates, as many as 90% may show evidence of opioid withdrawal. Methadone and heroin represent the most commonly implicated opiates, although chronic use of virtually all opioids risks perinatal addiction, including codeine-containing cough preparations.

The time of abstinence syndrome onset is related to the half-life of the narcotic, such that drugs with shorter elimination half-lives will have more rapid onset of symptoms. Withdrawal symptoms are commonly first noted between 24 and 72 hours after delivery in heroin-addicted neonates, dissipating within about 2 weeks. For methadone-addicted infants, withdrawal symptoms typically begin between 3 and 7 days after birth, but delay

of symptoms for as long as 32 days postpartum has been reported.²² Signs of neonatal opioid withdrawal include irritability, hypertonia, tremors, tachypnea, tachycardia, high-pitched cry, diarrhea, yawning, sneezing, nasal congestion, poor feeding, and occasionally low-grade fever and vomiting. In rare instances, seizures have been reported. Jitteriness and hypertonicity may persist for several months postpartum.

Early diagnosis of neonatal abstinence syndromes is important not only for determining the need for pharmacologic intervention, but also so that appropriate steps can be taken to institute proper monitoring and social services. Opiate-addicted neonates are more commonly born prematurely and are small for gestational age. Monitoring and supportive care must be directed at the provision of ample fluid and calories as well as at the correction of possible hypoglycemia, polycythemia, and other problems ensuing from prematurity.

Determination of the need for pharmacologic intervention in the neonate undergoing opiate withdrawal is frequently a difficult process. Many nurseries use scoring systems similar to those suggested by Kahn and colleagues²³ to dictate therapeutic interventions. In that system, newborns with grade I (symptoms that are mild but obviously abnormal) and grade II (the neonate is symptomatic only when disturbed) effects are treated nonpharmacologically with environmental interventions such as gentle handling, demand feeding, and swaddling. The newborn who is symptomatic even when undisturbed (grade III) is eligible for pharmacologic intervention. These infants typically manifest constant crying, significant diarrhea or tremors, and poor feeding.

There are presently several pharmacologic agents used for the management of opioid withdrawal in neonates.²⁴ The more common regimens are listed in Table 18-5. When pharmacologic intervention is required, medication is started at the smallest recommended dose and titrated upward as required to achieve the desired level of well-being in the neonate. Once the infant has been asymptomatic for 2 to 3 days, the drug dose is tapered, first by lowering the dose, and subsequently by increasing the dosing interval. This process is continued every 2 to 3 days until symptoms of withdrawal have been completely ameliorated. The total duration of treatment is dependent on a number of factors, including the specific opioid to which the mother is addicted, the severity of maternal addiction, and the medication used for treating withdrawal in the neonate.

COCAINE

Cocaine readily crosses the placenta and the blood-brain barrier. Its use prenatally has been associated with preterm labor and delivery, strokes, abruptio placentae, and poor fetal growth.²² Intrauterine cocaine exposure has been associated with several postnatal neurobehavioral abnormalities as measured by the Neonatal Behavioral Assessment Scale.²⁵ These abnormalities include altered interactive behavior in the cocaine-exposed neonate and an abnormal response to environmental stimuli.²⁶ Hypertonia and coarse tremor have been described

TABLE 18-4 Medications Used to Treat Neonatal Opiate Withdrawal

DRUG	DOSE	DOSING INTERVAL	COMMENTS
Paregoric	0.05–0.1 mL/kg per dose, PO	q4h	Constituents can cause local mucosal irritation and CNS stimulation
Tincture of opium, USP (diluted 25-fold)	0.05–0.1 mL/kg per dose, PO	q4th	No irritating CNS stimulating constituents
Phenobarbital	1–2 mg/kg per dose, PO or IM	q6h	Dose not control diarrhea, may result in poor suck
Chlorpromazine	0.4–0.7 mg/kg per dose, IM or PO	q6h	May cause extrapyramidal symptoms
Clonidine	0.5–1.0 µg/kg per dose, PO	q6h	Experience is limited in neonates

CNS, central nervous system; IM, intramuscularly; PO, orally.

postnatally.²⁷ In addition, these infants may manifest a syndrome composed of jitteriness, sleep difficulties, poor suck, and behavioral lability. There is disagreement as to the extent that these abnormal behaviors represent an abstinence syndrome versus a direct effect of cocaine.^{28–30} Lester and colleagues have suggested that many of the observed cocaine effects can be categorized into two neurobehavioral syndromes, excitable and depressed.³¹ They suggest that these two syndromes are the result of direct neurotoxic (excitable) effects of cocaine and indirect or consequent (depressed) effects, such as poor fetal growth. Evidence exists that cocaine metabolites, which can continue to be eliminated for more than a week in the neonate, may additionally contribute to the neonatal cocaine withdrawal syndrome.³² Fortunately, postnatal effects of intrauterine cocaine exposure infrequently require pharmacologic intervention.

Cocaine also readily passes into breast milk, and maternal use of cocaine in the breast-fed infant has been reported to result in signs and symptoms of cocaine intoxication, including tachycardia, hypertension, irritability, and tremulousness.²⁸

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

SSRIs are commonly used in the treatment of depression, panic disorder, and obsessive-compulsive disorder. While in utero exposure to SSRIs does not appear to increase the risk for major fetal malformations,^{33,34} exposure to these agents in the third trimester of pregnancy has been associated with a higher rate of neonatal complications, including a neonatal withdrawal syndrome.^{33,35–37}

Toxic Environmental Exposures in the Neonate

HEAVY METALS

Although acute neonatal exposure to heavy metals is rare, such exposures have been reported for both lead and mercury. A more common mechanism for heavy metal intoxication in the neonate is from prenatal placental transfer of the metal. This has been reported for a number of heavy metals including lead, mercury, and cadmium.^{38–40} Mercury and lead are also secreted into the breast milk of exposed mothers.¹⁵

Until recently, it was believed that the consequences of prenatal exposure to lead were primarily limited to an increased risk for minor anomalies.^{6,41} Cases have now been reported of serious neurodevelopmental injury postnatally in infants whose mothers had high blood lead levels during pregnancy (see Chapter 73).^{42,43} Furthermore, there is also significant evidence that low-level fetal lead exposure (maternal levels less than or equal to 25 µg/dL) may lead to mild developmental delay for at least the first few years of life.⁴⁴ Although this delay appears to be reversible for many by school age, it is not yet clear whether this is universally true. It is known that infants of mothers with the potential for high-level exposures are at greatest risk. These include pregnant women residing near industrial point sources of lead (e.g., smelters), women with lead-related hobbies (e.g., manufacture of jewelry, stained glass, fishing sinkers), and those involved in construction, particularly the rehabilitation of older, lead-based paint-containing dwellings. Chelation therapy for maternal lead poisoning during pregnancy is controversial partly because of the apparent teratogenic potential of such therapy.⁴⁵ Similarly, the blood lead level at which a newborn should be chelated is also undecided, although most authorities agree that chelation is appropriate for levels greater than 40 to 45 µg/dL, with some recommending chelation at even lower levels.^{46,47} Further discussion of the treatment of lead poisoning can be found in Chapter 73.

Mercury also readily crosses the placental barrier, particularly organic mercury compounds, such as methylmercury. There have been numerous reported cases of fetal toxicity secondary to maternal exposure to methylmercury (see Chapter 71).⁴⁸ It is believed that all forms of mercury are capable of producing fetal toxicity, but that methylmercury is the most toxic. Of the reported cases of fetal mercury poisoning, most have been the result of maternal occupational exposure to mercury compounds or substantial ingestion of contaminated fish.⁴⁹ Two epidemics of methylmercury poisoning due to consumption of seafood contaminated by industrial waste occurred in Japan (Minamata Bay in 1956 and Niigata in 1965).⁵⁰ Approximately 64 cases of infants with intrauterine methylmercury poisoning, 13 of which resulted in death, have been identified.⁵¹ Clinical manifestations of methylmercury poisoning in these

infants included mental retardation, ataxia, dysarthria, abnormalities of posture, chorea, and other nonspecific neurologic findings.⁵⁰

Postnatal exposure to toxic doses of mercury is much less common, although reports of acrodynia in neonates occurred as early as the 1920s.⁵² In 1981, several hundred infants in Argentina were poisoned when their commercially laundered diapers were contaminated with mercury.⁵³ Mercury thermometers in infant incubators have been shown to liberate unacceptably high levels of mercury vapor,^{54,55} although few, if any, cases of serious toxicity from this source have been reported. The topical application of merbromin (mercurochrome [no longer manufactured in the United States]) to omphaloceles in neonates has resulted in mercury toxicity,^{56,57} including several fatalities.⁵⁸⁻⁶¹ Toxic exposure to mercury from breast-feeding has also been well documented, being responsible for an epidemic of methylmercury poisoning in Iraq in 1971 and 1972. In this incident, grain contaminated with methylmercury was used to make bread, and resulted in more than 6500 hospitalizations and over 450 deaths due to mercury poisoning. Numerous infants developed severe toxicity from breast milk exposure alone.⁶² Toxic manifestations included mental retardation; impaired motor, sensory, and autonomic function; delayed motor development; and progressively worsening hyperreflexia in several infants.^{63,64} Other sources of mercury poisoning in infants have been reported^{65,66} but generally represent rare occurrences.

In 1999, an initiative to remove thimerosal, a mercury-containing preservative, from all childhood vaccines was launched following the recognition that the exposure to ethylmercury from a single vaccination could exceed the Environmental Protection Agency's guideline for maximum mercury exposure of 0.1 µg/kg/day.⁶⁷

Results of the Tagum studies conducted in the Philippines suggest that fetal trapping of mercury occurs during pregnancy⁶⁸ and that prenatal mercury exposure may result in lower scores on neurodevelopmental screening tests at 2 years of age.⁶⁹

Treatment of mercury poisoning depends on a number of factors, such as the duration of exposure and the form of mercury responsible for the poisoning (metallic, organic, inorganic). Management of mercury poisoning, particularly chelation therapy, is discussed in Chapter 71.

HALOGENATED HYDROCARBONS

Polychlorinated biphenyls (PCBs), dioxins, and furans have been postulated to produce a wide range of toxic effects (see Chapter 93). Due to their persistence in the environment and secretion in breast milk, these compounds have raised concerns as potential toxins to the neonate.⁷⁰⁻⁷³ To date, however, there have been few, if any, reports of acute toxicity due to these substances in newborns. Toxic effects from these compounds are likely to occur only after chronic exposure. Studies are currently being conducted to determine whether such toxicity does occur in infancy.⁷⁴⁻⁷⁶

Concern has also been expressed about the potential toxicity of chlorinated hydrocarbon pesticides to neonates.

These compounds, which include dichlorodiphenyl-trichloroethane (DDT), have well-described toxicities, persist indefinitely in human tissues, and are secreted in the milk of exposed mothers. As with PCBs and dioxin, it is clear that neonates are being exposed to chlorinated hydrocarbon pesticides.⁷⁷ The consequences of such exposures, however, are presently unknown. Carbamate pesticides have also been shown to be transmitted transplacentally⁷⁸ and could prove toxic to the fetus.

Iatrogenic Poisoning In the Neonate

DERMATOLOGIC EXPOSURES

The newborn infant may be exposed to a large number of chemicals and drugs through topical exposure.¹³ Low-molecular-weight substances are particularly well absorbed, and the skin of the premature infant is especially vulnerable.⁷⁹ Over the past 100 years, there have been abundant accounts of toxicity caused by transcutaneous absorption of drugs and chemicals in the neonate. Exposure through contamination of diapers has led to outbreaks of methemoglobinemia due to the aniline dyes previously used to mark new cloth diapers.^{80,81}

Hexachlorophene is a trichlorophenol antiseptic that was formerly used in nurseries to prevent *Staphylococcus* infections. Frequently, it was used for total-body bathing of newborns. However, after having been considered safe for nearly 20 years, hexachlorophene was implicated as the cause of central nervous system (CNS) depression, seizures, and death in several infants in France. A distinct histologic brain lesion was subsequently found to be present in both animal models of hexachlorophene poisoning and at autopsy in preterm infants regularly bathed in hexachlorophene solutions.¹² Iodine has also been shown to be absorbed systemically when repeatedly administered topically in neonates, with reports of associated goiter and hypothyroidism.⁸²

Alcohols are also frequently used topically in newborns, primarily as antiseptic agents. Hemorrhagic necrosis of the skin in preterm infants who have been lying in alcohol-soaked bedding is well described.¹² In addition, isopropyl alcohol has been reported to have systemic effects when used topically as part of umbilical cord care.⁸³ Similarly, methanol poisoning leading to metabolic acidosis and visual changes has been reported after the use of topical methanol.⁸⁴ A cluster of six infant deaths that occurred in Egypt in 1999 was attributed to prolonged exposure to methanol ("red alcohol") compresses at vaccination injection sites.⁸⁵ It is also believed that isopropyl alcohol can cause systemic toxicity when used for sponging for fever reduction, although toxicity is thought to occur from inhalation of the isopropyl vapor.⁸⁶ A case of fatal inhalational isopropyl alcohol poisoning in a newborn infant following the accidental placement of 70% isopropyl alcohol in the humidifier of a ventilator has also been described.⁸⁷

Adhesive tape remover pads, which often contain solvents such as methylchloroform, have been used in numerous intensive care nurseries. Although systemic toxicity has been rare, cases of toxic epidermal necrolysis associated with their use has occurred more frequently.⁸⁸

One study has shown that use of these pads produces detectable levels of methylchloroform in incubator air.⁸⁹

Topical corticosteroids have been associated with the development of Cushing's syndrome in the neonate.⁹⁰ In addition, there is concern that extended administration may lead to depression of the hypothalamic-pituitary-adrenal axis. Under such circumstances, withdrawal of the topical steroid should occur slowly, by gradually tapering the dosage.

Topical application of over-the-counter products containing camphor has resulted in seizures in a neonate⁹¹ and hepatotoxicity in a 2-month-old infant.⁹² While ingestion is the most common route of toxic exposure, toxicity via percutaneous absorption and inhalation has been described.⁹² Camphor, which is used in a multitude of cold remedies (e.g., Vicks VapoRub, Vicks VapoSteam, Procter & Gamble, Cincinnati, OH) and in topical anesthetic preparations (e.g., Camphophenique, Bayer Consumer Care, Morristown, NJ), may produce gastrointestinal and CNS toxicity as well as hepatotoxicity in overdose (see Chapter 99).⁹³

METHEMOGLOBINEMIA

Neonates are susceptible to the same methemoglobin-producing toxins as older children and adults (see Chapter 14). The risk of methemoglobinemia, however, is increased in neonates due to the immaturity of the methemoglobin reductase pathway in this population.⁹⁴ There is additional evidence that neonates may be more sensitive to the oxidizing effects of toxins than older age groups. The problem is further complicated by the high concentration of fetal hemoglobin in the neonate, which further restricts oxygen delivery to tissues. Toxin-induced methemoglobinemia has been reported after inhalational exposures to aniline vapors⁹⁵ and nitric oxide,^{94,96-98} as well as after administration of local anesthetic agents.⁹⁹⁻¹¹⁰ Since local anesthetics are known to cross the placenta, their use in the mother during labor and delivery may result in methemoglobinemia in the newborn infant.⁹⁹⁻¹⁰² Methemoglobinemia secondary to injection of local anesthetic agents in neonates has also been reported.¹⁰²⁻¹⁰⁵ Cases of methemoglobinemia related to the use of topical anesthetics, including EMLA (AstraZeneca LP, Wilmington, DE)^{94,106-109} and benzocaine,¹¹⁰ have also been described. EMLA cream is a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine. In its product insert, the manufacturer of EMLA recommends that it not be used in neonates younger than 37 weeks' gestational age, in infants younger than 12 months of age who are receiving treatment with methemoglobin-inducing agents, or in patients with congenital or idiopathic methemoglobinemia. In addition to methemoglobinemia, intoxication with local anesthetics may result in hypotonia, bradycardia, apnea, and seizures (see Chapter 63).⁶

Neonatal methemoglobinemia is relatively uncommon, but when it occurs its treatment must be undertaken with caution. It has been shown that the antidote, methylene blue, is toxic to the neonate at doses only slightly higher than those recommended to treat methemoglobinemia.¹¹¹

ALCOHOLS

In addition to the transcutaneous and inhalational exposures discussed above, ethyl alcohol exposures occasionally occur in infants by accidental or intentional means and may result in severe intoxication (see Chapter 31). Associated hypoglycemia may be particularly problematic in this age group. Similarly, accidental administration of methanol in infant formula has resulted in systemic toxicity.¹¹² In the early 1980s, administration of intravascular flush solutions containing the preservative benzyl alcohol was noted to produce metabolic acidosis, gasping respirations, CNS depression, seizures, hypotension, renal failure, and occasionally death. This "gasping-baby syndrome" was attributed to large blood concentrations of benzyl alcohol and its metabolite, benzoic acid. In the neonate, immature hepatic metabolism of benzoic acid leads to its bioaccumulation. Benzoic acid was also used as a preservative in a number of parenteral medications frequently administered in neonatal intensive care units.⁶ Subsequently, use of intravascular fluids containing benzyl alcohol was discontinued in this setting.

ANTIBIOTICS

Antimicrobials are among the most commonly used medications in neonates and are frequently associated with adverse effects in this age group. Perhaps the best described of the antibiotic-induced toxicities is that produced by chloramphenicol. During the first 2 weeks of life, hepatic glucuronidation of chloramphenicol is significantly less than in later life. Consequently, chloramphenicol may bioaccumulate and lead to the "gray baby syndrome." This syndrome is manifested by lethargy, abdominal distention, hypotension, hypoxemia, and acidosis.² Careful attention to dosing and monitoring of chloramphenicol drug levels will minimize this complication. When it occurs, exchange transfusion appears to be the treatment of choice.¹¹³

Several other antibiotics pose a potential threat to the newborn, particularly the premature infant. As noted earlier, sulfonamide therapy has been associated with an increased incidence of kernicterus¹ and tetracycline treatment with calcification disturbances. In addition, aminoglycoside antibiotics are associated with an augmented risk for nephrotoxicity and ototoxicity to the neonate. Although not unique to infants, neonates are at greater risk for these adverse events since they have impaired renal clearance of aminoglycosides, which results in a prolonged elimination half-life and increased risk for drug accumulation during treatment. Vancomycin administration has also been associated with adverse effects in neonates. Rash and shock occur most commonly,¹¹⁴ but cardiac arrest has also occurred in a neonate following rapid intravenous injection of vancomycin.¹¹⁵ As with chloramphenicol, it appears that mindful attention to dose considerations and drug levels will generally prevent these toxic effects.

ANTIFUNGALS

Amphotericin B is frequently used for the treatment of systemic fungal infections in infants. Adverse effects

associated with its use include nephrotoxicity, hepatotoxicity, leukopenia, thrombocytopenia, chills, and death.¹¹⁶ Cardiac toxicity, manifested as frequent premature ventricular contractions (PVCs), was reported in a 6-week-old full-term infant after receiving a cumulative dose of 8.5 mg/kg of amphotericin B. The PVCs ceased on discontinuation of therapy.¹¹⁷ Two premature infants, who received a 50-fold overdose of amphotericin B, suffered cardiopulmonary collapse and death.¹¹⁸ Another very-low-birth-weight infant, who received 50-fold overdosing for 3 days, survived.¹¹⁶ The only adverse effect noted in this neonate was hypokalemia.

ANTIRETROVIRALS

Administering zidovudine (ZDV) antepartum and intrapartum to pregnant women with HIV disease and to the neonate for the first 6 weeks of life reduced the risk for maternal-infant HIV transmission by approximately two thirds in the Pediatric AIDS Clinical Trials Group 076 study.¹¹⁹ The only toxic effect noted among infants in the ZDV group was a significantly higher incidence of anemia. Hemoglobin values of neonates in the ZDV group and the placebo group were similar by 12 weeks of age. While the HIV transmission rate in the Agence Nationale de Recherches sur le SIDA 075 study was only 1.6%, infants exposed to perinatal lamivudine-ZDV in this study had more adverse effects, including neutropenia, anemia, abnormal liver function tests, elevated lipase, and death in two children from neurologic complications related to mitochondrial dysfunction.¹²⁰ Additional cases of mitochondrial dysfunction associated with ZDV alone or in combination with lamivudine in the perinatal period have been reported.^{121,122} Severe lactic acidosis in an uninfected neonate who received prophylactic ZDV therapy has also been described.¹²³

METHYLXANTHINES

The methylxanthines (e.g., theophylline and caffeine) are commonly used for the treatment of apnea of prematurity. While theophylline is still extensively used, caffeine may emerge as the preferred pharmacologic agent due to its comparable therapeutic efficacy, longer half-life, fewer side effects, and wide therapeutic index.¹²⁴ Disadvantages of theophylline administration include fluctuating plasma concentrations that require frequent monitoring and a low therapeutic index for the drug.¹²⁴ In addition, theophylline is metabolized to caffeine by methylation, which may result in accumulation of caffeine in the neonate. Manifestations of methylxanthine toxicity generally include agitation, tachycardia, tachypnea, diuresis, hyponatremia, hypokalemia, metabolic acidosis, hyperglycemia, and seizures (see Chapter 65).¹²⁵ Other reported manifestations include jitteriness, vomiting, feeding intolerance, hypertonia, diaphoresis, opisthotonus, and tremors.^{124,126,127} Numerous cases of neonatal theophylline toxicity¹²⁸⁻¹³⁵ and caffeine toxicity^{125-127,136-138} have been reported in the literature. Management of infants with methylxanthine intoxication

should include fluid and electrolyte replacement as necessary and close monitoring of blood glucose. Dysrhythmias and seizures should be managed in the standard fashion. While most infants with methylxanthine toxicity are managed with supportive care alone, selected cases of severe intoxication may require more invasive therapy. Although charcoal hemoperfusion is the recommended therapy for older children and adults, it has not been tested in infants for this indication. Hemodialysis is an effective and safer alternative to hemoperfusion but may be technically difficult to implement due to the small size and blood volume of certain neonates. Exchange transfusion has been utilized in the setting of both caffeine toxicity¹²⁶ and theophylline intoxication.¹³² The successful treatment of severe theophylline toxicity in a preterm neonate with hemodialysis¹³⁴ and peritoneal dialysis¹³³ has also been described. In addition, three reports have suggested a role for the administration of activated charcoal.^{130,131,139}

SEDATIVE-HYPNOTICS

Chloral hydrate is a sedative-hypnotic agent that has been widely used in the past for conscious sedation of children and for maintenance sedation of ventilated infants. Use of this medication has decreased in recent years due to numerous reports of toxicity and death, including cases involving both preterm¹⁴⁰ and full-term infants.¹⁴¹⁻¹⁴³ Manifestations of toxicity in the neonate include CNS depression, paradoxical excitation, dysrhythmias, hypotension, hyperbilirubinemia, renal failure, and apnea (see Chapter 34).¹⁴⁴

Fentanyl is a potent opioid that is commonly used for sedation and analgesia in neonates. One well-described adverse effect is generalized muscle and/or chest wall rigidity. A number of cases of chest wall rigidity have been reported following low to moderate dose infusions of fentanyl in infants.¹⁴⁵⁻¹⁴⁷ Chest wall rigidity has also occurred in neonates following maternal fentanyl administration during cesarean section.^{148,149} Chest wall rigidity is treated with either an opiate antagonist (e.g., naloxone) or neuromuscular blockade.¹⁴⁷

OPHTHALMIC DROPS

Because of the risk for retinopathy of prematurity in low-birth-weight infants who have required oxygen therapy, frequent funduscopic examinations are often necessary. To facilitate these examinations, mydriatic and cycloplegic agents must be instilled into the infants' eyes. The potential toxicities of these agents include hypertension, tachycardia, ventricular dysrhythmias, and subarachnoid hemorrhage.¹⁵⁰ Premature infants are especially sensitive to these side effects, and a fatal outcome has been reported.¹⁵⁰ Consequently, current recommendations are to dilate the eyes of infants with a single drop of 0.5% cyclopentolate, one drop of 2.5% phenylephrine, and one drop of 1% tropicamide. Further dilution to 1% phenylephrine and 0.2% cyclopentolate is recommended for premature infants.

In addition to the commonly used mydriatic and cycloplegic agents, toxicity following topical adminis-

tration of an α_2 agonist for the treatment of glaucoma in infants has also been described.¹⁵¹ Cases of CNS depression ranging from lethargy to coma in infants following a single drop of brimonidine tartrate 0.2% ophthalmic solution have been reported.^{151,152} Infants receiving brimonidine have also been noted to develop hypotonia, hypothermia, apnea, bradycardia, and hypotension.¹⁵¹ The manufacturer currently recommends that this medication not be given to children younger than 2 years.

Therapy for Neonatal Poisonings

The priorities for management of the poisoned neonate are similar to those for patients of any age with a suspected poisoning: supportive care, decontamination, enhancement of elimination, and administration of any available antidote.¹⁴ Not surprisingly, little research has been conducted to examine the latter three issues in the newborn population. Supportive care is the first priority, and cardiorespiratory status of the infant should be considered particularly fragile in the face of a toxic insult. Once airway, breathing, and circulation have been stabilized, decontamination should be performed whenever acute exposures have occurred. The route of exposure determines the type of decontamination. Bathing may be the only decontamination required when topical exposure has occurred. After gastrointestinal exposure to toxins, decontamination must be carried out carefully due to the frailty of the neonate. Little data exist on the safety of syrup of ipecac in this age group; thus, its routine use cannot be advocated. Nasogastric tubes can be inserted in even the premature neonate with relative ease, although lavage should be conducted with normal saline rather than water, and in aliquots of approximately 15 to 25 mL to avoid fluid and electrolyte shifts. Furthermore, cathartics may represent a risk to the neonate's osmotic balance and therefore should be avoided. The use of activated charcoal is somewhat controversial in the newborn because of the vulnerability of the infant's gastrointestinal tract. Nevertheless, it has been used successfully in this age group.¹³⁹ Consequently, the use of activated charcoal may represent a viable treatment option under certain conditions.

Enhancement of the elimination of toxins in neonates is also relatively untested. The use of forced diuresis, a technique more commonly used in older children and adults, may represent a serious risk to even the healthy neonate, since renal function is immature. Furthermore, when the infant has pulmonary or cardiac disease, the risks of this technique are obvious, and thus it is not commonly used. Similarly, hemodialysis and hemoperfusion are technically complex in even full-term infants and can be carried out only in a few specialized centers. Exchange transfusion may be used for eliminating certain toxins in the neonate; it can be performed with relative ease. Its use is restricted to instances in which the toxin is primarily confined to the vascular space (low volume of distribution). This method of treatment is particularly attractive for severe cases of methemoglobinemia and methylxanthine toxicity.

CONCLUSION

The physiologic and pharmacokinetic characteristics of neonates make them particularly vulnerable to poisoning. Toxic exposures in the neonate may be particularly difficult to diagnose, particularly since the signs and symptoms are frequently similar to those that occur with other neonatal ailments, such as sepsis or cardiac disease. While the incidence of toxic exposures is presumably low, it is imperative that all of those caring for newborns maintain a high index of suspicion for poisoning.¹¹² Due to the possibility of accidental iatrogenic poisoning, a thorough review of administered medications should occur during the initial evaluation of all sick neonates. In instances when a toxic exposure is suspected, the clinical toxicologist must work in concert with the neonatologist or pediatrician, using his or her knowledge of the unique aspects of neonatal physiology to obtain a diagnosis and institute the appropriate therapy.

INTRODUCTION AND EPIDEMIOLOGY

The elderly are the fastest growing segment of the population of the United States. Twelve percent of the population is 65 years of age or older, and this figure is projected to almost double by the year 2040.¹ Older adults are a heterogeneous group, with marked differences in physiologic aging and disease states. With advancing age, pharmacodynamic and pharmacokinetic responses to drugs and toxins are altered, usually increasing susceptibility to toxicity.² Physiologic changes as well as concurrent diseases and medications have an impact on the ability of older adults to compensate for the physiologic stress of an overdose.

Of 2,438,644 human exposure cases reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System in 2004, only 115,232 (4.7%) cases occurred in persons 60 years of age and older.³ Fatalities occur at a disproportionately high rate, with 157 of the 1183 fatalities (13.3%) occurring in persons 60 years of age and older. Suicide and therapeutic error/unintentional misuse were responsible for 943 and 27 deaths, respectively. Drugs were the primary substance in 73% of deaths. Higher death rates have been reported from poisonings for men 70 years of age and older and for women 60 years of age and older than for younger people.⁴

Unintentional Poisoning

Poison centers report that the majority of potentially toxic exposures in older adults are unintentional.⁵⁻⁷ Of 237 older patients prospectively evaluated by a poison center, 66% were women; reasons were 83.1% unintentional, 14.9% suicide or attempted suicide, and 1.7% drug abuse.⁵ Older patients who require emergency department management are more likely to be admitted than are younger patients.^{5,7} The geriatric patient may be less able to cope with acute injury and, therefore, be less likely to improve rapidly while being evaluated and treated in the emergency department. Possible reasons include increased sensitivity to drugs, exaggerated or unusual responses to drugs, and impaired elimination of drugs resulting in prolonged symptomatology.

Adverse Drug Events

As a group, older adults consume more drugs than any other age segment of the population, taking on average 2 to 6 prescription drugs and 1 to 3.4 nonprescription drugs.⁸ Older adults account for 25% of total drug expenditures, which is projected to be 40% in 2030.⁹ A consequence of age and disease-related effects on drug action and disposition as well as polypharmacy is a high

incidence of adverse drug events (ADEs). Of 1523 ADEs during 1 year in ambulatory older adults, 578 (38.0%) were considered serious, life threatening, or fatal, and 244 of these were considered preventable.¹⁰ Most common preventable ADEs were electrolyte/renal, gastrointestinal, hemorrhagic, metabolic/endocrine, and neuropsychiatric. Most commonly implicated drug categories associated with preventable ADEs were cardiovascular drugs, diuretics, nonopioid analgesics, hypoglycemics, and anticoagulants. The severity of ADEs increases with age, and older patients are at higher risk for ADE-related admissions. ADEs are responsible for approximately 10% of hospital admissions in older patients.¹¹

Older adults are vulnerable to drug-drug interactions, with important risk factors including number of drugs prescribed and number of physicians treating the patient.¹² Serious interactions most frequently involve drugs commonly used in older adults that have narrow therapeutic indices such as digoxin, calcium channel blockers, antiarrhythmics, oral hypoglycemics, cyclic antidepressants, warfarin, salicylates, centrally acting analgesics, phenytoin, and theophylline. Risk increases when older patients take combinations of drugs that interact to cause additive hypotension, sedation, or anticholinergic effects.

Alcohol, drug misuse, and drug abuse are common, yet frequently underdiagnosed.^{13,14} Abuse of legal substances such as sedative-hypnotics, antipsychotics, antidepressants, antianxiety agents, stimulants, and analgesics is more common in older adults than abuse of illicit substances. The incidence of alcohol abuse is 2% to 10%. Psychosocial factors such as inability to deal with loss as well as perceived loss of independence or control of one's life contribute to drug and alcohol abuse.

Suicide

Depression is common among older persons, and suicide rates are higher for older adults than for other age groups.^{15,16} Possible explanations for the higher rate of completed suicides in older adults include greater intention to die, social isolation (which decreases chance of early discovery), use of more lethal means, and poorer recuperative powers (e.g., due to chronic disease or impaired drug elimination).¹⁷ Although firearms are most often used in completing suicides, overdose is common in attempting suicide.¹⁸ In women, drug overdose is responsible for suicides almost as frequently as firearms.¹⁹ Drugs commonly used in suicides in older patients include acetaminophen, benzodiazepines, antidepressants, and opiates.²⁰

Although suicide attempts by acute overdoses are easy to recognize, purposeful mixing of drugs or failure to

take life-sustaining drugs with the intention of ending one's life may be much less obvious. Underdetection of poisoning is an issue in determining the magnitude of the problem in the older patient. A study of the fatal overdose rates for cyclic antidepressants concluded that lower apparent fatality rates with age were most likely an artifact of underreporting of deaths in older patients. Deaths from poisoning cannot always be easily identified and may be attributed to natural causes in the elderly.²¹

RELEVANT ANATOMY, PHYSIOLOGY, AND PHARMACOLOGY

Table 19-1 summarizes age-related physiologic changes that alter the pharmacodynamics and pharmacokinetics of drugs and toxins.¹¹ These factors, coupled with pre-existing diseases and poor nutritional status, can increase the likelihood of toxicity, alter toxic manifestations and time course, and affect the geriatric patient's ability to cope with a toxic exposure.

Physiologic and Pharmacodynamic Features

Although deterioration of physiologic functions of all organs occurs with age, there is wide interindividual variability in the extent. Older adults experience changes in neurologic, cardiovascular, pulmonary, hepatic, renal, immunologic, and endocrine function.¹¹ Older persons have a reduced physiologic reserve, increasing the possibility of decompensation under stress. Older patients are less able to regulate body temperature, blood pH, blood glucose, blood pressure, heart rate, and oxygen consumption. Age-related changes in receptor density and sensitivity have been documented for drugs (e.g., opioids, benzodiazepines), hormones (e.g., androgens, estrogens, gonadotropin, thyroid), and neurotransmitters (e.g., cholinergic, dopaminergic, β -adrenergic, serotonergic receptors, γ -aminobutyric acid [GABA]).^{11,22,23}

Geriatric patients are more sensitive to centrally acting drugs such as benzodiazepines, β blockers, central

TABLE 19-1 Age-related Physiologic Changes

SYSTEM	AGE-RELATED CHANGE	EXAMPLES OF DRUG-RELATED EFFECTS
Neurologic	Reduced brain weight Loss of neurons Increased conduction time Decreased cerebral blood flow Altered permeability of blood-brain barrier	Enhanced sensitivity to drugs Decreased coordination and prolonged reaction time leading to increased risk of falls
Cardiovascular	Hypertrophy Decreased cardiac output Prolonged contraction Decreased resting heart rate Increased systolic blood pressure Increased vessel thickness Increased total vascular resistance Decreased baroreceptor sensitivity	Decreased response to stress, including overdose Decreased perfusion of organs Increased symptomatic orthostasis
Liver	Decreased mass Decreased blood flow Decreased number of hepatocytes Reduced phase I drug metabolism	Increased bioavailability of drugs with first pass metabolism Altered drug metabolism (usually diminished)
GI tract	Decreased gastric acid secretion Decreased intestinal epithelium surface Decreased splanchnic blood flow Decreased gut motility	Minimal effects on drug absorption
Kidneys	Decreased mass Decreased blood flow Decreased glomerular filtration rate Decreased creatinine clearance Decreased tubular secretion	Decreased drug excretion
Body composition	Decreased total body water Decreased lean body mass Increased adipose tissue Decreased plasma albumin	Decreased volume of distribution and increased plasma concentration of hydrophilic drugs Decreased clearance of lipophilic basic drugs
Endocrine	Increased α_1 -acid glycoprotein Decreased estrogens Impaired insulin release Decreased number of insulin receptors Decreased thyroid hormone Decreased response of hypothalamic-pituitary axis to glucocorticoids	Increased susceptibility to drug-induced hypoglycemia Increased risk of drug-induced hypothermia Increased sensitivity to drug effects (e.g., digoxin)
Receptors	Altered density and/or sensitivity of drug, hormone, and neurotransmitter receptors	Altered drug response (usually increased sensitivity to drugs)

α -agonists, cyclic antidepressants, barbiturates, and opiates than are younger adults.^{22,24} Altered thermoregulation can be exacerbated by phenothiazines. Postural hypotension is more likely in older patients taking nitroglycerin, phenothiazines, diuretics, nifedipine, methyldopa, and prazosin because of diminished baroreceptor sensitivity and responsiveness.²² As a result of reduced postural stability, older adults are more prone to falls and fractures, especially when taking central nervous system (CNS) active drugs.

Geriatric patients are vulnerable to peptic ulcer disease and congestive heart failure associated with nonsteroidal anti-inflammatory drug (NSAID) therapy.^{25,26} Salicylates can exacerbate gastritis, resulting in gastrointestinal (GI) bleeding. Older patients with alcoholism, preexisting liver disease, or poor nutritional status are at risk for chronic acetaminophen toxicity. Preexisting alteration in gastrointestinal motility predisposes elderly patients to constipation with therapeutic use of opioids and drugs with anticholinergic properties.

Interplay between organs with diminished function is evident in older persons and may affect drug pharmacokinetics or response. For example, the responsiveness of the cardiovascular system decreases with age. Changes in cardiac output, contractility, total vascular resistance, heart rate, and blood pressure may lead to decreased perfusion of the kidneys and liver, which in turn decreases drug metabolism and excretion. Delivery of drugs to other tissues, such as the CNS, may be reduced. Alternatively, drug-induced changes in blood flow may have adverse consequences in an older person because perfusion of vital organs already is diminished.

Pharmacokinetics

ABSORPTION

Although aging is associated with altered physiology and function of the GI tract, drug absorption is generally unchanged.^{11,22} Some drugs (e.g., antihistamines, cyclic antidepressants, opioids) may slow drug absorption by inhibiting GI motility. Reduced first pass metabolism in older adults may increase bioavailability of drugs such as propranolol, verapamil, nifedipine, and nefazodone.¹¹

DISTRIBUTION

With aging, intracellular and extracellular water and lean body mass decrease while adipose tissue increases.²² The increased ratio of fat to lean body mass results in reduced volumes of distribution and increased plasma concentrations for hydrophilic drugs and the reverse for lipophilic drugs. Examples of drugs with reduced volume of distribution in older adults include cimetidine, acebutolol, digoxin, levodopa, lithium, and morphine.¹¹ Reduced plasma protein binding associated with a decline in plasma albumin may be important for drugs with low volumes of distribution such as oral anticoagulants and sulfonyleureas. α_1 -Acid glycoprotein, which binds to lipophilic basic drugs such as lidocaine, propranolol, imipramine, and morphine, increases with age, which decreases drug clearance.

METABOLISM

With age, changes in liver mass, blood flow, and hepatocytes alter phase I metabolism (oxidation and reduction) while having little effect on phase II metabolism (conjugation).^{11,27} Despite declines in hepatic function, drug metabolism is not significantly diminished, possibly because interindividual variation in metabolism exceeds the effect of age.^{11,24}

RENAL EXCRETION

Decrease in drug elimination due to decreased renal function is the most important pharmacokinetic change with age. Serum creatinine does not predictably increase with reduced creatinine clearance, owing to diminished muscle mass, so it is an unreliable guide to renal excretory capacity. Chronic therapeutic intoxications resulting from decreased renal clearance have been reported with drugs such as lithium, digoxin, and salicylates. Impaired renal function may also prolong the course of an overdose for drugs primarily excreted by the kidneys.

High-risk Drugs

Box 19-1 lists drugs with high risk of toxicity as a result of high prevalence of use in older adults and low therapeutic index. Additional detail on drugs of particular concern follows.

SALICYLATES

Older adults have a higher mortality rate following acute salicylate overdoses.²⁸ Patients with chronic salicylate

BOX 19-1

DRUGS WITH HIGH RISK OF TOXICITY IN THE GERIATRIC PATIENT

Analgesic Acetaminophen NSAIDs Opioids Salicylates	Anticholinergic Antihistamines Cyclic antidepressants Neuroleptics
Anticoagulant Warfarin	
Cardiovascular Antiarrhythmics β -Adrenergic blockers Calcium channel blockers Digoxin	Oral Hypoglycemic Metformin Oral sulfonyleureas
Psychotherapeutic Cyclic antidepressants Lithium Neuroleptics (e.g., phenothiazines) Sedative-hypnotics (e.g., benzodiazepines)	
Theophylline	

intoxications are older, have associated medical problems, and experience more serious symptomatology, especially CNS effects and pulmonary edema.^{29,30} Factors that predispose older patients to salicylate intoxication include impaired renal function and dehydration. Salicylate poisoning can mimic other illnesses, such as diabetic ketoacidosis, cerebrovascular accidents, cardiopulmonary disease, encephalopathy, and alcohol withdrawal, and should be considered whenever an older patient presents with recent deterioration in activities of daily living with no known cause, with delirium or dementia, or with unexplained acid–base disorders.^{29,30}

ANTICHOLINERGICS

Diminished cholinergic transmission may increase sensitivity of geriatric patients to drugs having anticholinergic effects (e.g., antihistamines, cyclic antidepressants, phenothiazines).³¹ Polypharmacy with more than one drug with anticholinergic properties is contributory. These drugs may worsen medical conditions such as angina, constipation, glaucoma, and urinary dysfunction.³¹ Control of bladder function is lessened with advancing age and may be further reduced by anticholinergic drugs with sedating properties.³¹ Older patients are more susceptible to anticholinergic-induced cognitive impairment, including disorientation, confusion, delirium, memory impairment, and obtundation.³² Pupillary dilatation and inability to accommodate may increase the risk of falls.

PSYCHOTHERAPEUTIC DRUGS

Plasma concentrations of *cyclic antidepressants* and long-acting *benzodiazepines* (e.g., diazepam, flurazepam, chlordiazepoxide) are higher because of reduced hepatic clearance with aging.^{33,34} ADEs include confusion, delirium, memory impairment, daytime sedation, and ataxia as well as increased risk for falls.^{32,35} Older adults with preexisting ischemic heart disease or conduction disturbances may be at greater risk for myocardial infarction, cerebrovascular accident, or congestive heart failure (CHF) following a cyclic antidepressant overdose. *Lithium's* volume of distribution and renal clearance are reduced with age.³⁶ Other drugs (e.g., thiazide, angiotensin-converting enzyme [ACE] inhibitors, NSAIDs) and medical conditions (e.g., CHF, renal failure) can also decrease lithium clearance and increase the risk of toxicity in the geriatric patient.

CARDIOVASCULAR DRUGS

Older adults are more likely to experience digoxin toxicity because of high prevalence of use, decreased renal function, lower volume of distribution, increased number of comorbid conditions and concurrent interacting medications, and more frequent occurrence of electrolyte abnormalities (usually related to diuretic therapy).³⁷ *Calcium channel blockers* and *β blockers* are available at high doses as extended-release products and so only a few extra tablets can cause prolonged toxicity. For some drugs, higher blood concentrations result from either increased bioavailability (e.g., propranolol, verapamil, nifedipine) or decreased clearance (e.g.,

verapamil, nifedipine). Older patients with nodal disease may be at increased risk for bradycardia with therapeutic doses. Older adults are more sensitive to confusion and cognitive impairment associated with β blockers as well as bronchospasm in those with chronic obstructive pulmonary disease (COPD). Hypotension is a potential adverse effect in older patients taking a calcium channel blocker or β blocker while concurrently receiving a drug that lowers blood pressure (e.g., cyclic antidepressant, phenothiazine, nitrate, ACE inhibitor).¹²

ORAL HYPOGLYCEMICS

Oral sulfonylureas, including acetohexamide, tolbutamide, glipizide, and glyburide, can cause hypoglycemia from therapeutic use with inadequate food intake or following an overdose. Risk of hypoglycemia is increased in patients with liver or renal impairment; poor nutrition and living alone compound the potential for severe hypoglycemic episodes in older patients. Prolonged hypoglycemia after small doses of glyburide have been reported in older adults.^{38,39} The risk of lactic acidosis from metformin increases with impaired renal function, advancing age, or concomitant use of drugs that affect creatinine clearance or renal tubular secretion of metformin.

TREATMENT PRINCIPLES

Patient Evaluation

History includes information regarding the toxin, patient's condition, and circumstances of the exposure as well as past medical history, including preexisting medical conditions and medications. For older patients with cognitive impairment querying family members or caregivers is necessary.

Older patients treated for toxic exposures in the emergency department are more likely to be admitted.⁵ Because of greater susceptibility to toxicity, aggressive initial treatment of acute overdose or chronic intoxication may be required. Recognition of poisoning may be problematic because of atypical manifestations of toxic ingestions in older adults, further compounded by the fact that many diseases present with similar features. Toxicologic syndromes must be diagnosed with caution in the geriatric patient, because normal aging, chronic disease, and polypharmacy may obscure expected findings and lead to misdiagnosis. Toxicity may occur at blood concentrations considered therapeutic in younger adults, further confusing the diagnosis.

Treatment

The principles of management in older patients are similar to those for younger ones (see Chapter 2). Treatment of the ingestion should not exacerbate concomitant disease. Preexisting medical conditions may alter the older patient's response to the overdose and can necessitate additional treatment considerations. Another potential factor complicating management is

**TABLE 19-2** Considerations in Managing Poisoning in Geriatric Patients

ASSESSMENT/TREATMENT	MANAGEMENT CONSIDERATIONS
History	Need detailed past medical history and medication history
Seizure management	Query relatives if patient is confused or demented Greater sensitivity to benzodiazepines and barbiturates may increase need for subsequent intubation and respiratory support
GI decontamination	
Ipecac syrup	Avoid
Activated charcoal	If aspirated, preexisting pulmonary disease may lead to more significant deterioration
Cathartic	Greater susceptibility to fluid and electrolyte problems
Whole-bowel irrigation	Greater susceptibility to fluid and electrolyte problems
Elimination Enhancement	
Multiple-dose activated charcoal	Use cautiously in patients with poor GI motility
Hemodialysis/hemoperfusion	Consider at lower blood concentrations (e.g., salicylates, theophylline, lithium)
Antidote	Adverse effects more likely (e.g., precipitation of heart failure by digoxin-immune Fab in patients who require digoxin's inotropic effect to maintain cardiac output; hypernatremia with hyperosmolarity from administration of sodium bicarbonate to alkalinize the blood for cardiotoxic drugs affecting the sodium channel or for salicylate overdose can lead to fluid overload and pulmonary edema, especially in patients with diminished cardiac or renal function) Need for dose modifications (e.g., additional Fab dosing if impaired renal function leads to rebound in free digoxin)

the effect of concurrent medications as well as the increased risk of ADEs and drug-drug interactions that the superimposed acute overdose poses during treatment of the overdose. Table 19-2 describes special considerations for managing overdoses in older adults.

PREVENTION

Psychiatric evaluation is imperative in cases of intentional ingestion. In addition to referral for psychiatric care, prevention strategies in older suicidal patients include recognizing and managing depression, treating alcohol abuse, limiting the number of doses dispensed per prescription, and decreasing social isolation.⁴⁰

ADEs can be minimized by evaluating the need for drug therapy and by using the safest drug, starting with low doses and adjusting doses by small increments over long intervals.³² Drug-drug interactions can be prevented by avoiding or limiting polypharmacy, adjusting drug dosages when interacting drugs are prescribed, and regularly monitoring drug regimens for continued benefit (and possibly eliminating drugs) as well as evidence of toxicity.¹²

Many unintentional poison exposures are preventable. Physiologic changes in older adults (e.g., decreased vision, hearing, memory) contribute to therapeutic errors and unintentional misuse of household products. Examination of unintentional exposures in older adults discloses four types of contributing factors⁵: (1) dementia and confusion (e.g., eating substance for no reason; repeating doses after forgetting earlier dosing), (2) improper use of the product (e.g., topical or inhalation exposures during product use), (3) improper storage of the product (e.g., consuming nonfood products stored in food containers), (4) mistaken identities (e.g., cleaning product mistaken for mouthwash). Using

medication calendars or compliance packaging for ambulatory older patients can reduce confusion regarding dosing schedule. Providing written information for the hearing impaired and larger type size on labels for the visually impaired older adult can aid in proper use of medications and household products. For older adults who are unable to care for themselves or are confused about their medication regimen, help from family members or caregivers is essential. For demented patients, prevention strategies include limiting access to drugs, personal care products, and cleaning products by storing these products so that they are inaccessible.⁴¹

A Prevention of Childhood Poisonings

ALAN DAVID WOOLF, MD, MPH

During the past 30 years, childhood morbidity and mortality due to poisoning have decreased as a result of new prevention strategies, along with improved triage and management techniques. Poisoning nevertheless remains a threat to the health of young children. More than 1.2 million poison exposures in children age 5 years and younger were reported by 62 reporting poison centers in the United States in 2004.¹ Although the prevention of poisonings might be broadly defined to include the prevention of excessive morbidity and mortality due to the injury once a poison exposure has taken place, in this chapter the definition is restricted to those measures that attempt to avert the poisoning exposure itself. Indeed, targeted education, improved technology, and more effective government regulations in the interest of poisoning prevention have served as models for efforts to prevent other types of injuries.

PASSIVE VERSUS ACTIVE STRATEGIES

Poisoning prevention strategies can be divided conceptually into passive and active interventions. Passive interventions are those measures that do not depend on behavioral changes by the public for their success. Examples include federal regulations prohibiting the retail sale of caustic agents in household products in concentrations higher than those regarded as safe for home use. Since highly concentrated corrosives have become less accessible to the public, the probability that they will cause poisoning is automatically reduced.

Another example of a passive safety strategy is packaging potentially dangerous medications in child-resistant containers. Such packaging limits a young child's chance of exposure to a toxic dose of a drug before being discovered by a supervising adult. Because the child-resistant cap is automatically part of the packaging, a parent does not need to make an active decision to implement this safety measure.

Active poisoning prevention strategies, on the other hand, are those that require sustained behavioral change in the target population if they are to be effective. For example, counseling parents to poison-proof their household requires continued vigilance to ensure proper handling of potential toxins entering the household and a sustained and repeated effort to ensure that those

household products that might be poisonous to toddlers are stored safely.

THE ETIOLOGY OF POISONING

Motor and cognitive developmental milestones achieved by the infant and toddler increase the risk for a poisoning. Children start to walk at about 1 year of age, and thereafter they can explore a much expanded environment. With well-honed gross motor skills, they can climb onto countertops and open cabinets. Fine motor skills, including a newly developed pincer grasp, allow them to undo the lids of containers and place small objects in their mouths. Their oral exploratory behaviors, matched with a lack of discriminatory abilities for potable versus nonpotable objects, put them at high risk for ingesting poisons.²

Children living in families whose system of supervision has broken down are vulnerable to poisoning incidents. Some particular stress such as a recent move, family loss, or financial hardship can cause parents to relax their vigilance. Poisonings often occur when a parent is distracted—for example, around mealtime or when entertaining guests. Many poisonings occur when the parent-child interaction is not in the “business-as-usual” routine of everyday life. For example, at holiday time, the parents may be distracted from their usual supervisory activities by parties and family social gatherings. A pregnant woman who already has a toddler at home may inadvertently put him at risk for a poisoning by leaving an open container of prenatal iron pills on the counter. Grandparents may overlook the chore of poison-proofing their home before their grandchildren visit, leaving potent medications in easy reach on a nightstand. Previous studies have suggested that many childhood poisonings occur when a product is in use,^{3,4} and the occurrences reinforce the idea that lack of supervision is what places a child at high risk. Another common etiology for childhood poisoning is the circumstance of medication giving; the child has access to an open medicine container, or the parent gives the child the wrong dose or the wrong medicine.⁴

Considerable evidence shows that complex family dynamics sometimes underlie poisoning incidents. Families of childhood poisoning repeaters are charac-

terized as disorganized, socially isolated, and operating under the stress of poor housing, frequent moves, or the psychiatric or physical illness of family members.⁵⁻⁷ Sobel and Margolis have suggested that children who repeatedly poison themselves use such incidents as tactics in an ongoing power struggle with their parents.⁸ They found that the mothers of such poisoning repeaters often came from disorganized households and had poor parental role models. The children were often products of an unwanted pregnancy and tended to be hyperactive and negativistic. The importance of such disordered family relationships in poisoning causation is reinforced by Baltimore and Meyer's findings that the poisoning recognition and storage habits of parents of 52 poisoned children were no different from those of parents of 52 control children.⁹ Thus, the environmental hazards present seemed to be the same; what differed between families that had experienced childhood poisoning events and those that had not seemed to involve psychosocial and behavioral factors.

Poisoning prevention strategies that fail to address important moderators such as the behavior of the child, the organization and structure of the family, and the nature of the child-parent interaction have little chance for success. Although child-proofing changes in the house may remain static, the circumstances in which the threshold to a poisoning injury is breached are dynamic (e.g., opened household products or medications, poor supervision, altered family routines). Modification of these circumstances requires patience, counseling, increased social supports, and behavioral adaptations by both children and parents. These goals are somewhat elusive and are part of the challenge in the development of new poisoning prevention strategies.

GENERAL POISONING PREVENTION STRATEGIES

Model poisoning prevention strategies have sought to combine improved technologic advances with enlightened government regulations and effective public education to reduce the risk for a poisoning injury. Baker and colleagues¹⁰ enumerated such general injury prevention strategies, when applied to poisonings, as follows:

1. Banning or reducing the manufacture or sale of an injurious toxin
2. Decreasing the concentration of a poison or the total amount available to the individual to sub-injurious levels
3. Preventing access to the substance
4. Creating barriers between the host and agent during the use of a potentially hazardous product
5. Substituting products with less inherent toxicity but equal efficacy for more dangerous products
6. Changing the formulation of a product to make it less injurious
7. Introduction of an aversive (bittering or pungency) agent to a household product to discourage ingestion

Each of these various principles has been successfully applied to various causes of poisoning among adults as well as children. The banning of dichlorodiphenyl-trichloroethane (DDT) exemplifies legislation targeted at preventing environmental toxic exposures. Limiting the number of baby aspirin to 36 tablets per bottle reduces the likelihood that toddlers can ingest an injurious dose. Child-resistant containers, blister packs for medication, and safe storage of hazardous products prevent access or create a barrier between the child and an injurious dose of the drug or household product. The substitution of acetaminophen for propoxyphene gives equal analgesia while avoiding propoxyphene's considerable toxicity in the event of overdose. The reformulation of children's cough and cold preparations and mouthwashes to exclude alcohol removes a potential source of toxicity to young children and infants. Model legislation in Oregon has required that bittering agents such as denatonium benzoate be added to automotive products such as ethylene glycol-based antifreeze and methanol-based windshield wiper fluid.¹¹ Whether such measures can decrease the volume of the products swallowed by young children in unintentional exposures and thereby reduce the severity of subsequent injury remains unclear.¹¹

Although a number of excellent poisoning prevention strategies have been implemented to reduce adult injuries due to exposure to occupational or environmental poisons, strategies to prevent injuries to children due to environmental toxins are equally compelling if not more so. Such measures include regulations on the amount of pesticide residues allowed in foods or the amounts of contaminants in drinking water. However, this chapter addresses only those specific prevention strategies effective in reducing home poisoning among young children. The following strategies to prevent home poisonings are discussed:

1. Product packaging changes
2. Sticker trials
3. Community-wide programs
4. Clinic-based counseling
5. Growth of poison control centers

SPECIFIC POISONING PREVENTION STRATEGIES

Product Packaging Changes

As early as 1960, the federal government began to take regulatory steps to reduce the incidence of poisoning in the United States by passing the Federal Hazardous Substance Labeling Act. This consumer-oriented legislation required proper labeling of products but did not attempt to regulate their packaging, sale, or use.¹² During the next 15 years, better designs of child-resistant containers were developed and field tested. The rationale for such technology was developmental—that children at highest risk for accidental poisoning (i.e., those 18 to 36 months old) lacked the ability to combine

gross motor skills (the palmar exertion of a sufficient straight vector force) simultaneously with fine motor skills (the finger-exerted twisting of sufficient torque) to easily open products secured by child-resistant containers.

The technologic advances in the engineering of child-resistant containers, combined with enough education of the public to convince them of the potential worth of such packaging changes, culminated in passage of the Poison Prevention Packaging Act in 1970.¹³ This legislation established standards for special packaging of household products and pharmaceuticals, defined appropriate testing procedures and those products that were subject to the regulation, and set a timetable for gradually phasing in the regulations during an 8-year period. The first products to be regulated were those containing aspirin. The products covered and the dates of implementation are listed in Table 20A-1. This regulation provides that if a consumer product presents a serious danger to children and special packaging is both technically feasible and practical, then a safety closure design must be submitted before the product is approved for marketing. Premarketing tests must demonstrate that 85% of a panel of 200 children younger than 5 years failed to open the package in a 5-minute period. A panel of adults is also allowed a single 5-minute period in which 90% must be able to open the safety closure after reading the opening instructions on the package. The regulations were recently extended to require child-resistant packaging for prescription drugs that are switched to over-the-counter status.¹⁴

The purpose of child-resistant containers is to separate the child physically from the potential poison by

providing a barrier between the two. The intent of the regulation was not to poison-proof the container but simply to delay children long enough in their attempts to get at a poison for an adult to discover and correct the hazardous situation. Follow-up studies suggest that the effectiveness of child-resistant containers has been dramatic.¹⁵⁻²¹ As a result of child-resistant packaging, an estimated 86,000 poisoning injuries were averted between the years 1974 and 1981.¹⁵ Walton's study during a 6-year period (1972 to 1978) demonstrated a decline from 7500 to 2300 ingestions during the first 6-year period after the regulations took effect, whereas ingestions of various unregulated products either increased or stayed the same.¹⁶ A recent modeling study estimated a 34% reduction in aspirin-related child mortality rates (preventing about 90 deaths) during 1973 through 1990, attributable to child-resistant packaging.²⁰

In one public survey, more than 98% of parents could describe safety packaging.²² An overwhelming 85% of the 636 families surveyed approved of the idea of safety packaging, and 89% had safety packages in the home. Only 3% of respondents had discontinued use of a product because of difficulty with the package. Vigilance concerning enforcement of the law is important. One study suggested that only 75% of medications dispensed by pharmacists were in compliant child-resistant containers.²³ However, overall the Poison Prevention Packaging Act is a model of well-crafted legislation brought about by successful combination of physician advocacy, improved technology, and effective public education.

The fact that many childhood poisonings occur with open products already in use^{2,24} tempers the gains

TABLE 20A-1 Products Covered by the Poison Prevention Packaging Act (PPPA)

PPPA REGULATION	EFFECTIVE DATE	CHARACTERISTICS OF PRODUCTS REGULATED
Aspirin	8/14/72	Products for oral human use
Furniture polish	9/13/72	Nonemulsion liquid form, low viscosity, containing $\geq 10\%$ mineral seal oil or petroleum distillates
Methylsalicylate	9/21/72	Liquid products containing $\geq 5\%$ by weight
Controlled drugs	10/24/72	For oral human use
Sodium and/or potassium hydroxide	4/11/73	Dry form $\geq 10\%$ by weight; other forms $\geq 2\%$ by weight
Turpentin	7/1/73	Liquid form $\geq 10\%$ by weight
Kindling and/or illuminating preparations	10/29/73	Prepackaged liquid, low viscosity, containing $\geq 10\%$ petroleum distillates
Methyl alcohol	7/1/73	Liquids containing $\geq 4\%$ by weight
Sulfuric acid	8/14/73	Substances containing $\geq 10\%$ by weight
Prescription drugs	4/16/74	For oral human use
Ethylene glycol	6/1/74	Liquids containing $\geq 10\%$ by weight
Paint solvents	4/23/77	Solvents for paints that contain $\geq 10\%$ by weight of benzene, toluene, xylene
Iron-containing drugs	10/17/78	Noninjectable animal and human drugs containing 250 mg or more elemental iron (total package)
Dietary supplements	10/17/78	Dietary supplements containing 250 mg or more elemental iron (total package)
Acetaminophen	2/27/80	Preparations for oral human use with 1 g or more acetaminophen (total package)

From Walton W: An evaluation of the Poison Prevention Packaging Act. *Pediatrics* 1982;69:364.

realized by the implementation of child-resistant packaging. Reducing the total number of pills per container sold and reducing the concentration of the drug in each pill are effective strategies for lowering the severity of a poisoning by lowering the attainable total dose.²⁵ More recent product changes have included the use of unit dosing with blister packs. Such dispensers are expensive but accomplish the dual purposes of lowering the risk for unintentional drug overdoses because of misinterpretation of dosing instruction and decreasing the risk for an overdose by children, who must spend more time unwrapping each individual pill and, thus, it is hoped, cannot ingest a harmful quantity before being discovered. The advent of tamper-resistant containers with protective plastic-wrapped seals has also decreased the risk that a product might be intentionally altered without being noticed by an unwary consumer. Such an outer wrap theoretically imposes yet another barrier to children. The success of such tamper-proof packaging in preventing poisonings has yet to be fully evaluated.

Sticker Trials

Older children can be educated to recognize hazardous agents and to avoid them. Such education usually includes the use of warning stickers that parents affix to hazardous household products to alert children to the danger. These stickers, picturing a skull and crossbones, angry serpent, or frowning face (Mr. Yuk), are meant to evoke psychologically unpleasant or fearsome images in a child's mind so that she or he will be deterred from sampling the poisonous contents. Braden found that such a method of discriminating hazardous agents was necessary; preschool children incorrectly identified 40% of poisonous products with which they were confronted.²⁶ When children were exposed to an educational program on products labeled with warning stickers, their accuracy of recognition improved to 86%. Krenzelok and Garber introduced poison recognition teaching aids into a daycare center program serving 3285 children 30 to 60 months old and tested 195 randomly selected children 6 weeks later.²⁷ The children showed improvements in their recognition of the warning symbol, Mr. Yuk, and in their understanding of which products were poisonous. However, no decrease in the incidence of poisonings has been associated with exposure to such a program. When Fergusson's group performed a controlled field trial that distributed labels to 583 families with 543 matched controls, no significant differences in poisoning rates could be appreciated.²⁸ More than 40% of the parents thought Mr. Yuk labels were not useful, had misgivings about the program, or did not use the warning labels to cover all the poisons in the home. Other concerns have been expressed about the use of warning stickers on household products. Some researchers and parents fear that young children may be attracted instead of repulsed by the warning stickers or may not be able to understand what a poison means.²⁹ Furthermore, many poisons (e.g., plants) cannot be labeled with a warning. Finally, those poisoning incidents occurring outside the household, which may represent

as many as 13% of all poisonings in children younger than 5 years,³⁰ cannot be effectively forestalled by a home-centered program.

While well-intentioned home-based educational programs and the teaching of poisoning prevention to children continue to be espoused as important poison prevention measures,³¹⁻³³ there is no good evidence that such strategies can effectively reduce the incidence of early childhood poisoning.

Community-Wide Educational Efforts

Relatively few programs have attempted to implement poisoning prevention on a community-wide basis. The health department or a poison control center has usually spearheaded such projects with the cooperation of local government officials, health professionals, community action groups, and even businesses and merchandisers. Fisher and colleagues³⁴ introduced one such intervention, which included community outreach seminars, school curriculum changes, point-of-purchase education efforts by retailers, and mass media and educational material distribution activities in Monroe County, New York. As a result, the number of poisonings requiring emergency department treatment in area hospitals declined 66%, and poisoning admissions diminished 71%, whereas hospitalization rates in comparable control communities remained stable. Maisel and associates³⁵ organized a poisoning prevention project in Charleston County, South Carolina, involving education of the public about the recognition of potential poisons and techniques for their safe storage. Activities such as programs for community groups, poster contests, mass media presentations, and group discussions were used. Results of preintervention versus postintervention surveys suggested that 88% of parents had been reached by the educational campaign and had implemented the recommendations. Researchers noted that the number of children hospitalized in Charleston County for poisoning declined. Sumner and associates³⁶ implemented a similar mass media campaign in North Carolina and demonstrated that it significantly increased the public's knowledge of the poison control center's availability and telephone number. Such model programs have demonstrated that community awareness about poisoning prevention can be increased and can perhaps even lower transiently the rate of poisoning. How long such educational efforts can be sustained remains unclear; whether a more modest but self-perpetuating program of education can be a truly effective long-term deterrent needs to be tested.

Clinic-Based Educational Programs

One strategy for promoting the prevention of poisonings among young children is clinic-based education for their parents. Such education invariably includes information about the recognition of hazardous chemicals in the home environment; elimination of the hazard by not purchasing the poison, safely storing it in the home, and disposing of partially used products; and readiness for a

poisoning event by the use of telephone stickers with emergency telephone numbers and knowledge of the appropriate first response (first aid) if a toxic exposure occurs in the home. The Injury Prevention Program (TIPP), an American Academy of Pediatrics–sponsored schedule of safety counseling of families by health care practitioners during a child’s primary health care visits, includes such poison prevention advice.³⁷

The success of such programs has been found to depend on a number of factors (see Box 20A-1):

1. *Content:* The educational message must be clear, readable at the fifth grade level, succinct, and targeted at the intended audience in terms of sophistication.
2. *Timeliness:* Education is most effective when the audience is addressed during a window of receptivity to such a message, that is, when they recognize its importance, are not distracted, and are personally motivated enough to take action.
3. *Relevance:* The message must be important to the audience and perceived as crucial to their well-being. They must be motivated by its relevance to their own health or that of their family in order to take action.
4. *Lack of barriers:* The education must give information that is practical and for which compliance is not too difficult or beset with barriers (interposed tasks the parent must complete to make the effort effective).
5. *Repetitiveness:* The most effective educational modules are repeated to reinforce the message, if it is intended for the parent to carry out active safety behaviors routinely (e.g., checking labels for toxic ingredients and containers for child-resistant caps).
6. *Educator:* The professional stature of the educator has been found to relate to the success of the compliance with educational recommendations. Parents are much more likely to value their physician’s personal suggestions than they are a written summary or slide show, for example. Other cultural, ethnic, and social forces may also enhance or detract from the educator’s effectiveness in delivering the message.
7. *Attention span:* The educational program cannot be so abbreviated that the parent does not recognize its importance. Conversely, the education should not be preachy and should not tax the attention or time constraints of the audience. A program that engages parents in an active and collaborative learning experience is more effective.

Previous investigations of clinic-based educational programs have been limited by structural or research design problems. Dershewitz and Williamson failed to show an effect when a safety counseling program to child-proof a home was instituted in the clinic setting.³⁸ Several studies have shown that a more focused message directed at a specific population might be more effective.

Ipecac is no longer routinely recommended as a method of oral decontamination for the poisoned child,³⁹ so that its universal home storage seems unnecessary. While the storage of activated charcoal in the home has been recommended by some,⁴⁰ others are skeptical of its value in home-based poisoning emergencies.⁴¹ However, families can adopt a variety of other prevention strategies applicable to home settings, such as informed choices of nontoxic household products, safe storage of drugs and toxic products, and ready access to the emergency number for poison control (1-800-222-1222). Physicians and other health care providers routinely provide such counseling to families with young children,⁴² and medical residents are routinely taught during their training to give such advice.⁴³ Poisoning prevention advice given in health care settings can substantially improve family safety practices and readiness in the event of an emergency.^{44,45} A meta-analysis of 20 studies of injury prevention counseling in primary care settings showed positive effects in the majority.⁴⁶

Poison Control Centers

Regionalization of poison control centers across the United States has contributed to the remarkable progress in poisoning prevention and improvements in poisoning management.⁴⁷ This success is derived from the leadership that poison control centers have provided in four different areas:

1. Accuracy of toxicologic information and advice for the management of human poisonings
2. Advocacy as a lead agency in poisoning prevention outreach programs
3. Training for health professionals
4. Research into the etiology, management, and prevention of poisonings

Access to a regional poison control center undoubtedly improves the medical triage and management of a toxic exposure, thus preventing excessive morbidity and mortality. Studies of the use of health services in states with and without poison control centers demonstrate remarkable improvements in telephone triage patterns, avoidance of excess emergency department visits, and improved quality and quantity of pertinent information given for those poisonings in states with regional poison control centers.

It is perhaps underappreciated that poison control centers also serve a focusing role as the lead agency in the community for poisoning prevention programs. They serve as valuable resources for providing public and professional information about the identification of toxic compounds,

acceptable exposure levels, and safe storage and use. Poison control centers have expanded their roles to include calls requesting information about occupational or environmental exposures, and they serve as a highly visible networking resource, making referrals to other community facilities with more specialized knowledge about teratogenicity, public health implications of specific exposures, and plant or animal identifications.

Poison control centers also serve in poisoning prevention by improving the toxicology training of health professionals through tutorials, staff lectures, in-service programs, and regional workshops and symposia. In addition, poison control centers can alert health professionals, through surveillance of adverse drug reactions, of changes in prescribing style or precautions that must be taken. By pursuing active public education goals via newsletters, public service announcements, health fairs, and media campaigns (e.g., National Poison Prevention Week), poison control centers help to keep the public alert to the principles of poisoning prevention.

Finally, poison control centers often serve as the stimulus to develop new techniques in poisoning prevention. The centers accumulate a dynamic clinical poisoning experience from which epidemiologic trends in poisoning types and circumstances can be identified. Table 20-2 shows the comparative hazard of common drugs and household products as measured by the frequency and extent of injury associated with the poisonings reported to poison control centers nationally.⁴⁸ Ideally, such an early warning surveillance system regarding a community's specific toxic exposure problems can lead to directed programs aimed at averting microepidemics of poisoning injuries. Because poison control centers are respected by the public and by health professionals for possessing a particular type of expertise, they can stimulate interest in new research and regulations for poisoning prevention.

THE PHYSICIAN'S RESPONSIBILITY

Physicians have a dual role in the prevention of poisonings, as advocates for their patients' families and as influential and respected community leaders. Physicians must recognize those circumstances that pose a higher than usual potential risk for a poisoning and must take corrective action. This action may include diverse recommendations, such as changing or simplifying a prescribed drug or recommending or advocating daycare, nursing home care, other social supports, psychiatric evaluation, or family counseling. Physicians must give adequate attention to poisoning prevention topics that they discuss with patients as part of their routine health care.

Physicians, in their capacity as community leaders, have an obligation to advocate changes necessary to decrease the risk for poisoning and to alert the community to new or previously unrecognized toxic hazards. Such advocacy includes support for the local or regional poison control service serving the community and for its programs in poisoning prevention. Physicians

TABLE 20A-2 Agents with High Hazard Factors Associated with Poisonings of United States Children Younger than 6 Years (1985–1989)

SUBSTANCE*	TOTAL PEDIATRIC EXPOSURES [†]	HAZARD FACTOR [‡]
<i>Pharmaceuticals</i>		
Amphetamines	6409	4.5
Acetaminophen and propoxyphene	2171	4.5
Aspirin	10,002	3.1
Amitriptyline	2897	22.8
Antiarrhythmics	1203	4.0
Anticholinergics	6516	3.2
Antihypertensives	8099	27.6
Barbiturates (long acting)	4475	13.3
Barbiturates (short acting)	1051	6.1
Carbamazepine	4113	32.5
Cardiac glycosides	3846	10.9
Cocaine	546	59.0
Cyclic antidepressant and phenothiazine	832	19.4
Desipramine	935	27.6
Diphenoxylate and atropine	2500	12.2
Doxepin	887	14.5
Imipramine	2503	20.0
Iron	11,234	8.5
Lithium	1054	10.7
Marijuana	694	7.0
Oral hypoglycemics	2609	6.8
Phenothiazines	7451	12.8
Phenytoin	3619	9.3
Propoxyphene	514	6.3
Theophylline	8622	7.7
Valproic acid	1197	6.7
<i>Nonpharmaceuticals</i>		
Alkali	10,267	3.8
Alkali drain cleaners	1474	21.9
Alkali industrial cleaners	938	29.2
Alkali oven cleaners	4619	3.5
Carbon monoxide	3103	31.1
Chlorinated hydrocarbons	9694	4.8
Chlorine gas	2208	4.4
Ethanol	2622	8.0
Ethylene glycol	2321	3.5
Hydrochloric acid	784	6.2
Kerosene	10,751	7.9
Lighter fluid	8865	4.4
Methane, natural gas	700	9.2
Methanol	1883	5.1
Mineral seal oil	6564	3.2
Organophosphate alone	16,560	5.6
Organophosphate and other pesticides	1806	3.6

*Specific substances only—broader categories are not all included; bites and envenomations are not included.

[†]Only substances with more than 500 exposures included.

[‡]Only hazard factors > 3.0 included.

Adapted from Litovitz T, Manoguerra A: Comparison of pediatric poisoning hazards: an analysis of 3.8 million exposure incidents. A report from the American Association of Poison Control Centers. *Pediatrics* 1992;89:1002–1004.

might also make use of public forums to change the public perceptions of poisoning prevention strategies (e.g., the need for child-resistant containers, the importance of following directions for the use of medications, and the dangers of drug abuse). Physicians

can also be influential consultants to legislative bodies considering new initiatives restricting or regulating the use and disposal of drugs and toxins. Internet websites with educational content on poisoning prevention (see Box 20A-2) can provide physicians with additional resources to assist them in their community advocacy efforts.

Dedicated health professionals must make a concerted effort to continue the momentum and consolidate the gains that have been made in poisoning prevention and to advance new aspects of the field.

POISONING PREVENTION RESOURCES

See Box 20A-2 for online poisoning prevention resources.

BOX 20A-2 SELECT INTERNET WEBSITES: POISONING PREVENTION RESOURCES

American Association of Poison Control Centers (AAPCC): www.aapcc.org

This is the official website of the AAPCC, which inventories contact information for all of the poison control centers in the United States. It also includes poisoning fact sheets, a downloadable poison prevention brochure, prevention tips, a list of educators at poison control centers, and information about Poisoning Prevention Week.

American Association of Poison Control Centers' Toll-Free Emergency Number Website: www.1-800-222-1222.info/poisonhelp.asp

This website contains information about the AAPCC's toll-free telephone number for poisoning emergencies. It also contains public education information about poisoning prevention and a module targeted to preschool children.

American Academy of Pediatrics: www.aap.org

This is the official website of the American Academy of Pediatrics. Under the button "You and Your Family," information is available about the Bright Futures project, which includes injury prevention objectives. The "You and Your Family" section also includes The Injury Prevention Program (TIPP) age-related injury prevention fact sheets, which include poisoning prevention information.
