B Poisonings in Children with Unique Metabolism

REBEKAH C. MANNIX, MD ■ MICHAEL W. SHANNON, MD, MPH

At a Glance...

- Each year, newborn screening identifies approximately 3000 new cases of potentially fatal metabolic disorders, hematologic disorders, and endocrinopathies.
- These patients with unique metabolism are prone to unique drug responses.
- Clinicians should review basic metabolic pathways and recognize adverse drug reactions when caring for these patients.

According to the Center for Disease Control and Prevention, approximately 4 million babies in the United States have dried blood spots analyzed through newborn screening programs.¹ These screens, which can detect metabolic disorders, hematologic disorders, and endocrinopathies, identify an estimated 3000 new cases of potentially fatal or debilitating disease each year for which outcomes are improved with early identification and treatment.¹

Long-term survival of these children poses new challenges for clinicians. Previously well-delineated drug response in the general population may not apply to this subpopulation. Indeed, the toxic effects of drugs in these patients are not merely an extension of current clinical toxicology. The basis for understanding the idiosyncratic drug response of children with unique metabolism requires careful attention to the basics of biochemistry and physiology.

This chapter reviews some of the best characterized adverse drug reactions in children with unique metabolism. It is by no means a complete summary since there is a paucity of information available on drug physiology in these special circumstances. The chapter is intended to act as a guide to clinicians faced with adverse

drug reactions in children with unique metabolism and to assist efforts at preventing these adverse drug reactions.

VALPROATE TOXICITY IN PATIENTS WITH DISORDERS OF FATTY ACID METABOLISM

The toxicity of valproic acid (VPA) has been attributed in part to its effects on multiple metabolic pathways, most notably fatty acid synthesis and degradation. It is therefore logical to presume that patients with disorders of fatty acid metabolism are at increased risk for VPA toxicity. An overview of the pharmacokinetics, drug interactions, and manifestations of VPA overdose in the general population may be found in Chapter 40, while the special considerations in patients with defects in fatty acid metabolism are described below.

VPA (2-propylpentanoic acid) is a simple branched-chain carboxylic acid used therapeutically as an anticonvulsant, primarily in pediatric populations.² Like other fatty acids, VPA undergoes β -oxidation (incomplete) and competes for the physiologic substrates coenzyme A (CoA) and L-carnitine. This competition does not produce clinically significant derangements in healthy subjects with therapeutic dosing of VPA. However, patients with underlying defects in fatty acid oxidation may develop significant toxicity from “therapeutic” doses of VPA. A review of fatty acid oxidation is necessary to better understand the basis of that toxicity (Fig. 20B-1).

The metabolism of free fatty acids begins with the formation of fatty acid conjugates with CoA to form acyl-CoA esters of varying chain lengths. These are transesterified to acylcarnitines at the mitochondrial membrane and shuttled across the mitochondrial matrix

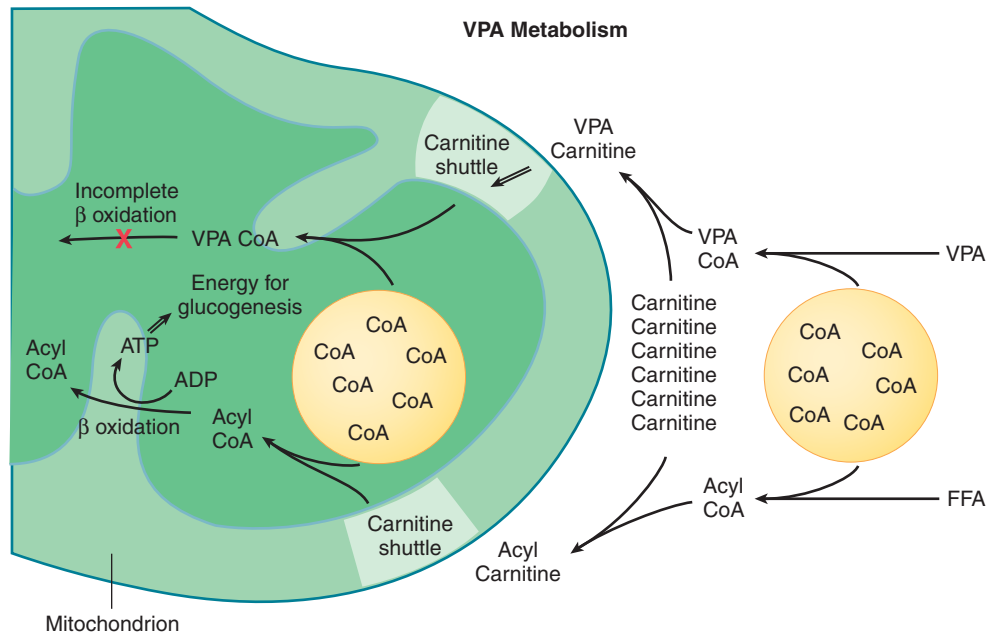

FIGURE 20B-1. Fatty acid metabolism begins with the formation of fatty acid–CoA conjugates to form acyl CoAs. These acyl CoAs are then transesterified to acylcarnitines at the mitochondrial membrane and shuttled across the mitochondrial matrix. Once inside the mitochondrion, acyl CoAs are regenerated and ultimately oxidized the acetyl CoA, which generates ATP via the citric acid cycle. Valproic acid (VPA) competes for the physiologic substrates CoA and carnitine without producing significant amounts of ATP.

where the acyl CoAs are regenerated. The fatty acyl CoAs undergo β -oxidation, forming acetyl CoA, which either enters the citric acid cycle to generate adenosine triphosphate (ATP; fatty acid oxidation being the major source of the ATP required for gluconeogenesis in times of fasting) or becomes the substrate for ketogenesis, lipogenesis, or steroidogenesis.

Regulation of the free and esterified CoA pool of the cell is therefore important in a large number of catabolic and anabolic biochemical reactions. The total cellular CoA pool is small and cannot be increased quickly and the cell is dependent on continued turnover of acyl CoAs to make CoA available.

VPA can be activated to the corresponding acyl CoA (valproyl CoA or VPA CoA), which can be metabolized by mammalian tissues to a variety of energy-poor metabolites.³⁻⁵ The overproduction of poorly metabolized VPA-CoA thioesters jeopardizes multiple biochemical pathways by impeding flux through this entire energy-harvesting pathway, particularly in patients in whom fatty acid metabolism and synthesis are impaired.

Valproylcarnitine (VPA-carnitine) can be generated from VPA CoA, although this is a quantitatively minor pathway of VPA elimination in normal subjects.^{6,7} Most studies demonstrate that VPA therapy is associated with a mild decrease in plasma carnitine concentrations, likely through renal excretion of VPA-carnitine esters.^{8,9} Data on tissue carnitine contents during VPA therapy are not available.

Recent data suggest that other conjugation pathways, most significantly glutathione, may also play a role in VPA toxicity in both children with fatty acid oxidation defects and healthy, normal children.^{10,11} Indeed, it is this depletion of glutathione that may produce the hepatotoxicity associated with VPA overdose.

Although not clinically significant in most therapeutic situations, the depletion of CoA, carnitine, and reduced glutathione by VPA becomes relevant in patients with underlying metabolic disorders as well as those who take a VPA overdose.^{12,13} Patients with disorders of fatty acid oxidation such as very long chain acyl-CoA dehydrogenase deficiency, medium chain acyl-CoA dehydrogenase deficiency, trifunctional protein deficiency, and medium and short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency have limited ability to metabolize fatty acids. This deficiency results in a restricted ability to harvest the requisite energy (stored in fatty acids) for gluconeogenesis. Further restriction of the metabolism of free fatty acids (as in the case of the sequestration of CoA by VPA) or increased energy demands (fever, fasting) shifts the relative deficiency to an absolute deficiency. Similarly, patients with relative carnitine deficiency (e.g., in familial epilepsies) may be thrown into metabolic crisis by the VPA-induced depletion of carnitine. Repletion of carnitine and glutathione (in the form of *N*-acetylcysteine) may ameliorate the toxicity associated with valproate in patients with fatty acid oxidation defects and hereditary carnitine deficiency.

ANTIDEPRESSANTS IN PATIENTS WITH ORNITHINE TRANSCARBAMYLASE DEFICIENCY

Ornithine transcarbamyl transferase (OTC) deficiency is the most common of the urea cycle disorders. OTC deficiency is an X-linked disorder that occurs primarily in males, although it can also manifest itself in females. Clinical presentation of OTC can vary from fulminant

cerebral edema in the neonate, impulsivity and attention deficit in older children, and mood disorders and psychosis in adults; mental status changes are a frequent presentation in adults. Many clinicians have anecdotally noted severe worsening of mood and psychosis in patients with OTC who begin to take serotonin and norepinephrine reuptake inhibitors. The mechanism of this adverse reaction is discussed below.

Deficiency of OTC leads to the inability of liver to condense carbamyl phosphate and ornithine into citrulline, the initial ammonia-incorporating step in the urea cycle. This impairment leads to reduced ammonia incorporation, which, in turn, causes systemic hyperammonemia. Plasma ammonia (NH_3) is a weak base in equilibrium with the cation ammonium (NH_4^+), and only freely crosses the blood-brain barrier in the unionized NH_3 form. Cerebral uptake of ammonia is thus greatly enhanced by alkalemia, which is often present in ammonemic patients.

Elevated levels of NH_3 in the brain stimulate the astrocyte-restricted enzyme glutamine synthetase.¹⁴ The accumulation of astrocyte glutamine drives heteroexchange (the exchange of one amino acid for a different one) of neutral (zwitterionic) amino acids across the LAT1 transporter, leading to accumulation of brain tyrosine, tryptophan, and other essential amino acids.¹⁵⁻¹⁷ The accumulation of tyrosine promotes the formation of norepinephrine (NE) and dopamine (DA), while the build-up of tryptophan produces increased

5-hydroxytryptamine (5-HT, or serotonin) (Fig. 20B-2).¹⁸ High synaptic concentrations of DA, NE, and 5-HT in patients with urea cycle defects may contribute to psychosis, mood disorders, attention deficits, combative temperament, and impulsivity.

As discussed in Chapter 27, antidepressants (tricyclic antidepressants) act by inhibiting the uptake of NE, DA, and 5-HT in the synapse. Selective serotonin reuptake inhibitors (SSRIs) function primarily by inhibiting the reuptake of serotonin; they also possess an ability to inhibit reuptake of DA and NE. Use of these antidepressants in patients with OTC may worsen symptomatology by increasing already high synaptic concentrations of these neurotransmitters. It is uncertain whether 5-HT antagonists such as cyproheptadine and methysergide have any benefit in this setting.

BENZODIAZEPINES IN MAPLE SYRUP DISEASE

Maple syrup disease (MSD) is an autosomal-recessive disorder caused by decreased activity of branched-chain α -ketoacid dehydrogenase, an enzyme in the degradative pathway of the branched-chain amino acids leucine, isoleucine, and valine.¹⁹ The consequence of this deficiency is toxic accumulation of these amino acids in tissues and plasma. The accumulation of leucine further leads to a proportional accumulation of α -ketoisocaproic

FIGURE 20B-2. Elevated ammonia in the brain of patients with OTC leads to increased formation of glutamine. Increased tissue glutamine drives heteroexchange of glutamine for tryptophan, tyrosine, and other essential amino acids. The accumulation of tyrosine promotes the formation of norepinephrine (NE) and dopamine (DA) while the buildup of tryptophan produces increased serotonin (5-HT).

FIGURE 20B-3. Decreased activity of branched-chain α -ketoacid dehydrogenase (BCKAD) causes buildup of leucine, isoleucine, and valine. The accumulation of leucine further leads to a proportional accumulation of α -ketoisocaproic acid, its ketoacid analog. Excessive intracerebral levels of α -ketoisocaproic acid drive a transamination reaction which depletes glutamate and in turn GABA. (Adapted from Strauss KA, Morton DH: Branched-chain ketoacyl dehydrogenase deficiency: Maple syrup disease. *Curr Treat Options Neurol* 2003;5:329–341.)

acid, its ketoacid analog. Excessive intracerebral levels of this ketoacid drive a transamination reaction that depletes glutamate and in turn γ -aminobutyric acid (GABA) (Fig. 20B-3).^{20,22}

This relative GABA deficiency may lead to chronic up-regulation of GABA receptors and increased sensitivity to the effects of benzodiazepenes at this receptor. Clinicians should be aware that patients with MSD may display toxic effects at doses used therapeutically in the normal population. Reversal with flumazenil should be approached warily by the clinician because increased receptor sensitivity may lower seizure threshold with flumazenil-induced receptor blockade.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY AND OXIDANTS

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common human enzyme deficiency, with an estimated 400 million people worldwide affected by this enzymopathy.^{23,24} G6PD is the most common hereditary cause of “idiopathic” hyperbilirubinemia in newborns, and can be associated with significant nonhemolytic jaundice in this age group. G6PD catalyzes the first reaction in the hexose monophosphate shunt, an oxidation/reduction reaction that oxidizes glucose-6-phosphate while concomitantly reducing nicotinamide-adenine dinucleotide phosphate (NADP). G6PD is responsible for maintaining adequate cellular levels of reduced NADP (NADPH). NADPH functions as a cofactor in many biosynthetic reactions, including maintenance of glutathione in its reduced form. Reduced glutathione acts as a scavenger for dangerous oxidative metabolites in the cell. While other cells in the body have diverse mechanisms for generating NADPH,

the red cell is fully dependent on G6PD to generate this important molecule.¹⁹ Having only one NADPH-producing enzyme to remove oxidants, red blood cells are therefore especially sensitive to oxidative stresses. Oxidant stress can be precipitated by infection, food, and drugs (Chapter 14). As a result of oxidant stress, these red cells undergo massive hemolysis, leading to hyperbilirubinemia. Removing the cause of oxidative stress is first-line treatment for G6PD hemolysis. Vitamin E and folic acid have both been suggested for treatment of G6PD hemolysis.²⁵ Treatment for severe cases may include exchange transfusion.

CRIGLER-NAJJAR DISEASE AND CEFTRIAXONE

Crigler-Najjar disease is an autosomal-recessive disorder in which bilirubin metabolism is impaired. Patients with Crigler-Najjar disease are subject to markedly elevated levels of bilirubin that can manifest by icterus, kernicterus, and encephalopathy. Drugs that exacerbate hyperbilirubinemia (either through displacement of bilirubin from albumin or from cholestasis) must be avoided in patients with Crigler-Najjar disease.

Bilirubin is a lipophilic molecule that requires conversion to a polar derivative in order to be eliminated. This conversion of bilirubin occurs in the liver, where the molecule glucuronic acid attaches to bilirubin in a process called glucuronidation. Glucuronidation is carried out by the enzyme uridine diphosphate glucuronyl transferase (UDPGT). Patients with Crigler-Najjar disease have either an absolute lack of this enzyme (type 1) or markedly decreased activity of this enzyme (type 2), resulting in very high levels of unconjugated bilirubin. Importantly, treatment with phenobarbital, which can induce the expression of UDPGT, is not effective in the setting of absolute lack of the enzyme (type 1) but may be effective in ameliorating type 2 disease.

The lipophilic unconjugated bilirubin must be bound to carrier protein to be transported in the aqueous environment of the serum. Albumin has one primary high-affinity binding site for bilirubin and two lower-affinity sites. Albumin bound bilirubin cannot pass through the blood-brain barrier to exert its toxic effect. At physiologic pH, the amount of free bilirubin is very low (less than 0.1% of total) and the brain is protected from the neurotoxic effects of bilirubin. Decreased albumin-binding capacity and/or decreased albumin-binding affinity can increase the amount of free serum bilirubin.

The risk of kernicterus in any jaundiced patient increases as the serum bilirubin-albumin molar ratio exceeds 0.7. Brain injury is imminent when this ratio exceeds 1.0. The quantitative effect of any displacing drug on the toxic level of free bilirubin depends on four major variables: (1) the prevailing bilirubin-albumin molar ratio, (2) peak molar concentration of the drug after administration, (3) fractional protein binding by the drug, and its specific binding affinity for the bilirubin binding pocket, and (4) drug half-life. The latter three

BOX 20B-1 DRUGS TO AVOID IN PATIENTS WITH CRIGLER-NAJJAR DISEASE

Afelimomab	Edatrexate	Micafungin
Alprostadil	Erlotinib	Molgramostim
Atazanavir	Etoposide	Montelukast
Azacitidine	Flavopiridol	Novobiocin
Busulfan	Ganciclovir	Oxytocin
Capecitabine	Hemoglobin	Pancuronium
Carmustine	Indinavir	Quinupristin/dalfopristin
Ceftazidime	Lamivudine/zidovudine	Ribavirin
Ceftriaxone	Lithium	Tacrine
Clozapine	Menadiol sodium	Tasosartan
Crosfumaril	diphosphate	Temozolomide
Cyclosporine	Methenolone	Trazodone
Cytarabine	Methylene blue	Valspodar
Dapsone	Mezlocillin	

variables can be obtained from standard pharmacology texts, while the serum bilirubin-albumin ratio can be calculated as:

$$\begin{aligned} \text{Bilirubin in mg/dL} \times 17 &= \text{Bilirubin in } \mu\text{mol/L} \\ \text{Albumin in g/dL} \times 152 &= \text{Albumin in } \mu\text{mol/L} \end{aligned}$$

Drugs that raise bilirubin either through cholestasis or displacement of bilirubin from albumin should be assiduously avoided in patients with Crigler-Najjar (Box 20B-1).²⁶⁻²⁸

METHOTREXATE AND DISORDERS OF FOLATE AND VITAMIN B₁₂ METABOLISM

The enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10-methylenetetrahydrofolate (5,10-methylfolate) into 5-methyltetrahydrofolate (5-methylfolate), the major circulating and bioactive form of folate. It is important to note that total circulating folate levels (as measured by standard laboratory assays) are normal in these patients, while the fraction of 5-methylfolate in the total folate pool is low (normally more than 50% of total, typically less than 5% of total in patients with severe MTHFR deficiency). Folate is used in many vital biochemical pathways, including the conversion of homocysteine to methionine and the synthesis of nucleotides, and in numerous methylation reactions (Fig. 20B-4).

The effects of abnormal folate metabolism are still incompletely understood, although there is ample evidence that abnormally low MTHFR activity leads to lower circulating levels of the bioavailable forms of folate, lower availability of methionine, and higher levels of homocysteine. Folic acid and folinic acid supplementation do not help these patients; both drugs require activity of MTHFR to be converted to the bioactive 5-methyl-THF.

Similarly, patients with hereditary cobalamin (vitamin B₁₂) disorders are unable to convert homocysteine to

FIGURE 20B-4. The folate metabolism cycle. The enzyme 5,10 methylenetetrahydrofolate reductase (MTHFR) catalyzes the conversion of 5,10 methylenetetrahydrofolate (5,10-methylfolate) into 5-methyltetrahydrofolate (5-methylfolate), the major circulating and bioactive form of folate. Abnormally low MTHFR activity leads to lower circulating levels of the bioavailable forms of folate, lower availability of methionine, and higher levels of homocysteine.

methionine. As in the case of MTHFR deficiency, those with elevated levels of homocysteine are at risk for a wide array of metabolic derangements, including neurotoxicity, vasculopathy, and thrombosis.

Dihydrofolate reductase (DHFR) inhibitors, most notably methotrexate, decrease cellular 5-methyltetrahydrofolate. Use of DHFR inhibitors in patients with MTHFR deficiency can lead to a metabolic crisis and significantly increased risk for methotrexate-induced neurotoxicity, vasculopathy, and thrombotic events.²⁹ Notably, folinic acid (“leucovorin rescue”) is ineffective in these patients because folinic acid is not bioavailable due to the underlying enzymatic defect. The best treatment for patients with MTHFR deficiency is to avoid exposure to drugs that disrupt folate metabolism.

Inhaled nitrous oxide anesthesia should also be avoided in patients with disorders of folate and vitamin B₁₂ metabolism because nitrous oxide functions as an irreversible inhibitor of cerebral methionine synthase. Use of nitrous oxide in these patients can produce a sudden and lethal neurologic deterioration due to rapid intracerebral accumulation of S-adenosylhomocysteine, adenosine, homocysteine, and excitatory homocysteine metabolites.^{30,31}

INHALED ANESTHETICS AND MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is an autosomal-dominant pharmacogenetic disorder triggered by exposure of susceptible individuals to commonly used inhaled anesthetics and depolarizing muscle relaxants.³² Most patients are asymptomatic prior to the exposure, although MH is associated with central core disease (a rare neuromuscular disorder that is most often characterized by weakness in the legs), other myopathies, and dystonias. Patients with malignant hyperthermia are thought to have abnormal regulation of calcium through the calcium release channel, known as the ryanodine receptor (RYR1), in the sarcoplasmic reticulum of skeletal muscle.³³ About 50% of familial MH is linked to the chromosome 19q13 region, where the RYR1 gene is

located.³⁴ To date, more than 30 different mutations in the RYR1 gene have been associated with MH susceptibility.³⁵

Administration of an inhaled anesthetic or depolarizing muscle relaxant in patients with a predisposition to MH triggers calcium dysregulation within the muscle cell. Excessive intracellular calcium, or interference with return to storage of calcium, creates a high intracellular calcium level that leads to continuous contractures of skeletal muscles, which manifests clinically as muscle rigidity and spasm. This hyperaction of skeletal muscles increases myocyte oxygen consumption, heat production, and use of ATP; these produce the signs of lactic acidosis and hyperthermia. The mortality rate of malignant hyperthermia is as high as 5% to 10%.

Inhalational anesthetics and depolarizing muscle relaxants should be avoided in patients with a known prior history of malignant hyperthermia or strong family history of malignant hyperthermia. The treatment of choice is intravenous dantrolene 2.5 mg/kg per dose to a maximum total dosing of 10 mg/kg, which blocks calcium release. Adjunctive therapy includes cooling, control of acidosis, and 100% O₂.³⁶

In addition to malignant hyperthermia in patients with congenital myopathies, the use of depolarizing muscle relaxants can produce severe hyperkalemia, rhabdomyolysis, and renal failure. The mechanism of this response is likely due to an adaptive increase in acetylcholine receptors on denervated muscle, leading to massive depolarization.

ACUTE INTERMITTENT PORPHYRIA

Acute intermittent porphyria (AIP) is an autosomal-dominant disorder resulting from an error in pyrrole metabolism due to deficiency of uroporphyrinogen I synthetase (Fig. 20B-5).

AIP is characterized by recurrent attacks of abdominal pain, gastrointestinal dysfunction, neurologic disturbances, and large amounts of aminolevulinic acid and porphobilinogen in the urine. Paresthesias and paralysis

BOX 20B-2 DRUG SAFETY IN ACUTE INTERMITTENT PORPHYRIA

Unsafe (Strong Evidence)	Possibly Unsafe
Alkylating agents	Methyldopa
Androgens	Metroniazole
Aminophylline	Metyrapone
Barbiturates	Miconazole
Bemegride	Nalidixic acid
Estrogens	Nifedipine
Ethanol	Nikethamide
Griseofulvin	Nitrazepam
Hydantoins	Nortriptyline
Progesterones	Chloroquine
Sulfonamides	Danazol
	Phenazone
	Dapson
	Phenoxybenzamine
	Disopyramide
	Phensuxamine
	Enflurane
	Phenylbutazone
	Ergotamine
	Primidone
	Etomidate
	Pyrazinamide
	Eucalyptol
	Rifampin
	Glutethimide
	Spirolactone
	Halothane
	Succinimides
	Hyalazine
	Theophylline
	Imipramine
	Tolazemide
	Ketamine
	Tolbutamide
	Ketocanazole
	Trimethadone
	Mepivacaine
	Troxidone
	Meprobamate
	Valproate
	Methsuximide
	Verapamil

can also occur, with death resulting from respiratory paralysis.³⁷

Multiple drugs have been shown to trigger a porphyric crisis (Box 20B-2). Treatment for acute attacks is mostly supportive with dextrose infusions.³⁸ Successful treatment of acute attacks with hematin, a specific feedback inhibitor of heme synthesis, has been repeatedly reported, although this is not a viable strategy at most centers due to the unavailability of hematin.³⁹

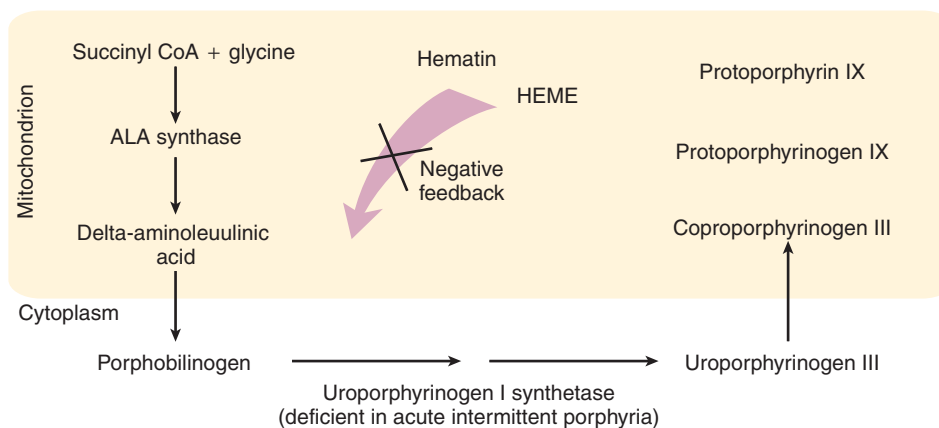

FIGURE 20B-5. Heme synthesis pathway. A defect in the enzyme uroporphyrinogen synthetase causes acute intermittent porphyria. Hematin, a feedback inhibitor of heme synthesis, may be useful in treating acute attacks.

Venomous Snakes

A North American Crotalinae Envenomation

FRANK G. WALTER, MD ■ PETER B. CHASE, MD, PHD ■ MIGUEL C. FERNÁNDEZ, MD ■ JUDE MCNALLY, BSPHARM, RPH

At a Glance...

- North American vipers belong to the subfamily Crotalinae and include rattlesnakes (*Crotalus* and *Sistrurus* spp), copperheads, and water moccasins (both belonging to the genus *Agkistrodon*).
- Snakebites by North American pit vipers are common, and most victims are seen in health care facilities. Morbidity is usual and may be significant and persistent. Death is rare.
- Young males are the most frequent victims; ethanol use preceding the bite is not uncommon.
- Venoms are composed of multiple polypeptides, designed to immobilize, kill, and digest.
- Coagulopathy, rhabdomyolysis, and hypovolemia dominate the clinical picture of envenomation, with potentially limb-threatening edema of bitten extremities.
- Treatment is based primarily on the history and physical examination. A simple scoring system of mild, moderate, and severe envenomation is presented.
- First aid measures include immobilization of the injured part and prompt transport to an appropriate emergency department for evaluation. The practices of packing the wound in ice, applying tourniquets, and “cut and suck” techniques have been abandoned due to lack of efficacy and potential for harm.
- Crotalidae Polyvalent Immune Fab (CroFab) has largely replaced the use of Wyeth-Ayerst Antivenin (Crotalidae) Polyvalent (ACP) (equine). Antivenoms and their indications, contraindications, and relative efficacies are discussed.
- Fasciotomy is rarely indicated in snakebites and should be entertained only in the presence of sustained, elevated compartment pressures after the failure of adequate doses of antivenom and limb elevation.
- Prophylactic antibiotics are not indicated.

ETIOLOGY

North America has two snake families with venomous members, the Viperidae (subfamily Crotalinae) and Elapidae (subfamily Elapinae).^{1,2} North America has three genera of Crotalinae (previously known as Crotalidae): *Crotalus*, *Sistrurus*, and *Agkistrodon* (Table 21A-1).^{2,3} Rattlesnakes are members of the genera *Crotalus* and *Sistrurus*.^{2,4} Members of the genus *Agkistrodon* lack rattles. North America has 18 species of Crotalinae and numerous subspecies (see Table 21A-1).^{3,5}

EPIDEMIOLOGY

The 2002 report of the American Association of Poison Control Centers documented 2325 indigenous venomous snakebites (Table 21A-2) from North American snakes.⁶ Of these, 50% were by rattlesnakes, 38% by copperheads, 7% by cottonmouths, 4% by coral snakes, and 1% by unspecified crotalines (see Table 21A-2). In this case series, 87% of victims were treated in health care facilities (see Table 21A-2) and 2 patients died (0.1%); 2271 patients suffered morbidity (98%); and 54 patients had no significant health effects (2%). The latter could be considered to have had “dry bites” (i.e., bites from venomous snakes that do not result in signs or symptoms of envenomation) (see Table 21A-2).⁴ This 2% dry bite incidence is in contradistinction to the 20% to 25% dry bite incidence quoted by many investigators.⁷ Russell estimated that 20% of crotaline bites were dry bites, while Parrish found 27% dry bites; however, Wingert and Chan found a low incidence of dry bites (1%).^{4,8,9}

Snakebite is most common in school-aged children, adolescents, and young adults, with the highest snakebite

rates in 5- to 19-year-olds in two studies.^{8,10} Another study found that 55% of victims were 17 to 27 years old, with a mean age of 24 years and a median age of 22 years.⁹ Tokish and colleagues found a mean age of 29 years for snakebite victims.¹¹

Most snakebite victims are male. Two studies reported 2:1 male-to-female ratios.^{8,10} One study reported a 9:1 male-to-female ratio.⁹ One study reported 55% males and 45% females.¹²

At least one species of indigenous snake is found in every state of the United States except Alaska, Hawaii, and Maine.⁸ Snakebites occur most frequently in the Southeastern, South Central, and Southwestern United States. The 10 states with the highest incidence of snakebite are detailed in Table 21A-3.⁸

Snakebite varies not only by geographic region, but also by anatomic region. In one study, 58% of victims were bitten in a lower extremity; 38% in an upper

extremity; 0.7% in the torso; 0.5% in the head, face, or neck; and in 2.8% of bites, the site was not clearly specified. This same study also found more victims were bitten on the right side of their bodies (55%) than the left.⁸ In a second study, 55% of snakebites were to upper extremities and 51% were to the right side of the victims' bodies.¹¹ In a third study, 87% of victims were bitten in an upper extremity, 12% in a lower extremity, and 1% in the torso.⁹ In a fourth study, snakebite anatomic region was classified as proximal or distal. Distal was defined as distal to the proximal interphalangeal joint of a finger or toe, or distal to the interphalangeal joint of the thumb or great toe. Distal snakebites occurred in 35% of patients and proximal snakebites occurred in 65%. Distal snakebites produced less severe clinical manifestations than proximal snakebites.¹³

The bite site is related to the victim's activity at the time of the bite. In one study, victims were engaged in

TABLE 21A-3 Geographic Distribution of Snakebite in the United States

STATE	INCIDENCE PER 100,000 PEOPLE/YR
North Carolina	18.79
Arkansas	17.19
Texas	14.70
Georgia	13.44
West Virginia	11.29
Mississippi	10.83
Louisiana	10.25
Oklahoma	8.85
Arizona	7.83
South Carolina	7.72

From Parrish HM: Incidence of treated snakebites in the United States. *Pub Health Rep* 1966;81:269.

the following activities when they were bitten, in descending order of frequency: playing, working, or walking in their own yards; working on a farm or ranch; playing outside of their own yards; hunting or fishing; pursuing other outdoor recreational activities; handling a venomous snake; walking on or near a highway; working or playing inside a barn or henhouse; picking up logs or lumber; picking berries; reaching into obscure places; and engaging in military maneuvers. Only 4% of patients were handling a venomous snake. This correlates with more numerous lower extremity bites (63%) and fewer upper extremity bites (34%) in this study.¹⁰ This is in contradistinction to another study in which 57% of victims were handling a venomous snake, 28% were clinically intoxicated with ethanol, and 87% were bitten in an upper extremity.⁹

Snakebites occur most commonly during the warmest months of the year, when snakes are most active and people are more frequently outdoors. In one study, 94% of snakebites occurred from April through October.⁸ In a second study, 88% of snakebites occurred from April through October.¹¹ In a third study, 73% of snakebites occurred from April through September.⁹ Snakebites occur most commonly during the morning, afternoon, and evening hours when people are most active outdoors. The vast majority of victims are bitten between 9 AM and 10 PM.^{8,9}

CROTALINAE SNAKEBITE

Clinical Presentation

PATHOPHYSIOLOGY

Crotaline venom has multitudinous chemical constituents that act in concert to produce snake venom poisoning in a specific victim.⁴ The clinician must always remember to treat the patient, not the snake, the venom, or the known or suspected venom constituents.

Venom is 70% water by weight. Lyophilized or desiccated venom is 90% protein and polypeptides by dry weight.^{14,15}

The main functions of crotaline venom are immobilization, death, and digestion of prey. Not only do crotalines use venom offensively to obtain food, but also defensively to protect against predators and aggressors. Most crotaline venoms do not produce immobilization through neuromuscular blockade.

Immobilization is usually due to polypeptide, lethal venom components that produce hypovolemic shock so prey cannot escape. These polypeptide, lethal venom components ultimately kill prey due to hypovolemic shock.⁴ Digestion is mediated via numerous proteolytic and other enzymes.^{1,4} This digestive function is critical to snakes because they swallow prey whole and do not masticate their food. The digestive ability of crotaline venom is facilitated by injection into live prey while some perfusion continues to distribute venom. The venom's polypeptide, lethal components damage endothelial cells and allow plasma to exude and blood to extravasate into surrounding tissues, producing hypovolemic shock due to third spacing. Leaky capillaries also allow delivery of digestive components of snake venom to tissues; this speeds digestion. When live prey was fed to the crotaline *Bothrops jararacussu*, digestion time was 4 to 5 days versus 12 to 14 days for dead prey.⁴

The Mojave rattlesnake *Crotalus scutulatus scutulatus*, with venom A, is the classic exception to the fact that most crotalines immobilize prey with polypeptide, lethal venom components that produce hypovolemic shock.¹⁶⁻²³ Mojave rattlesnakes with venom A have Mojave toxin that immobilizes prey by neuromuscular blockade.¹⁶⁻²⁴ Mojave toxin is an acidic protein that consists of a basic phospholipase A₂ subunit and an acidic peptide subunit.¹⁶⁻²⁰ Some other North American crotaline species (e.g., *Crotalus tigris*, *C. viridis concolor*, *C. horridus*, *C. atrox*) have been shown to have some amounts of Mojave toxin in their venoms; however, Mojave rattlesnake venom A has the most Mojave toxin and the lowest median lethal dose (LD₅₀) values of any North American crotaline venom.^{12,16-27} Other populations of Mojave rattlesnakes with venom B lack Mojave toxin and immobilize prey by producing hypovolemic shock from third spacing similar to other crotalines.^{21-23,25-29} Mojave rattlesnakes with venom B are located predominantly in areas surrounding and between Phoenix and Tucson, Arizona.²¹⁻²³

CLINICAL MANIFESTATIONS

Pathophysiologic, clinical manifestations of crotaline envenomation can be thought of in a familiar "A,B,C,D,E" paradigm.³⁰ The cardiovascular and neuromuscular systems are primarily at risk because these primary targets of toxicity are fundamentally affected by venom (Table 21A-4).^{4,31,32}

The primary target of toxicity for most crotaline venoms is the cardiovascular system, especially vascular endothelial cells.^{4,31,33} Crotaline venom produces capillary endothelial cell damage, resulting in endothelial cell swelling and rupture, which leaves large gaps in the microvasculature that allow third spacing of plasma and extravasation of erythrocytes.³³ Endothelial cell damage is caused by relatively low-molecular-weight polypeptides.^{1,34} These polypeptides have molecular weights between

TABLE 21A-4 Targets of Crotaline Venom's Toxic Effects

BODY COMPONENTS AT RISK	PRIMARY TARGETS
Airway	
Breathing	
Cardiovascular system	X
Disability (neuromuscular system)	X
Elimination (kidneys and liver)	

about 4500 and 6000 daltons. They produce shock with intravascular hemoconcentration and hypoproteinemia due to exudation of plasma through the damaged capillary endothelium.⁴ This correlates clinically with profound edema that does not necessarily involve extravasation of large numbers of erythrocytes; therefore, hypovolemia can result from third spacing of plasma.^{2,4}

While endothelial cells are damaged by lower-molecular-weight nonenzymatic polypeptides, vascular basement membranes and perivascular extracellular matrices are destroyed by hemorrhagic metalloproteinases (zinc-containing enzymes with molecular weights between 20,000 and 100,000 daltons) that allow extravasation of erythrocytes.³⁵ This correlates clinically with hemorrhage into envenomated parts of the body.^{1,35} This extravasation of plasma and erythrocytes leads to shock and death in prey animals and can lead to shock and death in severely envenomated humans.

Other significant cardiovascular effects of venom are its direct actions on the clotting ability of blood.^{1,4} Crotaline venom characteristically causes a disseminated intravascular coagulation (DIC)-like syndrome through fibrinogenolysis by thrombin-like, enzymatic venom glycoproteins with molecular weights between 29,000 and 35,000 daltons. These thrombin-like glycoproteins produce fibrin monomers, either fibrinopeptide A, most commonly, or fibrinopeptide B, rarely, depending on the specific venom, without utilizing the victim's own thrombin.^{1,4,36-41}

These thrombin-like venom glycoproteins do not activate factor XIII, which rapidly and efficiently produces cross-linked fibrin, whereas thrombin does activate factor XIII in true DIC to rapidly and efficiently produce cross-linked fibrin that yields D-dimer on fibrinolysis. Non-cross-linked fibrin formed from thrombin-like crotaline enzymes is rapidly lysed to fibrin degradation (split) products, but not D-dimer, and the intravascular thrombosis with microangiopathic hemolytic anemia and intravascular consumption of platelets that is typical of true DIC does not occur. Exsanguination is rare from crotaline envenomations because the victim's ability to form thrombin, and thereby cross-linked fibrin, remains intact, and hemostasis can occur.^{1,4,36-41}

The fundamental difference between true DIC and DIC-like syndromes from crotaline venoms is that true DIC always involves pathologic generation and activity of the victim's endogenous thrombin, whereas DIC-like syndromes do not. Other differences between true DIC

and DIC-like syndromes from crotaline venoms are outlined in Table 21A-5. The pathophysiologic differences between true DIC and DIC-like syndromes from crotaline venoms have important therapeutic implications. Crotaline antivenom is effective for crotaline, venom-induced coagulopathies, but heparin and blood products are not. Heparin is ineffective for crotaline, venom-induced coagulopathies because crotaline, thrombin-like enzymes are not inhibited by antithrombin III (heparin cofactor).^{1,4,36-41} Transfused blood product coagulation factors and platelets are ineffective for crotaline, venom-induced coagulopathies because they are destroyed by circulating venom.^{1,4,36-40} Therefore, administration of blood products to patients with crotaline, venom-induced coagulopathies exposes patients to the risks of blood product therapy without the benefits, unless they are actively and significantly bleeding despite copious antivenom administration and intensive supportive care.^{1,4,31,36-40,42,43}

Although a characteristic DIC-like syndrome from crotaline venoms is described, crotaline venom-induced coagulopathies often vary markedly from case to case.^{4,36} Many crotaline envenomations are accompanied by no significant laboratory abnormalities.⁴ Others demonstrate isolated hypofibrinogenemia, isolated thrombocytopenia, or some combination of these, with or without prolongation of the prothrombin time, partial thromboplastin time, or elevated fibrin degradation (split) products.^{4,36,38} In general, certain species of crotaline may produce characteristic coagulopathies in their victims.³⁶ For example, the Southern Pacific rattlesnake (*Crotalus helleri*) characteristically produces severe thrombocytopenia without significant hypofibrinogenemia.^{36,43} Timber rattlesnake (*Crotalus horridus*) envenomations characteristically produce severe thrombocytopenia, with or without prothrombin time prolongation.^{43,44} Despite generalizations, exceptions always exist; although 90% of victims of pigmy rattlesnake (*Sistrurus miliarius*) bites had no defibrination, 10% did.³⁶ One pigmy rattlesnake envenomation even resulted in true DIC, a rare and reportable event.^{36,45} Not only do venom constituents vary within and between crotaline species, but they also vary in the same snake, depending on its age and the season of the year.^{46,47}

Fibrinolysis due to DIC-like syndromes from crotaline venom is caused by indirect activation of plasminogen by release of tissue plasminogen activator from damaged vascular endothelial cells.³⁹

Crotaline envenomation can cause thrombocytopenia by multiple mechanisms.^{1,4,31,36-40,42,43} Thrombocytopenia is predominantly caused by consumption of platelets at the envenomation site, where disrupted microvasculature exposes platelets to collagen in basement membranes, producing local platelet deposition and aggregation.^{33,35,40} Crotaline venom can also cause platelet aggregation without serotonin release.^{38,39} Investigators isolated a timber rattlesnake (*Crotalus horridus*) toxin, a serine protease called crotalocytin, that aggregates platelets.^{48,49}

The major clinical problems encountered in caring for victims of crotaline envenomations are local tissue

TABLE 21A-5 Comparison of True Disseminated Intravascular Coagulation (DIC) with DIC-like Syndromes from Crotaline Venoms

MANIFESTATION AND THERAPY	DIC	DIC-LIKE SYNDROMES
Pathologic thrombin production and activity	Yes	No
Pathologic activation of factor XIII by thrombin	Yes	No
Thrombin production of both fibrinopeptides A and B	Yes	No
Production of either fibrinopeptide A or B, but not usually both	No	Yes
Production of cross-linked fibrin	Yes	Less common
Production of fibrin degradation (split) products	Yes	Yes
Production of D-dimer	Yes	Less common
Antithrombin III depletion	Yes	No
Thrombocytopenia	Almost always	Sometimes
Active bleeding	Commonly	Rarely
Intravascular thrombosis	Commonly	Rarely
Heparin therapy helpful	Possibly	No
Crotaline antivenin therapy helpful	No	Yes

destruction due to digestive enzymes, edema due to exudation of plasma, hemorrhage due to destruction of the microvasculature, shock due to hypovolemia, and neuromuscular blockade in some victims (see Table 21A-4). Although the cardiovascular and neuromuscular systems are primarily at risk in snake venom poisoning, airway and breathing can be at risk due to massive orofacial or neck edema when the victim is envenomated in the mouth, face, or neck.⁵⁰⁻⁵² Airway and breathing can also be at risk because of neuromuscular blockade due to Mojave toxin's effect on muscles involved in airway patency and ventilation.²⁷ Airway and breathing can also be compromised as a result of coma from intravenous or perivenous envenomations, or coma from shock with a decreased ability to maintain airway patency and ventilation.^{53,54} Airway and breathing can also be compromised by venom-induced anaphylaxis.⁵² Elimination via the kidneys can be disrupted because of acute tubular necrosis due to shock or myoglobinuric renal failure due to rhabdomyolysis.^{27,53,55} Canebrake rattlesnake (*Crotalus horridus atricaudatus*) envenomations characteristically produce rhabdomyolysis.⁵⁵ The most common clinical manifestations from crotaline bites in one case series are reported in Table 21A-6.⁴

Diagnosis

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of snakebite includes puncture wounds and abrasions from other causes, wound infections, cellulitis, deep venous thrombosis, DIC, thrombocytopenia from other causes, inherited bleeding disorders, septicemia, hypovolemic shock from other causes, weakness as a result of neuromuscular blockade from other causes, and rhabdomyolysis from other causes.

The diagnosis of snake venom poisoning is usually simple because the patient, family, or friends tell the clinician that the patient has been bitten by a snake. However, it is important to consider snake venom poisoning in the differential diagnosis of preschool children, developmentally delayed patients, patients with ethanol or drug intoxication, or unconscious patients who present

with puncture wounds, abrasions, edema, or ecchymoses, with or without coagulopathies, shock, rhabdomyolysis, fasciculations, or neuromuscular blockade. Snake envenomation must be considered in the patient with an unknown bite. This is especially true in areas in which a high incidence of snakebites occurs (see Table 21A-3).⁸ Numerous cases of snakebites have been noted in small children who came in crying after playing in the yard.¹⁰

It is essential to completely undress and examine all nonspeaking patients and patients with altered sensoria to search for snakebite punctures or abrasions, and to search for other local, regional, or systemic signs of envenomation.⁵⁴ We have cared for diabetic patients with poor vision due to diabetic retinopathy and poor lower

extremity sensation due to diabetic neuropathy who were unaware of a snakebite but presented with wounds in edematous, ecchymotic legs and had crotaline venom-induced coagulopathies.

CLINICAL DIAGNOSIS

Diagnosis of envenomation from a snakebite is a clinical diagnosis. A history of snakebite is the most helpful diagnostic tool. This history can be obtained from the patient, family, friends, or prehospital health care professionals. Signs and symptoms of crotaline envenomation are detailed in Box 21A-1 and Tables 21A-7 to 21A-9.^{4,32,36} The most important aspects of clinical diagnosis of crotaline envenomation are determining the degree of envenomation on presentation (see Box 21A-1 and Tables 21A-7 to 21A-9) and determining whether progression of the envenomation syndrome (i.e., worsening of clinical signs and symptoms) is occurring over time. Three common systems are used to determine the degree of envenomation on presentation: (1) the minimal-moderate-severe scoring method, (2) the

grade 0 through IV scoring method, and (3) the snakebite severity score (see Box 21A-1 and Tables 21A-7 to 21A-9).⁵⁶ The snakebite severity score (see Table 21A-8) is a research tool and was not intended for general clinical use. We use a modified minimal-moderate-severe scoring method that integrates portions of all three systems; this is detailed in Table 21A-9.³²

Serial physical examinations and assessment of vital signs and clinical status, searching for tissue edema, induration and tenderness, progression of swelling, and development of systemic signs and symptoms, are essential to proper diagnosis and management of the snakebite victim.

LABORATORY DIAGNOSIS

Laboratory diagnosis of snake venom poisoning focuses predominantly on detection of the following: coagulopathies; hemoconcentration due to third spacing of plasma; anemia due to extravasation of erythrocytes or other sources of bleeding; rhabdomyolysis as indicated by elevated creatine phosphokinase values, elevated creatinine levels not attributable to renal failure, and myoglobinuria; and hematuria or hemoglobinuria on urinalysis. Laboratory tests to detect these potential abnormalities should be obtained on presentation and periodically thereafter. We recommend obtaining a complete blood count with platelets, prothrombin time, partial thromboplastin time, fibrinogen, and fibrin degradation (split) products on presentation and every 4 hours thereafter for at least the first 12 hours of hospitalization. This is recommended because laboratory evidence of coagulopathy may not be evident initially or can worsen after initial presentation. Frequency of obtaining these laboratory data should be determined by the clinician, depending on the patient's clinical course, the results of the laboratory tests, and whether and when the patient receives antivenom. After administering antivenom, we prefer to obtain these laboratory data every 4 hours until values have returned to normal or to stable near-normal levels.

We often screen for laboratory abnormalities caused by concurrent illnesses that can confound the care of envenomated patients. This also helps to determine whether coagulopathies are the result of an envenomation or of underlying severe liver disease.

Chest radiography and electrocardiograms should be obtained for patients with preexisting cardiopulmonary diseases and for patients with cardiopulmonary signs or symptoms. We do not routinely obtain these for all

TABLE 21A-7 Crotaline Envenomation: Grade 0-IV Scoring Method

GRADE	CHARACTERISTICS
0	No envenomation: fang marks and minimal pain
I	Minimal envenomation: fang marks, pain, 1–5 in. of edema and erythema during the first 12 hr; no systemic symptoms
II	Moderate envenomation: fang marks, pain, 6–12 in. of edema and erythema in the first 12 hr; systemic symptoms may be present along with rapid progression of signs from grade I; may be bloody ooze at bite site
III	Severe envenomation: fang marks, pain, edema > 12 in. in first 12 hr; systemic symptoms, including coagulation defects after crotaline bites; signs of grades I and II appear in rapid progression, with immediate systemic signs and symptoms
IV	Very severe envenomation; local reaction develops rapidly; edema may involve ipsilateral trunk; ecchymoses, necrosis, blebs, and blisters develop; at tightly restrictive fascial planes, tension may become great enough to obstruct venous or even arterial flow

**TABLE 21A-8** Crotaline Envenomation: The Snakebite Severity Score

CRITERIA	POINTS*
Pulmonary System	
No symptoms/signs	0
Dyspnea, minimal chest tightness, mild or vague discomfort, or respirations of 20–25/min	1
Moderate respiratory distress (tachypnea, 26–40 breaths/min; accessory muscle use)	2
Cyanosis, air hunger, extreme tachypnea, or respiratory insufficiency/failure	3
Cardiovascular System	
No symptoms/signs	0
Tachycardia (100–25 beats/min), palpitations, generalized weakness, benign dysrhythmia, or hypertension	1
Tachycardia (126–75 beats/min) or hypotension, with systolic blood pressure >100 mm Hg	2
Extreme tachycardia (>175 breaths/min), hypotension with systolic blood pressure <100 mm Hg, malignant dysrhythmia, or cardiac arrest	3
Local Wound	
No symptoms/signs	0
Pain, swelling, or ecchymosis within 5–7.5 cm of bite site	1
Pain, swelling, or ecchymosis involving less than half of the extremity (7.5–50 cm from bite site)	2
Pain, swelling, or ecchymosis involving half to all of the extremity (50–100 cm from bite site)	3
Pain, swelling, or ecchymosis extending beyond affected extremity (>100 cm from bite site)	4
Gastrointestinal System	
No symptoms/signs	0
Pain, tenesmus, or nausea	1
Vomiting or diarrhea	2
Repeated vomiting, diarrhea, hematemesis, or hematochezia	3
Hematologic System	
No symptoms/signs	0
Coagulation parameters slightly abnormal: PT, <20 sec; PTT, <50 sec; platelets, 100,000–150,000/mL; or fibrinogen, 100–150 µg/mL	1
Coagulation parameters abnormal: PT, 20–50 sec; PTT, 50–75 sec; platelets, 50,000–100,000/mL; or fibrinogen, 50–100 µg/mL	2
Coagulation parameters abnormal: PT, 50–100 sec; PTT, 75–100 sec; platelets, 20,000–50,000/mL; or fibrinogen, <50 µg/mL	3
Coagulation parameters markedly abnormal, with serious bleeding or the threat of spontaneous bleeding: unmeasurable PT or PTT; platelets, <20,000/mL; or undetectable fibrinogen; severe abnormalities of other laboratory values also fall into this category	4
Central Nervous System	
No symptoms/signs	0
Minimal apprehension, headache, weakness, dizziness, chills, or paresthesia	1
Moderate apprehension, headache, weakness, dizziness, chills, paresthesia, confusion, or fasciculation in area of bite site	2
Severe confusion, lethargy, seizures, coma, psychosis, or generalized fasciculation	3

PT, prothrombin time; PTT, partial thromboplastin time.
 *Points are assessed on the basis of manifestations caused by the venom itself (antivenom reactions not included). Ranges given are for adults; appropriate compensation should be made for age.
 From Dart RC, Hurlbut KM, Garcia R, et al: Validation of a severity score for the assessment of crotalid snakebite. *Ann Emerg Med* 1996;27:321.

patients with crotaline envenomations. All snakebitten patients should receive an intravenous lifeline, continuous cardiac monitoring, frequent automated blood pressure measurements, and pulse oximetry.

Treatment

POISONING TREATMENT PARADIGM

Care of envenomated patients can be thought of in a familiar “A,B,C,D,E” paradigm.³⁰ Basic resuscitation is similar for all envenomated patients. This includes a primary survey and resuscitation consisting of management of airway and breathing; cardiovascular resuscitation,

including administration of intravenous fluids; treatment of any disability (i.e., preserving neuromuscular function); and complete exposure of the patient with environmental control.³⁰ In addition to the primary survey and resuscitation, the “A,B,C,D,E” mnemonic can be modified to organize care of envenomated patients by utilizing the poisoning treatment paradigm (Box 21A-2).³² The poisoning treatment paradigm organizes therapy of poisoned patients by considering whether kinetic aspects of a toxin can be modified, by determining whether the effects of the toxin can be modified pharmacodynamically with an antidote, and by reemphasizing basic care of the patient (i.e., the primary survey and resuscitation).

TABLE 21A-9 Crotaline Envenomation: Determining the Degree of Envenomation

DEGREE OF ENVENOMATION	CONTIGUOUS MANIFESTATIONS	SYSTEMIC MANIFESTATIONS	LABORATORY ABNORMALITIES
None or trivial ("dry bite")	Punctures or abrasions; pain and tenderness at bite	None	None
Mild or minimal	Punctures or abrasions; pain, tenderness, edema, and erythema at and adjacent to bite	Perioral paresthesias	None
Moderate	Punctures or abrasions; pain, tenderness, edema, and erythema beyond area adjacent to bite	Perioral paresthesias; peripheral paresthesias; gustatory changes; nausea; emesis; diarrhea; weakness; light-headedness; diaphoresis; chills	↑ PT; ↑ PTT; ↓ platelets; ↓ fibrinogen; ↑ hemoglobin
Severe	Punctures or abrasions; pain, tenderness, edema, and erythema of entire extremity	Ventilatory insufficiency; hypotension; shock; bleeding; altered mental status; fasciculations; seizures	↑↑ PT; ↑↑ PTT; ↓↓ platelets; ↓↓ fibrinogen; ↑↑ hemoglobin

PT, prothrombin time; PTT, partial thromboplastin time.

Change catabolism	None
Distribute differently	None
Enhance elimination	None

IMMEDIATE MEASURES: FIRST AID AND PREHOSPITAL CARE

All patients who may have been bitten by a venomous snake should be taken to a health care facility as soon as possible. The most important principle of first aid for snakebite victims is, "*Primum non nocere*," that is, "First, do no harm." First-aid measures have never been proven to decrease morbidity or mortality from crotaline envenomations. One study found no differences in clinical courses between those patients who did and those who did not receive first aid.⁹ In fact, more recent research found nearly a threefold increase in necrotic and infectious complications that required surgery in patients who received first-aid treatments, such as cryotherapy (ice), cut and suck, tourniquets, or superficial constriction bands.¹¹

Pros and cons of first-aid measures have been discussed in detail elsewhere, and first-aid recommendations are summarized in Table 21A-10.^{12,57,58} First aid should never be considered a substitute for definitive medical care and should never delay in-hospital admin-

istration of antivenom, if indicated. Any delay can be fraught with danger. The most helpful first-aid tool is a cellular phone. This allows rapid summoning of emergency medical services (EMS) without moving the victim. Walking decreased transit time of ersatz venom in a human study.⁵⁹ All patients who may have been bitten by a venomous snake should be taken to an appropriate health care facility as soon as possible. Rapid EMS transport is the safest form of first aid and prehospital care for snakebite.

First aid and prehospital measures for snakebite can be considered to fall into three categories: (1) those that may be helpful and are unlikely to be harmful, (2) those that are controversial and may become harmful, and (3) those that are unhelpful or harmful.

First aid and/or prehospital care that is likely to be helpful, or at least not harmful, includes applying a sling to bitten upper extremities and keeping the bite site in a neutral position (i.e., at heart level). Another reasonable prehospital EMS intervention is to start a large-bore intravenous line in a nonbitten extremity to infuse

isotonic crystalloid. This serves as an intravenous lifeline to allow administration of isotonic crystalloids if noticeable swelling begins.

Although snake identification may be helpful, it is unnecessary to capture or kill the snake for identification. Attempts to capture or kill the snake could result in more bites to the victim and bites that could turn potential rescuers into victims.^{57,58} Administration of either Crotalidae Polyvalent Immune Fab (ovine) antivenom (Protherics, Nashville, TN) or Antivenin (Crotalidae) Polyvalent (equine origin) (Wyeth-Ayerst, Philadelphia, PA) is effective for all crotaline envenomations and does not require definitive identification of the envenomating crotaline.^{31,57,58}

Controversial crotaline bite first aid and prehospital measures that may become harmful include use of constriction bands, and splints involving constriction bands. Most researchers use the term *constriction band* to describe a device that impairs efflux of superficial venous and lymphatic flow from bitten extremities (see Table 21A-10).^{42,57-62} Although some studies with envenomated animals and one human study with ersatz venom indicated decreased efflux from extremities with constriction bands, no human clinical studies have proven the safety or efficacy of this practice.⁵⁹⁻⁶² An animal study showed that systemic absorption of crotaline venom was decreased with constriction band therapy using a sphygmomanometer cuff with the pressure maintained at 45 mm Hg. Continual adjustments, allowing air to escape from the cuff, were necessary to avoid limb-threatening constriction as the envenomated animal's leg swelled.⁶⁰ Continual cuff adjustments would be difficult in first aid and prehospital care. In addition, the 45 mm Hg cuff pressure exceeds the normal capillary perfusion pressure of about 30 mm Hg. Another animal study found that elastic wrapping of an envenomated

extremity at 55 mm Hg and splinting decreased systemic absorption of Australian elapid venom; however, Australian elapid venom causes minimal tissue edema.⁶¹ This study also showed that splinting alone or pressure wrapping alone did not limit systemic venom absorption. Both techniques had to be used simultaneously to limit venom absorption.⁶¹ Another study used similar elastic wrapping and splinting and showed decreased systemic absorption of Eastern diamondback rattlesnake venom; however, the high pressure (initially 55 mm Hg) could cause extreme pain in a swollen envenomated extremity and could cause limb-threatening ischemia as swelling increased.⁶² Splinting the envenomated limb is also controversial because splinting involves circumferential elastic wrapping that could also compromise limb perfusion as swelling increases because of crotaline envenomation. In summary, constriction bands have not been studied clinically in North American patients with crotaline envenomations; therefore, their safety and efficacy are unproven and we do not recommend them. A constriction band could turn what is uncommonly a life-threatening event (0.1%) into a limb-threatening event (see Table 21A-2).⁶

The remaining first aid and prehospital measures are mentioned only to condemn them, because they are either ineffective or dangerous.^{31,42,57,58;}

1. Do not incise fang marks.^{1,57,58} Incision by persons without training or experience can result in damage to deep structures and can introduce infection and exacerbate tissue necrosis.^{31,57,58}
2. Do not use oral suction. Oral suction can introduce human oral flora and carries the theoretical possibility of causing a human bite infection.^{31,57,58} Oral suction can also result in envenomation of the lips and/or mouth if the lips are cracked or have lesions or if there is a break in the oral mucosa.
3. Do not apply ice or immerse the envenomated extremity in ice, ice water, or snow.^{4,31,57,58,63} So-called cryotherapy can result in profound tissue necrosis due to further vasoconstriction and ischemia in marginally perfused tissues.^{4,31,57,58}
4. Do not apply a tourniquet that would result in obstruction of deep venous or arterial flow. This will exacerbate ischemia, infarction, and necrosis in a limb that already may have marginal perfusion due to envenomation. A tourniquet also endangers a limb in which a patient has received a dry bite, without any envenomation or risk of morbidity.^{4,31,57,58,63}
5. Do not use electric shock to treat snakebites.^{53,57,58,64-68} Studies have shown that electric shocks are ineffective, and clinical experience has shown that they can be dangerous.

Newly published data on extraction devices do not support their use.⁶⁹⁻⁷² In a study from the 1980s, radiolabeled crotaline venom was injected into rabbits and an extraction device was applied 3 minutes after injection. After 3 minutes of suction (i.e., 6 minutes after venom injection), 23% of the injected venom was removed by the extraction device. Thirty-four percent of radiolabeled

venom was removed after suction for 30 minutes (i.e., 33 minutes after injection).⁷³ The same group published data on use of extraction devices in patients in an abstract describing three people bitten by rattlesnakes.⁷⁴ Two of the three patients exhibited clinical signs of envenomation, and venom was recovered from the wounds of these two patients with an extraction device. The device was left in place until its cup filled with serosanguineous fluid; this was repeated five times in each patient. The largest portion of venom was recovered during the initial application of the extraction device. The clinician should be aware that both of these references are abstracts and include small numbers of subjects. These abstracts raised questions regarding use of extraction devices: Does removal of some portion of injected venom improve the patient's clinical course? Do such devices concentrate venom at the bite site and result in more bite site necrosis? Use of these devices remained unproven and controversial until recently.⁶⁹⁻⁷² The weight of evidence now does not support the use of extraction devices.⁶⁹⁻⁷² Bush and colleagues found that an extraction device did not reduce swelling in a randomized, controlled trial injecting rattlesnake venom into study pigs. In fact, some pigs developed circular lesions at the site of application of the extraction device, and these lesions subsequently necrosed and sloughed, with prolonged healing.⁷¹ Similar local lesions have been described in humans after use of these devices.^{70,72} Alberts and colleagues found that an extraction device removed virtually no mock venom (radiolabeled albumin) in a simulated snakebite model in human volunteers.⁶⁹

Hospital Care

When a snakebitten patient arrives at the hospital, the clinician should perform a standard primary survey and resuscitation ("A,B,C,D,E").³⁰ Most patients will not require airway or breathing interventions such as oxygen administration or endotracheal intubation, because most crotaline envenomations are not life threatening.⁶ However, patients with signs or symptoms of dyspnea or hypoxia should receive oxygen and assisted ventilation, if necessary. Endotracheal intubation should be performed for the usual indications.³⁰ Prompt endotracheal intubation is necessary for any patient with any signs of envenomation to the lips, tongue, head, or neck.^{46,51,52} Endotracheal intubation must be done as soon as possible, before massive swelling of the airway occurs, which would make endotracheal intubation difficult or impossible, and because cricothyroidotomy would be extremely difficult in the presence of a swollen neck and venom-induced coagulopathy. Not only are airway patency and breathing in danger of being compromised as a result of head and neck envenomations, but also because of rare occurrences of anaphylactoid, angioedematous reactions involving the upper airway caused by intravenous or perivenous envenomations and also because of rare envenomations being associated with acute adult respiratory distress syndrome (ARDS).^{29,53,54,75}

Cardiovascular resuscitation is critical in moderate and severe crotaline envenomations with marked third

spacing of plasma into subcutaneous tissue and extravasation of erythrocytes through damaged microvasculature. Intravascular volume resuscitation should be guided by the usual clinical parameters (e.g., administering enough intravenous isotonic crystalloids to relieve the patient's thirst and to produce urine output of at least 1 mL/kg/hr).^{29,53,75,76}

Basic neuromuscular resuscitation involves endotracheal intubation with mechanical ventilation for those uncommon patients with moderate to severe Mojave toxin envenomations that produce neuromuscular blockade and ventilatory insufficiency.^{16-23,25,27} Ventilatory insufficiency can also develop because of a decreased level of consciousness due to shock and hypoperfusion of the brain,⁵³ in rare cases of snakebite complicated by seizures,⁴ and in rare cases of intravenous or perivenous envenomations associated with coma.⁵⁴

Basic resuscitation to preserve the organs of elimination (i.e., the liver and kidneys) is directed primarily at preserving renal perfusion and urine output. The liver is rarely damaged by crotaline venom poisoning. Occasionally, the kidneys are damaged by acute tubular necrosis from hypoperfusion and hypovolemia or by myoglobinuric renal failure from rhabdomyolysis.^{9,27,29,45,55,76-78}

Other basic supportive care for crotaline snakebites includes cleansing the wound and keeping it clean and dry. We usually recommend application of a dry 4 × 4 gauze pad to the wound itself, without tape. Taping the dressing in place can result in vesiculation and formation of bullae caused by shearing forces from the tape on the skin as the affected extremity swells. Tetanus immunization should be given if needed.

Prophylactic antibiotics are not necessary for snakebite because there is no evidence that they are effective.^{79,80} Routine use of prophylactic antibiotics is no longer recommended. Broad-spectrum antibiotics are indicated only if signs of wound infection are present.^{7,79,80} Older recommendations to prophylactically administer antibiotics to patients with snakebite were based on studies of the oral flora of snakes and not on the incidence of wound infection after North American snakebites.⁸¹

ADMINISTRATION OF THE ANTIDOTES

Wyeth-Ayerst ACP has been commercially available in the United States since 1954 (Table 21A-11).⁸² This antivenom, manufactured by immunizing horses with venom from four crotaline species, *Crotalus adamanteus* (Eastern diamondback rattlesnake), *C. atrox* (Western diamondback rattlesnake), *C. durissus terrificus* (South American or tropical rattlesnake), and *Bothrops atrox* (fer-de-lance),⁸³ is capable of neutralizing venom from all North, Central, and South American crotalines (see Table 21A-11).^{82,83} Because it is of equine origin, it can cause true anaphylactic reactions (type I hypersensitivity), anaphylactoid reactions, and serum sickness (i.e., immune-complex disease [type III hypersensitivity]).^{7,31,42,82,83}

A polyvalent, crotaline, ovine-derived, fragment antibody (Fab) antivenom has been developed (initially [premarketing], CroTab, Therapeutic Antibodies, Inc., Nashville, TN; however, now [postmarketing], CroFab, Protherics, Nashville, TN). This new polyvalent

**TABLE 21A-11** United States Crotaline Antivenoms

antivenom was developed by immunizing sheep with the venom from four North American crotalines: *Crotalus atrox* (Western diamondback rattlesnake), *C. adamanteus* (Eastern diamondback rattlesnake), *C. scutulatus scutulatus* (Mojave rattlesnake with venom A), and *Agkistrodon piscivorus piscivorus* (Eastern cottonmouth) (see Table 21A-11). These venoms were chosen on the basis of their clinical importance in snakebites occurring in the United States and northern Mexico, the geographic ranges of the snakes, genetic dissimilarities of the four immunizing venoms, and cross-antigenicity with venoms from other clinically important crotalines. An animal study showed that CroTab was very effective.⁸⁴ Human studies also demonstrated CroTab's and now CroFab's efficacy.^{5,85-90} Premarketing CroFab is somewhat different than premarketing CroTab (Table 21A-12).⁹¹

Prior to administration of any medication, the clinician must ask a five-part question: What are the indications, contraindications, complications, dosage, and route of administration for the medication?³² Answers to the five elements of this general question are summarized for Wyeth-Ayerst ACP and CroFab in Table 21A-13.

Table 21A-11 compares and contrasts Wyeth-Ayerst ACP with CroFab.⁵

Wyeth-Ayerst ACP (Equine Origin)

Wyeth-Ayerst ACP is indicated in moderate and severe cases of crotaline envenomation and in mild crotaline envenomations with progression (worsening) of clinical signs and symptoms. Progression is defined as worsening of the local injury, laboratory abnormalities, or systemic manifestations.⁴

The clinician should never be lulled into a false sense of security just because the patient and/or clinician knows the envenomation is from a copperhead bite because fatal copperhead bites have been reported.^{87,92-95} We have consulted on an intravenous or perivenous copperhead bite to a patient's medial malleolus that

TABLE 21A-12 Minimum Mouse Median Lethal Dose (LD₅₀) Neutralizing Units per Vial

VENOM	PREMARKETING CROTAB	POSTMARKETING CROFAB
<i>Crotalus adamanteus</i>	1805	800

resulted in shock, ventilatory failure, seizure, and coma and required immediate endotracheal intubation, mechanical ventilation, massive intravenous fluid administration, and antivenom therapy. Ultimately, the patient recovered without permanent sequelae.

Relative contraindications to Wyeth-Ayerst ACP include a history of horse product allergy, a history of previous allergic reaction to Wyeth-Ayerst ACP, and inability of the clinician to manage an anaphylactic or anaphylactoid reaction in a patient with a life-threatening envenomation (see Table 21A-11).³² Absolute contraindications to Wyeth-Ayerst ACP include lack of informed consent and inability of the clinician to manage an anaphylactic and/or anaphylactoid reaction in a patient without a life-threatening envenomation.

The main complications of Wyeth-Ayerst ACP are anaphylactic reactions (type I hypersensitivity), anaphylactoid reactions, and serum sickness (type III hypersensitivity).^{7,31,42} Anaphylactic or anaphylactoid reactions are immediate complications of antivenom therapy that occur during antivenom administration. Serum sickness, an immune-complex disease, is a delayed complication of antivenom administration.

Anaphylactic and anaphylactoid reactions are indistinguishable clinically, but differ on the basis of pathogenesis.⁹⁶⁻⁹⁸ An anaphylactic reaction is a type I

TABLE 21A-13 Guidelines for Use of Crotaline Antivenoms

5 GENERAL QUESTIONS		ANSWERS FOR CROTALINE ANTIVENOMS	
Indications		Mild crotaline envenomations with progression Moderate and severe crotalid envenomations	
Contraindications		Relative contraindications Horse product allergy (Wyeth-Ayerst) Sheep product allergy (CroFab) Papaya or papain allergy (CroFab) Inability to manage anaphylactic and anaphylactoid reactions with life-threatening envenomations Absolute contraindications Refusal after informed consent Inability to manage anaphylactic and anaphylactoid reactions with non-life-threatening envenomations	
Complications		Immediate Anaphylactoid reactions Anaphylactic reactions (type I hypersensitivity, IgE mediated) More common with Wyeth-Ayerst Less common with CroFab Delayed Serum sickness (type III hypersensitivity; antigen-antibody, immune complex mediated) Virtually inevitable with Wyeth-Ayerst Uncommon with CroFab Recurrent coagulopathy Less common with Wyeth-Ayerst More common with CroFab

hypersensitivity reaction, an anamnestic reaction, that requires initial exposure to an antigen that resulted in production of immunoglobulin E (IgE) antibody that attaches to mast cells via its Fc portion. After this initial sensitization step, reexposure to even the smallest concentration of the inciting antigen elicits an anaphylactic reaction due to the antigen binding to preformed IgE attached to mast cells, resulting in degranulation of mast cells with release of histamine and other mediators. Anaphylactoid reactions also result in release of histamine and other mediators from mast cells, but this release is not dependent on IgE. Another important distinction between anaphylactic and anaphylactoid reactions is that the smallest concentrations of the antigen will elicit an IgE-dependent anamnestic response in true anaphylactic reactions; however, substances that elicit anaphylactoid reactions are not acting as antigens for preformed IgE, and therefore the smallest concentrations of these substances will not necessarily elicit an anaphylactoid reaction.⁹⁶⁻⁹⁸ In other words, anaphylactoid reactions are elicited in a fashion that is dependent on concentration, rate, route, and dose.

This has important therapeutic implications, especially when administering heterologous proteins such as Wyeth-Ayerst ACP. By maximally diluting the Wyeth-Ayerst ACP and administering it slowly, anaphylactoid

reactions can be modulated or prevented. True IgE-mediated anaphylactic reactions cannot be prevented with dilution or slower administration. One study showed a 23% incidence of anaphylactic or anaphylactoid reactions in patients treated with Wyeth-Ayerst ACP. Half of these patients manifested only cutaneous signs and symptoms, whereas half of the affected patients manifested systemic signs and symptoms. Treatment of these antivenom reactions was uniformly effective, with no mortality, minimal morbidity, and no permanent sequelae.⁹⁹ Another study found that 14% of antivenom-treated patients developed urticaria, 10% developed pruritus, 6% suffered hypotension, 1% suffered bradycardia, and 1% suffered apnea that investigators thought was related to antivenom administration.⁹ No patient in this study suffered permanent sequelae from any of these complications. A third study found that 14% of antivenom-treated patients developed a rash, 4% developed a rash and fever, and 14% suffered hypotension and/or respiratory distress.¹⁰⁰

Serum sickness, a subtype of type III hypersensitivity, is an immune-complex disease due to antigen-antibody complexes.¹⁰¹ Clinically, serum sickness can manifest the following signs and symptoms: fever, malaise, urticaria, lymphadenopathy, myalgias, arthralgias, and, rarely, vasculitis, glomerulonephritis, or neuritis.^{82,101} Onset of

serum sickness after Wyeth-Ayerst ACP administration usually occurs 3 days to 3 weeks after administration, with an average onset of about 1 week.

The incidence of serum sickness seems dose related. One study found an 83% incidence of serum sickness in patients who received more than eight vials of Wyeth-Ayerst ACP versus a 38% incidence in patients who received less than eight vials; however, due to the small sample size, this difference was not statistically significant.⁹⁹

Dosage of Wyeth-Ayerst ACP is determined by the victim's degree of envenomation and has nothing to do with the victim's age or weight.^{4,32,56} This is because antivenom neutralizes a specific amount of venom. Clinically, the amount of venom is estimated by the effect that the venom has on the patient. This can be estimated by various grading systems (see Box 21A-1 and Tables 21A-7 to 21A-9).^{32,56}

When the decision for antivenom therapy has been made, it is important to note that the recommended dose of antivenom has increased over the years.⁴ Although regional differences have been noted, 10 vials (given intravenously) of Wyeth-Ayerst ACP is the initial dose in all treated rattlesnake envenomations.^{32,42} In rapidly progressive envenomations or in those with hemodynamic instability, up to 20 vials of Wyeth-Ayerst ACP may be required initially, in addition to aggressive resuscitation.^{7,32,42} After the initial antivenom administration, serial laboratory data should be obtained every 4 hours and serial physical examinations at least hourly for evidence of continuing progression (i.e., worsening of clinical signs and/or laboratory data). Repeat antivenom therapy, usually in the range of 10 to 20 vials of Wyeth-Ayerst ACP at a time, may be necessary, until the patient's condition becomes stable.^{7,42}

The route of antivenom administration is always intravenous.^{7,32,42} Intravenous administration allows systemic antivenom distribution to counteract systemic venom effects and allows precise titration of antivenom to help prevent or modulate anaphylactoid reactions that are dependent on concentration, rate, and dose. Antivenom should not be administered intramuscularly or into the wound area.

Prior to intravenous administration of Wyeth-Ayerst ACP, a skin test can be administered.^{7,31,32,42,83,100} The skin test should only be given after the physician has decided to administer antivenom, based on progression of signs or symptoms in mild to moderate crotaline envenomations or based on a severe envenomation at presentation (see Box 21A-1 and Tables 21A-7 to 21A-9). This should be done after the patient has given informed consent, if possible, and before any antihistamines are given. Skin testing can sensitize patients to horse antigens and has resulted in life-threatening anaphylactic and anaphylactoid reactions. Antihistamines can mask the signs of a positive skin test, which can include a wheal and/or flare response larger than 10 mm in diameter, urticaria, and systemic anaphylactic or anaphylactoid reactions. A wheal and/or flare reaction larger than 10 mm in diameter is all that is necessary to declare a skin test result positive.^{7,31,32,42,83} Prior to the administration of

the skin test, the clinician should read the package insert and call a consultant in medical toxicology or a regional poison center, unless he or she has sufficient experience in administering the skin test and treating crotaline-envenomated patients. A clinician and all equipment and drugs necessary to manage anaphylactic and anaphylactoid reactions should be at the bedside. Two intravenous lines with isotonic crystalloid should be in place. The patient should be attached to a cardiac monitor, a pulse oximeter, and a blood pressure monitor.³² After these precautions are taken, 0.02 mL of a 1:10 dilution of normal horse serum is injected intradermally into one shoulder and 0.02 mL of normal saline control is injected into the other shoulder. The 1:10 diluted normal horse serum is already packaged, premixed, and ready for injection.⁸³ The control and horse serum sites should be observed for 30 minutes to see if wheal, flare, urticaria, or systemic anaphylactic or anaphylactoid reactions develop.^{7,31,32,42,83}

If the skin test result is positive, the clinician should reconsider using antivenom in mild and moderate envenomations and discuss the therapeutic pros and cons with the patient in light of the positive result.^{32,100} If antivenom will be given, we suggest pretreating the patient with diphenhydramine 1 mg/kg intravenously (50 mg in the average adult) and ranitidine 3 mg/kg intravenously* (150 mg in the average adult).³² Steroids are not necessarily indicated. Steroids have not been proven safe or effective in treatment of crotaline envenomation.^{4,63}

Concurrent with the skin test, the lyophilized Wyeth-Ayerst ACP should be mixed. The antivenom is diluted with enough bacteriostatic water or normal saline to fill the vial. Filling the vial completely helps prevent foaming.⁸³ Solubilization of the lyophilized antivenom may be facilitated with an automated blood vial rocker. Vigorous shaking of the antivenom denatures it. Foaming may indicate that some denaturation has occurred.⁸³

After solubilizing the lyophilized antivenom, we prefer to dilute the antivenom approximately 10:1 (i.e., dilute 10 vials of antivenom in 1 L of normal saline).^{32,83} Although this differs from more concentrated solutions recommended by some experts, it is the most dilute solution suggested in the *Physicians' Desk Reference*, and this more dilute solution may help prevent anaphylactoid reactions that are dependent on concentration, rate, and dose.^{31,42,83} For children, we dilute the initial dose of antivenom in enough normal saline so the patient will receive an antivenom infusion that does not exceed 20 mL/kg, the usual resuscitation bolus dose for crystalloid infusions in pediatric resuscitation.^{30,32} The dilute antivenom infusion should be started slowly and gradually increased over time to help prevent anaphylactoid reactions. We use the antivenom infusion guidelines detailed in Box 21A-3. The guidelines are based on an integration of product information from the

*Use of H₂ histamine blockers for prophylaxis and treatment of allergic reactions is a common, but off-label, prescribing practice.

BOX 21A-3 ANTIVENOM INFUSION GUIDELINE FOR 10 VIALS OF WYETH-AYERST ANTIVENIN (CROTALIDAE) POLYVALENT DILUTED IN 1 LITER OF NORMAL SALINE

Start the antivenom infusion at no more than 60 mL/hr (1 mL/min)
 If no adverse reactions occur in 3 min, increase the drip rate to 120–125 mL/hr
 If no adverse reactions occur in 3 min, increase the drip rate to 240–250 mL/hr
 If no adverse reactions occur in 3 min, increase the drip rate to 480–500 mL/hr
 If no adverse reactions occur in 3 min, increase the drip rate to 960–1000 mL/hr

Physicians' Desk Reference, our own clinical experience, and guidelines from other experts.^{7,31,32,42,83} We believe these to be reasonable guidelines, although they have never been validated by a clinical trial. Although life-threatening anaphylactic or anaphylactoid reactions can occur at any time during antivenom infusion, they usually occur while the infusion rate is gradually increased to the maximum of 960 to 1000 mL/hr. It is prudent to have a clinician able to manage all aspects of anaphylaxis at the bedside, until the maximum infusion rate of 960 to 1000 mL/hr has been achieved without complications.

If signs or symptoms of an anaphylactic or anaphylactoid reaction occur during antivenom infusion, one should immediately stop the infusion and treat the patient with intravenous diphenhydramine and ranitidine, or other H₁ and H₂ antagonists. If these steps do not achieve the desired result, epinephrine and steroids (considering glucagon in patients on β -blocker therapy), should be administered, as in any anaphylactic or anaphylactoid reaction. If the clinician has not yet consulted with a regional poison control center or medical toxicologist, he or she should do so at this time.

Life-threatening crotaline envenomations complicated by anaphylactic and/or anaphylactoid reactions to antivenom have been treated with concomitant antivenom and intravenous epinephrine infusions.^{7,31,32,42,99,102} Intravenous epinephrine is titrated to effect during antivenom infusions in which the risk-benefit ratio seems to favor administration of antivenom. We are involved in a handful of such cases each snakebite season. To date, the authors' patients have suffered no permanent sequelae from this treatment.

Surgery is rarely necessary for crotaline envenomation. Almost 30 years ago, surgery was recommended by some as the primary treatment for crotaline envenomations with early excisional débridement or fasciotomy^{103,104}; however, animal and human studies do not support this position.¹⁰⁵⁻¹¹⁰

Fasciotomy should only be performed when clinical signs and symptoms of compartment syndrome are present and hourly, serially measured compartment pressures remain greater than 30 mm Hg despite elevation of the affected limb and administration of 20 vials of Wyeth-Ayerst ACP or 6 to 12 vials of CroFab.^{7,31,32,42} This 30 mm

Hg pressure limit is based on the fact that capillary perfusion pressure is usually about 30 mm Hg.¹¹¹⁻¹¹³

Compartment perfusion pressure is also dependent on the patient's blood pressure.^{112,114-116} Significant decreases in compartmental perfusion occur when compartment pressures rise to within 30 mm Hg of the diastolic blood pressure.¹¹⁴ An experimental study found that CroFab limited the decrease in perfusion pressure in the anterior leg compartment in a porcine, crotaline envenomation model.¹¹⁷ Another study found compartment muscle hypoperfusion and anaerobic metabolism when compartment pressures were within 30 mm Hg of the mean arterial pressure (MAP) in nontraumatized muscles.¹¹⁶ In traumatized muscles, compartment hypoperfusion and anaerobic metabolism occurred when compartment pressures were within 40 mm Hg of the MAP.¹¹⁶

The duration of clinical signs and symptoms of compartment syndrome also relates to prognosis. If compartment syndrome signs or symptoms are allowed to persist for 12 hours or more, residual functional deficits almost always occur. Series of patients who undergo fasciotomy within 12 hours of onset of signs or symptoms of compartment syndrome have from 0% to 17% incidence of residual functional deficits.^{112,118}

To allow for maximum antivenom dosing and effect, it is reasonable to obtain a few hourly serial compartment pressures if the patient has signs or symptoms of compartment syndrome and the initial pressure was elevated.^{7,31,32,42} Consider fasciotomy if the compartment pressure stays pathologically elevated after infusion of at least 20 vials of Wyeth-Ayerst ACP or 6 to 12 vials of CroFab, with elevation of the affected extremity, and well before the patient has had symptoms or signs of compartment syndrome for 12 hours.^{7,31,32,42,112,118} Guidelines for management of potential compartment syndromes from crotaline envenomations have been published.⁴²

Some experts advocate intravenous mannitol to decrease compartment pressures.^{7,31,42} We are unaware of any published experimental or clinical data on mannitol therapy for suspected compartment syndrome from crotaline envenomations and have not used this therapy to date. When considering whether to administer mannitol, the clinician must realize that an antivenom infusion is hyperosmolar and a large volume load. If mannitol, 1 to 2 g/kg, were administered in addition to this, the patient would receive a significant osmotic and volume challenge that could compromise patients with tenuous cardiopulmonary or kidney function. If using CroFab and mannitol, the clinician should be aware of possible increased renal clearance of the antivenom, thereby altering its half-life. In addition, both crotaline antivenoms and mannitol have been associated with anaphylactoid reactions, believed to be related in part to their hyperosmolarity. This is similar to anaphylactoid reactions that occur with hyperosmolar radiographic contrast media.

Surgical débridement of frankly necrotic tissue is reasonable. However, it is difficult to determine which tissue is frankly necrotic and which tissue may still be viable early in the course of snake venom poisoning. In

addition, necrosis occurs in a minority of patients with snake venom poisoning.⁴ In Russell's series of 100 snakebitten patients in Southern California, 27% developed some necrosis of local tissue.⁴ Bullae are usually left intact unless they are on digits and are circumferential or are becoming circumferential and appear to compromise digital perfusion as evidenced by lower skin temperatures measured with a thermistor, by narrower pulse volume amplitude measurements from a Doppler flowmeter, or by lower oxygen content on pulse oximetry distal to a proximal blister.^{32,109} Pulse oximetry through a hemorrhagic blister itself is not necessarily accurate, due to the presence of deoxyhemoglobin in blood of the blister. Digital dermatomy has been recommended by some.¹¹⁹ Potential complications of any surgical procedure include infection, scarring, and anesthetic complications.

Patients who may have had a snakebite from a North American Crotalinae require medical observation for at least 12 hours because development of signs and symptoms of envenomation may be insidious.^{7,120,121} During this observation period, hemoglobin, hematocrit, prothrombin time, partial thromboplastin time, fibrinogen, fibrin split products, and platelets should be assayed on presentation and every 4 hours thereafter to assess for development of venom-induced coagulopathies. Every 15 to 60 minutes, the patient's affected extremity should be palpated on both the medial and lateral aspects, starting proximally at the torso and gently moving distally until the leading edge of induration, edema, and tenderness is felt.^{7,31,42} This leading edge of induration, edema, and tenderness should be marked on the skin with the corresponding time of observation. If proximal progression of the leading edge of induration, edema, and tenderness occurs, the patient should be admitted and treated with antivenom after his or her informed consent is obtained.^{7,31,32,42} Antivenom administration requires an intensive care setting within the emergency department or intensive care unit. If the patient has a coagulopathy on initial presentation or develops one during observation, he or she should be admitted and receive antivenom after informed consent has been given.^{7,31,42} If after 12 hours of close clinical observation and serial laboratory tests the clinician is certain that the snakebite was of Crotalinae origin, and the patient has no sign of snakebite other than punctures or abrasions (i.e., no signs of envenomation and no coagulopathy), a reliable patient can be sent home with instructions to return immediately if he or she notes any of the following: increase in pain; onset of redness, swelling, fever, or pus formation; bruising; bloody nose; red or dark urine; weakness; nausea or vomiting; faintness; dyspnea; diaphoresis; or any sign or symptom other than the mildest pain at the bite site.^{7,31,42,120,121}

CroFab: Crotalidae Polyvalent Immune Fab (Ovine)

CroFab was approved by the U.S. Food and Drug Administration (FDA) on October 2, 2000. FDA labeling states that CroFab is indicated for the management of patients with minimal or moderate North American crotaline envenomations (see Table 21A-9).⁹¹ In practice,

the indications for CroFab are moderate or severe cases of crotaline envenomation and mild crotaline envenomation with progression (worsening) of clinical signs and symptoms (see Table 21A-9).

Relative contraindications for CroFab include a history of allergic reactions to sheep products, papaya, papain, chymopapain, and other papaya extracts; the pineapple enzyme bromelain; dust mites, and latex. CroFab is obtained from sheep immunized with North American crotaline venoms, and papain, a papaya derivative, is used to separate the Fab fragments from the Fc fragments of the immunoglobulins. Bromelain, some dust mite allergens, and some latex allergens share antigenic structures with papain. Obviously, when a relative contraindication is present, the treating clinician must carefully weigh the risks and benefits of CroFab versus the risks of the envenomation. The decision to administer CroFab in a patient with a known relative contraindication is a decision that the treating clinician must make in consultation with the patient. In addition, we recommend that the clinician remain at the bedside for the first administration of CroFab with all critical care equipment and resuscitative medicines at hand.

Absolute contraindications to CroFab are a patient's refusal after informed consent, requiring the patient to be awake, alert, fully oriented, with a clear sensorium, or the inability of the clinician to manage an anaphylactic and/or anaphylactoid reaction in a patient without a life-threatening envenomation.

The main complications of CroFab include anaphylactic and anaphylactoid reactions and serum sickness as well as failure to achieve initial control of local effects; recurrence of local effects, low platelets, elevated protime, high partial thromboplastin time (PTT), low fibrinogen, and hospital readmission; late onset of low platelets, high protime, high PTT, and low fibrinogen; persistent low fibrinogen; and clinical bleeding with recurrent low fibrinogen or late onset of low platelets.

The evidence base for Crotalidae polyvalent immune Fab (ovine) includes two premarketing CroFab studies (Box 21A-4) and four postmarketing CroFab studies, to date. These six studies are summarized in Table 21A-14, with more detailed information from these studies in Tables 21A-15, 21A-16, 21A-17, and 21A-18.

Immediate hypersensitivity (i.e., anaphylactic reactions and anaphylactoid reactions) occurred in 6% of patients (i.e., 8 of 129 patients) in the two premarketing CroFab and four postmarketing CroFab case series published to date (see Table 21A-18).^{5,85-90} This incidence of immediate hypersensitivity reactions with CroFab is less than the reported incidence of immediate hypersensitivity reactions to Wyeth-Ayerst antivenom. No hypersensitivity reactions were reported in the first premarketing and the first two postmarketing studies.^{85,86,90} In the second premarketing study, 6 of 31 patients (20%) had immediate hypersensitivity reactions to CroFab. On further analysis, 3 of 31 patients (10%) had CroFab that had been incompletely purified of the Fc fragment, which is more allergenic; however, 3 of 31 patients (10%) received normal CroFab. In other

words, immediate hypersensitivity was equally frequent in patients who received standard CroTab and in those who received a batch of CroTab with excess Fc. Therefore, standard CroTab can cause immediate

hypersensitivity.⁸⁸ In the two most recent postmarketing case series of CroFab published to date, one patient in each series had an immediate hypersensitivity reaction: 7% in Bush and colleagues' case series and 3% in Lavonas and colleagues' case series.^{5,87} In summary, although immediate hypersensitivity reactions to CroFab are uncommon, varying from 0% to 20% in published case series, with an average incidence of 6%, we recommend that the patient give informed consent and that all equipment and drugs necessary to manage immediate hypersensitivity reactions be at the bedside.^{7,31,32,42} A clinician capable of managing immediate hypersensitivity reactions should also be at the bedside. Two intravenous lines with isotonic crystalloid should be in place. The patient should be attached to a cardiac monitor, a pulse oximeter, and a blood pressure monitor. These precautions generally require that the patient be managed in an intensive care setting in the emergency department or intensive care unit.

Overall, delayed hypersensitivity reactions were reported in 8% of patients (i.e., 11 of 129 patients) in the two CroTab premarketing and four CroFab postmarketing published studies (see Table 21A-18).^{5,85-90} No patients who received only CroTab had delayed hypersensitivity reactions reported in the first CroTab premarketing study; however, only 8 of 11 had follow-up for 14 days to assess for delayed hypersensitivity.⁸⁶ In the second premarketing study of CroTab, 6 of 31 patients (19%) developed delayed hypersensitivity reactions to CroTab; however, 5 of the 6 had received a batch of CroTab that had incomplete removal of Fc fragments, predisposing them to greater allergenicity (see Table 21A-18).⁸⁸ This predominance of delayed hypersensitivity in patients who received the batch of CroTab that

BOX 21A-4 CROTAB PREMARKETING CLINICAL TRIALS

Study Design

Prospective
Multicenter
Open-label (unblinded)
No control group

Inclusion Criteria

Age: ≥10 years
Mild to moderate North American crotaline envenomation
With progression: worsening clinical signs or lab values
< 6 hr since snakebite

Exclusion Criteria

Copperhead (*Agkistrodon contortrix*) bite
Dry bite: no venom effects
Lack of progression (worsening) of clinical signs or lab values
Severe crotaline envenomation on presentation
>1 vial of Wyeth-Ayerst antivenom
Significant preexisting comorbidity
Sheep allergy
Systemic steroids within 4 wk
Experimental medications within 4 wk
Pregnancy
Lactation
Inability to give informed consent
Previous entry in this study

had excess Fc fragments is in contradistinction to the equal incidence of immediate hypersensitivity reactions between those patients who did and those who did not receive batches of CroFab with excess Fc fragments in the second premarketing study (see Table 21A-18).^{86,88} Only 26 of 31 patients had 14-day follow-up to assess for delayed hypersensitivity in the second CroTab premarketing study.⁸⁸ In the first postmarketing study of CroFab, 2 of 28 patients (7%) had delayed hypersensitivity (see

Table 21A-18).⁸⁵ All patients in this study had 14 days of follow-up by phone to assess for delayed hypersensitivity. The second published postmarketing study of CroFab had no patients with delayed hypersensitivity (see Table 21A-18).⁹⁰ All patients in this study had clinic or phone follow-up for at least 1 month. In the third postmarketing CroFab study, 1 of 15 patients (7%) had delayed hypersensitivity (see Table 21A-18).⁵ All patients in this study had follow-up for at least 21 days. In the fourth

extant case series with CroFab, 1 of 32 patients (3%) had delayed hypersensitivity (see Table 21A-18).⁸⁷ However, only 6 of 32 patients had follow-up for at least 21 days. In summary, in the two premarketing CroTab studies and the four postmarketing CroFab studies, 95 patients had follow-up for at least 2 weeks to assess for delayed

hypersensitivity. Overall, 5 of 95 patients (5%) had delayed hypersensitivity reactions to CroTab or CroFab, with no confounding variables such as excess Fc or concurrent Wyeth-Ayerst antivenom.^{5,85-90} Confounding variables existed for 6 of 95 (7%) patients with delayed hypersensitivity reactions who had follow-up for at least

14 days.^{86,88} One patient with delayed hypersensitivity in the first CroTab premarketing study also received 10 vials of Wyeth-Ayerst antivenom because 8 vials of CroTab had failed to control the local effects.⁸⁶ Delayed hypersensitivity reactions occur in almost all patients receiving 10 vials of Wyeth-Ayerst antivenom. When all patients with and without confounding variables are included for the analysis of the overall incidence of delayed hypersensitivity reactions, 11 of 95 patients (12%) had delayed hypersensitivity (see Table 21A-18).^{5,85-90}

Failure to achieve initial control of local effects within 12 hours occurred in 3 of 129 patients (2%) and involved the first premarketing CroTab study and the fourth postmarketing CroFab study (see Table 21A-15).^{5,85-90}

Failure to achieve initial control of local effects within 12 hours of envenomation first occurred in one patient in the first CroTab premarketing study, in which the maximal dose of CroTab was only 8 vials.⁸⁶ This patient received an additional 10 vials of Wyeth-Ayerst antivenom to control spread of local effects, spreading from his entire right upper extremity onto his chest. Local effects were halted with the additional 10 vials of Wyeth-Ayerst antivenom. The remaining two patients with failure to achieve initial control of local effects within 12 hours occurred in the most recent CroFab postmarketing case series of patients envenomated by the copperhead (*Agkistrodon contortrix*).⁸⁷ In one patient, local effects continued after receiving four vials of CroFab but stopped when an additional four vials were given 17 hours later. In the other patient, local effects continued to progress for 31 hours in spite of 24 vials of CroFab. The first two patients with failure to achieve initial control of local effects within 12 hours might be attributable to underdosing of CroTab or CroFab; however, the third patients received 24 vials of CroFab within 31 hours and local effects continued to progress.⁸⁷ These data highlight the fact that treatment with antivenom involves empiric titration of dose to achieve initial control.

Overall, local effects recurred in 20 of 129 patients (16%) in the six published CroFab studies (see Table 21A-16).^{5,85-90} The incidence of recurrent local effects in individual studies varied between 0% and 25%. Recurrence of local effects were prevented in the second premarketing CroTab study with scheduled administration of two vials of CroFab, repeatedly, 6, 12, and 18 hours after achievement of initial control.^{88,89} In contrast, patients who received nonscheduled dosing of CroFab after initial control (i.e., repeat CroTab dosing on an as-needed basis) had a 50% incidence of recurrent local effects in 8 of 16 patients.^{88,89} This study finding is the basis for the recommended scheduled dosing with two vials of CroFab, repeatedly, 6, 12, and 18 hours after achievement of initial control.^{88,89} Recurrent local effects occurred in some patients in all four postmarketing CroFab studies, in spite of receiving scheduled dosing of two vials of CroFab, repeatedly, 6, 12, and 18 hours after achieving initial control.^{5,85,87,90} This highlights the fact that treatment with antivenom is an empiric titration, not only to achieve initial control, but to treat recurrent local effects.

Recurrent coagulopathies, including low platelets and low fibrinogen, as well as high protime and PTT, occurred frequently in premarketing CroTab studies and postmarketing CroFab studies (see Table 21A-16).^{5,85-90} In premarketing CroTab studies, 38 of 42 patients had complete laboratory data for 14 days. Among these 38 patients, 28 (74%) had a coagulopathy before or within the first hour of treatment. Of these 38 patients, 14 (37%) developed thrombocytopenia, 22 (58%) developed hypofibrinogenemia, and 17 (45%) developed prolonged protime or PTT. Among the 38 patients, 20 (53%) developed multicomponent coagulopathies involving combinations of the preceding individual component coagulopathies. Coagulopathic abnormalities resolved in all patients with CroTab treatment; however, coagulopathies recurred in 20 (53%) patients (69% of the 28 patients with initial coagulopathy), within 2 to 14 days after envenomation. In other words, recurrent coagulopathies occurred in about half of all treated patients and in about two thirds of those patients with initial coagulopathies studies.^{89,122} The only CroFab postmarketing study that documented whether recurrent coagulopathies found them (see Table 21A-16).⁸⁵

Recurrent hospital admissions (readmissions) occurred in the first premarketing CroTab study and the first postmarketing CroFab study.⁸⁵ One of 11 patients (9%) in the first premarketing CroTab study developed recurrent hypofibrinogenemia, which was discovered when he had incision and drainage of thrombosed external hemorrhoids 12 days after envenomation. At the time, his fibrinogen was undetectable.⁸⁹ His hematocrit had been 36% on the second day after envenomation, and this decreased to 36% on his readmission, 12 days after envenomation. His local bleeding was controlled with pressure, and no blood products were administered. No CroFab was readministered.⁸⁹ In the first postmarketing CroFab study, 4 of 28 patients (14%) had recurrent hospital admissions for recurrent coagulopathies.⁸⁵ Three of these had no clinical bleeding. The fourth patient had spontaneous rectal bleeding for 2 days prior to readmission on the 10th day after his envenomation, with a platelet count of 15,000/mm³ at that time. This was a late-onset thrombocytopenia. His hemoglobin had also decreased from 36% at discharge from his previous admission to 30% on readmission for spontaneous rectal bleeding. He was retreated with a total of 18 vials of CroFab, which was temporally associated with a slow, gradual rise in his platelet count. Blood products were not administered and the patient had no further bleeding.⁸⁵

Late-onset coagulopathy manifested by low platelets, high protime, high PTT, or low fibrinogen occurred in 0% to 18% of patients in the two premarketing CroTab studies and four postmarketing CroFab studies. Pooled data for all pre- and postmarketing studies, in patients who had laboratory follow-up for individual coagulopathies for at least 2 weeks, indicated an overall incidence of late-onset thrombocytopenia of 4%, late-onset high protime of 3%, late-onset high PTT of 10%, and late-onset of hypofibrinogenemia 6% (see Table 21A-17).^{5,85-90}

Persistent coagulopathy with low fibrinogen was documented only in the two premarketing CroTab studies occurring in 1 of 11 patients (9%) in the first CroTab study and in 2 of 31 patients (6%) in the second CroTab study (see Table 21A-17).^{86,88,89} No persistent coagulopathies were documented in any postmarketing CroFab studies.^{5,85,87,90} Pooled data for premarketing CroTab and postmarketing CroFab studies indicate that 3 of 97 patients (3%) had persistent hypofibrinogenemia for up to 14 days of follow-up after envenomation.^{5,85-90}

Dosage of CroFab, like other antivenoms, is determined by the victim's degree of envenomation and has nothing to do with the victim's age or weight.^{4,32,56} This is because antivenom neutralizes a specific amount of venom. Clinically, the amount of venom is estimated by the effect that the venom has on the patient. This can be estimated by various grading systems (see Box 21A-1 and Tables 21A-7 to 21A-9).

According to the FDA-approved labeling, "administration of antivenom should be initiated as soon as possible after crotalid snakebite in patients who develop signs of progressive envenomation (e.g., worsening local injury, coagulation abnormality, or systemic signs of envenomation)." In other words, "time is tissue," analogous to reperfusion in acute myocardial infarction. CroFab was shown to be effective in the premarketing CroTab studies when given within 6 hours of snakebite.

Initial dosing of CroFab is empirically titrated to achieve what is called "initial control," defined as complete arrest of progression of local manifestations and return of coagulation tests and systemic signs to normal.⁹¹ If this initial control is not achieved with the first dose of CroFab, additional CroFab should be repeated until initial control of the envenomation syndrome has been achieved. After initial control has been established, additional two-vial doses of CroFab, every 6 hours for up to 18 hours (six additional vials) is recommended.⁹¹ In the studies reported to date, six vials of CroFab is the overall mean number of vials necessary to achieve initial control in a weighted average of 101 patients for whom these data were available (see Table 21A-15).^{5,85-90} The mean number of vials of CroFab needed to achieve initial control in the individual studies varied between 4 and 8 vials, with a dose range of 1 to 16 vials. The overall mean total dose of CroFab vials on the first admission for patients in pre- and postmarketing studies was 13 vials of CroFab, which is a weighted average for 97 patients for whom these data were available. The total dose range of CroFab vials in these studies varied between 1 and 47 vials.^{5,85-90}

It is important to remember that the FDA-approved package insert for CroFab, which recommends an initial dose of four to six vials, is based only on two premarketing CroTab studies with a total of 42 patients, all of whom had mild or moderate crotaline envenomations at the time of enrollment in the study (see Table 21A-14).^{86,88,89} Data in the second premarketing CroTab study and the third postmarketing CroFab study clearly indicate that up to 12 vials of CroFab may be necessary to achieve initial control (see Table 21A-15).^{86,89,90} In fact, the second postmarketing CroFab study had one patient

in whom 16 vials of CroFab were necessary to achieve initial control.⁹⁰

In summary, reasonable dosing guidelines for the initial number of CroFab vials are contained in Table 21A-13, with dose ranges for mild crotaline envenomations with progression (4 to 6 vials) and for severe envenomations (6 to 12 vials). For clinicians desiring an even simpler initial dosing regimen without ranges, a reasonable recommendation is an initial dose of 4 vials of CroFab for mild envenomations with progression, 6 vials of CroFab for moderate envenomations, and 12 vials of CroFab for severe envenomations. These initial dosing guidelines have not been validated by prospective randomized studies, but are reasonable recommendations based on the authors' experiences and review of dosing data in the six extant published studies regarding CroTab and CroFab.^{5,85-90}

Each vial of CroFab should be reconstituted with 10 mL of sterile water for injection and mixed by continuous gentle swirling.⁹¹ Studies have shown that CroFab reconstitutes more rapidly than the Wyeth-Ayerst antivenom.¹²³ The contents of the reconstituted vials should be further diluted in 250 mL of 0.9% sodium chloride and mixed by gentle swirling. The reconstituted and diluted products should be used within 4 hours. The antivenom infusion should be begun at no more than 50 mL/hr. If no adverse reactions occur in 3 minutes, then increase the drip rate to 125 mL/hr. If no adverse reactions occur in another 3 minutes, then increase the drip rate to 250 mL/hr. This dosing guideline will allow the entire 250 mL of reconstituted antivenom to be infused in slightly more than 1 hour. No skin test is recommended nor given prior to administration of CroFab.⁹¹

After achievement of initial control of the envenomation with CroFab and then scheduled dosing with two vials of CroFab, 6, 12, and 18 hours after achievement of initial control, further CroFab dosing is unnecessary unless or until recurrent local effects, or recurrent or late-onset coagulopathy, occurs. The optimal dosing for recurrent coagulopathy is unclear. Recurrent coagulopathies are difficult to treat and may not respond to copious amounts of repeated CroFab as evinced by dosing up to 47 vials of CroFab in one patient with late-onset thrombocytopenia.⁸⁵ Although 127 of 129 patients (98%) in the extant CroTab and CroFab studies had no clinical bleeding, 2 of 129 patients (2%) did have clinical bleeding. Based on these concerns, the most conservative recommendation is that all patients restrict their physical activity and avoid all contact sports and unnecessary driving or other activities that could be dangerous with resultant trauma for at least 2 weeks after any crotaline envenomation. Based on these data, it is also recommended that patients receive follow-up complete blood counts with platelets, as well as a protime, PTT, and fibrinogen, every 2 to 3 days for 2 weeks after discharge for crotaline envenomation.

When coagulopathies recur or have late onset in these patients, it is critical that the patient be informed of this and that they are at greater risk for bleeding with any trauma or surgical procedure. Surgical procedures should be deferred for at least 2 weeks after enven-

omation and until coagulation studies return to normal, if at all possible. In addition, patients should understand that they should return for clinical evaluation immediately if there are any signs of bleeding.

Redosing of CroFab in patients with recurrent coagulopathy is dependent on the individual clinician's and patient's degree of comfort or discomfort with the possibility of either spontaneous bleeding or bleeding with trauma or a surgical procedure. Researchers have promulgated guidelines for thresholds beyond which CroFab would be administered. Yip recommends giving CroFab in any patient with clinically significant bleeding and any abnormal coagulation parameter or when a symptomatic patient has developed multicomponent coagulopathy with an International Normalized Ratio (INR) of more than 3.0, a PTT of more than 50 seconds, a fibrinogen concentration of less than 75 mg/dL, and a platelet count of less than 50,000/mm³. He further recommends that the treatment should be continued until coagulation parameters are stabilized above what he calls critical values (i.e., INR more than 3.0, PTT more than 50 seconds, fibrinogen concentration less than 75 mg/dL and platelet count less than 50,000/mm³).¹²⁴ Boyer and colleagues recommend retreatment of recurrent crotaline coagulopathy with CroFab for the following indications: fibrinogen less than 50 µg/mL, platelet count less than 25,000/mm³, INR more than 3.0, PTT more than 50 seconds, any multicomponent coagulopathy, a worsening trend in the patient with prior severe coagulopathy, patients with high-risk behavior for trauma, and patients with comorbid conditions that increase hemorrhagic risk.¹²² Regardless of these published guidelines, each individual clinician and patient must be aware of the risks involved, and the patient must give informed consent to be treated with additional CroFab in the face of recurrent or late-onset coagulopathy. Optimal dosing with CroFab may also be limited by the fact that supplies of CroFab have been extremely limited since it was approved by the FDA. De facto rationing of CroFab has occurred in some regions due to shortages,

with clinicians trying to do the greatest good for the greatest number of crotaline-envenomated patients when supplies of CroFab are limited.^{92,125}

New Crotaline Antivenoms of the Future

A new antivenom, Antivipmyn (Fab)², is currently being studied and shows great promise.¹²⁶

Prognosis

Although any significant snakebite is potentially lethal, death is unusual (0.1%) after North American Crotalinae bites in cases reported to the American Association of Poison Control Centers (see Table 21A-2).⁶ The Western Envenomation Database, a consecutive case series of crotaline bites in which the Arizona Poison Control Center was consulted by clinicians from throughout the United States, reported a mortality rate of 1.4%.¹²⁷ This mortality rate may be artifactually high because the Arizona Poison Control Center commonly receives calls from throughout the United States for consultation on severe or unusual crotaline envenomations, resulting in potential selection bias. Selected details from the three fatal cases are provided in Table 21A-19. Common characteristics of these fatal cases include more proximal bite sites, bites due to *Crotalus* species, little or no intravenous fluid infusion in two patients, minimal or no antivenom administration, and nonaccidental upper extremity envenomations in two patients. One treating physician thought that one patient's bite was from a nonvenomous snake prior to the patient's fatal cardiorespiratory arrest 5 hours after the bite.¹²⁷

The Western Envenomation Database has also tabulated nonfatal sequelae from crotaline envenomations. Long-term morbidity (i.e., permanent sequelae) are more common in upper extremity and face bites. This may be caused by the circumstances of these bites. Most patients with upper extremity or facial bites were handling the snake at the time of the bite. Snakes that feel threatened from handling may inject larger amounts of venom. The

TABLE 21A-19 Fatal Crotaline Envenomations

STUDY PARAMETERS	PATIENT 1	PATIENT 2	PATIENT 3
Age (yr)	2	7	32
Sex	F	M	M
Bite site	Shoulder	Knee	Forearm
Snake	<i>Crotalus viridis</i>	<i>Crotalus</i> , unknown species	<i>Crotalus atrox</i>
Time to hospital	30 min	30 min	40 min
IV fluids	Very slow rate	No	Several liters
Antivenom	1 vial	No	4 vials, hours after shock ensued
Other therapy	No	No	Fasciotomy, steroids
Initial assessment by physician	Severe envenomation	Nonvenomous bite	Severe envenomation
Course	Cardiorespiratory arrest at 3 hr	Cardiorespiratory arrest at 5 hr	Prolonged hypotension and death at 16 hr
Circumstances	Nonaccidental; adult placed snake around child	Accidental, while playing	Nonaccidental; rattlesnake roundup

complexity of fine motor functions and sensation in the face and upper extremities may also be more easily impaired by venom effects, and disability would be more apparent. Most long-term morbidity involved weakness, pain, decreased range of motion, hypesthesia, paresthesia, anesthesia, or skin discoloration. The most common long-term morbidity was decreased range of motion. Only one amputation was necessary. This was an amputation of an envenomated finger.¹²⁷ These data suggest that a patient's physical therapy should begin as soon as possible after antivenom administration has halted progression of signs of envenomation and no further antivenom therapy is needed.^{42,127}

B Elapidae: North American and Selected Non-native Species

STEPHEN W. BORRON, MD, MS ■ PETER B. CHASE, MD, PHD ■ FRANK G. WALTER, MD

At a Glance...

- The Elapidae family is a large group of snakes, characterized by short, anterior, fixed, grooved, venom-conducting fangs.
- The only native representatives of this family in the United States are the coral snakes, of the subfamily Elapinae.
- Non-native Elapidae are responsible for bites in the United States, both in zoos and in homes of keepers of pet snakes.
- Other important Elapidae discussed here include the cobras, kraits, Australian brown snakes, mambas, tiger snakes, and death adders.
- The primary toxic mechanism for many Elapidae, including the corals, is neurotoxicity, with respiratory failure posing the greatest life threat. However, some species cause significant tissue necrosis and cardiotoxicity as well.
- Antivenoms are available for many of the Elapidae. While effective against the neural components of toxicity, they are generally derived from horse serum and can cause serious allergic reactions, thus requiring careful administration and consideration of prophylactic measures to reduce anaphylaxis.
- Anticholinesterases, such as edrophonium and neostigmine have been used successfully in reversing neurotoxicity as well, but are not universally effective.
- As always, intensive supportive care is paramount to success in treating snakebite victims.
- It cannot be emphasized too strongly that potentially fatal respiratory failure may occur precipitously more than 12 hours after a bite, so that even well-appearing bite victims should be observed closely for a minimum of 24 hours.
- It is not uncommon for fang marks to be absent, and local tissue injury is often minimal or absent. Thus, the history of a bite should be considered sufficient evidence for observation and absence of local effect not equated with absence of envenomation.

Mortality from snakebite worldwide is an enormous problem, estimated by some at up to 100,000 deaths per year.¹ Even this substantial figure is probably an underestimate of the real incidence, given the number of poor rural victims who do not seek care in hospitals, or simply die at home. Many of these bites are inflicted by members of the Elapidae family, which are found throughout Asia, Africa, Australia, and the Americas, but not in Europe. Worldwide, most bites occur in agricultural workers, fishermen, and hunters,² but in the United States a substantial number of bites occurs in handlers of “pet snakes.”³⁻⁶ The importance of this problem can be appreciated by examining the cases consulted upon personally by Minton between 1977 and 1995 (Table 21B-1).⁵ Clearly, many more bites occurred during this period, suggesting a much higher overall incidence.

Dry bites (nonvenomous bites) are said to occur, on average, in about 50% of cases, with high variability among species.² In bites where venom is injected, the case fatality rate remains extremely high in some regions (upwards of 50%), but with antivenom and modern medical care, the mortality rate approaches that of other poisonings (i.e., less than 5%).⁷

The Elapidae family, defined in part by the presence of a pair of short, anterior, fixed, venom-conducting fangs, is composed of five subfamilies (although there is some disagreement as to classification): the Elapinae (coral snakes), Bungarinae (cobras, mambas, kraits) Oxyurinae (Australian elapids), and Hydrophiinae and Laticaudinae (Sea snakes, which will not be described here). In North America, elapids account for relatively few snakebites and low mortality, compared with the more common bites of the Crotalinae (see Chapter 21A). However, elapids endemic to Asia (cobras

and Australia (taipan, death adder, brown snake, tiger snake, and others) account for significant morbidity and mortality. This chapter will focus primarily on Elapinae (coral snakes), but we will briefly discuss other terrestrial Elapidae of global importance.

U.S. CORAL SNAKES

North America has two genera of Elapidae, *Micruroides* and *Micrurus*.⁸ *Micrurus* is represented by two subspecies in the United States: *Micrurus fulvius fulvius*, which is the Eastern coral snake, and *Micrurus fulvius tener*, which is the Texas coral snake. *Micruroides* consists of one subspecies, *Micruroides euryxanthus euryxanthus*, the Sonoran or Arizona coral snake.⁸

Coral snakes are Elapidae and differ from the Crotalinae in that coral snakes have a pair of short, fixed, grooved, but not hollow, anterior fangs that carry venom along open, unsealed grooves from the ducts located at the base of the fangs.⁸⁻¹¹ This inefficient venom delivery apparatus (proteroglyphous) is but one reason why coral snake envenomations are relatively uncommon in the United States, when compared with the more efficient venom delivery system of pit vipers (solenoglyphous).¹² Other reasons include the coral snake's small mouth, which is unable to achieve a large jaw aperture to bite a human, the fact that coral snakes are not aggressive, and the fact that they live mostly underground. For an effective envenomation to occur, a coral snake usually must gnaw or hang onto its victim for at least several seconds because its venom is not injected directly through hollow fangs as in crotalids.^{10,11,13}

In the United States, only a small percentage of snakebites are caused by coral snakes, usually *M. fulvius fulvius* and *M. fulvius tener*.¹³ The only other U.S. coral snake, *M. euryxanthus euryxanthus* is located in the Sonoran Desert of Arizona, New Mexico, and Mexico. A bite from *M. euryxanthus euryxanthus* may have the distinction of being the only coral snakebite that does not deliver enough venom to kill an adult human.^{11,13} The average and maximum extracted venom yields of 0.12 mg and 6 mg, respectively, obtained from *M. euryxanthus euryxanthus*, is significantly below that obtained from the *Micrurus* species. The estimated lethal dose of *M. euryxanthus euryxanthus* venom for an adult human is 6 to 8 mg. This is in contradistinction to bites from *M. fulvius fulvius* in Florida and Alabama, and *M. fulvius tener* in Texas, where bites by both species have produced adult human fatalities.¹⁴

Pathophysiology

Elapinae snake venoms contain a complex mixture of polypeptides. Whereas pit viper venom contains protein that causes coagulopathies, thrombocytopenia, and tissue necrosis, coral snake venom contains α neurotoxins and phospholipase A₂ (PLA₂), which cause paralysis and myonecrosis, respectively.¹⁵ The neurotoxic components are polypeptides devoid of enzymatic activity and act primarily by binding postsynaptically at the nicotinic

acetylcholine receptors of the neuromuscular junction, causing flaccid paralysis of striated muscles.^{13,16-18} This competitive, nondepolarizing blockade of nicotinic acetylcholine receptors differs from the action of curare in that its onset is slower, its duration of action is much longer, and it is not necessarily reversed by anticholinesterases.^{9,18-21} In addition, it should be noted that infusion of lethal doses of *M. fulvius fulvius* venom in dogs (0.3 mg/kg) or cats (2 mg/kg) produced profound hemodynamic changes (shock) primarily due to decreases in cardiac output despite ventilatory support.^{22,23} The target of myotoxic PLA₂ is the plasmalemma, similar to pit viper PLA₂; however, evidence suggests these phospholipases evolved independently from each other.²¹

Clinical Manifestations

Coral snake envenomations differ clinically from crotaline envenomations in three major ways: Coral snake envenomations primarily produce neurotoxicity with comparatively little local tissue toxicity, although there can be myonecrosis, indicated by serum creatine kinase elevations.^{10,11,20,24-27} Coral snake envenomations also differ from crotaline envenomations in that the onset of signs and symptoms can be delayed for more than 13 hours and then occur precipitously.^{11,18,26-29} Venom effects can occur earlier; in fact, death due to ventilatory failure has occurred within 4 hours of envenomation.²⁹ Finally, unlike crotaline envenomation, the signs of coral snake envenomation are difficult to reverse or may even progress after administration of antivenom. Therefore, early coral snake antivenom administration is advisable.¹¹ Without infusion of antivenom, the neurologic complications of a coral snake bite may last 3 weeks to a month.

Victims of Arizona (Sonoran) coral snakebites (*M. euryxanthus euryxanthus*) have reported local paresthesias, weakness, hand incoordination, drowsiness, nausea, and abdominal pain.²⁴ Envenomation by Eastern and Texas coral snakes (*M. fulvius*) can produce severe neurotoxic effects. Detailed signs and symptoms of Eastern coral snake envenomations in a 20-patient subset of a 39-patient case series included fang marks (85%), a small amount of local swelling (40%), paresthesias (35%), vomiting (25%), euphoria (15%), weakness (15%), dizziness (10%), dyspnea (10%), diaphoresis (10%), muscle tenderness (10%), fasciculations (5%), and confusion (5%). Six of 39 patients in this case series (15%) were endotracheally intubated. Three of these patients received elective intubation before frank ventilatory failure and none developed aspiration pneumonia; however, three other patients who were intubated immediately before frank ventilatory failure developed aspiration pneumonia.¹¹ Seizures have also been reported after *M. fulvius* envenomation, particularly in children; it is unclear whether these were caused by hypoxia.²⁸ Ventilatory failure is the ultimate cause of death and is usually, but not always, preceded by signs of cranial nerve dysfunction, including ptosis, dysarthria, dysphagia, and/or hypersalivation.^{28,29}

Diagnosis

Clinical diagnosis of coral snake envenomation can be difficult. Coral snake envenomations can occur with or without visible fang marks.^{11,20,25} The patient and clinician may not realize a coral snake envenomation has occurred without positively identifying the snake and realizing that onset of signs and symptoms is often delayed. Although several U.S. snakes resemble the bright red-, yellow-, and black-banded coloration of coral snakes, the mnemonic, "Red on yellow, kill a fellow; red on black, venom lack," identifies the color pattern of coral snakes in the United States, but not elsewhere.^{8,10,13} No significant laboratory abnormalities occur, other than hypercarbia or hypoxia in patients who have ventilatory insufficiency.²⁴

Treatment

PREHOSPITAL TREATMENT

No first aid should delay rapid transport to a medical facility. Vigorous washing with copious amounts of water and detergent should be done as soon as possible to remove venom that can remain on the skin's surface and could enter through punctures or abrasions. Emergency medical service notification and transportation to a medical facility are the most effective prehospital treatments. During the time of transportation to a medical facility, it is possible to provide a pressure wrap to the victim's extremity similar to what has been recommended for envenomation by the Australian Elapidae species.^{30,31} It should be emphasized that the pressure immobilization technique has never been demonstrated clinically to be effective in treatment of *M. fulvius* envenomations. Nonetheless, German and colleagues recently demonstrated marked reduction in mortality in a porcine model of *M. fulvius fulvius* envenomation using this technique.³² Briefly, the technique involves wrapping a long, wide swath or bandage around the bitten area in a firm but not occlusive manner. The bandage should be extended to cover as much of the bitten extremity as possible and then the limb immobilized to limit activity.

HOSPITAL TREATMENT

Antivenin (*Micrurus fulvius*) (equine origin) (Wyeth-Ayerst Laboratories, Philadelphia, PA) is available for Eastern and Texas coral snake (*M. fulvius*) envenomations, but not for Arizona coral snake (*M. euryxanthus euryxanthus*) envenomations (F.E. Russell, personal communication, 1996).²⁴⁻²⁶ However, Wyeth-Ayerst production of *M. fulvius* antivenom was discontinued in 2001. There is evidence that other antivenoms from Mexico, Australia, and Costa Rica may have potential for use in the treatment of coral snake (*M. fulvius fulvius*) envenomations.^{12,33,34}

Although it is generally not advisable to capture a venomous snake because of the risk for further envenomations, positive field identification is helpful in determining the duration of patient observation for a potential coral snakebite. If the patient has been bitten and if a reliable, positive, field identification has been

made, or if there are signs or symptoms of *M. fulvius* coral snake envenomation, then *M. fulvius* coral snake antivenom treatment is indicated.^{11,24,25}

Before intravenous administration of antivenom, a skin test can be performed. Wyeth-Ayerst *M. fulvius* antivenom skin testing and intravenous administration involve similar risks and require similar precautions as with the Wyeth-Ayerst polyvalent crotalid antivenom, because both are of equine origin. Life-threatening anaphylactic and anaphylactoid reactions can occur.¹¹

The recommended initial dose of Wyeth-Ayerst *M. fulvius* antivenom varies among researchers (F.E. Russell, personal communication, 1996).^{11,24,35} Investigators agree with the recommendation of a recognized authority who suggested an initial dose of at least 5 vials of Wyeth-Ayerst *M. fulvius* antivenom (F.E. Russell, personal communication, 1996). An initial dose of 10 vials of Wyeth-Ayerst *M. fulvius* antivenom may be necessary with bites caused by large coral snakes, bites involving long exposures with difficulty disengaging the biting snake, and in bites of small children (F.E. Russell, personal communication, 1996).^{11,24,35} A subsequent dose of 5 vials of Wyeth-Ayerst *M. fulvius* antivenom is indicated if the patient has worsening of signs or symptoms after the initial dose of antivenom.^{11,25,26,35}

Once a patient has developed neurotoxic signs or symptoms, these signs or symptoms may progress in spite of antivenom therapy.¹¹ Good supportive care is paramount with early endotracheal intubation, before frank ventilatory failure and respiratory arrest.^{11,24}

As with other bites, administer tetanus prophylaxis, if indicated. Prophylactic antibiotics are not recommended.

Other Antivenoms to Consider

Presently there are equine immunoglobulin F(ab)₂ fragments available from Mexico (Coralmyx, Instituto Bioclon, Mexico) that have good neutralizing capacity for venom of *M. fulvius* from the United States.^{12,34} In addition, another nondomestic antivenom from Australia for use against the tiger snake (*Notechis scutatus*, CSL Limited, Parkville, Victoria, Australia) has also been shown to be effective in preventing lethality due to *M. fulvius fulvius* envenomation in an animal model.³⁴ Neither Coralmyx nor the Australian tiger snake antivenom is FDA approved, but both may become available from U.S. zoos that house Central and South American coral snakes or Australian snakes.³⁶

Disposition

Patients should be admitted, observed, and monitored for at least 24 hours, even if bite marks or other signs or symptoms are lacking. Patients may be discharged after at least 24 hours if no signs of toxicity develop.^{25,26}

Prognosis

Prognosis is excellent in most cases; however, some patients have required endotracheal intubation and mechanical ventilation for paralysis that has lasted as long

as 1 week.¹¹ Death is caused by ventilatory failure and is unusual.^{28,29} Death occurs early in most fatal cases. Approximately 10% of patients treated with antivenom in one case series developed serum sickness¹¹ (Fig. 21B-1).

NON-NATIVE (NON-ELAPINAE) ELAPIDAE

Epidemiology

Elapid envenomation is rare in the United States, but it is a major cause of morbidity and mortality in other parts of the world. According to Bawaskar,³⁷ there are 52 known poisonous snake species in India; the major families are of the Elapidae family and including common cobras (*Naja naja*), the king cobra (*Ophiophagus hannah*) and the common krait (*Bungarus caeruleus*). There are an estimated 200,000 snake bites reported annually in India, with an estimated 35,000 to 50,000 deaths.³⁸ Snakebites are also extremely common in Papua New Guinea, where up to 36% of patients presenting to the major treating hospital will require ventilation. Unfortunately, both ventilators and antivenom are in scarce supply.³⁹ Fernando, in a report on the first 10 years of the existence of the Sri Lankan National Poisons Information Centre, pointed out that snakebites are responsible for only 6% of enquiries, but for 42% of poisoning hospitalizations. The case fatality rate was, compared with neighboring India, surprisingly low, at 0.5%. Fernando attributes some of this success to a massive information campaign regarding the benefits of antivenom over traditional Ayurvedic therapy. This information resulted in a fivefold increase in hospital admissions over a 10-year period ending in 1996.⁴⁰ This case fatality rate compares with that of Australia, where hospitalization is rapid and antivenom widely available. Currie recently catalogued the incidence of snakebite in a hospital in the Northern Territory of Australia. An estimated 23 bites per 100,000 population occur annually. The bite victim is typically male (2:1 predominance), older than 15 years, and Aboriginal (61 bites per 100,000 population versus 20 in others). The most commonly involved elapids were the Western brown snake (*Pseudonaja nuchalis*), Mulga snake (*Pseudechis australis*), and death adder (*Acanthophis* species), all viewed as extremely toxic. The majority of bite victims of these species received antivenom (81%, 75%, and 29%, respectively). In spite of early collapse with unconsciousness occurring in 15% of patients, there were no deaths.⁷ In fact, there are only about two fatalities from snakebite in Australia each year, in spite of many incidents. In summary, it appears that the availability of antivenoms and adequate systems for life support have a profound impact on elapid bite mortality. A brief review of some of the specifics regarding the various genera of non-Elapinae elapids is followed by a general overview of treatment.

Pathophysiology and Clinical Manifestations

As is the case for coral venoms, the venoms of non-native Elapidae are complex mixtures, containing neurotoxins,

FIGURE 21B-1 Response to antivenom and neostigmine in a patient with decreased mental status and cranial nerve deficits. (From Bawaskar HS, Bawaskar PH: Envenoming by the common krait (*Bungarus caeruleus*) and Asian cobra (*Naja naja*): clinical manifestations and their management in a rural setting. *Wilderness Environ Med* 2004;15(4):257–266. Used with permission.)

myotoxins, cardiotoxins, and other components. Neurotoxins may act at presynaptic or postsynaptic sites (Table 21B-2), which may affect their onset and, in part, their response to anticholinesterase drugs.

COBRAS (NAJA SPECIES, OPHIOPHAGUS HANNAH, AND OTHERS)

Cobras produce a venom that is neurotoxic, cardiotoxic, and hemotoxic (Fig. 21B-2). The neurotoxic component is most often cited as predominating, but the venoms vary from one subspecies to another: Some cause more

tissue necrosis than neurotoxicity.⁴¹ Conversely, the Philippine cobra (*Naja naja philippinensis*) has a neurotoxicity:tissue necrosis ratio of 14:1, inducing neurotoxic symptoms in as many as 97% of bite victims in the study by Watt.⁴² One of the principal neurotoxic components of the venom is α -bungarotoxin, which reversibly blocks postsynaptic acetylcholine receptors. Neostigmine may reverse these effects.⁴³ As mentioned, *Naja* species may produce severe local tissue necrosis, which is not prevented by administration of antivenom. The venom contains hyaluronidase⁴⁴ and phospholipases,

**TABLE 21B-2** Representative Neurotoxins and Active Sites of Various Elapid Venoms

GENUS	TOXIN	ACTIVE SITE
<i>Acanthophis species</i> (death adder)	Acanthophis antiarcticus b and others	Postsynaptic
<i>Micrurus species</i> (corals)	α neurotoxin	Postsynaptic
<i>Naja species</i> (cobras)	α bungarotoxin	Postsynaptic

resulting in anticoagulant effects.⁴⁵ A hemolysin, phosphatidase, produces enzymatic destruction of the endothelium and red blood cells. This may lead to hemolysis and acute renal failure. Other components include proteases, cholinesterases, and erepsin.³ Cardiotoxicity appears to be rare,³ although some of the venom peptides appear to affect calcium transport. Cobra venom administration results in significant conduction disturbances in rats.⁴⁶

Bawaskar and Bawaskar reported on a series of cobra and krait bites in rural India. Among the seven cobra bites, two were dead on arrival, one died upon seeing the cobra (without apparent bite), for a bite mortality rate of 29%. Four subjects recovered with a combined therapy of antivenom, anticholinesterase drugs, and/or artificial ventilation. According to Bawaskar and Bawaskar, the cobra, unlike the krait, deposits its venom deeply. This, in combination with hyaluronidase, allows spreading of the venom to occur rapidly and symptoms to arise abruptly. Interestingly, this rapidity of onset prompts rural victims in India to seek care quickly after a cobra

bite, while the more insidious onset of symptoms induced by the bite of the krait more often results in a visit to the local traditional healer (mantrik or tantrik) for natural curatives. A number of social issues likewise enter into the difficult decision to seek hospital care.⁴³

A number of cobra bites have been reported in the United States as well. Britt and Burkhart reported on a bite by *N. naja* (described in this case as a black Pakistani cobra) maintained as a pet. A 26-year-old man with a collection of about 65 snakes was bitten on the right index finger by the snake and suffered severe pain within minutes. He was tachycardic and tachypneic on hospital arrival, was observed on a cardiac monitor for a few hours, and was then discharged. He returned within 8 hours complaining of chest pain, abdominal pain, and nausea. The right arm had swollen considerably since his first admission. The patient was started on five vials of polyvalent cobra antivenom but had received only about one fifth of the infusion when he developed generalized urticaria. He was given diphenhydramine and methyl prednisolone, with resolution of the rash. The remainder

of the antivenom was withheld. The patient was discharged after 3 days with complaints of persistent occasional swelling of the affected finger.³ This case nicely illustrates several of the typical characteristics of elapid snake bites in the United States: the patient is often a man in his twenties or thirties who keeps the snake for a pet. Symptoms may be delayed for many hours after a bite, and administration of antivenom often results in allergic (anaphylactic or anaphylactoid) phenomena. Although not specifically mentioned in this case, it is not uncommon that consumption of alcohol precedes the bite. Ronan-Bentle and colleagues recently reported on a bite to the right index finger of a 30-year-old man who was feeding his pet Asiatic Suphan cobra (*Naja kaouthia*). The patient presented to an emergency department, was given neostigmine and atropine, and was transferred to a tertiary care center. On arrival there, he complained of paresthesias, muscle cramps, inability to keep his eyes open, and diplopia on lateral gaze. The patient was found to have ptosis, ophthalmoplegia, and tongue fasciculations. He was pretreated with subcutaneous epinephrine and given five vials of South African polyvalent antivenom. Nevertheless, his bulbar palsy worsened and he became cyanotic, requiring intubation. He was given an additional five vials of Thai Red Cross purified antivenom. He was admitted to the intensive care unit and ventilated for 12 hours before successful extubation. He was discharged in good condition but subsequently required amputation of the finger.⁶

Davidson and colleagues have published a nice review of cobras and a (now somewhat dated) list of available antivenoms and sources.⁴¹ The Antivenom Index can provide updated availability information of these vital resources.³⁶

KRAITS (*BUNGARUS SPECIES*)

The krait produces β -bungarotoxin, which has a high affinity for, and irreversibly blocks, presynaptic neuromuscular receptors. The krait has the most lethal venom (by weight), but the effects are delayed due to slow absorption from subcutaneous or skin deep bites because of the snake's short sharp fangs. Kraits in India often enter the dwellings of rural families in search of prey, such as rats and mice. Because many rural Indians sleep on the floor, it is common to be bitten at night. In spite of the slow onset of toxic symptoms, the common krait is considered the most dangerous species on the Indian subcontinent, with a 35% to 50% case mortality rate.⁴³ In a series of 30 elapid bites that occurred in rural India, 23 krait bites were recorded, with 2 patients dead on arrival, 7 deaths in the hospital, and 14 recoveries (mortality rate 39%). Four patients required artificial respiration, antivenom, and anticholinesterases. One had a dry bite and the remaining nine survived with supportive care.⁴³ The investigators reported success with anticholinesterase treatment (see Fig. 21B-1). While signs and symptoms are similar to those of cobra bites, there are important differences, as illustrated in Table 21B-3.

TIGER SNAKE (*NOTECHIS SPECIES*)

Tiger snakes have venom that is neurotoxic, myotoxic, and procoagulant. Notexin is the major neurotoxin, acting, like β -bungarotoxin, on presynaptic neuromuscular junctions. It is described as resistant to treatment with antivenom. Notexin is also responsible for muscle damage and myoglobinuria. A procoagulant component has been identified, which acts by cleaving peptide bonds of prothrombin, resulting in conversion to thrombin. The procoagulant action is rapid, preceding the onset of neuromuscular paralysis.⁴⁷ The tiger snake is the second most common cause of death from snakebite in Australia, following the brown snake (*Pseudonaja* species). It was responsible for 8 of 30 deaths reported on that continent between 1981 and 1994. Ferguson and colleagues studied complete coagulation parameters in 3 patients bitten by *Notechis ater occidentalis*. All three cases had markedly prolonged International Normalized Ratio and activated partial thromboplastin time values and diminished fibrinogen. D-dimers were elevated, indicative of fibrinolysis. Factor V was also markedly diminished, while factor VIII was moderately diminished. Interestingly, platelet counts remained normal in all three. Two of three patients survived their coagulopathy and snakebite after receiving fresh frozen plasma (FFP) and tiger snake antivenom. Two patients, including a 14-year-old boy, received cryoprecipitate as well. The child suffered cardiac arrest approximately 30 minutes after the bite, was resuscitated, but developed ischemic brain damage and died about 30 hours after envenomation.⁴⁷ The researchers signaled the importance of giving both FFP and cryoprecipitate to replace the factor V and fibrinogen.

DEATH ADDER (*ACANTHOPHIS SPECIES*)

The death adder is the most common poisonous snake in Papua New Guinea and is likewise found in Irian Jaya, Australia, and parts of eastern Indonesia.⁴⁸ The venom of the death adder contains at least four distinct neurotoxins that cause postsynaptic blockade. Like the krait, the death adder is a nocturnal hunter; however, bites do occur during the day as well. According to Lalloo, the death adder causes less severe envenomation than the taipan. The researchers reported signs of neurotoxicity in 15 of their 16 envenomated patients, but intubation was required in only 5 (27.1%).⁴⁸

MAMBAS (*DENDROASPIS SPECIES*)

The venom of mambas contains dendrotoxins, small proteins that enhance acetylcholine release at the neuromuscular junction (thus, presynaptically, like kraits and tiger snakes). The toxins of the green mamba (*Dendroaspis angusticeps*) have been shown to block particular subtypes (Kv1.1, Kv1.2, and Kv1.6) of potassium channels, serving as probes for the study of potassium channels in physiology and pathophysiology.⁴⁹ The toxin is likewise used to study subtypes of muscarinic receptors.^{50,51}

Munday and colleagues recently reported on a healthy 40-year-old female neurobiochemist who presented with

progressive numbness of the left malar region and lateral orbit that progressed to include the medial orbit and tongue. One hour prior to presentation she used her bare hands to remove residual petroleum jelly from a dish that had previously contained 500 nanoliters of 500 nanomolar dendrotoxin. She recalled rubbing her left eye prior to the onset of symptoms. She had previously washed the dish with 70% ethanol while using latex gloves. Physical examination was remarkable only for weakness to superior gaze and some mild tongue fasciculations. The symptoms resolved within 12 hours of exposure.⁵²

TAIPANS

The taipan (*Oxyuranus scutellatus*) is one of the deadliest snakes in the world, with the third most lethal venom of all snakes and the second largest average venom yield (120 mg) of Australasian snakes. The rare inland taipan (*Oxyuranus microlepidotus*) has the most potent venom of all Australasian snakes. The principal neurotoxin of the taipan is taipoxin, which acts presynaptically. The taipan has extremely long fangs (8 to 12 mm) and an efficient

venom delivery system on biting, with a “snap-release” action. Survival from an effective taipan bite was very rare before antivenom and ventilation were available.⁵³

Diagnosis

Diagnosis for non-native elapid bites is largely clinical, based on the history and identification of the snake, when available. Because bite marks are not always visible (apparently a particular problem with kraits) and swelling and ecchymosis are quite variable (see Table 21B-3), the diagnosis may be elusive. The history may sometimes be misleading, as in the case of one man who was about to be whisked off to the operating room for exploratory laparotomy due to abdominal pain, who finally admitted that the scratches on his hand were actually the bite of his pet cobra.⁵⁴ Sudden onset of ptosis or other cranial neuropathies and/or respiratory muscle failure should prompt the suspicion of an elapid bite under appropriate circumstances. A micro-ELISA (enzyme-linked immunosorbent assay) kit for the detection of snake venom and venom antibody exists,³⁷

but is unlikely to be found in most hospitals. Hung and colleagues reported good correlation of their ELISA for the Taiwan cobra (*Naja atra*) with the severity of local tissue destruction.⁵⁵

Treatment

SUPPORTIVE CARE

As in all envenomations, the primary treatment for non-native elapid poisonings is careful observation and intensive supportive care. Due to the neurotoxic effects of the venoms, respiratory depression is common and often requires intubation (see Table 21B-3). Given that the median time to requirement for intubation and ventilation in a series of death adder envenomations was 13 hours (range 2 to 23.5 hours), it seems prudent to recommend that patients who suffer bites by non-native elapids be observed for at least 24 hours in the hospital.

ANTIBIOTICS

While prophylactic antibiotics are often recommended in elapid bites, very few studies of their actual need have been undertaken. Blaylock, in a prospective study of snake bites in South Africa, looked at antibiotic use in 310 patients (data were missing for 53 additional bites). The protocol called for antibiotics not to be used unless the bite was necrotic or “necrosis was anticipated.” Infected wounds were cultured. A number of protocol violations occurred, but there were no infections in patients who did not receive antibiotics. Where positive cultures occurred, the most frequent organisms were gram-negative enterobacteriaceae. No anaerobes were cultured. The researcher concluded that antibiotics should be reserved for those snakebite patients with necrosis and should cover gram-negative aerobic bacilli and gram-positive aerobic cocci.⁵⁶ Studies of antibiotic use in pit viper envenomations^{57,58} and nontoxic snake bites^{59,60} have strongly suggested that routine antibiotics are not necessary in these cases. While it is thorny to generalize across families and species of snakes, there currently appears to be insufficient evidence to support the use of antibiotic prophylaxis in elapid bites.

SURGICAL INTERVENTIONS

A recent retrospective analysis of snakebites in pediatric patients presenting to a hospital in India over 6 years was conducted by Chattopadhyay and colleagues. Records were reviewed for the type of surgical lesions seen and the treatment offered and their results. Fifty-five percent of bites were from unidentified poisonous snakes, followed by cobras, then nonpoisonous snakes. Forty-four of the 58 children required some form of local, and in most cases, conservative therapy. Twenty-eight percent required débridement for local necrosis, and only five needed a skin graft, with good functional results over a period of 1 to 45 days. One child underwent an above-knee amputation. Patients who required surgical intervention received significantly more vials of antivenom. The investigators concluded that complications of snakebite are frequent, but can be managed conservatively, that delayed excision of the resultant local

necrosis is associated with good outcomes, and that the need for fasciotomy is rare.⁶¹

ANTIVENOMS

Antivenoms for non-native snakes are manufactured around the world, are maintained in a number of zoos across the United States, and can usually be located with the assistance of the regional poison control center. It is advisable to contact the poison center in your area immediately upon presentation of a patient with a bite to see what antivenom may be available for the species involved. Because of the relative rarity of these products, it is not uncommon to use expired antivenom,³ but as adverse reactions to all horse-derived antivenoms are common, it is probably wise to obtain specific informed consent for their administration, particularly if the product is outdated. Unlike crotaline antivenoms, elapid antivenoms appear to have little effect on the myotoxic properties of the venoms. The antivenom is administered primarily to combat the respiratory effects of the venom. According to Bawaskar and Bawaskar, citing Ponchanugool, antivenom does not prevent local tissue necrosis.^{43,62} Accordingly, local swelling should not be used as a guide to the administration of antivenom.³

In India⁶³ and Sri Lanka, it is common to precede antivenom treatment with prophylactic epinephrine, given subcutaneously. Premawardhena and colleagues⁶⁴ performed a prospective, double-blind, randomized, placebo-controlled trial in 105 patients with signs of envenomation after snakebite. Fifty-six patients from 14 to 65 years of age received epinephrine (0.25 mL 1:1000 subcutaneously) and 49 controls (ages 17 to 65 years) received placebo as pretreatment. Six patients (11%) receiving epinephrine and 21 control patients (43%) developed acute adverse reactions to antivenom serum ($P = .0002$). Significant reductions in acute adverse reactions to serum were also seen in the epinephrine group of patients for each category of mild, moderate, and severe reactions. There were no significant adverse effects attributable to epinephrine.

Other investigators have recommended corticosteroids and/or antihistamines as prophylaxis. Gawarammana and colleagues performed a double-blind, randomized, placebo-controlled trial of a parallel infusion of hydrocortisone with or without a bolus injection of chlorpheniramine to attempt to reduce acute adverse reactions to antivenom. The group that received both hydrocortisone and chlorpheniramine had significantly fewer reactions (52%) to a polyvalent antivenom (Vins Bioproduct Limited, Mumbai, India) than those who received hydrocortisone alone (80%) or placebo (81%).⁶⁵

ANTICHOLINESTERASES

Edrophonium was shown in a small, double-blind, placebo-controlled study to temporarily reverse the neurotoxic symptoms of bites of the Philippine cobra.⁶⁶ A subsequent study by the same group, comparing edrophonium and antivenom, revealed better response to the anticholinesterase.⁶⁷ Bawaskar has reported improvement after administration of neostigmine, with some decrease in ptosis within 20 minutes. Gold likewise

reported dramatic improvement in symptoms using neostigmine after the bite of an Asiatic cobra.⁵⁴ The efficacy of neostigmine could not be demonstrated by Tin-Myint and colleagues,⁶⁸ however, in a king cobra (*O. hannah*) bite (cited in Gold⁴).

ANTICOAGULANTS

Heparin has been shown in rats to ameliorate the cardiotoxicity associated with cobra venom.⁶⁹ Interestingly, heparin and tetracycline can also prevent the corneal opacification induced by the venom of the spitting cobra, *Hemachatus haemachatus*.⁷⁰ Tibballs found no benefit of post-exposure heparin treatment in experimental therapy of brown snake (*Pseudonaja textilis*) envenomation in dogs⁷¹ and recommended against its use in humans, but found that preadministration of heparin prevented both cardiovascular and hematologic effects of venoms from the brown snake and the tiger snake.^{72,73} While employed in some centers, heparin administration cannot be recommended at present based on lack of published clinical evidence of efficacy.

OBSERVATION

Once again, it must be strongly emphasized that the neurotoxic effects of elapid bites may be delayed by many hours and that envenomation is not disproved by lack of bite wounds or early clinical signs. Observation in an intensive care unit for 24 hours is prudent and justified when the history suggests a bite may have occurred.

SUMMARY

Elapid bites are uncommon in the United States but are quite common throughout Australia, Asia, and Africa. Elapids represent some of the most poisonous snakes, with thousands of deaths reported each year, particularly in developing countries without access to adequate transportation, health centers capable of advanced life support, and antivenoms. Intensive care of victims, concentrating on respiratory support and attention to hemodynamics and hematologic disorders, can be life saving. Antivenoms, when available, may reduce the neurotoxic symptoms. Allergic reactions are common, but may be diminished by prophylactic administration of subcutaneous epinephrine, corticosteroids, and antihistamines. Anticholinesterases may also benefit patients suffering from neurotoxic effects.

A Spiders

ANDIS GRAUDINS, MBBS (HONS), PHD

At a Glance...

- Although virtually all spiders produce venom, only a small number are potentially venomous to humans.
- Widow spiders (*Latrodectus* species) are responsible for a significant number of spider envenomations worldwide.
- Widow spider envenomation is also called latrodectism.
- The most significant symptom occurring with latrodectism is pain.
- Treatment with widow spider antivenoms appears to be the most effective and rapid way to reverse the effects of latrodectism.
- Brown recluse spider (*Loxosceles* species) envenomation may result in the production of necrotic skin lesions.
- Specific treatments for necrotic arachnidism have included dapsone and hyperbaric oxygen therapy, but there is little controlled evidence suggesting that these are effective therapies.
- In most cases, standard wound care is all that is required to facilitate healing of skin lesions from necrotizing arachnids.

Spiders can be divided into two major groups: (1) the Mygalomorphae (the primitive spiders), which are large, powerful ground-dwelling spiders with vertically down-facing chelicerae, usually living in burrows with rudimentary web structures; and (2) the Araeneomorphae (true spiders), which include all other web-building spiders with horizontally opposed chelicerae. Examples of the Mygalomorphae include the Australian funnel web and mouse spiders and examples of the Araeneomorphae include the black widow and brown recluse spiders.¹ Almost all spiders are venomous. The venom is used to kill and digest their live prey. Of the 20,000 or more species found in the United States, only about 50 of these have fangs that can penetrate human skin.² Fortunately, even fewer cause clinical problems because their venom is too weak. Medically important spiders include the genera *Latrodectus* (widow spiders), *Steatoda* (cupboard spiders), *Loxosceles* (recluse spiders), and *Atrax* and *Hadronyche* (Australian funnel web spiders). The true incidence of spider bite is probably underestimated. This is primarily due to the voluntary nature of most reporting processes.

BLACK WIDOW SPIDERS (GENUS LATRODECTUS)

Black widow spiders are found on all continents excluding Antarctica. They are, arguably, responsible for

the largest number of medically important spider bites around the world. In 2003, there were 2739 black widow spider exposures reported to U.S. poison centers, of which 30% were treated in a health care facility. No deaths were reported, but 12.7% had “moderate” to “major” outcome.³ In Australia, an estimate of 2000 to 3000 *L. hasselti* (red back spider) bites per year has been made, with clinically significant envenomation requiring antivenom therapy in about 20% of cases.⁴ The female is responsible for all significant bites. It is considerably larger than the male, whose chelicerae are not large enough to penetrate human skin. The female is commonly 1 to 1.5 cm in length with a large bulbous black abdomen exhibiting a distinctive red hourglass mark ventrally. Some species, such as the Australian red back spider (*L. hasselti*) also exhibit a dorsal abdominal red/pink stripe of varying length.

Five species have been found in the United States, and *Latrodectus mactans* is the most common. Other species include *L. hesperus* (found more commonly in the west), *L. variolus*, and *L. bishopi*. One notable variant is the brown widow spider of Florida, *L. geometricus*, also found along equatorial regions of many other continents. Widow spiders are known to have been transported large distances, most likely in shipping containers. Colonies of *L. hasselti* (Australian red back spider) have been found in port areas of Osaka, Japan, and in Belgium.

The female black widow spider creates webs near the ground in secluded dark areas such as barns, garages, abandoned burrows, sheds, under unused chairs and benches, and even in outdoor lavatories.^{5,6} All *Latrodectus* species produce a similar envenomation syndrome regardless of geographic location.⁶⁻⁹ However, the potency of venom may vary across species and even within species based on geographic location, seasonality, and size of the spider.¹⁰

Steatoda spp. (cupboard spiders) are commonly found in houses, in cupboards, and under furniture. They have a similar body shape to widow spiders but are either black or brown and without abdominal coloring and are often misidentified as widow spiders. The bite usually causes local irritation only but can uncommonly produce a systemic envenomation syndrome resembling latrodectism.¹¹⁻¹³

Pathophysiology

The best characterized widow spider venom is that of the European widow spider, *L. tenebrosus*. It contains a

120-kD vertebrate-specific toxin, α -latrotoxin, and a number of insect-specific latroinsectotoxins of similar molecular weight.¹⁴⁻¹⁷ It had long been presumed that similar toxins were also present in other *Latrodectus* spp. This presumption was based on the similar clinical envenomation syndromes produced by all *Latrodectus* spp., similar in vitro effects observed with whole venom extracts, and that antivenoms prepared from one widow spider species reversed the envenomation effects of other *Latrodectus* spp. Recently, this presumption has been proven correct; partial amino acid sequences for α -latrotoxin and α - and δ -latroinsectotoxins have been derived for both *L. mactans* and *L. hasselti*.¹⁸ Venoms from these two *Latrodectus* spp. have high sequence homology and similar toxins to the venom of *L. tredecimguttatus*.¹⁸

Alpha-latrotoxin binds to synaptic membranes and leads to release of massive amounts of norepinephrine and acetylcholine from nerve terminals. Specifically, α -latrotoxin binds to the calcium-dependent receptor neurexin-1 α and calcium-independent receptor latrophilin, found on presynaptic nerve terminal membranes. Subsequent to receptor binding, there is an influx of calcium from cation channels, exocytosis of the synaptic vesicles, and release of neurotransmitter into the synaptic cleft.¹⁹⁻²¹ α -Latrotoxin is also assimilated into the presynaptic membrane directly and produces membrane pores, which result in an influx of calcium into the synaptic nerve terminal. This is partly responsible for the uncontrolled release of neurotransmitters such as acetylcholine and norepinephrine.²¹ The toxin is also internalized into the synaptic terminal and exhibits other less defined effects that increase synaptic vesicle degranulation and neurotransmitter release.²² Amplifying these effects is the fact that the venom also reduces presynaptic neuronal reuptake of acetylcholine and amines.²³ The end result is the stimulation of the autonomic nervous system through the release and depletion of catecholamines at adrenergic nerve endings. *Steatoda* spp. (cupboard spiders) venom is likely to contain latrotoxin-like toxins that may produce an envenomation syndrome similar to latrodectism.²⁴

Clinical Presentation

The envenomation syndrome from the bite of a widow spider is known as latrodectism. The initial bite of the widow spider is often described as a mild pinprick sensation or similar to a bee sting. This is followed by a dull ache 20 to 30 minutes later. All that may be visible is one or two puncture wounds 1 to 2 mm apart. Local erythema and, in some cases, a diffuse, erythematous, maculopapular rash extending beyond the bite site may occasionally be noted.⁶

The most significant symptom of latrodectism is pain.^{6,8,9,25,26} This may be local to the bite site, regional, or generalized. Mild to moderate envenomation results in localized symptoms at the bite site. Signs and symptoms include increasing pain, sweating, and muscle fasciculation, which develop in the 30 minutes to few hours following the bite. In more severe cases, signs and symptoms may become regional; severe pain, sweating,

and muscle fasciculation may progress to the entire limb over several hours. In cases of generalized envenomation, patients often present with severe systemic pain, sweating, muscle fasciculation, anxiety, moderate hypertension, and insomnia.⁶ Abdominal and back pain are common complaints with systemic illness.²⁵ Abdominal pain may be so severe as to mimic an acute abdomen, particularly in children where a history of spider bite may not be elicited.²⁷ Other, less common, signs and symptoms seen in severe envenomation include chest pain, priapism, parvor mortis (fear of death), facies latrodectismica (facial grimacing due to pain), flushing, periorbital edema, conjunctivitis, and tachycardia.^{6,8,9,25} Death from envenomation is rare and has not been reported since the 1950s.^{28,29} Left untreated, systemic signs and symptoms may last for 24 to 48 hours, and occasionally for days to weeks.

Diagnosis

The diagnosis of latrodectism is clinical and based on a positive history of spider exposure (if available) and suggestive signs and symptoms. No laboratory tests will substantiate the diagnosis, although a marked response to antivenom strongly supports the correct diagnosis.

Treatment

Treatment recommendations of latrodectism vary from continent to continent. The bite of *Latrodectus* species may result in a distressing and incapacitating syndrome of envenomation that has a relatively slow onset as compared with snake envenomation. It is extremely painful but unlikely to be fatal. Current recommendations for first aid or prehospital care are to avoid the application of pressure immobilization bandages and tourniquets; these may increase local pain due to pressure on the bite site.³⁰ Local application of ice to the bite site has been suggested as a temporizing measure, but there are no clinical trials to prove the efficacy of such treatment. Application of heat to the bite site may actually result in worsening of pain.³¹ The use of opioids may afford some relief to patients with distressing symptoms until more definitive therapy can be instituted.

Antivenom therapy has been shown to be the most effective treatment in alleviating the symptoms and signs of latrodectism.^{5,8,25,32-35} Clark and colleagues reported that patients receiving antivenom therapy (Black widow antivenom from Merck & Company, Inc., West Point, PA) in the United States were more likely to be discharged home from the emergency department and have a much shorter hospital stay than those receiving supportive measures alone. Additionally, patients receiving antivenom had a significant decrease in the signs and symptoms of envenomation, with a mean time of 31 minutes from administration of antivenom until clinical improvement. In this series, the mean duration of symptoms (from time of the bite) was 9 hours for the antivenom-treated patients as compared with 25 hours for patients treated with analgesics alone.²⁵ Rapid relief of symptoms, usually within 1 to 2 hours, has also been reported with other

antivenom formulations around the world.^{6,8,9} Mild to moderate cases of local envenomation may respond to analgesic therapy alone. In patients with regional or systemic symptoms, treatment with antivenom should be strongly considered because it is likely to significantly reduce the severity and duration of symptoms.

All *Latrodectus* spp. antivenoms appear capable of reversing the effects of envenomation from any widow spider.^{36,37} This may have implications for regions of the world where no local antivenom is available. A list of available antivenoms is shown in Table 22A-1.

The threshold for use of antivenom appears to vary from region to region. In the United States, there appears to be the greatest reluctance to use specific immunotherapy in cases of envenomation. This may be due to isolated case reports of death following administration of widow spider antivenom²⁵ and/or a presumed risk for anaphylaxis extrapolated from the use of crotalid polyvalent snake antivenom. Spaite and colleagues showed that the risk for anaphylaxis to crotalid polyvalent antivenom was as high as 86% in patients who tested positive to skin testing with horse serum and 9% in those who tested negative.³⁸ These anaphylactic risk estimates were determined for patients that subsequently received large volumes of horse protein intravenously (e.g., as required for most crotalid snake envenomations). It is unlikely that the risk is as large for patients who receive equine-derived widow spider antivenom since the amount of protein administered is significantly lower than for the treatment of crotalid envenomation. In large series of *Latrodectus* spp. envenomations, symptom relief commonly occurs after the administration of one vial of antivenom.^{8,25} Occasionally, two or more vials may be necessary. Manufacturer recommendations for the use of widow spider antivenom in the United States suggest that it should be reserved for “severe cases” of envenomation or those occurring at the extremes of age. Little data exist on the true incidence of allergic reactions following the use of widow spider envenomation in

the United States. Clark and colleagues observed an 8% incidence of allergic reactions (urticaria and bronchospasm) with widow spider antivenom use.²⁵ In general, antivenoms contain a significant amount of protein with anticomplement activity, which may result in anaphylactoid reactions when infused rapidly.³⁹ This activity is reported to be reduced in trypsin-digested antivenoms, which contain only Fab-IgG fragments, such as Australian red back spider (*L. hasselti*) antivenom, which has a reported incidence of mild allergic reactions of 0.54%.⁸ The incidence may be greater in antivenoms produced as crude hyperimmune IgG equine sera, such as Merck & Company’s, U.S. widow spider antivenom.³⁹ Consequently, when given intravenously, antivenom should always be diluted in 100 to 200 mL normal saline or 5% glucose first and then infused slowly (over 30 to 60 minutes). Infusions should occur in a monitored environment with immediate access to resuscitation facilities capable of treating untoward allergic reactions.

Late presentation or pregnancy is not a contraindication to antivenom administration. Antivenom was used successfully in a woman who was 20 weeks pregnant and manifested signs of systemic latrodectism. She subsequently had a normal full-term delivery.³³ Antivenom has been reported to be effective at reversing the effects of latrodectism presenting 1 to 2 days postbite.^{21,33-35} Antivenom therapy has been effective up to 2 weeks after bites of *L. hasselti*, the Australian red back spider.^{40,41}

Other therapies recommended for the relief of pain and muscle spasms have included intravenous calcium infusions and muscle relaxants such as methocarbamol and diazepam. Controlled trials are lacking, but these therapies have not proven more effective than opioid analgesia or antivenom therapy and do not provide effective or lasting relief of symptoms of latrodectism.^{25,42,43} Calcium salts are not recommended based on their lack of efficacy.²⁵ For patients with mild to moderate latrodectism, when antivenom administration may not be necessary, the administration of opioid analgesics and benzodiazepines are recommended for controlling pain and muscle spasm, respectively.

Red back spider antivenom has also been used successfully to reverse systemic envenomation that followed the bite of *Steatoda grossahas*. Red back spider antivenom has been shown to experimentally reverse and inhibit in vitro toxicity of the venom of this species.^{11,12}

TABLE 22A-1 Currently Available Widow Spider Antivenoms Worldwide

VENOM USED TO RAISE ANTIVENOM	SOURCE	COMPOSITION
<i>L. mactans</i>	Merck & Co., Inc., West Point, PA	Equine IgG

<i>L. hasselti</i>	Commonwealth Serum Laboratories, Melbourne, Australia	Equine F(ab) ₂ IgG fragment

BROWN RECLUSE SPIDER (GENUS *LOXOSCELES*)

The genus *Loxosceles* is notorious for producing local wound necrosis (dermonecrotic arachnidism) and, in rare cases, systemic illness. These brown spiders are small (6 to 22 mm) and have a distinctive violin-shaped marking on the dorsum of their cephalothorax (fiddleback spiders). These spiders are found in several areas of the world, such as Africa, Australia, southern Europe, the Mediterranean, the Pacific Islands, South and Central America, and the United States.⁴⁴ In the United States, *Loxosceles* spp. are found throughout the South but are

rarely seen because of their shy, reclusive nature. These spiders form small, inconsequential webs and are often encountered in home storage areas or outdoors, typically in woodpiles.

Loxosceles reclusa (the brown recluse spider) is found predominantly in south central and southeastern states (except Florida), whereas *Loxosceles apachea*, *arizonica*, and *destera* are found in the southwestern states.⁴⁴ Two additional species have been discovered in the United States, *Loxosceles laeta* in California and *Loxosceles rufescens* in Hawaii.⁴⁴ *Loxosceles laeta* is typically endemic to South America whereas *Loxosceles rufescens* is endemic to Africa. Loxoscelism, the envenomation syndrome seen after a *Loxosceles* spp. bite, is seen most commonly after a bite from *Loxosceles reclusa* or *Loxosceles laeta*.³¹

In a survey of South Carolina physicians, patients seeking medical treatment for presumed brown recluse (*Loxosceles reclusa*) spider bites outnumbered those seeking treatment for black widow spider bites, 478 to 143 for the year 1990.⁴⁵ In 2003, there were 2843 brown recluse spider exposures reported to United States poison centers, of which 40% were treated in a health care facility. Of all exposures, 23.3% had a “moderate” to “major” outcome, and one death occurred.³ Dermonecrotic arachnidism in the United States occurs predominantly from the brown recluse spider. Bites by other genera of spiders, however, can also produce necrotic wounds. These other spiders include *Chiracanthium* species (the clubionid spiders), *Phidippus* (the jumping spider), *Argiope*, and *Tegenaria agrestis* (the hobo spider) and are sometimes the actual culprits when the brown recluse is mistakenly blamed.

Pathophysiology

The venom of the brown recluse spider contains various cytotoxic enzymes, which include sphingomyelinase D, ribonuclease, hyaluronidase, deoxyribonuclease, lipase, phosphohydrolase, and alkaline phosphatase. Sphingomyelinase D, the primary dermonecrotic factor, disrupts cellular membranes.^{46,47} Sphingomyelinase D also causes serotonin release, which is associated with platelet aggregation and thus thrombosis of small capillaries.⁴⁸⁻⁵¹ Hyaluronidase facilitates the ability of the venom to spread locally in the tissue, thus indirectly enhancing tissue destruction. All the cytotoxic elements of the venom produce local endothelial cell damage, which attracts neutrophils, which subsequently release more destructive enzymes and promote further platelet aggregation and thrombosis.^{52,53} Polymorphonuclear leukocyte migration into cutaneous lesions appears to be a significant event in the development of dermonecrosis. The venom can also cause erythrocyte hemolysis, which contributes to systemic effects.⁵⁴ The systemic effects of the venom occur largely from the release of cytokines by leukocytes and activation of complement.

Clinical Presentation

A brown recluse spider bite is usually mild and often not noted by those afflicted. Within 24 hours, the patient

presents for treatment of a painful purple papule. This central violaceous lesion is often surrounded by a blanched ischemic zone and a rim of indurated erythema. The central papule or vesicle can coagulate and become thrombosed. A necrotic, ulcerating wound results and may progress for as long as a week after the initial bite.⁵⁵ The eschar may slough, and the lesion may extend into subcutaneous fat and create a disfiguring ulcer that can take weeks to heal and occasionally requires surgical grafting.⁵⁶ Patients may occasionally present with systemic loxoscelism, which can include fever, chills, nausea, arthralgias, a morbilliform rash, and hemolysis.⁵⁵ In rare cases, patients can develop disseminated intravascular coagulation, renal failure, and even seizures.⁵⁷ Systemic loxoscelism typically develops 24 to 72 hours after the bite and is not correlated with the size or severity of the necrotic skin reaction.

Very young and immunocompromised patients have a greater susceptibility to morbidity and mortality from brown recluse spider envenomations.

Diagnosis

The diagnosis of a brown recluse spider bite is often presumptive and based on suggestive physical findings in an endemic area. A positive history of spider bite is not usually evident since the bite is not very painful and the spider is shy. Patients usually present after several days, when the lesion has become necrotic. Numerous techniques have been developed to facilitate the diagnosis of brown recluse spider bite. They include a serologic assay (i.e., detecting the presence of IgG antibodies to venom components), a passive hemagglutination inhibition assay (i.e., testing for the presence of venom components by inhibition of antiserum-induced agglutination of venom-coated red blood cells), an enzyme-linked immunoabsorbent assay (i.e., detection of specific venom antigens from the wound), and tissue biopsy (i.e., detect the presence of typical histopathologic changes in the wound).⁵⁸⁻⁶¹ However, these tests are not routinely or readily available and are not 100% sensitive at the time of patient presentation. Routine laboratory work is indicated in severe envenomations. Blood cell count, urinalysis, renal function tests, and a disseminated intravascular coagulation screen may be indicated in patients with systemic symptoms of loxoscelism. In most cases, however, patients show only a local lesion without any significant systemic effects.

Treatment

Generally, all that is required for most presumed brown recluse spider bites is routine wound care, including tetanus prophylaxis. This can include débridement of necrotic tissue as well as watching for late infection. Routine prophylactic antibiotics are not indicated. If a patient appears ill, blood and urine tests can be performed to preclude systemic hemolysis. Treatment for hemolytic anemia would be supportive, with red blood cell replacement provided as needed. Since serious complications are rare, supportive care is the best approach.⁶²

Several experimental therapies have been advocated for patients with brown recluse spider bites, especially for those with the threat of a disfiguring scar. The most popular has been the use of dapsone. The theoretic basis of this agent lies in inhibiting the polymorphonuclear leukocytes from aggregating at the wound site and causing tissue necrosis. In a poorly described study of dermal envenomation, pretreatment of guinea pigs with oral dapsone resulted in skin lesions less than 50% the size of those seen in control animals.⁶³ In a similar model, initiation of dapsone treatment after envenomation also resulted in smaller necrotic lesions as compared with animals not treated with dapsone.⁶⁴ However, two recent studies were unable to reproduce these favorable results.^{65,66} Clinical experience has been limited and uncontrolled. In a small, observational study, Rees and colleagues reported that scars were smaller and healing appeared improved in patients administered dapsone.⁶⁷

Dapsone should still be considered an experimental treatment for presumed brown recluse spider bites pending controlled study of its efficacy. If it is to be used, the potential adverse effects of this drug must be acknowledged. The most serious are hemolysis and methemoglobinemia, occurring most commonly in patients with glucose-6-phosphate dehydrogenase deficiency.⁶⁷ Short-term therapy can result in dizziness, fatigue, dyspnea, and anxiety. Longer treatment courses have caused agranulocytosis, erythema nodosum, toxic epidermal necrolysis, nephrotoxicity and hepatotoxicity. Adverse effects have been reported with use of dapsone for brown recluse spider bites, including hypersensitivity reactions, methemoglobinemia, and hemolysis.⁶⁸ Because of the lack of proven clinical efficacy for dapsone, it should probably only be considered for bites in cosmetically sensitive areas. The recommended dapsone dosing regimen is to begin with 25 mg two to three times a day, increasing the dose gradually to 50 to 100 mg twice a day for 1 to 2 weeks.⁶⁹

Hyperbaric oxygen has been used in brown recluse bites with purported successes in observational studies.⁷⁰ More recent controlled studies utilizing animal models have yielded equivocal results. Maynor and colleagues reported that a single hyperbaric oxygen treatment as long as 48 hours postenvenomation caused a 50% reduction in lesion size after experimental envenomation in rabbits.⁷¹ However, two other studies failed to show any beneficial effects of hyperbaric therapy on gross lesion appearance in similar animal models.^{66,72} Risks to patients include barotrauma and the expense of an unproven therapy. Potential beneficial effects of hyperbaric oxygen in recluse bites are multifaceted but not specific for this envenomation and are similar to those for patients suffering from chronic skin ulceration from other causes. These include reoxygenation of the wound and sequestration of polymorphonuclear leukocytes away from the wound.⁷³ Although it has also been purported that hyperbaric therapy inactivates venom toxicity, Merchant and colleagues have reported that activity of sphingomyelinase D in *Loxosceles reclusa* venom is not reduced by exposure to hyperbaric oxygen.⁷⁴ The U.S. Undersea and Hyperbaric Medical Society has yet to

approve routine hyperbaric treatment for brown recluse spider bites. Hyperbaric therapy could be considered in cases of severe necrotic ulceration that has not responded to routine wound care.

Other recommended treatments, such as antivenom, steroids, electric shock, cyproheptadine, colchicine, and nitroglycerin, either have been disappointing in controlled trials or have not been studied adequately. Intralesional injection of experimental antivenin (Fab fragments) in patients and animals results in attenuated dermonecrosis with little or no scarring.^{55,75} The effect of the antivenin becomes minimal when delayed by several hours after envenomation; the venom rapidly spreads away from the bite site. Electric shock was shown to be of no value in a guinea pig envenomation model.⁶⁴ Cyproheptadine, an antihistamine with serotonin antagonist properties, was of no benefit in a rabbit model.⁶⁶ Surgical excision guarantees a scar at a site that could potentially heal without any disfigurement.⁶⁷ Surgical débridement and skin grafting (if necessary) should be reserved for days to weeks later, when the inflammatory effects of the venom have subsided and revascularization of the wound edges have occurred.

OTHER SPIDERS

Although the black widow and brown recluse are the most important spiders clinically, occasional bites by other species are notable. Necrotic arachnidism cannot always be assumed to be due to *Loxosceles*. Several other U.S. spiders have been implicated in the production of direct tissue damage. These include *Chiracanthium* spp. (the clubionid spider),⁷⁶ *Phidippus* species (the jumping spider),⁷⁷ and *Tegenaria* spp. (the hobo spider).^{78,79} The hobo spider, imported to the Pacific Northwest, can cause identical local and systemic symptoms and signs as seen with *Loxosceles*. The majority of cases of necrotic arachnidism in the Pacific Northwest are due to hobo spiders; these cases are often mistaken for brown recluse spider envenomation. Furthermore, clinicians should be wary of making the diagnosis of necrotic arachnidism in cases where there is no objective evidence of spider bite. Many case reports are based on retrospective data with little or no evidence of the spider involved.⁸⁰ The best example of this is the *Lampona cylindrata* (Australian white tailed spider), frequently implicated in cases of unexplained dermonecrosis. Following a prospective collection of 130 white tail spider bites with positive identification of the spiders in all cases, it was found that no cases of dermonecrosis were seen.⁸¹ Similar scientific rigor needs to be pursued when necrotic arachnidism is suspected in the differential diagnosis of unexplained skin ulceration. All efforts should be made to identify the spider when possible.

Specific mention should be made of the Australian funnel web spiders (*Atrax* and *Hadronyche* spp.) found along the eastern seaboard of Australia. These large, aggressive, mygalomorphic spiders produce, arguably, the most toxic spider venom to humans and other primates. The venom of the *A. robustus* (Sydney funnel web spider)

contains a primate-specific δ -atracotoxin-Ar1, which acts by inhibiting the conversion of axon sodium channels from the active to the inactive state. This results in massive neurotransmitter release from all nerve endings.⁸² The envenomation syndrome is characterized by marked pain at the bite site, rapid development of muscle fasciculation, diaphoresis, salivation, tachycardia, hypertension, respiratory paralysis, pulmonary edema, and death.^{83,84} A specific funnel web antivenom produced from the venom of *A. robustus* is available; it is life saving and also neutralizes the venom of various other Australian funnel web species.^{84,85}

Other spiders usually cause only local painful reactions and swelling, most notably *Argiope* (golden orb weaver) and *Lycosa* (wolf spider).²⁶ Tarantulas, members of the primitive mygalomorph suborder of spiders, can inflict a histamine-like reaction either by a painful bite or by brushing hairs toward their prey. Treatment for all of these envenomations is supportive, with the possible exception of tarantula encounters, which can be treated with oral antihistamines and topical steroids as needed.

B Scorpions and Stinging Insects

JERRY D. THOMAS, MD ■ KAREN E. THOMAS, MPH ■ ZIAD N. KAZZI, MD

At a Glance...

- Scorpion envenomation cause significant morbidity and mortality worldwide.
- Most envenomations require only supportive treatment.
- Antivenom use remains controversial. Currently there is no commercially available antivenom in the United States.
- Hymenoptera and other stinging insects are a frequent cause of human injury.
- Anaphylaxis from stings is the major cause of morbidity associated with hymenoptera envenomations.
- For patients with significant sensitivity reactions, education on avoidance, epinephrine auto-injector prescription, and referral to an allergist may be life saving.

SCORPIONS

Introduction and Relevant History

Scorpions are invertebrate arthropods that have existed for longer than 400 million years.¹ They belong to the phylum Arthropoda, the class Arachnida, and the order Scorpiones. Taxonomic classification is evolving and consists of anywhere from 9 to 20 living families. Of the over 1400 species of scorpions worldwide, less than 50 are considered dangerous to humans.^{2,3} All potentially lethal scorpions belong to the family Buthidae with the exception of one genus, *Hemiscorpius*, which belongs to the family Scorpionidae.

Scorpions are found on all continents except Antarctica and live in tropical and temperate regions within 50 degrees north and south of the equator.^{2,4} The only medically important species in the United States is *Centruroides sculpturatus*, also known as *Centruroides exilicauda* or the bark scorpion (Fig. 22B-1). Recent research may suggest that *C. sculpturatus* and *C. exilicauda* are in fact two distinct species.⁵ *C. sculpturatus* is found in

FIGURE 22B-1 *Centruroides sculpturatus* or *exilicauda*. (Courtesy of Scott Stockwell, PhD.)

the Southwestern United States, primarily in Arizona, but also in parts of California, New Mexico, Texas, and on the shores of Lake Mead, Nevada.¹ Other medically important species and their distribution are shown in Table 22B-1. Scorpions can be transported to other nonendemic locations, either unintentionally as stowaways in shipped goods or intentionally as exotic pets.

The body of the scorpion consists of two major segments: the anterior prosoma and the posterior opisthosoma. The opisthosoma contains seven mesosomal segments, five metasomal segments, and the venom apparatus known as the *telson* (Fig. 22B-2). The scorpion also possesses a pair of claw-like pedipalps used for grabbing prey, a pair of pincher-like chelicerae near the mouth used for feeding, and four pairs of legs. Scorpions range in color from light yellow to black.⁶ A unique feature of scorpions is that all are thought to fluoresce under ultraviolet light. Although not well understood, this is thought to be secondary to one or more substances located in the cuticle of their exoskeletons. This phenomenon is used to harvest, study, and protect against them. Freshly molted scorpions, however, do not fluoresce.

There are no hard and fast rules to determine which scorpions are dangerous based on appearance. The size of the scorpion does not correlate to its aggressiveness or venom potency.⁷ Commonly, however, scorpions with slender pedipalps are more toxic than those with thicker ones.^{6,8} Additionally, one structural difference that helps distinguish Buthidae scorpions from other families is a triangular sternal plate as opposed to a more pentagonal plate seen in the other families.

Scorpions are primarily nocturnal creatures that prey on insects, arachnids, and small lizards. They grab their prey with pedipalps, inject the venom from their telson by arching their tails over the back, and then tear their prey apart with their chelicerae. They are often found around dwellings, hiding in woodpiles and other concealed locations. *C. sculpturatus* does not burrow like some scorpions but prefers to be in or around trees, particularly sycamore, mesquite, and cottonwood trees.¹ The life span of scorpions varies by species but generally ranges from several months to several years.²

Epidemiology

Worldwide, scorpions are the most important cause of arachnid morbidity and mortality.⁹ In Mexico, Tunisia, Algeria, Morocco, and Libya, scorpions are the most important venomous animal, and in many other tropical areas, they are second only to snakes.⁶ There are an estimated 5000 deaths from scorpion stings worldwide each year.⁷ In Tunisia, each year an estimated 40,000 people are stung by scorpions, of whom 1000 require

TABLE 22B-1 Medically Important Scorpion Species

NAME	LOCATION	APPROXIMATE SIZE	COLOR
<i>Androctonus australis</i> (Yellow fat tail scorpion, yellow desert scorpion, Sahara scorpion)	North Africa (Tunisia, Algeria), Israel	Up to 10 cm	Brownish yellow
<i>Androctonus crassicauda</i> (Black fat tail scorpion, black scorpion)	North Africa (Egypt), Saudi Arabia, Persian Gulf	Up to 8.5 cm	Black or dark brown
<i>Buthus occitanus</i> (Common European scorpion, Tunisian scorpion, Moroccan scorpion)	North Africa (Tunisia, Algeria), Spain	4–7.5 cm	Yellow
<i>Centruroides sculpturatus</i> (Bark scorpion)	Southwestern United States, Northern Mexico	6.5 cm	Yellow, tan, or brown without stripes
<i>Centruroides suffusus</i> (Mexican scorpion)	Mexico	5–8 cm	Yellow, tan, or brown
<i>Hemiscorpius lepturus</i>	Middle East (Iran, Iraq, Pakistan, Yemen)	Females 5 cm Males 8.5 cm	Yellow to yellow brown
<i>Leiurus quinquestriatus</i> (Yellow scorpion, death stalker, five-keeled gold scorpion, Egyptian scorpion)	Saudi Arabia, Middle East, Egypt	Females 8 cm Males 7 cm	Yellow
<i>Mesobuthus tamulus</i> (Red scorpion, Indian red scorpion, Eastern Indian scorpion)	India	Up to 10 cm	Yellow to black
<i>Parabuthus</i> species	Southern Africa	Up to 10–14 cm, depending on species	Brownish
<i>Tityus serrulatus</i> (Brazilian scorpion, yellow scorpion)	Brazil	6–7 cm	Yellowish brown

hospitalization and 100 die.¹⁰ In Algeria, 50,000 people are stung and 150 die.¹¹ Mexico records about 100,000 cases each year, with 800 dying, and North Africa reports about 30 fatalities a year.⁶

In the United States in 2003, the Toxic Exposure Surveillance System reported 14,417 exposures to scorpions, 908 (6.3%) of which were treated in medical facilities. The majority of exposures were in adults 20 years and older (71.7%). Of the 3245 persons in whom follow-up was conducted, most (88%) had no or minor effects from the sting, 11.7% had moderate effects, and 10 people (0.3%) had life-threatening effects.¹² No deaths from scorpions were reported by U.S. poison centers in 2003. In 2002, however, two deaths were reported: one from a *Centruroides* sting and one resulting from the antivenom.¹³ In 2000, there was one death due to anaphylaxis from a scorpion sting.¹⁴ The National Vital Statistics System also reported one death in 2001 from a scorpion sting.¹⁵

Scorpion stings to humans are usually accidental. Scorpions are not aggressive and would rather escape from humans. Stings most commonly occur when a human unintentionally steps on or squeezes a scorpion or reaches under a stone or piece of wood. Children are often stung when playing with scorpions.⁶ Since scorpions are nocturnal, envenomations occur more commonly at night. In areas where scorpions are endemic, care should be taken to prevent scorpion envenomations (Box 22B-1).

Pharmacology and Pathophysiology

Scorpion venom has evolved primarily to aid in the immobilization of prey.⁷ Scorpion venom in general contains a complex mixture of mucopolysaccharides, hyaluronidase, phospholipase, acetylcholinesterase, serotonin, histamine, protease inhibitors, histamine releasers, and neurotoxins.⁴ Serotonin is thought to mediate most of the immediate pain experienced after an envenomation. *Hemiscorpius* venoms contain cytotoxic substances that cause significant tissue destruction; this is not typical of most scorpion venoms, which cause systemic toxicity. In humans, the neurotoxins are the most clinically significant component of scorpion venom. Each species of scorpion has its own collection of neurotoxins, but they share a similar structure. The neurotoxins are low-molecular-weight proteins composed of a single chain of 60 to 70 amino acids. The composition of the venom and its toxicity varies not only by species but also with the season, and with the age and the nutritional status of the scorpion.¹⁶

Of more than 14,000 scorpion species, the venoms of only 30 or so have been thoroughly characterized.¹⁷ Scorpion venom composition varies by species, and this variation may aid in taxonomy disputes.³ Only 0.02% of the estimated 100,000 unique peptides have been identified at present. Many of these peptides bind to and alter the function of cell membrane, voltage-dependent ion channels, specifically Na⁺, Cl⁻, K⁺, and Ca²⁺ channels.^{3,17} The affinity and effect of these ion channel effectors vary by species. Although not completely understood, action potentials are thought to be affected

BOX 22B-1 PREVENTION OF SCORPION STINGS

There are a number of precautions that you can take if you live in or are traveling in an area where scorpions are endemic:

- Reduce the amount of garbage and keep it covered. Insects are attracted to garbage and scorpions to insects.
- Avoid the accumulation of wood and other building materials near the house; such piles are good homes for scorpions.
- Before putting on clothes and shoes, check for the presence of scorpions.
- Check the covers and around the room before going to sleep.
- Do not walk barefoot at night.
- Wear gloves, closed-toe shoes, and other protective clothing when working in areas where scorpions may live (piles of wood, stones, etc.).
- Monitor children when they may be playing near areas where scorpions may hide.
- Keep beds and other furniture away from walls.
- Ensure windows have screens.
- In Mexico and other endemic areas, a row of glazed tiles around the walls and steps are recommended because scorpions cannot climb smooth surfaces.
- To attract scorpions, lay a piece of damp burlap on the floor before going to sleep. Scorpions will move under the burlap during the night where they can be killed the following morning.
- Chickens are natural enemies of scorpions, as are birds, bats, ducks, and monkeys.
- If chemical control is employed, it should be understood that scorpions can hide for extended periods of times. Insecticide effect should be long lasting or applied frequently.
- If you do feel something crawling on you, removed it with the palm of your hand instead of slapping it.

Data from references 2, 3, 4, 6, 7, and 35.

by several mechanisms. Certain peptides produce incomplete inactivation of sodium channels, thus resulting in a slowing and prolonged duration of the action potential. Other peptides produce spontaneous opening of sodium channels, which results in spontaneous depolarization, hyperexcitability, and repetitive neuronal firing.¹⁷ Increased calcium channel permeability of presynaptic neurons enhances neurotransmitter release and enhanced neuronal activity. Neurons of the autonomic nervous system (nicotinic, muscarinic, and adrenergic neurons) are largely affected and result in enhanced parasympathetic and sympathetic nervous system activity. Peripheral sensory and motor nerves are also affected and result in significant pain and motor hyperactivity.^{1,4} The human lethal dose of venom ranges from 100 to 600 µg, which is equivalent to the maximum amount of venom present in the scorpion's telson at any one time.³

Pharmacokinetics

Many of the distribution and pharmacokinetic studies on scorpion venom were carried out by Ismail and colleagues in animals.¹⁸ Scorpion venom is injected subcutaneously and rapidly absorbed into tissues.³ Using radiolabeled venom from *Leiurus quinquestriatus*, *Buthus*

FIGURE 22B-3 *Androctonus australis*. (Courtesy of Scott Stockwell, PhD.)

judaicus, and *Androctonus amoreuxi*, they demonstrated that the venoms appeared to demonstrate a two-compartment pharmacokinetic model. Following intravenous administration, there is rapid tissue redistribution (alpha phase) over 4 to 7 minutes followed by an overall elimination (beta phase) half-life of 4.2 to 13.4 hours.^{3,18} An Algerian study using an enzyme-linked immunosorbent assay (ELISA) in 182 cases of *Androctonus australis* envenomations showed a correlation between the clinical severity of envenomation on presentation and blood venom concentrations (Fig. 22B-3). They showed an elimination half life of 2 hours, and antivenom administration did not effectively neutralize the scorpion venom.¹¹ In another study, which used a sandwich ELISA method in three victims of *Centruroides* envenomation, the elimination of venom was consistent with a two-compartment model, with half-lives ranging from 313 to 515 minutes.¹⁹

Special Populations

The severity of envenomation will depend on both scorpion and host factors. The species and size of the scorpion, number of stings, and amount of venom delivered will affect illness severity.³ Host factors that are important include age, weight, and health of the victim.³ Because the severity of symptoms is age and weight dependent, children usually sustain more severe scorpion envenomations than adults.¹⁶ The mortality rate in children is also higher. Children younger than 5 years stung by *Centruroides sculpturatus* are more likely to develop severe neuromuscular hyperactivity and respiratory effects.²⁰ Elderly patients with preexisting cardiac problems are also considered to be at a greater risk for severe effects and mortality from scorpion envenomation.^{3,6}

Little is known about the effect of scorpion envenomation in pregnant women.²¹ Animal studies have shown that the uterus of pregnant rats may be more sensitive to scorpion venom early in pregnancy.²² In humans, there

FIGURE 22B-4 *Leiurus quinquestriatus*. (Courtesy of Scott Stockwell, PhD.)

are some anecdotal reports of first-trimester spontaneous abortion in pregnant women stung by *L. quinquestriatus* (Fig. 22B-4).²¹

Clinical Manifestations

Most scorpion stings are characterized by severe localized pain with little visible evidence of envenomation. There may be slight edema, pruritus, numbness, and occasionally small blisters at the bite site.⁶ Paresthesias and hyperesthesias travel up the extremity and may become generalized.¹ Performing a tap test may be helpful to distinguish a *C. sculpturatus* from other envenomations in the United States. Tapping gently on the site of the sting will substantially worsen the pain if the sting is from a *C. sculpturatus* scorpion.⁴

Local tissue effects vary among species. The *Hemiscorpius lepturus* can cause significant dermal lesions. However, the presence of significant local effects practically rules out *C. sculpturatus* envenomation.²³

There have been several grading systems developed for use in scorpion envenomations. One has been developed for *C. sculpturatus* envenomations commonly seen in the United States (Table 22B-2).¹ Grade I consists of pain and paresthesias at the site of envenomation only. In grade II, the pain and paresthesias have progressed to other areas distant from the envenomation site and the patient may also experience perioral numbness. Patients with a grade III envenomation exhibit either cranial nerve or skeletal neuromuscular dysfunctions. Grade IV consists of both cranial nerve and skeletal neuromuscular dysfunction.

In Algeria, a three-grade system is used to classify scorpion envenomations.²⁴ Grade I envenomations are considered mild; patients manifest local pain and burning only. Grade II envenomations include systemic signs and symptoms (e.g., shivering, restlessness, faintness, or vomiting and other gastrointestinal signs). Grade III envenomations are characterized by serious systemic

TABLE 22B-2 Grades of *Centruroides sculpturatus* Envenomation

Grade I	Local pain and/or paresthesias at the site of envenomation
Grade II	Pain and/or paresthesias remote from the site of envenomation, in addition to local findings
Grade III	Either cranial nerve or somatic skeletal neuromuscular dysfunction: <ol style="list-style-type: none"> 1. Cranial nerve dysfunction: blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculations, problems with upper airway, slurred speech 2. Somatic skeletal neuromuscular dysfunction: jerking of extremities, restlessness, severe involuntary shaking and jerking, which may be mistaken for seizure activity (but are not)
Grade IV	Both cranial nerve and somatic skeletal neuromuscular dysfunction

Adapted from reference 1.

complications such as neurologic findings, hyperthermia, priapism, respiratory failure, pulmonary edema, or shock.

A study of calls to the Arizona Poison Center,¹ where a majority of envenomations would be expected to involve *C. sculpturatus*, showed that evidence of grade I envenomations such as pain and paresthesia was immediate in all cases. Progression to higher grades was variable but always happened in less than 5 hours. Infants sometimes progressed to grade IV in 15 to 30 minutes. A more rapid onset of signs and symptoms in young children is felt to reflect quicker absorption from their thinner dermis.^{8,25} In general, clinical effects occur immediately after envenomation (local pain initially), progress to peak effects by 5 hours, and may last for over 24 hours.⁴

Autonomic nervous system effects are prominent in higher-grade scorpion envenomations. Sympathetic or adrenergic signs include extreme agitation, hyperthermia, hypertension, tachycardia, mydriasis, piloerection, and diaphoresis. These effects may culminate in hypotension

**FIGURE 22B-5** *Buthus occitanus*. (Courtesy of R. David Gaban.)

and cardiovascular collapse. Priapism has been noted in males. Scorpion envenomations often associated with autonomic storm include the *Tityus* species of the Caribbean and South America, *Androctonus* and *Buthus occitanus* of North Africa, and the *Mesobuthus tamulus* (also known as *Buthus tamulus*) of India (see Figs. 22B-3 and 22B-5). Parasympathetic or cholinergic effects include bradycardia, salivation, bronchorrhea, nausea, vomiting, diarrhea, lacrimation, and urination. Without the history of a sting, these symptoms may be confused with exposure to an anticholinesterase pesticide, especially if such agents are being used for scorpion control.²⁵ Scorpions often associated with cholinergic excess include the *Centruroides* of the United States and Mexico and *Parabuthus* species of southern Africa (Fig. 22B-6).

Neurologic signs (peripheral and central effects) may include “roving eyes,” anisocoria, opsoclonus, disconjugate gaze, pharyngeal muscle dysfunction, and muscle and tongue fasciculations. Extreme muscle rigidity, twitching,

A

B

FIGURE 22B-6 Color variations of *Centruroides vitatus*. (Courtesy of Scott Stockwell, PhD.)

and jerking have also been described. Choreiform and ballistic motor activity is not uncommon. Seizures have been described with some scorpion envenomations but there is significant controversy among experts as to whether those envenomated by *C. sculpturatus* have true seizures. Most patients with motor hyperactivity are conscious. Cerebral infarction, cerebral thrombosis, and acute hypertensive encephalopathy have been described with *Buthidae* envenomations.

Gastrointestinal symptoms may be a reflection of cholinergic excess and profuse nausea, vomiting, and abdominal pain. Envenomation by *Tityus* species are well known to cause pancreatitis and are a major cause in endemic areas.

Severely symptomatic patients should be monitored for cardiac effects. Sequelae have included bradycardia, tachycardia, ventricular dysrhythmias, and cardiovascular collapse. Myocardial infarction has been documented with elevations of creatine kinase. This may be due to a direct myotoxic effect, although it is not well understood. Transient myocardial “stunning” or reversible mechanical dysfunction without tissue necrosis has also been documented with echocardiography.⁶ Respiratory function may be compromised by increased secretions and loss of protective reflexes. Pulmonary edema and cardiorespiratory collapse have also been noted. Anaphylactic reactions to scorpion stings, while rare, should be considered in people who have been previously exposed.⁷

Severe dermatologic changes, hemolysis, and central nervous system (CNS) changes are a prominent feature of the *H. lepturus*. In Southwestern Iraq, this scorpion is thought to account for only 10% to 15% of envenomations but for the majority of fatalities. Severe skin sloughing and disfiguring wounds have been described.²³

Diagnosis

The diagnosis of scorpion envenomation is made primarily from the patient's history and physical examination.

LABORATORY TESTING

The extent of laboratory evaluation will depend on the severity of the patient's clinical presentation. Even though venom assays have been used in studies, there are no routinely available tests for the detection of scorpion venom. Laboratory evaluation is used to rule out other medical illnesses and to facilitate the provision of supportive care (i.e., evaluate for complications of envenomation). A complete blood count with platelet count and coagulation studies may be warranted since defibrination syndrome has been reported after *M. tamulus* envenomation,^{26,27} and massive hemolysis may occur after *H. lepturus* envenomation.²³ Renal failure has occurred secondary to hemolysis or rhabdomyolysis and may merit monitoring of electrolytes, blood urea nitrogen, creatinine and creatine kinase, and urinary output. Because *T. trinitatus* envenomation has been associated with pancreatitis, amylase and lipase levels may be helpful. In addition, arterial blood gases may be necessary to guide therapy in patients with severe respiratory distress.

OTHER DIAGNOSTIC TESTING

An electrocardiogram (ECG) may be helpful because some scorpions such as *L. quinquestriatus* have caused arrhythmias (e.g., atrioventricular block and bradycardia). Other ECG changes such as ST-T wave abnormalities and QTc segment prolongation have also been reported. Echocardiography of patients with shock typically demonstrates global hypokinesia.²⁸ Chest radiography may be helpful in patients with respiratory symptoms to assess for pulmonary edema.

DIFFERENTIAL DIAGNOSIS

If the scorpion is not seen at the time of the bite, the differential is wide. It includes spider bites, insect bites, and abrasions. The differential diagnosis for patients presenting with neurologic signs and symptoms includes acute dystonic reactions; seizures; poisoning with CNS stimulants, cholinergic agents, and strychnine; acute cerebrovascular accident; CNS infections; botulism; and tetanus.

Occasionally, the similarity in presentations between *Centruroides* stings and CNS stimulant ingestion is used by parents to conceal the cause of their children's illness. In a case series of 18 cases of methamphetamine ingestion, two children were misdiagnosed as victims of scorpion envenomation. The two children were treated with anti-venom, and one of the patients developed anaphylaxis.²⁹

Management

SUPPORTIVE CARE

Most envenomations are minor and can be treated symptomatically with analgesics, local wound care, tetanus prophylaxis, and a period of observation to determine whether the envenomation will progress. In healthy adults, many envenomations can be managed at home. Judicious application of ice, light compression wrapping, and immobilization of the effected area often offer some relief.⁷ Oral analgesics are helpful, but parenteral therapy may be required. Some recommend local anesthesia with lidocaine, bupivacaine, or dehydroemetine by infiltration or a nerve block.⁴ Prophylactic antibiotics are not indicated and should be withheld until evidence of infection occurs. The use of steroids has not proven beneficial.¹⁰ If the scorpion has been killed and brought with the patient, it may be helpful to have it identified by an entomologist.

For patients exhibiting systemic envenomation, advanced life support measures (including endotracheal intubation) should be instituted as necessary to treat respiratory compromise. Continuous cardiovascular and respiratory monitoring should be employed. Hyperthermia and hypothermia should be addressed. Fluid resuscitation should be administered as necessary along with careful observation for pulmonary edema. Excessive secretions may require frequent suctioning.

When envenomation is complicated by hyperthermia, acetaminophen and external cooling methods have been recommended.¹⁸ Dipyrone intravenously has been advocated in *Tityus serrulatus* envenomation. Vomiting should be treated with antiemetic therapy (e.g., metoclopramide) and aggressive rehydration with intravenous crystalloid.

Seizures or neuromuscular hyperactivity should be treated initially with benzodiazepines and/or barbiturates.

Routine administration of atropine or neostigmine for their parasympatholytic effect is controversial. These agents have been used successfully to decrease secretions associated with *Centruroides* and *Tityus* envenomations.^{3,30} These agents may also exacerbate sympathetic effects and result in hypertension and pulmonary edema.³ Thus, anticholinergics should probably be reserved for cases of severe bradycardia.

Hypertension is a hallmark of most severe envenomations and should be treated aggressively. Nitroprusside is the agent of choice for severe hypertension and can be more easily titrated to effect.⁷ Prazosin is a selective α_1 -adrenergic receptor blocker that has been recommended for scorpion envenomation, particularly from *M. tamulus* envenomation. Case series in India have shown beneficial effect, and Bawaskar strongly recommends early administration.³⁰ The use of nifedipine for hypertension is discouraged because it may cause reflex stimulation of the sympathetic nervous system and lead to cardiac stimulation and dysrhythmia. Angiotensin converting enzyme inhibitors are discouraged because they may exacerbate venom toxicity by increasing bradykinin levels.¹⁸ Hydralazine has been used extensively for the treatment of hypertension but has been associated with unpredictable hypotension.

When it occurs subsequent to envenomation, pulmonary edema should be treated with oxygen and positive pressure mechanical ventilation as necessary. Loop diuretics should be used with caution due to volume depletion in many patients.

Historically, initial treatment recommendations included heavy sedation with so-called "lytic cocktails." Heavy sedation with benzodiazepines and aggressive opioid analgesic therapy is now sometimes discouraged due to the associated risk for respiratory compromise. When used, these therapies should be used judiciously.

Hemiscorpius stings in Iraq have exhibited local tissue destruction and hemolysis. Local authorities have advocated early local excision, alkalization of urine to prevent renal failure, and steroids. Randomized trials to support these recommendations have not been conducted.²³

ANTIDOTES

The use of antivenom for envenomations is controversial. Since the risk for death with scorpion envenomation is so small and the risk for allergic reaction from antivenom administration is high, the benefit of antivenom administration is unclear. Thus, supportive care is probably similar in efficacy and safer than the use of antivenom.⁷ Many complex antivenom regimens have been promulgated for symptomatic scorpion envenomations without clear evidence of efficacy. Rigorous testing of these regimens is difficult due to the wide variety of scorpions and the limited resources where most envenomations occur (i.e., limited availability of specific medications, critical care support, or antivenom). Perhaps not surprisingly, the extant regional literature seems to support regimens commonly used in each region.

Antivenom recommendations are not clearly defined, and antivenom is not readily available in many areas or

for many specific species. For areas that have antivenoms, there has been little control over their manufacture and quality, yet most are used in the belief that they represent the standard of care. Antivenom use has been predicated on the premise that any venom should respond to antivenom. Trials to prove efficacy have been rare, and future trials are questionable ethically in areas where administration has become the standard of care. In general, use of antivenom should be reserved for patients with severe signs and symptoms of envenomation (grades III and IV), particularly young children.

To date, the greatest use of scorpion antivenoms has occurred in regions of frequent envenomations, such as Northern Africa, the Middle East, Mexico, and Brazil. Large series of patients treated with antivenom have been reported supporting the use of antivenom. In one series of patients, antivenom administration was reported for over 20,000 cases of *Centruroides* scorpions in Mexico.³¹ No patient developed immediate hypersensitivity from antivenom, and no deaths were recorded. In another large series of patients from Brazil, antivenom use was reported in 3860 patients stung by *T. serrulatus*.³² The mortality rate was 0.28%. All deaths occurred in children treated 3 or more hours after envenomation. In the few controlled clinical trials that have been conducted evaluating antivenom therapy, however, a benefit from antidotal therapy has not been shown.^{9,10} Proponents of antivenom use argue that antivenom is the only specific treatment to directly counteract the primary physiologic effects of the venom, and its administration significantly improve outcomes. The disappointing results seen from the controlled trials probably result from inadequate dosing.⁴ Opponents to antivenom therapy believe that since the major effects of envenomation result not from the toxin, but from the release of endogenous neurotransmitters, antivenom will have minimal effect at reducing morbidity and mortality.⁴ However, until more controlled trials are conducted, antivenom use appears to be justified in cases of severe systemic envenomation, particularly in high-risk groups such as children.^{6,9,33} In some areas where there is limited access to clinical care (e.g., rural Mexico), early antivenom use has become the standard of care.

Until recently, a goat serum antivenom for *Centruroides sculpturatus* envenomation had been available in the United States from the University of Arizona. This antivenom was not approved by the Food and Drug Administration (FDA), however, and could not be used outside the state of Arizona. In small, uncontrolled studies, this antivenom appeared to be effective but was also associated with a significant incidence of hypersensitivity reactions.^{9,34} Its intravenous administration produced rapid resolution of the respiratory, cardiovascular, and neurologic toxicity associated with the sting of *C. sculpturatus*.⁴ Symptoms resolved within 3 hours for patients who received antivenom, whereas symptoms lasted 15 to 24 hours for those not treated with antivenom.³⁴ Of those receiving the antivenom, however, 3% to 8% experienced an immediate hypersensitivity reaction and 58% to 61% developed delayed serum sickness.^{25,34} The production of this antivenom has recently ceased, and the remaining supply is becoming depleted. The FDA

has approved clinical testing of an antivenom, Alacramyn Fab2 fragment, produced by the Mexican Ministry of Health. This product is polyvalent and equine derived and has been used extensively for the Mexican *Centruroides*.³

If antivenoms are used, they should be administered as soon as possible after envenomation to contain the release of endogenous reactive substances.^{4,6} In addition, the tissue distribution of the antivenom immunoglobulins is much slower than that of the venom, with redistribution half-lives 11 to 102 times longer than that of venom.¹⁰ The antivenom should be administered intravenously because intramuscular administration further slows tissue distribution.^{6,35,36} The Mexican antivenom is administered with an H₁-antihistamine (e.g., chlorpheniramine).³ During administration of antivenom, patients should be observed closely for any signs and symptoms of type I immediate hypersensitivity reactions. Patients should also be monitored for serum sickness (typically occurs 7 to 21 days after antivenom), which can be treated with oral antihistamines and corticosteroids.

Patients with grade III or IV *Centruroides* stings and other severe Buthidae envenomations should be admitted to an intensive care unit (ICU) and/or treated with antivenom. Occasionally, patients with grade III envenomation are discharged home after resolution of their symptoms with antivenom. In general, young children are more likely to require inpatient observation.

Disposition

The disposition of the patient depends primarily on the severity of illness at presentation. Those who exhibit significant symptomatology will require intensive care monitoring and support. Observational monitoring should continue until patients are hemodynamically stable and no longer at risk for rhabdomyolysis. For *C. sculpturatus* envenomations, the rapidity of sign and symptom resolution is dependent on the patient's age and severity of envenomation. Improvement usually occurs by 10 hours for those not treated with antivenom.⁴ However, the pain and paresthesias from the scorpion sting may persist for 1 to 2 weeks.

Those treated with antivenom should be followed closely after hospital discharge due to the significant risk for serum sickness. These patients should be educated as to the signs and symptoms of serum sickness (e.g., arthralgias) and appropriate initial treatment (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]).

STINGING INSECTS AND OTHER VENOMOUS ARTHROPODS

Hymenoptera

INTRODUCTION AND RELEVANT HISTORY

Hymenoptera is a very large order of the phylum Arthropoda and the class Insecta. Species of medical importance belong to the following families: Vespidae (wasps, yellow jackets, and hornets), Apidae (honeybees and bumblebees), and Formicidae (fire ants, Australian

jumper ant, and others). In general, hymenoptera are not aggressive toward humans.⁶ The greatest risk to humans is not the toxicity of their venom, but rather the risk of type I allergic reactions. The earliest depiction of such a reaction is in the tomb of the Egyptian pharaoh Menes, who died in 2621 BC following an insect sting.³⁷

The family Apidae contains a number of types of bees. Honeybees (*Apis mellifera*) are social creatures that live in colonies of 30,000 to 50,000 workers. These creatures most frequently sting to protect their colony from honey-loving predators.⁶ "Killer" bees (*Apis mellifera scutellata*) are African honeybees that were introduced to Brazil because they were thought to be more efficient at producing honey in tropical climates. They first escaped from hives in Brazil in 1957 and have since spread widely, reaching the southern United States in 1990. There are now populations in Texas, Arizona, New Mexico, and California.³⁸ Killer bees are of concern because they are more aggressive than typical hymenoptera, attack in swarms, and chase victims for greater distances from their hive than other species.³⁸ Bumblebees (*Bombus* and related genera) are generally mild mannered and live in smaller colonies of around 1,000 individual insects in underground nests or in hollow trees.^{6,38} Sweat bees (family Halictidae) are small insects attracted to sweaty skin. Their sting is not very painful but can cause anaphylaxis, and their venom is not immunologically related to that of other bees and wasps.³⁸

The family Vespidae mainly contains social wasps; a small number of solitary species are also included. Social wasps are found throughout the world but are predominantly a medical problem in the United States and Europe (Fig. 22B-7).³⁸ They live in colonies of 30 to several thousand individuals.³⁹ While some species may use their stinger to capture prey, the stinger is primarily used to defend the colony.⁶ Wasps seldom sting away from the nest unless trapped or disturbed.⁴⁰

Ants are social insects whose venom is used primarily for defense and, occasionally, for capturing prey.^{6,38} The most medically important ant in the United States is the fire ant. Fire ants (*Solenopsis invicta*) were initially

FIGURE 22B-7 Paper wasps. (Courtesy of Nancy Hinkle, PhD, University of Georgia.)

introduced to Mobile, Alabama, in 1939 as a stowaway in a shipment of nursery products and sod.^{38,41} Currently, fire ants infest Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia, Puerto Rico, Arizona, New Mexico, and California.⁴² Harvester ants (*Pogonomyrmex*), which are found in the Southwestern United States and Mexico, also have some medical importance. They can produce a painful sting, which may result in systemic symptoms and anaphylaxis.³⁸

The venom apparatus of hymenoptera is located at the end of the abdomen and consists of venom glands, a reservoir for the venom, and a hollow structure for piercing the integument and injecting the venom.³⁸ The stingers are actually modified ovipositors, and therefore, only the females can sting.⁶ When honeybees sting, they leave the entire venom apparatus in their target and eventually die.⁶ Because bumblebees and wasps do not have barbed stingers, they can remove their stinger and sting repeatedly.^{6,41} In some species of ants, the stinger is absent and the ant sprays venom into a wound created by its bite.³⁹

EPIDEMIOLOGY

In 2003, the American Association of Poison Control Centers reported 12,516 exposures to bees, wasps, yellow jackets, and hornets and 2480 exposures to ants.¹² There was one reported death in a 3-month-old from fire ant stings and one death from multiple yellow jackets stings to a 2-year-old.¹² Between 40 and 55 deaths a year in the United States are attributed to insect stings, primarily from anaphylaxis.^{6,15} Current numbers may underestimate the problem because many unexplained sudden deaths in outdoor workers and others may be undiagnosed anaphylactic reactions to hymenoptera.^{43,44} In the United States and Europe, the majority of deaths due to venomous animals are caused by hymenoptera.³⁹

Hymenoptera stings more frequently occur to the head or neck, followed by the lower and upper extremities. Stings in the mouth, pharynx, and esophagus can occur when an insect is accidentally ingested.³⁸ In temperate areas, stings occur more frequently in the summer and early fall because hymenoptera are more active in higher temperatures and humidity.^{38,39} About twice as many men experience severe reactions to stings than females, but this may likely be a difference in exposure rates rather than a physiologic difference.⁴¹ Adults are more likely to experience severe reactions than children³⁸; most deaths are in people over 40 years of age.³⁹ In the United States, 0.4% of the population exhibits some type of allergic reaction to insect venom.³⁸ Large local reactions to hymenoptera stings occur in 2% to 19% of patients. Systemic reactions are seen in 1% to 3% of adults and less than 1% of children.³⁷ Of those individuals who exhibit a systemic reaction, 27% to 57% will react systemically to a future envenomation by the same type of insect.³⁷

Multiple stings often occur when a nest is disturbed. Either the venom or an alarm pheromone released by the first insects threatened stimulates the other members of the colony to attack.^{38,39} Another dangerous situation

BOX 22B-2 PREVENTION OF HYMENOPTERA STINGS

Precautions that can reduce the risk of sustaining a hymenoptera sting:

Bees and wasps are attracted to sweet things and wasps are also attracted to meat, so keep food covered when eating outdoors. Frequently clean garbage cans and recycling bins and dispose of decaying fruit to make the area less attractive to bees and wasps.

Do not walk around barefoot outside.

Wear gloves, shoes, and other protective clothing when gardening.

Do not wear strong-smelling perfumes and lotions when spending significant time outdoors.

Dark-colored clothing and that with colorful patterns are attractive to bees and wasps; white and light khaki clothing is less attractive.

Exercise caution around fallen tree trunks because wasps may build nests inside.

Avoid fast movements around bees and wasps.

If you disturb a nest, stay still as opposed to running away. Fast movements will attract the attention of the insects and make multiple stings more likely.

Insect repellents used with mosquitoes are not effective with hymenoptera.

Hymenoptera are susceptible to many insecticides. It is safer to spray nests at night.

Antihistamines taken prophylactically before high-risk activities (e.g., beekeeping) can prevent large local reactions but are not protective against more severe reactions.

Allergic individuals should carry an emergency kit with epinephrine and wear a medical identification tag indicating the allergy.

Kits should be available in work and recreation areas where the possibility of stings is high.

Data from references 6, 37 through 40, and 47.

exists when wasps or bees are accidentally trapped in motor vehicles. Not only are the occupants at risk for stings, but they are also at risk for crashes as they attempt to kill or remove the insect from the car.³⁸ General measures that can be taken to prevent hymenoptera envenomation are listed in Box 22B-2.

Fire ant stings usually occur in children and to the lower extremities. Stings most often occur in the summer, although there may be a seasonal difference in the venom protein concentrations.⁴² It is estimated that 30% to 60% of people in endemic areas are stung each year.⁴² There have also been reports of massive sting attacks in residents of nursing homes.⁴² Approximately 0.6% to 16% of people stung will exhibit an anaphylactic reaction. Most of these individuals have received previous stings, but some will develop a reaction after their first sting. However, most of these people appear to be sensitized to yellow jackets and research suggests that these two venoms cross-react.⁴²

PHARMACOLOGY AND PATHOPHYSIOLOGY

The venoms of hymenoptera varies by family and species, but in general, most contain a mixture of low-molecular-weight substances (i.e., peptides) and high-molecular-weight substances (i.e., enzymes). During one single bee

or wasp sting, a volume of only 0.5 to 2 μL of venom is injected.^{38,39} Most venoms cause predominantly local pain and discomfort. More severe sequelae can be caused by their respective allergenicity.

The low-molecular-weight substances include histamine, tyramine, dopamine, serotonin, epinephrine, and norepinephrine. These agents predominantly cause pain, mast cell degranulation, and further catecholamine release. Ant venoms contain formic acid, and fire ant venom contains dialkylpiperidines.³⁹

Peptides present in hymenoptera venom are responsible for further mast cell degranulation. These include a number of wasp kinins, mastoparans, and chemotactic peptides. About 50% of dry bee venom is melittin, a peptide consisting of 26 amino acids. It acts as a detergent in cell membranes and is responsible for pain. Other peptides found in bee venom are Oa-Adolapsin, apamin, and mast cell degranulating peptide. Apamin blocks calcium-dependent potassium channels.³⁹

Enzymes or high-molecular-weight substances include hydrolytic enzymes that have a digestive effect on tissues. These high-molecular-weight substances include phospholipase A2, phospholipase B, hyaluronidase, acidic phosphatase, alkaline phosphatase, cholinesterase, histidincarboxylase, saccharidase, DNase, and protease. These high-molecular-weight compounds are potential allergens and may precipitate severe allergic reactions in sensitive people.³⁹

Allergic manifestations are the result of an immunoglobulin E (IgE)-mediated (type I) hypersensitivity reaction. The initial contact with the allergenic venom components, usually phospholipase A2, hyaluronidase, or melittin, stimulates the body to produce IgE antibodies. Upon subsequent contact with the sensitizing allergen, there is aggregation of the IgE antibodies by mast cells, which leads to degranulation and histamine release.⁶

There is little cross-sensitization between bees and wasps. There is, however, almost 100% cross-sensitivity between yellow jacket and hornet venom. Cross-sensitivity is also seen between fire ants and bees or wasps. Of people allergic to bees or wasps but without exposure to fire ants, 51% of patients had a positive radioallergosorbent test reaction to fire ant venom.³⁸

PHARMACOKINETICS

In general, the venom is injected 2 to 3 mm into the subcutaneous tissue.⁶ In the case of intravenous injection or a sting in a highly vascular area, systemic reactions may be more likely.³⁷

Toxic reactions are produced by venom in a dose-dependent manner.³⁷ The amount of venom injected per sting varies by species. Bees usually inject 50 to 100 μg of venom per sting, while wasps and hornets inject 2 to 10 μg per sting.⁶ The number of stings necessary to produce a life-threatening reaction vary from 40 to 50 for a large species like the white-faced hornet to 500 to 1400 stings for a honeybee.³⁸ For Africanized “killer” honeybees, 50 stings can cause systemic toxicity and an estimated 500 are necessary to cause death due to toxicity. The intravenous median lethal dose in mice for honeybees

in 6 mg/kg and for different hornet venoms is 1.6 to 4.1 mg/kg.³⁸

SPECIAL POPULATIONS

Due to the dose-dependent toxicity from hymenoptera venom, those with smaller body mass are more susceptible to the toxic effects produced by multiple stings. Thus, fewer stings are needed to become life-threatening in children. Glucose-6-phosphate dehydrogenase deficiency may predispose some populations to greater hemolytic toxicity from envenomation.⁴⁰

CLINICAL MANIFESTATIONS

Most patients will present with instant pain and a wheal and flare reaction at the site of envenomation.³⁸ Stings in the mouth, throat, or larynx can cause swelling of mucous membranes and laryngeal edema.⁶ Local erythema and swelling may also occur.

Large local reactions spreading more than 15 cm and persisting more than 24 hours are thought to represent cell-mediated (type IV) hypersensitivity. Half of the patients with large local reactions, however, will also have elevated serum IgE (indicative of type I reaction) or a positive skin test result. Subsequent stings in these victims usually result in another large local reaction as opposed to a more severe systemic reaction.⁴⁴

Fire ant stings start with the typical wheal and flare reaction that occurs within 20 minutes of the sting. Sterile pustules or necrotic lesions develop within 24 hours, and may last for several days and are pathognomonic for fire ant stings. Pustules are often observed in a ring pattern because the ant bites the skin and then stings as it pivots around the bite site.⁴¹

The most serious complication of hymenoptera envenomation is an allergic reaction. Severe allergic reactions and anaphylaxis are common. Allergic symptoms may include skin rash, edema, bronchial constriction, cardiovascular failure, difficulties swallowing and speaking, labored breathing, burning sensation in the pharyngeal cavity, itching of palms and soles, hot flashes, hypotension, and general weakness.⁶ Over 50% of severe reactions occur within 10 minutes, and almost all in the first 5 hours. Most deaths occur within 1 hour.³⁸

Massive hymenoptera envenomations, as occur from multiple stings (i.e., 20 to 50), may also cause systemic effects. These effects include vomiting, diarrhea, generalized edema, dyspnea, hypotension, tachycardia, and cardiovascular collapse. Widespread necrosis of skeletal muscle (rhabdomyolysis) may occur and result in hyperkalemia, acute renal failure from acute tubular necrosis, and hepatorenal syndrome. In addition, hemolysis, hemoglobinuria, acute pancreatitis, disseminated intravascular coagulation, acute respiratory distress syndrome, myocardial infarction, atrial fibrillation, optic neuropathies, and cerebral infarction have been reported after multiple stings.³⁸

Atypical reactions can include serum sickness, Arthus reaction, nephritic syndrome, thrombocytopenic purpura, grand mal or focal motor seizures, transient ischemic attacks, Guillain-Barré syndrome, and progressive demyelinating neurologic disease.³⁸

DIAGNOSIS

Diagnosis is usually made by history and suggestive physical findings. If the patient has not seen a hymenoptera insect or is unable to give a history, the diagnosis may be more difficult. It is often difficult to distinguish between symptoms of an immediate allergic reaction and a systemic, dose-related, toxic reaction to multiple stings.³⁷

Laboratory Testing

Laboratory evaluation should be based on clinical presentation. Most uncomplicated envenomations will require observation only. For severe allergic reactions and patients with multiple stings, urinalysis, complete blood count, and serum measurements of electrolytes, renal function, creatine phosphokinase, and lactate dehydrogenase should be obtained.³⁸

Serum IgE levels and tryptase levels may be elevated following allergic reactions to hymenoptera stings, although this is rarely readily available or helpful in acute management of patients. In a study of sera collected in 142 cases of sudden unexpected death, 23% contained elevated IgE to at least one insect venom as compared with 6% of sera from 92 living blood donors.⁴³ In an additional study of 68 of the previous samples, 9% were found to have elevated tryptase levels in addition to the elevated IgE levels.⁴⁵ Similarly, anti-fire ant IgE and an elevated tryptase level were observed in a fatal fire ant envenomation.⁴⁶ Patients with significant reactions should be referred for evaluation by an allergist for more specific testing and consideration of immunotherapy.

Differential Diagnosis

Hymenoptera envenomations can be confused with stings from other insects and spiders. Similar signs and symptoms may also occur with allergic reactions of unknown etiology.

MANAGEMENT

Decontamination

Many authorities recommend immediate removal of retained stingers with the thought that the retained venom apparatus continues to pump venom.^{37,47} The time until stinger removal is correlated with severity of reaction.⁴⁷ Although many procedures are advocated, the stinger can be removed by gentle scraping of a straight edge such as a credit card. For most cases, washing the area with soap and water is the only decontamination necessary. If the person is sprayed with ant venom, water should be used to rinse the formic acid from the eyes and mucous membranes.⁶

Supportive Care

For most envenomations, all that is necessary is local wound care, analgesia, tetanus prophylaxis, and a brief period of observation to make sure hypersensitivity does not occur. Secondary infections are likely greater with vespid envenomations as compared with honey bees since vespids reuse their stinger and sometimes break the skin with their mandible.⁴⁰ Regardless, the risk for infection is small, and prophylactic antibiotics are not

recommended. Ice packs, antihistamine lotion/cream, and topical antimicrobials may be helpful. Oral antihistamines are often used but are of questionable effectiveness except with more severe local reactions or generalized urticaria.^{37,38} Oral corticosteroids may be effective in extensive local reactions.³⁸ Immobilization and elevation of the stung extremity will help reduce swelling.³⁷

There are no uniformly effective treatments for fire ant envenomation.⁴⁸ Cold compresses, oral antihistamine, and corticosteroids may be helpful for symptoms.⁴² Reactions are thought to be primarily immunogenic, and prophylactic antibiotics are not routinely recommended. Proactive breaking of blisters is discouraged.³⁸ Massive fire ant stings in the absence of allergic reactions can usually be managed with topical corticosteroids and oral antihistamines.⁴²

Treatment of severe signs and symptoms of anaphylaxis is beyond the scope of this chapter. Multiple stings that produce systemic toxicity or severe hypersensitivity reactions (e.g., anaphylaxis) require aggressive therapy and ICU observation. Those patients with greater than 50 to 100 bee stings should be hospitalized and observed for signs of systemic toxicity.³⁹ The treatment of all severe reactions includes the administration of intravenous crystalloid, parenteral corticosteroids, H₁- and H₂-receptor antagonists (antihistamines), epinephrine (subcutaneous or intravenous), and inhaled β₂-adrenergic receptor agonists. Close cardiac, hemodynamic, and urine output monitoring is warranted in such patients. All patients with systemic symptoms or that require epinephrine should have a 12-lead electrocardiogram performed.^{6,37,38} These patients should be admitted and monitored for 12 to 24 hours for coagulopathy and evidence of renal compromise.³⁸ Massive envenomations may be at risk for subsequent delayed type III serum sickness reactions that can typically be treated with NSAIDs and corticosteroids.

Antidote

A group in the United Kingdom has developed an antivenom for use in patients with multiple bee stings. While it has been effective in animal models, there has been no documented use in humans.³⁸

DISPOSITION

Patients presenting immediately after envenomation should be monitored for an appropriate period of time, usually 1 to 2 hours, for signs and symptoms of hypersensitivity progression and anaphylaxis. Patients who are asymptomatic or have minimal local reactions without progression may then be safely discharged. They should be instructed to return immediately for recrudescence or delayed-onset allergic signs and symptoms (e.g., urticaria, difficulty breathing). For mildly symptomatic patients with appropriate access to health care or asymptomatic patients with a documented prior sensitivity, many advocate a short 3-day course of oral antihistamines and corticosteroids. Moderate hypersensitivity reactions, such as isolated urticaria without hypotension or respiratory difficulty, may be treated with a short

observation period until their signs and symptoms improve or resolve. They should also receive a 3-day course of antihistamines and corticosteroids. If a patient has been treated with epinephrine prior to arrival or during observation, they should be observed for at least 2 hours after the administration of epinephrine to ensure that they exhibit no hypersensitivity recrudescence; significant symptom recurrence is uncommon. Severe symptomatology requires observation for 24 hours or longer if persistently symptomatic. Fifty stings in a child or 100 stings in an adult may also be life threatening,³⁹ so patients who are victims of severe attacks with multiple stings merit 24-hour observation.

Patients that develop moderate to severe hypersensitivity reactions should always be discharged with a prescription for an epinephrine auto-injector and education regarding the use of the auto-injector and prevention of further hymenoptera stings (see Box 22B-2). In addition, they should schedule outpatient follow-up with an allergist for more specific testing and consideration for immunotherapy.

OTHER VENOMOUS ARTHROPODS

Lepidoptera

Lepidoptera is the order of the class Insecta that includes butterflies and moths. Sixteen families have venomous species, which are largely caterpillars with venomous spines. One such stinging caterpillar is the saddleback caterpillar (*Sibine stimulea*) in the family Limacodidae (Fig. 22B-8). Envenomation generally occurs accidentally when brushing against one of these caterpillars or attempting to remove it by hand from clothing or on the body. These sharp hairs or spines are either hollow, connected to poison glands (venom flows on contact), or similar to glass fibers (hairs break off in skin easily) sometimes causing pain like a needle prick. The venom of stinging caterpillars is poorly characterized and

typically produces an urticarial rash and minimal local discomfort after contact.³⁸ This rash may develop over a few hours and last for a week. In addition, detached spines can lodge in the eye and cause conjunctivitis or keratitis.³⁸ The recommended treatment is to remove the spines with an adhesive tape while trying to avoid rubbing the area of contact. Analgesics, including anti-inflammatory drugs (e.g., NSAIDs), antihistamines, and topical corticosteroids are also recommended. Patients with a spine lodged in their eye need to be referred to an ophthalmologist for microscope-assisted removal. Lepidoptera envenomations can be prevented by not handling caterpillars, wearing protective clothing when participating in activities that put one in contact with the caterpillar habitat, spraying trees with appropriate pesticides, and using window screens.^{6,38}

The puss caterpillar or woolly caterpillar (*Megalopyge opercularis*) is the most medically significant species in the southern United States (Fig. 22B-9); its habitat extends between Texas and Missouri. Puss caterpillar stings can cause dyspnea, seizures, abdominal pain, hypotension, and characteristic hemorrhagic pinpoint papular lesions (Fig. 22B-10).³⁸

In South America, *Lonomia achelous* and *Lonomia oblique* are caterpillars that can cause severe envenomations and have a mortality rate three to six times higher than envenomations from snakebites.⁶ The venom contains a component (Lonimine V) believed to be responsible for coagulopathy by inactivating factor XIII.⁶ Contact with *Lonomia* spines causes immediate pain followed by headache a few hours later. The contact site develops ecchymosis that may spread to the rest of the body. Brain hemorrhages secondary to coagulopathy can develop.⁶ Patients with coagulopathy may benefit from administration of *L. oblique* antivenom.⁴⁹

Hemiptera (Sucking Bugs)

These bugs include the traitomines (kissing bugs, vinchuca bugs), assassin bugs (family Reduviidae), and

FIGURE 22B-8 Saddleback caterpillar (*Sibine stimulea*). (Courtesy of J.D. Hinkle.)

FIGURE 22B-9 Puss caterpillar (*Megalopyge opercularis*). (Courtesy of Christopher Holstege, MD, University of Virginia.)

FIGURE 22B-10 Papular lesions from contact with the puss caterpillar. (Courtesy of Alexander Baer, MD, University of Virginia.)

bed bugs (family Cimicidae). They are 2 to 4 cm in length and have a proboscis that allows them to suck blood from their prey. The venom is used to subjugate prey and may aid with their digestion. The bites are painless but cause pruritic papules that form a line or a cluster. Patients may develop fever, lymphadenopathy, hemorrhagic bullae, urticarial wheals, and even anaphylactic reactions. Treatment is supportive and symptomatic. Preventive actions include using insecticides and wearing protective garments.

Beetles

Blister beetles (family Meloidae) and rove beetles (genus *Paederus* from family Staphylinidae) are found in the Eastern United States, Europe, Africa, and Asia. These beetles produce harm to humans primarily when they are crushed against the skin, releasing secretions that contain cantharidin (blister beetles) and pederin (rove beetles), respectively. Skin contact with cantharidin causes noninflammatory vesicles or bullae that are painless unless they are ruptured.³⁸ Ingestion of Spanish fly, an aphrodisiac composed of dried blister beetles, may lead to burning sensation in the pharynx and esophagus, hematemesis, flank and suprapubic pain, and occasionally nephritis. Eye contact with cantharidin causes severe edema and conjunctivitis.⁶ Skin contact with pederin causes vesicular lesions that appear 12 to 36 hours after the exposure. The lesions follow the shape of the area of contact with the crushed beetle. They last up to 2 weeks and are followed by a postinflammatory hyperpigmentation. Other parts of the body such as the eyes may become affected secondary to autoinoculation.⁵⁰ The skin should be washed promptly with water after contact with the beetle's secretions. General chemical burn care should be followed; treatment with antihistamines and steroids is not helpful. Preventive actions include turning off lamps at dusk in endemic areas and avoiding crushing the beetles on the skin.⁵⁰

Ticks

Ticks belong to either one of two families: Ixodidae (hard body) or Argasidae (soft body). They are ovoid in shape and reach a maximal size of 1.5 cm when engorged with blood. They are known for their ability to stick to their prey using their teeth and secretions. Ticks are better known as vectors for infectious diseases such as Rocky Mountain spotted fever, typhus, tularemia, and Lyme disease, among others. However, tick paralysis is a toxin-mediated syndrome. Tick paralysis is caused by 43 species of ticks, only 4 of which are medically important. These are *Dermacentor andersoni* and *Dermacentor variabilis* in North America and *Ixodes holocyclus* and *Ixodes cornuatus* in Australia. Ticks produce a neurotoxin in their salivary glands that inhibits the release of acetylcholine at the neuromuscular junction, thus leading to flaccid paralysis. The toxin that is injected along with their saliva has local anesthetic and anticoagulant properties.⁶

Clinically, the symptoms of tick paralysis appear within 4 to 7 days after the bite. It is an acute, ascending, flaccid motor paralysis that can be confused with Guillain-Barré syndrome, botulism, and myasthenia gravis. Prodromal symptoms are seen with *Dermacentor* bites, which include facial and limb paresthesias. Children bit by *Ixodes* ticks may present with ataxia. Symptoms progress further to generalized weakness, flaccid paralysis, and respiratory and bulbar paralysis. Treatment of tick paralysis is tick removal and supportive care. The signs and symptoms typically improve with time after removal of the tick but may initially progress for 48 hours prior to clinical improvement. Australian antivenom is occasionally used in cases of severe muscle paralysis.⁶ Its efficacy, however, is unproven.⁴⁹ Preventive measures include wearing long-sleeved garments when present in a forest, use of insect repellants, checking for ticks on a regular basis, and avoiding squeezing the tick if attached to the skin. Medium-tipped, blunt forceps may be used, if available, to remove the ticks.⁵¹ When using insect repellants, permethrin applied to garments, and *N,N*-diethyltoluamide applied to exposed skin are effective agents.

Centipedes

Centipedes are arthropods that belong to the Chilopoda family. They comprise more than 3000 species within four orders, only two of which, Scolopendromorpha and Scutigleromorpha, are of medical importance.⁵² They have an elongated segmented body with a pair of legs in each segment. The first pair of legs is modified into a biting structure that injects venom stored in a sack to paralyze the prey. Centipedes range in size from 1 to 30 cm and are distributed widely in warm, temperate, and tropical regions.⁵³ Their venom contains proteins like serotonin, histamine, and various enzymes.⁵⁴

A bite from a centipede consists of two puncture wounds with localized pain, edema, and regional lymphadenopathy (Fig. 22B-11). In a prospective study that examined the clinical course of 44 centipede bites,

FIGURE 22B-11 Centipede bite. (Courtesy of Scott Stockwell, PhD.)

it was found that systemic symptoms were absent and the clinical course was usually short (less than 2 days).⁵² Occasionally, the wound is complicated by necrosis and gangrene, possibly from secondary infections.⁶

Certain tropical centipedes may cause systemic findings such as nausea, headache, restlessness, tachycardia, and fever.⁶ Myocardial ischemia has been reported after centipede envenomation.^{54,55} Eosinophilic cellulitis or Wells' syndrome has also been associated with a centipede sting.⁵⁶ Treatment for centipede envenomation includes local wound care, analgesics, and tetanus prophylaxis. Antibiotics should be reserved for infected wounds.^{53,57}

Millipedes

Millipedes are arthropods that belong to the Diplopoda family. They have elongated segmental bodies with one pair of legs per segment. They do not bite, but can secrete and spray a noxious substance that causes a mahogany-colored skin lesion. This skin discoloration has been confused with child abuse, thermal burns, and gangrene. It may persist for months.⁵⁸ Some can spray secretions up to 25 cm, which can affect the eyes, leading to periorbital edema, chemical keratoconjunctivitis, corneal ulcers, and even blindness, in rare cases.⁵⁹ Management is symptomatic and supportive. Eye exposures require irrigation with normal saline followed by examination with fluorescein dye to look for corneal abrasions. Antibiotic, corticosteroid, and cycloplegic (for ciliary spasm) eyedrops are recommended.⁵⁹

JEFFREY BRENT, MD, PHD ■ ROBERT B. PALMER, PHD

At a Glance...

- Life-threatening or major organ-threatening mushroom syndromes typically present with symptoms starting greater than 6 hours following ingestion.
- Gastrointestinal symptoms that occur within a few hours of ingestion do not rule out poisoning by the more dangerous mushrooms.
- As with most poisonings, supportive care is of primary importance in toxic mushroom ingestions.
- The mushrooms of greatest concern are the hepatotoxic species of *Amanita*.
- Although several antidotes have been proposed and are used for the treatment of hepatotoxic *Amanita* poisoning, none have been proven to be efficacious.
- Mushrooms containing orellanine may cause renal failure, which may not become evident for days to weeks postingestion.
- Poisonings by mushrooms containing gyromitrin, such as the *Gyromitra* spp. (false morels), may benefit from treatment with pyridoxine.
- Poisonings by mushrooms containing muscarine, such as some *Inocybe* and *Clitocybe* spp., may benefit from treatment with atropine if there are excessive muscarinic cholinergic effects.

INTRODUCTION AND RELEVANT HISTORY

Mushrooms are the sexual organs, or fruiting bodies, of fungi. The word *mushroom* is derived from an early Greek term which roughly translates to “mucus”—the stuff the ancients thought to be the substance of origin of both mushrooms and frogs.¹ Of the possibly 10,000 species of mushrooms worldwide, only 50 to 100 are known to be toxic. Little is known about the toxic effects of ingestion of most mushrooms, although fatalities do occur. However, toxins derived from mushrooms cannot be universally condemned because many such compounds have been used as leads for antimicrobial and antineoplastic agents. Mushroom poisonings most frequently result from the growing trend worldwide of foraging for edible fungi. They are used for food, in religious ceremonies, and even as medication by herbal healers. Typically, mushrooms are identified by experience, through guidebooks, or simply by feeding them to domestic animals as a bioassay of toxicity. Of the earliest reports of mushroom poisoning, the most notable was the tragic account of the Greek poet Euripides, who described the death of his wife and three children due to the ingestion of poisonous mushrooms.²

It is probably easiest to understand mushroom toxicology by categorizing mushrooms into groups based on the toxins they contain and the symptoms and signs

they may cause. For a patient with a history of toxic mushroom ingestion, the clinical picture may help determine to which group the mushroom belonged, pending definitive identification. In the majority of cases, the true identity of the offending mushroom is unknown. Analysis of exposures reported to poison control centers in the United States indicates that the precise species of mushroom is identified in only 3.4% of all exposures.³ However, even in the absence of positive identification, the clinical syndrome being treated may be identified and appropriate therapeutic measures undertaken. In the majority of cases, no illness results from mushroom ingestion.³ The possible mushroom-associated syndromes and the typical causative species are listed in Table 23-1. Determining the type of mushroom ingested based on the presenting syndrome is analogous to what is encountered daily in the clinical practice of clinical toxicology with patients who overdose on unknown medications.

GENERAL MANAGEMENT

Current concepts of the management of mushroom poisoning are evolutionary and dynamic, and, thus, fraught with debate and controversy. As with all poisonings, supportive care is of primary importance in toxic mushroom ingestions. Airway management and cardiopulmonary resuscitation, along with maintenance of vital signs, should take priority over positively identifying the toxin or searching for specific antidotes.

Guidelines for initial management of toxic mushroom poisoning are listed in Box 23-1. Most patients with symptoms after mushroom ingestion have prominent gastrointestinal (GI) complaints: vomiting, diarrhea (possibly bloody), and abdominal pain. If vomiting and diarrhea are severe enough to result in significant hypovolemia, intravenous fluid and electrolyte repletion with a glucose-containing solution should be initiated. It is critical to determine the time course of the development of symptoms after ingestion. Symptoms developing more than 6 hours after ingestion can be assumed to be due to mushrooms belonging to the cyclopeptide (commonly the deadly *Amanita*), gyromitrin, or orellanine groups. With mushrooms from the orellanine group, symptoms may develop more than 24 hours after ingestion. It is emphasized, however, that GI symptoms occurring within a few hours of ingestion do not rule out poisoning by the more dangerous mushrooms. It is common for people to ingest a number of different mushrooms simultaneously, including those that cause early symptoms. In addition, ingestion of cytotoxic mushrooms may rarely produce symptom onset within 6 hours of ingestion.

TABLE 23-1 Summary of Common Mushroom-Associated Syndromes*

SYNDROME	CLINICAL COURSE	TOXIN(S)	TYPICAL CAUSATIVE MUSHROOM(S)
Delayed gastroenteritis followed by hepatorenal syndrome	Stage 1: 24 hr after ingestion: onset of nausea, vomiting, profuse cholera-like diarrhea, abdominal pain, hematuria Stage 2: 12–48 hr after ingestion: apparent recovery; levels of hepatic enzymes are rising during this stage Stage 3: 24–72 hr after ingestion: progressive hepatic and renal failure, coagulopathy, cardiomyopathy, encephalopathy, convulsions, coma, death	Cyclopeptides, principally amatoxins	"Deadly <i>Amanitas</i> ," <i>Galerina</i> species
Hyperactivity, delirium, coma	30 min–2 hr after ingestion: delirium, hallucinations, and coma	Muscimol, ibotenic acid	<i>Amanita muscaria</i> , <i>Amanita pantherina</i>
Delayed gastroenteritis with central nervous system abnormalities	6–24 hr after ingestion: nausea, vomiting, diarrhea, abdominal pain muscle cramps, delirium, convulsions, coma; hemolysis and methemoglobinemia may occur	Gyromitrin	<i>Gyromitra esculenta</i> ("false morel")
Cholinergic syndrome	30 min–2 hr after ingestion: bradycardia, bronchorrhea, bronchospasm, salivation, perspiration, lacrimation, convulsions, coma	Muscarine	<i>Boletus</i> species, <i>Clitocybe</i> species, <i>Inocybe</i> species, <i>Amanita</i> species
Disulfiram-like reaction with ethanol	30 min after drinking ethanol (may occur up to 1 wk after eating coprine-containing mushrooms): flushing of skin of face and trunk, hypotension, tachycardia, chest pain, dyspnea, nausea, vomiting, extreme apprehension	Coprine	<i>Coprinus atramentarius</i>
Hallucinations	30 min–3 hr after ingestion: hallucinations, euphoria, drowsiness, compulsive behavior, agitation	Psilocybin and psilocyn	<i>Psilocybe</i> species
Delayed gastritis and renal failure	Abdominal pain, anorexia, vomiting starting over 30 hr after ingestion, followed by progressive renal failure 3 to 14 days later	Orelline, orellanine	<i>Cortinarius</i> species
Immune-mediated hemolytic anemia	Syncope, gastroenteritis, oliguria, hemoglobinuria, back pain, hemolysis	Immunoglobulin mediated	<i>Paxillus involutus</i>
General gastrointestinal irritants	30 min–2 hr after ingestion: nausea, vomiting, abdominal cramping, diarrhea; may recover without treatment	Unidentified, probably multiple	<i>Chlorophyllum molybdites</i> , backyard mushrooms ("little brown mushrooms"), many others

*See Box 23-2 for an extensive list of mushrooms causing these syndromes.

Activated charcoal, if administered in the first hour or two postinjection, may be of benefit in adsorbing any toxin remaining in the gut. Any gastric contents obtained by spontaneous emesis should be saved and examined for spores. To examine for spores, the gastric aspirate or emesis sample should be filtered through cheesecloth and centrifuged for 10 minutes. The heavier layer at the bottom of the test tube contains the spores, and a sample is carefully removed with a pipette. A drop of water is then added, a coverslip placed, and the slide examined under oil immersion. Generally, mushroom spores are similar in size to red blood cells (8 to 20 μm). Spores found in either the gastric contents or the lamellae of the mushroom should be examined under the microscope for (1) general appearance, (2) shape,

(3) color, (4) thick or thin walls, and (5) the presence of pores.⁴

Identification of suspected toxic mushrooms can be difficult. In fact, because even veteran mushroom hunters occasionally make an error, many have adopted the practice of eating only one kind of mushroom at a time and saving a sample in case unanticipated effects occur. A spore print can be helpful in identifying the mushroom in question. This is formed by placing the cap of the mushroom on a white piece of paper (Fig. 23-1) and allowing the spores to fall on the paper, imparting a characteristic color. An example of a spore print is shown in Figure 23-2. Because an adequate spore print generally takes several hours to develop, one should be started as soon as possible. It is usually helpful to cover the cap with

BOX 23-1 GENERAL MANAGEMENT OF MUSHROOM INGESTION

1. Determine history of ingestion: how many types of mushrooms ingested, what time, if anyone else ate them, and what symptoms are present.
2. Attempt to determine which of the possible syndromes (see Table 23-1) the patient may have. For example, gastrointestinal symptoms occurring more than 6 hr after ingestion strongly suggest cyclopeptide, gyromitrin, or *Cortinarius* poisoning.
3. Administer activated charcoal. If the patient has diarrhea, do not give a cathartic. If a cathartic is used, give it only with the first dose of activated charcoal. Use repeated doses of activated charcoal for suspected amatoxin poisonings.
4. If feasible and when indicated, send gastric aspirate or emesis, along with any remaining mushrooms, to a mycologist for identification.
5. Try to perform a preliminary identification of mushroom and spores. Start to develop a spore print as soon as possible.
6. Maintain supportive measures, including airway support, intravenous fluids, and vasopressors (if needed). Monitor volume status.
7. Avoid antispasmodics for gastrointestinal symptoms.
8. Anticipate the clinical course (see Table 23-1).

Rights were not granted to include this figure in electronic media.

a glass or bowl while the spore print is being formed to prevent the dispersion of spores by drafts. Other techniques, such as digital imaging, may also assist in mushroom identification.⁵

A professional mycologist should be able to describe the principal types of mushrooms in a given region and may also assist in mushroom identification. Local or regional poison centers should know how to reach mycologists in their region. When a patient is seen after a mushroom ingestion, family members or friends should be asked to bring in a similar mushroom (if possible) for identification purposes. The specimen should be refrigerated, wrapped in wax paper, and stored in a paper bag (a thorough discussion of mushroom identification may be found in appropriate references).⁶ It should also be kept in mind that, with the Internet and the associated increase in international commerce, even professional mycologists may have difficulty identifying foreign mushroom species.

Of greatest concern in mushroom poisoning is the ingestion of the potentially deadly *Amanita* species. Although many antidotes and treatments have been suggested for *Amanita* poisoning, most of them are unproven. By consulting Table 23-1, the group to which the ingested mushrooms may belong should be apparent. For ease of discussion, further management recommendations are described under the specific toxins. Common mushroom species containing the toxins discussed are listed in Box 23-2.

CYCLOPEPTIDE POISONING

Overview

The cyclopeptide-containing mushrooms are responsible for more than 90% of all deaths due to mushroom poisonings in the Western world. These mushrooms are found predominantly throughout Europe and North America. The cyclopeptides are found mainly in species from three genera: *Amanita*, *Galerina*, and *Lepiota* (see Box 23-2 and Figs. 23-3 to 23-5). The vast majority of serious poisonings and fatalities in this group of mushrooms, however, result from *Amanita*, particularly *Amanita phalloides* (see Fig. 23-3). Ingestion of deadly *Amanita* most commonly occurs after misidentification of the mushroom by foragers, although the possibility of criminal or terrorist use of toxins isolated from *Amanita* species has also been suggested.⁷ These mushrooms are most commonly found during the late summer or autumn in well-forested areas. The cyclopeptide toxins consist primarily of amatoxins, which contain eight amino acids, and the seven residue phallotoxins and virotoxins. More than 15 cyclopeptides have been isolated from the genus *Amanita*. Note, however, that not all mushrooms of the *Amanita* species contain significant quantities of amatoxin. *Amanita muscaria* and *Amanita pantherina*, for example, contain no amatoxin, and ingestion of these mushrooms is not associated with development of hepatotoxicity.

The phallotoxins are extremely potent hepatotoxins but are not well absorbed from the GI tract and therefore

BOX 23-2 SOME MUSHROOM SPECIES, BY CLINICAL GROUPING OF TOXINS**Cyclopeptides (Amatoxins, Phallotoxins)**

Amanita phalloides ("death cap" or "green death cap")
A. verna ("death angel")

 "Little brown mushrooms" (backyard mushrooms)
Chlorophyllum molybdites
Omphalates illudens ("jack-o-lantern")

contribute little to *Amanita* toxicity following ingestion. They may contribute to the initial gastroenteritis-like picture, although this has also been questioned.⁸ Laboratory animals cannot be poisoned by oral administration of the phallotoxin phalloidin, whereas they die within hours after intravenous injection of the same compound.

Pathophysiology

Amatoxins are not only extremely potent hepatotoxins but are also actively absorbed from the GI tract.

Although α -amanitine is the principal toxin in this group, nine cyclic octapeptide amatoxins with molecular weights of approximately 900 Daltons, have been identified. Nucleoli of liver cells disintegrate soon after exposure to α -amanitine, resulting in interference with transcription of DNA by inhibiting RNA polymerase II. α -Amanitine accomplishes this by binding to the 140,000-Dalton subunit of RNA polymerase II. Because the primary action of amatoxins is inhibition of DNA transcription, tissues that are highly dependent on protein synthesis (namely, the GI tract and liver) are most sensitive to this poisoning. Once absorbed through

FIGURE 23-4 The destroying angel, *Amanita virosa* (cyclopeptide). (Courtesy of D.H. Mitchel and the Denver Botanic Gardens–Herbarium of Denver, CO.)

FIGURE 23-5 Fool's mushroom, *Amanita verna* (cyclopeptide). (Courtesy of Donald Simon, Wilmington, DE.)

the gut, amatoxins are transported into hepatocytes by a nonspecific transport system. Circulating amatoxin is not metabolized but excreted by the biliary system and the kidneys. Enterohepatic recirculation and biliary excretion of amatoxins are significant. The cyclopeptides are not denatured by boiling, and hence cooking deadly *Amanita* mushrooms does not render them nontoxic. It is estimated that approximately 0.1 mg/kg of oral amatoxin or the amount contained in one *A. phalloides* mushroom may be lethal to an adult.⁶

Clinical Presentation

The classic clinical presentation of *Amanita* poisoning can be divided into three stages (see Table 23-1). Patients do not have GI symptoms for at least 6 hours after ingestion,

and then they develop colicky abdominal pain, vomiting, and severe diarrhea (stage 1). The onset of symptoms may occur from 6 to 24 hours after ingestion. The diarrhea may contain blood and mucus and may be so severe that it has been termed *cholera-like*.

Even without treatment, patients may apparently recover (stage 2), although their hepatic enzyme levels may be rising. Two to 4 days after ingestion, patients may suffer fulminant hepatic, cardiac, and renal failure (stage 3). Pancreatitis, disseminated intravascular coagulation, convulsions, and death may then occur in the subsequent 2 to 4 days. The pathologic picture of hepatic necrosis tends to be most marked in the centrilobular (zone III) areas. In series of treated patients, the death rate due to *A. phalloides* poisoning ranges from 10% to 30%. Although many patients with cyclopeptide-induced hepatotoxicity recover fully, approximately 20% develop immune complex–mediated chronic active hepatitis with anti–smooth muscle antibodies. It is important to understand that not every patient will develop fulminant hepatic failure but may develop mild gastrointestinal and hepatotoxic effects.

Diagnosis

The diagnosis of cyclopeptide mushroom poisoning is made largely from a positive history of ingestion coupled with suggestive physical findings (e.g., acute gastroenteritis, toxic hepatitis). Any patient with gastroenteritis should be specifically questioned about recent wild mushroom foraging and ingestion. Optimally, the mushroom (obtained from meal leftovers or from visiting the site of foraging) could be identified by an experienced mycologist, but this is rarely possible.

Several analytical techniques may be employed to assist diagnosis, which include detection of amatoxins from body fluids or utilization of bedside tests. Circulating amatoxins can be detected for hours after ingestion.⁹ Most of the ingested α -amanitine is excreted renally, and urine levels tend to be higher than serum levels. Although amatoxins can be detected by very sensitive radioimmunoassay or high-pressure liquid chromatographic methods, these assays are not usually clinically available. The Meixner test is a bedside assay that can detect substituted indoles such as amatoxins. In this test, gastric material or pulverized mushroom juice is spotted on pulp paper and allowed to dry. Although newspaper is generally recommended in most references, it may be too thin to give a clear reaction and the ink may bleed, further obscuring the result. Telephone book paper gives a more satisfactory result.¹⁰ Several drops of concentrated (10 to 12N) hydrochloric acid are added to the spot. A blue response developing within 30 minutes of acid treatment constitutes a positive test result. If the mushroom has been dried, it should be extracted with methanol and the methanol washings tested as described above. Because some types of paper can actually produce a false-positive result, a section of paper on which no mushroom material has been applied should also be tested as a control. Other substituted indoles such as serotonin or indoles in other mushroom genera may also

give a positive Meixner test result.^{4,10} Thus, the Meixner test is not specific. Although the amount of amatoxin present in deadly amanitas theoretically should give a positive reaction, the sensitivity of the Meixner test in clinical practice has not been determined.

Identifying deadly *Amanita* mushrooms in the field should not be difficult, but for various reasons even those who have picked and consumed mushrooms with impunity for many years are not immune to making that fatal mistake. Figure 23-6 demonstrates the maturation course of a typical *Amanita* mushroom and how the classic annulus and “death cup” develop. These structures are not always obvious, however, and may be obliterated in the act of picking the mushrooms out of the ground. The immature “buttons” in many ways resemble edible puffballs. It is useful to remember that all species of deadly *Amanita* have white gills and spore prints.

Management

The basic facets of treatment of known or suspected cyclopeptide mushroom poisoning includes the provision of supportive care (e.g., fluid and electrolyte repletion and antiemetic therapy), gastrointestinal decontamination (e.g., administration of activated charcoal), enhanced elimination techniques (e.g., multiple-dose activated charcoal and/or charcoal hemoperfusion), antidotal therapy (e.g., penicillin G and silibinin administration), and treatment of secondary complications (e.g., coagulopathy, and liver and renal failure) as necessary. All patients with suspected or confirmed cytotoxic mushroom ingestion should be admitted to the hospital for close observation.

A wide variety of antidotes to *Amanita* poisoning have been touted to be beneficial, but clinical assessments of these therapies have for the most part been anecdotal. The use of thioctic acid has been lauded in the literature on the basis of anecdotal reports. Being a dithiol compound, it has been postulated to function as a free radical scavenger. However, there is no convincing human evidence of its efficacy in *A. phalloides* poisoning.

Intravenous penicillin has also been recommended on the theory that it inhibits the uptake of amatoxins by hepatocytes. Various other protective mechanisms for penicillin have also been proposed. Animal data and retrospective human data suggest that benzylpenicillin (penicillin G) in a dose range of 300,000 to 1,000,000 units/kg per day is hepatoprotective; however, this could not be demonstrated in a prospective study.

Silibinin, a water-soluble preparation of silymarin, which is composed of a group of flavonolignans isolated from milk thistle (*Silybum marianum*), has been shown to be effective in animals in reducing hepatotoxicity by inhibiting amatoxin uptake by hepatocytes and interfering with enterohepatic recirculation of amatoxin.^{11,12} It has also been postulated to act as a free radical scavenger. Intravenous silibinin (20–30 mg/kg/day in three or four divided doses or as a continuous infusion) is routinely administered in Europe when amatoxin-containing mushroom ingestion is suspected.¹³ The oral preparation of silymarin is the only preparation available for use in the United States. Oral silymarin is available in health food stores as a food supplement and can be dosed at 140 mg two to three times daily. Definitive studies for silibinin and silymarin as treatments in human amatoxin poisoning have not been conducted. Anecdotal reports of efficacy coupled with the lack of adverse effects of this therapy render it a potentially beneficial but still unvalidated therapy for human amatoxin poisoning.^{6,13}

A report of 11 patients with apparent poisonous *A. phalloides* poisoning treated with infusion of *N*-acetylcysteine (NAC) reported survival in all, with only one patient requiring liver transplantation.¹⁴ However, these patients were also treated with an intensive regimen of venovenous hemodiafiltration with activated charcoal and high-dose penicillin G; thus, the contribution of the NAC could not be assessed.

Anecdotal reports and preliminary animal data suggest a number of additional antidotes, including hyperbaric oxygen, plasmapheresis, cimetidine, ascorbic acid, cephalosporins, corticosteroids, cytochrome C, bile salts, heavy metal salts, D-penicillamine, and diethyldithiocar-

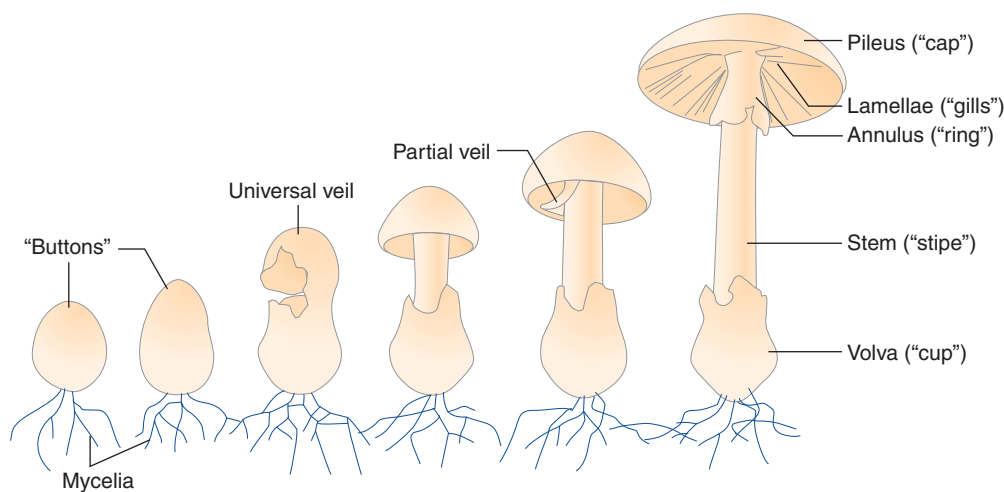

FIGURE 23-6 Maturation of *Amanita* species. The early stages (“buttons”) may resemble nontoxic puffballs. The lamellae and spores are white in all *Amanita* species, whereas the pileus may be white, as in *Amanita phalloides*, *Amanita verna*, or *Amanita virosa*, or bright orange-red, as in *Amanita muscaria*. The distinguishing features of all amanitas include the annulus and volva (“death cup”); however, these are frequently destroyed in the process of picking and preparing the mushroom. Poisonous *Amanita* mushrooms are toxic during all stages of development. (Adapted from Litten W: The most poisonous mushrooms. *Sci Am* 1975;232;90.)

bamate. However, no firm clinical data indicate that any of these are useful.

Although it is unclear if any of these specific antidotes are of value in the management of amatoxin poisoning, there is little doubt that optimization of a patient's fluid status is of great importance.

Hemoperfusion, hemodialysis, or plasma exchange¹⁵ may be theoretically useful in enhancing elimination early after ingestion. However, these have never been proved to be beneficial and may be impractical because most patients present late.

Of these, plasmapheresis appears to be the technique of choice. A recent uncontrolled series of six children poisoned with hepatotoxic mushrooms reported dramatic improvement in multiple biochemical and clinical parameters in four after use of a molecular absorbent regenerating system (MARS) using albumin as the absorbent.¹⁶ One of the two nonresponders had been in cardiac arrest and remained in deep coma postresuscitation. A second series¹⁷ reported using the MARS system on six *A. phalloides*-poisoned patients (mean age 46 years). Although the treatment was started an average of 76 hours postingestion, there was substantial improvement in metabolic parameters, and five of these six survived. Because of the late use of MARS in these patients, it is likely that the survival advantage conferred by MARS was from correction of the effects of hepatic dysfunction rather than the removal of amatoxins. Since both of these series were uncontrolled, it is impossible to conclude definitively that the MARS treatments were beneficial.

Antiamatoxin Fab fragments have been studied in animal models, but these strongly enhance the observed toxicity.

Liver transplantation has been successfully performed on patients with severe cyclopeptide-induced hepatotoxicity. Because most patients with amatoxin poisoning recover with aggressive supportive care, partial or total transplantation should not be considered to be standard treatment for hepatotoxicity. However, if a patient shows signs of severe hepatotoxicity, transfer to a transplantation center may be beneficial to facilitate the procedure should it become necessary. Although no universally agreed on criteria exist for transplantation, high-grade encephalopathy is generally considered such a poor prognostic sign that liver transplantation should be considered.

Because amatoxins have been reported to undergo enterohepatic recirculation, it may be useful to administer multiple doses of activated charcoal for at least 48 hours after ingestion. Duodenal suction is also of theoretic benefit during this period. However, neither of these therapeutic approaches has been proven helpful.

Amanita (see Figs. 23-3 to 23-5) is by far the most commonly ingested genus that results in significant clinical toxicity. As mentioned previously and noted in Box 23-2, several species of *Galerina* and *Lepiota* contain cyclopeptides and are therefore capable of causing similar toxicity to *Amanita* spp.¹⁸⁻²⁰ *Galerina* spp. (see Fig. 23-7) are common, indiscreet, small brown mushrooms; approximately 15 to 20 *Galerina* mushrooms contain the same

FIGURE 23-7 *Galerina autumnalis* (cyclopeptide). (Courtesy of Linnea Gilman, Denver, CO.)

amount of toxin as one mature *A. phalloides*. They may be ingested by crawling children or by those seeking psychoactive mushrooms. *Galerina* tends to contain small amounts of amatoxins, and it is commonly believed, although not empirically verified, that ingestion of at least one to two dozen mushrooms is required for toxicity. Several species of *Lepiota* contain amatoxin. Ingestion of these mushrooms has been associated with human fatalities from fulminant hepatic failure in France and Germany.^{6,21}

One of the common errors made in identification of mushrooms of the *Amanita* and *Lepiota* species is confusing them with *Chlorophyllum molybdites* mushrooms, which also possess an annulus and a swelling at the base resembling a cup. Persons ingesting *C. molybdites* mushrooms, however, usually develop severe vomiting and diarrhea within 2 hours, although many are able to consume these mushrooms without becoming symptomatic. Differentiating between *C. molybdites* and *Amanita* and *Lepiota* spp. should not be difficult. *Chlorophyllum* spp. are the only mushrooms with greenish gills and spores (create greenish spore print), and the spores are thick walled and contain pores. The mushroom itself stains reddish orange where it is injured, and the annulus is movable; in *Amanita* and *Lepiota*, the annulus is fixed.

MUSCIMOL AND IBOTENIC ACID POISONING

Overview

Certain *Amanita* species contain the closely related isoxazoles muscimol (a hallucinogen) and ibotenic acid (a potent insecticide) (see Box 23-2 and Fig. 23-8). Ingestion of these mushrooms often produces the rapid onset of altered sensorium and mentation. *A. muscaria* and *A. pantherina* (Figs. 23-9 and 23-10) are responsible for most cases of isoxazole mushroom poisoning.^{6,22} These two mushroom species are very common and have a wide geographic distribution. *A. muscaria* is found in conifer or deciduous forests and *A. pantherina* is usually found under Douglas fir trees.⁶ *A. muscaria* is commonly known as the “fly agaric” because it attracts and kills flies that land on it. These mushrooms have been used for their psychoactive effects for at least 3000 years in the

FIGURE 23-8 Chemical structures of ibotenic acid and muscimol and the analogy with the conversion of glutamic acid to γ -aminobutyric acid.

FIGURE 23-9 The fly agaric, *Amanita muscaria* (muscimol, ibotenic acid). (Courtesy of Linnea Gilman, Denver, CO.)

FIGURE 23-10 *Amanita pantherina* (muscimol, ibotenic acid). (Courtesy of Linnea Gilman, Denver, CO.)

rituals of many Asian and Indian tribes. Purposeful ingestion of urine from people who have eaten these mushrooms has been reported as a way to elicit the psychoactive effects of the excreted muscimol.⁶ Many cases of *A. muscaria* poisoning still occur in individuals who deliberately seek and ingest the mushroom for its hallucinogenic properties. Exposure history (e.g., patient intent) is, thus, very important in patient evaluation.

A. pantherina (“panther caps”) may be confused with edible agarics (“meadow mushrooms”) by inexperienced collectors. Despite its toxic effects, *A. pantherina* is used as a food, mostly in the Pacific Northwest. This requires peeling off the skin of the cap, which contains the highest concentration of isoxazoles, and parboiling the

remaining parts. Because the isoxazoles are water soluble, they are extracted by this process. Needless to say, the water should be discarded.

Pathophysiology

The pharmacologically active toxins in these mushrooms include the isoxazoles ibotenic acid, muscimol, and muscazone.^{6,23} Additional compounds have been isolated from these mushrooms but are present in insufficient quantity to be physiologically active. These inactive compounds include muscarine, muscardine, pilzatropin (levehyoscyamine or “mushroom atropine”), indole derivatives, stizolobic acid, and amino acids.⁶

Although the pathophysiology of muscimol poisoning is imperfectly understood, its central nervous system (CNS) effects seem to be the result of its action as a γ -aminobutyric acid (GABA) agonist. Conversely, ibotenic acid acts as an agonist at excitatory glutamic acid receptors (e.g., *N*-methyl-D-aspartate receptor).²⁴ In addition, both toxins have produced increased brain levels of serotonin, decreased levels of brain dopamine, CNS sympathetic effects, and impaired CNS control of motor activity.⁶ The resultant picture can be one of alternating CNS depression and stimulation with varied motor effects. Both toxins readily cross the blood-brain barrier. Ibotenic acid is spontaneously decarboxylated to muscimol. Muscimol is approximately five times more potent than ibotenic acid. These compounds are excreted in the urine and detected within 1 hour of mushroom ingestion.

Although toxic doses of both ibotenic acid and muscimol can be found in a single mushroom, large numbers of these mushrooms typically must be ingested before a toxic effect is manifested.²⁵ Typically, 2 to 4 *A. muscaria* mushrooms must be ingested to produce psychoactive effects and more than 10 mushrooms must be ingested to produce death.⁶ Fatalities, however, are rare.

Clinical Presentation

Toxic effects typically occur within 30 minutes of ingestion but may be delayed for up to 3 hours. Signs and symptoms include nausea, vomiting, abdominal cramps, diarrhea, CNS depression alternating with CNS agitation and excitation, ataxia, incoordination, dizziness, euphoria, visual perceptual changes, vivid dreams, hallucinations, frank psychosis, irregular pulse and respirations, hypotension, mydriasis or miosis, diaphoresis, pale or flushed skin, myoclonic jerking, muscle fasciculations, seizures, coma, and death. It appears that seizures are more common in pediatric patients.²³ Death as a result of poisoning from these mushrooms is rare.⁶ Waxing and waning mental status and bizarre behavior are common. The clinical duration of toxicity may last from 4 to 24 hours.⁶

Muscarine was first extracted from *A. muscaria* in 1869, and its use as a pharmacologic research tool has enhanced our knowledge of the muscarinic receptors of the parasympathetic nervous system. Paradoxically, most patients poisoned by *A. muscaria* do not have cholinergic findings. In fact, poisoning by this group of mushrooms has been described as causing anticholinergic manifes-

tations. However, despite some similarities to a classic anticholinergic syndrome, neither the pathophysiology nor clinical manifestations of poisoning by this group of mushrooms are truly anticholinergic.

Diagnosis

The diagnosis of isoxazole-containing mushroom poisoning is made from a positive history of mushroom ingestion coupled with the rapid onset of symptoms and the presence of suggestive physical findings (e.g., altered sensorium, alternating agitation and obtundation, myoclonic jerking). Diagnosis is greatly facilitated by either a description of the mushroom or uneaten specimens brought to the health care facility. Identification of *A. muscaria* and *A. pantherina* mushrooms should be relatively easy. The *A. muscaria* cap is 8 to 24 cm in diameter, bright orange or red in color, and covered with small white plaques, which are remnants of the universal veil (see Fig. 23-9). The *A. pantherina* cap is 5 to 12 cm in diameter, yellowish brown in color, with similar small white warts or plaques spread across its surface (see Fig. 23-10). As in all *Amanita* species, the annulus and volva for these mushrooms are prominent, and the spores are hyaline, thin walled, and without pores. The spore prints are white.⁶

Management

Treatment of this group of poisonings consists of appropriate supportive care and GI decontamination (see Box 23-1). There is little to suggest, based on either pathophysiology or published clinical experience, that the once touted antidote physostigmine is effective in controlling any toxic manifestation of ibotenic acid or muscimol poisoning. Patients with unstable vital signs or significant alterations in their mental status should be admitted to an intensive care unit until their toxic effects resolve.

GYROMITRIN

Overview

The *Gyromitra* spp., or false morels, are an extremely interesting genus toxicologically. Many species of *Gyromitra* contain the hydrazone gyromitrin (acetaldehyde methylformylhydrazone) and small amounts of other hydrazones. Gyromitrin is metabolized to monomethylhydrazine (Fig. 23-11). The common toxic species in this genus are listed in Box 23-2.

Gyromitra spp. are found in Asia, Europe, and North America. The *Gyromitra* species are nongilled fungi, the spores of which develop in asci, or microscopic sacs, on the surfaces of the fruiting bodies. The caps of *Gyromitra* are orange-brown to brown in color and highly convoluted, hence the nickname “brain fungi” (Figs. 23-12 and 23-13). Toxicity is variable and unpredictable but typically occurs only after intentional ingestion of *Gyromitra* spp. Many species of *Gyromitra* are edible, but

FIGURE 23-11 Chemical structures showing the conversion of gyromitrin to monomethylhydrazine.

FIGURE 23-12 *Gyromitra esculenta* (monomethylhydrazine). (Courtesy of Joy Spurr, Issaquah, WA.)

FIGURE 23-13 *Gyromitra infula* (monomethylhydrazine). (Courtesy of the late George Grimes.)

determining which ones may be safely ingested is best left to experts. Despite their name, false morel, these mushrooms do not resemble members of the genus *Morchella* or true morels.

In post-World War II Poland, death due to ingestion of *Gyromitra esculenta* exceeded that caused by *A. phalloides*.²⁶ Poisoning by this mushroom occurs in the spring, in contrast to poisoning by *A. phalloides*, which tends to be common in the autumn.

Poisoning can occur after ingestion of either raw or cooked mushrooms. The hydrazones in these mushrooms may be destroyed and volatilized by cooking; however, this should not be considered a foolproof strategy for rendering them edible. In addition, toxicity has occurred from inhaling the steam during the cooking process.^{6,27}

Pathophysiology

The toxin gyromitrin (acetaldehyde *N*-methyl-*no*-formylhydrazone) and its breakdown product, monomethylhydrazine, produce toxic effects similar to those of

isoniazid overdose. These toxins inhibit the formation of GABA in the brain by inducing a state of pyridoxine (vitamin B₆) deficiency. Specifically, these toxins inhibit the enzyme pyridoxine phosphokinase, thus preventing activation of pyridoxine to pyridoxal phosphate (active form of vitamin B₆). These toxins also bind and inhibit pyridoxal phosphate directly and inhibit glutamic acid decarboxylase, the enzyme that catalyzes the formation of GABA from glutamate. CNS depletion of GABA results in seizures associated with *Gyromitra* spp. poisoning.

Clinical Presentation

Six to 48 hours after ingestion of mushrooms from the *Gyromitra* spp., patients develop nausea, vomiting, abdominal pain and bloating, diarrhea, dizziness, fatigue, and muscle cramps.²⁸ These symptoms are usually mild and limited largely to gastrointestinal effects. Toxicity, however, may progress to neurologic, hematologic, and hepatorenal dysfunction. Serious neurologic effects include delirium, coma, and convulsions. Hematologic effects include methemoglobinemia and hemolysis. Hepatic failure usually occurs by 48 hours and is heralded by right upper quadrant tenderness, hepatic transaminitis, jaundice, coagulopathy, and hypoglycemia. Renal dysfunction may result from rhabdomyolysis or prolonged hypotension or as part of the hepatorenal syndrome. In parts of Eastern Europe, fatalities due to *G. esculenta* are common; mortality rates as great as 10% have been reported.²⁹

Diagnosis

The diagnosis of gyromitrin-containing mushroom poisoning is made from a positive history of mushroom ingestion, positive identification of uneaten specimens, and the presence of suggestive physical findings (e.g., seizures, hepatorenal syndrome). The presence of a latency between mushroom ingestion and the onset of clinical effects may assist diagnosis. Gas chromatography, gas chromatography-mass spectrometry, and thin-layer chromatography may be used to identify hydrazone and hydrazine compounds in mushrooms. Laboratory testing for gyromitrin is not likely to be readily available.

Management

Treatment consists of supportive care, administration of methylene blue for significant methemoglobinemia, blood transfusions if required, and intravenous pyridoxine for monomethylhydrazine-induced seizures. Replacement of ongoing fluid and electrolyte losses is an important aspect of early treatment. Gastrointestinal decontamination is unlikely to be useful due to the long latency between ingestion and patient presentation. Pyridoxine, which is depleted in poisoning by hydrazines, is a necessary cofactor for the synthesis of GABA. Pyridoxine also forms a chemical complex with hydrazines, and this may have a role in its antidotal effect in treating monomethylhydrazine poisoning. Hydrazines also inhibit the metabolic conversion of folic acid to its

active form, tetrahydrofolate, and supplementation with folic acid has been suggested on theoretical grounds.

High doses of pyridoxine are known to cause peripheral neuropathy, and thus excessive use should be avoided. An empiric initial dose of 5 g administered intravenously (or 25 to 50 mg/kg) is generally regarded as appropriate for the initial management of seizures in an adult suffering from *Gyromitra* poisoning. This should be repeated only for recurrent seizures or coma. Pyridoxine does not reverse the other aspects of poisoning by these mushrooms.³⁰ Benzodiazepines and/or barbiturates may be useful adjunctive treatments for seizures associated with *Gyromitra* poisoning.

MUSCARINE

Overview

More than 30 species of *Inocybe* and 6 species of *Clitocybe* contain muscarine (see Box 23-2 and Figs. 23-14 and 23-15). These inconspicuous mushrooms are found worldwide but commonly grow in lawns and public parks. *A. pantherina* and *A. muscaria* contain muscarine (hence the name) but usually in quantities that are insufficient to cause a cholinergic syndrome. Muscarine was initially isolated from *A. muscaria*.³¹

Pathophysiology

Mushrooms in this group predictably cause symptoms and signs of poisoning by the cholinergic alkaloid mus-

FIGURE 23-14 *Inocybe fastigiata* (muscarine). (Courtesy of the late George Grimes.)

FIGURE 23-15 *Clitocybe cerrusata* (muscarine). (Courtesy of Linnea Gilman, Denver, CO.)

FIGURE 23-16 Chemical structures of muscarine and acetylcholine.

carine. Muscarine is a quaternary ammonium compound structurally similar to acetylcholine and causes depolarization of neurons by binding to the acetylcholine receptor at postganglionic cholinergic neurons (Fig. 23-16). Because muscarine does not possess an ester bond,³² it is not hydrolyzed by cholinesterases. Thus, the cholinergic or parasympathomimetic effects of muscarine are prolonged. As a quaternary compound that carries a charge, muscarine is not well absorbed from the gastrointestinal tract and does not readily cross the blood-brain barrier. Thus, CNS toxic effects do not readily occur.

Clinical Presentation

Minutes to an hour after ingestion, patients may develop the classic cholinergic syndrome consisting of diaphoresis, bradycardia, bronchospasm, profuse bronchorrhea, miosis, seizures, salivation, lacrimation, involuntary loss of urine and stool, and vomiting. Unlike the cholinergic crisis occurring after poisoning by organophosphate insecticides, the syndrome in these cases, although highly uncomfortable, is usually mild compared with organophosphate poisoning and seldom life threatening. This may be at least partially due to the poor GI absorption of muscarine. Unlike organophosphates, muscarine does not stimulate nicotinic receptors. Muscarine is heat labile, so vigorous cooking of these mushrooms may prevent their cholinergic effects. Clinical effects are usually self-limited and last approximately 2 hours but may persist for 6 to 24 hours if large amounts of muscarine have been consumed.⁶

Diagnosis

The diagnosis of muscarine-containing mushroom poisoning is made from a positive history of mushroom ingestion coupled with the rapid onset of parasympathomimetic clinical effects. The best analytical method for detecting muscarine in mushrooms is high-performance thin-layer chromatography.³³ Although of theoretic utility, this analytical technique has not been applied to body fluids.

Management

Treatment consists of GI decontamination, supportive care, and administration of atropine. Although activated charcoal is theoretically beneficial in preventing absorption of muscarine, it is important to emphasize that cathartics should not be administered to patients with diarrhea syndromes. Atropine has been recognized as a treatment for this poisoning since the mid-1800s.³¹ Atropine may

be given in sequential doses until pulmonary secretions are dried. The recommended intravenous starting dose of atropine is 0.1 to 0.5 mg in adults and 0.02 mg/kg in children. Glycopyrrolate is an alternative anticholinergic agent that may be preferable to atropine since it does not cross the blood-brain barrier. Like atropine, it is dosed sequentially with recommended intravenous doses of 0.05 to 0.1 mg in adults and 0.005 to 0.01 mg/kg in children. The use of inhaled ipratropium bromide may be beneficial for patients with significant bronchospasm.

COPRINE

Overview

Coprine poisoning is most commonly associated with ingestion of *Coprinus atramentarius*, or the “inky cap” (Fig. 23-17). It is so called because the mature specimens have lamellae that deliquesce or autodigest into an inky black fluid that is obvious on examination of the mushroom. The mushrooms themselves are edible, but disulfiram-like toxicity occurs when these mushrooms are ingested concurrently with or shortly before alcohol.

Pathophysiology

These mushrooms contain coprine, which is a glutamic acid derivative that induces hyperacetaldehydemia in the presence of ethanol by inhibiting acetaldehyde dehydrogenase. Coprine itself is not an inhibitor of this enzyme.^{34,35} However, it has been speculated that a metabolite of coprine, 1-aminocyclopropanol, functions like disulfiram and inhibits the metabolism of ethanol at the acetaldehyde dehydrogenase step, resulting in clinical symptoms (Fig. 23-18).³⁶ Coprine is not a heat-labile toxin and, thus, toxicity will still occur if these

FIGURE 23-17 *Coprinus atramentarius* (coprine). (Courtesy of Joe H. Restivo, Savannah, GA.)

FIGURE 23-18 Chemical structure of coprine and its proposed active metabolite, 1-aminocyclopropanol.

mushrooms are cooked and consumed with alcohol. The active toxin, 1-aminocyclopropanol, irreversibly inactivates aldehyde dehydrogenase by forming a covalent bond with the enzyme. Thus, a disulfiram-like reaction may occur even if alcohol is consumed up to 5 days after coprine-containing mushroom ingestion.⁶ The symptom complex engendered by this interaction has been referred to as “Clayton’s hangover.”³⁷

Clinical Presentation

Signs and symptoms usually occur within 20 to 30 minutes of ethanol ingestion and spontaneously resolve after 3 to 6 hours.⁶ Symptoms, however, may persist for 24 hours. Sensitivity to alcohol usually occurs within 2 hours of eating coprine-containing mushrooms. Effects will be less prominent when ethanol is consumed concurrently with inky caps than when consumed after the mushrooms since coprine must be bioactivated to 1-aminocyclopropanol to create the disulfiram effect. Clinical effects include flushing of the face, neck, and trunk; headache; a metallic taste; nausea; vomiting; palpitations; dyspnea; chest pain; tachycardia; and diaphoresis. Hypotension may occur secondary to peripheral vasodilatation.^{36,38-40} Other effects include cardiac arrhythmias, confusion, coma, and patient apprehension.

Diagnosis

Diagnosis is made by history and clinical effects suggestive of a disulfiram-like reaction. A positive history of mushroom ingestion and the rapid onset of clinical effects after consumption of ethanol is highly suggestive. Coprine may be detected by thin-layer chromatography. Because coprine is an amino acid, a coprine-containing spot stains when sprayed by ninhydrin.^{34,40,41}

Management

Treatment of the coprine syndrome is supportive. Patient reassurance and rehydration are often the only necessary treatments. Gastrointestinal decontamination is not likely to be beneficial and is unnecessary. Although antihistamines and propranolol have been suggested as specific treatments, these agents have not been proven useful and are not recommended.³⁶ The coprine syndrome is self-limited and usually abates within several hours.

Because of its disulfiram-like effect, coprine has been suggested as a potential agent for chemoprevention of alcohol abuse. However, the mutagenic, carcinogenic, and male gonadotoxic effects render it inappropriate for this use.³⁶

INDOLES

Overview

The psilocin-psilocybin-containing mushrooms have been used by Aztec and American Indians in religious ceremonies for thousands of years⁴² and are frequently

FIGURE 23-19 *Psilocybe cyanescens* (indole). (Courtesy of Kit Scates, Post Falls, ID.)

FIGURE 23-20 *Psilocybe cubensis* (indole). (Courtesy of the Rocky Mountain Poison Center, Denver, CO.)

referred to as “magic mushrooms.” Psilocybin is found largely in four genera of mushrooms that include *Conocybe*, *Gymnopilus*, *Panaeolus*, and *Psilocybe* (see Box 23-2 and Figs. 23-19 and 23-20). These mushrooms are found throughout the United States but are more commonly found in warm climates. The *Psilocybe* genus contains more than 100 species of small brown, slender-stalked mushrooms. They are commonly, but not exclusively, found growing in piles of horse and cow dung and fertilized grasses, especially after a spring rain. Also growing in a similar environment and with a similar appearance is the cyclopeptide-containing mushroom *Conocybe filaris*. Indole-containing mushrooms are found in moist areas all over the United States, most commonly in the South. The spores are smooth purple and contain pores. A classic feature of the *Psilocybe* mushrooms is the blue-green areas where it has been injured or handled. Although this color is usually the result of the oxidation of psilocin,³⁷ this color change is not specific for hallucinogenic mushrooms.

Pathophysiology

The clinical effects from ingestion of these mushrooms are caused by the psychoactive indole tryptamine derivatives, psilocybin and psilocin, which are chemically related to both lysergic acid and serotonin (Fig. 23-21). The psychedelic effects of these compounds are mediated largely by agonist activity at CNS serotonin 5-HT_{2A} receptors (see Chapter 45). Psilocybin was first isolated in 1958 by Albert Hoffman, the discoverer of lysergic acid diethylamide (LSD). Intravenous use of

FIGURE 23-21 Chemical structures demonstrating the structural relationships between lysergic acid, serotonin, psilocin and psilocybin. For clarity the structural comparison area in lysergic acid is shown in boldface.

these mushrooms has also been reported.^{43,44} Psilocybin is quite stable; both dried mushrooms and boiled extract retain their hallucinogenic potency. Although use of this mushroom is generally limited by its supply, these mushrooms tend not to be expensive.⁴⁵

Concentrations of psilocybin vary greatly from mushroom to mushroom, by season, and location.^{6,13} The initial hallucinogenic effects of psilocybin are evident with as little as 4 mg of toxin, while a dose of 12 mg or more produces vivid hallucinations.^{6,13} Because of the small amounts of psychoactive indoles in these mushrooms, ingestion of several caps is usually required to elicit a hallucinogenic effect. It may take the ingestion of 3 to 60 mushrooms to achieve the desired effect. In general, 4 to 8 mg of psilocybin is present in 20 g of fresh and 2 g of dried mushroom.

Clinical Presentation

Thirty to 60 minutes after the psychotropic *Psilocybe* is ingested, a feeling of euphoria develops, followed by perceptual distortions and hallucinations that are usually, but not always, considered pleasant.⁴⁶ Sensory and perceptual distortions and illusions occur more commonly than true hallucinations. Tachycardia, mydriasis, and paresthesias are common effects. Hyperadrenergic effects may occur. Seizures have been reported.⁴⁷ The experience generally lasts 4 to 6 hours. Flashbacks may occur.⁴⁵ Among connoisseurs of the psychoactive effects of indoles, these mushrooms are often preferred over LSD.^{14,45} Mortality is extremely rare following recreational use of psilocybin-containing mushrooms.

Diagnosis

Diagnosis is based on a positive history of mushroom ingestion and the presence of corroborating clinical effects

(e.g., sensory or perceptual distortions, hallucinosis, sympathomimetic effects). As with any illicitly purchased substance, the actual material used may not be what is suspected by history. In a study of 886 samples sold as psilocybin mushrooms, only 28% contained psilocybin. An additional 31% contained LSD or phencyclidine, and in 37%, no psychoactive substances could be identified.⁴⁸

Many analytic techniques have been described for the identification of psilocybin and other psychoactive indoles.²³ However, it is unlikely that most hospital clinical laboratories will be equipped to perform these assays and the results will generally not affect the treatment or disposition of the patient.

Management

Most patients who ingest psilocybin-containing mushrooms have no serious adverse effects and do not require hospital treatment. Patients who require medical care usually need little more than reassurance,⁴⁹ but sedation may be required. Benzodiazepines are generally considered the drugs of choice in this case. Gastrointestinal decontamination is not necessary.

ORELLANINE

Overview

Some mushrooms of the genus *Cortinarius* contain the bipyridyl toxin orellanine (Fig. 23-22).⁵⁰ The syndrome of poisoning by these mushrooms was first described after a large outbreak of cases in Poland in 1952. Ingestion of these mushrooms may result in the development of gastroenteritis, thirst, polyuria, chills, headaches, and myalgias, after a hiatus of several days. A small percentage of these cases progress to renal failure, evident days to weeks later.⁵⁰⁻⁵³ Few cases of *Cortinarius* poisoning have been reported in the United States and Australia, but many occurrences have been documented in Europe and Japan. Some species of *Cortinarius* are edible, creating a dangerous temptation to seasoned yet adventurous mushroom hunters. Mushrooms of this genus are distinguished by their medium-sized orange-brown caps (2 to 5 cm) and rusty brown spores (Figs. 23-23 and 23-24). *Cortinarius* is the largest genus of mushrooms, containing more than 800 species, making the differentiation between the edible and poisonous varieties extremely difficult. Although orellanine is the primary nephrotoxin in these fungi, some species appear to contain other related nephrotoxins known as cortinarins (cortinarin A and B).^{54,55} These nephrotoxins appear to require activation by cytochrome P-450.⁵⁶

FIGURE 23-22 Chemical structure of orellanine.

FIGURE 23-23 *Cortinarius speciosissimus* (orellanine). (Reprinted from Lampe KF [ed]: AMA Handbook of Poisonous and Injurious Plants. Chicago, American Medical Association, 1985.)

FIGURE 23-24 *Cortinarius orellanoides* (orellanine). (Courtesy of Joseph Ammirati, PhD, University of Washington, Seattle.)

Pathophysiology

Orellanine is a heat-stable toxin that is chemically closely related to the herbicides paraquat and diquat. Orellanine is not deactivated by cooking, parboiling, drying, or freezing the mushrooms. The mechanism of cytotoxicity of orellanine is not well known, but it appears to involve disruption of the actin cytoskeleton and protein synthesis in renal tubular cells.^{57,58} Poisoning by these compounds results in tubulointerstitial nephritis and fibrosis.⁵² Despite the structural similarity between orellanine and herbicides like paraquat and diquat, no cases of pulmonary damage as a result of *Cortinarius* poisoning have been reported.

Clinical Presentation

The onset of symptoms occurs after a latent period of 36 hours to 17 days following mushroom ingestion.⁶ Over a period of days, patients develop headache, thirst, chills, dizziness, malaise, nausea, vomiting, abdominal and back pain, myalgias, and polydipsia. Progressive renal insufficiency develops over 1 to 3 weeks and is manifested by polyuria, oliguria, microscopic hematuria, leukocyturia, proteinuria, and anuria. The severity of poisoning is inversely correlated with the length of the latent period, such that the shorter the latent period, the greater the severity of poisoning.⁶ Renal insufficiency occurs in approximately one third (30% to 46%) of patients and becomes chronic in about half of patients.⁶ Recovery is gradual and takes several weeks.

Diagnosis

Diagnosis is based on a positive history of mushroom ingestion, a long latency between the ingestion and the onset of clinical effects, and the presence of acute renal failure. Diagnosis is not commonly made prior to the onset of renal insufficiency.⁶ Orellanine may be detected by thin-layer or high-performance liquid chromatography.²³

Management

There are no antidotes for poisoning by these mushrooms. Because patients tend to become symptomatic more than 24 hours after ingestion, activated charcoal is unlikely to be helpful. Treatment therefore consists of aggressive fluid management and close monitoring of renal function. In the majority of cases (50% to 70%), renal failure improves over time.⁵² Chronic hemodialysis and renal transplantation may be necessary.

AMANITA SMITHIANA

A syndrome of delayed renal failure similar to orellanine-containing mushrooms has also been more recently attributed to the mushroom *Amanita smithiana*.⁵⁹ *A. smithiana* is found in the Pacific Northwest of the United States. These mushrooms contain alienic norleucine, and pentanoic and aminoheptanoic acids, which are believed to produce renal toxicity.^{59,60} Unlike *Cortinarius* spp., these mushrooms produce gastrointestinal effects within 2 to 12 hours of ingestion. Renal failure occurs 2 to 5 days after mushroom ingestion. The treatment of *A. smithiana* mushroom toxicity is supportive. Most patients recover renal function within several weeks; hemodialysis may be required temporarily.

TRICHOLOMA EQUESTRE

In 2001, 12 cases of rhabdomyolysis were associated with the ingestion of *Tricholomas equestre* in France (Fig. 23-25). Initial symptoms developed 24 to 72 hours after eating the last of several large consecutive meals of the mushroom.⁶¹ Symptoms included fatigue, myalgias, weakness, nausea, and diaphoresis. Rhabdomyolysis was diagnosed by significant elevations of serum creatinine phosphokinase. Three cases resulted in fatality. In a subsequently performed animal study, extracts from *Tricholomas equestre* have been shown to produce rhabdomyolysis in rats.⁶¹ The myotoxin contained in the mushroom is still unknown.

Tricholomas equestre (also known as *Tricholomas flavovirens* or “Man on Horseback”) is found in coniferous forests throughout North America in the late summer and fall. The mushroom has a smooth, yellowish-brown or greenish-brown cap (3 to 5 cm) with yellow gills. Subsequent cases of rhabdomyolysis resulting from repeated ingestion of large amounts of this mushroom have been reported.⁶² If this mushroom is to be eaten, small, non-consecutive meals (less than 100 grams) are recommended so as to avoid human toxicity.⁶²

FIGURE 23-25 *Tricholoma equestre* (L.:Fr.) Kummer. (Photograph by R. E. Halling. Copyright 2003.)

PAXILLUS SYNDROME

Overview

Paxillus involutus (“brown rim-roll” mushroom; Fig. 23-26) is, for most people who ingest it, a simple GI irritant.^{52,63} However, a small proportion of those eating this mushroom develop immune-mediated hemolytic anemia, referred to as the *Paxillus* syndrome.^{64,65} This syndrome typically follows long periods of ingestion of these mushrooms and manifests, once started, as progressively worsening reactions.^{64,65} This reaction is not a true mushroom poisoning but rather a food allergy. Given these characteristics, it is of little surprise that the *Paxillus* syndrome is rarely encountered clinically.

Although the *Paxillus* syndrome is generally described as occurring after repeated ingestion of the brown roll-rim mushroom, one case was reported after ingestion of *Suillus luteus* (“slippery Jack”),⁶⁶⁻⁶⁸ a bolete generally regarded as edible, although this has been questioned.^{69,70} The clubfoot mushroom, *Clitocybe clavipes*, has also been suggested as a possible cause of the *Paxillus* syndrome,⁵⁴ but it is more likely that any observed reactions to this mushroom are simply the result of its disulfiram-like effect.⁷¹

FIGURE 23-26 *Paxillus involutus* (hypersensitivity). (Courtesy of Marilyn Shaw, Denver, CO.)

Pathophysiology

The precise mechanism defining the pathophysiology of the *Paxillus* syndrome is unknown. It appears to be an immunoglobulin-mediated hemolysis provoked by exposure to a yet unidentified antigen.

Clinical Presentation

The *Paxillus* syndrome typically manifests 1 to 2 hours after ingesting the fungi. Clinical features generally reported are syncope, gastroenteritis, decreased urine output, hemoglobinuria, decreased haptoglobins, and low back pain.

Diagnosis

The diagnosis is suggested by the presence of anemia, hemolysis on peripheral blood smear, a decrease in serum haptoglobin, and hemoglobinuria. A hemagglutination test in which a mushroom extract, the patient’s serum, and erythrocytes are incubated together has been described to assist diagnosis.^{64,72-74} Agglutination that occurs within 30 minutes of incubation is a positive test result and confirms diagnosis.⁶

Management

Treatment consists primarily of aggressive fluid management and, if the mushroom was recently ingested, oral activated charcoal. Plasmapheresis has been used in severe cases,⁷² but no convincing evidence shows that this technique provides any therapeutic benefit.

GASTROINTESTINAL IRRITANTS

This group has traditionally been a catch-all category for mushrooms that (1) usually produce nausea, vomiting, and diarrhea shortly (within 2 to 3 hours) after ingestion and (2) do not produce other significant systemic symptoms or signs. The number of species considered in this classification is so great that to list them would be unproductive. Not all species of this group of mushrooms cause symptoms in all people. The same species may cause symptoms in one person at one time and not at another time. The toxins responsible for the GI symptoms are, for the most part, unidentified.

Among the most common species causing acute gastroenteritis is *C. molybdites*.⁷⁵ In its juvenile form, it resembles the “shaggy mane,” and it is quite often mistaken for this edible mushroom. It is, however, easily distinguished from virtually all other mushrooms by its green gills and spore print (see Fig. 23-2). However, sterile forms of this mushroom, which produce no spores, are known to exist.⁷⁵ Another common GI irritant mushroom is *Omphalotus olearius* or *illudens* (“Jack O’Lantern”). This mushroom has a bright orange stalk and large cap (7 to 11 cm) that may glow in the dark. Although formerly classified in the genus *Clitocybe*, more recent study confirms that this mushroom does not

contain muscarine but other GI irritants.⁶ This mushroom is commonly found in Europe and North America. The European variety is associated with more severe illness and hepatotoxicity.

Many common backyard mushrooms or “little brown mushrooms” can be considered to be in this group. When these mushrooms are ingested by children or in large quantities by adults, it is still safest to presume them to be toxic and to have them identified.

Generally, no therapy is required for ingestion of gastrointestinal irritant mushrooms. If symptoms are significant or if signs of volume depletion are evident, it is advisable to provide hydration and GI decontamination with activated charcoal. However, it must be emphasized that administration of cathartics with activated charcoal is very likely to exacerbate the condition being treated and thus should be avoided.

ENVIRONMENTAL AND MUSHROOM FARMING ISSUES

Mushrooms are occasionally used as environmental sentinel species for toxins including pesticides⁷⁶ and radionuclides.^{77,78} This is especially true with respect to monitoring heavy metals such as cadmium, lead, and mercury and radionuclides including potassium 40, cesium 137, cesium 134, and radon 222. These elements may not only be detected on the surface of the mushrooms as a result of atmospheric deposition, but may also be incorporated into the flesh of the mushroom. Mushrooms also appear to be good accumulators of elements such as rubidium, copper, cesium, and selenium.⁷⁹ In most cases, the cap accumulates heavy metals to a greater extent than the stipe or stalk of the same mushroom. Furthermore, the species of mushroom may also influence the extent of metal accumulation. For example, fly agaric (*A. muscaria*) demonstrates a preferential uptake of mercury relative to other mushroom species.⁷⁸ Despite the accumulation of these potentially toxic elements in mushrooms, the total exposure through ingestion of mushrooms is usually well below any level of concern. No cases of ill health effects as a result of exposure to toxic elements through mushroom ingestion were found. However, mushrooms should be considered as potential contributors to total body burden of metals such as mercury.

Although the majority of mushroom-related toxicity is the result of ingestion, some additional maladies attributable to mushroom exposure in the absence of ingestion have been described. Most often, these noningestion toxicities are the result of hypersensitivity reactions and can be broadly categorized as either dermatologic or pulmonary. The primary dermatologic effect is allergic contact dermatitis, which frequently clears with removal from the source.⁸⁰ This is commonly seen in persons working on mushroom farms or mushroom packing facilities.

A syndrome of hypersensitivity pneumonitis termed *mushroom worker's lung* has been described in mushroom farm workers in Japan and numerous American states,

including Florida, Pennsylvania, and Washington.⁸⁰⁻⁸³ Patients often present with episodic shortness of breath, persistent cough, fever, chills, and malaise. In some instances, the cough may improve or disappear during weekends and holidays. Pulmonary function testing typically reveals restrictive ventilatory impairment with diffuse interstitial pulmonary infiltrates, while chest radiography shows diffuse infiltrates. Histologic examination of mushroom-related pneumonitis may reveal granulomatous alveolitis. Some cases of mushroom workers lung have been severe enough to cause sufferers to seek alternative employment. One case report exists in which the researchers suggest that chronic hypersensitivity pneumonitis from Shiitake mushroom spores was a causative agent for adenocarcinoma of the lung,⁸⁴ although this has not been a commonly reported complication.

The causative agents appear to be constituents of the organic dusts, which are ubiquitous to nearly all areas of the mushroom farms. Spores of a variety of mushroom species as well as elevated airborne endotoxin concentrations are reported causes of chronic cough and pneumonitis in mushroom workers. This has led at least one investigator to ask if mushroom workers' chronic cough is actually the same as byssinosis and what the occupational exposure limits should be for endotoxin.⁸⁵ However, it is often not possible to isolate a specific antigen responsible for the condition, and the results of serologic assessments in many asymptomatic workers may demonstrate exposure to antigenic substances.

The medical management of mushroom workers lung is symptomatic and supportive. Removal from the source of the antigenic substances is the first order. β -Adrenergic agonists and steroids may be warranted in cases with acute effects. Follow-up provocation testing may or may not be able to isolate a specific cause.

CONCLUSION

The management of mushroom poisoning is best thought of by dividing mushrooms into clinical syndromes based

BOX 23-3

POSSIBLE PITFALLS IN THE TREATMENT OF MUSHROOM POISONING

- Forgetting that “mushroom poisoning” may actually be an allergic reaction or food poisoning secondary to bacteria
- Forgetting that “mushroom poisoning” may actually be secondary to pesticides sprayed on the mushroom or edible mushrooms laced with drugs (e.g., phencyclidine) or from a concomitant medical or surgical disease
- Assuming that all persons ingesting the same mushroom must become ill
- Assuming that if symptoms occur before 6 hr after ingestion, deadly *Amanita* species could not have been eaten
- Discharging patients when they appear to have recovered from their gastrointestinal symptoms when those symptoms developed more than 6 hr after ingestion and therefore may have been due to a potentially very toxic mushroom
- Forgetting the principles of supportive care while concentrating on toxin identification and antidotes

on the toxins they contain. The treatment of mushroom poisoning is not significantly different from that for drug overdose; supportive care must take highest priority pending identification of the toxin.

Common pitfalls in the management of mushrooms poisoning are listed in Box 23-3. By avoiding these common errors and emphasizing supportive care and continued monitoring, the outcome in most cases of mushroom poisoning should be favorable.

24 *Poisonous Plants*

SUSAN C. SMOLINSKE, PHARMD ■ G. PATRICK DAUBERT, MD ■ DAVID G. SPOERKE, MS, RPH

At a Glance...

- Most pediatric unintentional ingestions of plants and berries can be safely managed at home.
- A few plants can cause serious toxicity with one bite of berry/leaf/root:
 - Autumn crocus
 - Castor bean
 - Common oleander
 - Glory lily
 - Jequirity bean
 - Lily of the valley
 - Monkshood
 - Poison hemlock
 - Water hemlock, water hemlock dropwort
 - Yellow oleander
- Gastric decontamination is generally not indicated.
- Few specific antidotes are available.
- Physostigmine can be considered for serious *Datura* exposures.
- Digoxin Fab fragments can be considered for cardiac glycoside poisoning.
- Photographs of many toxic plants can be found on pages 14 to 21.

INTRODUCTION AND RELEVANT HISTORY

Plants are one of the most common sources of accidental poisoning in children. In 2003, there were 57,778 plant exposures in children under the age of 6 years reported to the Toxic Exposure Surveillance System (TESS), 4.6% of total poisonings in that age group. In contrast, adult plant poisoning is much less common. In the same year, there were only 10,048 plant poisonings in patients older than 19 years.¹ Fatalities are rare in developed countries. Between 1983 and 2000 in the United States, there were 30 fatal plant exposures; 7 were related to *Cicuta* species, 5 to *Datura* species, 1 to *Conium maculatum*, 1 to oleander extract, and 1 to *Gloriosa superba*.² In 2003, there were three plant-related fatalities: a 34-year-old man who drank absinthe liquor and died of complications from aspiration pneumonitis, a 61-year-old man who injected crushed castor beans intravenously, and a 50-year-old patient who ingested yew. A series of five plant-related deaths were reported in Switzerland between 1966 and 1994. Species involved were *Colchicum* (two cases), *Oenanthe crocata*, *Taxus baccata*, and *Narcissus* (daffodil).³

These facts are in contrast with international experiences with more widespread plant poisonings, particularly in developing countries, due to unsafe food-handling practices or cultural choice of plants as a common mode of suicide. For example, intentional ingestion of yellow

oleander is a major clinical problem in Sri Lanka, with a fatality rate of up to 9%. In two studies, involving 631 patients hospitalized for plant poisoning over 2 years, 12% to 17% were related to *Thevetia*, with 6% to 7% fatal outcomes. A follow-up study in 1996 showed 4361 patients over 3 years, with 32% to 36% related to *Thevetia* and 3% to 4% fatal.⁴ In the Indian state of Kerala, plants are responsible for 10% of all poisonings, with *Cerbera odollam* (the suicide tree) accounting for half of the plant exposures, most involving suicide or homicide. *Atractylis* poisoning in Maghreb populations of Morocco, Algeria, and Tunisia carries a 65% case fatality rate. Ingestion of unripe ackee fruit is estimated to cause thousands of deaths annually in the Caribbean. Epidemics of ascending peripheral neuropathy are common in Mexico and Central America due to ingestion of buckthorn fruit. These examples serve as reminders that serious toxicity can occur from plant poisoning, particularly with intentional exposures.

The antimuscarinic symptoms of various plants have been recorded throughout history. Henbane, deadly nightshade, and thorn apple (*Datura* species) are mentioned among favorite poisonings in ancient Rome.⁵ The wives of the Roman emperors Augustus and Claudius are reputed to have used deadly nightshade to murder large numbers of Romans. The more famous history of intoxication from *Datura* species came in 1676, when British soldiers were sent to Virginia near Jamestown to stop the Rebellion of Bacon. As part of a final meal before entering the rebellion, several soldiers were offered a salad which included a local weed (Jamestown weed, today known as Jimson weed). The ensuing toxicity rendered the soldiers incapable of fighting for several days.^{6,7}

Another historical example is provided by a paper presented by Dr. Barton to the American Philosophical Society in 1794. It described with great detail epidemics of poisoned honey made from toxic plants, including rhododendron, yew, oleander, water hemlock, and others, particularly in colonial America. In one European case cited, he described an account by Xenophon in the *Anabasis* that reported the poisoning of his troops by the honey of *Rhododendron ponticum* flowers.⁸

Table 24-1 lists toxic plants found in the United States and their characteristics.

STRUCTURE-ACTIVITY RELATIONSHIPS

Alkaloids

Webster's online dictionary traces the origin of the term *alkaloid* to popular literature sometime before 1887. At the time it was applied to any organic base, for example, a nitrogenous substance that forms salts with acids. In

TABLE 24-1 Some Toxic Plants Found in the United States

COMMON NAME	SCIENTIFIC NAME	TOXIC PART	TOXIC AGENT
Akee	<i>Blighia sapida</i>	Fruit except aril	Hypoglycin A and B
*Allamanda	<i>Allamanda cathartica</i>	All except root	Unknown cathartic
*Alocasia	<i>Alocasia</i> species	Leaves, stems	Oxalates
Aloe	<i>Aloe</i> species	Latex	Barbaloin
Anthurium	<i>Anthurium</i> species	Foliage, fruit	Oxalates
Ape	<i>Alocasia</i> species	Leaves, stems	Oxalates
Apple	<i>Malus</i> species	Seed	Cyanide glycosides
Apricot	<i>Prunus</i> species	Seed kernel	Cyanide glycosides
Autumn crocus	<i>Colchicum autumnale</i>	All	Colchicine alkaloids
Azalea	<i>Rhododendron</i> species	All	Andromedotoxin
*Baneberry	<i>Actaea</i> species	Berries, roots	Protoanemonin
Belladonna	<i>Atropa belladonna</i>	All	Atropine, scopolamine
Bethlehem star	<i>Ornithogalum umbellatum</i>	All	Colchicine alkaloids
Bird of paradise	<i>Casalspinia gilliesii</i>	Pods	Unknown
Bittersweet	<i>Solanum dulcamara</i>	Variable, foliage	Solanine, tropane alkaloids
*Black locust	<i>Robinia pseudoacacia</i>	Seeds, young leaves	Robin, robitin, phasin
Bleeding heart	<i>Dicentra formosa</i>	Foliage, root	Isoquinolines
*Blue flag	<i>Iris</i> species	Leaves, root stalks	Irisin, iridin, irigenin
*Buckeye	<i>Aesculus glabra</i>	Foliage, seed, flower	Esculin
Burn bean	<i>Sophora secundiflora</i>	All	Cytisine
*Buttercups	<i>Ranunculus</i> species	All	Protoanemonin
Daffodil	<i>Narcissus</i> species	Bulb	Lycorine, narcissine
*Caladium	<i>Caladium bicolor</i>	All	Oxalates
Candlenut	<i>Aleurites molluccana</i>	All, seeds	Phorbol
Carolina jasmine	<i>Gelsemium sempervirens</i>	All, berries	Gelsemine
*Castor bean	<i>Ricinus communis</i>	All (seeds mainly)	Ricin
Celandine	<i>Chelidonium majus</i>	Roots	Isoquinoline alkaloids
*Century plant	<i>Agave americana</i>	Sap	Unknown
Chinaberry	<i>Melia azedarach</i>	Fruit	Possible resinoid
*Christmas rose	<i>Helleborus niger</i>	Foliage, root	Helleborin
Corn cockle	<i>Agrostemma githago</i>	Seeds	Githagin
*Cowbane	<i>Cicuta</i> species	All	Cicutoxin
Crab's eye	<i>Abrus precatorius</i>	Seeds	Abrin, abric acid
Daffodil	<i>Narcissus</i> species	Bulb	Lycorine and others
Daphne	<i>Daphne</i> species	All	Mezereinic anhydride
Deadly nightshade	<i>Atropa belladonna</i>	All	Atropine, scopolamine
Delphinium	<i>Delphinium</i> species	All	Delphinine, ajacine
Desert potato	<i>Jatropha macrorrhiza</i>	Root	Phytotoxins
Desert rose	<i>Adenium</i> species	All	Cardiac glycosides
Dieffenbachia	<i>Dieffenbachia</i> species	All	Oxalates, proteins
*Dogbane	<i>Apocynum</i> species	Rhizome	Apocynamarin
Dog's parley	<i>Aethusa cynapium</i>	All	Aethusanol A, coniine
Doll's eyes	<i>Actaea</i> species	Berries, roots	Protoanemonin
Donkeytail	<i>Euphorbia myrsinites</i>	Foliage, sap	Diterpenes, phorbols
Dumbcane	<i>Dieffenbachia</i> species	All	Oxalates, proteins
Dutchman's breeches	<i>Dicentra cucullaria</i>	Foliage, root	Isoquinolines
Elephant's ear	<i>Alocasia, Colocasia</i>	All	Oxalates
Fava beans	<i>Vicia faba</i>	Seed, pollen	Enzyme deficiency
Fool's parsley	<i>Aethusa cynapium</i>	All	Aethusanol A coniine
Four o'clock	<i>Mirabilis jalapa</i>	Root, seed	Trigonelline
*Foxglove	<i>Digitalis purpurea</i>	Leaves, seeds	Digitalis glycosides
Golden chain	<i>Laburnum anagyroides</i>	Seed capsules	Cytisine
Gordolobo	<i>Senecio longilobus</i>	All	Pyrrrolizidines
Groundsel	<i>Senecio longilobus</i>	All	Pyrrrolizidines
Heavenly blue	<i>Ipomoea violacea</i>	Seeds	Ergine, isoergine
Holly	<i>Ilex</i> species	Berries	Illicin
Honeysuckle	<i>Lonicera</i> species	Berries	Unknown gastrointestinal irritant
Horse chestnut	<i>Aesculus hippocastanum</i>	Foliage, seed, flower	Esculin
Hyacinth	<i>Hyacinthus orientalis</i>	Bulb	Narcissine
Hydrangea	<i>Hydrangea</i> species	All	Cyanide glycosides
*Indian licorice	<i>Abrus precatorius</i>	Seeds	Abrin, abric acid
*Indian tobacco	<i>Lobelia inflata</i>	All	Lobeline
Indian turnip	<i>Arisaema triphyllum</i>	Rhizome	Oxalates
*Inkberry	<i>Phyllolacca americana/decandra</i>	All parts, fruit least	Saponin, glycoprotein, and phytolaccotoxin
*Iris	<i>Iris</i> species	Leaves, root stalks	Irisin, iridin, irigenin
Jack-in-the-pulpit	<i>Arisaema triphyllum</i>	Rhizome	Oxalates
Japan oil tree	<i>Aleurites cordata</i>	All, seeds	Phorbol

**TABLE 24-1** Some Toxic Plants Found in the United States (Cont'd)

COMMON NAME	SCIENTIFIC NAME	TOXIC PART	TOXIC AGENT
Jasmine, yellow	<i>Gelsemium sempervirens</i>	All, berries	Gelsemine
*Jequirity bean	<i>Abrus precatorius</i>	Seeds	Abrin, abric acid
Jerusalem cherry	<i>Solanum pseudocapsicum</i>	Berries	Solanine, tropane alkaloids
Jimsonweed	<i>Solanum stramonium</i>	All	Solanine and tropane alkaloids
Narcissus	<i>Narcissus</i> species	Bulb	Lycorine, narcissine
Nightshades	<i>Solanum</i> species	Variable, foliage	Solanine and tropane alkaloids
Laburnum	<i>Laburnum anagyroides</i>	Seed capsules	Cytisine
*Lantana	<i>Lantana camara</i>	Berries (unripe)	Lantadene A
Larkspur	<i>Delphinium</i> species	Seeds, young foliage	Delphinine
Lesser hemlock	<i>Aethusa cynapium</i>	All	Aethusanol A, coniine
Lily of the valley	<i>Convallaria majalis</i>	All	Digitalis-like alkaloids
*Marsh marigolds	<i>Caltha palustris</i> , <i>Caltha leptocephal</i>	All	Protoanemonin
Mescal	<i>Lophophora williamsii</i>	All (button)	Mescaline and others
Mistletoe	<i>Phoradendron</i> species	Berries	Phenylethylamine, tyramine, choline
*Monkshood	<i>Aconitum</i> species	Roots, seeds, leaves	Aconitine
Moonseed	<i>Menispermum canadense</i>	All	Dauricine
Morning glory	<i>Ipomoea violacea</i>	Seeds	Ergine, isoergine
Mountain laurel	<i>Sophora secundiflora</i>	All	Cytosine
Narcissus	<i>Narcissus</i> species	Bulb	Lyconine and others
Nightshades	<i>Solanum</i> species	Variable, foliage	Solanine alkaloids
*Oleanders	<i>Nerium oleander</i>	All	Oleandrin, nerioside
Pasque flower	<i>Anemone patens</i>	All	Protoanemonin
Peach	<i>Prunus</i> species	Seed kernel	Cyanide glycosides
Pearly gates	<i>Ipomoea violacea</i>	Seeds	Ergine, isoergine
Pencil tree	<i>Euphorbia tirucalli</i>	Foliage, sap	Phorbols
Peyote	<i>Lophophora williamsii</i>	All	Mescaline, others
*Philodendron	<i>Philodendron</i> species	All	Oxalates
*Pigeon berry	<i>Phytolacca americana/decandra</i>	All parts, fruit least	Saponin, glycoprotein, and phytolaccotoxin
Poinciana	<i>Casualpinia gilliesii</i>	Pods	Unknown
*Poison hemlock	<i>Conium maculatum</i>	All	Coniine
*Poison ivy	<i>Toxicodendron radicans</i>	All	Urushiol
*Pokeweed	<i>Phytolacca americana/decandra</i>	All parts, fruit least	Saponin, glycoprotein, and phytolaccotoxin
*Precatory bean	<i>Abrus precatorius</i>	Seeds	Abrin, abric acid
Privet	<i>Ligustrum japonicum</i>	All	Andromedotoxin
Red squill	<i>Urginea maritima</i>	Bulb	Cardiac glycosides
Rhododendron	<i>Rhododendron</i> species	All	Andromedotoxin
Rhubarb	<i>Rheum rhaponticum</i>	Leave blade	Oxalates, anthraquinones
*Rosary pea	<i>Abrus precatorius</i>	Seeds	Abrin, abric acid
Snowdrop	<i>Ornithogalum umbellatum</i>	All	Alkaloids (colchicine)
Skunk cabbage	<i>Symplocarpus foetidus</i>	All	Oxalates
Sweet pea	<i>Lathyrus odoratus</i>	Seeds	Aminopropionitrile
Texas mountain laurel	<i>Sophora secundiflora</i>	All	Cytosine
Thornapple	<i>Solanum stramonium</i>	All	Solanine and tropane alkaloids
Threadleaf groundsel	<i>Senecio longilobus</i>	All	Pyrrrolizidines
Tree tobacco	<i>Nicotiana</i> species	All	Nicotine alkaloids
Tung nut	<i>Aleurites fordii</i>	All, seeds	Phorbols
*Water hemlock	<i>Cicuta</i> species	All	Cicutoxin
White snakeroot	<i>Eupatorium rugosum</i>	Above ground parts	Tremetone
Wild tobacco	<i>Nicotiana</i> species	All	Nicotine alkaloids
Wisteria	<i>Wisteria floribunda</i> <i>Wisteria sinensis</i>	Seeds	Gelsemine and gelseminine
*Wolfsbane	<i>Aconitum</i> species	Roots, seeds, leaves	Aconitine
Yellow jasmine	<i>Gelsemium sempervirens</i>	All, berries	Gelsemine
Yellow oleander	<i>Thevetia peruviana</i>	All parts	Thevetin A and B
Yew	<i>Taxus</i> species	All part, aril least	Taxine

the updated 1911 version, the definition changed to restrict the term to bases of vegetable origin and characterized by remarkable toxicologic or pharmacologic effects. Treating the plant with a dilute acid and precipitating

the bases with potash, soda, lime, or magnesia can chemically extract the base. The separation of the mixed bases obtained occurs through repeated fractional crystallization, or by taking advantage of certain properties

of the constituents. Structure-activity relationships of selected plant toxins are discussed in the ensuing paragraphs.

Pyrrolizidine alkaloids, such as sececionine and symphytine, have three structural requirements for toxicity. They must contain an unsaturated (double bond at the 1:2 position) heterocyclic ring, the ring nucleus must have an esterified hydroxyl group, and the ester side chains must contain at least one branched carbon chain. The parent compounds are converted by CYP1A2 and 2E1 to pyrrolic esters and then further to pyrrolic alcohols. The acute toxicity is most likely related to the more reactive esters, which can alkylate DNA.

Colchicine is an alkaloidal amine without a heterocyclic nitrogen atom. It contains four methyl groups. When hydrolyzed to trimethylcolchicinic acid, with loss of a methyl group, activity is lost.

Grayanotoxins are diterpenoid alkaloids, also known as andromedotoxins. To produce toxicity, a hydroxyl group at R1 is essential. An ester group at R3 decreases toxicity, but larger ester groups have greater toxicity. The interaction of grayanotoxin with the sodium channel involves contact by hydrogen binding with the 3- β -OH, 5- β -OH and 6- β -OH sites and by hydrophobic bonds in binding to the sodium channel. Grayanotoxins, and perhaps aconitine and vertradine as well, appear to contain four hydroxyl groups essential for optimal hydrophobicity and biologic activity. Altering the number of hydroxyl groups reduces the toxin's biologic activity.⁹

Diterpene Ester Alkaloids

Three groups of compounds are considered to be diterpene esters. Phorbol esters are most commonly associated with irritant properties in *Euphorbia* species. Ingenol esters and daphnane esters are also irritants. Structural requirements for irritancy include an ester group at carbon 13, a rigid tetracyclic structure, a C ring in a *cis* transfiguration, AB rings in the *trans* transfiguration, and a four- β function. Irritancy is enhanced when R1 becomes unsaturated and with increasing chain length at R1.

Another diterpene compound, salvinorin A, from *Salvia divinorum*, is a potent and selective κ opioid receptor agonist, resulting in hallucinations. Screening of salvinorins and derivatives for binding affinity and functional activity at opioid receptors have suggested that the methyl ester and furan ring are required for activity but that the lactone and ketone functionalities are not.¹⁰

Aconitine alkaloids with diester bonds appear to have the most toxicity compared with those alkaloids with no ester side chain, which have few clinical effects.¹¹

Glycosides

Glycosides are defined as any compound that contains a carbohydrate molecule that is convertible by hydrolytic cleavage into a sugar (glycone) and a nonsugar component (aglycone or genin). Examples include the cardenolides, bufadienolides, amygdalin, anthraquinones, and salicin. Saponins consist of an aglycone with a triterpenoid or steroid backbone linked to a carbo-

hydrate molecule. This confers their ability to form soap-like foams in aqueous solutions.

Cardenolides are 23-carbon steroids with an α,β -unsaturated five-membered lactone ring on carbon 17. These include digitoxin, convallatoxin, and evonoside. Bufadienolides are 24-carbon steroids with a double unsaturated six-membered lactone ring on carbon 17. Examples include convallamarin, scillaren, and hellebrin. The lactone ring was initially considered to be responsible for the inotropic activity of the cardiotonic steroids. However, research conducted with digitalis and differing lactone rings demonstrated little cardiotonic activity among the lactone rings.¹² The five- and six-membered lactone rings more likely contribute energy to the cardiac steroid/adenosine triphosphatase (ATPase) bond through a conformational change promoted by the steroidal binding.¹³

Three positions of the steroid nucleus appear to be essential for the activity of the cardiac glycosides. These are the carbons at the 3-, 14-, and 17-positions. The 17-carbon position links the steroid nucleus to the lactone ring. The hydroxyl group at the C14 position is not an essential feature for inotropic activity, although when it is replaced by hydrogen, potency decreases considerably.¹⁴ To retain cardiac toxicity, the hydroxyl group at C14 confers added potency, and the configuration of the C/D ring must be in *cis* configuration. Additional hydroxyl groups confer more rapid onset and shorter duration of activity. Its larger role probably resides in its ability to modify the spatial disposition of ring D enabling an interaction of the lactone with ATPase.¹⁵ Otherwise, the D ring does not appear to be essential for cardiotonic activity.¹⁶

The wide range of toxicity among the cardiac glycosides resides in the complex interaction of the steroid nucleus, sugar moiety, and the lactone ring with ATPase. The steroid nucleus is key to the cardiac glycoside interacting with ATPase. Plant cardiotoxin sterols differ from mammalian sterols in the ring orientation. The difference is mostly in the orientation of the A ring to the B ring. In mammalian steroids, the A/B ring juncture is in a *trans* configuration. However, plant cardiac glycosides have an A/B ring juncture that is *cis*, and the two hydrogens are on the same side of the rings.¹⁷ The change of the A/B junction does not necessarily imply a decrease of activity of the steroid, although it does for the corresponding glycosides, indicating that the main influence of A/B junction arises from its ability to place the sugar into a suitable position.

Although the fundamental pharmacologic activity of these plant toxins resides in the steroid nucleus, the sugar residues play an integral role in their activity. The sugar residue increases the water solubility of the steroid nucleus, making it more available for translocation into the myocardium. The lipophilic steroid nucleus is important in the compound's onset and duration of action. The presence of an acetyl group on the sugar moiety also affects the lipophilic character and the kinetics of the entire glycoside. In general, cardiac glycosides with more lipophilic character are absorbed faster and exhibit longer duration of actions as a result of slower urinary excretion rate. Lipophilicity is markedly

influenced by the number of sugar residues and the number of hydroxyl groups on the aglycone part of the glycoside. As the steroidal rings are substituted with polar hydroxy substitutes, the onset of action becomes faster and the duration decreases.¹⁸ Cardiac glycosides with monosaccharide sugar residues appear to have great potency, suggesting that only the first sugar molecule is involved in receptor binding.¹⁹⁻²¹

Polyacetylenes

Cicutoxin is a noncompetitive γ -aminobutyric acid (GABA)-mediated chloride channel antagonist. The compound is a long π -bond conjugated polyacetylene system, with a terminal hydroxyl, and an allylic hydroxyl group. The length and geometry of the π -bond and O-functional groups correlated with neurotoxicity and with potency in inhibition of the GABA channel. Other polyacetylene compounds, such as falcarinol, which have a carbonyl group conjugated with both double and triple bonds, have been associated with phototoxicity, but not neurotoxicity. Plants containing falcarinol include *Hedera helix*, *Panax pseudoginseng*, *Schefflera arboricola*, *Tagetes patula*, and *Daucus carota*.

PHARMACOLOGY

Pharmacokinetics

Pharmacokinetic data are available for only a few plant-derived constituents. Examples of onset and duration of effect from plant poisonings are given in Box 24-1.

PATHOPHYSIOLOGY

Due to the multiple constituents of many plants, the mechanism by which a plant causes toxicity can be complex. Many plants may also possess features that cause toxicity in more than one organ system. The most common type of plant intoxication is gastrointestinal (GI) irritation.

Gastrointestinal Irritation: Amaryllidaceae Alkaloids

Plants from the Amaryllidaceae family contain several alkaloids that have been linked to GI distress in humans.²² Most of these alkaloids are derived from phenanthridine, and are typically in highest concentration in the outer layers of the bulbs.²³ Daffodil bulbs may be mistaken for onions by the unwary consumer. Some plants containing Amaryllidaceae alkaloids include *Narcissus* spp. (daffodils and jonquils), Liliaceae spp. (spider lily), *Momordica charantia* (balsam pear), *Hippeastrum equestre* (amaryllis), *Hyacinthus orientalis* (hyacinth), *Amaryllis belladonna* (March lily), *Ammocharis coranica* (ground lily), *Boophone disticha* (fan-leaved boophone, poison bulb, sore-eye flower, tumblehead), *Brunsvigia* spp. (candelabra flowers), *Clivia miniata* (St. John's lily), *Crinum* spp., *Cyrtanthus* spp., *Galanthus nivalis* (snowdrop), *Haemanthus coccineus* (April

fool), *Nerine* spp., *Scadoxus* spp., and *Zephyranthes* spp. (zephyr lilies). The Amaryllidaceae alkaloids most well described include galanthamine, narciclasine, and lycorine. These alkaloids are specific protein inhibitors and have strong emetic properties. Galanthamine possesses anticholinesterase actions similar to physostigmine and has been evaluated in the treatment of Alzheimer's disease.²⁴ It also has antimuscarinic and analgesic effects. Narciclasine acts as a microtubule inhibitor similar to colchicine, particularly at concentrations above 0.5 mg/kg.²⁵

Gastrointestinal Irritation: Triterpene Saponin

Another group of plant components that cause more specific intestinal mucosa irritation rather than gastric irritation is the triterpene alkaloids. Plants with triterpene alkaloids include *Aesculus hippocastanum* (horse chestnut), *Hedera helix* (English ivy), *Phytolacca americana* (pokeweed), *Actaea* spp. (baneberry), and *Medicago truncatula* (barrel medic). Triterpenes are related to steroids and cholesterol and are broadly described as saponins because of their ability to form a soapy consistency when concentrated. Pokeweed is the most well-described plant in this group. It has been commonly used in cooking, salads, and herbal remedies. Teas from pokeweed are reputed to treat rheumatism, helminth infections, and constipation. The pokeweed root may also be mistaken for horseradish.²⁶ The triterpene alkaloids are heat labile, but the process of parboiling is recommended if the leaves or berries are to be used. The toxic triterpene saponins of Pokeweed include phytolaccatoxin and phytolaccagenin. *P. americana* also contains proteins exhibiting mitogenic^{27,28} and antiviral²⁹ properties. The mitogenic activity is attributed to pokeweed lectin, specific for *N*-acetylglucosamine-containing saccharides, which stimulates peripheral lymphocytes to undergo mitosis by binding to their cell surfaces.

Irritation from Plants that Contain Calcium Oxalate

Plants may contain several types of oxalates, commonly separated into soluble and insoluble oxalates. Insoluble oxalates produce localized tissue injury. Plants with insoluble oxalates are found in a variety of common houseplants and ornamental plants. The most common include *Philodendron*, *Dieffenbachia*, *Caladium*, *Axisaema triphyllum* (Jack-in-the-pulpit), *Colocasia* (elephant ear), *Rheum raponticum* (rhubarb), *Scindapsus aureus* (pothos), *Calla palustris* (wild calla), and *Symplocarpus foetidus* (skunk cabbage). Oxalic acid is a by-product of a plant's cellular metabolism and often takes the form of a crystal when it combines with calcium.³⁰ The crystalline structure varies among calcium oxalate crystals, and the shape may dictate the extent of local injury. Parallel needle-shaped crystals arranged in bundles are known as raphides and are a common source of intoxication. Raphides are commonly contained within a cellular structure called an idioblast. Calcium oxalate crystals not contained within idioblasts (*Inpatiens* spp.) have not been shown to produce significant toxicity.³¹ When stimulated (chewing

BOX 24-1 TOXIC PRINCIPLES**Aconitine-like Alkaloids**

Symptoms: Numbness, tingling of lips and tongue, bradycardia or irregular pulse, gastroenteritis, respiratory failure, vagal nerve stimulation.

Pharmacokinetics: three active metabolites, excreted in urine up to 6 days, not dialyzable due to high molecular weight (645 kD) and lipophilicity; onset 3 minutes to 2 hours, usually 10–20 minutes; dermally absorbed.

Source: monkshood

Agave americana Irritant

Symptoms: Sap contains an unknown dermal irritant that may produce rash (sometimes hemorrhagic). Systemic signs may be fever and leucocytosis.

Source: *Agave americana*

Aminopropionitrile

Symptoms: Skeletal abnormalities, growth suppression, muscle paralysis with chronic ingestion.

Pharmacokinetics: Onset 4–8 weeks; duration 1 month or more after removal from diet.

Source: sweet pea (*Lathyrus*)

Andromedotoxin (Synonym: Grayanotoxin)

Symptoms: Gastroenteritis, muscle paralysis, CNS depression, respiratory failure, heart muscle inhibition, cardiac poison, paralyzes vagus and motor nerve ends in striated muscle.

Pharmacokinetics: Onset 30–120 minutes; duration less than 24 hours.

Sources: mountain laurel, buttercups, *Andromeda* species, *Rhododendron* species

Anthraquinone Glycosides

Symptoms: Purgative, irritant, nephritis with large doses.

Pharmacokinetics: Onset 6–8 hours.

Sources: Many Aloe species

Example: barbaloin

Casesalpinia Toxin

Symptoms: Exact toxin unknown, usually produces severe vomiting and diarrhea that may lead to dehydration.

Pharmacokinetics: Symptoms may persist for 24 hours.

Source: *Casesalpinia gilliesii*

Cicutoxin

Symptoms: Abdominal pain, salivation, vomiting, mydriasis, delirium, severe seizures.

Pharmacokinetics: Onset 5 minutes to 1–2 hours; may be dialyzable.

Source: water hemlock

Colchicine-like Alkaloids

Symptoms: Symptoms include oral irritation and pain, vomiting, violent diarrhea, renal failure, and shock.

Pharmacokinetics: Peak plasma levels in 30 minutes to 2 hours. Serious symptom onset may be delayed for 2–6 hours. Lethal cases have occurred after a quiescent period. High enterohepatic circulation; high volume of distribution (10–12 L/kg); elimination half-life 1.7–32 hours.

Sources: autumn crocus, meadow saffron, star of Bethlehem

Coniine

Symptoms: Vomiting, initial CNS stimulation followed by CNS depression, muscle paralysis, respiratory failure.

Pharmacokinetics: Onset within 30 minutes.

Source: poison hemlock

Cyanogenic Glycosides

Symptoms: Cyanide-like, hyperpnea, shock, coma, marked metabolic acidosis. Lethal ingestions recorded, usually of large quantities of kernels or seeds.

Pharmacokinetics: Onset 90 minutes to 2 hours or longer.

Sources: Seed kernels of peach, pear, apricot, apple seeds, purified glycosides used medically, *Hydrangea* species

Examples: amygdalin, prunisin, hydrangin, githagin, linamarin

Cytisine

Symptoms: Nicotine-like in effects; dysphagia, vomiting, headache, incoordination, vertigo, possible confusion, excitement, respiratory stimulation, renal failure, convulsions, mydriasis, death via asphyxiation possible.

Pharmacokinetics: Onset 15–60 minutes; peak plasma level 2 hours in mice; elimination half-life 200 minutes in mice.

Sources: Golden chain tree, *Laburnum* species, Texas mountain laurel

Daphnin

Symptoms: Skin vesicant; ingestion may lead to vomiting, diarrhea, renal failure, convulsions and death.

Source: daphne

Delphinine Alkaloid

Symptoms: Gastroenteritis, respiratory depression, hypotension, paresthesias, salivation, headache, heart arrhythmias.

Sources: larkspur, delphiniums

Digitalis-like Glycosides

Symptoms: Possible dizziness and vomiting; these are cardiac glycosides that may produce arrhythmias. Atrioventricular block may occur.

Pharmacokinetics: Peak effect 4–12 hours; volume of distribution of digitoxin is 0.6 L/kg; digitoxin is metabolized to digoxin; half-life of digitoxin 4–6 days.

Sources: Foxglove, lily of the valley

Examples: digitoxin, digitalin, digitonin, convallarin, convallamarin, convallatoxin, apocynamarin, gitoxin, gitalin, hellebrin, evonoside

Diterpene Irritants

Symptoms: Irritation of skin, eyes, mucous membranes; vomiting, diarrhea.

Pharmacokinetics: Form acyl groups upon hydrolysis, which are cocarcinogenic; onset 2–8 hours; peak skin irritation and vesicle formation 4–24 hours; duration 3–4 days.

Sources: *Euphoria* species like donkey tail, pencil tree, crown of thorns

Examples: phorbols, tiglane

Esculin

Symptoms: Vomiting, diarrhea, muscle twitching, ataxia, paralysis, mydriasis, CNS depression, death.

Sources: horse chestnut, buckeye seeds

Gelsemine

Symptoms: Motor neuron depression and paralysis may lead to respiratory failure.

Sources: yellow or Carolina jasmine

Examples: gelsemine, gelseminine

BOX 24-1 TOXIC PRINCIPLES (Cont'd)
Helleborin/Helleborein

Symptoms: If ingested, oral inflammation and numbness leading to vomiting, diarrhea, and convulsions in severe cases. May affect the CNS and has a strong action on the heart, resembling digitalin.

Sources: Christmas rose roots and leaves

Hypoglycin A and B

Symptoms: Vomiting, may progress to severe hypoglycemia convulsions or coma. Lethal ingestions are recorded.

Pharmacokinetics: Hypoglycin is metabolized to a toxic metabolite, methylenecyclopropylacetic acid; onset 2–6 hours.

Source: *Blighia sapida* "ackee" fruit, except edible ripe aril

Illicin

Symptoms: Vomiting, abdominal pain, diarrhea.

Sources: Primarily berries from various *Ilex* (holly) species

Example: other saponins

Irisin

Symptoms: A resinous agent that may produce dermatitis. Ingestion may cause oral irritation, vomiting, diarrhea, possible pancreas and liver damage.

Sources: *Iris* species, commercial and wild

Examples: Similar resinous agents are irigenin and iridin.

Isoquinoline-type Alkaloids

Symptoms: Dyspnea, excessive salivation, labored breathing, tremors, unusual gait, convulsions, death by paralysis. An uncommon human poisoning, since roots and foliage are most toxic.

Sources: Bleeding heart, Dutchman's breeches, other *Dicentra* species

Examples: apomorphine, dauricine, protoberberine, protopine

Lantadene A

Symptoms: Somewhat similar to anticholinergic poisoning; gastroenteritis, cyanosis, circulatory collapse, muscle weakness. Cholestatic hepatitis, jaundice, photosensitization from ingestion of leaves.

Pharmacokinetics: Onset 2–6 hours.

Source: lantana

Examples: Lantadene is a polycyclic triterpenoid.

Lobeline

Symptoms: An alkaloid with nicotine-like symptoms. May cause vomiting, tremors, convulsions, weakness, coma, or death.

Source: Indian tobacco (*Lobelia species*)

Examples: lobelamine, lobeline

Lycorine-like Alkaloids

Symptoms: Gastroenteritis, possible liver toxicity, convulsions, hypotension. Most human cases result in mild gastroenteritis.

Pharmacokinetics: Peak galantamine level in 2 hours, several active metabolites, duration of effect 3 hours; elimination complete in 72 hours; half-life 5.7 hours.

Sources: daffodils, narcissus, hyacinth (similar)

Examples: lycorine, narcissine, galantamine, others

Melia Resinoid

Symptoms: Dyspnea, slowed movement, tachycardia, vomiting.

Pharmacokinetics: Onset one to several hours; death can occur in 12–24 hours; hepatorenal syndrome can develop after several days in survivors.

Sources: Chinaberry (*Melia azedarach*). Most often a poisoning in animals but gastrointestinal symptoms have been reported after 6 to 8 berries in a child.

Mescaline

Symptoms: Visual hallucinations, altered sensorium.

Pharmacokinetics: Onset 30 minutes to 2 hours; duration 6–12 hours.

Source: peyote

Mezerenic Acid Anhydride

Symptoms: Skin vesicant, oral irritant, produces bloody vomiting and diarrhea. May lead to renal failure, convulsions and death.

Source: daphne

Nicotine

Symptoms: vomiting, muscle tremors, initial CNS stimulation followed by CNS depression, muscle paralysis, and respiratory failure.

Pharmacokinetics: Onset 15 minutes to 1 hour; duration 3–12 hours; inactive metabolite cotinine is measured in the urine as a marker of exposure; nicotine half-life 0.5 hours in smokers, 1.3 hours in nonsmokers; cotinine half-life 10–20 hours.

Sources: tobacco, tree tobacco

Olavine Alkaloids

Symptoms: Psychotomimetic effects, nausea, euphoria, uterine stimulation.

Pharmacokinetics: One morning glory seed is equivalent to about 1 µg of LSD (effective dose 20–50 seeds); *Agryreia* is more potent (effective dose 4–12 seeds); onset 4–6 hours; duration 12–24 hours.

Sources: Morning glory, Hawaiian baby woodrose (*Agryreia nervosa*)

Examples: ergine, isoergine, elymoclavine

Oleander-type Glycosides

Symptoms: Irritations of mouth and stomach, vomiting, diarrhea, irregular pulse, possible ventricular fibrillation.

Pharmacokinetics: More rapid onset than digoxin; extensive enterophepatic circulation; oleander toxins cross-react with digoxin and digitoxin immunoassays.

Sources: Oleander, red squill, yellow oleander

Examples: oleandroside, oleandrin, nerioside, thevetin A and B, thevetoxin

Oxalates

Symptoms: Symptoms vary greatly. Initial oral pain may lead to swelling of the lips and tongue, dysphagia, and sometimes vomiting. Serious poisonings may lead to renal failure and dyspnea. Ocular exposure may produce corneal opacity.

Sources: Philodendrons, caladiums, dumbcanes, calocasias, aloacasias, Virginia creeper, rhubarb leaf, jack-in-the-pulpit, and many others

Examples: Usually calcium oxalates in needle-like structures. Many of these plants also contains additional chemical irritants.

Phytolaccine

Symptoms: Gastroenteritis (characteristic foamy diarrhea), tremors, amblyopia followed by salivation, diaphoresis, weakness, prostration, respiratory depression, leukocytosis, heart block.

Pharmacokinetics: Onset 2–3 hours, duration 48 hours.

Source: pokeberry

Examples: phytolaccine, phytolaccotoxin

BOX 24-1 TOXIC PRINCIPLES (Cont'd)**Protoanemonin**

Symptoms: burning sensation of the mouth and throat, gastroenteritis

Sources: clematis, anemones, buttercups

Examples: anemonin, ranunculin (glycoside containing protoanemonin)

Pyrrrolizidine Alkaloids

Symptoms: Hepatotoxicity (veno-occlusive disease), abdominal pain, vomiting, diarrhea, apathy, emaciation.

Pharmacokinetics: Onset days to weeks, metabolized by CYP1A and 2E to toxic pyrrolic esters and alcohols; eliminated within 24 hours.

Sources: Senecio species such as threadleaf groundsel

Saponins

Symptoms: Emetic, mucous membrane irritant, gastroenteritis, growth suppression or bloat in some animals, increase cell membrane permeability, diuretic.

Sources: common in plants

Examples: A diverse group of glycosides; mainly of the triterpenoidal type (e.g., oleanolic acid and hedagenin). Coffee weed, purple sesban, yucca, rattlebox, and soapwort.

Solanine

Symptoms: Intact glycoalkaloid is an irritant. Vomiting, diarrhea, abdominal pain, may lead to respiratory depression, CNS depression, convulsions, circulatory collapse.

Pharmacokinetics: Onset 1–25 hours after eating potatoes; peak levels 4–8 hours; half-life of α -solanine 11 hours; half-life of α -chaconine 19 hours; duration of gastroenteritis 3–6 days.

Sources: potato leaves, tomato leaves, nightshades, eggplant, Jerusalem cherry, ground cherry, horse nettle, and bittersweets

Examples: α -solanine, α -chaconine

Taxine

Symptoms: Gastroenteritis, dyspnea, circulatory failure, heart function depression, prolonged QRS. Possible dermatitis after skin exposure.

Pharmacokinetics: Onset 30 minutes to 3 hours; duration up to 24 hours.

Source: yew

Toxalbumins (RIPs)

Symptoms: Initial symptoms are oral burning, violent vomiting and diarrhea, which may progress to shock, hemolysis, renal failure, CNS depression and death. Many sources have attractive seeds.

Pharmacokinetics: half-life 2 days

Sources: include black locust, castor bean, desert potato, and rosary pea

Examples: abrin (rosary pea), robin, robitin, phasin (black locust), ricin, ricinine (castor bean)

Trigonelline

Symptoms: May cause skin irritation, eye irritation, vomiting, and diarrhea.

Sources: four o'clocks, green coffee beans

Tropane Alkaloids

Symptoms: Antimuscarinic in nature, dry mouth, thirst, irritability, flushing, delirium, tachycardia, mydriasis, fever, convulsion, coma. Pharmacokinetics: Onset 2–6 hours; duration up to 72 hours.

Sources: *Datura* (one seed equivalent to 0.1 mg atropine), *Hyoscyamus*, *Atropa* species

Examples: hyoscyamine (atropine), scopolamine (hyoscine)

Urushiol

Symptoms: Allergic dermatitis, inflammation, blistering, vesicles

Pharmacokinetics: Onset hours to 5 days; duration 1–3 weeks.

Source: poison ivy

Example: 3-*N*-pentadecylcatechol

Wisterin

Symptoms: gastroenteritis, dizziness, confusion

Pharmacokinetics: Duration 5–7 days.

or biting a leaf or stem), the idioblast releases the raphides with some force for a distance of two to three cell lengths.³² Raphide microstructure and size both contribute to irritation. In addition, many calcium oxalate crystals contain barbs and grooves that may contribute to local tissue injury. However, tissue irritation is not consistent among crystals and the presence of an additional chemical toxin has been proposed as a second mechanism of toxicity.³³

Delayed Gastroenteritis from Plants That Contain Ribosome-Inactivating Proteins

A vast amount of research has been conducted into the pathophysiology of plants containing toxins that inhibit ribosomes. Ribosome-inactivating proteins (RIPs) are found in a number of toxic and nontoxic plants. RIPs are divided into two main groups: type 1 RIPs, consisting of

a single polypeptide chain, and type 2 RIPs, consisting of an A (active) chain and a B (binding) chain with lectin properties. The type 2 RIPs have also been referred to as toxalbumins or as lectins based on properties of the B chain. The type 1 RIPs are considered nontoxic because they lack the ability to enter the cell membrane. For instance, pokeweed contains a type 1 RIP termed PAP that does not contribute to its cellular toxicity.

The type 2 RIPs have been found in a number of plant species, including *Ricinus communis* (castor bean), *Abrus precatorius* (rosary pea), *Robinia pseudoacacia* (black locust), *Hura crepitans* (sandbox tree), *Jatropha multifida* (coral bush), and *Phoradendron* spp., and in small quantities of *Viscum album* (mistletoe). The most common type 2 RIPs described are ricin from the castor bean and the toxin abrin from the rosary pea. A wide range of toxicity is induced by type 2 RIPs. The mechanism of toxicity of the type 2 RIPs begins with the binding of the B chain to the cell surface. The cytotoxicity of type 2 RIPs

is (partly) determined by the binding of the B chain to a sugar-containing receptor on the cell surface. The B chain (lectin) first binds to glycolipids and/or glycoproteins containing β -1,4-linked galactose residues on the cell surface, inducing endocytosis of the A and B chains. The toxin is transported to the Golgi apparatus and endoplasmic reticulum (ER), with subsequent release into the cytosol.³⁴ A partial unfolding of the A chain enables it to translocate across the ER membrane via a translocon using the pathway normally followed by misfolded ER proteins targeted for ER-associated degradation. Refolding of the A chain in the cytosol into a protease-resistant, enzymatically active structure enables its interaction with the sarcin-ricin domain of the large ribosome subunit RNA.³⁵ The A chain acts as an *N*-glycosidase by hydrolyzing a single *N*-glycosidic bond between adenine and ribose within a highly conserved sequence on the large recombinant RNA of animal ribosomes.³⁶ This interrupts translation at the step of guanosine triphosphate (GTP)-dependent binding of the elongation factor 1 and/or 2 to ribosomes.³⁷ There is recent evidence that the A chain is also capable of inactivating many nonribosomal nucleic acid substrates,³⁸ and hence can be considered a polynucleotide: adenosine glycosidase.

Delayed Gastroenteritis from Plants That Contain Glycoalkaloids

Plants containing glycoalkaloids, such as solanine, are a common cause of gastric irritation. This is due in part to the common variety of plants containing such glycoalkaloids, including *Solanum tuberosum* (potato), *Solanum nigrum* (black nightshade), *Lycopersicon esculentum* (tomato), *Solanum pseudocapsicum* (Jerusalem cherry), and *Physalis heterophylla* (ground cherry). Young plants/roots and unripe fruit tend to have a much higher concentration of toxin. Glycoalkaloids have been shown to destabilize membranes and inhibit serum acetylcholinesterase,³⁹ which may partially explain the GI toxicity. The glycoalkaloids are able to interact strongly with sterol-containing membranes, thereby causing membrane disruption specific for the type of glycoalkaloid and sterol.⁴⁰ Several of the glycoalkaloids have also demonstrated inotropic activity, which may be partly explained by the structural resemblance to the cardiac glycosides.⁴¹ Most relevant, the clearance of glycoalkaloids usually takes more than 24 hours, which suggests that the toxicants may accumulate after daily consumption.⁴²

Cytotoxic Plants That Produce Multiorgan Failure

This diverse group of plants is commonly involved in research on cancer and cellular function. They contain alkaloids with the common characteristic of binding to microtubules. Microtubules are involved in a wide variety of cellular function, including cell division and axonal transport. Microtubules are required for the transport of various metabolites and the movement of organelles, including mitochondria and secretory granules, along neuronal processes. Microtubules are composed of the

protein tubulin, which consists of α and β subunits. The α subunit binds GTP, retaining it within its structure. The β subunit hydrolyzes GTP to guanosine diphosphate (GDP) during protofilament formation. The tubulin-binding alkaloids interfere with protofilament formation by binding to various sites along the tubulin molecule. Cell division is arrested during metaphase at the G_2/M phases of the cell cycle.

Colchicine, found in the autumn crocus (*Colchicum autumnale*) and glory lily (*Gloriosa superba*), binds to the β subunit at the colchicine-binding site, inhibiting polymerization of tubulin polymers.⁴³ Podophyllotoxin from the mayapple plant (*Podophyllum peltatum*) inhibits GTP hydrolysis at the β subunit, thereby preventing β - and α -subunit polymerization during protofilament formation.⁴⁴ The vinca alkaloids derived from *Catharanthus* spp. (formally *Vinca rosea*) include the toxins vincristine and vinblastine. The vinca alkaloids also bind to the β subunit at the vinca-binding site, inhibiting the hydrolysis of GTP to GDP and inhibiting the binding of GDP to its nucleotide site.⁴⁵

Another antineoplastic drug with plant derivation is *Taxus brevifolia*, containing the alkaloid taxol. Taxol differs in its mechanism of microtubule inactivation by promoting assembly of microtubules. Early assembly of microtubules reduces the critical concentration of tubulin required for assembly. Other intracellular processes affected by microtubule inhibition include inhibition of synthesis of proteins and nucleic acids, elevation of oxidized glutathione, alteration of lipid metabolism and the lipid content of membranes, elevation of cyclic adenosine monophosphate (cAMP), platelet membrane integrity, and inhibition of calcium-calmodulin-regulated cAMP phosphodiesterase.⁴⁶

Plants That Produce Cardiovascular Disturbances

Plants containing cardiac glycosides (steroids) are well known because of their long history in the treatment of heart failure. Plants that have been known to contain cardiac glycosides include foxglove (*Digitalis purpurea*), lily of the valley (*Convallaria majalis*), oleander (*Nerium oleander*), squill (Liliaceae family), yellow oleander (*Thevetia peruviana*), dogbane (*Apocynum cannabinum*), wallflower (*Cheiranthus cheiri*), milkweed (Asclepiadaceae family), *Strophanthus* (*Strophanthus kombe/hispidus*), suicide tree (*Cerbera odollam*), hellebores (*Helleborus* spp.), star of Bethlehem (*Ornithogalum* spp.), spindle tree (Euonymus family), Crassulaceae family, crownvetch (*Coronilla* spp.), wistorm, *Thesium lineatum*, Iridaceae family, Melianthaceae family (*Bersama* and *Melianthus* spp.), Natal plum (*Carissa* spp.), and the frangipani tree (*Plumeria rubra*).

Although a wide variety of plants contain cardiac glycoside toxins, their mechanisms of action are quite similar. The myocardial effects of these compounds are attributable to increased intracellular concentrations of calcium and sodium, resulting from inhibition of the transmembrane Na^+/K^+ -ATPase pump. The cardiac glycosides consist of a C_{23} (cardenolide) or C_{24} (bufadienolide) steroid with one or more sugar moieties

attached to the C₃ carbon of the steroid nucleus.¹³ The majority of plant cardiac glycosides are cardenolides. The exceptions are the *Urginea* spp., *Hellebore* spp., several toxins within *Convallaria* spp., several toxins within the Crassulaceae family, *Thesium lineatum*, Iridaceae family, and the Melianthaceae family (*Bersama* and *Melianthus* spp.).

Plants with Sodium Channel–Binding Properties

Plants and their associated toxins with sodium channel-binding properties include aconitine, from monkshood (*Aconitum napellus*); veratridine, from false or green hellebore (*Veratrum* family); grayanotoxins, from azalea and rhododendron (*Rhododendron* spp.), death camas (*Zigadenus*), mountain laurel (*Kalmia latifolia*), and taxine from *Taxus brevifolia*. The sodium channel-binding characteristics of this group of plants have been known for some time. Aconitine has been found in a number of Chinese herbals, including both *chuanwu* (*A. carmichaeli*) and *caowu* (*A. kusnezoffii*). These herbs are believed to possess anti-inflammatory, analgesic, and cardiotoxic effects and have been used in Chinese traditional medicine mainly for the treatment of musculoskeletal disorders.⁴⁷ Roots of monkshood have also been mistaken for horseradish (*Armoracia rusticana*).

Grayanotoxins have largely been reported to cause intoxication in regions where honey is produced from *Rhododendron* spp. Approximately 18 different types of grayanotoxins have been isolated, but grayanotoxin I appears to be responsible for the majority of poisonings.⁴⁸

Veratridine has historically been used in both insecticides and medicinals. Major toxicity from veratridine came from the use of sneezing powders in Europe that contained the ground root of white hellebore (*Veratrum album*). *Veratrum* species have also been ingested intentionally after being mistaken for leeks, skunk cabbage, ramps (*Allium tricoccum*), and plants from the Gentian family.⁴⁹

All of the toxins from these plants are large, complex diterpenoid alkaloids. The diterpenoid alkaloids are lipid soluble, allowing them to access the sodium channel-binding site embedded within the plasma membrane.⁵⁰ Aconitine, veratridine, and grayanotoxins reversibly bind to site 2 along the inner membrane of the channel. Site 2 is an intracellular region expanding between domains I and IV. This site overlaps the known binding site of local anesthetics, and is shared by the *Phylloides*-derived toxin batrachotoxin. All the diterpenoid alkaloids preferentially bind to the open state of the voltage-gated sodium channel (VGSC).⁵¹ They exert their action on nerve and muscle membranes by persistent activation of VGSC at the resting membrane potential.⁵² Veratridine's persistent opening of the VGSC may reduce single-channel conductance by 75%.⁵³

The activation of VGSC is explained by two effects: first, a shift of the voltage dependence of activation of VGSC toward more negative effects, and second, a block of the fast inactivation of these channels.⁵⁰ Therefore, their binding is enhanced by other toxins or drugs that enhance prolonged opening of sodium channels.

Prolongation of sodium channels with a subsequent increase in intracellular sodium causes an increase in intracellular calcium due to inhibition of the sodium-calcium pump. This increase in intracellular calcium has a similar effect as that seen with the cardiac glycosides, with increased ionotropicity. However, since Na⁺/K⁺-ATPase is not inhibited, hyperkalemia is notably absent. The negative ionotropic effects and cardiodepressant effects (particularly aconitine) are most likely due to vagal stimulation, since they are reversed with atropine.⁵⁴ Aconitine also has a propensity to cause early and delayed after-depolarizations in ventricular myocytes that may be due to increased intracellular calcium and sodium. This may explain the reports of biventricular tachycardia and torsades de pointes in patients with aconitine intoxication.^{55,56} Other effects of these alkaloids include antinociceptive and antiepileptiform properties, and reuptake inhibition of norepinephrine and serotonin.⁵⁷ The *Aconitum* species also contain a compound called songorine that has demonstrated noncompetitive antagonism at GABA_A and agonistic action at dopamine receptors in the rat cerebral cortex.⁵⁸

The toxins produced by *Taxus brevifoli* (yew) include both taxol and taxine. In Caesar's time, the yew plant was known as the tree of death. American species, like *Taxus cuspidata* (Japanese yew) and *Taxus canadensis* may be found as ornamental shrubs or Christmas decorations. All parts of the plant except the fleshy fruit contain taxane alkaloids. Taxine is a mixture of more than seven alkaloids, with taxine A and taxine B as its main constituents. Taxine B is the most potent cardiotoxin of this group. The taxines have been known since the 1940s, but with the discovery of taxol (leading to paclitaxel) the taxines have since been overshadowed. In contrast to aconitine, grayanotoxin, and veratridine, taxine B reduces cardiac contractility and the maximum rate of depolarization of the action potential similar to class I antiarrhythmic drugs.^{59,60} Taxine B and paclitaxel share the same skeletal structure and differ only in their side chains. The taxines do not demonstrate antitumor activity, and the cardiotoxicity of taxol is lower than that of taxines.

Plants That Act Primarily on the Nervous System

PLANTS THAT HAVE A NICOTINE-LIKE ACTION

Nicotine alkaloids have been in use for many centuries, and the presence and addictive potential of nicotine in tobacco is well known. The nicotine plant alkaloids are highly toxic. They are widely used as insecticides, which is most likely an extension of their natural role in the plant kingdom. Plants and plant alkaloids with nicotine or nicotine-like mechanisms of action include γ -coniceine and coniine from poison hemlock (*Conium maculatum*), *Aethusa cynapium* (fool's parsley), nicotine from wild tobacco (*Nicotiana tabacum*; 0.5% to 9% nicotine), *Nicotiana rustica* (18% nicotine), lobeline (*Lobelia* spp.), anabasine (*Anabasis aphylla*), sparteine (*Cytisus scoparius*), *N*-methylcytisine from blue cohosh (*Caulophyllum thalictroides*), and cytisine from *Sophora* spp., golden chain

(*Laburnum spp.*), and *Gymnocladus dioica* (Kentucky coffee bean). Nicotinic pyridine and piperidine alkaloids share common receptor agonism for nicotinic acetylcholine receptors (nAChRs). Nicotine and nicotine-like alkaloids interact with presynaptic nAChRs to facilitate the release of a variety of neurotransmitters, including acetylcholine, dopamine, norepinephrine, serotonin, GABA, and glutamate. Some nicotinic alkaloids also inhibit aromatase, preventing androstenedione conversion to estrogen.⁶¹ However, at high concentrations of nicotine, nAChRs become desensitized due to increasing affinity for substrate at the receptor. With this, initial central nervous system (CNS) and muscle stimulation is typically followed by paralysis of motor nerve endings and CNS depression.

Poison hemlock (*Conium maculatum*) belongs to the Umbelliferae family and is closely related to carrots, parsnips, cow parsley, parsley, and caraway. Death from poison hemlock has often occurred from mistaken identity.⁶² Three main alkaloids are responsible for the toxicity of poison hemlock. The most toxic chemical, γ -coniceine, is an unsaturated piperidine alkaloid and is abundant in the leaves and flowers but less common in the fruits, where it is quickly converted to coniine and N-methylconiine. Gamma-coniceine is considered to be seven or eight times more toxic than coniine.⁶³ The actions of coniine are similar to nicotine, but produce greater CNS and skeletal muscle nerve ending paralysis. The actions of coniine have been said to resemble that of strychnine.

TROPANE ALKALOIDS: ANTIMUSCARINIC PLANTS

The tropane alkaloids are found in a number of plant families, including Solanaceae, Erythroxylaceae (e.g., *Erythroxylum coca*; cocaine), and Convolvulaceae (morning glory family). Tropane alkaloids possessing antimuscarinic properties are primarily from the Solanaceae family. Common alkaloids in this family include atropine, scopolamine, hyoscyamine, and hyoscyne. These plants include *Atropa belladonna* (belladonna; deadly nightshade), *Solandra spp.* (trumpet flower), *Datura stramonium* (jimson weed), *Mandragon officinarum* (mandrake; not to be confused with *Podophyllum peltatum*, also referred to as Mandrake), *Brugmansia* (angel's trumpet), *Cestrum diurnum* (day jessamine), *Lantana camara* (lantana, shrub verbenae), and henbane (*Hyoscyamus niger*).

The tropane alkaloids from these plants are all structurally similar. Atropine and hyoscyamine are racemic isomers, as are hyoscyne and scopolamine. Atropine consists of a mixture of equal parts of D- and L-hyoscyamine and does not exist as a single alkaloid in plant species. Both hyoscyamine isomers may bind to muscarinic receptors, although the pharmacologic activity is thought to be due almost entirely to L-hyoscyamine.^{64,65} Scopolamine and L-hyoscyamine are most likely the primary compounds responsible for the toxic effects of these plants. The toxicity of these compounds results from competitive blockade of acetylcholine at peripheral and central muscarinic receptors. The most commonly affected organ systems include the

CNS, cardiac myocytes and conduction system, exocrine glands, and smooth muscle cells.

NEUROLOGIC INJURY

Plants that cause neurologic injury are some of the most well-known and toxic species. Several of these plants contain specific toxic alkaloids producing seizures upon ingestion. The water hemlock species *Cicuta virosa* and *Cicuta maculata* that belong to the Umbelliferae family have been responsible for a number of reported deaths. The Umbelliferae family also contains several edible plants such as celery, water parsley, parsnip, and wild carrot. Severe poisonings have occurred while foraging for these edible relatives.⁶⁶ There are also reported cases of people mistaking wild ginseng for water hemlock.⁶⁷ The early practice of making toy whistles from the water hemlock stem has been associated with several deaths in children.⁶⁸ Cicutoxin is a noncompetitive GABA_A receptor antagonist acting at both the GABA agonist site and on the chloride channel of the GABA_A receptor-channel complex.^{69,70} This mechanism explains the high rate of seizures reported with cicutoxin exposure.

The ginkgo tree (*Ginkgo biloba*) is the oldest tree living tree species. It has been employed in medicinal treatments for centuries and recently promoted for treatment of memory impairment, commonly as standardized extracts of *G. biloba* leaves. Ginkgo is primarily composed of two constituents: terpenoids and flavonoids. The terpenoids include ginkgolides A, B, C, J, and bilobalide. Flavonoids found in *Ginkgo* include a wide variety of compounds, but the best described is quercetin. Ginkgolides are moderate potent antagonists at GABA_A receptor.⁷¹ They also have been shown to cause vasodilation by inhibiting calcium influx through calcium channels and simulate the activation of nitric oxide release in the endothelium.⁷² Ginkgolide B is a potent platelet-activating factor antagonist⁷³ and ginkgolide C has demonstrated potent and selective antagonism at inhibitory glycine receptors.⁷⁴ Ginkgo-induced seizures are probably multifactorial. The flavonoid quercetin is an antagonist at both GABA_A and GABA_C receptors, and probably modulates other ligand-gated ion channels.⁷⁵ In a recent case, a ginkgo seed constituent, 4-methoxyppyridoxine, was thought to be responsible for seizure activity. The concentration of 4-methoxyppyridoxine was elevated in this case and linked to decreased GABA synthesis.⁷⁶

Another hemlock species linked to seizure activity after ingestion is the *Oenanthe* species, hemlock water dropwort. The roots of water dropwort are yellow and typically composed of five or more tubers. This characteristic appearance has earned it the name "dead man's fingers." Water dropwort has produced significant toxicity from concentrated teas made from the plant or in its confusion with edible plants (i.e., water parsnips).⁷⁷ The water dropwort produces oenanthotoxin, which is the *cis*-isomer of cicutoxin. Oenanthotoxin is thought to inhibit neuronal sodium and calcium channels, resulting in potential seizure activity.⁷⁸ Its effect on GABA receptors has not been demonstrated.

The use and known toxicity of *Anamirta* species of plants also has existed for many centuries. *Anamirta paniculata* produces the toxin picrotoxin. The plant originates from the coast of Malabar and the islands around India. The common names for *Anamirta paniculata* (fishberries or Indian berries) derived from native fishermen using the crushed seeds to stupefy fish. It was also once employed in India and Great Britain as an antidote in morphine overdose.⁷⁹ Picrotoxin is an allosteric, noncompetitive inhibitor of both GABA_A and GABA_C⁸⁰ receptors. The mechanism of picrotoxin is believed to involve binding to residues that line the pore in the second transmembrane domain (M2) of the α subunit. The M2 domain is a common feature of many transmembrane receptors, including GABA, glycine, and acetylcholine receptors. The common binding site is the probable mechanism for picrotoxin's additional antagonism noted at nAChRs and glycine receptors.⁸¹

The *Coriaria* species of plants are most well known in Great Britain and New Zealand. *Coriaria* grows wild in southern Europe and may be cultivated in gardens because of its rich foliage. The leaves have been found as adulterants in senna and sweet marjoram. In the early 1900s, a reported Mexican drug called *Tolocopetale* was said to be the product of *C. myrtifolia* and was acutely poisonous.⁸² The active toxin in *Coriaria* species is coriamyrtin. The New Zealand species of coriaria (New Zealand toot-plant; *Coriaria ruscifolia*, *Coriaria sarmentosa*) contains a glucoside similar to coriamyrtin, called tutin. Coriamyrtin and tutin are structurally similar to picrotoxin and appear to be antagonists at GABA receptors.⁸³ However, the extent of their receptor binding and inhibition has not been revealed.

The strychnos plant (*Strychnos nux-vomica*) is associated with violent seizures, paralysis, and death. Strychnos is a native plant of India and Southeast Asia. The strychnine alkaloid is a reversible and competitive inhibitor of glycine receptors in the spinal cord and cerebral cortex.

The indolizidine alkaloid swainsonine isolated from the plants *Swainsona canescens*, *Astragalus mollissimus* (locoweed), and *Oxytropis* species (also locoweed) causes a debilitating chronic neurologic disease often leading to death. Swainsonine is a potent inhibitor of α -mannosidase II, resulting in a lysosomal storage disease termed mannosidosis.⁸⁴ It is currently being investigated in the treatment of advanced neoplasms.⁸⁵

Lathyrism, a disease caused by the grass pea (*Lathyrus sativus*), is mediated by a stereospecific plant amino acid (β -N-oxalylamino-L-alanine) that serves as a potent agonist at the (RS)- α -amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) subclass of neuronal glutamate receptors.⁸⁶

HALLUCINATIONS

The use of hallucinogenic drugs dates back many centuries. The vast majority of early plant use for hallucinogenic effects was through psychoactive snuffs. Recent literature supports the theory that hallucinogenic drugs produce their effects through partial agonist action at serotonin 5-HT₂ receptors.⁸⁷ One of the most

commonly known hallucinogens found in plant species is lysergic acid amide (LAA). It is structurally similar to lysergic acid (LSD). Lysergic acid amide is found primarily in *Ipomoea violacea* (morning glory) and *Turbina corymbosa* (ololiuqui). The content of LAA varies by plant but is most abundant in the *Ipomoea* varieties pearly gates, wedding bells, and Scarlet O-hara.⁸⁸ In addition, *Ipomoea* seeds contain other alkaloids such as isolysergic acid amide 0.005%, chanoclavine 0.005%, elymoclavine 0.005%, and ergometrine 0.005%.^{89,90} However, chanoclavine and ergometrine both possess open indole rings and lack hallucinogenic properties.⁹¹ Several species of plants and cacti produce their hallucinogenic effects from phenethylamine derivatives. Mescaline is a phenethylamine (3,4,5-trimethoxy- β -phenethylamine) found in cactus species of *Lophophora williamsii* (peyote), *Trichocereus pachanoi* (San Pedro cactus), and *Trichocereus peruvianus* (Peruvian torch). Its crown, or "button," is used as the source of mescaline. It is cut from the cactus and dried into a hard brown disc.⁹²

Nutmeg contains myristicin, which is metabolized to a methylenedioxymethamphetamine (MDMA) analog in animals; this pathway has not been demonstrated in humans. Myristicin is also a serotonin 5-HT₂ agonist. It contains elemicin, which is metabolized to 3,4,5-trimethoxy amphetamine.¹⁵

The leaves of the tropical plant *Mitragyna speciosa* (ithang, korth, kratom) have been traditionally used as a substitute for opium. It has also been used in the Middle East as a traditional medicine for treating stomach and intestinal disorders (diarrhea). *M. speciosa* contains several alkaloids that possess opioid agonistic activities. It has been recently discovered that the 7-hydroxymitragynine metabolite of the parent alkaloid mitragynine (9-methoxy-corynantheidine) has the highest opioid activity of this plant.⁹³

DEMYELINATION

An illness associated with peripheral neuropathy has been associated with the plant *Karwinskia humboldtiana* (buckthorn, coyotillo). This plant is a large tree or bush that is commonly seen in northern Mexico and the southern United States. Intoxication typically results from the ingestion of the plant's fruit. Only recently has the toxin been completely identified. The toxin from *K. humboldtiana* is called peroxisomicine. It is also known as T-514 or tullidol. Peroxisomicine destroys peroxisomes and generates free radicals, resulting in lipoperoxidation of cell membranes and leading to cell death.⁹⁴ Peroxisomicine has been shown to specifically target thick, distal nerve segments causing demyelination.⁹⁵ Histologically, there is widening of the periaxonal space and a redistribution of axonal organelles to a marginal position. Ultimately, axons undergo wallerian degeneration.⁹⁶

CYANOGENIC PLANTS: AMYGDALIN, CYANOGENIC GLYCOSIDES

Approximately 2500 different plant species have the ability to produce cyanogenic glycosides.⁹⁷ The compounds all

share the common feature of yielding hydrogen cyanide on complete hydrolysis. Considering the vast amount of plant taxa producing cyanogenic glycosides, the majority of exposures occur with cassava (*Manihot esculenta*) and seeds from the *Prunus* species (apple, peach, apricot, plum, etc.). Cassava contains the cyanogenic glycoside linamarin, which has been responsible for significant acute and chronic toxicity.^{98,99} Toxicity typically occurs from improperly cooked cassava. The pathogenesis of the chronic diseases associated with cassava (e.g., epidemic spastic paraparesis or konzo) is probably multifactorial. The neurologic symptoms of konzo resemble that seen with neurolethyrism acquired from the grass pea. The principal metabolite of cyanide, thiocyanate, has been shown to be a potent agonist at AMPA receptors, similar to lectins from the grass pea. The metabolism of cyanide, however, is dependent on the sulfur-dependent enzyme rhodanese. In protein-deficient people where sulfur amino acids are low, cyanide may conceivably be converted to cyanate.¹⁰⁰ Cyanate has been shown to cause neurodegenerative disease in humans and animals.¹⁰¹ It has been assumed that linamarin is enzymatically converted to cyanide by bacteria in the intestine. However, unmetabolized linamarin has been found in the urine after ingestion of cassava. Linamarin may be neurotoxic by entering cells via a glucose transporter and competing with cytochalasin B and glucose for those transporters.

The principal cyanogenic glycoside found in the *Prunus* species is amygdalin. Amygdalin was first isolated from bitter almonds in 1830. It is metabolized to cyanide by the intestinal enzyme complex emulsin (glucosidase, benzocyanase, nitrilase). Amygdalin is the active ingredient in the apricot extract Laetrile (derived from laevorotatory mandelonitrile) that was promoted as an antineoplastic agent. It continues to be marketed primarily in Mexico as an anticancer drug.

Metabolic Effects

SAPONIN GLYCOSIDES

The licorice root (*Glycyrrhiza glabra*) is one of the oldest known plant-derived medicines, having been used by Egyptians, Romans, and Greeks. It is one of the most frequently used traditional Chinese medicines¹⁰² and has become one of the leading natural compounds for clinical trials of chronic active viral hepatitis or human immunodeficiency virus infections. Glycyrrhizic acid is the major bioactive triterpene glycoside of licorice root. It has demonstrated a wide range of pharmacologic properties, including anti-inflammatory, antiulcer, anti-allergic, and antiviral effects.¹⁰³ The content of glycyrrhizic acid in licorice root is 2% to 24% of the dry weight. Upon ingestion, glycyrrhizic acid is hydrolyzed in the intestine to the pharmacologically active compound glycyrrhetic acid, which inhibits the enzyme 11- β -hydroxysteroid dehydrogenase. 11- β -hydroxysteroid is responsible for the interconversion of cortisol to cortisone and confers ligand specificity to the mineralocorticoid receptor.¹⁰⁴ Inhibition of 11- β -hydroxysteroid dehydro-

genase leads to increased serum cortisol levels. This promotes a hypermineralocorticoid state since cortisol binds with the same affinity as aldosterone at the mineralocorticoid receptor.¹⁰⁵ The ensuing pseudo-primary hyperaldosteronism is reversible, but may take several months to resolve. The protective function of glycyrrhizic acid on the liver has recently been explained as an inhibitory effect on nuclear factor κ B, which is known to activate genes encoding inflammatory cytokines within the liver.¹⁰⁶

NEPHROTOXIC PLANTS

Toxicity from *Aristolochia* species has most commonly been seen with Chinese herbal medications.^{107,108} An epidemic occurred in Belgium when the Chinese herbal *Stephania tetrandia* was substituted by *Aristolochia fangchi*. However, endemic nephropathy in Croatia has recently been linked to wheat grain flour, likely contaminated with seeds of *Aristolochia clematitis* during harvesting.¹⁰⁹ Aristolochic acids present in *Aristolochia* species undergo reduction of the nitro group by CYP1A1 and CYP1A2 peroxidases in extrahepatic tissues to reactive cyclic nitrenium ions.¹¹⁰ Reaction with intracellular proteins leads to a specific pattern of tubulointerstitial fibrosis¹¹¹ and Fanconi syndrome,¹¹² and may lead to urothelial carcinoma.¹¹³

HEPATOTOXIC PLANTS

Hypoglycin

The ackee tree (*Blighia sapida*) originates from West Africa and was introduced into Jamaica around 1778. Its scientific name derives from the British explorer Captain William Bligh, who apparently introduced the tree to Jamaica in 1793 as a food source for West African slaves.¹¹⁴ In West Africa, the green fruits are used for laundering and the crushed fruits are employed as a fish poison. When burned, the ashes from the seeds and jackets may be used as soap due to their oil and potash contents. Various parts of the Ackee tree are still used medicinally in South America for fever, headache, dysentery, and as an anthelmintic. Jamaican vomiting sickness (JVS) has been a well-described illness resulting from eating the fruit from the ackee tree. For many years the source of the toxin was thought to come from the overripe or decomposing arils. It is now known that the toxin in ackee fruit is found in the unripe arils and seeds. The ackee fruit contains two primary toxins, hypoglycin A and B.¹¹⁵ Hypoglycin A [α -amino- β -(2-methylenecyclopropyl) propionic acid] is found primarily in the aril of the ackee fruit, but is degraded as the aril opens and ripens.¹¹⁶ The ripe fruit may still contain a small portion of toxin, however. The seeds contain hypoglycin B [γ -L-glutamyl α -amino- β -(2-methylene cyclopropyl) propionic acid], the γ -glutamyl derivative of hypoglycin A. The seeds are always poisonous, but hypoglycin B is reported to be less toxic than hypoglycin A.

Hypoglycin undergoes transamination and oxidative decarboxylation to form methylene cyclopropyl acetic acid (MCPA), which then combines with coenzyme A (MCPA-CoA). MCPA-CoA is a suicide inhibitor of several

distinct acyl-CoA dehydrogenases: short-chain acyl-CoA, medium-chain acyl-CoA, and isovaleryl-CoA dehydrogenases.^{117,118} Long-chain acyl-CoA dehydrogenase does not appear to be significantly inactivated. Inhibition of acyl-CoA dehydrogenase prevents the β -oxidation of fatty acids, leading to a decrease in the substrates needed for gluconeogenesis and oxidative phosphorylation. The release of insulin is not affected by MCPA, MCPA-CoA, or hypoglycin.¹¹⁹

Pyrrilizidine Alkaloids

More than 350 pyrrolizidine alkaloids have been identified in over 6000 plants.¹²⁰ Not all pyrrolizidine alkaloids are known to be toxic. In those that are known to cause toxicity, a number have been discovered to be carcinogenic in rodents. Due to the vast number of plants containing pyrrolizidine alkaloids and their worldwide distribution, they probably are the most common poisonous plants affecting livestock, wildlife, and humans.¹²¹ Plants containing toxic pyrrolizidine alkaloids belong to the Boraginaceae, Compositae, and Leguminosae families. The most commonly encountered plants containing these alkaloids are *Amsinckia* spp. (fiddle neck, tarweed), *Crotalaria* spp. (rattle box), *Cynoglossum officinale* (hound's tongue), *Echium vulgare* (blue weed), *Heliotropium* species (giant hog weed), *Hypericum perforatum* (heliotrope), *Senecio* spp. (ground-sels, *Senecio*), and *Symphytum officinale* (comfrey).

The mechanism of hepatotoxicity is thought to be the formation of toxic metabolites by cytochrome P-450.¹²² Pyrrolizidine alkaloids are metabolized by CYP450 to highly reactive pyrroles such as dehydroretroecine. The toxicity of the necine alkaloids is inherent upon their ability to bind and alkylate various intracellular constituents. Intracellular toxicity leads to defects of sinusoidal endothelia, with increased permeability and red blood cell extravasation into the space of Disse. Obstruction of vessels is subsequently caused by reticulin fiber formation within the lumen of central and sublobular veins. The thickening of hepatic veins leads to a functional outflow obstruction and massive organ congestion. The end result is necrosis of hepatocytes and mesenchymal cells.¹²³ Signs of inflammation are usually lacking.¹²⁴ Although the liver is the most commonly reported effect, other organ systems may also be affected. Endothelial defects may occur within the lung similar to those seen within the liver parenchyma, leading to the development of pulmonary hypertension.¹²⁵

In Western Europe, comfrey has been applied for inflammatory disorders such as arthritis, thrombophlebitis, and gout and as a treatment for diarrhea. Toxicity is most likely due to various hepatotoxic pyrrolizidine alkaloids such as lasiocarpine, symphytine, and symphytoxide A.^{126,127} The main liver injury caused by comfrey (*Symphytum officinale*) is veno-occlusive disease. Symphytoxide A has also exhibited hypotensive effects in anesthetized rats.

In the rat model the alkaloids have been found to be tumorigenic. Hepatocellular adenomas have been induced in rats fed a diet of comfrey roots and leaves.¹²⁸ There have been no definitive reports of human cancers

in those exposed to pyrrolizidine alkaloids. Maté tea (*Ilex paraguensis*) contains pyrrolizidine alkaloids as well as tannins, and has been associated with increased risk for esophageal cancer, which is related to both amount and temperature of the ingested beverage.¹²⁹

OTHER HEPATIC PLANT TOXINS

Germander has been used in herbal remedies for 2000 years.¹³⁰ Alcoholic extracts may use germander as a flavor ingredient, providing a bitter aromatic taste to the beverage. In 1992, several cases of hepatitis surfaced in France due to germander. At that time, germander (*Teucrium chamaedrys*) was being used for supportive treatment of obesity and diarrhea. An interesting feature in the original cases in France was that in approximately half of the patients, a rechallenge of germander caused early recurrence, suggesting an immunoallergic type of hepatitis.¹³¹⁻¹³³ The furan ring of the diterpenoids in germander has been shown to be oxidized by CYP3A4 to a reactive epoxide neoclerodane.^{134,135} Neoclerodane depletes cellular thiols, decreases cell glutathione, increases intracellular calcium, and causes DNA fragmentation, resulting in apoptosis.¹³⁶ Research conducted on the mechanism of abrupt disease recurrence with reintroduction of germander demonstrated that epoxide hydrolase was the target of germander-induced auto-antibodies on the surface of human hepatocytes. Epoxide hydrolase may in turn act as a target for reactive metabolites from the neoclerodane diterpenoids. *Teucrium polium* (felty germander) has also been used as an herbal medication primarily in Iran as a hypoglycaemic adjunct. The *Teucrium* species contain saponins, glycosides, flavonoids, and a number of furan-containing neoclerodane diterpenoids (teucrolivin, teucin A). *Teucrium polium* has been shown to reduce high blood glucose levels by enhancing insulin secretion in the β islet cell.¹³⁷

Sassafras (*Sassafras albidum*) contains the toxin safrole that is a potent inhibitor of human CYP1A2, CYP2A6, and CYP2E1.¹³⁸ Safrole has been used recently in the manufacturing of MDMA by way of an aminomercuration process. Safrole has been linked, however, to the development of cancer. The carcinogenicity of safrole is mediated through 1'-hydroxysafrole formation, followed by sulfonation to an unstable sulfate that reacts to form DNA adducts.¹³⁹

The primary toxin in pennyroyal is the terpene pulegone. Pulegone may have toxic properties but it is likely its proximate metabolite methofuran that is responsible for significant hepatotoxicity. Methofuran is formed by oxidation of the allylic methyl groups of pulegone by CYP3A4.^{140,141} Methofuran reacts with nucleophilic groups on proteins to form covalent adducts¹⁴² and extensively depletes glutathione.¹⁴³ Histologically, dilatation of the central veins and distention of sinusoidal spaces occurs within 6 hours of exposure. Centrilobular necrosis is evident within 12 hours of exposure.¹⁴⁴

Both *Atractylis gummifera* (Mediterranean thistle) and *Callilepis laureoa* (impila) have been shown to be considerably toxic, with a high rate of mortality. *C. laureoa*

thrives in the KwaZulu-Natal region of South Africa and has been used as a traditional herbal medicine by the Zulu. It is estimated that up to 1500 deaths occur annually in this region due to ingestion of *C. lauroea*.¹⁴⁵ Ingestions of *A. gummifera* continue to occur in the Middle East and southern Europe because of its use as an herbal medicine. Children have been poisoned by this plant, mistaking the root for wild artichoke.¹⁴⁶ The toxicity of *A. gummifera* resides in its three diterpenoid glucosides: atractyloside, carboxyatractyloside, and apocarboxyatractyloside. The atractylosides are capable of inhibiting mitochondrial oxidative phosphorylation as specific inhibitors of the mitochondrial ADP/ATP translocase.¹⁴⁷ Human poisoning may present with either acute hepatic or renal pathology. At varying concentrations of atractyloside, cells may exhibit frank necrosis or apoptosis.¹⁴⁸ Because of the varying pathology between the liver and renal tissue histologically, it is possible that there is a second, different mechanism of toxicity in hepatocytes.¹⁴⁵

Plant Dermatitis

CHEMICAL IRRITANT DERMATITIS

The spurge family (Euphorbiaceae) is notorious for its highly irritant latex. The classic plants in this family associated with dermatitis include *Euphorbia myrsinites* (creeping spurge), *Euphorbia tirucalli* (pencil cactus), *Euphorbia lactea* (candelabra cactus), *Euphorbia pulcherrima* (poinsettia), and *Euphorbia milii* (crown of thorns). The latex has been used medicinally for centuries. In AD 50, a Greek physician named Pedanius Dioscorides mentioned several species of *Euphorbia* in the treatment of warts, calluses, and torpid ulcers of the scalp.^{149,150} The active toxins in the latex are phorbol (tigliane polyol) and diterpenoid esters.^{151,152}

Perhaps the most notorious plant known to cause an irritant dermatitis is the chili pepper. Members of the genus *Capsicum* have been used in recipes longer than any other spice, dating back to 7000 BC.¹⁵³ Upon contact with the skin, capsaicin binds to C-polymodal nociceptors, causing depolarization and leading to vasodilation, smooth muscle stimulation, glandular secretions, and sensory nerve activation.¹⁵⁴ Since only C-afferent nerve fibers are affected, and not the skin, no blistering is seen.

Members of the buttercup family (*Ranunculaceae*) have also caused significant skin irritation. Buttercup leaves have long been used in Europe and elsewhere as vesicants.¹⁵⁵ Buttercups contain an unsaturated lactone called protoanemonin, which is formed after injury to the plant by the breakdown of the glycoside ranunculin.^{156,157} Local tissue injury may be due to inhibition of DNA polymerase and increase of oxygen free radicals by protoanemonin. Protoanemonin rapidly metabolizes to anemonin, which is nontoxic. Therefore, only freshly damaged plants typically cause a skin reaction.

ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis is the result of a type IV hypersensitivity reaction that requires a previous exposure before symptoms develop. The most common sub-

stances known to elicit such a reaction are the urushiol oleoresins. Urushiol contains a mixture of catechols (1,2-dihydroxybenzenes) and resorcinols (1,3-dihydroxybenzenes) and is found in *Toxicodendron* (poison tree) species, including poison ivy (*Toxicodendron radicans*), poison oak (Eastern, *Toxicodendron toxicarium*; Western, *Toxicodendron diversilobum*), and poison sumac (*Toxicodendron vernix*). It also includes fruit and nut trees such as ginkgo (*G. biloba*), cashew (*Anacardium occidentale*), and mango (*Mangifera indica*). Cashew nut shell oil contains cardol, a resorcinol with a similar side chain to poison oak and poison ivy allergens. Members of Ginkgoaceae and Proteaceae contain sensitizing resorcinols.¹⁵⁸ In severe cases, type I hypersensitivity reactions may develop.

Occupational exposures to plants represent another common source of toxicity. People working in the tulip industry have known for years of the condition termed “tulip fingers.” This painful hyperkeratosis of the fingertips is caused by exposure to the toxin tuliposide A.¹⁵⁹ People working with lilies of the *Alstroemeria* family have developed a similar condition due to the tuliposide found in *Alstroemeria*. Tuliposide is hydrolyzed to a butyrolactone, which probably acts as the true allergen in these cases. Cross-reactivity may occur among workers already sensitized to tulips or *Alstroemeria* species. Occupational exposure to primroses is another cause of allergic dermatitis due to the toxin primin (2-methoxy-6-pentyl-1,4-benzoquinone).¹⁶⁰

CONTACT URTICARIA

Toxin-mediated contact urticaria occurs without prior sensitization and does not involve a hypersensitivity mechanism. Members of the family Urticaceae, including stinging nettle (*Urtica dioica*), account for the majority of contact urticaria throughout the world.¹⁶¹ Plant species known to cause contact urticaria contain small outgrowths of epidermal cells known as trichomes. A trichome is composed of two components: a proximal siliceous hair and a distal calcified bulb. When traumatized, the bulb is dislodged from the end of the hair, revealing a beveled, hypodermic needle-like, siliceous hollow.¹⁶² Glandular trichomes linked to urticaria most often contain histamine, choline, and serotonin as active toxic components.^{163,164} Cowitch (*Mucuna pruriens*) also produces a “sea bean,” which contains 6% levodopa and tryptamines.

PHYTOPHOTODERMATITIS

Recognition of plants associated with photodermatitis developed through treatment of preexisting skin conditions such as vitiligo. Four plant families have been primarily implicated in causing photodermatitis and include Umbelliferae (Apiaceae), Leguminosae (Fabaceae), Moraceae, and Rutaceae. Throughout the late 1800s and early 1900s, the dermatitis of a number of plants was recognized, although the necessity of concomitant ultraviolet radiation (UVR) exposure was not identified until the 1940s. Photochemotherapy (e.g., pulsed ultraviolet actinotherapy) continues to be an avid treatment for skin conditions such as vitiligo, psoriasis, atopic dermatitis, and many others.¹⁶⁵

The compounds responsible for phyto dermatitis are furocoumarins, which are tricyclic compounds with both linear (psoralens) and angular structures. The two most clinically relevant photosensitizing psoralens are 8-methoxypsoralen (8-MOP, or xanthotoxin) and 5-methoxypsoralen (5-MOP, or bergapten). The phototoxic effect of furocoumarins is related to their ability to absorb photon energy. In particular, psoralen molecules exposed to UVR are elevated into an excitable state that causes covalent bonding between the psoralen molecule and the cell's DNA. The alteration of DNA structures stimulates mitosis in epidermal skin cells, particularly keratinocytes and melanocytes.¹⁶⁶ Melanocytes have been observed to have enhanced tyrosinase activity as well as larger, dispersed melanosomes contributing to enhance pigmentation. In general, the psoralens are more phototoxic than the angular furocoumarins, with the exception of angular furocoumarin (known as pimpinellin) found in members of the genus *Heracleum* (Umbelliferae). The most severe reactions occur with bergapten isolated from *Citrus bergamia* (Rutaceae), the bergamot orange, and xanthotoxin isolated from *Fagara xanthoxyloides* (Rutaceae). The majority of toxicity develops from common fruits and plants in these families such as *Citrus aurantifolia* (lime), *Apium graveolens* (celery), *Heracleum sphondylium* (cow parsley), *Ruta graveolens* (garden rue), *Ficus carica* (fig tree), and *Psoralea corylifolia* (scurf-pea).

TOXICOLOGY

Clinical Manifestations (Acute and Chronic)

GASTROINTESTINAL IRRITATION

The majority of plant exposures result in mild toxicity, typically in form of GI distress. However, a number of animal cases have demonstrated more a significant level of toxicity, including hypotension, sedation, seizures, and hepatic degeneration with *Narcissus*.¹⁶⁷

Calcium oxalate crystals are found in a wide variety of common houseplants and are frequently involved in pediatric poisonings. *Dieffenbachia* species are the most potent mucosal irritants. Mechanical stimulation is needed for forced extrusion of the crystals and other bradykinin-like substances, resulting in mucosal injury, salivation, and swelling of the lips, tongue, and mouth. Due to immediate tissue irritation, large amounts of the plant are seldom ingested, reducing the likelihood of systemic oxalate intoxication. In grazing animals, however, oxalic acid poisoning has occurred due to larger ingestions. Swelling rarely causes obstruction, but loss of voice can last for several days. Plant juice exposures to the eye can also produce significant eye irritation, with calcium oxalate crystals detected up to 8 weeks after exposure.¹⁶⁸

Plants containing RIPs [jequirity bean, castor bean, black locust, Barbados nut (*Jatropha*)] are only toxic if masticated or injected. One masticated seed is potentially lethal to a child, and 8 to 10 seeds to an adult.¹⁶⁹ Clinical effects include severe hemorrhagic gastroenteritis with a

delay of 2 to 6 hours, followed by complications of fluid-electrolyte loss (hypotension, tachycardia, prerenal impairment). Transient liver damage occurs in most cases. Metabolic effects include metabolic acidosis, leukocytosis, hyperglycemia or hypoglycemia, and increased creatine kinase. QT prolongation was observed in 5 of 10 serious pediatric cases. Fever is an important initial finding. If death occurs, it is usually related to multiorgan failure after the third day.¹⁷⁰

Pokeweed contains phytolaccine, a saponin that produces a severe hemorrhagic gastroenteritis within 2 to 4 hours of ingestion, consisting of hematemesis, abdominal cramps, foamy diarrhea, and melena. There is typically initial burning in the mouth and throat. Unripe berries are more toxic, but serious toxicity has occurred with as few as 10 ripe berries in a child. Toxicity can generally be avoided by parboiling the shoots. Mitogens accompany the GI irritants and commonly result in the presence of immature plasma cells on peripheral smears; plasmacytosis may last 2 months or more. A tea made from leaves is more toxic and causes rapid onset of hypotension, respiratory depression, cholinergic symptoms, and seizures.¹⁷¹

Solanine is a bitter-tasting alkaloid found in *Solanum* species such as climbing nightshade, horse nettle, potato eyes, eggplant, tomato, and Jerusalem cherry. It is removed by boiling but not baking. Ingestion results in both GI and neurologic symptoms. Unripe berries are more toxic, and it is estimated that up to 10 berries of *Solanum dulcamara* or up to three berries of *Solanum nigrum* or *Solanum pseudocapsicum* can be ingested without toxicity. Vomiting, diarrhea, headache, and flushing are the most common symptoms, with the potential for altered mental status, hallucinations, and delirium resembling the antimuscarinic toxidrome.¹⁷²

Holly berries and leaves contain saponins, which may cause gastroenteritis. However, most casual ingestions result in no toxicity. Vomiting generally occurs within 6 hours, and diarrhea follows within 20 hours. It is estimated that ingestion of 20 to 30 berries could be fatal to a child; however, this is poorly documented.¹⁷³

The American variety of mistletoe contains phoratoxin, which is 10 times less toxic than the viscotoxin found in European varieties. Nevertheless, the berries from both remain a common source of GI poisoning, with all parts of the plant being potentially toxic. Up to 20 berries or five leaves have been ingested without toxicity¹⁷⁴; 90% of exposures reported to poison centers remained asymptomatic in a large series.¹⁷⁵ The ingestion of mistletoe tea is potentially fatal, as concentrated forms of the toxins are cardiotoxic. Mistletoe hepatitis has also been reported.¹⁷⁶

It is estimated that 15% of the world's total population chews betel nut on a daily basis. The fruit of the areca palm tree (*Areca catechu*) is chewed alone or mixed with other components to form a quid, usually containing catechu gum from the Malaysian acacia tree, and calcium hydroxide. The chief ingredients are arecholine and arecatcine, which act as acetylcholine agonists at central and peripheral sites. Acute effects are similar to nicotine, with dizziness, nausea, diaphoresis, and vomiting.

Cholinergic toxicity with classic SLUDGE (salivation, lacrimation, urination, defecation, gastric distress, emesis) syndrome occurs with initial or heavy use. Tachycardia is typically observed. A dose-related bronchospasm occurs in asthmatic subjects. Long-term effects include betel chewer's perleche (fissures at the angles of the mouth), red staining of the oral mucosa, gingival leukoplakia that can progress to squamous cell carcinoma, brown staining of teeth, and milk-alkali syndrome related to the oyster shell lime paste component of the quid.¹⁷⁷

HEPATOTOXIC PLANTS

JVS remains prevalent in the Caribbean. The Centers for Disease Control and Prevention reviewed reported cases of JVS from 1989 to 1991 and found 38 cases and 6 deaths, with 76% of cases occurring between January and March.¹⁷⁸ Hypoglycin toxin is similar in structure to a valproic acid metabolite and causes hypoglycemia, hyperammonemia, lethargy, vomiting, coma, and cerebral edema resembling Reye's syndrome. The ackee fruit is still available for sale in some European countries, but the U.S. Food and Drug Administration has banned its importation due to the potential risk for toxicity.

Reports of hepatic disease surfaced in South Africa in 1920 after ingestion of *Senecio longilobus* (threadleaf, groundsel) led to the development of liver cirrhosis in several people.¹⁷⁹ Another outbreak of severe liver toxicity occurred in Jamaica in the 1950s when several children developed ascites, hepatomegaly, jaundice, and eventually cirrhosis after the ingestion of "bush tea." The tea consumed contained the leaves from *Crotalaria* species, now known to contain toxic pyrrolizidine alkaloids. More recent cases in both adults and infants have occurred in India, Afghanistan, and the United States.^{180,181} Reports to the French Regional Centers of Pharmacovigilance revealed an association of germander ingestion and hepatitis. The severity of the illness ranged from mild hepatitis to cirrhosis to fulminant hepatic failure.¹⁸²⁻¹⁸⁵ More recently, the ingestion of *Teucrium polium* was implicated in acute cholestatic hepatitis in Greece.¹⁸⁶ The liver disease that has now been well described for the pyrrolizidine alkaloids resembles that of Budd-Chiari syndrome, with thrombotic and nonthrombotic occlusion of terminal centrilobular hepatic veins.^{187,188}

Pennyroyal has long been used as an abortifacient, particularly in areas of central and South America.¹⁸⁹ The oil is also used in cosmetic formulations as a fragrance component. Pennyroyal oil has been an adulterant in mint teas used as home remedies to treat minor ailments and colic, resulting in at least one infant death.¹⁹⁰ Severe toxic effects may develop after ingesting as little as 10 mL, and fulminant hepatic failure may be observed after ingesting as little as 15 mL.¹⁹¹

Cardiovascular Toxicity

CARDIAC GLYCOSIDES

Cardiac glycoside poisonings are characterized by initial GI symptoms of nausea and vomiting, followed by bradycardia, dysrhythmias, hypotension, hyperkalemia,

and altered mental status. Dysrhythmias generally include various degrees of heart block and bradycardia, with subsequent ventricular ectopy. However, a wide range of toxicity exists among plants containing cardiac glycoside toxins. For example, although poisoning from yellow oleander,¹⁹²⁻¹⁹⁴ lily of the valley,¹⁹⁵ and squill¹⁹⁶ are remarkably similar, significant intoxication leading to mortality is rarely reported with lily of the valley ingestions.

A 10-year analysis of TESS exposures to lily of the valley found only three patients with serious outcomes among 2639 cases. The great majority of these exposures occurred in children younger than 6 years (93%), and there is no documentation of amount of exposure in the report.¹⁹⁷

SODIUM CHANNEL TOXINS

In a series of 356 ingestions of *Taxus baccata* (English yew tree), only 4% of patients had minor symptoms. In more severe cases, systemic toxicity evolves within a few hours and consists of vomiting, abdominal cramps, syncope, bradycardia, hypotension, and cardiovascular collapse. Fatal cases have involved a toddler who chewed berries, a 20-year-old woman who ingested yew to commit suicide, a man who developed ventricular arrhythmias after drinking a tea made from boiled leaves, a 28-year-old woman who ingested yew leaves, three prisoners who ingested a boiled extract of leaves, and ingestion of 150 leaves by a psychotic woman. Preterminal arrhythmias reported in these cases included ventricular flutter, ventricular fibrillation, and idioventricular rhythms. In a previous report of the cardiac toxicity of *Taxus brevifoli*, the cardiac toxicity was partially attributed to cardiac glycoside activity.¹⁹⁸ However, the cardiac toxicity in this case is most likely due to the plant's taxine alkaloids and not a cardiac glycoside, since the plant does not appear to possess any cardenolide and bufadienolide compounds.

Cardiovascular toxins such as hellebore, death camas, rhododendron, azalea, and monkshood share a mechanism of maintaining sodium channels in the open position, resulting in a combination of cardiovascular and neurologic toxicity. Initial symptoms may include sneezing, diaphoresis, chills, and paresthesias, followed by vomiting, diarrhea, bradycardia, dysrhythmias (including torsades de pointes), hypotension, CNS and respiratory depression, and seizures. The amount and composition of *Aconitum* alkaloids are the main factors determining the severity of intoxication and vary greatly with different species, time of harvesting, and the method of processing.^{199,200}

NEUROTOXINS

Nicotine is an alkaloid that is well absorbed from the skin, lungs, and GI tract. Initially, it is a potent emetic, which somewhat limits its toxicity in small ingestions. Serious intoxication, however, is well reported. Early symptoms are those of both parasympathetic and sympathetic stimulation (GI distress, miosis, lacrimation, bronchorrhea, transient hypertension, and tachycardia followed by cardiovascular collapse). Neuromuscular

symptoms include fasciculations, weakness, paralysis, coma, and seizures. Several distinct illnesses have been described among the nicotine alkaloids. Green tobacco sickness is an illness associated with nicotine exposures among tobacco harvesters. This illness develops through transdermal absorption of nicotine through contact with the green tobacco plant. Symptoms include weakness, headache, nausea, vomiting, dizziness, abdominal cramps, diarrhea, chills, fluctuations in blood pressure or heart rate, and increased perspiration and salivation. The onset of the illness is 3 to 17 hours after exposure and the duration of illness is 1 to 3 days.²⁰¹

Coniine and its metabolites, found in poison hemlock, act similarly to nicotine and characteristically cause an ascending paralysis with terminal asphyxia. Ataxia, salivation, and coma have been described. Seizures are usually absent. In humans, 3 mg of coniine is said to have produced symptoms, but 150 mg have been tolerated without discomfort. It has been reported that a lethal dose may be six to eight fresh leaves or approximately 100 to 300 mg.²⁰² The infamous death of Socrates in 399 BC is attributed to the ingestion of a beverage that contained poison hemlock (*Conium maculatum*). After Socrates drank the poison, “he walked about and, when he said his legs were heavy, lay down on his back, for such was the advice of the attendant.” The jailor then began to examine Socrates, much in the way a modern physician might do.⁶²

The man . . . laid his hands on him and after a while examined his feet and legs, then pinched his foot hard and asked if he felt it. He said “No”; then after that, his thighs; and passing upwards in this way he showed us that he was growing cold and rigid. And then again he touched him and said that when it reached his heart, he would be gone.²⁰³

Anticholinergic toxins include scopolamine, atropine, and hyoscyamine and are found in a variety of plants, such as jimson weed (*Datura stramonium*), henbane, deadly nightshade (*Atropa belladonna*), night-blooming jessamine, and mandrake (*Madranga officinarum*). The typical toxidrome involves dry mouth, mydriasis, fever, flushing, blurred vision, hallucinations, urinary retention, ileus, seizures, tachycardia, hypertension, and coma. Symptoms may be recurrent and prolonged. There are also reports of antimuscarinic symptoms developing following the use of Chinese herbal products. The Chinese herb yangjinhua contains dried flowers from *Datura metel* and has been used in treatment of bronchial asthma and chronic bronchitis.²⁰⁴ Other herbal products linked to antimuscarinic toxicity include Panax ginseng and naoyangua. These products were most likely contaminated with *Mandragora officinarum* or other Solanaceae species and not part of the original Chinese material medica. There is also a case reporting the unintentional poisoning by deadly nightshade in a patient mistaking the plant for burdock (*Arctium lappa*) leaves while foraging.²⁰⁵ *Datura* has been used as a hallucinogen in the United States, resulting in sporadic cases of antimuscarinic poisoning and death.²⁰⁶⁻²⁰⁹

Cicutoxin, from water hemlock, is the most lethal

indigenous North American poison. Most human exposures occur in patients who mistake *Cicuta* for wild edible species, such as wild carrot. The root contains the highest concentration of the toxic alkaloid cicutoxin. Ingestion of a 2- to 3-cm portion of the root can be fatal in adults.²¹⁰ Toxicity begins with severe GI symptoms within 15 to 90 minutes of ingestion. Seizures rapidly develop, with status epilepticus and respiratory arrest contributing to the 30% mortality rate. Other movement disorders and spasticity may occur. Complications include rhabdomyolysis and renal failure.

HALLUCINOGENIC PLANTS

Hallucinogenic plants include marijuana, nutmeg, peyote, morning glory seeds, Hawaiian baby woodrose, Scotch broom, ibogaine, khat, *Salvia*, *Mitragyna*, and yohimbine.

Marijuana ingestion in children, with as little as 1 g of hashish or a few “cigarette” butts, causes rapid onset of drowsiness, conjunctival redness, mydriasis, ataxia, pallor, nystagmus, marked hypotonia, and eyelid lag. Rarely, coma, hypothermia, and respiratory obstruction can occur. Recovery typically occurs in 6 to 12 hours. Acute marijuana inhalation or ingestion can induce transient brief episodes of visual hallucinations, illusion, and auditory distortions, particularly with oral ingestion.²¹¹⁻²¹³

Morning glory and Hawaiian baby woodrose seeds contain D-lysergic acids and produce a toxidrome similar to LSD. Altered sensorium and sympathomimetic toxidrome occurs with 20 to 50 morning glory seeds (equivalent to 20 to 50 µg of LSD) and 4 to 12 Hawaiian baby woodrose seeds. Very high doses (200 to 300 seeds) have resulted in lethargy, numbness, cool extremities, diarrhea, and dysuria. Onset is typically within 4 to 6 hours and resolves in 12 to 24 hours.²¹⁴

Peyote cactus tops are ingested for the mescaline hallucinogenic effect, which is achieved with seven to eight dried cactus tops. An early phase of mild GI distress occurs, followed by a sympathomimetic phase, with the sensory phase peaking at 4 to 6 hours and lasting 6 to 12 hours.²¹⁵

Nutmeg use continues to be reported among youths. The usual recreational dose is 1 to 3 tablespoons of ground nutmeg (approximately equivalent to one to three whole nutmeg kernels). Initially, nausea, vomiting, diarrhea, abdominal pain, and agitation occur. Later a hallucinogenic/delirium phase may ensue, but is inconsistently present. Onset is 3 to 8 hours, with a duration of up to 24 hours.¹⁵

Ibogaine, from *Tabernanthe iboga*, is an N-methyl-D-aspartate (NMDA) antagonist and opiate κ agonist that is being used as a treatment for drug withdrawal. The typical experience is a dreamy state lasting 4 to 6 hours. Two fatalities have been reported, from ingestion of 29 and 85 mg/kg. Vomiting, hypotension, and tremor preceded sudden collapse 2 hours and 24 hours after ingestion, respectively.

Scotch broom (*Cytisus scoparius*) is touted as a legal high, containing hydroxytryptamine and sparteine. Blossoms are aged in a sealed jar for 10 days, then rolled into a cigarette and smoked. Deep relaxation, followed

by enhanced color perception, without true hallucinations, is reported by users. Large doses can cause hypotension and tachycardia.²¹⁶

Ayahuasca (also known as daime, yaje, natema, vegetal) is ritually used by shamans in the Amazon. The preparation consists of two herbs prepared as a mixture. All contain a source of harmaline, *Banisteriopsis caapi*. The second component is one of two plants that contain *N,N*-dimethyltryptamine (also known as DMT), either *Psychotria viridis* or *Diplopterys cabrerana*. The harmaline alkaloids are monoamine oxidase inhibitors, and prevent presystemic metabolism of DMT, enhancing its psychotomimetic effects. In addition to hallucinations, mild sympathomimetic effects, such as hypertension, tachycardia, and fever, occur.²¹⁷

Salvia divinorum is a hallucinogenic plant in the mint family that contains a diterpene compound called salvinorin A, the most potent known plant-derived hallucinogenic compound, with an effective dose of 200 to 1000 µg when smoked. The plant's leaves are dried and smoked, or chewed, to produce a rapid onset of hallucinations, within a minute, that last about 30 to 60 minutes.²¹⁸

The Rhamnaceae family (buckthorn, wild cherry, coyotillo) consists of small woody shrubs and trees, the seeds of which are potent peripheral neurotoxins, causing a segmental demyelination, presenting as a neurologic syndrome similar to that for Guillain-Barré syndrome or other polyradiculoneuropathies.²¹⁹ GI symptoms may also occur. Onset is after a latency of 4 to 7 weeks, with progression over months. The peripheral neuropathy classically starts in the lower extremities and may progress to respiratory compromise and death.²²⁰ Most patients recover after several months with supportive care.

Multisystem Organ Failure

There are several plants with cytotoxic mechanisms of action that produce multisystem organ failure. The most common are the colchicine-containing plants of autumn crocus and glory lily, and *Podophyllum* resin from mayapple.

Colchicine plant poisoning often results from mistaken identity for edible foods such as autumn crocus leaves for salad greens, bulbs for onions, and glory lily tubers for sweet potato. Children have been poisoned from use of the dried seed parts of autumn crocus as rattles. Each seed contains approximately 3.5 mg of colchicine. Ingestion of 10 to 12 flowers has been fatal in adults.²²¹ *Gloriosa superba* tubers contain 6 mg per 10 g. Colchicine toxicity is characterized by oral paresthesias and hemorrhagic gastroenteritis within 2 to 12 hours, followed by progression in 24 to 72 hours to multisystem organ failure. Symptoms include fever, confusion, coma, ascending polyneuropathy, progressive respiratory distress, renal failure, hepatic failure, leukocytosis followed by disseminated intravascular coagulation and bone marrow suppression, and cardiovascular shock or sudden cardiac arrest. Death is generally related to respiratory failure, cardiovascular collapse, sudden asystole, or sepsis

related to bone marrow suppression. Ingestion of more than 0.8 mg/kg is universally fatal.²²²

Podophyllum toxicity is similar to that of colchicine, with a delay in onset of up to several hours after ingestion, and up to 13 hours, following dermal application. However, neurologic toxicity is more predominant, with sensory motor peripheral neuropathy, paralysis, and encephalopathy reported after as little as 8 to 25 mL of the 25% resin ingested, with progression over months.^{223,224}

CYANOGENIC GLYCOSIDES

There are at least 150 plants that contain cyanogenic glycosides. Amygdalin is found in the kernels of plants in the *Prunus* species. The intact seed is not harmful. When the seed is crushed, the release of an enzyme, emulsin, catalyzes the hydrolysis of amygdalin to cyanide. Some gut bacteria also contain glucosidases. The clinical picture is like that of cyanide poisoning. Within 30 minutes of ingestion, dyspnea, cyanosis, vomiting, diaphoresis, weakness, seizures, coma, and cardiovascular collapse occur. Apricot kernels contain the highest concentration of amygdalin (8%), followed by peach pits (6%) and plum pits (2.5%). One gram of amygdalin releases 60 mg of hydrogen cyanide. Ingestion of 20 to 40 apricot kernels has resulted in serious toxicity.^{225,226} Apple seeds also contain amygdalin, and ingestion of 50 seeds in one case and a cup of seeds in another case was fatal.¹⁷² Hydrangea contains hydrangin, another cyanide-releasing glycoside, in the leaves and buds; however, there have been no reported cases of cyanide toxicity from hydrangea.

DERMATOLOGIC TOXINS

The most notorious member of the Euphorbiaceae family is the manchineel tree. This tree once grew along beaches throughout the Caribbean, but is now mostly seen in areas of the Virgin Islands and Everglades National Park.¹⁵¹ The manchineel tree was once planted on graves to deter grave robbers, and the latex has been used to brand horses.¹⁶¹ The toxic effects from spurge vary by species, but many are capable of producing erythema, blistering, and desquamation. Contact with the latex from the spurge plants produces both local and mild systemic symptoms. Spontaneous, self-limited vomiting may occur in a small percentage of patients. Initial symptoms of skin reddening and swelling occur in 2 to 8 hours, with formation of vesicles and blisters within 4 to 12 hours. Eye contact often causes corneal abrasions, with effects lasting up to 3 weeks. Although poinsettia is in the same family, few cases of toxicity have been reported.²²⁷ Contact with sap caused caustic burns in an adult who was bundling plants in a greenhouse, with a latency of 24 hours. Poinsettia obtained an unwarranted reputation for significant toxicity after a poorly documented case report in Hawaii in 1918. In general, poinsettia latex induces little local skin toxicity in humans and animals.²²⁸ An analysis of TESS data showed oral irritation in 28%, vomiting in 24%, and throat irritation in 15% of poinsettia exposures.²²⁹

One of the most common plant exposures reported to poison centers is related to *Capsicum* peppers, producing

mucosal irritation and increased pain sensitivity, also known as human hand syndrome. Erythema and an intense burning sensation occur, generally without vesiculation. Massive ingestions can cause diarrhea or “jaloproctitis.” The New Mexico Poison and Drug Information Center receives up to 90 calls per year for “chili burns” of the hands. Their study showed that the best home remedy for chili burns was hand washing with soap and water followed immediately by 1 hour of immersion in vegetable oil.²³⁰

Dermatitis following exposure to trichomes of such plants as stinging nettle usually lasts about 12 hours. The most impressive skin reactions result from contact with plants and trees from the genus *Dendrocnide*. This tree is primarily found in eastern Australia and has been linked to severe dermatitis lasting up to 3 weeks.¹⁵⁵ This reaction is exacerbated by water and has been attributed to one death.¹⁵⁰

Delayed contact dermatitis is associated with plants containing urushiol, such as poison ivy, poison oak, and poison sumac. Lacquer also contains urushiol. Cross-reacting compounds are present in mango, cashew, and ginkgo. Onset of rash is typically delayed for 24 to 48 hours. Eruptions are classically linear streaks of erythema, followed by clusters of fluid-filled lesions that are intensely pruritic. The fluid contains no antigen and is not contagious, but patients often spread lesions by scratching areas contaminated with the oleoresin. Resolution typically occurs after 3 weeks or longer. Delayed contact dermatitis has also been reported from contact with ragweed, castor beans, and western red cedar. *Urtica urens* has also been reported to cause allergic contact dermatitis.²³¹

Photodermatitis due to furocoumarins and psoralens has been reported following exposures to lime, bergamot, bitter orange (*Citrus aurantium*), dill, celery, carrot, fennel, parsnip, mustard, fig, buttercup, and common rue. Bartenders have developed vesicles on their fingers from squeezing limes into cocktails. Phytophotodermatitis is an oxygen-independent, nonimmunologic reaction that may occur with only 15 to 30 minutes of exposure. The resulting hyperpigmentation may last for several months.

DIAGNOSIS

Laboratory Testing

Osterloh and colleagues²³² described cross-reactivity of oleander glycosides on radioimmunoassay for digoxin. Clinical symptoms, however, are more indicative of toxicity. Postmortem serum concentrations of cardiac glycosides are known to increase and do not predict the premortem levels.²³³ The majority of polyclonal assays designed to detect digoxin or digitoxin will probably cross-react sufficiently to detect plant cardiac glycosides. If results are in question, a separate assay may provide additional confirmation. Other diagnostic testing used to detect plant toxins includes ultraviolet absorption, thin layer chromatography, high-performance liquid chromatography and mass spectrometry. There are

sufficient case reports that chromatography can be used to confirm plant exposure. Similar to the cardiac glycosides, however, clinical symptoms will be more indicative of toxicity.

Differential Diagnosis

The most common diagnostic dilemma is the presentation of an asymptomatic child to an emergency department or a poison center with a history of ingesting an unknown berry. Although crude berry identification keys are available, these are not routinely useful.²³⁴ Identification of the plant through faxed copies of the material and/or having a family member bring the plant to a plant nursery has been successful. In patients presenting with suspected plant-related delirium in the presence of antimuscarinic findings, a diagnostic challenge with physostigmine can often provide the answer. The section on Pathophysiology contains a list of plants contained within each defined presenting toxidrome and can be used as a differential diagnostic tool when plant poisoning is suspected in a symptomatic patient.

MANAGEMENT

Supportive Measures

As with other poisonings, support of airway, breathing, and circulation should be provided when necessary.

Decontamination

Gastric decontamination is not well studied for treatment of plant-related poisonings. The use of syrup of ipecac has declined in the United States to negligible amounts, but plant poisoning remain an indication for some poison centers, despite no evidence to document efficacy. A prospective randomized clinical trial of syrup of ipecac in 103 children who ingested less than six toxic berries showed no benefit from decontamination.²³⁵ It is reasonable to assume that gastric emptying could benefit patients who present early and have ingested a potentially serious plant (see At a Glance section). In theory, large plant parts would be more completely retrieved by ipecac-induced emesis than by gastric lavage, particularly in children, in whom large-bore tubes are not practical. This same group of patients with very toxic plant ingestions may warrant more aggressive decontamination with whole bowel irrigation and activated charcoal. Given the benign nature of most plant ingestions in children, this should be a rare occurrence in the pediatric population.

Nasogastric lavage performed 3 to 9 hours after ingestion of jimson weed seeds did not improve outcomes of length of stay or intensive care unit (ICU) admission, despite recovery of some seeds in 57% of patients where this was attempted. In cases where small seeds of plants with serious toxicity are ingested, it may be considered when orogastric lavage cannot be performed.²³⁶

Skin decontamination is indicated for plants causing dermatologic toxicity. Plant trichomes from *Mucuna* or stinging nettle have been removed using such methods as adhesive tape, nontoxic glue dried and peeled, and facial masks. Skin areas in contact with poison ivy can be decontaminated with several washings of soap and water to remove the resinous material and prevent further areas of skin contamination.

Eye decontamination is similar to that with other ocular exposures. It is particularly important following ocular exposures to plant saps known to cause eye irritation or injury, such as insoluble oxalates, Euphorbiaceae family, and trichome-containing plants.

Laboratory Monitoring

Laboratory studies will be dictated by the type of plant poisoning involved. Routine laboratory studies are seldom indicated for accidental plant exposures.

Antidotes

CARDIOVASCULAR PLANT POISONING

Large doses of Fab-anti-digoxin antibodies (60 mg/kg) corrected both rhythm and hyperkalemia in dogs poisoned by oleander.²³⁷ Lower doses might have been effective, but were not tested. Shumaik and colleagues²³⁸ reported the use of digoxin-specific Fab fragments in the treatment of a 37-year-old man who had ingested *Nerium oleander* leaves, and other reports suggest efficacy of Fab fragments in this setting.²³⁹ Indications for Fab fragments include:

1. Hyperkalemia ($K^+ > 5$ to 5.5 mEq/L)
2. Life-threatening supraventricular and ventricular dysrhythmias
3. Hemodynamically significant bradycardia unresponsive to atropine

The treatment of aconitine and other sodium channel-opening plant toxins is therapeutically challenging and based primarily on case report data. Bradycardia may respond to atropine. Amiodarone is a reasonable first-line agent for ventricular tachycardia, and was effective in five of nine patients in one series. Cardioversion was uniformly unsuccessful.²⁴⁰

It is reasonable to suppose that plants with sodium channel blocking activity may respond to intravenous sodium bicarbonate infusion. This was ineffective in a swine model of yew (*Taxus*) poisoning with widened QRS. Treated animals had lower blood pressures and wider QRS over time than controls. This treatment was effective in a case report of a patient with suicidal ingestion of yew cookies, however. Other anecdotal treatments have included vasopressors, transvenous pacing, cardioversion, atropine, magnesium sulfate, and lidocaine. Digoxin Fab fragments are ineffective, since the plant alkaloids have no cardiac glycoside structure. Taxine B also displays calcium channel blockade; therefore, intravenous calcium infusion may theoretically be beneficial.⁶⁰

HEPATOTOXICITY

Pulegone is metabolized in a manner analogous to acetaminophen. *N*-acetylcysteine was administered in a patient who did not develop hepatotoxicity in one case, and should be considered in any patient with significant ingestion of the pennyroyal plant,²⁴¹ despite lack of efficacy shown in an animal model.²⁴²

There is no specific antidote or treatment of hepatic veno-occlusive disease caused by plants containing pyrrolizidine alkaloids

MULTIORGAN FAILURE

Anticochicine Fab fragments have been developed in France, with evidence of efficacy in one human poisoning case and favorable animal research. However, these are not in commercial production and are currently not available.²⁴³

The U.S. army has recently developed an experimental vaccine against ricin. It has shown efficacy in mice.

NEUROLOGIC PLANT TOXICITY

Physostigmine has been compared with benzodiazepine therapy in the treatment of jimson weed-induced delirium in two studies. Burn and colleagues found that only physostigmine reversed delirium, and was associated with decreased agitation, less complications, and shorter recovery time compared with benzodiazepines in a retrospective study of 52 patients with anticholinergic poisoning. *Datura* was the substance in 4 patients in each treatment group.²⁴⁴ In the second study, the combination of benzodiazepines with physostigmine did not reduce length of stay or ICU admission in 3 patients compared with benzodiazepines alone in 14 patients.²⁴⁵ Repeated doses of physostigmine are often necessary due to prolonged absorption of the plant toxins.

Benzodiazepines remain part of the supportive care for other plant-related hallucinations and agitation syndromes, as well as initial therapy for plant-related seizures. Pyridoxine should be tried in cases of seizures suspected to be related to *Ginkgo biloba*, particularly with ingestion of the seeds, known to contain a pyridoxine antagonist.

ELIMINATION

There is no evidence for plant toxins to benefit from hemodialysis or hemoperfusion. Digitoxin, derived from *Digitalis lanata*, may benefit from enhanced elimination with multiple-dose activated charcoal. However, given the marked efficacy of the digoxin-specific Fab fragments, the utility of this modality will be low.

DISPOSITION

Patients who have ingested plants with a predilection for delayed onset of toxicity should be admitted, even if initially asymptomatic. This includes pennyroyal, RIPs (ricin, abrin), podophyllum, and colchicine-containing plants. Disposition for other toxic plants will be determined by their exhibiting signs and symptoms.

ROBERT P. DOWSETT, BM, BS

At a Glance...

- Marine life is toxic to humans through envenomation by:
- Stinging: jellyfish, corals, and sea anemones.
- Spinous puncture injury: stingray, catfish, scorpion fish, weever fish, starfish, and sea urchins.
- Bites: sea snake, cone shell, and the blue-ringed octopus.
- Poisoning by ingestion: paralytic shellfish poisoning, scombroid fish poisoning, puffer fish poisoning, and ciguatera.
- Toxins injected by an animal into its prey are usually high-molecular-weight proteinaceous substances, and those that produce symptoms after consumption are generally low-molecular-weight molecules.
- Management of marine toxins is largely supportive.
- Specific first aid is required for jellyfish stings, spinous puncture injury, and envenomation by the blue-ringed octopus, cone shells, and sea snakes.
- Careful débridement and cleaning of marine wounds is important.
- Antivenom is available for the treatment of envenomation by the box jellyfish, stonefish, and sea snake but is only readily accessible in Australia.
- A number of specific therapies have been suggested for the management of ciguatera poisoning, but the use of mannitol is no longer recommended.

MARINE ENVENOMATION**Introduction and Relevant History**

Some of the substances known to be most toxic to human beings are found in marine organisms (Table 25-1 and Box 25-1). Important species causing marine envenomation are contained in the phylum Cnidaria, Mollusca, and Echinodermata (all invertebrates) and Chordata, Subphylum, and Vertebrata (vertebrates). The phylum Cnidaria (formerly Coelenterata) is composed of four classes of invertebrates that have the dominant characteristic of tentacles equipped with nematocysts that discharge toxins on contact. Three classes in the phylum are species commonly known as jellyfish; the fourth consists of the corals and anemones. The phylum Mollusca contains the blue-ringed octopus and cone shells. The phylum Echinodermata contains starfish and sea urchins. The phylum Chordata contains venomous fish, stingrays, and sea snakes.¹

Documented deaths from jellyfish worldwide probably only run into the hundreds, and *Chironex fleckeri* (the Australian box jellyfish) has only been associated with 72 confirmed deaths despite its reputation as being nearly universally fatal. There are only 10 well-recorded deaths from cone shell envenomation, but sea snakes are

estimated to cause 150 deaths a year. Deaths from marine spines are rare and, with the exception of the stonefish, appear to result from complications of infection.¹ The three most common marine organisms causing emergency department visits in the mainland United States are stingrays, catfish, and jellyfish.

Epidemiology

The four Cnidaria classes are as follows:

1. Hydrozoa: This group of jelly-fish like animals includes *Physalia physalis* (the Atlantic Portuguese man-of-war and the Pacific man-of-war or blue bottle); *Physalia utriculus*, found off Hawaii and in the Indo-Pacific; and the hydroid corals, which are commonly found growing in tufts on rocks, seaweed, and dock pilings. Examples include *Millepora alcicornis*, the stinging fire coral; *Gonionemus vertens*, the orange-striped jellyfish; and *Lytocarpus philippinus*, the feather hydroid.
2. Cubozoa: This group includes the “box” jellyfish (with tentacles at the corners of a square body), such as the Australian box jellyfish, *Chironex fleckeri*; the sea wasp of Indo-Pacific waters, *Chiropsalmus quadrigatus*; and *Carukia barnesi*, the cause of Irukandji stings to swimmers around Queensland, Australia.
3. Scyphozoa: This group of “true” jellyfish (with tentacles at regular intervals around their bell) includes *Chrysaora quinquecirrha*, the sea nettle of the Atlantic coast, Philippines, and Japan, and the thimble jellyfish, *Linche unguiculata*.
4. Anthozoa: Only some species of coral have stinging nematocysts that harm humans. More dangerous are the cuts and lacerations one can suffer from handling coral or brushing against it. The class also includes the sea anemones, tube anemones, and zoanthids.

Most jellyfish are pelagic (inhabiting the surface of the sea). They may vary in size from a few millimeters to more than 2 m across the bell, with tentacles up to 36 m in length. Because the tentacles in some species are long, it is possible to encounter them without seeing the bell. After a storm during which jellyfish have been broken up and washed ashore, one can be stung while walking along a beach. Even when dry, the nematocysts retain the capacity to discharge and produce typical symptoms.

Nematocysts are cell organelles in specialized epithelial cells. They consist of a capsule wall enclosing a tightly coiled hollow tube that bursts forth like a dart on contact with a human being or animal (Fig. 25-1). During discharge, the coiled internal tubule everts progressively, bringing spines to the external surface. The venom in the capsule is conveyed to the victim through the now

TABLE 25-1 Relative Toxicities of a Selected Group of Toxic Substances

TOXIN	MINIMUM LETHAL DOSE ($\mu\text{g}/\text{kg}$)*	SOURCE
Botulinum toxin A	0.00003	Bacterium: <i>Clostridium botulinum</i>
Tetanus toxin	0.00010	Bacterium: <i>Clostridium tetani</i>
Ricin	0.02000	Plant: castor bean, <i>Ricinus communis</i>
Palytoxin	0.15000	Zoanthid: <i>Palythoa</i> species
<i>Crotalus</i> toxin	0.20000	Snake: The rattlesnake, <i>Crotalus atrox</i>
Diphtheria toxin	0.30000	Bacterium: <i>Corynebacterium diphtheriae</i>
Cobra neurotoxin	0.30000	Snake: <i>Naja naja</i>
Kokoi venom	2.7	Frog: <i>Phyllobates bicolor</i>
Tarichatoxin	8	Newt: <i>Taricha torosa</i>
Tetrodotoxin	8	Fish: <i>Sphoeroides rubripes</i>
Saxitoxin	3.4–9	Produced by the dinoflagellate <i>Gonyaulax catenella</i> transvected by shellfish
Bufotoxin	390	Toad: <i>Bufo vulgaris</i>
Curare	500	Plant: <i>Chondodendron tomentosum</i>
Strychnine	500	Plant: <i>Strychnos nux-vomica</i>
Muscarin	1100	Mushroom: <i>Amanita muscaria</i>
Samandarin	1500	Salamander: <i>Salamandra maculosa</i>
Diisopropyl fluorophosphate	3000	Synthetic nerve gas
Sodium cyanide	10,000	Inorganic poison

*Minimal lethal dose refers to mouse, except for ricin, in which it refers to guinea pig, and for bufotoxin and muscarin, in which it refers to cat. From Mosher HS, Fuhrman FA, Buckwald HD, Fisher HG: Tarichatoxin-tetrodotoxin: A potent neurotoxin. *Science* 1964;144:1103. uncoiled tube. Although all coelenterates have nematocysts, most are not injurious to humans.

The Portuguese man-of-war (Fig. 25-2) is characterized by a floating stem with several tentacles dangling from

the underside of the float. One or more of the tentacles are markedly elongated and are called fishing tentacles. *Physalia* is found worldwide in warmer waters. One fishing tentacle may contain almost a million nematocysts. Sea wasps (Fig. 25-3) are the potentially lethal cubomedusans, *Chironex fleckeri* of Australia and *Chiropsalmus quadrigatus* of the Philippines. Death in less than 3 minutes has been caused by stings of *C. fleckeri*.

Hydroid corals are upright, clavate, bladelike, or branching calcareous growths that are important in the development of reefs. The stinging coral is not a true coral but a hydroid with an exoskeleton of calcium

FIGURE 25-2 Portuguese man-of-war, *Physalia physalis*. (Courtesy of Bruce W. Halstead and the World Life Research Institute, Colton, CA.)

FIGURE 25-3 The sea wasp, *Chironex fleckeri*. (Courtesy of Bruce W. Halstead and the World Life Research Institute, Colton, CA.)

carbonate, the surface of which is covered with numerous minute pores. Hydroid corals are widely distributed throughout tropical seas in shallow water. *Millepora* is the best-known genus, and includes the fire coral, *Millepora alcicornis*, a nuisance to divers off the Florida Keys and in the Caribbean.

Sea anemones are some of the most abundant seashore animals, especially in tropical and warm temperate waters. Commonly known is the hell's fire sea anemone, *Actinodendron plumosum*. Anemones have a flower-like appearance under water when their tentacles are extended. In addition to having stinging nematocysts, some sea anemones are poisonous if eaten.

Corals, the major constituent of living reefs, are composed of an external calcium carbonate skeleton that houses small anemone-like polyps. Corals of the genera *Goniopora*, *Plerogyra*, and *Physogyra* contain stinging nematocysts, and *Acropora* species injure by direct mechanical abrasion.

The crown-of-thorns starfish, *Acanthaster planci*, is the main venomous starfish, although other species of the

genus can be venomous. The crown-of-thorns starfish inhabit coral reefs in the Indian and Pacific oceans from east Africa to central America. Divers and trawl fishermen are the main victims. Sea urchins (Fig. 25-4) also have spines, some of which may contain toxins. Surfers, fishermen, and divers are those typically stung.

Venomous molluscs include the Australian blue-ringed octopus, *Hapalochlaena maculosa* (Fig. 25-5) and cone shells. The Australian blue-ringed octopus rarely exceeds 8 inches in full extension and can fit in the palm of the hand. The octopus is brown with yellow bands and blue rings; when it becomes excited, the blue rings take on an iridescent glow.² Normally reclusive creatures, human bites have occurred mainly when they are captured or provoked. The octopus bites with its beak and secretes tetrodotoxin from its posterior salivary gland. Tetrodotoxin has an unusual distribution in nature; found in such diverse life as puffer fish, the California newt *Taricha*, and the central American frog *Atelopus*.² Cone shells are carnivorous snails that have a harpoon-like venom apparatus. They can fire a

detachable radular tooth into their prey, and this paralyzes the victim.^{3,4} Envenomation is uncommon in humans and only occurs when the shells are handled outside of water. *Conus geographus* is the only species known to cause human fatalities.

Marine catfish are abundant silvery fish with smooth, scaleless skin. They have four to five barbels or “whiskers” around the mouth, giving them their name. The dorsal and pectoral spines of many species, especially juvenile catfish, are venomous and capable of inflicting painful wounds. Stinging usually results from handling the fish, such as when removing the fish from the net or taking a hook out of its mouth. There are unsubstantiated claims that the striped catfish (*Plotosus lineatus*) of the Indian and western Pacific oceans has caused deaths.¹

Scorpion fish belong to the family Scorpaenidae.³ Examples of venomous fish in this family include the butterfly fish (*Pterois lunulata*), the zebra fish (*Dendrochirus zebra*; Fig. 25-6), the lionfish (*Pterois volitans*; Fig. 25-7), sculpin (*Scorpaena* species), and rockfish (*Sebastes* species). Most venomous Scorpaenidae are found in tropical water, but a somewhat less venomous species of scorpion fish lives along the coast of California and the southeastern coast of the United States. Most scorpion fish stings occur when handling the fish in home aquariums. The stonefishes (genus *Synanceja*), of which *Synanceja horrida* is the most venomous (Fig. 25-8), are

FIGURE 25-8 The stonefish, *Synanceja verrucosa*. (Courtesy of Sea World, Orlando, FL.)

bottom-dwelling fish that are difficult to see and easily trodden on.

The weever fish, of the family Trachinidae, is found in the Mediterranean Sea, along the Atlantic coast of Europe and North Africa, and up to the North Sea. *Trachinus draco*, or dragon fish, has five dorsal and two opercular spines that can inflict on unwary fishermen a painful venom.³ Weever fish often hide in mud or sand with only the head exposed, only to dart out to attack their prey.⁵

Three common stingrays are the round stingray, *Urolophus halleri*, found along the Pacific coast from California to Panama; the blunt-nosed stingray, *Dasyatis sayi*, found along the eastern Atlantic coast; and the spotted eagle ray, *Aetobatus narinari*, found throughout tropical waters from the Atlantic to the Pacific (Table 25-2). The *Dasyatis* stingrays (Fig. 25-9) are difficult to detect because of their habit of lying buried in the mud or sand with only a portion of the body exposed. Accidents usually occur when bathers step on a buried ray. The ray then whips its tail up and forward, driving the stinger into the foot or leg. Commercial fisherman are sometimes stung on the hand or arms when emptying nets. Divers may be stung on the chest or abdomen.

Sea snakes belong to the family Hydrophiidae and have evolved from the Elapid family of snakes (Table 25-3). Their anatomy has been highly adapted for marine life. The body and particularly the tail are vertically compressed to provide swimming ability, the nostrils are located on top of the head rather than on the side, and specialized glands secrete salt in order to permit life in a saline environment.^{3,6} Sea snakes inhabit the Indian and Pacific oceans from the Arabian Sea to Malaysia in the north to Australia and New Zealand in the south. A common sea snake is *Pelamis platurus*, or the yellow-bellied sea snake. This snake has the widest distribution and has been found from the Indian Ocean all the way to the Pacific coast of Central America. It is the only sea snake found to inhabit deep ocean waters; the other species inhabit reefs or coastal waters. No venomous sea snake has ever been found in the Atlantic Ocean or Caribbean Sea. The most highly toxic sea snake is the beaked sea snake, *Enhydrina schistosa*,

**TABLE 25-2** Some Important Venomous Stingrays

FAMILY AND COMMON NAME	PROPER NAME	GEOGRAPHIC DISTRIBUTION
Dasyatidae		
Blunt-nosed stingray	<i>Dasyatis sayi</i>	Atlantic coast of the Americas
Southern stingray	<i>Dasyatis americanus</i>	Cayman Islands, U.S. Atlantic coast to Brazil
Caribbean stingray	<i>Himantura scararde</i>	Caribbean
Atlantic stingray	<i>Dasyatis sabina</i>	Chesapeake Bay to Gulf of Mexico
Diamond stingray	<i>Dasyatis brevis</i>	California to Peru and Galapagos Islands
Red stingray	<i>Dasyatis akajei</i>	China, Japan, Korea
Common stingray	<i>Dasyatis pastinaca</i>	Mediterranean Sea
Porcupine ray	<i>Urogyrnus africanus</i>	Indian Ocean from Africa to Australia
Feathertail stingray	<i>Hypolophus sephen</i>	Indian and Pacific oceans
Ribbontail ray	<i>Taeniura lymna</i>	Indian Ocean, Red Sea to Australia
Thorntail stingray	<i>Dasyatis thetidis</i>	New Zealand and Australia
Tahitian stingray	<i>Himantura fai</i>	Tahiti, Polynesia, to Thailand
Urolophidae		
Round stingray	<i>Urolophus halleri</i>	U.S. Pacific coast to Panama
Yellow stingray	<i>Urolophus jamaicensis</i>	U.S. Atlantic, Gulf of Mexico and Caribbean
Crossback stingaree	<i>Urolophus cruciatus</i>	Australia, Tasmania
Common stingaree	<i>Trygonoptera testaceus</i>	Australia
Myliobatidae		
Spotted eagle ray	<i>Aetobatus narinari</i>	Tropical oceans from Atlantic to Indo-Pacific
Bat stingray	<i>Myliobatis californicus</i>	U.S. Pacific coast, California to Sea of Cortez
Bull ray	<i>Myliobatis aquila</i>	Mediterranean Sea
Southern bat ray	<i>Myliobatis tenuicaudatus</i>	Australia and New Zealand
Rhinopteridae		
Cownose ray	<i>Rhinoptera bonasus</i>	U.S. Atlantic coast to Brazil
Flapnose ray	<i>Rhinoptera javanica</i>	Pacific, Indonesia to Japan

responsible for the largest number of envenomations (Fig. 25-10). Divers and fishermen are the usual victims.

Pharmacology

Jellyfish venoms are poorly understood. Potential toxins isolated include vasoactive amines (histamine, serotonin, and dopamine), elastase, hemagglutinin, protease,

collagenase, and palytoxins. The venom of *Chironex fleckeri*, the Australian box jellyfish, has been shown to cause skin necrosis, cardiac depression, respiratory depression, and anaphylaxis, but the pharmacologic basis of these effects is uncertain. Some effects may be mediated by interaction with calcium channels. Irukandji venom causes a release of catecholamines that is partly responsible for some of the symptoms of envenomation.⁷ Anemone venoms contain neurotoxins, cardiotoxins, hemolysins, and protease inhibitors.⁸

The crown-of-thorns starfish venom contains saponins and possibly hemorrhagic toxins. Sea urchin venom is thought to contain proteins, steroid glycosides, and inflammatory mediators.¹

Tetrodotoxin blocks the movement of sodium ions by inhibiting the sodium channel, thus causing failure of nerve conduction and subsequent paralysis. Different conopeptides, peptide toxins of cone shells, have been shown to block sodium, potassium, and calcium channels, delay inactivation of sodium channels, and inhibit nicotinic and *N*-methyl-D-aspartate (NMDA)-glutamate receptors.

Catfish venom contains vasoconstrictors. Stonefish venom contain heat-labile proteins that have myotoxic, neurotoxic, and myocardial effects in animals. Stingray venom is primarily protein: extracts contain serotonin and enzymes such as 5-nucleotidase and phosphodiesterase.⁹⁻¹² Stingray venom is one of the most powerful

TABLE 25-3 Important Venomous Sea Snakes (Family Hydrophiidae)

COMMON NAME	SCIENTIFIC NAME	GEOGRAPHIC DISTRIBUTION
Beaked sea snake	<i>Enhydrina schistosa</i>	Australia, Southeast Asia, India
Stoke's sea snake	<i>Astrotia stokesi</i>	Australia, Southeast Asia, India
Annulated sea snake	<i>Hydrophis cyanocinctus</i>	Southeast Asia, India
Yellow sea snake	<i>Hydrophis spiralis</i>	Southeast Asia, India
	<i>Hydrophis klossi</i>	India
	<i>Hydrophis elegans</i>	Australia

vasoconstrictors found among natural toxins. The venom is highly unstable and is markedly heat labile. The venom of scorpion fish, weever fish, and other fish spines are high-molecular-weight proteins that are poorly characterized. Sea snake venom contains postsynaptic neurotoxins and myotoxins.^{8,10,11}

Toxicology: Clinical Manifestations

The severity of jellyfish stings in humans depends on the type of nematocysts, their penetrating power, the area of the victim's skin exposed, and the sensitivity of the victim to the venom. Injurious effects resulting from an encounter with coelenterate nematocysts range from mild dermatitis to rapid death.¹³ Severe stings can occur with the man-of-war and blue bottle jellyfish; only the former has resulted in fatalities. The sting of a Portuguese man-of-war is far more severe than that of the common jellyfish and produces intense local pain extending up the extremity. Generalized symptoms such

as headache, urticaria, muscle cramps, nausea, and vomiting may occur. Two confirmed deaths due to *Physalia* have been reported.^{14,15}

Stings by *Chironex fleckeri* and *Chiropsalmus quadrigatus* are potentially dangerous. The effects usually consist of extremely painful localized areas of wheal, edema, and vesiculation, which later result in necrosis involving the full thickness of the skin. The initial lesions, caused by the structural pattern of the tentacles, are multiple linear wheals with transverse barring. The purple or brown tentacle marks form a whip-like skin lesion. Painful muscle spasms, shock, and pulmonary edema can occur rapidly. Death may occur in the water or shortly after leaving it. The prognosis for victims who arrive alive at the hospital is good.

Carukia barnesi is probably not the only species that causes the Irukandji syndrome; similar presentations have occurred in Western Australia and Hawaii, where *C. barnesi* has not been identified. The syndrome typically begins with minor pain at the sting site, low back pain, generalized muscle cramps, sweating, nausea, vomiting, headache, and anxiety.¹ A reversible cardiomyopathy and acute pulmonary edema has been reported. Two deaths have occurred following *C. barnesi* stings.

Stings from anemone contact typically produce a burning pain. The skin blanches and wheals form, with surrounding edema and erythema. Vesicle formation, ulceration, and necrosis may occur.

Coral stings produce initial pain, followed by weeping of the lesion, wheal formation, and itching. If coral cuts or stings are left untreated, a superficial scratch may within a few days become an ulcer, with a septic sloughing base surrounded by a painful zone of erythema. Cellulitis, lymphangitis, enlargement of the local lymph glands, fever, and malaise may ensue. The ulcer may be quite disabling, and the pain is usually out of proportion to the physical signs. If the ulcer occurs in a lower extremity, the patient may be unable to walk for weeks or months after the injury. Relapses, which occur without warning, are common.

Stings from the crown-of-thorns starfish cause severe pain and the wounds become inflamed and may bleed excessively. The affected limb may become swollen, and infection is common. Sea urchin stings are extremely painful, and the spines often become embedded in the patient. The sea urchin spines of *Diadema setosum* contain purplish dye, which may temporarily stain the skin and give the false impression of a retained foreign body.¹⁶ Multiple stings by the black sea urchin *D. setosum* has been followed by a delayed severe bulbar polyneuritis.¹⁶

Envenomation by the blue-ringed octopus is described as painless, but the patient rapidly succumbs, becoming weak and unconscious, and develops respiratory arrest, often within 15 minutes. Cardiac arrest and death follow. Because the toxin has a short duration of action, patients may survive with prompt resuscitation.^{17,18} Pain following cone shell envenomation is variable, and the skin blanches or has a bluish discoloration. This is followed by numbness and swelling. In severe poisoning nausea, pruritus and muscle weakness occur; vision and hearing may be affected. Death results from respiratory paralysis.¹

Catfish stings are common, painful, and often become secondarily infected. A patient often has a painful, swollen, and infected wound days after the initial result. A puncture wound by a weever fish produces instantaneous, often crippling pain. Local ischemia, secondary infection at the wound site, and systemic involvement may occur.¹⁰ Intense pain results from stings by stonefish. Systemic symptoms, including headache, seizures, paralysis, abdominal pain, and hypotension, generally result only from envenomation by fish of the Synanceiidae family (stonefishes).^{1,3}

The stingray spine has a sharp, arrow-like tip and backward-pointing serrations along the sides so that after penetration the barb is difficult to remove and lacerates the tissues as it is withdrawn. The venom apparatus consists of a spine, integumentary sheath, and associated venom glands. When this is torn, the venom is released. Parts of the spine are typically left behind in the wound. Most stings occur on the ankle or foot. The stingray spine is very sharp, and by virtue of the mechanism of injury, it is common for a patient to receive a laceration rather than a puncture wound. Patients who present to the emergency department may describe walking in the ocean and feeling a fluttering under their foot and then a sudden stabbing pain. The usual presenting symptom is severe shooting pain that increases in intensity during the first hour. Systemic symptoms, such as chest pain, syncope, and other neurologic sequelae, have been described. Death has been reported but is uncommon and is usually related to chest or abdominal injuries. One highly unusual fatality occurred in a 12-year-old boy who was riding in a boat when a manta ray leaped out of the water and impaled him in the chest.⁸

Sea snake bites are often painless. The fangs are often small, frequently only 2 to 3 mm in length; thus, bites are often difficult to detect.^{2,8} One third to one half of bites do not result in envenomation.¹ Symptoms occur within 3.5 hours of the bite. The first symptoms are usually muscle pain; this may be preceded by headache and vomiting. After some hours, a flaccid paralysis may

develop and can progress to respiratory paralysis.^{8,19} Rhabdomyolysis, myoglobinuria, and subsequent renal failure may occur.

Diagnosis

A jellyfish sting can be identified by the patient or a companion. When a patient experiences an unknown sting, the diagnosis is usually made by observing a row of urticarial lesions or the presence of a tentacle adherent to the patient's skin. Stingrays leave a penetrating wound, and snakes leave fang marks. Catfish leave a barb, and this occurs only on handling the catfish.

A differential diagnosis with respect to the type of coelenterate is not so important in the United States, but where lethal coelenterates exist, as in Australia, identification of nematocysts—if time permits—on the patient by examining the skin wheals on the victim may be important. Halstead suggests that the wheal should be scraped with the edge of a microscope slide or scalpel and the material examined microscopically for the presence of nematocysts.¹ Nematocysts may also be obtained by microscopic examination of a strip of transparent tape that has been pressed against the surface of the wheal. The nematocysts adhere to the sticky side of the tape. Identification of nematocysts from the skin of the victim yields positive identification of coelenterate sting, but it requires an expert to identify the species.

LABORATORY TESTING

Biochemistry and hematology analyses should be undertaken in patients with systemic envenomation from jellyfish, blue-ringed octopus, cone shell, and stonefishes. Muscle enzymes should be tested following envenomation by a sea snake.

OTHER DIAGNOSTIC TESTING

X-ray films are indicated in marine spine stings. If the foreign body is seen on the radiograph, the wound should be opened and explored and the spine removed. Patients with chest pain, irregular pulse, or hypotension should have an electrocardiogram and should be placed on a cardiac monitor.

DIFFERENTIAL DIAGNOSIS

The presentation of Irukandji syndrome may be misdiagnosed as a myocardial infarction. When occurring in divers it may be difficult to distinguish from decompression illness. The differential diagnosis of an ascending paralysis, in addition to tetrodotoxin and paralytic shellfish poisoning, include rapidly progressive Guillian-Barré syndrome or a spinal cord hemorrhage.

Management

Treatment of coelenterate stings is symptomatic and supportive. Advanced cardiac life support may be necessary for patients who sustain cardiac arrest, either from toxic effects of the venom (e.g., *C. fleckeri*) or from anaphylaxis. Considerable success has been achieved in

management of jellyfish and Portuguese man-of-war stings in the United States by applying a slurry of paste of sodium bicarbonate (baking soda) to the wound. After an hour the baking soda should be moistened with water and scraped off with a dull object, such as a spoon, to remove any remaining nematocysts.⁴ The application of baking soda is not recommended for box jellyfish, which should be scraped off the skin after pouring 5% acetic acid (vinegar) for a minimum of 30 seconds.

Jellyfish can cause allergic reactions, but anaphylaxis is uncommon.¹ For anaphylactic shock, intravenous (IV) epinephrine, oxygen, IV fluids, dopamine, diphenhydramine, and a glucocorticoid may be indicated. Some jellyfish stings may cause severe pain requiring narcotics; morphine or fentanyl is recommended. Generalized symptoms, including hypotension, may be present, and IV fluid therapy with normal saline and general supportive measures may be indicated. For as long as 1 to 4 weeks after the initial sting, it is not uncommon for patients to return with recurrence of urticarial lesions at the site of the sting. These should be treated symptomatically with antihistamines. For this reason, follow-up is recommended for all patients with jellyfish stings.

Symptoms of Irukandji syndrome have responded to the administration of intravenous magnesium.²⁰ The mechanism may be by antagonism of epinephrine. A loading dose of 20 mEq or 0.2 mEq/kg (10 mmol or 0.1 mmol/kg) over 15 minutes followed by an infusion of 10 mEq/h or 0.02 mEq/kg/h (5 mmol/h or 0.01 mmol/kg/h) is recommended for patients who do not respond to initial opiates. Cardiogenic shock responds to positive pressure ventilation and epinephrine.

Coral cuts or abrasions should be scrubbed using fresh (not salt) water and a soft brush. Large or deep wounds should be surgically débrided, preferably within 3 hours.¹

There are no clear first aid recommendations for treatment of sea anemone stings; one suggestion is to remove adherent tentacles with forceps or gloved fingers, blot dry, and apply cold packs.¹ Simple analgesia may be effective. Systemic antihistamines and steroids may be needed to treat local allergic reactions. Topical agents are ineffective.

Sea urchin (and starfish) toxin is remarkably heat labile, and hot water immersion therapy is indicated for pain relief and deactivation of the venom.¹ Surgical removal, especially of the thick calcium-containing spines, is indicated.

The immediate treatment for cone shell and blue-ringed octopus envenomation is the application of pressure immobilization by wrapping the limb in a crepe bandage using the same tension as if bandaging a sprained ankle—not sufficient to obstruct blood flow.⁸ The limb is then splinted. The bandage can be left on until the patient stabilizes. Treatment is otherwise supportive. Assisted ventilation, if required, may only be necessary for a few hours.

Most cases of marine stings and spine envenomation can be treated in a standard fashion. The key to therapy involves care of the wound, relief of pain, hot water immersion, observation, and hospitalization in severe

cases. The affected part should then be immersed continuously in comfortably hot water for at least 60 minutes; this deactivates the heat-labile venom and relieves the pain. Patients should not be asked to test the water; they may be too distraught to judge effectively. In the emergency department, hot water immersion should be continued. Hot water immersion alone often provides pain relief, and pain medication may not be necessary. After an hour of continuous hot water immersion, the patient should take the affected part out of the water. If he or she suffers no pain, hot water treatment may stop. Wounds should then be irrigated, cleansed, débrided, and explored if necessary to remove any foreign body. Lacerations may then be surgically closed, although leaving the wound open with follow-up may be preferable, depending on the clinical situation.

Patients who suffer a wound on the chest or abdomen may require surgical exploration. In the case of stingray injuries, all wounds must be surgically explored to exclude injury to deeper tissues and to remove foreign material that is usually left behind when the barb breaks off.

Hot water immersion is effective early in treatment for pain relief and deactivation of weever fish venom; intravenous calcium is useful for pain relief.^{5,16} Exploration of the wound is often necessary. Supportive therapy and long-term wound care are generally indicated. Treatment of scorpion fish injury is similar to that for stingray injury. Hot water immersion, wound débridement, and supportive care are indicated.¹⁹

Tetanus prophylaxis should be given if indicated. Despite the potential for marine wounds to become infected, prophylactic antibiotics are not recommended for healthy people, but a course of doxycycline should be considered for patients who are immunosuppressed, have chronic renal or liver illness, or are diabetic. Empiric therapy for seawater wound infections is doxycycline.

LABORATORY MONITORING

Repeat measurement of creatine kinase (CK), potassium, and renal function is required for patients envenomated by sea snakes.

ANTIDOTES

Box jellyfish antivenom (Commonwealth Serum Laboratories, Melbourne, Australia) is a sheep-derived *Chironex fleckeri* antivenom. It should be administered as soon as possible in settings of collapse, cardiac arrest, or hypotension. Ideally three vials should be given IV, although it can be effective given intramuscularly. In persistent severe toxicity, a further three vials can be given. It is also indicated for severe pain.^{17,19} The antivenom may be effective against other chirodroid stings in the Indian and Pacific oceans.¹

Commonwealth Serum Laboratories (CSL) produces an Australian stonefish antivenom made from horse immunoglobulin. It should be given only intramuscularly, not IV. It is indicated for severe pain: For one to two spine puncture wounds, one vial may be

administered; for three to four wounds, two vials; if more than four wounds, three vials. There is limited evidence that it may be effective in stings from the bullrout fish (*Notesthes robusta*), but it is not recommended for use in other species of scorpion fish.¹⁹

Sea snake antivenom is also produced by CSL and contains horse antiserum against *E. schistosa* (sea snake) and *Notechis scutatus* (terrestrial tiger snake) venoms and is effective for most sea snake envenomations.^{17,19} Monovalent sea snake antivenom for *E. schistosa* is also produced by the Halfkine Institute of Bombay, India, and is also effective for most sea snake envenomations in that region.⁶ If these are unavailable, CSL monovalent tiger snake (*N. scutatus*) antivenom may be used in a ratio of three vials of tiger snake antivenom to each vial of sea snake antivenom.¹⁷ Sea snake antivenom should be given to any patient with signs of rhabdomyolysis or neuropathy. One vial should be given intravenously, up to three if severely poisoned, and can be repeated, up to a total of 10 vials if signs are progressing.

Intravenous antivenom should be diluted to a 10% solution and each vial run over 15 to 30 minutes. The preadministration of epinephrine is not currently recommended before administering CSL antivenom, but facilities for the management of anaphylaxis should be immediately available.

ELIMINATION

There are no known effective measures to increase the clearance of marine venoms.

DISPOSITION

Most cases of marine stings and spine envenomation respond to treatment and 4 hours of observation in the emergency department. Serious wounds require outpatient follow-up. Hospitalization may be necessary for surgical débridement of marine wounds or patients who have systemic envenomation. Even with potentially lethal envenomations such as those of the box jellyfish, blue-ringed octopus, or cone shell, signs of systemic poisoning will be evident within 4 hours.

SEAFOOD POISONING

An enormous variety of marine life is toxic to humans because of poisons that are ingested. Common poisonings are paralytic shellfish poisoning (PSP), scombroid fish poisoning, tetrodotoxin poisoning, and ciguatera. Less common are neurotoxic shellfish, clupeotoxic fish, and amnestic shellfish poisoning. With the exception of tetrodotoxin and scombroid poisoning, the causative toxins originate in dinoflagellates; these are unicellular eukaryotic marine algae that are consumed by marine organisms and passed up the food chain, to either shellfish or fish, and ultimately are consumed by humans. Scombroid poisoning and possibly tetrodotoxin have a bacterial origin. The affected fish and shellfish are usually unaffected by the toxins. Scombroid-affected fish are often reported to taste metallic or peppery, but other toxins are tasteless. All toxins are heat stable.

Epidemiology

The dinoflagellates primarily responsible for outbreaks of PSP include *Gonyaulax catenella*, which is found along the Pacific Coast from Alaska and California to Venezuela and west to Japan; *Gonyaulax tamarensis* var. *excavata*, which is found on the Atlantic Coast from Massachusetts and Nova Scotia to the North Sea; and *Pyrodinium bahamense* var. *compressa*, which is found from Central America to the Philippines.²¹ Outbreaks of PSP occur worldwide and result from the consumption of shellfish such as mussels, clams, oysters, cockles, and scallops that have fed on toxic dinoflagellates. The shellfish are not adversely affected by the algal toxins, which are known as saxitoxins.²¹⁻²⁶ Less commonly, PSP has resulted from the ingestion of starfish, crabs, and pufferfish.²⁷

Red tides result from excessive growth of algae species, including those that cause PSP. Pigments contained within the algae give the water a red-brown appearance. Red tides are a coastal phenomenon that occur sporadically. Poisonings related to red tides of oceans have been described for thousands of years. Because of a red tide in 208 BC, the name Red Sea was given to all the coasts of Arabia by the ancient Greeks. The first large epidemic recorded in the United States was in San Francisco in 1927; 102 persons became ill, and 6 died.²⁸ The toxin of *Ptychodiscus brevis*, which causes red tides off the Florida coast, can act as an upper respiratory tract irritant. The death of large numbers of fish, seabirds, and shellfish became associated with blooms of this microorganism.²⁹ Blooms of toxic algae associated with paralytic shellfish poisoning appear to be increasing worldwide.³⁰

Greater than 80 µg of saxitoxin per 100 g of raw shellfish meat is considered toxic. The best prevention of paralytic shellfish poisoning in humans is strict adherence to public health agency guidelines on harvesting, processing, and consumption of shellfish.

Scombroid fish poisoning is a clinical syndrome produced by histamine release from spoiled fish of the family Scombroideae, which include tuna and mackerel, skipjack, albacore, and bonito.³¹⁻³⁴ Other fish implicated include mahi-mahi, herring, sardine, anchovy, bluefish, amberjack, and the Japanese saury.^{32,33} Proper refrigeration and handling of raw seafood will prevent scombroid poisoning.

Puffer fish (Fig. 25-11) are named for their ability to inflate themselves to a nearly spheric shape when disturbed. Puffer fish poisoning is a highly lethal form of fish poisoning.³⁵ Fugu in Japan and the tambor puffer in Cuba are species of pufferfish eaten as a delicacy. In Japan, a 59% mortality rate was reported in 6386 cases of puffer fish poisoning during a 78-year period.³ At least three deaths due to eating puffer fish have been reported in Florida. Some common tetrodotoxic puffers in various areas of the world are blowfish (United States), akeke (Hawaii), tambores (Cuba), fugu (Japan), West Indian swellfish, tinga tinga (Philippines), mamaiacu (Brazil), qarrad (Red Sea), kend (India), buntal pisang (Malaysia), tetraodon, porcupine fish, globefish, tiger

FIGURE 25-11 The puffer fish, *Arothron meleagris*. (Courtesy of Sea World, Orlando, FL.)

puffer, rabbit fish, and botete.³ Even with extensive regulations, fugu is still a major cause of death due to food poisoning in Japan. Outside of these countries, poisoning occurs when people from other countries misidentify local toxic pufferfish as an edible species.

Numerous species of tropical and subtropical coral reef fish have been linked to ciguatera.³⁶⁻⁴⁰ Toxins from the photosynthetic dinoflagellate *Gambierdiscus toxicus* pass up the food chain when herbivorous fishes consume them.³⁶⁻⁴¹ These are, in turn, eaten by carnivorous fishes, which are then consumed by humans. Barracuda, amberjack, dolphin fish, the moray eel, surgeonfish, grouper, red snapper, sea bass, and Spanish mackerel are the more common of the 400 species that have been implicated in causing ciguatera.³⁶⁻⁴¹ Sixty percent of the cases reported in the area around Miami, Florida, followed ingestion of grouper.³⁹ So many reports of ciguatera followed the ingestion of barracuda that its sale is prohibited in southern Florida.³⁹ Common causes of ciguatera in Hawaii include the kingfish ulua (*Caranx ignobilis*), the jack papio (*Caranx sexfasciatus*), and the amberjack kahala (*Seriola dumerili*).³⁶⁻⁴² A common cause of ciguatera in the Indo-Pacific, including Hawaii, is the surgeonfish *Ctenochaetus strigosus*, also known as maito in Tahiti.⁴²

Neurotoxic shellfish poisoning results from algae blooms of *Ptychodiscus brevis*, a dinoflagellate in the coastal waters of southeastern North America and western Europe. The toxins are accumulated by clams and oysters. The resultant toxins, brevetoxins, can be carried inland, affecting people several miles from the coast.

Clupeotoxin poisoning is caused by herrings, anchovies, and sardines caught offshore of tropical islands after heavy rains or floods. The identity and origin of the toxin is unknown, although a phytoplankton origin is suggested.⁴³

A unique illness occurred in Canada in November and December of 1987. It was characterized by gastrointestinal and neurologic symptoms.⁴⁴ In a month, more than 250 cases were reported to the Health Department in Canada. The outbreak was tracked to mussel cultivation beds primarily from the Cardigan River estuary of Prince Edward Island.⁴⁴⁻⁴⁶ Domoic acid, an amino acid neuroexcitatory transmitter, was identified as

the causative toxin, the source of which was *Nitzschia pungens*, a form of marine vegetation.⁴⁴⁻⁴⁷ The poisoning has been termed amnesic shellfish poisoning. No other outbreaks of amnesic shellfish poisoning have been reported, although domoic acid-producing dinoflagellates have been isolated in other parts of the world. Domoic acid produced by the diatom *Pseudo-nitzschia australis* was responsible for the deaths of over 400 California sea lions in the Monterey Bay region in 1998.⁴⁸

Structure and Structure-Activity Relationships

Paralytic shellfish poisoning is caused by saxitoxin and a number of related compounds, sometimes termed gonyautoxins. These compounds are among some of the more potent toxins known. They attach to fast sodium channels in nerve and muscle, blocking the initial influx of sodium during depolarization, resulting in a conduction block.^{49,50}

Scombroid fish poisoning results from the activity of bacteria, such as *Proteus morgani*, utilizing the enzyme histidine decarboxylase to metabolize histidine to histamine.^{11,51}

Puffer fish poisoning is caused by tetrodotoxin, which, like saxitoxin, inhibits fast sodium channels during depolarization, but at a separate site. Conduction of peripheral motor, sensory, and autonomic nerves is reduced.

Ciguatoxin, the cause of ciguatera, also attaches to fast sodium channels but increases sodium permeability. After an initial stimulation, prolonged refractoriness and decreased conduction velocity occurs.⁵²

Neurotoxic shellfish poisoning results from the effects of brevetoxins A, B, and C. These polycyclic ethers bind to fast sodium channels near the binding site for ciguatoxin. Their main effect is on the peripheral cholinergic nerves, increasing the release of acetylcholine.⁵³

Amnesic shellfish poisoning is caused by domoic acid, an amino acid neuroexcitatory transmitter.^{44,45} It has been suggested that the neurotoxic effect is secondary to through activation of glutamate receptors in the amygdala and hippocampus, resulting in neural necrosis.⁴⁵ The exact mechanism is uncertain.

Pharmacology

Paralytic shellfish poisoning results in progressive neurologic impairment that initially affects sensory fibers, bulbar nerves, peripheral motor neurons, and the central nervous system. Scombroid fish poisoning resembles immunoglobulin E-mediated food allergies, replicating the typical features of endogenous histamine production. In addition to inhibiting conduction in peripheral nerves, tetrodotoxin also activates the chemoreceptor trigger zone and may depress the respiratory and vasomotor centers. Effects on cardiac, vascular smooth muscle, and skeletal muscle may occur in high doses. Puffer fish poisoning has a predictable progression of neurologic impairment affecting peripheral sensory nerves, peripheral motor nerves, bulbar

nerves, the central nervous system and respiratory muscles. Ciguatera produces a complex presentation with multiple symptoms affecting many systems; the mechanisms responsible are unclear. Neurotoxic shellfish poisoning, when caused by ingestion of seafood has a similar picture to ciguatera, but when inhaled it can trigger asthma via the stimulation of cholinergic nerve fibers, resulting in bronchospasm. Amnestic (domoic acid) shellfish poisoning results from the destruction of neurones in the amygdala and hippocampus, leading to permanent neurologic deficits.

Pharmacokinetics

Saxitoxin and related toxins associated with paralytic shellfish poisoning are heat stable and water soluble. Histamine is not normally absorbed across the gastrointestinal mucosa but metabolized by diamine oxidase. In scombroid poisoning it may be assisted by the presence of other toxins: putrescine and cadaverine. Tetrodotoxin is heat stable and water soluble. Ciguatoxin is heat stable and can be transferred across the placenta and by semen or breast milk. The pharmacokinetics of these toxins are poorly understood.

Pharmacologic Agents

Taking monoamine oxidase inhibitors, which may also inhibit diamine oxidase, may make patients more sensitive to scombroid.³² Medications containing cyclic ethers (opiates, barbiturates) may exacerbate the symptoms of ciguatera.

Toxicology: Clinical Manifestations

Patients with paralytic shellfish poisoning may develop neurologic symptoms and, in severe cases, motor paralysis and respiratory failure. Affected shellfish can not be distinguished by odor or taste. A case review reported that in 113 of 117 patients, the initial manifestation of poisoning consisted of paresthesia around the lips, mouth, upper airway, and fingers, which may become apparent within a few minutes after eating poisonous shellfish.⁵⁴ Nausea, vomiting, and diarrhea can occur. As the illness progresses, respiratory distress and muscle paralysis become more severe. Death results from respiratory paralysis within 2 to 12 hours. Children appear to be more susceptible.⁵⁵ If a patient survives for 24 hours, the prognosis is favorable, and there appears to be no lasting effect.⁵⁶

Patients who have eaten scombroid-affected fish often report a peppery or metallic taste and then present with signs and symptoms of histamine intoxication, often within 30 minutes.^{32,34} Flushing of the upper body, urticaria, headache, chills, vomiting, diarrhea, and abdominal cramps are common. Conjunctival erythema may occur.³² Severe cases that include bronchospasm and hypotension have been reported.³²

The clinical manifestations of puffer poisoning begin within 45 minutes of ingestion, initially including paresthesia about the lips, then affecting the peripheries.

Diaphoresis, hyperemesis, and salivation occur. Ascending peripheral and bulbar muscle paralysis occurs, ultimately resulting in respiratory failure. In some cases patients may be completely paralyzed, with loss of all brainstem reflex but retain consciousness.^{3,35,57}

Features of ciguatera poisoning usually occur within 6 hours of ingestion but may be delayed up to 72 hours. Typically, vomiting and diarrhea are followed by perioral and peripheral paresthesias and ataxia.^{36-42,58-63} Reference is often made of a cold-to-hot sensory reversal dysesthesia, with patients usually describing a burning sensation on exposure to cold water, for example. This is not a true sensory reversal, but is probably an exaggerated pain response to minor temperature extremes; patients can accurately detect temperature.⁶⁴

Headache, arthralgias, abdominal pain, tremors, pruritus, and weakness are common complaints. Another unusual feature is that patients may complain that their teeth feel loose and may fall out of their sockets or are painful. Hypotension and bradycardia (including heart blocks) can develop. Paresthesia, pruritus, and prolonged weakness after the acute phase may persist for several weeks to months.³⁶⁻⁴¹ It has also been noted that repeated episodes of ciguatera may be more severe in character. Ingestion of nonaffected seafood, grains, and alcohol, as well as exercise, may exacerbate symptoms.

Neurotoxic shellfish poisoning produces a similar clinical picture to ciguatera poisoning, but generally less severe. Inhalation of brevetoxins can produce upper and lower airway irritation and bronchospasm. Clupeotoxin poisoning results in a metallic taste, followed by vomiting, diarrhea, and cardiovascular collapse. Headaches, muscle cramps, paresthesia, and progressive muscular paralysis may occur. Seizures and coma resulting in death have occurred.¹⁹ Amnestic (domoic acid) shellfish poisoning was characterized by acute onset of gastrointestinal symptoms within 24 hours of eating mussels, followed by rapid onset of confusion, disorientation, and memory loss within 48 hours.⁴⁴ Serious neurologic impairment such as seizures, coma, and mutism have occurred.⁴⁵ Deaths have occurred and chronic residual memory deficits may result.^{44,46}

Diagnosis

A diagnosis of seafood poisoning is made on the history of seafood ingested and the clinical presentation. Analyses of toxic shellfish and toxic dinoflagellate algal organisms for toxins have helped establish a diagnosis in patients involved in certain outbreaks of shellfish poisonings. A presumptive diagnosis of paralytic shellfish poisoning should be made in a patient who develops neurologic symptoms after ingestion of mussels during seasons of risk in areas where paralytic shellfish poisoning occurs. Other causes of neurologic illness may appropriately have to be ruled out. Patients presenting with allergic symptoms and signs should be asked if they have eaten any of the potentially causative fish and if they noted a peppery taste.

Tetrodotoxin causes an ascending paralysis and the fish ingested are usually distinctive.

The diagnosis of ciguatera is made on clinical grounds. The history of consumption of fish such as grouper, barracuda, or amberjack with subsequent gastrointestinal symptoms and unusual neurologic symptoms will suggest the clinical diagnosis. Neurotoxic shellfish poisoning can be differentiated from ciguatera by the history of shellfish poisoning.

LABORATORY TESTING

Hospital laboratories generally do not have the capability to detect seafood poisoning toxins, but the appropriate food or health regulatory body may have access to laboratories to detect toxins in any uneaten samples.

DIFFERENTIAL DIAGNOSIS

The clinical presentation of ciguatera and neurotoxic shellfish poisoning may be similar, as may tetrodotoxin and paralytic shellfish; the principal symptoms and the seafood eaten can usually be used to determine the specific etiology.

Infectious gastroenteritis is the main differential diagnosis to consider. The lack of neurologic features should differentiate these diseases.

The history of fish ingested should differentiate scombroid poisoning from true anaphylactic reactions. Other toxic causes of erythema to consider are niacin, vancomycin, rifampicin, monosodium glutamate, and ethanol-disulfiram reactions.

Management

SUPPORTIVE MEASURES

The treatment of seafood poisoning is largely supportive. Careful assessment of airway control and ventilatory function should be undertaken because patients may require intubation and mechanical ventilation. Intravenous saline should be used to replace fluid losses. Ionotropes may be required for paralytic shellfish poisoning or severe ciguatera poisoning. Intravenous calcium gluconate (1 g over 30 minutes, followed by 2 to 4 g/day IV) has been used to treat hypotension secondary to ciguatera.

Seafood toxins are absorbed by activated charcoal and should be given to patients who present within 1 hour of ingestion. Control of vomiting may be required first.

Administration of antihistamines such as the H₂ blocker ranitidine and the H₁ blocker diphenhydramine is key to treatment of scombroid poisoning, as are intravenous fluids, steroids, and general supportive care. Epinephrine may be indicated in the presence of bronchospasm, angioedema, or hypotension. The syndrome is usually self-limited, resolving within a few hours.

Intravenous mannitol has been promoted as a treatment of acute ciguatera poisoning.⁶⁵ However, a randomized controlled trial failed to demonstrate that it was superior to normal saline in reducing symptoms by 24 hours, and its use can no longer be recommended.⁶⁶ Chronic ciguatera may be bothersome, because symptoms may wax and wane.⁶⁰⁻⁶³ The most success in treatment has been with the use of amitriptyline, possibly

by an effect on sodium channels.^{67,68} Treatment is generally begun with amitriptyline 25 mg twice a day. Remissions and exacerbations may occur. Alternatively, gabapentin has provided symptomatic improvement for persistent neurologic sequelae of ciguatera poisoning.⁶⁹

DISPOSITION

Patients poisoned by tetrodotoxin, paralytic shellfish, or clupeotoxin require monitoring of ventilatory function in an appropriate setting. Most other patients can be discharged after treatment in the emergency department. Patients should be admitted if they have severe dehydration, persistent abnormal vital signs, systemic anaphylactoid reactions, or neurologic symptoms. The level of care required depends on clinical severity. Local departments of health should be informed of suspected cases of seafood poisoning.

MICHAEL D. SCHWARTZ, MD ■ BRENT W. MORGAN, MD

At a Glance...

- The clinician must make the initial diagnosis of botulism on clinical grounds.
- Visual disturbances, dysarthria, dysphagia, and dry mouth are the four most specific neurologic symptoms of botulism.
- The treatment of botulism requires meticulous attention to airway and ventilatory status and the early administration of botulism equine trivalent antitoxin.
- Careful history (timing and duration of symptom onset) and physical examination will help narrow the broad differential of food-borne illness.
- Fever, blood in the stool, and a longer incubation period are clues to an enteroinvasive (salmonellosis, shigellosis, campylobacteriosis) food-borne illness.

Many different organisms and toxins are capable of causing food poisoning. This chapter primarily discusses botulism, the most deadly food-related toxicologic disease known. In addition, the food-borne toxicologic syndromes of *Staphylococcus aureus*, *Clostridium perfringens*, cholera and noncholera vibrios, *Bacillus cereus*, *Salmonella*, *Shigella*, and *Campylobacter* are reviewed.

BOTULISM**Introduction**

Botulinum toxin is produced by the anaerobic, spore-forming, gram-positive bacillus *Clostridium botulinum*. Botulinum toxin is the most potent toxin known, with as little as 100 ng being lethal to humans.¹ Botulism is the clinical syndrome characterized by neuroparalytic signs and symptoms that result from the actions of the botulinum toxin. Ironically, despite the potency and inherent danger of botulinum toxin, its paralytic actions have made it useful as a therapeutic and cosmetic remedy.

There are three forms of naturally occurring human botulism: food-borne botulism, wound botulism, and intestinal botulism. *Iatrogenic botulism* is a term used to describe patients who develop some symptoms compatible with systemic botulism after receiving botulinum toxin A for therapeutic purposes.² Food-borne botulism is the best-known form of botulism. Fortunately, food-borne botulism is rare in the United States, with an average of less than 25 cases a year reported in the past few decades.³ It occurs when an individual consumes food contaminated with preformed toxin. Historically, wound botulism was extremely rare. Since the 1990s, however, there has been an increased incidence of wound botulism, which has been most commonly associated with the subcutaneous injection of black tar

heroin.⁴ Wound botulism occurs when wounds become contaminated with spores of *C. botulinum* that germinate and produce toxin that is absorbed systemically. Intestinal botulism occurs when the gastrointestinal (GI) tract because colonized with *C. botulinum*. This most commonly happens in infants and is frequently termed *infant botulism*. Infant botulism, which is the most common type of botulism in the United States, occurs when an infant consumes foods contaminated with spores of *C. botulinum*. Disease occurs when the spores germinate and proliferate in the GI tract and produce toxin.^{5,6} Although uncommon, adults can also develop intestinal botulism.⁷ These patients typically have an abnormality of the GI tract that can make them susceptible to intestinal colonization.

Bacteriology/Structure

Botulism spores are ubiquitous; they are found in the soil and in marine sediments worldwide. The species is subdivided into seven antigenically distinct serologic types (A to G), which produce disease in either humans or animals.^{8,9} The botulinum toxin is produced after the botulinum spore germinates and begins cell growth. Toxin is released when the mature cell wall lyses.⁹ The spores of *C. botulinum* are surrounded by an inner and outer coat of keratin-like structure rich in disulfide bonds that makes them highly resistant to heating, freezing, aerobic and anaerobic conditions, ionizing radiation, and exposure to various chemical agents.¹⁰ Moist heat at temperatures greater than 120°C for at least 30 minutes is required to destroy them.^{8,11} Environmental factors that favor spore germination include low acidity, a temperature between 4°C and 70°C, low oxygen, and high water content.^{9,12} However, growth of E-type organisms has been reported at temperatures as low as 3°C and in nonanaerobic environments.⁸

Epidemiology and Types of Botulism

Toxin types A, B, and E account for almost all cases of human botulism.^{8,13} Types F and G are very rare in humans. Toxin types C and D are associated with botulism in mammalian animals and birds.¹³ Between 1973 and 1996, approximately half of the cases of food-borne botulism were caused by type A. In that same period, the remaining cases were almost equally divided between types B and E.³ Geographic distribution of spore types parallels the toxin type identified in outbreaks. In the western United States, type A spores predominate in the soil, and the majority of disease is due to type A toxin.^{8,14} Type B spores predominate in the central and eastern United States, and the majority of cases in these areas are due to type B toxin.^{8,14} Type E spores are less

ubiquitous but are most commonly found in damp locations, including sediments around the Great Lakes and the coasts of Washington and Alaska. These coastal areas are the same locations where type E botulism occurs.

The name *botulism* originally comes from the Latin word *botulus*, meaning “sausage.” Improperly prepared blood sausage was first implicated in causing the disease in the late 18th century. The organism was first reported to be associated with the disease in 1897 after it was isolated from uncooked ham after an outbreak of 23 cases at a music club in Belgium.¹⁵ Although poorly preserved meat was the cause of most cases of botulism in the past, most present-day cases of types A and B botulism in the United States result from improper home canning of vegetables.

While restaurant-acquired botulism accounts for only 4% of the total number of outbreaks, restaurant-associated outbreaks account for 40% of the total number of cases of botulism.¹⁶ Several large outbreaks have been caused by onions and potatoes that were left at warm temperatures for more than 12 hours in incubator-like conditions.¹⁶⁻¹⁸ Either insufficient heating to kill the spores or introduction of spores to the food after cooking led to proliferation of the organism with subsequent toxin production. Anaerobic conditions may exist, especially if the food is immersed in a liquid or is covered. The onions, which were immersed in butter, were used in patty melt sandwiches and resulted in 28 cases.^{16,17} The potatoes were wrapped in aluminum foil and later used in potato salad and caused 34 cases.¹⁸ A similar incubation process has been implicated in other outbreaks involving beef and chicken pot pies, turkey loaf, and beef stew, all of which were kept warm and left to stand for longer than 12 hours without reheating.^{16,19,20}

Cases of type E botulinum food poisoning result from either poor vacuum packing or improper home preparation or preservation techniques.²¹ Common foods in the Inuit Eskimo communities are urraq (uncooked seal flipper in seal oil), muktuk (chunks of white whale skin, blubber, and meat), and fermented salmon eggs; these foods allow growth of the botulinum organism when left to ferment at room temperature because the foods are low in carbohydrates and thus do not become acidic.²¹ The largest outbreak of type E botulism to date recently occurred in Egypt and involved at least 91 people. It resulted from the consumption of *faseikh*, which is a traditional ungutted, salted fish that was placed in a barrel and kept in a warm environment.²² Conditions present in the fish intestines during preservation allowed for type E spores to proliferate.²³

Pathophysiology

The botulinum toxin is the most lethal human toxin known; it has an estimated oral lethal dose of 70 µg in a 70-kg human.²⁴ Despite its potency, botulinum toxin is easily denatured.⁸ Sunlight, chlorine, and heating at 80° C for 30 minutes or 100° C for 10 minutes denatures the active toxin.^{13,16} Boiling under pressure is required at

higher altitudes. Botulinum toxins form complexes with other proteins that prevent destruction by proteolytic activity in the stomach after ingestion. The toxins are absorbed in the small intestine. The botulinum toxin is composed of a heavy and light chain held together by a disulfide bond. Once the toxin has been absorbed, it spreads via blood and the lymphatic system to peripheral acetylcholine synapses. Botulinum toxin cannot cross the blood-brain barrier. The heavy chain binds to specific receptors on the presynaptic nerve terminal and the toxin crosses the cell membrane via endocytosis. The heavy chain undergoes a reconfiguration that is triggered by the more acidic pH within the vesicle. The reconfiguration allows the heavy chain to penetrate the vesicle and results in release of the light chain into the cytoplasm. The light chain is a zinc-dependent endopeptidase enzyme that is highly specific for one of three synaptic proteins (SNAP-25, syntaxin, or synaptobrevin) essential for docking and fusion of vesicles.^{25,26} Without these synaptic proteins, acetylcholine-containing vesicles cannot fuse with the presynaptic membrane or release the neurotransmitter into the synaptic cleft.

The toxin's blockade of acetylcholine occurs at four separate sites: (1) the neuromuscular junction, (2) ganglionic nerve endings, (3) postganglionic parasympathetic nerve endings, and (4) postganglionic sympathetic nerve endings that use acetylcholine.⁹ At high toxin concentrations, adrenergic systems may also be affected.¹⁴ The toxin affects only the release of acetylcholine and does not affect acetylcholine's synthesis, storage, or metabolism.⁹ Botulinum toxin does not affect impulse conduction down nerves or impulse conduction at nerve terminals.^{11,27}

Food-borne Botulism

CLINICAL MANIFESTATIONS

The first symptoms of botulism usually occur within 12 to 48 hours of ingestion of contaminated foods.^{12,28-30} The onset of symptoms, however, may be delayed for as long as 14 days after ingestion. The latent period is inversely proportional to dose of toxin ingested, such that the more toxin consumed, the more rapid the onset of symptoms. The initial signs and symptoms of botulism may be gastrointestinal and can include abdominal pain, nausea, vomiting, and diarrhea. Constipation is the most common GI symptom.

Patients may also present initially with only neurologic signs and symptoms due to cholinergic blockade. Visual disturbances, dysarthria, dysphagia, and dry mouth are the four most specific neurologic symptoms.^{8,17,29,31} Additional nonspecific neurologic symptoms associated with botulism include malaise, generalized weakness, headache, dizziness, and paresthesias.^{8,17,29,31} As the disease progresses, oculobulbar signs, descending paralysis, and progressive respiratory weakness occurs, which often leads to respiratory failure.

Oculobulbar symptoms are exceedingly common findings in botulism.^{8,32,33} Blurring of vision, lateral rectus palsy, ptosis, dilated pupils, and external ophthalmoplegia occur in most patients who develop neurologic

symptoms.^{17,29,31} Fixed or dilated pupils are seen in almost half the patients who present in botulism epidemics. Sixth nerve palsy and accommodative paresis are frequent, early ophthalmic signs of botulism.^{31,33} Third nerve palsy, if seen, may indicate a higher likelihood of respiratory failure and the need for mechanical ventilation.^{31,33} Because botulism is so rare and is associated with nonspecific symptoms, the Centers for Disease Control and Prevention (CDC)⁸ and others¹⁷ have suggested various constellations of signs and symptoms to help clinicians consider the diagnosis of botulism early in its presentation (Table 26-1).

Table 26-2 lists the differential diagnoses of botulism.^{8,12,34} The disease is most commonly confused with Guillain-Barré syndrome. Approximately 10.5% of persons reported to the CDC with suspected botulism are ultimately diagnosed as having Guillain-Barré syndrome. Other diseases commonly confused with botulism include carbon monoxide poisoning (3.4% of reported cases of botulism), food poisoning of unknown etiology (3.2%), and food poisoning due to staphylococcal organisms (3.0%).⁸ Physicians should suspect botulism whenever a patient presents with generalized weakness, particularly if there is ocular or oropharyngeal involvement.

DIAGNOSIS

Because rapid treatment is critically important and results of diagnostic testing take time, the clinician must make the initial diagnosis of botulism on clinical grounds. When botulism is clinically suspected, samples of serum, stool, and stomach contents should be cultured and assayed for botulinum toxin. Epidemiologically suspected foods should also be assayed for the neurotoxin. The mouse neutralization bioassay is the most reliable method for detecting the toxin. Laboratory confirmation cannot be relied on to make treatment decisions because the mouse bioassay requires 4 days to complete. Since *C. botulinum* is ubiquitous, cultures of the suspected food are not usually helpful and can result in false-positive results. Postmortem diagnosis may be aided by detecting toxin or organisms in autopsy specimens of the small intestines, large intestines, or liver.¹⁴

An electromyogram (EMG) can be useful by correctly differentiating botulism from myasthenia gravis,

Guillain-Barré syndrome, and Eaton-Lambert syndrome. The EMG of a patient suffering from botulism demonstrates a decrease in the evoked action potential at slow-frequency stimulation (2 Hz/s) and incremental increase in amplitude at rapid stimulation (50 Hz/s).³⁵ The EMG findings in myasthenia gravis show decreased evoked muscle responses at both slow and fast stimulation, and these EMG findings improve with the use of edrophonium chloride.³⁵ A decrease in evoked potential is usually noted as the muscle is repetitively stimulated, the opposite of what is found in botulism.³⁵ The EMG findings of a patient with Eaton-Lambert syndrome are very similar to those of a patient suffering from botulism.^{35,36} EMG findings for botulism, however, are very dissimilar between different muscle groups and evolve over time, whereas EMG findings between different muscles for Eaton-Lambert syndrome are very similar and stay relatively stable over time. EMG findings for Guillain-Barré usually show patchy slowing, which is indicative of demyelination.

The diagnosis of botulism may be difficult to make on initial patient presentation. The clinician should be familiar with the common presenting signs and symptoms (see Table 26-1) and the clinical features that differentiate it from other illnesses with similar findings (see Table 26-2). The findings on EMG can be helpful to solidify the diagnosis. The physician should consider botulism in the differential diagnosis of any patient who presents with a neurologic or neuromuscular complaint.

MANAGEMENT

The treatment of botulism requires meticulous attention to airway and ventilatory status. Most early deaths result from respiratory failure and occur before a patient has presented for health care or from the failure of health care workers to recognize early signs of respiratory impairment once a patient has presented.^{17,37} Patients should be placed in a well-observed treatment area on an electrocardiogram monitor and should have continuous pulse oximetry monitoring. An intravenous line should be established, and equipment necessary for intubation should be readily available. Patients should be asked if any of their family or friends have similar symptoms or whether they have eaten in a restaurant, any home-canned foods, or any unusually prepared meats. Although any food ingested during the prior 8 days could possibly cause botulism, food consumption during the past 2 to 3 days is the more likely source of illness.

Pulmonary function tests are required for all patients with suspected botulism.³⁸ Although arterial blood gas measurements are helpful in the complete assessment of any patient, they do not accurately predict a declining respiratory reserve.^{37,39} Hypercarbia due to respiratory muscle weakness usually develops very late in the course of botulism, just before respiratory arrest.³⁷ In an effort to predict those patients who will experience a declining ventilatory status, vital capacity and forced inspiratory volume should be measured regularly at 2- to 4-hour intervals. In one study, all adult patients with a vital capacity less than one third that predicted eventually required mechanical ventilation.³⁷ Elective intubation

TABLE 26-1 Most Common Presentations of Food-borne Botulism

Presenting complaints	Dry mouth and/or dysphagia Abdominal symptoms
Initial appearance	Anxious Normal mental status Weak
Medical history	Previously well
Vital signs	Afebrile Slow or normal pulse
Physical examination	Dysphonia Dysarthria Symmetric ocular weakness Symmetric neurologic abnormalities

TABLE 26-2 Differential Diagnosis in Botulism

DISEASE OR CONDITION	DIFFERENTIAL MANIFESTATIONS	DISEASE OR CONDITION	DIFFERENTIAL MANIFESTATIONS
Neurologic Diseases			
Guillain-Barré syndrome	Usually ascending paralysis Elevated CSF protein Paresthesias Preceding viral illness common Absent deep tendon reflexes	Eaton-Lambert syndrome	Underlying malignancy, especially oat cell carcinoma Progression much slower Predominant thigh and pelvic muscle involvement
Myasthenia gravis	Lack of autonomic findings Increased fatigability Improvement with edrophonium EMG findings	Cerebrovascular accident	Extraocular muscle involvement rare Pupillary findings almost never present EMG findings Asymmetric Unilateral Vascular distribution Asymmetric deep tendon reflexes
Biologic Infections and Toxins			
Bacterial food poisons (staphylococcal, clostridial, and so forth)	Rapid onset Gastrointestinal complaints predominate No paralysis No cranial nerve involvement	Encephalitis	Altered mental status Fever Meningeal signs
Diphtheria	Pseudomembrane Pharyngitis Schick's test Limb paralysis occurs weeks after cranial nerve involvement	Saxitoxin Trichinosis	Abnormal CSF Symptoms within 1 hr of fish ingestion Paresthesias of face predominate Tachycardia Vertigo Fever
Poliomyelitis	Fever Meningeal signs Crampy muscle pain Asymmetric distribution CSF may show encephalitis pattern	<i>Amanita</i>	Myositis Periorbital edema Eosinophilia Coma
Tick paralysis	More common in children Tick(s) found on physical examination Paralysis usually ascending Deep tendon reflexes may be absent	Tetanus	Violent vomiting Hepatic failure Trismus Risus sardonius Neck and jaw stiffness Muscle spasms
Poisoning and Overdose			
Phenothiazine reaction	Spastic muscle contractures Resolution with antihistamines	Aminoglycoside-induced paralysis	Postanesthesia History of renal impairment Serum levels
Carbon monoxide poisoning	Headache Altered mental status Elevated carbon monoxide level	Heavy metal exposure	Exposure history Rapidly of onset Serum or urine levels
Organophosphate overdose	Fasciculations Cholinergic symptoms Resolution with atropine	Hypermagnesemia	Medication history Renal impairment Serum magnesium level
Anticholinergic poisoning	Fever Altered mental status Tachycardia and vasodilation No cranial nerve involvement Medication history		
Medical Conditions and Emergencies			
Acute myocardial infarction	Classic signs and symptoms should evolve over time	Carcinomatous invasion of the base of the skull	Cranial nerves V and VIII involvement only Meningeal signs and symptoms
Appendicitis		Hysteria	Variable, inconsistent findings No objective findings
Bowel obstruction		Sepsis	Fever Leukocytosis Localized sites of infection Abnormal CSF findings Positive blood cultures
Bowel infarction			
Acute intermittent porphyria	History or family history Cranial nerve involvement rare Prior psychiatric or CNS complaints Urinary test abnormalities		

CNS, central nervous system; CSF, cerebrospinal fluid; EMG, electromyography.

before respiratory arrest decreases mortality from botulism.²⁹

The state health department should be contacted in all suspected cases of botulism. The CDC maintains a 24-hour telephone number to provide callers with their state's on-call consultant (404-639-2888). This telephone number provides 24-hour access to consultation regarding suspected cases of botulism. Information is also provided about the nearest location for obtaining the antitoxin. The state health department can assist in the epidemiologic and public health aspects of the outbreak. Samples should be obtained for testing by the CDC.³⁸ These samples should be kept refrigerated but not frozen.⁸

At the time of diagnosis, unabsorbed toxin-containing food may still be present in a patient's GI tract. While the efficacy of gastric decontamination in suspected cases of botulism is yet to be evaluated, it is recommended. Activated charcoal adsorbs *C. botulinum* type A in vitro and, thus, is recommended for cases of suspected food-borne botulism.⁴⁰ The utility of gastric lavage is unknown and should be reserved for patients who ingested known contaminated food within 1 to 2 hours of presentation. Non-magnesium-containing cathartics, enemas, and whole bowel irrigation are other options, but their efficacy is unknown.

Botulism equine trivalent (A, B, E) antitoxin should be administered as soon as possible in all cases of suspected botulism except infantile botulism. The antitoxin binds circulating toxin and is effective in preventing progression of illness but does not reverse neurologic effects that are already present. In a retrospective analysis of 134 cases of type A food-borne botulism, patients who received trivalent antitoxin within 24 hours of symptom onset had a lower mortality rate and a shorter hospital stay than patients who received delayed antitoxin (greater than 24 hours after symptom onset) or no antitoxin at all.⁴¹ Since 1996, the CDC has recommended the administration of only one vial intravenously per patient.³ Each vial contains 100 times that amount of antitoxin required to neutralize the largest amount of circulating toxin ever measured at the CDC.⁴² Pregnancy is not a contraindication to antitoxin administration. It is unknown if asymptomatic individuals that have likely consumed food contaminated with botulinum toxin should be treated empirically with antitoxin. The benefits of early administration must be weighed against the risk for anaphylaxis from the equine-derived antitoxin.

In one investigation, hypersensitivity reactions were noted in 9% of patients treated with the horse serum-prepared antitoxin.⁴³ Patients in this study were treated with less than one to greater than four vials. More than half of the reactions were nonfatal acute hypersensitivity reactions that ranged from urticaria to true anaphylaxis; the remainder were delayed serum sickness-type hypersensitivity reactions.⁴³ The incidence of delayed serum sickness-type hypersensitivity reactions was significantly more common in those administered more than four vials. The incidence of hypersensitivity reactions may be lower following administration of one vial, as is currently

recommended. Nevertheless, epinephrine should be readily available to treat serious reactions. Skin testing before treatment does not reliably distinguish those patients who will or will not have hypersensitivity reactions.⁴⁴

The incidence of mortality for botulism has declined dramatically during the past 40 years, from more than 60% to between 5% and 15%.^{8,16,29,37} There are many reasons for this, which include more widespread media coverage and heightened awareness, more aggressive early care, increased availability of antitoxin, and accumulated intensive care expertise by physicians. Cases of suspected botulism should be cared for by intensivists that are experts in ventilator management. In recent reports, almost all in-hospital deaths have been due to pulmonary and ventilator-related complications.^{29,37,45}

Severity of disease appears to be related to the type of toxin. Cases of type A botulism have had a significantly higher incidence of respiratory failure requiring intubation and mechanical ventilation than have cases of types B and E botulism.^{16,29,46} Type E botulism has the lowest incidence of intubation but has a shorter incubation period; almost all individuals have symptoms within 24 hours of ingestion.⁴⁶ Type B is intermediate in severity between types A and E and has the longest incubation period.

Recovery from botulism may be delayed for months.³⁵ Patients are often weak and tire easily for as long as a year after the acute phase of their disease. A vaccine developed from a recombinant fragment of *C. botulinum* neurotoxin serotype A has protected mice against intraperitoneal doses of toxin 10 million times the normal lethal dose.⁴⁴

Infant Botulism

Infant botulism, first reported in 1976, is now by far the most common form of botulism in the United States. In one 12-year period, 57 cases were reported at the Children's Hospital of Philadelphia alone.⁶ Infant botulism has also been implicated as a possible occult cause of the sudden infant death syndrome. Two non-botulinum *Clostridium* organisms, *Clostridium butyricum* and *Clostridium barati*, have been shown to cause infant botulism by elaboration of botulism toxins type E and F, respectively.^{45,47} As of 1996, more than 1400 cases of infant botulism have been reported to the CDC.³

Unlike classic adult botulism, which results from ingestion of preformed toxin, infant botulism is due to in vivo germination of botulism spores with concomitant toxin production. The human colon is believed to be the site of bacterial colonization, and symptoms occur when released toxin is absorbed from the gut.⁵ Botulism spores do not germinate in the presence of high acidity, a complex mix of aerobic and anaerobic bacteria, or a mature GI immune system.⁴⁸ Infants are at risk until about 4 to 6 months of age because of the unique characteristics of their GI tract, including a more alkaline gastric environment, a paucity of normal flora, and a lack of mature mucosal immunologic defenses, including lysozyme, complement, and secretory IgA.⁴⁸⁻⁵⁰

In infants, the median age at presentation is 2 to 4 months; cases of infant botulism after 6 months of age are very uncommon.

Breast-feeding remains a controversial risk factor for the development of infant botulism. A study has shown that before 2 months of age, there is no significant difference between the number of breast-fed and formula-fed infants diagnosed with the disease.⁵¹ The severity of disease in formula-fed infants younger than 2 months appears to be greater, however, and more formula-fed infants require intubation. In infants older than 2 months, those who have been breast-fed have a significantly higher chance of being diagnosed with infant botulism. Other risk factors for infant botulism include residing in regions that have a high soil load of botulism spores. The high spore load in local soils of California, Utah, and Pennsylvania parallels the frequency of disease, and more than half of the reported cases of infant botulism come from these regions.⁵ Additional risk factors for infant botulism include alkaline soil, nearby construction, high dust counts, and ingestion of corn syrup or honey.^{50,51} Natural honey is one of the causes of infant botulism. As many as 25% of samples have botulism spores. The CDC recommends that natural honey not be given to children younger than 12 months.⁵¹

Treatment of infant botulism involves aggressive supportive care. Use of equine antitoxin is to be avoided due to the risks associated with use of equine-derived product and the possibility of early sensitization to equine serum.¹ Current evaluation of a human volunteer-derived immune globulin preparation is ongoing and may offer an alternative antibody-based therapy.¹

Wound Botulism

Wound botulism occurs when *Clostridium botulinum* grows in localized wounds and elaborates sufficient neurotoxin for the systemic signs and symptoms of botulism to develop. First described in 1943, wound botulism has been frequently associated with infected abscesses from injection drug use. In 1982, a case of wound botulism resulted from the intravenous injection of cocaine.⁵² More recently cases of wound botulism associated with the intramuscular or subcutaneous (“skin popping”) administration of black tar heroin.^{53,54} In cases of wound botulism secondary to infected abscesses in which toxin typing is performed, botulinum toxin type A or B is most frequently identified.⁵³

Any wound in which *C. botulinum* germinate and elaborate toxin may be associated with clinical botulism. In 1991, botulinum toxin type A was isolated from a case of wound botulism secondary to an odontogenic abscess in a 5-year-old boy.⁵⁵

Treatment of wound botulism includes aggressive supportive care, early surgical débridement of wounds, and the administration of antitoxin.

Iatrogenic Botulism

Subsequent to the use of intradermal botulinum toxin (Botox, Allergan, Inc., Irvine, CA) in cosmetic dermatology, rare cases of systemic botulism have been

reported.⁵⁶⁻⁵⁸ These cases have all involved multiple subcutaneous or intramuscular injections for focal hyperhidrosis, spasticity secondary to multiple sclerosis, spasticity associated with multisystem atrophy, and cervical dystonia.⁵⁶⁻⁵⁸ Both pharmaceutical formulations, BoTox and Dysport (Ipsen, Ltd., Slough, UK), have been associated with iatrogenic botulism. Patients diagnosed with iatrogenic botulism have all developed generalized muscle weakness and have had EMG evidence of denervation.⁵⁶⁻⁵⁸ None of these patients received antitoxin treatment or required mechanical ventilation.

OTHER FOOD-BORNE TOXINS

Introduction

Illness caused by food consumption may be due to the direct action of an infecting organism, elaboration of a toxin by an infecting organism, or the presence of a preformed toxin in the ingested food (even in the absence of viable organisms). Food-borne illnesses are vastly underreported in the United States, with most estimates suggesting that about 1% to 5% of cases reach public health awareness.⁵⁹ In the past, food-borne illness outbreaks occurred on a small geographic scale with high attack rates and were more easily detected by public health authorities. The changing paradigm of this disease entity is one of broad geographic reach and is characterized by increased numbers of victims and less readily identifiable sources.⁶⁰ In a telling example from Minnesota in 1994, 593 cases of *Salmonella enteritidis* were linked to consumption of pasteurized ice cream transported in a tanker truck that had previously carried unpasteurized liquid egg. The inoculum of *Salmonella* found in the contaminated ice cream, if evenly distributed throughout the tanker, was estimated to have been enough to cause 224,000 cases of illness.⁶¹ The underreporting of food-borne illness, compounded by the unavoidable laboratory delay in detecting an event, could have a considerable public health impact if timely intervention to stop an outbreak is not taken.

In the current political climate, the possibility of malicious contamination leading to an outbreak must raise our awareness even more. Determination that the 1984 *Salmonella* outbreak in Oregon was biological terrorism came more than 2 years after the initial public health investigation.⁶² Today, the onus is on the frontline physician to report suspected food-borne illnesses, with the intent of identifying an outbreak early enough to intervene, rather than merely retrospectively arriving at a satisfying clinical diagnosis. The following section provides the clinical characteristics associated with the more common toxin-mediated, food-borne syndromes.

Bacterial food toxins may be heat stable or heat labile. Heat-stable enterotoxins are typically smaller proteins that primarily intoxicate intestinal lining cells.⁶³ The most common heat-stable toxins are those associated with *Staphylococcus aureus*, enterotoxigenic *Escherichia coli*, and *Yersinia enterocolitica*. The most common heat-labile toxins are associated with *Bacillus cereus*, *Clostridium perfringens*, and *Vibrio cholerae*.

Staphylococcal Food Poisoning

INTRODUCTION, EPIDEMIOLOGY, AND BACTERIOLOGY

Staphylococcal food poisoning is the second most common cause of reported food-borne illness in the United States.⁶⁴ The self-limited nature of this illness results in a low (10%) rate of presentation to health care facilities and, thus, a vast underreporting of the estimated 6 to 80 million cases that occur each year in the United States.⁶⁵

Approximately 2% to 5% of *S. aureus* isolates produce one of the seven identified heat-stable enterotoxins responsible for human disease.⁶⁶ One study of a large outbreak in California and Nevada has also identified and implicated an enterotoxin-producing strain of *Staphylococcus intermedius*.⁶⁷ Coagulase-negative staphylococci do not produce enterotoxins and have not been implicated in human food-borne illness.⁶⁸ Humans are the natural reservoir for *S. aureus*, although unpasteurized dairy products from cows with mastitis can also be a source of *S. aureus*.⁶⁸ Studies show that between 20% and 50% of healthy individuals are asymptomatic carriers of *S. aureus*.⁶⁹

S. aureus contamination occurs when a food handler, who is either a carrier of the organism or has an incidental infection (i.e., impetigo, cellulitis, or an open wound) inoculates the source food with bacteria. The food must maintain a permissive temperature for bacterial growth to allow elaboration of the toxin. For example, centralization of school lunch preparation—where lunches are prepared in one location and then distributed to satellite schools—was felt to contribute to a 1990 outbreak of staphylococcal enterotoxin A illness in two elementary schools in Rhode Island. Ham rolls in 662 lunches, inoculated by a contaminated food handler, were maintained at permissive temperatures for several hours while they were transported to the outlying facilities.⁷⁰

Optimum temperature for bacterial growth is 35° C to 40° C, but the organism can grow and produce toxin at temperatures between 3° C and 60° C.⁷¹ Thorough reheating before serving may kill the bacteria, but the heat-stable toxin will remain active. In a recent, large outbreak in the Kansai district in Japan linked to powdered skim milk produced at a factory in Hokkaido, staphylococci were killed by pasteurization at 130° C, but enterotoxin A remained in concentrations of 3.7 ng/g.⁷² Intake among cases was estimated to be 10 to 100 ng.

Foods rich in protein and sugars (e.g., poultry and ham), dairy products (e.g., milk, mayonnaise, cheese), or foods containing dairy products (e.g., sauces, desserts, dressings, and condiments) are most often implicated in *S. aureus* food poisoning.⁷⁰ However, any food may be implicated. For example, in a large European outbreak in 1984 that involved Great Britain, France, and Italy, packages of dried lasagna produced at a processing plant in Parma, Italy, were responsible for multiple mini-clusters of staphylococcal food poisoning.⁷³ This outbreak was a rare event both because of the implicated food item (dried pasta) as well as the point of contamination (during manufacture).

PATHOPHYSIOLOGY

It is well known that staphylococcal enterotoxins A through E and G through J, as well as toxic shock syndrome toxin (TSST, formerly staphylococcal enterotoxin F) act as superantigens and cause toxic shock by means of widespread T-cell activation and resultant cytokine elaboration. Superantigens bind nonspecifically to the T-cell receptor (TCR) of many T cells, resulting in unregulated activation of the inflammatory cascade. However, a different mechanism is implicated in the pathogenesis of staphylococcal food-borne illness, and is only now being intensively investigated. In vitro work has shown that enterotoxin B and TSST will undergo facilitated transport by intestinal lining cells (which lack both TCRs, as well as major histocompatibility complex class II molecules).⁷⁴ Mice fed staphylococcal enterotoxin B will demonstrate the presence of the toxin in the blood much more readily than will those fed staphylococcal enterotoxin A.⁶⁵ Staphylococcal enterotoxins are not cytotoxic to intestinal lining cells, nor do they stimulate fluid secretion in the gut by uncontrolled cycling of G proteins. Thus, the exact mechanism by which this family of toxins causes emesis and diarrhea remains elusive.

CLINICAL MANIFESTATIONS

The symptoms associated with staphylococcal food poisoning are the classic triad of abdominal pain and nausea, followed by vomiting and often diarrhea. Symptoms usually present between 2 and 6 hours after ingestion and are self-limited to 24 hours. Persistent symptoms should prompt a search for another cause. Significant morbidity is possible, especially in high-risk populations at greatest risk for dehydration, such as the very old and young and those with numerous comorbid conditions. About 9000 deaths a year occur as a result of staphylococcal food poisoning in the United States.

MANAGEMENT

Treatment is symptomatic and supportive.

Clostridium perfringens

INTRODUCTION, EPIDEMIOLOGY, AND BACTERIOLOGY

Clostridium perfringens food poisoning is another common, underreported cause of enterotoxin-mediated food poisoning. Data from 1988 through 1992 indicate that it was the second leading cause of food-borne disease.⁷⁵

C. perfringens is an anaerobic, gram-positive, spore-forming rod that is ubiquitous in the environment and is part of the normal intestinal flora of humans and many other organisms. In this respect, *C. perfringens* differs from *C. botulinum*, which is not considered normal gut flora. The bacterium is known to produce at least 13 different toxins that have been implicated in a number of human disease processes, including gas gangrene.⁶⁸ *C. perfringens* is subtyped into strains A through E, and an individual strain may only elaborate a limited repertoire of the 13 recognized toxins.⁶⁸ *C. perfringens* type A is the strain most often associated with production of the *C. perfringens* enterotoxin (CPE) implicated as the cause

of food poisoning.⁶⁸ While 90% of food poisoning isolates are type A, surveys of all *C. perfringens* cultures found the incidence of plasmids containing the *cpe* gene to be fewer than 5%.⁷⁶

Elaboration of enterotoxin occurs during spore formation, and sporulation is required for toxin release from the bacterial cell. The enterotoxin is thought to be a component of the spore coat. When heavily contaminated foodstuffs are ingested, the acidic environment of the stomach probably kills off large numbers of vegetative clostridial cells. However, if sufficient cells reach the small intestine, the bacteria may sporulate, and this leads to elaboration of the enterotoxin.⁷⁷ This second sporulation after ingestion suggests that CPE is not exactly a preformed toxin, but exerts its enterotoxigenic effect in such a fashion as to be indistinguishable clinically from ingestion of true preformed toxins associated with other infecting organisms.⁶⁸

C. perfringens tends to contaminate high-protein foods such as meats, poultry, stews, and gravies, because the spores tend to survive the kinds of temperatures associated with roasting. If the food is then left at room temperature, the spores will germinate and proliferate.⁶⁸ CPE is heat labile and is inactivated at temperatures greater than 75°C. The toxin has also been shown to be inactivated by freeze-thawing. However, these practices are unlikely to alter or prevent food-borne illness since secondary sporulation in the small intestine is the major source of synthesis and amplification of CPE production.

Improper food handling is the usual source for many food poisoning outbreaks. One of the first and best reported instances occurred in January 1964 at a college in Spokane, Washington.⁷⁸ Forty-seven students became ill with diarrhea (81.8%), abdominal pain (75.5%), and headache (40.0%) after eating lamb stew for lunch.

Roast pork was implicated as the source in a diarrheal illness that affected 17 patients in two orthopedic wards at a hospital in England in December 1989.⁷⁹ After isolating *C. perfringens* type A from the pork, an inspection of the processing plant showed that a quick-freezing “blast chiller” had been replaced by a slower “shower” that gradually lowered the cooked meats’ temperature to 2°C for packaging. Minced beef stew was implicated in a second large hospital outbreak in London in June 1989.⁸⁰ Sadly, 2 of the 58 ill patients died.

PATHOPHYSIOLOGY

The molecular mechanism by which CPE causes disease is not fully known. The toxin preferentially binds to intestinal lining cells of the ileum.⁷⁷ This results in the formation of a membrane complex that allows leakage of small molecules such as amino acids and ions.⁷⁷ In vitro work indicates that CPE does not affect fluid or electrolyte active transport,⁷⁷ nor does CPE act via cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP).⁶⁸ Fluids and electrolytes may passively follow the gradient set up by the membrane complex-mediated loss of small molecules, or the loss of brush border cells and compromised gut integrity may lead to passive fluid losses. The effect of CPE on the brush border ultimately leads to death and sloughing of the intestinal epithelium.⁷⁷

CLINICAL MANIFESTATIONS

Symptoms of *C. perfringens* food poisoning usually develop within 12 to 24 hours of ingestion. In vitro, however, CPE effects are seen in 15 to 30 minutes when applied to rabbit colon.⁷⁷ Diarrhea and abdominal cramps occur commonly, whereas nausea occurs only occasionally. Rarely, fever, chills, and vomiting may be present. In a November 1990 outbreak among conventioners in Michigan linked to minestrone soup, 32 of 42 attendees experienced diarrhea (94%) and abdominal pain (91%) a median 6.5 hours after the meal.⁸¹ Illness is generally self-limited and usually resolves within 24 hours. For instance, among 112 cases of clostridial-associated food poisoning after a firehouse luncheon in Maryland in 1984, illness lasted a mean of 21.2 hours after a median incubation period of 13.4 hours.⁸² Death is rare and more often occurs in elderly debilitated patients.⁸⁰

Serious hemorrhagic enteritis associated with toxins other than CPE has been associated with *C. perfringens* type C in both Germany and New Guinea.⁸³

MANAGEMENT

Care is generally supportive, with appropriate volume and electrolyte replacement.

Vibrionaceae

INTRODUCTION, EPIDEMIOLOGY, AND BACTERIOLOGY

Vibrios are halophilic (characterized by their salt requirement), motile, gram-negative rods endemic in many coastal areas worldwide, including coastal areas of the western and, more commonly, the southern United States. The family Vibrionaceae includes the genera *Vibrio*, *Aeromonas*, and *Plesiomonas*. Thirteen species of *Vibrio* have the potential to cause human disease: 10 species cause food-borne gastroenteritis or septicemia, while *Vibrio metschnikovii* and *Vibrio damsela* cause wound infections and otitis externa associated with exposure to contaminated water.⁸⁴ Vibrios are routine pathogens of seafood worldwide since they reside in the intestinal tracts of fish, in shellfish, and in plankton.

Between 1983 and 1992, seafood (including shellfish) was the third most common vehicle implicated in food-borne illness cases (see Chapter 25).⁸⁵ While the most frequently isolated pathogen in shellfish-implicated illness was a virus, 20% of shellfish-related infections were caused by naturally occurring bacteria and only 4% from fecal contaminating bacteria.⁸⁵ Reliance on levels of fecal coliform contamination in coastal and estuarine waters is not an accurate indicator of the risk of shellfish-associated illness because fecal contaminating organisms make up such a small percentage of pathogens.

Vibrio cholerae is still associated with large-scale morbidity and mortality in several parts of the world. Cholera is the exception to the fecal contamination rule of shellfish-related illness since the last seven worldwide cholera outbreaks have been related to sewage contamination. The main vehicle in cholera illness associated with the toxigenic 01 (epidemic biotype) strain is raw oysters.⁸⁵ The more common strains associated with GI illness in the United States include non-01 biotype

V. cholerae, *Vibrio parahaemolyticus*, *Vibrio mimicus*, *Vibrio fluvialis*, and *Vibrio hollisae*.⁸⁶

V. parahaemolyticus has been isolated from seafood all over the world. It is the leading cause of seafood-borne disease in Japan, and the leading cause of *Vibrio*-associated illness in the United States, followed closely by non-01 *V. cholerae*.⁸⁴ *V. parahaemolyticus* survives in slightly colder temperatures than other vibrios and has been isolated from northern U.S. coastal waters. While the organism will not multiply at temperatures below 10°C, intact organisms have been recovered from frozen shrimp.⁸⁵ In 1998 in New York, there was a summer outbreak of 23 laboratory-confirmed cases of *V. parahaemolyticus* infection. Harvested shellfish from Long Island Sound and particularly Oyster Bay were implicated in 22 of the 23 cases. A similar outbreak occurred in British Columbia and Washington State in August 1997, when 51 persons became ill from raw oysters harvested on the British Columbia coast.⁸⁷

PATHOPHYSIOLOGY

The mechanism by which *V. cholerae* 01 causes illness is well understood. Ingested organisms adhere to the intestinal lining epithelium and secrete a heterodimeric enterotoxin known as the cholera enterotoxin. One subunit of the cholera enterotoxin binds to ganglioside GM1 and facilitates entry of the active chain into the cell.⁸⁴ The active chain up-regulates adenylate cyclase, raising cAMP levels, which leads to uncontrolled chloride secretion into the lumen. Sodium absorption is coupled to chloride secretion, and its uptake into the cell is similarly impaired. Excess water follows the solute into the lumen. Ironically, it is absence or truncation of this chloride and water transmembrane transporter (cystic fibrosis transmembrane rectifier, or CFTR) that leads to lack of sufficient hydration of the mucus in the airways that characterizes classic cystic fibrosis. (The human impact of epidemic cholera in our past, and the high gene frequency of CFTR still maintained today, has led some anthropologists to hypothesize that while two copies of the defective gene confer the lethal recessive phenotype, carrier status for a defective CFTR may have conferred an evolutionary survival advantage against dehydration from cholera to past human populations.⁸⁸)

Much less is known about the toxin-mediated mechanisms of disease in non-01 *V. cholerae*, *Vibrio vulnificus*, and the minor *Vibrio* species. Polysaccharide encapsulation allows some pathogenic strains to evade the host defenses more effectively, and a capsule is associated with septicemia and extraintestinal manifestations.⁸⁴ *V. parahaemolyticus* causes diarrhea and gastroenteritis via a thermostable direct hemolysin enterotoxin, and this toxin is isolated from 96% of clinical isolates related to human illness, but only isolated from 1% of isolates in the environment.⁸⁴

CLINICAL MANIFESTATIONS

Symptoms of cholera usually occur within 24 hours of ingestion of all *Vibrio* organisms. With cholera, patients develop an intense watery diarrhea with profuse fluid

losses that may be as great as 1 L/hr. Severe cases (cholera gravis) often result in profound dehydration and death within 6 hours if not aggressively treated.

The signs and symptoms of noncholera, *Vibrio*-associated gastroenteritis almost always include diarrhea; vomiting, abdominal cramps, and fever are also common.⁸⁶ Bloody stool can also occur; as many as 86% of patients with *V. fluvialis* and 35% with *V. parahaemolyticus*-associated gastroenteritis develop bloody stool.⁸⁶ In the *V. parahaemolyticus* outbreak in New York in 1998, 17 of 23 patients (74%) with confirmed cases developed gastroenteritis a median of 19 hours after consumption of tainted shellfish; there were 2 patients (9%) with septicemia who had lower extremity edema and bullae.⁸⁹

MANAGEMENT

Treatment of gastroenteritis due to both cholera and noncholera *Vibrio* infections is generally supportive. Aggressive oral rehydration or intravenous fluids with isotonic saline, glucose, and electrolyte replacement are required. Administration of drugs that interfere with adenylate cyclase or electrolyte fluxes across gut epithelial cells may significantly decrease volume losses. Chlorpromazine, aspirin, indomethacin, and nicotinic acid all have been shown to be effective in treating cholera.⁹⁰ Epidemic cholera toxin-mediated diarrhea must be monitored for volume status since assumptions about the adequacy of rehydration efforts are always underestimated. Tetracycline will shorten the course of the diarrheal illness. The widespread use of tetracycline, however, has led to broad resistance patterns.⁸⁴

In non-01 *Vibrio*-associated gastroenteritis, supportive therapy is usually adequate. Special attention, however, must be given to patients at high risk for septicemia and shock (e.g., alcoholics, a history of liver disease, immunosuppression, and extremes of age). If a patient with a history of seafood consumption presents with GI signs or symptoms (particularly bloody diarrhea) and is at higher risk for severe illness, empiric treatment with tetracycline and an aminoglycoside is recommended. If systemic signs or symptoms of illness are present (e.g., shock, edema, and/or bullae), antibiotic treatment is clearly indicated.

Bacillus cereus

INTRODUCTION, EPIDEMIOLOGY, AND BACTERIOLOGY

Bacillus cereus is an aerobic, gram-positive, spore-forming rod that is ubiquitous in the environment and causes two distinct food-borne illness syndromes. These clinically and epidemiologically different illnesses are also associated with different foodstuffs. The rapid onset of emetic illness resembles staphylococcal food poisoning, while the delayed diarrheal disease mimics *C. perfringens* food poisoning. For this reason, *B. cereus* is an infrequently reported cause of food-borne illness outbreaks.⁹¹

In 1993, 14 of 67 children and daycare workers who ate a catered lunch with fried rice at two centers in Fairfax, Virginia, became ill with vomiting a median 2 hours after the meal and had resolution of symptoms a

median of 4 hours after onset.⁹² Fried rice is the foodstuff usually associated with the emetic form of *B. cereus* infection.⁷⁵ Rice that is cooked (boiled or steamed) and then cooled allows the spores of *B. cereus* to multiply and elaborate enterotoxins, including the emetic toxin cereulide. Subsequent reheating, such as pan frying, may not be enough to inactivate the toxins. Chinese food was implicated in 24 of 58 separate outbreaks in the United States between 1973 and 1987.⁹³ Measures of toxin production in foods implicated in 14 food-borne outbreaks have documented levels ranging from 10 to 1280 ng/g, and toxin titer correlates with the viable colony count of *B. cereus*.⁷⁶ Fried rice, boiled rice, dumplings, pasta, bread, noodles, tempura, and soba appear to yield the highest toxin production. Bacterial growth and toxin production are relatively inhibited on meat and eggs, milk products, and vinegar-, mayonnaise-, and tomato-based dishes.⁷⁶

In a food-borne outbreak in Quebec in 1999, 25 of 37 diners at a catered banquet became ill with diarrhea (100%), abdominal pain (100%), and nausea (20%) within 24 hours.⁹⁴ Mayonnaise used in potato salad grew *B. cereus*. Another caterer was implicated as the source of a hospital cafeteria outbreak in October 1985 in Memphis, Tennessee. One hundred sixty of 249 hospital employees who ate an ethnic meal on either the day shift (lunch) or evening shift (dinner) suffered diarrhea and abdominal pain within 24 hours of their individual meal.⁹⁵ Food items maintained at moderate heat during delivery were implicated in an unusual outbreak associated with Meals-on-Wheels in England in November 1976.⁹⁶ Forty-nine of 160 elderly people developed diarrhea and abdominal pain a mean 7 hours after eating; 1 woman was found dead. *B. cereus* was isolated from several patients and the leftovers of one refrigerated meal.⁸³

PATHOPHYSIOLOGY

Illness due to *B. cereus* is via the elaboration of two distinct enterotoxins. The emetic toxin cereulide is a 12-amino acid, hydrophobic, highly heat-stable toxin that causes a self-limited vomiting-type illness.⁹⁷ In vitro research suggests that cereulide may act as a potential potassium ionophore,⁷⁶ and may be a mitochondrial poison that uncouples oxidative phosphorylation.⁹⁸

In contrast to the emetic form of *B. cereus* food poisoning, the diarrheal syndrome of *B. cereus* may be caused by one or more heat-labile enterotoxins. Research has found two similar polypeptide toxins, a hemolytic enterotoxin (HBL) and a nonhemolytic enterotoxin (NHE), to be implicated in *B. cereus* diarrheal food poisoning. The mechanism by which this family of enterotoxins causes diarrheal disease is not well known; however, both HBL and NHE are heterotrimers, and all three peptide chains are required for toxin activity.⁶⁸ Similarities to other biologic protein toxins suggests that one peptide chain is responsible for translocation into the cell while another or both exert the cytotoxic effect.

CLINICAL MANIFESTATIONS

The emetic form of *B. cereus* food poisoning has a more rapid onset and shorter clinical course than the diarrheal

form. Patients usually become ill within 1 to 5 hours of tainted food ingestion and recover within 24 hours. Diarrhea and abdominal cramps may occur but are not a prominent feature of the emetic form. Despite the apparent innocuous nature of the emetic form of *B. cereus* food poisoning, serious illness is reported. For instance, death from liver failure occurred in a 17-year-old after infection.⁹⁹

The diarrheal form of disease is associated with a broader array of foodstuffs: meat, poultry, eggs, casserole, puddings, and dairy products. After an incubation period of 8 to 24 hours, the symptoms of diarrhea and crampy abdominal pain predominate, with nausea present in a minority of patients.

As with the emetic form of the illness, recovery is usually complete within 24 hours of symptom onset.

DIAGNOSIS

B. cereus food poisoning may be diagnosed by isolation of greater than or equal to 10⁵ organisms per gram of food. The diagnosis in outbreaks of the emetic form, however, may prove difficult if sufficient reheating has killed the organisms but has not inactivated the heat-stable toxin, cereulide. In these instances, testing for the toxin by means of the HEp-2 vacuolation assay may be diagnostic. In suspected outbreaks of the diarrheal form of *B. cereus* food poisoning, stool culture may be more reliable. Commercial assays for the detection of the hemolytic enterotoxin (latex agglutination) and the nonhemolytic enterotoxin (enzyme-linked immunosorbent assay) are available as a public health laboratory tool.⁶⁸

MANAGEMENT

Most cases of *B. cereus* food poisoning are mild and self-limited; treatment is supportive.

Salmonella, Shigella, and Campylobacter

Salmonella, *Shigella*, and *Campylobacter* are the most common forms of acute infective bacterial GI illness in the United States.¹⁰⁰ The three genera are remarkably similar in many ways, including source of infection, symptoms of illness, localized invasion of the bowel epithelium, and duration of disease. The clinical syndromes associated with these enteroinvasive pathogens are similar. Toxin-mediated pathophysiology can play a minor role in food-borne illness (*Salmonella* species), or it may lead to serious sequelae, as in the case of Shiga toxin and Shiga-like verocytotoxins.⁶³ The three infective bacterial food-borne pathogens are presented here with an emphasis on their toxin-mediated effects.

SALMONELLA

Introduction, Epidemiology, and Bacteriology

Salmonellae are motile, gram-negative rods that are ubiquitous in nature and are known to colonize the intestinal tracts of a wide variety of organisms, including mammals, reptiles, and even insects.¹⁰¹ The bacterium is resistant to freezing and drying but is rapidly killed by high temperatures. More than 2000 serovars of *Salmonella*

have been identified; the most common associated with food-borne illness are caused by *Salmonella enteridis*, *Salmonella typhimurium*, and *Salmonella paratyphi*.⁸⁶

Salmonella species were the most frequently isolated food-borne pathogen in the United States between 1988 and 1992.⁵⁹ From 1992 to 1995, the incidence of both *Salmonella* and *Shigella* infections (both notifiable illnesses) increased in the United States.¹⁰² The Foodborne Diseases Active Surveillance Network (FoodNet) 1996 data indicate that salmonellosis had the second highest incidence rate (16 per 100,000 population) among the top seven pathogens isolated at monitored sites.¹⁰³

In 1984, in Oregon, *Salmonella* was used as a biologic weapon; it was released on the population of several towns in an attempt to influence voter turnout in favor of candidates from a particular religious commune in the county.⁶² The disparate sources of infection at several nonchain restaurants, and the panantibiotic sensitivity of the *Salmonella* strain involved raised suspicion among public health authorities. Two years later, during a raid on the groups' compound, the offending strain of *Salmonella* was found in their infirmery freezer. The cult's chief scientist and a clinician were convicted of orchestrating the attack.¹⁰⁴

The two most common sources of salmonellosis are food or water contaminated with the organism. Transmission normally occurs via the fecal-oral route. Food sources commonly associated with outbreaks include raw or undercooked eggs, unpasteurized milk and dairy products, and various meats, especially poultry.⁸⁶ A study conducted in homes in four U.S. cities demonstrated significant levels of *Salmonella* (4.5×10^2 colony-forming units per mL) in the dishwasher wrung from used sponges and cotton dishtowels in 15.4% of the samples taken.¹⁰⁵

Sources implicated in the fecal-oral route include household dogs and cats and occasionally uninfected carriers, particularly children in daycare settings.⁸⁵ In the past, a number of infections were associated with pet turtles, which led to a prohibition of their sale in the United States.⁸⁵

Pathophysiology

Once ingested, the *Salmonella* bacterium must survive the host defenses, including gastric acidity and competition with normal flora. Medications that raise gastric pH may reduce the inoculum required.¹⁰⁶ Once past the gastric barrier, the organisms multiply in the small intestine and penetrate the intestinal mucosa, where they proliferate within mesenteric lymphoid tissue.¹⁰⁷ The majority of infections do not spread beyond the local lymphoid tissue. The actual mechanism by which *Salmonella* causes diarrhea is not well understood but may involve local infiltration of polymorphonuclear leukocytes and release of prostaglandins, which increase intestinal fluid secretion.⁹² It has been demonstrated that *S. typhimurium* produces a cholera-like enterotoxin, but its role in vivo is not clear.⁹²

Clinical Manifestations

Salmonella gastroenteritis has an incubation period of 5 to 72 hours. Symptoms of disease generally last from

2 to 5 days, but in certain cases, an asymptomatic carrier state may persist for as long as a year.⁸⁶ Nausea and vomiting are the most common symptoms and are usually followed by low-grade fever, chills, abdominal pain, and diarrhea.⁸⁶ In the largest single outbreak of food-borne illness aboard commercial airliners, 186 passengers on 29 transatlantic flights developed diarrhea (99%), abdominal pain (98%), fever (90%), and vomiting (58%) a median 2 to 72 hours after the planes landed.¹⁰⁸ The planes all originated in London and disembarked at 11 U.S. cities. The first-class meal was associated with illness, presumably due to its maintenance at a permissive temperature, and *Salmonella* was isolated from 56 (30%) cases.¹⁰⁸ In the same researchers' subsequent literature review, in 23 reported aircraft-involved food-borne outbreaks, *Salmonella* was the most frequently isolated pathogen ($n = 7$), followed by staphylococci ($n = 5$) and *Vibrio* species ($n = 5$).

Enteric (typhoid) fever, commonly associated with *Salmonella typhi* infection and popularized by the asymptomatic carrier Typhoid Mary, is a more severe form of salmonellosis associated with a longer incubation period (1 to 2 weeks), sustained fever, malaise, weakness, bacteremia, and occasionally shock and multiple organ dysfunction.⁸⁵ The largest U.S. outbreak of typhoid fever occurred at a New York hotel during a convention on July 13, 1989.¹⁰⁹ The incubation period was up to 3 weeks in conventioners who had consumed the contaminated orange juice at a breakfast.¹⁰⁹ While typhoid fever outbreaks do occur, the incidence of typhoid among returning travelers from endemic areas is in decline; an oral vaccine (TY21a, or Vivotif [Berna Biotech, Berne, Switzerland]) with 70% efficacy for a period of 3 to 5 months may account for the decrease.¹¹⁰

The course of the disease is more severe and protracted in the very young, the elderly, and immunocompromised patients. Patients with acquired immunodeficiency syndrome and patients with certain hemolytic anemias such as sickle cell anemia are at a much higher risk for developing *Salmonella* bacteremia owing to decreased clearance by the autolyzed spleen.¹¹¹ *Salmonella* is the most frequently isolated pathogen from patients with sickle cell disease who develop osteomyelitis.¹¹²

Diagnosis

The diagnosis of *Salmonella* gastroenteritis is based on a patient's history, and confirmation of diagnosis requires stool culture. Microscopic examination of the stool usually reveals fecal leukocytes, and the stool may contain occult blood.

Management

In most cases, the treatment of salmonellosis is supportive, with fluid and electrolyte replacement as needed. Antibiotics are not recommended in uncomplicated cases because they do not alter the severity of disease and may prolong the carrier state. Antibiotics are reserved for more serious cases such as those associated with significant colitis, or cases in high-risk patients.⁸⁶ First-line therapy in typhoid fever is a third-generation cephalosporin. Antimotility agents, which slow intestinal transport times, may lead to intestinal perforation and

are not recommended in cases of invasive diarrheas such as salmonellosis.

SHIGELLA

Introduction, Epidemiology, and Bacteriology

Members of the genus *Shigella* are small, nonmotile, gram-negative rods that are very similar morphologically and biochemically to *E. coli*. Four different species are associated with human infection: *Shigella dysenteriae*, *Shigella flexneri*, *Shigella sonnei*, and *Shigella boydii*. *S. sonnei* and *S. flexneri* are responsible for the majority of cases in the United States.¹¹³ FoodNet data from 1996 and 1997 showed shigellosis to have the third highest incidence (7.8 per 100,000 population) among the seven pathogens tracked at surveillance sites.¹¹⁴ A more severe form of infection, bacillary dysentery, is often associated with *S. dysenteriae* infection. The organism has a very low infectious dose, and disease developed in some volunteers fed as few as 100 organisms.⁹³

The fecal-oral route is the primary mode of transmitting *Shigella* infection. The majority of infections are spread by consumption of food or water contaminated with fecal material from an infected individual. *Shigella* outbreaks commonly occur in daycare centers, mental health institutions, prisons, and nursing homes, where overcrowding, poor hygiene, and unsanitary conditions may exist.⁹³

Outbreaks have been associated with various contaminated foods, and reports indicate that *Shigella* can live for many days on certain foods outside of its normal human host.

Pathophysiology

Shigella organisms possess a high degree of acid resistance and as such are able to survive passage through the acidic gastric barrier quite well. Once ingested, the organisms invade the epithelial lining cells of the intestine, multiply intracellularly, and spread to surrounding cells. Local damage to intestinal epithelium and superficial erosion of the intestinal mucosa are responsible for the presence of blood and fecal leukocytes in the stool.

S. dysenteriae produces the potent cytotoxin Shiga toxin. Shiga toxin is one of a number of naturally occurring cytotoxins that inhibit protein synthesis by inactivating the ribosome (ribosomal inhibitory protein II, or RIP II).¹¹⁵ This family of heteromeric polypeptides includes various plant-derived RIP IIs such as the toxalbumins (*Abrus precatorius*, *Viscum album*), of which ricin (*Ricinus communis*) is the most common.

Heterodimeric toxins in this family enter the cell (after binding of the B chain) via endocytosis, and are actively transported in retrograde fashion by carriers through the Golgi apparatus to the endoplasmic reticulum (ER).⁶³ Once the toxin reaches the ER, the A chain binds to the 60S subunit of the ribosome. The active site of the toxic A chain removes an adenine from the nascent 28S RNA, which prevents the attachment of elongation factor 2 (EF-2).¹⁰⁰ Left unprotected by EF-2, the RNA is rapidly degraded and protein synthesis

halted. In the intestinal lining cells of the gut, Shiga toxin's B chain binds to the neutral glycosphingolipid Gb3 to facilitate entry, and the A chain must be cleaved to an A1 fragment before it can bind to the ribosome.⁶³

Shigalike toxins (SLTs), also known as verocytotoxins because they act on Vero cells, may be elaborated by certain strains of enterohemorrhagic *E. coli* (EHEC).⁶³ SLTs are cytotoxic to a range of endothelial cells, whereby they cause end-organ injury. The two best studied of these SLTs (SLT-I and SLT-II) are associated with EHEC strain 0157:H7.⁶³ These toxins damage endothelial cells in the kidney, leading to renal failure, and vascular endothelial cells, causing microangiopathic anemia and thrombocytopenia: the hemolytic uremic syndrome. Another porcine strain of EHEC produces a variant SLT-IIv, which causes massive edema.⁶³

Clinical Manifestations

The incubation period in shigellosis is usually 24 to 48 hours. The clinical presentation has a wide spectrum; some individuals have nonspecific symptoms and a short course of watery diarrhea only.¹¹³ More severe forms of the disease may progress to true dysentery, including high fever, tenesmus, nausea, abdominal pain, and profuse watery diarrhea that evolves over hours to a few days to mucoid, bloody stools.¹¹³ Untreated shigellosis is usually self-limited, and the illness usually persists for 1 week. An individual may continue to shed organisms in the stool for several weeks after clinical infection subsides. Laboratory findings may include leukocytosis and the presence of fecal leukocytes in addition to occult or grossly bloody stool. Complications include seizures (especially in children), dehydration, and death in the very elderly or in children younger than 1 year.¹¹⁶

Diagnosis

Shigellosis is the principal bacterial cause of dysentery and should be suspected whenever a patient presents with bloody diarrhea. The diagnosis is based on culture of *Shigella* from stool. Diagnosis may also be suspected when polymerase chain reaction or commercial enzyme immunoassay techniques detect Shiga family toxins in stool.

Management

Treatment for shigellosis is initially supportive, with attention to correcting fluid and electrolyte abnormalities. Antibiotic therapy has been shown to improve the clinical course of the disease, but patients are often already improving when culture results become available. Antibiotics are therefore reserved for patients who are not showing signs of improvement or who have more severe forms of infection. All individuals who have culture-proven *S. dysenteriae* or those with other *Shigella* species who are at high risk for infecting others should receive antibiotics. Specific antibiotics recommended include fluoroquinolones (i.e., ciprofloxacin, 500 mg/day for 5 days in adults), ampicillin (50 to 100 mg/kg/day in children or 2 g/day in adults for 5 days), or trimethoprim-sulfamethoxazole (5/25 mg/kg po bid in children or 160 mg TMP/800 mg 5MX po bid in adults

for 5 days). *Shigella* infection is an invasive enterocolitis and, as such, antimotility agents are not recommended. Recommendations for children in daycare centers with culture-proven *Shigella* require antibiotic therapy and repeat negative follow-up cultures before returning to daycare.¹¹³

CAMPYLOBACTER

Introduction, Epidemiology, and Bacteriology

Campylobacter species are small, motile, curved or S-shaped, gram-negative bacteria. *Campylobacter* enteritis is today one of the most commonly identified bacterial causes of diarrhea. Human disease is most commonly caused by *Campylobacter jejuni*, which is a part of the normal flora of a wide variety of animals including cattle, sheep, pigs, and poultry.¹¹⁷ *Campylobacter* may also be found in unpurified drinking water such as that in rural areas or in contaminated springs, and unpasteurized dairy products from infected animals.⁹⁶ The primary mode of transmission of *Campylobacter* is fecal-oral.

In addition to infection from contaminated drinking water, various foods are associated with infection. Food may become contaminated with organisms at slaughterhouses whenever improper handling occurs or when intestinal spillage comes into contact with animal carcasses. Contaminated meat and poultry products are commonly associated with infection. *Campylobacter* does not proliferate on foods that it has contaminated as do other enteric organisms such as *Salmonella* species, *Bacillus* species, and *S. aureus*. The organism may actually survive longer if refrigerated and can survive in water or unpasteurized milk for weeks.¹¹⁶

Campylobacteriosis was the most frequently isolated food-borne pathogen (incidence 24.7 per 100,000 population) by the FoodNet sites in 1996 and 1997.¹⁰³

Clinical Manifestations

Fever, headache, malaise, myalgias, and cramping abdominal pain usually occur in the first 48 hours after ingestion of an infectious dose of organisms.¹¹⁸ Diarrhea usually presents within 24 hours after the onset of abdominal pain and may be described as watery, bile stained, mucoid, or grossly bloody.¹¹⁸

Clinical disease usually does not persist for more than a week. Relapse is not uncommon, and the organism may be shed for several weeks in the stools of asymptomatic individuals.

Diagnosis

The definitive diagnosis of *Campylobacter* enteritis is based on identification of the organism on stool culture.

Management

Treatment is primarily supportive; fluid and electrolyte repletion should be provided as necessary. The clinical benefit of antibiotic therapy for *Campylobacter* enteritis is not fully known; it is recommended for patients with significant local (e.g., bloody diarrhea) or systemic illness (e.g., high fever, toxic appearance) and protracted symptoms (e.g., beyond 7 days). First-line

therapy is erythromycin (adult, 500 mg erythromycin stearate, base or salt orally every 8 hours for 5 to 7 days; child, 30 to 50 mg/kg/day base orally divided every 6 to 8 hours for 5 to 7 days not to exceed 1 g/day). Alternative therapies include other macrolides (e.g., clarithromycin or azithromycin) or fluoroquinolones (e.g., ciprofloxacin). Full recovery is expected for nearly all patients, regardless of treatment with antimicrobial therapy.

SECTION B

CENTRAL NERVOUS SYSTEM

27

Tricyclic and Other Cyclic Antidepressants

D. ERIC BRUSH, MD ■ CYNTHIA K. AARON, MD

At a Glance...

- Primary toxicity related to sodium channel blockade and subsequent effects on cardiac cell depolarization leads to ventricular dysrhythmias. Sodium channel blockade, GABAergic effects, and biogenic amine reuptake effects lead to seizures.
- Secondary toxicity from inotropic depression and vascular dilation leads to profound hypotension.
- Hallmark of toxicity seen on electrocardiogram is QRS prolongation and rightward axis deviation of the terminal 40 msec of the QRS complex.
- Those at highest risk for seizures and ventricular dysrhythmias have a QRS greater than 100 msec or a terminal R wave in aVR greater than 3 mm.
- Sodium bicarbonate is the primary treatment modality for severe intoxication.
- Signs of significant toxicity mandate continuous monitoring until symptom free for 24 hours.

Toxicity due to cyclic antidepressant (CA) overdose dates back to 1959, shortly after the introduction of the antidepressant imipramine.¹⁻³ For several years preceding 1993, antidepressants were deemed responsible for the majority of deaths due to prescription drug overdose in the United States.^{4,5} More recently, the number of deaths from antidepressants, including cyclic and noncyclic compounds, has been superseded by analgesic medications, although the number of reported exposures involving antidepressants has not significantly decreased.⁶ Evolving epidemiology of antidepressant mortality may be due in part to prescribing practices. Preferential prescription of selective serotonin reuptake inhibitors (SSRIs) for depression, with their improved safety profile compared with cyclic antidepressants, may partly explain this trend. Some data suggest that the death-to-

prescription ratio for CAs exceeds that of other antidepressant classes.⁷ Nevertheless, physicians continue to prescribe CAs for depression as well as for neuropathic pain, migraine, obsessive-compulsive disorder, enuresis, and a variety of other maladies. The actual number of prescriptions written for CAs is unknown, which limits interpretation of poison center data regarding exposures and deaths. This fact, coupled with underreporting of exposures and deaths to poison centers, makes conclusions regarding decreased exposure versus improved treatment impossible.⁸ Among the antidepressant class of medications, CAs still account for the highest number of deaths. However, according to data from the Toxic Exposure Surveillance System (TESS), the number of deaths caused by SSRIs is gradually approaching that of CAs.⁶ Although deaths from CAs have decreased in recent years compared to the 1980s, the number of deaths has remained fairly constant over the last decade, with approximately 100 deaths per year reported by the TESS.^{4,6,9-16} These data are based on exposures reported to poison centers and require careful interpretation.

The number of children under 6 years of age exposed to CAs has remained relatively constant over the last few years according to TESS data. The majority of these cases are accidental exposures involving small ingestions or possibly no ingestion. The 2002 TESS data reports 1573 exposures to CAs in children less than 6 years of age.⁶ The only deaths occurred from malicious poisonings. A 5-year retrospective study (years 1993 to 1997) of a single poison center's data regarding ingestions of tricyclic antidepressants (excluding monocyclic and tetracyclic drugs) in children less than 6 years of age revealed no deaths.¹⁷ The majority of the children (92%) were asymptomatic, while the remaining patients exhibited mild sedation. Ninety percent of patients in this study ingested less than the age-appropriate dose. Although this study represents a small sample of patients in a retrospective poison center-based review, it identifies the typical features of CA exposure in young children: small

dose and low toxicity. Regardless, exposure histories in young children are difficult to elicit. One or two tablets may be sufficient to cause life-threatening toxicity in small children. Therefore, all exposures in this age group require careful evaluation.

STRUCTURE

Tricyclic antidepressants (TCAs) are a class of drugs that contain a three-ringed nucleus with various side chains and atomic substitutions (Fig. 27-1). The term *cyclic antidepressant* is more encompassing and includes drugs with ring structures beyond the three-ringed TCA nucleus (see Fig. 27-1). These include tetracyclic drugs such as amoxapine, maprotiline, and mirtazapine and bicyclics such as mianserin. The TCAs are broadly classified as secondary or tertiary amines in reference to the number of methyl groups on the propylamine side chain of the structure. The tertiary amines are imipramine, amitriptyline, clomipramine, chloripramine, doxepin, dothiepin, lofepramine, and trimipramine. The secondary amines include desipramine, nortriptyline, and protriptyline. In vivo demethylation of the tertiary amines amitriptyline and imipramine produces the active secondary amines nortriptyline and desipramine, respectively. Metabolism via hydroxylation creates multiple active metabolites (Table 27-1). Intermediate structures display differing degrees of pharmacodynamic actions; the extent of cholinergic receptor blockade in decreasing order of effect is tertiary amine > secondary amine > demethylated metabolites > hydroxylated metabolites.¹⁸⁻²⁰

Structural similarities between CAs and phenothiazines as well as other classes of antipsychotic medications yield a likely explanation for shared toxicity as well as cross-reactivity in immunoassays. Anticholinergic, antihistaminic, and some cardiovascular effects such as sodium channel blockade, QT_c prolongation, and peripheral α blockade are shared to various extents by medications from these classes.

PHARMACOLOGY

Pharmacodynamics

Cyclic antidepressants exert their therapeutic action in part by producing varying degrees of reuptake inhibition of norepinephrine, dopamine, and serotonin at nerve terminals in the central nervous system (CNS). While this mechanism of action forms the basis of the monoamine hypothesis of depression, it describes only one of the many effects CAs exert in vivo. Although the monoamine hypothesis remains a likely explanation for much of the therapeutic benefit of antidepressants, alterations in other CNS signaling pathways have recently been discovered and may significantly contribute to drug efficacy in depression. The identification of γ -aminobutyric acid (GABA) and its putative role in depression has recently been elucidated through human brain scans and cerebrospinal fluid analysis as well as in vivo animal and in vitro models.²¹ These studies demonstrate that CAs inhibit the influx of chloride through the GABA chloride channel.²² The extent to which the GABAergic system modulates depression is unclear. This drug effect provides a potential explanation for CA-induced seizures. Additional pharmacologic activity of CAs includes blockade of cholinergic, histaminic, and α_1 -adrenergic receptors. Chronic antidepressant dosing alters CNS neurotransmitter receptor expression and sensitivity. Effects on the neurohormonal system have been demonstrated in animal models; CAs have been shown to alter glucocorticoid mRNA receptor expression.^{23,24} The significance of this alteration is unknown.

Differences among CAs regarding their effects on neurotransmission are detectable at therapeutic dosing. The nontricyclic antidepressants amoxapine and maprotiline primarily affect norepinephrine while having no effect on serotonin. Amoxapine and its 7-OH-amoxapine metabolite block dopamine receptors to degrees comparable to thioridazine and haloperidol, respectively.²⁵ All CAs produce some degree of sodium channel blockade in the central and peripheral nervous tissue at

FIGURE 27-1 Structures of some cyclic antidepressants.

**TABLE 27-1** Pharmacokinetic Parameters of Selected Cyclic Antidepressants

DRUG	ELIMINATION HALF-LIFE (hr)*	THERAPEUTIC LEVEL (ng/mL) [†]	CYP METABOLISM [‡]	PRINCIPAL ACTIVE METABOLITES
Amitriptyline	9–25	125–150	1A2, 2C19, 3A4, 2D6, 2C9	Nortriptyline 10-OH amitriptyline 10-OH nortriptyline
Amoxapine	8, (30), (6.5)	160–800	2D6	8-OH amoxapine 7-OH amoxapine
Clomipramine	21, (36)		1A2, 2C19, 3A4, 2D6	Desmethylclomipramine
Desipramine	13–23	50–300	2D6	2-OH desipramine
Dothiepin	14–24 (23–46)	50–150		Desmethyldothiepin Dothiepin-5-oxide
Doxepin	8–24	75–200	2D6	Desmethyldoxepin
Imipramine	18–34 (12–30)	150–300	1A2, 2C19, 3A4, 2D6	Desipramine 2-OH imipramine 2-OH desipramine
Lofepramine	1.5–2.5 (12–30)		2D6	Desipramine
Maprotiline	43 (60–90)	50–300		Desmethylmaprotiline
Nortriptyline	16–36	50–150	2D6	10-OH nortriptyline
Protriptyline	55–198	50–150	2D6	
Trimipramine	23	30–170	2D6	Desmethyltrimipramine
Mirtazapine	20–40		2D6, 1A2, 3A4	Dimethylmirtazapine

CYP, cytochrome P-450.
^{*}Numbers in parentheses represent the half-life of the metabolites.
[†]Data are based on small numbers of usual concentrations and may not reflect optimal dosing. Therapeutic concentrations are not well established.
[‡]Metabolic pathways are not fully established for all drugs.

therapeutic dosing. This “membrane stabilizing” or “quinidine-like” effect leads to ventricular dysrhythmias in the setting of overdose. The efficacy of CAs for the treatment of neuropathic pain may stem from this effect.

Pharmacokinetics

Cyclic antidepressants share similar pharmacokinetic parameters. Following oral administration, drug absorption proceeds rapidly,²⁶ with the exception of the sustained-release (SR) formulation of clomipramine (Anafranil Retard), which has a delayed time to maximum concentration (T_{max}) of 9 hours versus 4.8 hours with the immediate-release (IR) formulation.²⁷ Currently, clomipramine SR is available only in the United Kingdom. Peak serum concentrations of other CAs are generally achieved within 2 to 6 hours.²⁶ All drugs in this class are highly lipophilic with a large apparent volume of distribution and rapid tissue redistribution.²⁶ Typically, CAs exhibit a volume of distribution between 10 and 20 L/kg. Tissue concentrations often exceed serum concentrations by 10- to 100-fold. The fraction of drug in the serum is highly protein bound.²⁶ Since CAs are weak bases, they are bound to α_1 -acid glycoprotein in the intravascular compartment. The fraction of free drug in the serum can be altered with changes in serum pH. Lowering pH creates a higher unbound fraction. Implications of acid-base status for overdose management are discussed in later sections.

Elimination is almost entirely hepatic, with little unchanged drug excreted in the urine. CAs do not undergo biliary excretion in any appreciable amount.²⁸

Biotransformation of CAs occurs via the hepatic micro-oxygenase P-450 enzyme system, and first pass metabolism significantly reduces their oral bioavailability.^{29–31} Many CAs form active metabolites following demethylation or hydroxylation (see Table 27-1). Active metabolites may accumulate after a period of 12 to 24 hours and could result in significant toxicity in therapeutic dosing.^{32,33} The most common hepatic enzyme isoforms involved in the biotransformation of CAs are CYP2D6 and CYP2C19.³⁴ Hydroxylation occurs via CYP2D6, whereas the 2C19 isoform is associated with *N*-demethylation.²⁶ CAs inhibit CYP2D6 and CYP2C19 activity.³⁵ Genetic polymorphisms in certain cytochrome P-450 (CYP450) enzymes alter the kinetics of hydroxylation for some CAs.³⁶ In the United States, 90% to 95% of people are “rapid hydroxylators.” In that population, the half-life of desipramine is 13 to 23 hours, whereas the half-life in the subpopulation of “slow hydroxylators” is 81 to 131 hours.³⁷ Cases of slow recovery from desipramine overdose³⁸ and toxicity from therapeutic dosing³⁹ have been reported in slow hydroxylators. Those with genetic defects in CYP2C19 activity have significantly higher plasma concentration curves of amitriptyline compared with normals.³⁴ Age presents an additional variable that alters serum concentrations of parent drug and metabolites. Across all age groups an increase in serum concentrations of drug and metabolite is seen with increasing age when dosing is weight adjusted. More efficient hepatic biotransformation and renal clearance in children compared with adults likely explains this phenomenon.⁴⁰ Half-life of elimination for therapeutic doses of CAs averages 8 to 30 hours with extension to 55 to 127 hours

for protriptyline. The same drugs have longer half-lives in the elderly.^{41,42} The prolonged elimination half-lives in this population may lead to drug accumulation with daily dosing.²⁶

Toxicokinetic parameters for CAs are altered in the setting of overdose. The anticholinergic properties of CAs may lead to delayed gastric emptying, possibly prolonging the absorptive phase, enhancing overall absorption, and delaying time to peak serum concentrations.²⁶ The onset of toxicity after overdose is typically rapid, and most deaths occur within the first 6 hours postingestion. An increased bioavailability following overdose may result from a decreased first pass metabolism as hepatic enzymes become saturated.⁴³ Since the unbound fraction of CAs increases with an acid medium, acidemia will enhance overall toxicity.

Kinetics in the postmortem state are dramatically altered. In the steady state, CAs are normally highly tissue bound. Following death, tissues release bound drug, creating a false elevation in serum drug levels. The serum concentrations increase as time proceeds post-mortem. This can lead to confusion regarding the manner of death. Strategies for postmortem laboratory analysis are further discussed under Diagnosis.

Drug Interaction

Potential drug-drug interactions may develop through various mechanisms (Table 27-2). Competitive inhibition of CYP isoforms could lead to increased toxicity of CAs or the drugs with which they compete for enzymatic biotransformation. The competitive inhibition of CYP2C19 by imipramine and nortriptyline has resulted in elevated phenytoin concentrations in some patients.^{44,45} Induction of CYP isoforms by CAs may, conversely, lead to decreased effectiveness of other medications. Additional drug interactions include medications that may potentiate the serotonergic or sympathomimetic properties of CAs, such as monoamine oxidase inhibitors (MAOIs), SSRIs, amphetamines, and others.

TOXICOLOGY

The most severe toxicities from CA overdose include hypotension, dysrhythmia, coma, seizures, and hyperthermia. Cardiovascular toxicity results primarily from effects on the cardiac cell action potential, negative inotropy, direct effects on vascular tone, and indirect effects mediated by the autonomic nervous system. CNS toxicity is less well understood and is likely a combination of effects on cholinergic and GABA neurotransmission along with sodium channel effects. Deaths are often a result of refractory hypotension.

Cardiovascular System Toxicity

CARDIAC CELL ACTION POTENTIAL

CAs alter the cardiac conduction system in a myriad of ways. The most distinctive toxicity relates to the inhibition of the fast sodium channels in the His-Purkinje tissue, leading to a slowing of phase 0 depolarization.^{46,47} This “membrane stabilizing” or “quinidine-like” effect is analogous to that of Vaughn Williams (VW) class I antidysrhythmic drugs.⁴⁸ Impaired depolarization of cells within the His-Purkinje system slows the propagation of ventricular depolarization. This appears on the electrocardiogram (ECG) as prolongation of the QRS interval, the hallmark of TCA toxicity. The degree of conduction delay is rate-dependent and worsens with tachycardia.⁴⁹ The QRS morphology is generally that of nonspecific intraventricular conduction delay, with discrete bundle branch block being less common. However, the longer refractory period of the right bundle relative to the left leads to the characteristic rightward axis deviation of the terminal 40 msec of the QRS complex seen in many patients with TCA toxicity.⁵⁰ On the ECG this appears as an increased R wave amplitude in lead aVR and a deep S wave in leads I and aVL (Fig. 27-2).⁵¹ A less specific finding is prolongation of the corrected QT interval (QT_c). This delay in myocyte repolarization may result from a direct effect of CAs on potassium channels.^{52,53} A prolonged QT_c may also be seen in therapeutic dosing.

TABLE 27-2 Cyclic Antidepressant Drug Interactions

DRUG	MECHANISM
Anticoagulants	Inhibition of oral anticoagulant metabolism with subsequent elevated PT
Amphetamines	Enhanced adrenergic stimulation via norepinephrine release
Carbamazepine	TCA metabolism, leading to subtherapeutic levels
Chloroquine	Induction of additive effect of QT prolongation
Cimetidine	Inhibition of TCA metabolism, leading to supratherapeutic levels
Class Ia and Ic antidysrhythmics	Additive effect of QT prolongation via Na channel blockade and QRS prolongation
MAOIs	Enhanced neurotransmitter release, leading to hypertensive crisis or serotonin syndrome
Phenothiazines	Additive effect on QT prolongation
Fluconazole	Inhibition of TCA metabolism, leading to supratherapeutic levels; also increased QT interval
Class III antidysrhythmics	Additive QT prolongation
SSRIs	Risk of serotonin syndrome; competitive inhibition of CYP2D6 and CYP2C19, leading to elevated steady-state TCA levels
Linezolid	Risk of serotonin syndrome
MDMA (“Ecstasy”)	Risk of serotonin syndrome

FIGURE 27-2 ECG from a TCA-poisoned patient.

NEGATIVE INOTROPY AND VASCULAR SMOOTH MUSCLE EFFECT

CAs inhibit the influx of calcium into cardiac and neural tissue and interfere with calcium-coupled muscular contraction.⁵⁴⁻⁵⁶ This may explain the direct depressant effect seen experimentally with isolated human myocardium in response to CAs.⁵⁷ Peripheral α -adrenergic blockade may cause postural hypotension at therapeutic doses. At toxic doses, vasodilation contributes to hypotension.⁵⁸

DYSRHYTHMIAS

Sinus tachycardia is the most common rhythm disturbance associated with CA overdose. The etiology is multifactorial and includes anticholinergic effects, increased norepinephrine release, and reflex tachycardia in response to vasodilation. Although the tachycardia does not generally cause morbidity itself, it is clearly a sign of significant toxicity.

Ventricular tachycardia (VT) is the most common ventricular dysrhythmia seen in overdose. However, discriminating this rhythm from the common underlying sinus tachycardia with aberrant conduction (QRS prolongation) may be difficult, since P waves are not always visible. Some cases of VT described in the literature may actually be supraventricular tachycardia (SVT). P waves may be obscured by the preceding T wave owing to the prolonged PR and QT_c intervals along with rapid heart rate. Intraesophageal electrode monitoring may reveal P waves not visible on the standard ECG. An alternative, less sophisticated technique useful in discriminating these rhythms is to follow serial ECGs. A gradual evolution of the QRS prior to loss of the P wave suggests SVT with aberrant conduction. The presence of fusion beats suggests a ventricular origin. Other criteria commonly used to differentiate ventricular and supraventricular rhythms, such as QRS morphology and duration, have not been tested in patients with CA overdose and may not be applicable in this setting.

Torsades de pointes (TdP) has been reported following CA overdose.^{59,60} This phenomenon appears to be a more common consequence of therapeutic dosing than of overdose. The increased risk for TdP in conjunction with a slow rhythm likely explains its higher

prevalence in therapeutic dosing, since most acutely poisoned patients are tachycardic. Several cases of sudden death in children taking therapeutic doses of CAs have been reported. QT prolongation with resultant TdP is the speculated mechanism for these events.⁶¹ Other less common rhythms seen in overdose are second- or third-degree atrioventricular block⁶² and premature ventricular beats. Patients close to death are more likely to develop bradycardia and atrioventricular blocks.

Refractory hypotension is a common cause of death due to CA overdose. Hypotension may occur in the absence of other signs of cardiac toxicity such as QRS prolongation.⁶³ Hypotension is due in part to vasodilation from α -adrenergic blockade, as well as direct myocardial depression.^{57,58,64-66} This inotropic depression is dose-dependent and independent of effects on the cardiac conduction system.⁵⁷ Significant sinus tachycardia may contribute to hypotension by decreasing the diastolic period. This effect decreases ventricular filling time and impairs coronary perfusion.

Central Nervous System Toxicity

CNS depression is a common feature of all CAs in overdose. Symptoms range from fatigue to coma. The greatest concern in CNS toxicity in overdose is seizures. Although they most commonly occur in patients who also display signs of cardiac toxicity, seizures may occur in the absence of this finding.^{67,68} Maprotiline and amoxapine are more likely than other CAs to cause seizures.^{69,70} Seizures due to CAs most often occur within 1 to 2 hours of presentation, are brief in duration, and resolve without the need for anticonvulsant medications.⁶⁸ However, seizures may cause a metabolic acidosis that could predispose patients to cardiac dysrhythmias. In some case series, 10% to 20% of patients with seizures abruptly developed cardiovascular deterioration (hypotension, ventricular dysrhythmias) during or within minutes after the seizure.^{68,71} Patients with more severe cardiovascular toxicity before the seizure were at highest risk. Therefore, cardiovascular deterioration may have been imminent regardless of the seizure, or potentially worsened by a seizure-induced acidosis. A clear cause and effect has not been identified. Other neurologic symptoms include delirium and myoclonus. Delirium is characterized by agitation, disorientation, and delusions and is most likely attributable to the anticholinergic properties of CAs. Although delirium may appear early in the course of intoxication, it may also manifest several hours later, after the initial period of sedation wanes. It is not uncommon to witness the development of a profound central antimuscarinic syndrome after 24 hours when patients have survived the initial cardiovascular consequences.

Toxicity in Other Systems

Peripheral anticholinergic toxicity may be seen with agents possessing potent anticholinergic properties such as amitriptyline. Signs and symptoms include urinary

retention, ileus, and dry skin. Pupil size may vary depending on the degree of anticholinergic versus α -adrenergic blockade. Pulmonary complications include aspiration pneumonitis and adult respiratory distress syndrome.⁷² These likely represent indirect toxicity secondary to coma, hypotension, excessive fluid administration, or increased capillary permeability from direct endothelial toxicity. Hyperthermia may ensue following excessive heat generation from seizures or myoclonus in the setting of decreased ability to dissipate heat through sweating.

Ultimately, most deaths occur prior to hospital presentation. Of those who survive to the hospital, death occurs within the first few hours of presentation with the majority of deaths occurring in the first 24 hours.⁷³ It is not uncommon for a patient's clinical condition to deteriorate rapidly with progression from no symptoms to life-threatening cardiotoxicity in less than 1 hour.⁷⁴ Late-occurring death results from complications of prolonged hypotension, status epilepticus, or aspiration.

DIAGNOSIS

Electrocardiogram

The ECG is the most rapidly available screening tool for predicting toxicity and guiding the management of CA poisonings. QRS interval prolongation is the most apparent ECG finding in serious CA toxicity and is a marker of the sodium channel blockade resulting from this drug class. The QRS axis is typically shifted to the right, along with the axis of the terminal 40 msec of the QRS complex. An increase in the R wave amplitude in aVR accompanies this finding (see Fig. 27-2).^{51,75,76} These parameters are useful in predicting serious adverse outcomes such as seizures and ventricular tachycardia.

In one retrospective study, a maximal limb-lead QRS duration greater than 100 msec identified patients at greatest risk for seizures.⁶⁷ However, these and other complications may occur with a lesser degree of QRS prolongation, and patients with any degree of QRS prolongation are considered at risk for developing life-threatening CA toxicity.⁷⁷ This was demonstrated in another retrospective study in which a maximal 12-lead ECG QRS duration greater than 100 msec was only 53% sensitive for ventricular dysrhythmias or seizures.⁷⁸ The low sensitivity for predicting serious outcomes despite the use of a more sensitive measurement (maximal 12-lead QRS) suggests that life-threatening complications may develop irrespective of narrow QRS duration.

The terminal 40 msec QRS axis deviation greater than 120 degrees has been used to diagnose TCA toxicity, with a range of sensitivities from 29% to 100%.^{50,75,77,79} The most common way to detect this measure is to identify a deep S wave in lead I or aVL and a terminal R wave in lead aVR (see Fig. 27-2). The height of the R wave in aVR also provides valuable information when evaluating CA overdoses. A height greater than or equal to 3 mm is 81% sensitive for predicting subsequent seizures or dysrhythmias.⁷⁶ This compares with a sensitivity of 82% in

the same study for a QRS duration greater than 100 msec. However, the positive predictive values for the aVR and QRS criteria were 43% and 35%, respectively.

The QT_c interval is mildly prolonged with therapeutic doses of CAs and becomes more prolonged with overdose.⁸⁰ A corrected QT_c greater than 480 msec in the setting of CA poisoning has been linked to an increased risk of seizures and dysrhythmias.⁵¹ However, this marker is not useful in the diagnosis of CA toxicity versus non-CA ingestions.^{75,79}

Interpretation of ECG criteria should be weighed with the knowledge that the ECG is a dynamic measurement. An initially normal ECG may rapidly evolve to reveal the characteristic changes cited above. At the time of presentation in one study, the maximum recorded QRS interval was present on the ECG in 80% of patients.⁸¹ The remaining patients reached a maximum QRS duration in a median time of 3 hours (range, 1 to 9). The maximum T40 msec axis occurred at the time of presentation in 86% in this same group, with the remaining patients reaching this maximum in a median time of 3 hours (range, 1 to 5). Therefore, frequent ECGs are required during the first few hours following a CA overdose to monitor potential changes.

Laboratory Studies

CAs can be detected qualitatively in urine by thin-layer chromatography or liquid chromatography, or quantitatively in serum by liquid or gas chromatography. Active demethylated metabolites are usually measured via the latter methods. Therapeutic CA concentrations are generally in the range of 50 to 300 ng/mL (see Table 27-1). Bedside immunoassays are available; however, they have not been extensively tested.⁸² False-positive results from CA immunoassays are well documented and include cross-reactions with quetiapine, carbamazepine, diphenhydramine, and many others (Table 27-3).⁸³⁻⁸⁶

The correlation of serum CA concentrations with toxicity is imprecise,^{67,73} and their measurement adds little to the management of CA overdose. Life-threatening toxicity is usually accompanied by a serum concentration of greater than 100 ng/mL, while concentrations greater than 300 to 500 ng/mL are often fatal.⁴⁷ The serum CA concentration may increase up to fivefold postmortem. When using CA levels to determine cause of death, the measurement of liver drug concentrations rather than blood concentration may avoid the tissue redistribution artifact that leads to dramatic elevations in blood CA content, even with therapeutic dosing.⁸⁷⁻⁸⁹ Another technique involves examining the ratio of parent drug to metabolite. Typically, the metabolites are found in greater concentration in patients taking therapeutic doses, whereas fatal overdoses lead to a much higher concentration of parent drug compared to metabolites.

Without a clear history of CA ingestion, the diagnosis may be confused with other drugs or disease states. CA toxicity is most likely to resemble other drugs that produce QRS prolongation. Drugs which may induce cardiotoxicity indistinguishable from that of CAs include

**TABLE 27-3** TCA Assays and Drugs Reported to Cause False-Positive Results

ASSAY	FLUID	DRUG CROSS-REACTIVITY
Abbott TDx/TDxFx TCA immunoassay	Blood	Carbamazepine
Syva EMIT immunoassay	Blood	Thioridazine, chlorpromazine, trimeprazine, cyproheptadine, cyclobenzaprine, norcyclobenzaprine, diphenhydramine, quetiapine
DuPont automatic clinical analyzer	Blood	Thioridazine
Triage plus TCA	Urine	Cyclobenzaprine
Homogenous enzyme immunoassay (Microgenics, Syva)	Urine	Quetiapine
Liquid chromatography	Blood	Diphenhydramine
High-performance liquid chromatography	Blood	Thioridazine, perphenazine, cyclobenzaprine, norcyclobenzaprine
Gas chromatography–mass spectrometry	Blood	No reported drug cross-reactivity

VW class IA (quinidine, procainamide) or IC (flecainide, encainide, propafenone) antidysrhythmic agents. Other drugs that may prolong QRS duration in overdose include cocaine, propranolol, quinine, chloroquine, hydroxychloroquine, high-dose antipsychotics (thioridazine, chlorpromazine), propoxyphene, and diphenhydramine. Nondrug causes of QRS prolongation include hyperkalemia, cardiac ischemia, and other conduction system abnormalities.

MANAGEMENT

Supportive Measures

Given the risk of rapid deterioration, patients with known or suspected CA overdose should have an intravenous line started and cardiac rhythm should be monitored continuously. An ECG on arrival can be compared with subsequent ECGs obtained during the monitoring period. Frequent measurement of vital signs including temperature is imperative. Patients with severe toxicity on presentation, including extreme lethargy, agitation, seizures, or dysrhythmias, require early intubation for airway protection. Particular attention to acid–base status is paramount in managing a severe CA overdose. Patients who develop acidosis from increased muscle activity, seizures, or inadequate ventilation may develop an increase in CA-protein dissociation and subsequent clinical deterioration.

Initial measures for blood pressure support include intravenous fluids and vasopressors such as norepinephrine. Because CA toxicity is reversible once the drug is metabolized and excreted, temporary mechanical support of the circulation may prove useful in hypotensive patients who are unresponsive to other measures. Serum CA levels often decline rapidly following overdose owing to distribution of the drug to tissues. A temporary period of mechanically assisted circulation might, therefore, allow time for spontaneous improvement. Isolated reports of a child who survived 2.5 hours of cardiopulmonary resuscitation during nonperfusing ventricular tachycardia and of an adult treated successfully

with femoral-femoral extracorporeal circulation for refractory hypotension support this possibility.^{90,91} Preliminary data in swine suggest that cardiopulmonary bypass may allow survival after ingestion of an otherwise fatal dose of CA.⁹² Augmentation of aortic outflow utilizing a balloon pump device could provide additional perfusion support when myocardial depression is severe.

Decontamination

Prompt administration of activated charcoal is indicated if the ingestion occurs within 1 hour of presentation. Charcoal may be given after this time period; however, its effectiveness diminishes rapidly with time. Patients who appear drowsy and are unable to drink the charcoal without assist should be protected with tracheal intubation prior to charcoal administration to prevent aspiration of charcoal and subsequent serious pulmonary sequelae.

Laboratory Monitoring

As discussed above, measurement of serum CA concentrations provides little information regarding emergent care of poisoned patients. However, qualitative screening immunoassays may occasionally prove useful in the detection of occult ingestion when overt clinical toxicity is not detected. Measurement of serum electrolytes, blood urea nitrogen, creatinine, creatine kinase, hematocrit, and liver function tests provide information regarding co-ingestions and other disease states that may affect drug metabolism and excretion. Arterial blood gas determinations are indicated for intubated patients and for monitoring acid–base status when sodium bicarbonate infusion is employed as a therapy for CA toxicity.

Antidotes

NaHCO₃

When CAs were introduced into clinical practice, the clinical characteristics of overdose were noted as sharing many features of quinidine toxicity, for which hypertonic sodium lactate (which is rapidly metabolized to bicarbonate) resulted in clinical improvement. The proposed

mechanisms for this therapy include increased plasma protein binding of CAs resulting from alkalemia, reduced binding of CAs within the cardiac myocytes, and overcoming the Na channel blockade via sodium loading.⁹³

Controlled animal studies clearly established that hypertonic NaHCO_3 is effective in reducing QRS prolongation, increasing blood pressure, and suppressing ventricular ectopy due to CA toxicity.⁹⁴⁻⁹⁶ This effect is demonstrated experimentally to be independent of and additive to the effect of vasopressors.⁹⁷ Some animal data suggest that hypertonic sodium chloride infusions provide additional benefit with respect to treating hypotension and ventricular tachycardia.⁹⁸ However, the amount of sodium delivered in these experiments was 15 mEq/kg or 10 mL/kg of 7.5% NaCl, a dose likely to cause severe toxicity in humans. Intracellular pH elevation has been shown to reverse the toxicity of imipramine in cardiac myocytes.⁹⁹ This intracellular alkalosis is correlated with a decreased binding of imipramine.¹⁰⁰ In human serum, alkalosis causes a decrease in the free CA concentration.¹⁰¹

No randomized controlled human trials are published relating to the efficacy of NaHCO_3 infusion for the treatment of CA poisoning.⁹³ Retrospective reviews of a few hundred patients in conjunction with case series and case reports provide the basis of confirmation for the effectiveness of NaHCO_3 therapy in the treatment of CA-induced hypotension, cardiac conduction delays, and dysrhythmias in humans.^{93,102-105}

Indications for therapy with NaHCO_3 infusion are acidemia (serum pH < 7.35), QRS width greater than or equal to 100 msec, R wave in aVR greater than 3 mm, or wide complex tachydysrhythmias. Optimal serum pH is not well established. The target pH recommended by various clinicians, as determined by survey, vary dramatically and range from a maximum of 7.45 to 7.8.¹⁰⁶ However, the majority of clinicians recommend a maximum serum pH of 7.55.¹⁰⁶ Dosing protocols also vary widely. The most common approach is to administer 1 mEq/kg NaHCO_3 as an intravenous bolus in the setting of a widened QRS or dysrhythmia. This may be increased to achieve resolution of the dysrhythmia or narrowing of the QRS (Fig. 27-3; see also Fig. 27-2). Serum pH should not be permitted to exceed 7.55. Continuous infusion may begin after improved cardiac parameters are achieved with the bicarbonate bolus. Adding 150 mEq of NaHCO_3 to 1 L of D5W yields an isotonic solution that can be infused at a rate 1.5 times maintenance for the patient's weight. The infusion rate may be titrated to hourly serum pH measurements to ensure adequate treatment without overalkalinization. Frequent measurement of serum potassium is critical owing to enhanced renal elimination of potassium in the setting of alkalemia.

PHENYTOIN

Phenytoin was reported to improve QRS duration in an uncontrolled series of patients and one preliminary report that showed more rapid improvement of cardiovascular toxicity in patients randomized to phenytoin.^{107,108}

FIGURE 27-3 ECG from a TCA-poisoned patient after NaHCO_3 administration.

Controlled animal studies have not confirmed a benefit, and possible aggravation of ventricular ectopy was noted in one report.¹⁰⁹⁻¹¹¹ These data do not support the clinical use of phenytoin for CA cardiotoxicity.

TCA ANTIBODIES

The use of TCA-specific antibody Fab fragments for the treatment of TCA overdose, analogous to those used to treat digoxin overdose, has been studied in rats. Fab doses capable of binding 10% to 30% of the TCA body burden rapidly reverse QRS prolongation and hypotension and prolong survival.^{112,113} The toxic dose of TCAs is more than 100 times higher than that of digoxin, however, and the theoretical Fab dose required to reverse toxicity is also much higher (1 to 3 g/kg). One case report details the successful use of experimental ovine Fab in a human amitriptyline overdose.¹¹⁴ The total dose of Fab administered was only 6% of the molar quantity of TCA ingested. The authors reported a rapid decrease in QRS and QT_c intervals as well as an improvement in mental status. No acute adverse reactions were noted. The ability of the antibodies to bind tetracyclic drugs such as amoxapine and maprotiline is unknown. More extensive experience is required before Fab fragments become part of routine therapy for TCA poisoning.

α_1 -ACID GLYCOPROTEIN

α_1 -Acid glycoprotein (AAG) has demonstrated some efficacy in the treatment of CA toxicity in animal models. Because CAs are bound to AAG in plasma, the administration of additional AAG would theoretically bind a portion of the free CA fraction, thereby reducing toxicity. Swine and rat studies have shown a trend toward decrease in CA-induced QRS prolongation after the administration of AAG.^{115,116} Currently, no evidence suggests that administration of AAG in humans has any role in the treatment of CA toxicity.

PHYSOSTIGMINE

Physostigmine was initially advocated as a treatment for CA poisoning in the 1970s.¹¹⁷ Indications at the time included seizures, coma, and tachydysrhythmias.¹¹⁸ The first case reports of asystole following the use of

physostigmine were in the context of treating CA-induced seizures.¹¹⁹ Anecdotal reports of successful treatment of seizures and dysrhythmias are not substantiated by controlled data. Balancing the reported successes are claims that physostigmine induces seizures and asystole when used for CA poisoning. Unfortunately, these are known complications of both CA poisoning as well as physostigmine in isolation. The reported cases linking physostigmine to these complications when used for CA poisonings do not demonstrate a conclusive cause and effect relationship.¹²⁰ Thus, seizures may have ceased in response to physostigmine or ceased despite this therapy. Seizures occurring after the administration of physostigmine may have occurred in response to therapy or may have occurred regardless of this drug. Similar logic applies to cases of asystole and bradycardia. Many conclusions may be drawn, and these are based on deductive reasoning rather than scientific evidence.

The pathophysiology of cardiac conduction delays and seizures resulting from CA poisonings is poorly explained by the anticholinergic properties of the drugs. These features are not seen in pure anticholinergic poisonings such as atropine and scopolamine. Rather, the sodium channel effects of CAs provide a more reasonable explanation. Therefore, the use of a purely cholinergic drug for reversal of seizures and dysrhythmias caused by sodium channel blockade lacks a rational basis. In view of the known toxicities including seizures and asystole from physostigmine in the absence of CA poisoning, its use in the context of CA poisoning, where seizures and cardiac dysrhythmias are a known complication, is not recommended. However, patients who survive the acute phase of CA poisoning and have no evidence of cardiac conduction delay may continue to suffer from the anticholinergic drug effects more than 24 hours after the ingestion. Physostigmine could be of benefit for controlling agitated delirium in this subset of patients provided that a patient has demonstrated cardiac stability for a prolonged period of monitoring.

Elimination Enhancement

Enhancing elimination of the CAs is difficult owing to their large volume of distribution. Several uncontrolled case reports note shorter than expected elimination half-lives for CAs with the use of repeated doses of activated charcoal. These data are of limited value because early sampling may have misconstrued the CA distribution phase as evidence of shortened half-life. In controlled studies, repeated oral doses of activated charcoal have been reported either to have no effect on the clearance of subtoxic doses of imipramine¹²¹ or to shorten the elimination half-life of doxepin or amitriptyline by 20%.¹²² Most deaths from CA overdose occur within hours of drug ingestion, thereby limiting the utility of a therapy that requires multiple doses over time. It is possible, however, that repeated doses of charcoal might shorten the duration of toxicity in slow hydroxylators who display long CA half-life kinetics. Little active CA is excreted in urine, and measures that enhance urinary CA excretion have a negligible effect on total clearance.¹²²

Hemodialysis is ineffective in enhancing the elimination of CAs because of their extensive protein binding and lipid solubility. Hemoperfusion overcomes these limitations but is relatively ineffective because of the drugs' large volume of distribution.¹²³ One case report noted removal of less than 2% of the ingested dose of imipramine as parent drug or active metabolite during 6 hours of hemoperfusion.³² Nevertheless, rapid improvement in cardiotoxicity after CA overdose has been anecdotally reported during hemoperfusion.¹²⁴⁻¹²⁶ However, rapid decline in serum CA levels secondary to drug distribution may explain this observation. In addition, improvements in acid-base status likely contributed to improved cardiovascular status. In the absence of supporting data, there is no role for hemoperfusion in the treatment of CA poisoning.

DISPOSITION

Patients displaying significant signs and symptoms of CA toxicity such as QRS prolongation, lethargy, or hypotension require admission and monitoring until symptom-free for 24 hours.^{127,128} QRS duration may be considered normal if it is less than 100 msec or similar to the patient's baseline QRS. When QRS duration is marginally prolonged (100 to 120 msec) and no baseline ECG is available, it may be unclear whether the observed QRS duration is normal for that patient or prolonged from the overdose. In this situation, measurement of the serum CA concentration may be helpful later in hospitalization as grounds for discontinuing therapy and monitoring when drug concentrations are therapeutic or low. A clearly elevated CA concentration would suggest that the QRS prolongation is drug induced, and therefore continued cardiac monitoring is indicated and NaHCO₃ therapy should continue. With the exception of overdoses involving a sustained-release drug, patients who are asymptomatic on presentation and do not manifest signs of toxicity after 6 hours require no further medical monitoring other than psychiatric evaluation.

WESLEY PALATNICK, MD

At a Glance...

- Overdose of selective serotonin reuptake inhibitors is less hazardous than cyclic antidepressants.
- Adverse effects and drug interactions are common during therapy.
- Most overdoses are not life threatening; however, fatalities have been reported.
- Venlafaxine, bupropion, and citalopram have been associated with more toxicity than other selective serotonin reuptake inhibitors.
- Deaths are usually associated with the ingestion of multiple agents.
- Seizures and decreased level of consciousness are the most common manifestations.
- Cardiac effects are usually mild and include prolonged QTc and bradycardia.
- Treatment is supportive.
- The serotonin syndrome may be associated with overdose or during therapy with other serotonergic agents and may be life threatening.
- Asymptomatic patients may be discharged after 6 hours of observation, unless prolonged release products ingested.

Depression is a common problem that results in enormous costs to society. These include the direct costs of treatment, as well as indirect costs due to lost productivity. Pharmacologic therapy is effective, with 65% to 75% of patients showing significant improvement and a complete cure in 40% to 50% of patients. Both the cyclic antidepressants and monoamine oxidase inhibitors (MAOIs) are very effective treatments. However, the cyclic antidepressants have a number of troublesome side effects as well as significant and life-threatening toxicity in overdose. Drug and food interactions with the MAOIs as well as their potential toxicity in overdose limit their acceptability as a treatment option.

The first selective serotonin reuptake inhibitor (SSRI) on the market still in use is fluvoxamine. It was introduced in Europe in 1983. Fluoxetine was introduced in the United States in 1988, followed by sertraline in 1992, paroxetine in 1993, and fluvoxamine in 1995. Bupropion was released in 1989, trazodone in 1992, and venlafaxine in 1994.¹

SSRI antidepressants are very effective for the management of depression, have a more attractive side effect profile than either the cyclic antidepressants or the MAOIs, and are much less toxic when taken in overdose.²⁻⁸ They are as effective as the cyclic antidepressants in the treatment of depression.⁹⁻¹¹

Aside from depression, SSRIs are also considered important therapeutic modalities for a number of other common psychiatric disorders such as anxiety, anorexia nervosa, bulimia, and obsessive-compulsive disorder.¹⁰ They are also used in the management of borderline personality disorder, attention-deficit hyperactivity disorder, and fibromyalgia.¹²

EPIDEMIOLOGY

In 2002, the American Association of Poison Control Centers reported 58,817 exposures to SSRIs and trazodone, with 116 deaths. This is in contrast to the 13,198 exposures and 118 deaths associated with cyclic antidepressants.¹³ In a review, Barbey reported only six verified overdose deaths involving SSRIs alone from 1985 to 1997. Of these, only two had been reported in the literature.¹⁴

A comparison of poisoning fatality records for England and Wales from 1993 to 1995 found 1 death per 411,800 3-month treatment episodes for SSRIs as a group compared to 1 death per 8130 3-month treatment episodes for cyclic antidepressants.¹⁵ A comparison of the number of deaths per million prescriptions of antidepressants in England from 1987 to 1992 found a significantly lower number of deaths for the SSRIs compared with both the cyclic antidepressants and MAOIs.³

The hospital costs for patients hospitalized for SSRI overdose are significantly lower than those associated with cyclic antidepressant overdose, due to a shorter hospital stay, less need for interventions such as intubation, and less need for admission to the intensive care unit.¹⁶⁻¹⁹

STRUCTURE

Most of the SSRIs are either aryls or aryl-oxyalkylamines. Citalopram and fluoxetine are racemic mixtures, while sertraline and paroxetine are separate enantiomers. The serotonin uptake blocking of citalopram is primarily due to the (+)-enantiomer with the 1-(S) absolute configuration.²⁰

Structure-activity relationships are not well described for the SSRIs. One example is the critical association of the *para*-location of the CF₃ substituent of fluoxetine on serotonin transporter potency.²¹

Bupropion is an aminoketone compound that is unlike most antidepressants. There are four chemical features that contribute to its uniqueness: chloro substituent, ketone function, tertiary alkyl group, and meta orientation of the substituent.²²

PHARMACOLOGY

The SSRIs all have a similar mechanism of action (Box 28-1). They inhibit the neuronal reuptake of serotonin and thus potentiate the effect of serotonin at the postsynaptic receptors. Most SSRIs have little or no effect on other neuroreceptors such as the histamine, acetylcholine, and adrenergic receptors. However, because the antidepressant effect is often delayed, it is postulated that there also may be a down-regulation of some of the postsynaptic serotonin receptors secondary to the increased serotonin in the synaptic cleft.^{23,24} The SSRIs include fluoxetine, paroxetine, sertraline, fluvoxamine, and citalopram.

The atypical antidepressants, including trazodone, nefazodone, venlafaxine, bupropion, and mirtazapine, have distinct pharmacologic properties that differ somewhat from the SSRIs. All are effective antidepressants.

Venlafaxine, a bicyclic phenylethylamine, is a potent inhibitor of serotonin receptors. It has norepinephrine uptake and is a weak inhibitor of dopamine. It has little affinity for muscarinic, histamine, or α -adrenergic receptors.²⁵

Trazodone is a triazolopyridine antidepressant that is structurally similar to the tricyclic antidepressants, but has weak inhibition of the reuptake of both norepinephrine and serotonin.²⁴

Nefazodone is a 5-HT₂ antagonist with limited inhibition of the presynaptic reuptake of both serotonin and norepinephrine with the net effect being enhanced serotonin neurotransmission. It has weak affinity for the 5-HT₂, α -adrenergic, and β -adrenergic receptors and does not bind to the histamine, muscarinic, and dopaminergic receptors.²⁵

Bupropion is a monocyclic antidepressant structurally related to amphetamine that acts by selectively inhibiting

the neuronal reuptake of serotonin as well as dopamine and norepinephrine. It is used as both an antidepressant as well as an aid to smoking cessation.

Mirtazapine has unique pharmacologic effects. It blocks the presynaptic inhibitory α_2 autoreceptors, and the presynaptic inhibitory serotonin receptors. Postsynaptically, mirtazapine has little effect of α_1 receptors but blocks 5-HT₂ and 5-HT₃ receptors. The net effect is enhanced release and effects of both norepinephrine and serotonin. Mirtazapine has a high affinity for histamine receptors, but low affinity for cholinergic, muscarinic, and dopaminergic receptors.^{1,25,26}

PHARMACOKINETICS

The SSRIs, unlike the cyclic antidepressants, are quite heterogeneous with respect to pharmacokinetic parameters, such as half-life and the presence of active metabolites (Table 28-1).²⁷ They are well absorbed from the gastrointestinal tract and undergo minimal first pass hepatic metabolism. The effect of food on drug absorption is variable with a decreased absorption for fluoxetine, increased absorption for sertraline, and no effect on paroxetine, fluvoxamine, and citalopram. The time to peak concentration averages 4 to 8 hours. SSRIs are all highly protein bound, varying from a low of 77% for fluvoxamine to over 90% for the remaining agents. The volume of distribution is large for most agents.²⁸

The elimination half-life varies considerably among the various agents, ranging from 2 to 4 hours for nefazodone to 48 to 96 hours for fluoxetine. In addition, fluoxetine has an active metabolite, norfluoxetine, that has a half-life of 7 days. Linear pharmacokinetics have been described for sertraline and citalopram, while the other agents undergo nonlinear kinetics.²⁷⁻²⁹

SPECIAL POPULATIONS

The Elderly

SSRIs may be particularly useful in the elderly because of the absence of significant cardiovascular and anticholinergic adverse effects. However, while the pharmacokinetic behavior is similar in all age groups, the drugs may be more slowly metabolized in the elderly and dosage reductions are required. One should start with lower doses and titrate them slowly. In most cases, the final dose in this group of patients should be lower than in the younger population.³⁰ There are no data supporting one SSRI over another for the elderly, and the choice of drug will be influenced by other factors such as the possibility of drug-drug interactions.²³

Patients with Renal and Hepatic Disease

Renal and hepatic disease delays the elimination of the SSRIs, and lower dosing or less frequent administration is required to avoid adverse effects. Paroxetine is mainly eliminated by the kidneys, and the dose should be

+, parameter has an effect on pharmacokinetics; 0, parameter has no effect on pharmacokinetics; ?, effect not known; T_{max} time to peak concentration. Data derived from references 23, 25, and 28.

carefully titrated in patients with kidney disease and avoided with renal failure.^{23,30,31} Dose reductions in patients with renal or hepatic disease are also required for mirtazapine.²⁵

Pregnant and Lactating Patients

Most medications should be avoided in pregnancy if at all possible. Mild depression may be managed with nonpharmacological approaches. However, in severe depression, pharmacologic therapy may be required, and the SSRIs, especially fluoxetine, appear to be relatively safe in pregnancy.^{30,32,33} Infant exposure during pregnancy is potentially significant due to placental passage, and therefore the lowest dosage that will provide adequate effects should be prescribed.^{34,35} A study of 267 women who took SSRIs (fluoxetine, fluvoxamine, and sertraline) during the first trimester of pregnancy showed no increase in birth defects.³⁶

The SSRIs have only been available for a relatively short time, and the potential long-term effects on breast-fed infants are unknown. However, postpartum depression has significant morbidity and mortality, and one needs to weigh the risks and benefits of the treatment of depression in women who are breast-feeding versus the potential risks to the infant. Again, the lowest effective dose of an agent that has minimal secretion in breast milk is recommended.

Paroxetine is secreted in breast milk, but it has no active metabolites, and adverse effects on breast-fed infants have not been reported. The majority of studies describing fluoxetine use in lactating women report no adverse effects on the infant. Sertraline as well as its metabolite desmethylsertraline have been detected in breast milk with low or nondetectable serum concentrations in the infant. Fluvoxamine has also been found in breast milk in very low concentrations, with no reported adverse effect on the infants. Venlafaxine and its metabolites have been found in the sera of breast-fed infants. However, no adverse effects were reported. Limited data exist on the effects of citalopram, trazodone, and nefazodone.³⁴

In summary, SSRIs should be avoided in lactating women if possible. A careful weighing of the risk-benefit ratio is required, and if indicated, an agent such as paroxetine, sertraline, or fluoxetine that has minimal secretion in breast milk is suggested.

Children and Adolescents

Although SSRIs are commonly used in the pediatric and adolescent population, its use in this group is controversial.³⁷⁻³⁹ Compared with adults, there is a paucity of data from controlled clinical trials in the pediatric population, and the best evidence for efficacy has been for the treatment of depression and obsessive-compulsive disorder. The evidence for other pediatric psychiatric disorders such as autism, social anxiety disorder, and eating disorders is mainly anecdotal.^{29,40,41} In addition, there is concern about significant potential adverse effects found in children, such as activation,

disinhibition, manic reactions, uncovering of comorbid disorders such as conduct disorders, frontal lobe symptoms (including apathy), and an increase in suicidal ideation.^{42,43}

The concern regarding increased suicidal behavior and presumed lack of efficacy has led to a call in the United Kingdom that SSRIs should not be used in children with the possible exception of fluoxetine. Regulatory bodies in the United States and Canada have raised similar concerns.⁴¹ However, this remains controversial.³⁷

DRUG INTERACTIONS

Drug interactions may be either pharmacodynamic, where one drug affects the mechanism of action of another drug, or pharmacokinetic, where the drug affects the metabolism or excretion of another drug. Both of these are common with the SSRIs and newer antidepressants⁴⁴ (Table 28-2).

The most important pharmacodynamic drug interaction involving the SSRIs is the development of the potentially life-threatening serotonin syndrome. This occurs when an SSRI is combined with another serotonergic agent. The serotonin syndrome is described in Chapter 10A. When SSRIs are combined with a number of agents, the drugs that are of most concern are the MAOIs. A washout period of 2 weeks for most SSRIs and 5 weeks for fluoxetine is mandatory when switching from an SSRI to an MAOI to avoid the development of the serotonin syndrome.⁴⁵

The cytochrome P-450 (CYP450) system metabolizes a number of medications including the SSRIs.^{8,46} Drug interactions may result from inhibition of the CYP450 system, thus slowing metabolism of other medications, by acting as a competitive substrate or by the induction of enzymes. A number of enzymes are inhibited by the SSRIs to varying degrees, including CYP2D6, CYP1A2, CYP2C, and CYP3A4. The result is a negative effect on the metabolism of the other drugs and possible elevation in plasma levels. This is especially problematic if the drug in question has a narrow therapeutic window.^{12,30}

All of the SSRIs are weak inhibitors of CYP2D6, which is also involved in the metabolism of a number of other common medications, including the cyclic antidepressants, some antipsychotics, β -adrenergic blockers, type Ic antidysrhythmics (encainide, flecainide, mexilitene, and propafenone), codeine, and dextromethorphan. Paroxetine has the greatest effect on CYP2D6 followed by norfluoxetine, fluoxetine, sertraline, fluvoxamine, venlafaxine, nefazodone, and mirtazapine.^{44,47}

The SSRIs as well as nefazodone inhibit CYP4A4, which also metabolizes terfenadine and astemizole, as well as the triazolo-benzodiazepines, such as triazolam, alprazolam, and midazolam.⁴⁴

CYP1A2 metabolizes theophylline as well as the tertiary cyclic antidepressants imipramine, clomipramine, and amitriptyline. Fluoxetine, paroxetine, and sertraline are weak inhibitors of this enzyme. Fluvoxamine is a potent inhibitor of this enzyme, and concomitant therapy has

TCA, tricyclic antidepressant.
 *Selective serotonin reuptake inhibitors and TCAs are indicated by bold type. Any two drugs that are substrates of the same cytochrome P-450 (CYP) enzyme may potentially compete with each other for that enzyme and thereby inhibit each other's metabolism. Some drugs may also inhibit a CYP enzyme without themselves being a substrate. Note that this table indicates potential interactions; not all have been demonstrated or are necessarily of clinical importance. Some drugs listed as inhibitors may actually be substrates for that particular CYP, but sufficient documentation is not available. Some drugs are substrates or inhibitors of more than one CYP enzyme.
[†]Demethylation of tertiary amine TCAs; imipramine, amitriptyline, and clomipramine.
[‡]Hydroxylation of desipramine, imipramine, clomipramine, amitriptyline, and nortriptyline.

resulted in elevated plasma theophylline and cyclic antidepressant levels.⁴⁴

Fluvoxamine, fluoxetine, and sertraline are mild to moderate inhibitors of CYP2C9 and -19, and interactions with warfarin and tolbutamide have been reported. Venlafaxine has no effects on CYP2C9 *in vitro*.⁴⁴

CYP3A4 is the most abundant of the cytochrome enzymes and therefore one of the most important with respect to drug interactions. Nefazodone is the most potent inhibitor of this enzyme, followed by fluvoxamine, norfluoxetine, paroxetine, desmethylsertraline, fluoxetine, sertraline, mirtazapine, and venlafaxine. One should avoid combining these antidepressants with other drugs with potent effects on CYP3A4, such as ketoconazole, terfenadine, and astemizole.^{30,44}

In summary, the drugs that are most likely to cause clinically significant pharmacokinetic drug interactions with drugs metabolized by the CYP450 system are fluvoxamine, fluoxetine, paroxetine, and nefazodone. Sertraline has fewer effects, while mirtazapine and ven-

lafaxine have the least propensity for such pharmacokinetic interactions.⁴⁴

Starting at lower dosing and careful titration of the medications can minimize drug interactions with the SSRIs and other medications that are oxidized by the P-450 system.⁴⁵

There is no pharmacokinetic interaction or potentiation of psychomotor impairment associated with ethanol.⁹

TOXICOLOGY

The ingestion of 50 to 75 times the therapeutic dose may result in minor symptoms such as drowsiness, tremor, weakness, nausea, and vomiting. Seizures and electrocardiographic (ECG) changes such as widening QRS or QT prolongation and a decreasing level of consciousness occur with larger ingestions. Death has occurred with extremely large overdoses of greater than 150 times the usual therapeutic dose.^{14,48}

Pure SSRI overdose rarely results in death, and most patients recover without long-term effects. Most of the reported deaths are associated with the ingestion of other drugs or in combination with alcohol.

CLINICAL MANIFESTATIONS

Acute Overdose

The SSRIs and atypical antidepressants are usually benign in overdose and considered much safer than either the cyclic antidepressants or MAOIs. However, each can manifest toxic effects, and there are anecdotal reports of significant toxicity for most of the drugs in this class.⁷

The most common symptoms after acute SSRI overdose include drowsiness, nausea, and vomiting. Other less common effects include dizziness, headache, tremor, and agitation. Serious effects such as dysrhythmias and seizures occur rarely and are much more common with citalopram or venlafaxine overdoses.⁴⁹

The serotonin syndrome has been reported after SSRI overdose, either alone or in combination with other antidepressants.⁵⁰ It is a potentially life-threatening syndrome characterized by autonomic dysfunction (hypo- or hypertension, tachycardia, hyperpyrexia, diaphoresis, diarrhea), abnormalities in mental status (disorientation, delirium, confusion, and agitation), and neuromuscular signs and symptoms (myoclonus, especially of the lower extremities, tremor, hyperreflexia, and rigidity). The serotonin syndrome is discussed in Chapter 10A.

Fluoxetine

Fluoxetine overdose is associated with either no or minor effects described in large case series.⁵¹⁻⁵⁶ Anecdotally, the most significant toxicities reported are seizures, lethargy, and mild cardiovascular effects such as increased QRS and QT.⁵⁷⁻⁶⁰

Sertraline

Sertraline overdose is usually benign.⁶¹⁻⁶⁴ Marked diarrhea has been reported with a sertraline overdose,⁶⁵ and the serotonin syndrome has been reported with massive overdose.⁶⁶⁻⁶⁸ Delayed angioedema necessitating tracheal intubation for airway control has been reported after a sertraline and trazodone overdose.⁶⁹ Deaths are uncommon, but have been reported associated with asthma⁷⁰ and markedly elevated postmortem serum concentrations.⁷¹

Citalopram

Most citalopram overdoses are associated with little or no clinical effects, although significant toxicity has been reported anecdotally, including seizures, wide complex tachycardia, supraventricular tachycardia, prolonged QTc, and widened QRS.^{49,72-75} Severe bradycardia without

QTc prolongation, hypotension, and syncope requiring a temporary pacemaker has also been reported.⁷⁶

Only mild symptoms are associated with ingestions of less than 600 mg, while ECG effects and seizures have been reported after ingestions of greater than 600 mg. All patients will have toxic effects with ingestions of 1900 mg or greater.⁷⁷ Cardiovascular effects occur in about 25% of overdoses.⁷⁸ Adult respiratory distress syndrome and renal failure, which resolved with supportive care, have been reported after an ingestion of 2400 mg of citalopram.⁷⁹ Fatalities with high postmortem blood concentrations have been reported.^{80,81} Lower postmortem concentrations may be seen when there are multiple ingestants.⁸²

Paroxetine

Paroxetine has a high therapeutic index, and overdose is usually benign in both adults and children. Symptoms are dose related and include minor gastrointestinal complaints, drowsiness, tachycardia, dizziness, and mydriasis.^{83,84} Significant hyponatremia occurred 5 days after a paroxetine overdose in an elderly woman.⁸⁵ The serotonin syndrome has been reported with combined paroxetine and moclobemide overdose.⁸⁶ Deaths have been reported in which there were significant postmortem paroxetine concentrations found in blood. However, there were other drugs involved in all of these cases.⁸⁷

Fluvoxamine

Fluvoxamine overdose is typically not associated with significant toxicity. The most commonly reported effects are drowsiness, tremor, nausea and vomiting, anticholinergic symptoms, and hemodynamically stable bradycardia.⁸⁸⁻⁹⁰ Nevertheless, a life-threatening intoxication with severe bradycardia, hypotension, seizure activity, and acute respiratory distress syndrome in a 4-year-old child has been reported.⁹¹

Trazodone

The clinical manifestations of trazodone overdose are generally mild, with drowsiness, nausea, and vomiting being the predominant symptoms, although coma has been reported.⁹²⁻⁹⁶ Because trazodone has little effect on norepinephrine reuptake and does not affect the sodium channels, there is no significant cardiovascular toxicity. A case of severe hyponatremia and late seizure after an overdose of trazodone in an elderly patient has been reported. The hyponatremia was presumed to be due to inappropriate antidiuretic hormone secretion.⁹⁷ The terminal half-life of trazodone after overdose was reported to be approximately 8.8 hours in a case report.⁹⁸ Deaths are uncommon except when trazodone is ingested with other agents or ethanol.⁹⁹

Nefazodone

Nefazodone has effects on both the serotonin and norepinephrine receptors, and the course after overdose

is usually benign, with patients either being asymptomatic or having minor effects such as drowsiness, nausea, vomiting, and dizziness.^{99,100} However, more serious effects have also been reported, including hypotension, bradycardia, seizures, and prolongation of the QTc.^{101,102}

Bupropion

The majority of cases of bupropion ingestion reported to poison control centers are benign, likely related to minor ingestions. The clinical manifestations seen in minor overdose included nausea and vomiting, tachycardia, hypertension, headache, dizziness, tremor, and mild drowsiness or agitation.¹⁰³⁻¹⁰⁵ However, bupropion is potentially more toxic in overdose compared with most of the SSRIs. Significant toxicity has been reported, including seizures and cardiac conduction abnormalities such as widened QRS and prolonged QTc.¹⁰⁶⁻¹¹³ The seizures may occur late in overdose of sustained release preparations.¹¹⁴ Cardiotoxicity has also been reported in a combined bupropion and ziprasidone overdose.¹¹⁵ While deaths are uncommon, they have been reported and are usually associated with a massive ingestion¹¹⁶ or multiple ingestants including alcohol.¹¹⁷

Venlafaxine

Venlafaxine is potentially more toxic in overdose than the SSRIs due to its effects on the reuptake of norepinephrine and to a lesser extent dopamine. It is available in both an immediate-release and extended-release formulation.²⁵ Venlafaxine is considered proconvulsant, and overdose has been associated with seizures.¹¹⁸⁻¹²³ Other toxic effects reported include prolonged QRS and QT, ventricular tachycardia, persistent myocardial ischemia, hypertension, and refractory hypotension.¹²²⁻¹²⁷ Serotonin-associated symptoms such as diarrhea, diaphoresis, and rhabdomyolysis, as well as the serotonin syndrome, have also been described.¹²⁸⁻¹³² Fatalities have been reported,^{127,132,133} and its fatality toxicity index is greater than other serotonergic agents and similar to the less toxic cyclic antidepressants.⁶

Mirtazapine

There are only a few reports of mirtazapine overdose in the literature, with only minor effects, including drowsiness, confusion, and tachycardia, described.¹³⁴⁻¹³⁸ Miosis and coma have also been described with significant overdose.¹³⁹

ADVERSE EFFECTS

Adverse effects associated with SSRI therapy are common and are dose related (Box 28-2).^{10,11} SSRI adverse effects, however, are generally mild due to the relative selectivity for serotonin receptors and relative absence of significant interaction with other receptors such as histamine and anticholinergic receptors, and they are better tolerated than the cyclic antidepressants.^{4,23,140}

BOX 28-2

ADVERSE EFFECTS OF SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Central Nervous System

Headache
Anxiety
Agitation
Insomnia
Seizures

Gastrointestinal

Nausea
Vomiting
Diarrhea
Anorexia

Other Effects

Hepatotoxicity
Hyponatremia
Discontinuation or withdrawal symptoms

The most common problems encountered include gastrointestinal effects such as nausea and vomiting, anorexia, diarrhea, headache, and stimulant effects such as agitation, anxiety, and insomnia.^{9,10,141-143} These are so-called serotonin-type symptoms⁴ and are worse at higher doses.¹⁰ Other adverse effects that are less common, but still considered of concern, include weight loss and sexual dysfunction. Trazodone has been associated with priapism.¹⁴⁴

While the general adverse effects are mild, there are differences between agents. Fluoxetine has been associated with a greater incidence of agitation compared with the other SSRIs, while sertraline appears to cause less agitation. Lethargy and apathy have also been reported.¹⁴⁴ Fluvoxamine has a significant rate of nausea, but this may be less prevalent with paroxetine. Of the SSRIs, sertraline appears to have a lower incidence of side effects.¹¹

There is a significant discontinuation rate with SSRI therapy that is directly related to the severity of these adverse effects. Nausea and agitation are the most common reasons for patients stopping therapy.¹⁴⁵

Cardiovascular side effects are less common with SSRIs. Nevertheless, increased angina, especially in patients with underlying coronary artery disease, has been reported. Dysrhythmias such as atrial fibrillation and bradycardia resulting in syncope, as well as blood pressure changes, have also been reported.^{12,144}

Sudden death, syncope, repolarization changes, prolonged QT, and polymorphous ventricular tachycardia (torsades de pointes) in patients taking SSRIs have been reported to regulatory agencies. These effects may be due to the SSRIs themselves or may be a result of increased plasma levels of other medications, due to effects on the CYP450 system.¹²

Severe hyponatremia has been reported in elderly patients taking SSRIs such as fluoxetine and sertraline. The mechanism is unknown, and the hyponatremia

usually responds to withdrawal of the medication.¹⁴⁶ The syndrome of inappropriate antidiuretic hormone (SIADH) has also been reported with SSRIs and may be mediated through serotonin-2A and -2C receptors.¹⁴⁴

Seizures are uncommon, but have been associated with therapy with a number of the SSRIs.¹⁴⁷ Bupropion has a higher reported incidence of seizures, especially in patients with anorexia. However, the incidence in the general population is comparable with that associated with cyclic antidepressants and is usually associated with higher dosing.¹⁴⁸

Nefazodone has been associated with hepatic abnormalities and has been removed from the market in Sweden, other parts of Europe, and recently Canada.¹⁴⁹

Adverse effects reported at therapeutic dosing of mirtazapine include akathisia and hepatotoxicity that resolved with discontinuation of the drug.^{150,151} The serotonin syndrome has been described with both monotherapy and in combination with SSRIs therapeutically and in overdose, although the role of mirtazapine in causation of the serotonin syndrome is disputed.¹⁵²⁻¹⁵⁷

Discontinuation reactions or the SSRI withdrawal syndrome have been reported after the abrupt cessation of treatment with all SSRIs as well as venlafaxine and nefazodone. They are most common with paroxetine and fluvoxamine, and much less common with sertraline and fluoxetine. This is most likely related to pharmacologic differences, being much more common with agents with shorter half-lives and can be ameliorated with tapering of the agents when stopping therapy. The symptoms are usually mild and short lived, and common effects include fatigue, headache, nausea, diarrhea, agitation, insomnia, and lethargy. However, more novel discontinuation reactions may also occur with the SSRIs. These can be grouped into three common symptom clusters: effects on balance (vertigo, dizziness, and ataxia), sensory symptoms (numbness, paresthesias, and “shocklike” sensations), and aggressive and impulsive behavior (suicidal and homicidal thoughts). There is often overlap of these symptom clusters.^{23,158,159}

DIAGNOSIS

Laboratory Testing

Initial laboratory investigations should include complete blood count and routine biochemistry, including renal function. Specific blood levels of the SSRIs and other atypical antidepressants¹⁶⁰ are rarely available and do not aid management and thus are not routinely indicated.⁸ False-positive urine drug screens for amphetamines have been reported with bupropion and trazodone overdose.^{112,113,161} A false-positive drug screen for phencyclidine not confirmed by gas chromatography-mass spectrometry has been reported after a massive venlafaxine overdose.¹¹⁸ If rhabdomyolysis or the serotonin syndrome is suspected, serum creatine kinase and myoglobin should be analyzed.

Other Diagnostic Testing

An electrocardiogram should be obtained because cardiac effects may occur with SSRI and atypical antidepressant overdose. Other investigations may be indicated based on the clinical presentation.

DIFFERENTIAL DIAGNOSIS

There is no specific toxidrome or laboratory test that is diagnostic, and the differential diagnosis will depend on the patient's signs and symptoms. While most overdoses are asymptomatic, patients with an SSRI overdose may present with a decreased level of consciousness, and the differential diagnosis should include the ingestion of any agent or clinical condition that could result in an alteration of the mental status. If the patient has a seizure, then one should consider the differential diagnosis of toxin-induced seizures.

MANAGEMENT

Supportive Measures

Cardiac monitoring and pulse oximetry are indicated in all patients. Venous access is indicated in patients with symptoms or signs of an SSRI overdose. The airway, breathing, and circulation should be evaluated and corrective actions taken if there are any abnormalities. Indications for tracheal intubation include a significant decrease in the patient's level of consciousness or the need to establish or protect their airway. Supplemental oxygen is indicated for hypoxia. Hypotension should be managed initially with intravenous crystalloid solution. Vasopressor therapy is rarely needed, but should be instituted if hypotension persists despite adequate fluid resuscitation.

Patients with an altered mental status should have a bedside glucose determination performed, and hypoglycemia should be treated with hypertonic dextrose.

Decontamination

Activated charcoal is indicated if the patient presents within 2 hours of ingestion of a potentially toxic overdose. However, one must be cautious and protect the airway if the patient has an altered level of consciousness or seizures. Whole bowel irrigation may be considered if a sustained-release preparation is ingested or for late presentation. Gastric lavage or administration of ipecac is not indicated.

Laboratory Monitoring

The indication for serial laboratory testing is initial abnormalities or the development of ongoing toxicity such as the serotonin syndrome or rhabdomyolysis. If

there is QT prolongation on the ECG, then serial ECGs should be obtained until the QT is normalized.

Elimination

Due to the large volume of distribution of the SSRIs and significant protein binding, methods to enhance elimination such as multiple doses of charcoal or hemodialysis are not effective or indicated.

Antidotes

There are no specific antidotes. Anecdotally, sodium bicarbonate has been used to treat presumed sodium channel blockade-induced cardiotoxicity.^{60,74} The administration of a sodium bicarbonate bolus followed by an infusion should be considered if there is evidence of QRS prolongation.

Disposition

Patients with significant symptoms will require admission to hospital. Indications for intensive care unit admission include significant decreased level of consciousness, cardiac dysrhythmias, and presence of the serotonin syndrome.

Patients who are asymptomatic with no signs of toxicity may be discharged after 6 hours of observation in the emergency department after appropriate psychiatric consultation.⁸

JEFFREY BRENT, MD, PHD ■ ROBERT PALMER, PHD

At a Glance...

- Monoamine oxidase types A and B are responsible for the intracellular degradation of biogenic amines.
- Serotonin is metabolized almost exclusively by monoamine oxidase type A.
- Hypertensive reactions can occur if monoamine oxidase is inhibited and indirect-acting amine-releasing substances are ingested (tyramine or cheese reaction).
- In overdose, monoamine oxidase type A inhibition is associated with a severe multisystem syndrome involving neuromuscular and sympathetic hyperactivity and cardiovascular collapse.
- Treatment of monoamine oxidase inhibitor overdoses is mostly supportive.
- Direct-acting vasopressors (e.g., norepinephrine or phenylephrine) should be used for monoamine oxidase inhibitor overdose; indirect agents (e.g., dopamine) should be avoided.
- If monoamine oxidase type A is inhibited and another serotonergic agent is administered, there is a high likelihood of developing a serotonin-excess syndrome.
- Serotonin syndrome is characterized by altered mental status, myoclonus, hyperreflexia, diaphoresis, diarrhea, ataxia, and shivering.
- The treatment of serotonin syndrome is primarily supportive, but preliminary data suggest that cyproheptadine may be effective.

The monoamine oxidase inhibitors (MAOIs) are a structurally diverse group of pharmaceuticals whose place in therapy has been the center of considerable controversy during the past 40 years. This controversial position is largely caused by the many toxic reactions and interactions for which MAOIs are responsible. This chapter reviews the biochemistry of the enzyme MAO, the pharmacology of the MAOIs, and the diagnosis, pathophysiology, and treatment of the various toxic responses associated with these agents.

RELEVANT HISTORY

In 1951, isoniazid and its isopropyl derivative, iproniazid, were introduced for the treatment of tuberculosis. Although the latter antibiotic is no longer marketed, it was quickly noted that patients treated with it experienced elevated mood. This psychotropic effect was attributed to the ability of iproniazid to inhibit MAO. Although severe hepatotoxicity resulted in the removal of iproniazid from the market, the effect on mood prompted the use of other MAOIs for the treatment of depression. These compounds were the first true specific antidepressant agents used. In 1962, enthusiasm for the

use of MAOIs as antidepressants was tempered when a fatality associated with Stilton cheese ingestion in a patient taking an MAOI was reported.¹ The realization of the potential severity of adverse MAOI interactions caused considerable retrenchment from their use, a situation that has only recently been reconsidered.

The mood-elevating properties of MAOIs are attributable to the inhibition of an MAO isoenzyme family referred to as MAO type A (MAO-A), which is distinctly different from the MAO type B (MAO-B) isoenzyme. Although less useful as a target of antidepressant therapy, inhibition of the MAO-B isozyme also has therapeutic application. In 1989, several reports^{2,3} suggested that a selective MAO-B inhibitor, L-deprenyl (selegiline), had a marked effect in the treatment of Parkinson's disease. Inhibitors of MAO-B, including selegiline and rasagiline mesylate (not available in the United States), appear to slow the progression of Parkinson's disease and extend the time before it is necessary to treat patients with this condition with L-dihydroxyphenylalanine.⁴ This observation has sparked numerous investigations into the therapeutic role of MAO-B inhibition.

Currently, MAOIs are used for a variety of psychiatric indications, the most common of which is the treatment of depression refractory to standard antidepressant therapy. MAOIs have assumed this secondary role partly because of the reluctance to use these agents as a first-line drug given the concerns about the danger of major toxic effects. Other therapeutic applications of MAOIs include the treatment of vascular headaches, narcolepsy, panic disorders, phobias, obsessive-compulsive disorder, eating disorders, and post-traumatic stress disorder. For a full description of the numerous medical uses of MAOIs, readers are referred to several of the excellent references on this topic.⁵⁻⁷

THE PHYSIOLOGY OF MONOAMINE OXIDASE

Catecholamines are metabolized by MAO and catechol-O-methyl transferase (COMT). COMT is responsible for the degradation of extracellular catecholamines, such as those in the synaptic cleft. In contrast, MAO, a flavin-containing intracellular enzyme tightly bound to the outer mitochondrial membrane, is the major enzyme responsible for the catabolism of intracellular bioactive amines. Because MAO is confined to the intracellular compartment, the physiologic response to the administration of direct-acting pressor amines (e.g., norepinephrine) is unaffected by MAOIs.⁸

The intracellular location of MAO is a critical factor in understanding the pathogenesis of toxic reactions

associated with MAOIs. Normally, the presence of functioning MAO keeps the intracellular concentration of free biogenic amines quite low. Because of its location, inhibition of MAO raises concentrations of intracellular biogenic amine substrates. Those amine substrates that are located in storage vesicles, however, are protected from MAO degradation. Similarly, exogenous biogenic amines that act directly at extracellular receptors are relatively unaffected by MAO. Thus, inhibition of MAO does not result in increased concentrations of, and subsequent toxic reactions to, directly acting agents.

MAO catalyzes the oxidative deamination of biogenic amines such as epinephrine, norepinephrine, dopamine, 5-hydroxytryptamine (5-HT, serotonin), and tyramine. The generic reaction of MAO on primary biogenic amines is described as follows.⁹

Note that one of the products of the MAO reaction is hydrogen peroxide, which is a generator of highly toxic free radicals.¹⁰ Examples of the specific reactions of MAO with specific biogenic amines are shown in Figure 29-1.

With the exceptions of erythrocytes, blood serum, and skeletal muscle, virtually all tissues contain some small amounts of MAO. This enzyme is found primarily in brain, peripheral noradrenergic neuronal axons, intestine, and liver. First pass catabolism by hepatic and gastrointestinal MAO prevents systemic absorption and significant physiologic effects following the oral ingestion of pressor amines (e.g., tyramine or phenylethanolamine). In general, MAO levels tend to increase with age. The two isoenzymes of MAO are separate gene products, although they share considerable sequence

homology. Both genes for MAO are found on the X chromosome.

Monoamine Oxidase Isoenzymes

The two MAO isoenzymes differ in both their anatomic distribution and substrate specificity (Table 29-1). Because of these differences, the roles of the two isoenzymes in the pathophysiology of toxic syndromes associated with MAOIs must be considered separately.

The highest concentration of MAO is in the liver, which contains a slight predominance of MAO-A. Brain similarly contains both isoenzymes, although type B is found primarily in glial cells and serotonergic neurons. Platelets contain exclusively MAO-B.¹¹

Although qualitatively most substrates are oxidized by both isoenzymes, the substrate specificities of the MAOs¹²⁻¹⁴ exhibit quantitative differences (see Table 29-1). The Michaelis constant (K_m) and maximal velocity (V_{max}) for epinephrine, norepinephrine, dopamine, and tyramine are similar for both isoenzymes. However, serotonin (5-HT) is almost exclusively metabolized by MAO-A, while 2-phenylethylamine (the parent compound for amphetamine and its derivatives) is primarily metabolized by MAO-B.

The substrate preferences of the MAO isozymes are determined by the relative electrostatic, steric, and lipophilic properties of the substrate when compared with the enzyme active site. The three-dimensional structure of both isoenzymes is such that they have two active sites, a larger one for bulky substituents, and a smaller lipophilic one. However, the relative sizes of these sites are different in the two isoenzymes.¹⁵

FIGURE 29-1 Representative reactions of monoamine oxidase (MAO).

**TABLE 29-1 Monoamine Oxidase Isoenzymes**

LOCATIONS	SUBSTRATE SPECIFICITY
MAO-A	
Intestinal mucosa	Serotonin
Placenta	Dopamine
Biogenic amine terminals	Norepinephrine
Liver	Tyramine
Brain*	Epinephrine
MAO-B	
Brain*	Dopamine
Platelets	Tyramine
Liver	Phenylethylamine
	Epinephrine
	Norepinephrine

MAO-A, monoamine oxidase type A; MAO-B, monoamine oxidase type B.

*Approximately equal quantities of both isoenzymes exist in the brain, but there are considerable differences in their regional distribution. In addition, monoamine oxidase type B is found primarily in glial tissue.

PHARMACOLOGY AND PHARMACOKINETICS OF MONOAMINE OXIDASE INHIBITORS

The MAOIs are available only as oral preparations. In general, MAOIs are rapidly and completely absorbed from the gastrointestinal tract, with peak plasma concentrations ranging from 1 to 4 hours after ingestion.¹⁶⁻¹⁸ Plasma elimination of these agents occurs largely by hepatic metabolism and is also rapid; half-lives range from 1 to 3 hours. In general, MAOIs are transported into cells by the neurotransmitter amine reuptake system. For irreversible MAOIs, maximal MAO inhibition takes 5 to 10 days after initiation of drug therapy. Thus, plasma drug concentrations do not correlate with the level of MAO inhibition.¹⁶⁻¹⁸ For reversible MAOIs, however, maximal inhibition of MAO occurs within a few hours of the first dose.

As can be seen in Table 29-2, MAOIs are generally classified according to their preferential effect on the isoenzyme they inhibit. For most of these agents, however, the selectivity is not complete and tends to be lost at higher doses and especially in overdose. The selective MAO-B inhibitor selegiline has been reported to lose some of its selectivity at doses as low as 10 mg/day, a dose that is in the therapeutic range.¹⁹

MAOIs may also be classified as either reversible or irreversible inhibitors of MAO. The classic MAOIs are irreversible inhibitors of the enzyme. Although serum concentrations of the MAOIs decline rapidly after last use, their effects are long-lived. It is generally believed that a period of 2 to 3 weeks is necessary to regain MAO activity after the cessation of the administration of an irreversible inhibitor, because new enzyme must be synthesized.¹⁷

A new class of reversible inhibitors of MAO,²⁰⁻²⁶ the prototype of which is moclobemide, have been devel-

oped (see Table 29-2). Other agents include bexloxadone, brofaromine, cimoxatone, and teloxantrone. The reversible inhibitors act primarily on MAO-A and are therefore referred to as reversible inhibitors of MAO-A (RIMAs). The effect of RIMAs is short lived, with MAO activity being reconstituted within hours to days of the last dose. Because of the reversible nature of the binding of RIMAs with MAO, adverse reactions such as the pressor effect with tyramine ingestion (“cheese reaction”) are unlikely to occur.²⁴ Approximately 150 mg of tyramine is needed to cause an increase in blood pressure while taking moclobemide. This is the equivalent of eating approximately 300 g of a tyramine-containing cheese.²⁷ Thus, although a tyramine reaction is theoretically possible, it is highly unlikely to occur given the doses required. The reason why MAO-A inhibition by moclobemide does not predispose to a tyramine reaction is a result of competitive substrate binding; the tyramine displaces the RIMA from the enzyme active site, allowing normal metabolism of the substrate.

Several of the older MAOIs are substituted hydrazine ($\text{NH}_2\text{-NH}_2$) derivatives (see Table 29-2). These MAOIs tend to be metabolized into active products and, like the well-known hydrazine isoniazid, are inactivated by *N*-acetylation at a genetically determined rate. The human population can be broadly separated into fast and slow acetylators on the basis of the rate of this reaction. For example, approximately equal numbers of American and European whites may be classified as fast versus slow acetylators. The rate of slow acetylators is higher in Asian populations. Slow acetylators may be at greater risk for developing adverse effects (e.g., drug and dietary interactions) with therapeutic doses. Various adverse effects are specifically associated with the hydrazine-derived MAOIs.²⁸ Most prominent among these are the inhibition of multiple enzyme systems, hepatotoxicity, and the induction of pyridoxine (vitamin B_6) deficiency with the associated problem of seizures. The hepatotoxicity of MAOI hydrazines has been well reviewed.²⁹⁻³¹

Among the various other enzyme systems inhibited by hydrazine MAOIs, the most important are pyridoxal kinase, L-amino acid decarboxylase, diamine oxidase, and cytochrome P-450.²⁸ In addition, hydrazines tend to form soluble complexes with pyridoxine, resulting in a deficiency of this vitamin by enhancing its urinary excretion.

In addition to the induction of pyridoxine deficiency, hydrazines prevent the use of pyridoxine for important metabolic reactions. Pyridoxine is not active as an enzyme cofactor until it is phosphorylated to pyridoxal phosphate by the enzyme pyridoxal kinase. Among the reactions for which pyridoxal phosphate is a cofactor is the synthesis of γ -aminobutyric acid (GABA) by the decarboxylation of glutamic acid, catalyzed by L-amino acid decarboxylase. Reduced production of GABA may cause the development of profound seizures as a result of poisoning by hydrazine MAOIs. The specific treatment for these seizures is administration of pyridoxine.

Virtually all MAOIs have a terminal phenyl group attached to a short aliphatic side chain, thus mimicking

the phenethylamine structure of amphetamines (Fig. 29-2). It is thus possible that excessive doses of these agents may cause amphetamine-like reactions. Conversely, amphetamine or its derivatives tend to have some inhibitory effects on MAO.

MAOIs enhance synaptic biogenic amine transmitter concentrations by various mechanisms (Box 29-1). By inhibiting the enzymatic degradation, the cytoplasmic concentrations of these neurotransmitters are increased, resulting in the tendency for release of these biogenic amines by a mass action effect. In addition, the act of

transporting the MAOI into the cell by the amine reuptake system causes the ligand-binding site of the membrane-bound transporter molecule to face inward, and it thus becomes available for the transport of neurotransmitter out of the cytoplasm into the synapse or neuroeffector junction. By being transported into the cell by the amine reuptake pump, the MAOIs act as competitive inhibitors of bioactive amine transport out of the synapse by this system. All of these factors tend to increase both intracellular and extracellular amine levels.

FIGURE 29-2 Chemical structures of selected monoamine oxidase inhibitors. The structures of phenethylamine, amphetamine, and methamphetamine are included for comparison.

**BOX 29-1****FACTORS CONTRIBUTING TO MONOAMINE OXIDASE TYPE A INHIBITOR TOXICITY**

Decreased biogenic amine degradation
 Amphetamine-like effect and increased catecholamine release from intracellular vesicles
 GABA deficiency (hydrazines)
 Decreased amine reuptake
 Depletion of biogenic amine stores
 GABA antagonism (tranylcypromine, isocarboxazid)
 Increased amine release
 Metabolism to amphetamine (tranylcypromine)

GABA, γ -aminobutyric acid.

Being amphetamine congeners, MAOIs provoke release of stored amines from presynaptic vesicles, and thus the free intracellular concentrations of these molecules are increased. Given the decreased degradation of these amines by virtue of inhibition of MAO, any free bioactive amine molecules resulting from either release from vesicles or from reuptake are relatively protected from catabolism.

As noted in Table 29-2, the MAOIs differ in their characteristics. Several of them, however, merit specific comment.

Although no longer available as a therapeutic agent, clorgyline is the prototypic inhibitor of MAO-A. By virtue of the fact that nanomolar concentrations of this agent irreversibly inhibit MAO-A in a selective manner, this particular isoenzyme was defined.

Moclobemide is the prototype RIMA.²⁰⁻²⁶ Although not available in the United States, moclobemide is available in most other parts of the world. In general, it appears that moclobemide and other RIMAs are safer than the traditional MAOIs.

In addition to the MAOIs noted in Table 29-2, various other agents have weak inhibiting properties of this enzyme. For example, procarbazine (Matulane, Sigma-Tau Pharmaceuticals, Gaithersburg, MD), a chemotherapeutic agent used in regimens to combat Hodgkin's disease, is also a weak, nonselective, irreversible MAOI. Linezolid (Zyvox [Pfizer, New York, NY]), a novel antimicrobial, is a reversible, nonselective MAOI. In addition, St. John's wort, an herbal supplement, has been noted to have weak MAOI activity. Fortunately, MAO inhibition by these agents is unlikely to have significant therapeutic implications.

Tranylcypromine is an MAOI with great structural similarity to amphetamine. It may be metabolized to amphetamine, which may have a role in some of the toxicity of this agent. In addition, tranylcypromine can inhibit the action of GABA at the GABA_A receptor by preventing chloride influx. This inhibition of GABA activity by tranylcypromine may be responsible for the seizures observed with therapeutic doses of this agent. A similar effect on GABA channels is possible with isocarboxazid.

Selective MAO-B inhibition with selegiline is utilized in the treatment of Parkinson's disease since it inhibits striatal dopamine degradation. Selegiline is metabolized to *l*-methamphetamine, which is substantially less active than its *d*-isomer. Although the serum half-life of selegiline is short (0.15 hour), it is an irreversible inhibitor of MAO-B and thus its effects are long-lasting. Although relatively safe compared with the nonselective MAOIs, when selegiline and levodopa are concurrently administered, dopaminergic effects (hallucinations and dyskinesia) may occur.

TOXICOLOGY AND CLINICAL MANIFESTATIONS OF OVERDOSE

Overdose with the classic irreversible inhibitors of MAO-A, although infrequent, is associated with extremely high morbidity and mortality. All classic MAO-A inhibitors can cause a similar severe toxic syndrome in overdose. Ingestion of these agents in amounts greater than approximately 2 mg/kg should generally be considered potentially life threatening.³² Although many factors affect the course of poisoning by these agents, a general chronologic framework may be noted in the construct of MAOI overdose. This syndromic description, promulgated by Linden and coworkers,³² highlights the following four phases:

1. Asymptomatic (latent)
2. Neuromuscular excitation and sympathetic hyperactivity
3. Central nervous system (CNS) depression with the potential for cardiovascular collapse
4. Secondary complications for survivors of the above

As noted in this scheme, a relatively asymptomatic period may precede the significant clinical manifestations of MAOI poisoning. Although it is unusual for this latent period to last for more than 6 to 12 hours, it is generally believed that patients ingesting these agents should be observed for a full 24 hours to adequately rule out significant toxicity.³²⁻³⁵

The clinical effects of MAO-A inhibitor overdose are varied. Early manifestations frequently include headache and mild agitation, which may progress to profound central and peripheral nervous system stimulation associated with increased agitation, hyperthermia, hyperreflexia, diaphoresis, tremor, myoclonus, seizures, rhabdomyolysis, and a general hypersympathetic state. More serious cases may evolve to frank rigidity. The hyperadrenergic state is often followed by obtundation and a sympatholytic syndrome, which may deteriorate to cardiovascular collapse. Common in cases of acute overdose are manifold complications that include adult respiratory distress syndrome, disseminated intravascular coagulation, multiple organ system failure, and rhabdomyolysis.^{32,33,35-39}

The pathophysiology of MAO-A inhibitor overdose involves many factors (see Box 29-1). The exact weight of the contribution of each of these factors is variable and

may depend on multiple factors, including exact drug, dose ingested, and the underlying physiology of the patient.

Inhibition of MAO-A is associated with various effects on the degradative metabolism of intracellular catecholamines, indoles, and histamine. Because MAO-A is the major enzyme involved in degradation of these intracellular amines, inhibition results in increased cytoplasmic concentrations of these substances. Normally stored in intracytoplasmic vesicles, these amines are generally inaccessible to MAO. However, any amine that is released from these vesicles, metabolically generated, or free amine resulting from reuptake will not be normally degraded by MAO.

5-HT is the major biologically active indole metabolized by MAO-A (Fig. 29-3). Thus, inhibition of MAO-A results in elevated levels of intracytoplasmic 5-HT.⁴⁰ It should be noted, however, that alternative minor pathways for 5-HT metabolism also exist.⁴⁰⁻⁴² Tryptamine is an eptogenic indole produced by the metabolic decarboxylation of tryptophan.⁴³ MAO is the major enzymatic pathway for the catabolism of tryptamine, which is oxidatively deaminated to indoleacetic acid.^{40,44} After poisoning by MAO-A inhibitors, urinary excretion of unmetabolized tryptamine increases.⁴⁰ This inhibition of tryptamine catabolism may contribute to the CNS excitation and seizures that occur after overdose with these agents.

FIGURE 29-3 Metabolism of tryptophan.

Histamine is metabolized either oxidatively to imidazole acetic acid or by *N*-acetylation to *N*-acetylhistamine.⁹ The oxidative metabolism of histamine is accomplished by either MAO or diamine oxidase. As already noted, hydrazine MAOIs inhibit both of these enzymes. Thus, overdoses with hydrazine MAOIs are expected to result in elevated histamine levels,⁴⁰ which would contribute to flushing and hypotension.

All of these factors associated with an overdose of an MAO-A inhibitor may be anticipated to increase intracytoplasmic biologically active amine concentrations. However, the exact contribution of the inhibition of MAO to the toxidrome engendered by an acute overdose of these agents is unknown. Some doubt may be raised about the significance of the inhibition of MAO in acute overdose because clinically effective MAO inhibition takes approximately 1 week with therapeutic dosing. It is possible that higher doses may cause faster inhibition of this enzyme.

Although moclobemide is safer than the traditional MAOIs, there are reports of overdose patients sustaining cardiovascular collapse after a delay of many hours. Fatalities have been reported at serum moclobemide concentrations of 55 mg/L and higher (therapeutic 1.5 to 2.5 mg/L).⁴⁵

DIAGNOSIS

The diagnosis of MAOI poisoning is made by a positive history of exposure and corroborating evidence from the physical examination. The presence of an altered mental status coupled with autonomic and neuromuscular dysfunction (e.g., a hyperadrenergic and hyperserotonergic state) suggest MAOI toxicity. In the absence of a positive history of ingestion, however, it is extremely difficult to make a definitive diagnosis of MAOI toxicity. The presence of “ping-pong” gaze (slow, rhythmic, saccadic eye movements or ocular clonus) may suggest MAOI toxicity, but there are no pathognomonic physical findings or laboratory findings commonly associated with MAOI poisoning. Serotonin syndrome and MAOI poisoning have a significant degree of overlap in their pathophysiology and clinical manifestations. Other conditions that could create a similar clinical picture include the neuroleptic malignant syndrome, sepsis, tetanus, meningoencephalitis, intracranial hemorrhage, heatstroke, malignant hyperthermia, sympathomimetic syndrome, central hallucinogen toxicity, lithium toxicity, salicylism, hypoglycemia, thyrotoxicosis, and pheochromocytoma.

Although toxicology screening may be useful to exclude other intoxications, screening methods are unlikely to detect MAOIs. Specific qualitative and quantitative testing for MAOIs are not readily available and do not correlate with the severity of toxicity.

TREATMENT

The treatment of MAO-A inhibitor overdose is primarily supportive. The early sympathomimetic component of MAO-A inhibitor poisoning may have associated hyper-

tension, which can be severe. However, caution must be used in the treatment of this hypertension because this early sympathomimetic state may unpredictably and suddenly be replaced by a sympatholytic syndrome. Thus, the treatment of MAOI-induced hypertension should involve a short-acting titratable agent such as phentolamine or nitroprusside. Standard agents should be used to treat cardiac dysrhythmias. Gastrointestinal decontamination for patients presenting after an MAOI overdose should include administration of activated charcoal if the ingestion occurred within 1 to 2 hours of patient presentation.

Although not systematically studied in a controlled trial, aggressive management of MAOI-induced hyperthermia should be considered to be of paramount importance in favorably altering a patient's prognosis.

The muscular hyperactivity and CNS stimulation in MAOI overdoses contribute to catecholamine release,⁴⁶ hyperthermia, and rhabdomyolysis. Thus, sedation of agitated, rigid, or hyperactive patients with benzodiazepines or barbiturates is generally beneficial. Benzodiazepines may be preferable because they are typically associated with fewer hemodynamic side effects. Linden and colleagues suggested that amobarbital would be an appropriate barbiturate to use because of its short duration of effect and rapid onset of action.³² If rigidity, agitation, or muscular activity cannot be readily and effectively controlled by simple pharmacologic maneuvers, then neuromuscular paralysis should be induced. It must be remembered, however, that neuromuscular blockade obscures the ability to observe seizures, and thus paralyzed patients may be experiencing unappreciated CNS seizure activity. It is therefore important to use a short-acting paralytic agent, induce a state of partial paralysis as measured by twitches, or to perform continuous electroencephalographic monitoring.

Blood pressure support should be accomplished using direct-acting sympathomimetic amines such as epinephrine, norepinephrine, or phenylephrine. The benefits of the direct agonists are that they act directly at smooth muscle receptors on blood vessels and do not require intracellular metabolism to generate an active pressor amine. In addition, direct agonists undergo COMT-mediated catabolism. However, because of decreased reuptake of these amines coupled with diminished degradation of any that is transported to the intracellular compartment, an exaggerated response is a theoretical possibility.⁴⁷ Therefore, low and titrated doses should initially be used.

The indirect-acting amines that are used for blood pressure support (e.g., dopamine) are metabolized to active pressors (epinephrine and norepinephrine) intracellularly. MAO normally prevents excessive amounts of these active metabolites from being generated; however, in the setting of MAO inhibition, elevated concentrations of these amines may lead to an exaggerated hemodynamic response. Thus, indirect pressor amines are generally considered to be contraindicated, although this notion is based primarily on theoretical grounds.

As already discussed, a hyperexcitable state or seizures in patients who have overdosed on a hydrazine

type of MAOI (see Table 29-2) should be treated with pyridoxine. Because one element of the toxidrome observed following MAOI overdose is an excess of 5-HT, it seems reasonable that a serotonin antagonist would be of benefit. However, this treatment approach has not been well studied. The primary sites at which excess serotonin causes significant clinical effects are the 5-HT₁ and 5-HT₂ receptors. Cyproheptadine is an antagonist at 5-HT₁ and 5-HT₂ receptors and is relatively devoid of potentially harmful effects; however, it is available only as an oral preparation. Methysergide is a 5-HT₁ and 5-HT₂ antagonist but is also not available as a parenteral preparation. Ondansetron is a 5-HT₃ antagonist, and it is unlikely that this receptor is involved in the pathogenesis of the MAOI toxidrome or serotonin syndrome. Procainamide, propranolol, and trazodone also have 5-HT antagonist properties; however, little is known about the effects of these agents in MAOI overdose, and these drugs may produce undesirable hemodynamic effects. Bromocriptine is an ergot derivative that is a direct partial agonist at the dopamine receptor and blunts the effects of excess dopamine. Its use has not been proven effective for the MAOI toxidrome. Dantrolene sodium is an inhibitor of calcium release from the sarcoplasmic reticulum of skeletal muscle and thereby attenuates excitation-contraction coupling. Theoretically, it may be of use in decreasing the muscle rigidity associated with MAOI poisoning. As noted earlier, hydrazine MAOIs (see Table 29-2) block histamine catabolism, and therefore antihistamines (e.g., diphenhydramine) may be of some benefit in these cases.

The antihypertensives tolazoline, pentolinium, and clonidine have been touted as appropriate agents to treat the hypertension associated with the early stages of MAOI poisoning.^{48,49} However, no evidence shows that these agents are preferable to other antihypertensives, and their half-lives may be too long.

Urinary acidification has a minor enhancing effect on the urinary excretion of tranlycypromine.⁵⁰ No data suggest that urinary acidification will further the clearance of other MAOIs. Given the almost inevitable rhabdomyolysis associated with the MAOI toxidrome and the lack of proven efficacy of urinary acidification, this treatment should be considered contraindicated.

INTERACTION OF MONOAMINE OXIDASE INHIBITORS WITH DIETARY AMINES

One of the greatest concerns in the therapeutic use of MAOIs is the potential hypertensive reaction associated with the ingestion of dietary amines. The amine most commonly implicated in these reactions is tyramine. Because the vast majority of all reported reactions and deaths have been associated with the ingestion of tyramine-containing cheese,^{51,52} the name generally applied to this phenomenon is the cheese reaction. Spontaneous cases in the absence of any apparent

exogenous amine have also been reported in patients taking both classic MAOIs and RIMAs.^{53,54}

Tyramine does not cross the blood-brain barrier. Therefore, the manifestations of the cheese reaction are due to its peripheral actions. Tyramine is an indirect-acting agonist that, similar to cocaine, competes for reuptake and thus increases synaptic concentrations of norepinephrine and dopamine.

Dietary tyramine is normally metabolized by gastrointestinal MAO-A,⁵⁵⁻⁵⁸ and, thus, little of it gains access to the systemic circulation. Approximately 87% of an oral dose of tyramine is metabolized by this pathway to *p*-hydroxyphenylacetic acid.⁵⁹ That fraction which is absorbed is further subject to degradation by neuronal MAO-A. Although tyramine is a substrate for both MAO isoenzymes, MAO-A provides protection from the cheese effect. Patients taking MAO-B inhibitors are much less vulnerable to a cheese reaction; they become susceptible only at supratherapeutic doses of the inhibitor when isoenzyme selectivity may be substantially reduced.⁶⁰

The literature contains considerable debate and misunderstanding about the potential dietary sources of tyramine and the resulting restrictions required of patients being treated with MAO-A inhibitors. The list of various foods that have been implicated in hypertensive reactions associated with MAO-A inhibitors is lengthy (Box 29-2). Such an extensive list of dietary restrictions is both impractical and not justified by scientific data. However, certain dietary restrictions do appear to be necessary.

The greatest concern with regard to food interactions with MAO-A inhibitors involves cheeses. On average, European cheeses contain 20 mg tyramine per 100 g of cheese.⁵⁹ However, marked differences may exist between individual types of cheese. Many aged cheeses are high in tyramine content and therefore should be restricted, but other aged cheeses such as Brie, Emmenthal, Mozzarella,^{61,62} and Gruyère contain little tyramine and can be eaten without concern.⁵¹ Cottage cheese, processed cheese slices, ricotta, cream cheese, Romano,⁶¹ Havarti, Boursin, Parmesan, bleu cheese dressing, Gorgonzola, feta, Muenster, sour cream, and yogurt can likewise be eaten because of their low tyramine content.⁵¹ Thus, it appears that a cheese pizza may be safe to eat when taking an MAO.⁶¹ Alcoholic beverages have been a source of concern, although few contain dangerously high concentrations of tyramine. Beer, even dealcoholized, has been implicated in hypertensive reactors.⁶³ Chianti wine has traditionally been singled out because of a 1964 report showing dangerously high tyramine levels.⁶⁴ However, more recent studies have failed to confirm this.⁵¹

The original reports of high levels of tyramine in pickled herring⁶⁵ have not been replicated by more recent studies.^{51,66} It has been suggested that the original report by Nuessle and colleagues in 1965⁶⁵ alleging a high concentration of tyramine in this fish was due to either an unreliable assay method or spoilage. Similarly, studies of smoked fish and caviar have also failed to demonstrate any significant tyramine content.⁵¹

BOX 29-2

FOODS IMPLICATED IN HYPERTENSIVE REACTIONS WITH MONOAMINE OXIDASE INHIBITORS

Cheese	Alcoholic Beverages	Fish	Meat	Fruit	Yeast Extracts
All cheeses except cottage cheese and yogurt	Red wine (especially Chianti) Sherry Vermouth Cognac Beer Liqueurs	Smoked fish Pickled Herring Caviar	All fermented/aged meat, including: Corned beef, Salami Pepperoni Liver Sausage	Spoiled or overripe fruits Canned or overripe figs Stewed or whole bananas (including peeled)	Vitamin supplements (brewer's yeast)
Sauerkraut	Bouillon	Soy Sauce	Beans Broad bean pods (Italian green beans) Fava beans		

Processed meat such as salami and some sausage have been shown to be high in tyramine.^{51,66} However, other meats such as liver, bologna, aged meat, corned beef, and pâtés have failed to demonstrate any significant tyramine content. Fruits and figs, including avocado, have virtually no tyramine content and should not be restricted. The one exception is banana peels, which contain approximately 1.4 mg of tyramine per peel. Therefore, preparations of whole banana should be eaten only in moderation.

Concentrated yeast extracts (Marmite [Unilever Best Foods, UK]) contain a significant amount of tyramine and should be restricted in patients taking MAO-A inhibitors.^{51,67} However, various brewer's yeasts have low to nonexistent tyramine content and may be eaten without concern.⁵¹ Sauerkraut contains nearly 14 mg of tyramine per 250-g serving and therefore should be considered contraindicated in patients who are taking MAO-A inhibitors. Bouillon and soy sauce have been found to contain very low amounts of tyramine and therefore can be eaten without any concern.⁵¹ Fava beans contain virtually no tyramine.⁵¹ Italian green broad bean pods are not a concern with regard to their tyramine content, although they do contain the indirect-acting pressor dihydroxyphenylalanine (DOPA) and therefore should not be eaten.⁶⁸

Given these data, it is clear that many of the existing lists of foodstuffs to be avoided by patients taking MAO-A inhibitors are unduly restrictive, and more liberalized and scientifically based suggestions have evolved.^{51,69,70} It appears to be safe for patients using MAO-A inhibitors simply to avoid aged cheeses, concentrated yeast extract (Marmite), Italian broad bean pods, sauerkraut, salami, and sausage.

If a patient does have a hypertensive response associated with the ingestion of a dietary amine, treatment is generally considered to consist of pharmacologic control of blood pressure and management of any complications associated with the hypertensive episode. If the ingestion was within the last 1 or 2 hours, administration of activated charcoal may be considered on theoretical grounds. Although no controlled studies have investigated the appropriate management of these

hypertensive responses, phentolamine in doses of 5 to 10 mg is generally recommended because it is an α -receptor antagonist and will antagonize the hypertensive effect of norepinephrine. However, no data suggest that other antihypertensive regimens would be any less effective.

It is generally considered that there is a lower risk for a cheese reaction with MAO-B inhibitors,^{24,71,72} except if they are taken in high doses, which may cause these agents to lose their isoenzyme selectivity.^{27,60} However, hypertensive reactions have been reported in patients taking selegiline.¹⁹ In contrast to case reports, a meta-analysis of clinical trials with selegiline found no difference in the incidence of clinical effects between those taking the drug and placebo.⁷³ Thus, it appears that these reactions are less likely to occur clinically with these agents than with MAO-A inhibitors, although the possibility cannot be ruled out. Data from human volunteer studies indicate that selegiline does appear to decrease the catabolism of tyramine.¹⁹

Reversible inhibitors of MAO-A are unlikely to cause a pressor response from ingested cheese because tyramine can displace RIMAs from the MAO-A binding site.^{24,25,60} Very large doses of tyramine can cause an elevation in blood pressure in patients taking RIMAs.²⁷ However, hypertensive responses to dietary amines have not been reported with the use of these agents.

SEROTONIN SYNDROME

Relevant History

In 1955, a "fatal toxic encephalitis" was described in a patient who received meperidine while he was being treated for tuberculosis with iproniazid. Before the patient's death, he exhibited severe muscular hyperactivity, rigidity, and clonus.⁷⁴ Shortly thereafter, Oates and Sjoerdsma⁷⁵ noted that tryptophan administered to patients who were taking an MAOI caused a phenomenon of unsteady gait, clonus, tremor, incoordination, feeling of lightheadedness, paresthesias, CNS excitation, dilated pupils, and hyperactive reflexes. Noting that

tryptophan is a precursor in the biosynthetic pathway of both 5-HT and the neuroexcitatory transmitter tryptamine (see Fig. 29-3), the researchers concluded that inhibition of MAO caused an increase in levels of these molecules.⁷⁵ That these effects were indeed likely due to a derivative of tryptophan was verified by Smith and Prockop,⁷⁶ who showed that high doses of this amino acid can cause a similar effect. The following year, similar effects were observed when rhesus monkeys were fed high doses of tryptophan.⁷⁷ That these effects were likely not due to the tryptophan itself but to a metabolic derivative was shown in 1964 by Hodge and colleagues,⁷⁸ who demonstrated that they can be prevented by the administration of an inhibitor of the enzyme L-amino acid decarboxylase, which prevents the formation of tryptamine and 5-HT from tryptophan (see Fig. 29-3).

In 1971, Grahame-Smith⁷⁹ produced a similar phenomenon in rats, thus creating the animal model most commonly used to study serotonin syndrome. That the observed syndrome is due to heightened levels of serotonin and not tryptamine was suggested by the clinical report by Beaumont,⁸⁰ which described four cases of a fatal interaction associated with similar symptoms as the prior reports, in patients taking an MAOI and the serotonergic antidepressant clomipramine (Anafranil). Although not specifically discussed in this report, this interaction suggested that 5-HT was responsible for this syndrome. In 1982, Insel and associates⁸¹ described a similar syndrome in patients taking clomipramine plus an MAOI and coined the term *serotonin syndrome*. The reader is referred to Chapter 10A for additional information on serotonin syndrome.

Pathophysiology of Serotonin Syndrome

Since the mid-1930s, it has been known that a substance in intestinal enterochromaffin cells had a stimulating effect on bowel motility.⁸² In 1948, a vasoconstrictor material was isolated from serum and named *serotonin*. This material was subsequently chemically characterized as 5-HT.⁸³ By 1952, it was known that 5-HT was the gut-stimulating material from the enterochromaffin cells.⁸²

It is now known that serotonin is synthesized from tryptophan (see Fig. 29-3) intracellularly and stored in vesicles by ion trapping. Any free 5-HT that is not so stored is metabolized by intracellular MAO to 5-hydroxyindoleacetaldehyde.

Serotonin is found in high concentrations in platelets, enterochromaffin cells of the gastrointestinal tract, and the brain. Platelet 5-HT is important in hemostasis. Intestinal enterochromaffin cells contain approximately 90% of the total-body 5-HT. Tumors of these cells produce excess amounts of 5-HT and give rise to the carcinoid syndrome.

Serotonin acts by interaction with a specific family of receptors. The universe of serotonin-binding sites was originally thought to be composed of two separate receptors known as M and D.⁸⁴ However, by the early 1970s, studies of lysergic acid diethylamide (LSD)

binding to serotonin receptors indicated that this scheme of two receptor types was too simple. Subsequently, seven families of serotonin receptors were demonstrated. Because there are subtypes within these families, we now know of 13 separate serotonin receptors.⁸⁵ All are G-protein coupled except the 5-HT₃ receptor, which is a ligand-gated ion channel (see Chapter 10). The 5-HT_{1A} and 5-HT_{2A} receptors appear to be of importance in the pathogenesis of the serotonin syndrome. Agonists at the 5-HT_{1A} receptor, which include LSD and 5-HT, inhibit the firing of raphe neurons. These neurons tend to modulate and attenuate sensory input. 5-HT_{2A} receptors are excitatory and stimulate vascular smooth muscle and the CNS neurons. Serotonin is an indole compound structurally similar to LSD and psilocybin. The effects of these hallucinogens are mediated through interaction with the serotonin receptors (see Chapter 45). Because 5-HT_{1A} and 5-HT₂ antagonists block features of the serotonin syndrome, it has been concluded that these receptors are responsible for the various manifestations of 5-HT excess. An alternative explanation for the serotonin syndrome derives from the similarity in clinical features between this condition and the neuroleptic malignant syndrome, which results from blockade of central dopamine effects (see Chapters 10A and 38). An excess of 5-HT inhibits brain dopaminergic neurons by blocking dopamine release or synthesis.⁸⁶⁻⁸⁸ If this hypothesis is true, then some or all of the clinical features of the serotonin syndrome could potentially be blocked or attenuated by dopamine agonists. This has not been well studied experimentally.

Clinical Manifestations

Serotonin syndrome is commonly identified by the presence of the triad of alteration of mental status, autonomic hyperactivity, and neuromuscular dysfunction. In 1991, Sternbach⁸⁹ reviewed 38 reported patients with serotonin syndrome and used the observed clinical features to define his diagnostic criteria (see next section). The most common manifestations were, in decreasing order of frequency, restlessness, confusion, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, hypomania, diarrhea, and incoordination. A later review found that the most common reported manifestations were, in order of decreasing frequency, hyperreflexia, altered mental status, myoclonus, ataxia, diaphoresis, fever, shivering, and diarrhea.⁹⁰ Mills conducted the most comprehensive analysis of reported cases and reported the signs and symptoms in 100 previously reported cases, dividing them into cognitive/behavioral, autonomic, and neuromuscular. The results of his analysis are shown in Table 29-3.

Diagnosis of Serotonin Syndrome

Given the clinical presentation of serotonin syndrome, the differential diagnosis to be entertained is broad and includes withdrawal states, tetanus, neuroleptic malignant syndrome, thyrotoxicosis, sepsis, and overdose of

TABLE 29-3 Signs and Symptoms of Serotonin Syndrome (Review of 100 Cases)

sympathomimetics, strychnine, MAOIs, or lithium. Sternbach⁸⁹ proposed the following three diagnostic criteria for the serotonin syndrome:

- A. Coincident with the addition of a known serotonergic agent to an established medication regimen or an increase in its dose, at least three of the following clinical features are present:
 1. Mental status changes (confusion, hypomania)
 2. Agitation
 3. Myoclonus
 4. Hyperreflexia
 5. Diaphoresis
 6. Shivering
 7. Tremor
 8. Diarrhea
 9. Incoordination
 10. Fever

- B. Other causes (e.g., infectious, metabolic, substance abuse or withdrawal) have been ruled out.
- C. A neuroleptic had not been started or increased in dose before the onset of the signs and symptoms listed earlier.

Insel⁸¹ and Dursun^{91,92} and their colleagues have suggested modifications of Sternbach's criteria by replacing the 10 items under the first diagnostic criterion with the following, of which three were believed to be required:

1. Uncontrollable shivering
2. Incoordination
3. Restlessness in the feet while sitting
4. Initial involuntary contractions followed by myoclonus-like movements in the legs
5. Hyperreflexia
6. Frightened, diaphoretic hyperarousal state
7. Agitation
8. Oculogyric crisis
9. Diarrhea
10. Fear

The diagnosis of serotonin syndrome is clinical. No laboratory tests confirm the diagnosis. It requires the presence of known exposure to serotonin-potentiating agents and the appropriate constellation of physical findings. More recently, an alternative algorithm for diagnosis has been proposed that is considered simpler to use and to have a higher sensitivity and specificity.⁹³⁻⁹⁶ Using this algorithm, the diagnosis of serotonin syndrome is made if a serotonergic agent has been recently introduced and there is the presence of any of the following: (1) tremor and hyperreflexia; (2) spontaneous clonus; (3) muscle rigidity, temperature greater than 38° C, and either ocular clonus or inducible clonus; (4) ocular clonus and either agitation or diaphoresis; or (5) inducible clonus and either agitation or diaphoresis. With this latter clinical algorithm, the presence of clonus is the single most important physical finding that suggests the diagnosis of serotonin syndrome.⁹³ It is also important to understand that the serotonin syndrome encompasses a broad spectrum of illness severity, from very mild to severe and immediately life-threatening stigmata.⁹³

Agents That Cause Serotonin Syndrome

Theoretically, any scenario that produces an increase of 5-HT concentrations can result in serotonin syndrome. However, this syndrome typically results from a combination of serotonergic agents rather than simply an increase in a single medication. This occurs most commonly when two agents that increase serotonin levels by different mechanisms are taken. The various serotonergic agents are listed in Table 29-4. In 1995, Bodner and associates⁹⁷ compiled a six-page table documenting the various interactions of serotonergic agents that may cause the serotonin syndrome. A comprehensive list would be much longer now and difficult to commit to memory. It is, thus, best to understand that any two serotonergic agents in combination are at least theoretically capable of causing this

TABLE 29-4 Serotonergic Agents

AGENT	MECHANISM
MAOIs	Inhibit serotonin breakdown
Clomipramine	Inhibits serotonin reuptake
Selective serotonin reuptake inhibitors	Inhibit serotonin reuptake
Tryptophan	Metabolized in serotonin
Lithium	Enhances serotonin release, potentiates effects of 5-HT _{1A} receptor
Amitriptyline/imipramine	Inhibits serotonin reuptake
Meperidine	Inhibits serotonin reuptake
Dextromethorphan	Inhibits serotonin reuptake
Levodopa	Causes serotonin release
Trazodone	Inhibits serotonin reuptake
MDMA	MAOI, cause serotonin release
Amphetamines	Cause serotonin release
Cocaine	Causes serotonin release
Lysergic acid diethylamide (LSD)	5-HT _{1A} agonist

MAOI, monoamine oxidase inhibitor; 5-HT, 5-hydroxytryptamine; MDMA, 3,4-methylenedioxymethamphetamine.

syndrome. The most common drug combinations reported to cause serotonin syndrome are MAOIs plus selective serotonin reuptake inhibitors (SSRIs)^{89,90,97-100} and MAOIs plus clomipramine.^{97,101} Another combination that has been frequently implicated in causing the serotonin syndrome is simultaneous administration of an MAOI and tryptophan.^{75,78,81,97,102-110} Overdose of a single serotonin-potentiating agent may also produce the serotonin syndrome. In one study, serotonin syndrome was diagnosed in 14% to 16% of patients that overdosed on SSRIs.¹¹¹ The serotonin syndrome may also occur when a drug is administered that interferes with the metabolism of a serotonin-potentiating agent (e.g., SSRI combined with erythromycin).¹¹²

One particular drug combination that has received considerable attention is the interaction between an MAOI and meperidine. In 1962, a woman who received meperidine in labor was reported to have developed coma and hypotension. It was subsequently noted that she had been self-administering phenelzine, and thus concern was raised about a possible drug interaction.¹¹³ Shortly thereafter, a patient on pargyline therapy was reported to have developed rigidity, coma, and clonus after receiving meperidine.¹¹⁴ Since then, several other cases of an interaction of a similar nature in patients taking meperidine in MAOIs have been reported.^{90,97} There are several unexplained curiosities about the serotonin syndrome generated by the interaction between meperidine and MAOIs. Despite the diverse group of serotonergic drugs in common clinical practice (see Table 29-4) and the frequent use of meperidine, few reports have described a serotonin syndrome with any other agent in combination with meperidine. Similarly, Ebrahim reported a series of 42 patients who were taking isocarboxazid and who were premedicated with meperidine for surgery; none of them had an adverse effect.¹¹⁵

An animal model developed for this syndrome almost three decades ago involved the sole administration of high doses of tryptophan to rats, which caused a unique constellation of tremors and movement abnormalities.⁷⁹ The same syndrome could be induced by simply administering high doses of an MAOI.⁷⁹ This observation provided evidence that some aspects of the clinical syndrome engendered by MAOI overdoses are related to serotonin excess. It is possible that a serotonin excess syndrome could occur after overdoses of SSRIs. However, this appears to occur rarely¹¹⁶⁻¹¹⁸ and was not a feature in a series of fluoxetine overdoses (see Chapter 28).¹¹⁹ A child ingested an excessive amount of sertraline and appeared to develop a serotonin syndrome manifested by tachycardia, hypertension, hallucinations, coma, hyperthermia, tremors, and skin flushing.¹²⁰

A serotonin syndrome–like toxidrome has been reported to follow the ingestion of methylenedioxymethamphetamine (MDMA, or “Ecstasy”).¹²¹⁻¹²⁹ Being a phenylethylamine type of agent, it is structurally similar to amphetamines and primarily affects serotonergic neurons. In addition, MDMA is frequently ingested in the context of a “rave,” a gathering at which so-called *smart drinks*, which are amino acid supplements that possibly contain significant amounts of tryptophan, are also ingested.^{123,130} Thus, it is possible that the complex clinical syndrome noted after MDMA ingestion may often be a drug interaction between two serotonergic agents. MDMA, in combination with other serotonergic agents, should be considered to have the potential of causing a serotonin syndrome. A series of deaths have been reported from serotonin syndromes caused by the intentional mixing of MDMA with moclobemide, the latter ingested in an attempt to heighten serotonergic effects.¹³¹

Although they appear to be safer than classic MAOIs, RIMAs are capable of causing a drug interaction resulting in a serotonin syndrome. Reported cases have involved the interaction of moclobemide and either clomipramine, citalopram, or another serotonin reuptake inhibitor, after both overdose^{5,132-134} and therapeutic use.¹³⁵ Two of the fatalities involve purposeful taking of the combination to achieve a psychological “high.”¹³²

As noted in Table 29-4, lithium has several serotonergic effects, which include stimulation of 5-HT release¹³⁶ and enhancement of the response to stimulation of 5-HT_{1A} receptors.^{137,138} Several case reports describe a serotonin syndrome caused by the therapeutic combination of lithium with SSRIs.¹³⁹⁻¹⁴¹ Given the frequency with which lithium is prescribed in combination with SSRIs, the relatively few cases of serotonin syndrome induced by these combinations suggest that this is an unusual interaction.

The use of MAOIs with tricyclic antidepressants has been the subject of considerable debate. Combining these two agents has been associated with a serotonin syndrome–like picture.^{142,143} However, given the frequency of the use of this combination and the rarity of adverse reports, it appears that the likelihood of an adverse effect from this combination is small.¹⁴⁴ However, particular caution must be exercised when using clomipramine,

which is a tricyclic antidepressant (3-chloroimipramine) that has a significant effect on inhibiting serotonin reuptake (see Table 29-4). The combination of a TCA with an RIMA appears to be safe, with the exception of agents such as clomipramine, which have a significant effect on serotonin uptake.¹⁴⁵

A body of literature suggests that the serotonergic effects of dextromethorphan (DM), in consort with other agents, may produce a serotonin syndrome. In 1970, Rivers and Horner described profound hyperthermia in a patient ingesting a DM-containing preparation while taking phenelzine.¹⁴⁶ Several reports have since described similar interactions.¹⁴⁷⁻¹⁴⁹ A similar syndrome has been described in rabbits pretreated with MAOIs.¹⁵⁰ Whether DM can cause a serotonin syndrome in concert with an SSRI has been the subject of controversy. Several cases have been reported.^{148,149} It has been proposed that the nature of the interaction in two cases, involving paroxetine and fluoxetine, respectively, is a result of an interaction at the level of the hepatic microsomal P-450 isoenzyme CYP2D6 (debrisoquin hydroxylase).¹⁵¹⁻¹⁵⁴ DM is metabolized by this enzyme to dextropropranolol, in a genetically determined manner by one of two phenotypes, known as extensive and poor metabolizers. Administration of DM to subjects who have had this isoenzyme inhibited by quinidine results in profoundly elevated DM levels and signs and symptoms similar to the serotonin syndrome. Both paroxetine and fluoxetine are inhibitors of this isoenzyme,^{153,154} as are sertraline and fluvoxamine.^{155,156} However, the significance of this enzymatic inhibition in the generation of a serotonin syndrome associated with the administration of DM has been questioned on the basis of the small amounts of DM requisite to the formation of a manifestation of 5-HT in these combinations.¹⁰⁰

Sandyk¹⁵⁷ reported an apparent serotonin syndrome in a patient with parkinsonism treated with bromocriptine in whom levodopa was started. The reported syndrome consisted of tremor, mild clonus, hyperreflexia, clonus, hypertension, tachycardia, diaphoresis, and diarrhea. Support that this was due to serotonin excess was suggested by its prompt response to the serotonin antagonist methysergide. Both bromocriptine and levodopa are serotonergic agents. Serotonergic neurons are capable of decarboxylating levodopa to dopamine, during which 5-HT may be released.^{158,159} Bromocriptine appears to increase brain levels of serotonin, inhibiting 5-HT catabolism^{160,161}; however, only one case of such an interaction has been described.¹⁵⁷

Trazodone is an antidepressant with complex serotonergic effects. At low doses, it appears to be a serotonin antagonist.¹⁶² At higher doses, however, it appears to be a mixed agonist/antagonist.¹⁶² Low doses appear to be safe when trazodone is taken in combination with an MAOI.¹⁶³ Cases of serotonin syndrome have been reported after the combined administration of trazodone and other serotonergic agents.¹⁶⁴

Selegiline and MAO-B inhibitors have been reported to cause the serotonin syndrome. Although 5-HT is metabolized by MAO-A, selegiline may cause an excess serotonin effect by virtue of its loss of MAO specificity

at higher doses. Cases of the serotonin syndrome, including death, have been reported with the combination of selegiline and SSRIs,¹⁶⁵⁻¹⁶⁷ tricyclic antidepressants,^{90,168} and other serotonergic agents.¹⁹

Buspirone is an anxiolytic agent that is a partial agonist at the 5-HT_{1A} receptor. Its potential role in the generation of the serotonin syndrome is unclear but probably unlikely because animals treated with high doses do not develop a full-blown serotonin syndrome. Several cases of the serotonin syndrome have been reported when buspirone has been used in conjunction with other serotonergic agents.¹⁶⁴

The “triptans” are serotonergic antimigraine agents that are generally implicated in the etiology of the serotonin syndrome. They act primarily on 5-HT_{1D} receptors. Their antimigraine effect is related to vasoconstriction of cephalic blood vessels. However, most of the triptans are catabolized by MAO and thus their use with an MAOI may cause elevated levels of these agents. A recent report, however, found no evidence of an adverse reaction from the combined use of moclobemide and sumatriptan.⁵

Tramadol is a serotonergic agent that blocks 5-HT reuptake^{169,170} and has been implicated in causing a serotonin syndrome.¹³⁴ The antibiotic linezolid represents the first of the oxazolidinones class and is a weak, nonspecific reversible inhibitor of MAO. Case reports have suggested the possibility of a serotonin syndrome when linezolid is used with SSRIs.¹⁷¹ A curious interaction, suggestive of a serotonin syndrome, has been reported in patients taking serotonergic medications and atypical neuroleptics, such as olanzapine.¹⁷² The significance of this is that the atypical agents are 5-HT₂ receptor antagonists, and thus would be expected to be protective against serotonin syndrome. However, it has been hypothesized that such blockade of the 5-HT₂ receptor may result in overactivation of the 5-HT_{1A} receptor.¹⁷²

St. John’s wort (*Hypericum perforatum*), a very popular and widely available herbal agent marketed as an antidepressant, is a weak MAOI that inhibits 5-HT reuptake. It has been reported to cause or contribute to serotonin syndrome¹⁷² probably on the basis of the latter activity.

Treatment of Serotonin Syndrome

No controlled prospective studies have investigated any specific treatment for serotonin syndrome. Virtually all of the data that we have to rely on come from anecdotal case reports and animal studies. From these, it can be gleaned that discontinuation of the provoking agents and supportive care are the cardinal principles in the treatment of this syndrome. Patients with agitation or neuromuscular hyperactivity should be treated initially with benzodiazepines. Benzodiazepines have been shown to improve survival in animal models of serotonin survival.^{173,174} Severe cases should be treated in the same manner as an MAOI overdose. Prompt neuromuscular paralysis with nondepolarizing agents is indicated for patients with severe neuromuscular

hyperreactivity and hyperthermia.^{93,174} The life-threatening complications associated with the serotonin syndrome (e.g., metabolic acidosis, rhabdomyolysis, hepatitis, renal failure, and disseminated intravascular coagulopathy) occur as a result of severe and/or prolonged hyperthermia.

Cyproheptadine, a general 5-HT receptor antagonist that is most potent at the 5-HT₂ receptor,¹⁷⁵ is the most commonly touted antidote for the serotonin syndrome. The apparent utility of cyproheptadine is derived from evidence that suggests that the 5-HT₂ receptor is important in the pathophysiology of the serotonin syndrome. In addition to being a serotonin antagonist, cyproheptadine is antihistaminic and anticholinergic. Animal studies suggest that cyproheptadine can block serotonin syndrome.¹⁷⁶

Several anecdotal reports describe treatment of serotonin syndrome with cyproheptadine.^{88,141,164,177} Unfortunately, cyproheptadine is available only as an oral preparation. A standard starting dose is 4 to 8 mg, typically followed by doses of 4 mg every 2 to 4 hours. Because of its antimuscarinic properties, anticholinergic side effects may occur; therefore, doses should not exceed more than 0.5 mg/kg per day (typically, 32 mg for an adult).

Methysergide maleate is a nonspecific serotonin antagonist that appears to have some efficacy in animal studies in preventing serotonin syndrome.¹⁷⁸ Clinical data evaluating the efficacy of methysergide in this toxidrome are sparse. In one case report, it appeared to be effective in the treatment of a serotonin syndrome induced by the therapeutic use of the combination of levodopa and bromocriptine.¹⁵⁷ Methysergide is available only as an oral preparation. It is usually given in doses of 2 to 6 mg, the latter being the typical total dose. It is frequently administered in a twice-a-day regimen.

β-Adrenergic receptor antagonists also tend to have some serotonin antagonist qualities. Propranolol is a 5-HT_{1A} blocker¹⁷⁹ that is effective in blocking the serotonin syndrome in animals.^{178,180} Responses to propranolol in human cases of serotonin syndrome have been inconsistent.^{88,98,108}

Dantrolene has been mentioned as an agent that might inhibit the neuromuscular hyperactivity component of the serotonin syndrome; however, there has been little clinical experience with it in this setting. In addition, dantrolene does not alter survival in animal models of serotonin syndrome.^{181,182}

Although certain antipsychotics (e.g., chlorpromazine, ziprasidone, olanzapine, risperidone) are 5-HT₂ antagonists and are available for parenteral administration, there has been little experience with them in the treatment of the serotonin syndrome. The few case reports studied have shown mixed results.^{145,183-185} Olanzapine (10 mg in a sublingual dose) was used with favorable results in one case of serotonin syndrome.¹⁸⁶

At a Glance...

- Lithium is a drug with a narrow therapeutic index.
- It has a two-compartment volume of distribution moving from extracellular to intracellular compartments.
- Lithium is eliminated almost entirely by the kidneys.
- Its toxicity is most commonly manifested by CNS symptoms.
- Acute lithium overdose differs significantly from chronic lithium intoxication.
- Serum levels do not correlate with systemic toxicity.
- Hemodialysis is an ideal treatment modality but should be reserved for patients exhibiting signs of severe intoxication and should be based on clinical and kinetic criteria.

INTRODUCTION

Lithium was discovered in 1818 and initially used for the treatment of gout, rheumatism, and renal calculi.^{1,2} In the early 1900s it was used as a salt substitute but was later abandoned because of toxic effects. It was also once present in the soft drink 7-Up.³ Although Aulde and Lange recognized in the 1880s that lithium could be used to treat depression, it was not until the 1950s that Cade and Schou established its use as a treatment for bipolar disorder.⁴ In 1970, the U.S. Food and Drug Administration (FDA) approved its use for the treatment of acute mania. Currently, lithium is used to treat a wide variety of disorders (Box 30-1) from bipolar affective disorder and alcoholism to prophylaxis for cluster

headache. It remains the drug of choice for the treatment of recurrent bipolar illness.⁵

With increasing use of lithium comes an increased risk for toxic effects. It is estimated that up to 90% of patients taking lithium have at some time experienced signs and symptoms of toxicity.⁶ In 1991, the American Association of Poison Control Centers reported 4149 cases of lithium exposure, with 622 (15%) resulting in moderate to severe intoxication and 12 in death.⁷ In 2002, 4954 cases were reported (one third being unintentional exposures) with 1527 resulting in moderate to severe intoxication and 15 in death. Although death is rare, the risks for morbidity and prolonged hospitalization emphasize the importance of appropriate management.

PHARMACOLOGY

Lithium is the lightest alkali metal and has no known physiologic role. Its mechanism of action is not clearly understood. It inhibits the release of norepinephrine and augments its reuptake.⁸ It also depletes brain inositol, which is a precursor in the phosphatidylinositol pathway assisting in signal transduction of hormones and neurotransmitters.¹ This effect may result in reduced responsiveness to α -adrenergic stimulation.⁹ Other proposed mechanisms include inhibition of G proteins crucial to ion channel opening,¹⁰ stimulation of release of serotonin from the hippocampus, and inhibition of adenylate cyclase.⁸ These inhibitory effects may decrease neuronal responsiveness to neurotransmitters. Additionally, because lithium is a cation, it behaves similarly to potassium and sodium, thereby affecting ion transport and cell membrane potential.

PHARMACOKINETICS

Lithium is dispensed in a variety of formulations (Table 30-1) some of which are sustained-release preparations. Lithium is rapidly absorbed, reaching peak levels in 1 to 3 hours in regular preparations and 4 to 12 hours in sustained-release preparations. The bioavailability for most preparations is nearly 100%. It is neither protein bound nor metabolized. Lithium initially has a volume of distribution approximately 0.4 L/kg. However, as the ion moves from extracellular compartments to intracellular compartments over 6 to 8 hours, the final volume of distribution is between 0.6 and 0.9 L/kg.¹¹ This process, which takes up to 6 to 10 days to reach final equilibrium, reflects the amount of time required to achieve therapeutic response. Serum lithium levels measure only the extracellular concentration of lithium. Yet, lithium exerts its effects once it has moved to its intracellular

BOX 30-1 THERAPEUTIC USES OF LITHIUM

Psychiatric Disorders	Nonpsychiatric Disorders
Manic-depressive (bipolar) illness*	? Pain
Unipolar depressive illness	Graves' disease
Behavior disorders	? Premenstrual tension
Character disorders	? Leukopenia/chemotherapy
Pain	? Felty's syndrome
Alcoholism/drug abuse	? Thyrotoxicosis
Premenstrual tension	? Tardive dyskinesia
Organic brain syndrome	? Huntington's chorea
Cycloid psychosis	? Pancreatic cholera syndrome
Anorexia nervosa	
Schizoaffective disorders	? Syndrome of inappropriate antidiuretic hormone secretion
Steroid-induced psychosis	

*Only approved use for lithium in the United States; other uses are experimental.

TABLE 30-1 Some Available Lithium (Li) Preparations*

TRADE NAME	CHEMICAL FORMULATION	DOSE FORMS
United States		
Lithane (Miles Pharmaceutical)	Lithium carbonate	Tablets, 300 mg
Lithium carbonate USP	Lithium carbonate	Capsules, 150 mg, 300 mg, 600 mg; tablets, 300 mg
Lithium citrate syrup USP (Roxane)	Lithium citrate	Syrup, 8 mEq/5 mL—equivalent to 300 mg of lithium carbonate
Cibalith-S (CIBA)	Lithium citrate	Syrup, 8 mEq/5 mL—equivalent to 300 mg of lithium carbonate
Lithobid (CIBA)	Lithium carbonate	Tablets, 300 mg (sustained release)
Eskalith (SmithKline)	Lithium carbonate	Capsules and tablets, 300 mg
Eskalith CR (SmithKline)	Lithium carbonate	Tablets, 300 mg, 450 mg; capsules, 300 mg (sustained release)
Canada		
Carbolith (ICN)	Lithium carbonate	Capsules and tablets, 300 mg
Lithane (Pfizer)	Lithium carbonate	As above
Lithizine (Maney)	Lithium carbonate	As above
United Kingdom		
	Lithium carbonate	400 mg tablets also available
Scandinavia		
Litrex	Lithium carbonate	Sustained-release formulation
*Molecular mass = 73.89 daltons; atomic number, 3; atomic weight, 6.94; emission line on flame photometer, 671 nm.		

compartment. This two-compartment phenomenon explains why patients can be initially asymptomatic in the setting of significantly elevated serum levels.

Lithium has a predilection for accumulation in liver, bone, muscle, brain, kidney, and thyroid.¹² The highest levels are found in the brain and kidney,¹¹ and toxicity is most commonly associated with these organs.

Ninety-five percent of lithium is excreted by the kidneys, while the remainder is eliminated via sweat and feces. Lithium is handled similarly to sodium by the kidney, and approximately 75% of the filtered load is reabsorbed in the proximal tubule.¹³ The renal clearance is between 10 mL and 40 mL/min.¹⁴ Sodium depletion can increase lithium reabsorption significantly. Consequently, volume depletion from diuretics, dehydration, febrile illness, or gastrointestinal (GI) loss can lead to elevated lithium levels in the serum.

The serum elimination half-life of lithium can vary from 12 to 27 hours. In patients with chronic intoxication the half-life can be prolonged up to 48 hours.¹⁵ The half-life of lithium may vary significantly with duration of therapy.¹⁶ It has been hypothesized that this phenomenon may be due in part to inhibition of lithium efflux from cells by the drug itself during chronic therapy.

The usual renal clearance of lithium is 10 to 40 mL/min. In the elderly, renal clearance may be reduced to 15 mL/min and the elimination half-life can be as long as 58 hours. There is also a propensity toward a smaller final volume of distribution in the elderly.¹⁷ In a study of hospitalized patients with lithium toxicity, age greater than 65 years was associated with a significantly higher likelihood of toxic lithium level.¹⁸

During the third trimester of pregnancy, lithium clearance will usually increase, thereby creating difficulties with serum monitoring.¹⁷ Lithium freely crosses the placenta and is also excreted in breast milk.¹⁹ It is labeled as pregnancy class D and has been implicated in causing

an increased risk of congenital cardiac defects, particularly Ebstein's anomaly. Breast-feeding infants of mothers taking lithium have been reported to have signs of cyanosis, hypotonia, and lethargy.²⁰

Multiple medication interactions are associated with lithium (Table 30-2). It has been reported to cause neuroleptic malignant syndrome in combination therapy with neuroleptic agents or by itself in overdose. Additionally, diuretics that deplete sodium and water will indirectly result in lithium toxicity by enhancing its reabsorption in the proximal tubules. Most notable, however, are the drug interactions that affect lithium clearance. Studies in both healthy patients given lithium and those receiving chronic lithium therapy have shown that nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease lithium clearance and raise plasma lithium levels.²³ This may be secondary to prostaglandin inhibition causing a reduction in glomerular filtration rate (GFR) and subsequent sodium (and lithium) reabsorption in patients with preexisting volume depletion. Angiotensin-converting enzyme (ACE) inhibitors also contribute to lithium toxicity in volume-depleted patients by causing a further decrease in GFR.

TOXICOLOGY

Lithium toxicity can be classified into three major categories. It may occur as the result of an *acute* overdose (in a lithium-naïve patient), acute overdose in a patient on chronic therapy (*acute-on-chronic*), or *chronic* overmedication or drug accumulation. Generally, chronic intoxication is associated with the most serious toxicity.

Accumulation of lithium may result from excessive intake or impaired excretion. Excessive intake is seen in the acute and acute-on-chronic overdose settings in which a patient intentionally ingests an excessive amount

**TABLE 30-2** Known Drug Interactions with Lithium

DRUG	EFFECTS OF INTERACTION
Haloperidol Tricyclic antidepressants (TCAs)	Rigidity, ataxia, oral tardive dyskinesia, ↑ depression, ↑ haloperidol toxicity Additive antidepressant effect, hypotension, delirium, seizures, increase in blood pressure if hypotension secondary to TCA
Phenothiazines Benzodiazepines Neuromuscular blockers Methyldopa	↑ Lithium and phenothiazine toxicity, ↑ depression along with toxicity ↑ Depression ↑ Neuromuscular blockade ↑ Parkinsonian syndrome
Nonsteroidal anti-inflammatory drugs: indomethacin, piroxicam, mefenamic acid, phenylbutazone Phenytoin Calcium channel blockers: verapamil, nifedipine, diltiazem	Partial reversal of nephrogenic diabetes insipidus and ↑ serum lithium, ↓ renal lithium clearance Polyuria, polydipsia, tremor
Angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril)	Additive or synergistic action with lithium Reduced glomerular filtration rate, ↓ lithium clearance
Diuretics	
Thiazides	↑ Serum lithium
Osmotics, acetazolamide, sodium bicarbonate	↑ Urinary lithium excretion
Furosemide	No change in serum lithium, unless induces significant sodium loss
Potassium-sparing diuretics and potassium supplements	Abolish distal renal tubular acidosis and may prevent renal lithium toxicity

of lithium tablets in a suicidal or accidental ingestion. Excessive intake also occurs when dose modifications are made for the patient chronically taking lithium.

Impaired excretion of lithium occurs from a variety of factors. Any condition in which sodium and volume depletion occurs may lead to increased reabsorption of the drug in the kidneys. Vomiting, diarrhea, febrile illness, renal insufficiency, excessive exercise, water restriction, excessive sweating, low sodium diet, and congestive heart failure all can increase the risk for lithium toxicity. Concomitant administration of drugs that decrease GFR will also contribute to chronic toxicity. Other factors that play a role in toxicity include duration of therapy¹⁶ and individual tolerance to lithium.²

Patients on chronic lithium therapy may develop nephrogenic diabetes insipidus (NDI), which can trigger a cascade of symptoms and signs of lithium toxicity. However, most patients will develop symptoms of polyuria without full-blown NDI. Up to 37% of patients taking therapeutic doses of lithium experience symptoms of polyuria.²⁴ This is attributable to impaired urinary concentrating ability by the kidneys. This effect coupled with any intercurrent illness can trigger the vicious cycle of lithium toxicity (Fig. 30-1). With sodium and volume depletion, the excretion and clearance of lithium decreases as the kidney increases its reabsorption of the cation. The increased reabsorption leads to elevated levels of serum lithium, which in turn continues to adversely affect the kidneys' ability to concentrate urine. Consequently, patients on chronic lithium therapy who exhibit symptoms of polyuria (or NDI) are at increased risk for developing lithium toxicity.⁶

CLINICAL MANIFESTATIONS

The clinical manifestations of lithium toxicity are primarily related to the central nervous system (CNS)

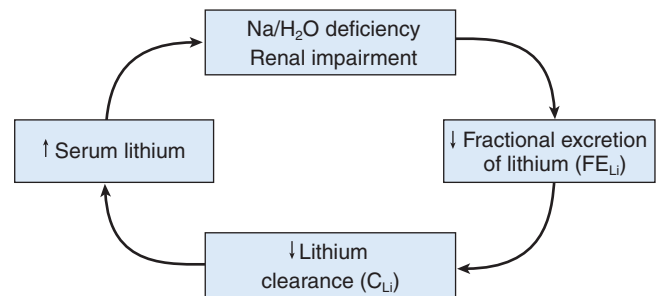

FIGURE 30-1 The vicious cycle of sodium and water depletion and lithium toxicity.

and kidneys. In addition, gastrointestinal, cardiovascular, and endocrine side effects are commonly reported.

Neurologic symptoms of intoxication include coarse tremor, dysarthria, ataxia, nystagmus, slurred speech, hyperreflexia, and myoclonia. Patients often have alterations in level of consciousness ranging from mild confusion to delirium, agitation, seizures, and coma. Some patients on chronic therapy complain of prodromal symptoms of nervousness prior to more objective signs of intoxication.⁸ Although most patients recover after lithium intoxication, there are reports of neurologic sequelae including scanning speech, ataxia, memory deficits, and choreoathetoid movements persisting for 12 months or even permanently.²⁵⁻²⁸

Renal toxicity is more common in patients on chronic lithium therapy. Toxicity includes impaired urinary concentrating ability, NDI, and sodium-losing nephritis. Previous studies have suggested the incidence of polyuria to be as high as 37% and worsened by concomitant use of serotonergic antidepressants.²⁴ Nephrotic syndrome, acute tubular necrosis, and chronic interstitial nephropathy have also been described in association with lithium therapy.

Lithium is the most common cause of drug-induced NDI.²⁹ The mechanism is not entirely understood. Lithium enters the renal tubules via sodium channels and modulates the function of certain G proteins, thereby lowering the levels of cyclic adenosine monophosphate (cAMP). The lowered intracellular cAMP may contribute to a decrease in transcription and expression of the antidiuretic hormone-sensitive aquaporin-2 water channels³⁰ responsible for water reabsorption in the kidney. NDI is characterized by polyuria, polydipsia, hypernatremia, and low urine osmolality. Elevated serum osmolality is also expected, but most patients are able to compensate by excessive fluid intake on a daily basis. NDI can significantly predispose patients to lithium toxicity via volume depletion, lithium reabsorption, and the vicious cycle of renal toxicity. Treatment of lithium-induced NDI includes discontinuation of the drug and administration of amiloride,³¹ NSAIDs, or thiazide diuretics.³²⁻³⁴ Cases of persistent NDI after discontinuation of lithium for up to 57 months have been described.³⁵

Cardiovascular effects are usually mild and non-specific. Patients may experience mild hypertension, bradycardia, or tachycardia. Electrocardiographic changes can include transient ST depression, flattened or inverted T waves, QRS widening, QT prolongation, or intraventricular conduction delays. Nearly all patients taking lithium will develop T wave flattening. Sinus node dysfunction is the most commonly reported conduction defect followed by QT prolongation, intraventricular conduction defects, and U waves. Although these findings are reversible, their prevalence and significance are undetermined.³⁶ In rare circumstances, severe ventricular arrhythmias and myocardial infarction have been described in acute overdoses.³⁷

Gastrointestinal symptoms are also more common in the acute overdose setting. Symptoms include nausea, vomiting, diarrhea, anorexia, and bloating and typically occur within 1 hour of ingestion.

Endocrine effects from lithium toxicity most commonly include hypothyroidism via inhibition of thyroid hormone synthesis and subsequent release (in 3% to 60% of patients taking lithium).³⁸ Less commonly seen is hyperthyroidism, which may not only mask symptoms of

lithium toxicity but can increase toxicity by inducing cellular unresponsiveness and altered renal tubular handling of lithium.³⁸ Lithium is also associated with hyperparathyroidism, hypothermia, and less frequently hyperthermia.

DIAGNOSIS

Degree of intoxication is important for understanding the diagnosis and management of lithium toxicity. Severity of lithium toxicity is most frequently arbitrarily divided into three grades: mild, moderate, and severe⁶ (Table 30-3). This grading system was first described by Hansen and Amdisen in 1978⁴ and has been used with some degree of consistency throughout the literature. *Mild* symptoms include nausea, vomiting, lethargy, tremor, and fatigue. Symptoms of *moderate* intoxication are confusion, agitation, delirium, tachycardia, and hypertonemia. Coma, seizures, hyperthermia, and hypotension characterize *severe* intoxication.

Patient History

Diagnosis and classification (acute, acute-on-chronic, or chronic) of lithium intoxication can be difficult. The prevalence of neurologic symptoms should alert the clinician to the possibility of lithium poisoning. Additional history from the patient and outside sources regarding previous level of functioning, other medications, prodromal symptoms, and recent intercurrent illness may be necessary. Other pertinent history should include the type of lithium preparation that was ingested and any underlying illnesses that predispose to toxicity. The diagnosis can be further complicated by the fact that many patients with toxicity on presentation may not have taken an intentional overdose of lithium, but rather may be suffering from chronic toxicity.

Physical Examination

Particular attention should be paid to the vital signs, degree of neurologic involvement, and cardiovascular status. Documentation of a thorough initial neurologic

TABLE 30-3 Serum Lithium and Toxic Manifestations†

SEVERITY OF SYMPTOMS	APPROXIMATE SERUM LITHIUM CONCENTRATION (mEq/L)	SYMPTOMS
No toxicity (therapeutic)	0.4–1.3	Usually none
Mild toxicity	1.5–2.5	Nausea, vomiting, lethargy, tremor CNS depression, fatigue, diarrhea
Moderate toxicity	2.5–3.5	Confusion, agitation, delirium, tachycardia, hypertonemia
Severe toxicity	>3.5	Coma, seizures, hyperthermia, hypotension

*Lithium toxicity may be manifested even at therapeutic levels, especially in the elderly, when the therapeutic level may be 0.2 mEq/L.

†Classification of Hansen and Amdisen.⁴ (Stages I and II: apathy, tremor, weakness, ataxia, motor agitation, rigidity, fascicular twitching, nausea, vomiting and diarrhea. Stage III: Latent convulsive movements, stupor, and coma.)

examination may be helpful in patients who may endure a prolonged hospital course.

Laboratory and Imaging Studies

Initial studies should include cardiac monitoring, electrocardiogram (ECG), assessment of oxygenation and monitoring of urine output, serum electrolytes, calcium, renal function, glucose, serum lithium level, and thyroid-stimulating hormone (TSH). Leukocytosis can be seen with therapeutic lithium use as well as intoxication. A low anion gap can also be present after acute ingestion of lithium carbonate⁸ possibly owing to the presence of and interference by the carbonate anion in the calculation of anion gap. In addition, in chronic poisoning, patients are likely to demonstrate evidence of renal insufficiency with elevated blood urea nitrogen and creatinine. In some cases in which the diagnosis is initially unclear, imaging of the brain may be necessary. Although some formulations of lithium may be radiopaque, radiography is not reliable for excluding ingestion.³⁹

Many hospitals have readily available serum testing for lithium levels (normal range, ~0.6 to 1.2 mEq/L). Serum levels should ideally be drawn at least 6 to 12 hours after the last therapeutic dose to avoid misinterpretation of predistributional levels. However, these levels can still be misleading because lithium has a low therapeutic index and levels frequently do not correlate with level of toxicity. Levels as high as 10.6 mEq/L (10.6 mmol/L) have been reported without evidence of neurologic toxicity after an acute overdose⁴⁰ because of the multicompartment kinetics of the drug. Furthermore, a normal level does not exclude toxicity, because serum levels do not accurately reflect the intracellular concentration or toxicity of the drug.

It is important to note that some specimen tubes contain lithium heparin as an anticoagulant and can falsely elevate serum lithium results. This phenomenon has been demonstrated to factitiously elevate serum lithium levels by as much as 2.0 mEq/L in healthy volunteers.⁴¹ Others have reported these tubes producing falsely elevated levels by as much as 6 to 8 mEq/L.⁴²

There is relatively poor correlation between serum levels and systemic toxicity, particularly after an *acute* or *acute-on-chronic* overdose. Hansen and Amdisen described 23 patients with lithium intoxication and concluded that there is *no clear-cut relationship between serum lithium levels and severity of symptoms*. However, 21 of their patients were suffering from chronic lithium intoxication. They suggested that levels of 1.5 to 2.5 mEq/L are associated with mild symptoms of toxicity, 2.5 to 3.5 mEq/L are considered serious, and greater than 3.5 mEq/L are considered life threatening (see Table 30-3). These levels, which were all drawn at approximately 12 hours after the last dose of lithium,⁴³ hold relevance only for patients with chronic lithium exposure.

Bailey and McGuigan prospectively studied all cases of lithium exposure brought to the attention of a poison control center over a 1-year period, and their study group included patients with acute, acute-on-chronic,

and chronic exposures plus one patient with *severe* lithium intoxication after a chronic exposure and a peak serum level of 1.5 mEq/L.⁴⁴ They noted that toxicity occurred at lower levels in patients with chronic exposures compared with those with acute-on-chronic exposures. They concluded that the Hansen and Amdisen classification is not a useful tool for predicting morbidity or mortality and does not correlate well with lithium level.

Oakley and colleagues conducted a retrospective analysis of 97 cases of lithium exposure at a regional center over a 13-year period. They concluded that peak serum levels are significantly higher in patients with severe intoxication and that chronic exposure carries a substantially higher risk of severe neurotoxicity than acute exposure. Furthermore, they identified risk factors contributing independently to the development of chronic intoxication: NDI, age over 50 years, thyroid dysfunction, and baseline endogenous creatinine clearance below normal.⁴⁵

Currently, most authors agree that clinical symptoms are more reliable than serum lithium levels. Additionally, management should be based on these clinical parameters rather than on drug levels.⁴⁶ Clinicians are cautioned about reliance on an isolated serum lithium level.

It has been suggested that erythrocyte, urine, or cerebrospinal fluid (CSF) levels of lithium might be useful in the assessment of lithium toxicity. The erythrocyte concentration does not fluctuate as much as plasma lithium levels, perhaps reflecting an intracellular lithium concentration. However, this value has not been shown to have clinical significance. CSF levels are about 40% to 50% of plasma lithium levels, but in animal studies they have demonstrated no advantage over plasma lithium levels in assessing toxicity.⁴⁷ In addition to being more invasive, CSF levels do not reflect intracellular levels of lithium. Urine levels do not correlate with clinical toxicity but can be useful in the calculation of renal lithium clearance.

Differential Diagnosis

Differential diagnosis of lithium toxicity includes psychosis, hypoglycemia, meningitis, encephalitis, gastroenteritis, food poisoning, drug withdrawal, intracranial bleeding, trauma, thyrotoxicosis, Parkinson's disease, and neuroleptic malignant syndrome. Intoxication by other psychotropic drugs that may be available to the patient should be considered, such as tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), valproic acid, and antipsychotic drugs.

MANAGEMENT

Supportive Measures

Initial treatment of lithium toxicity includes appropriate airway management, assessment of vital signs, and continuous cardiac monitoring. Peripheral IV lines should be inserted for the administration of fluids as well

as other general emergency treatment measures including dextrose and naloxone if needed. Hyperthermia or hypothermia should be treated appropriately. If seizures develop, they should be treated with standard measures including benzodiazepines and barbiturates (see Chapter 2A). Electrocardiographic findings such as flattened or inverse T waves and mild QT prolongation do not usually require treatment; however, severe arrhythmias should be treated with usual measures, including magnesium for marked QT prolongation or torsades de pointes.

The goal of fluid therapy is to maintain GFR and urine output in order to reduce the continued reabsorption of lithium. Fluid replacement should begin with isotonic saline. A few reports have suggested marked improvement with forced diuresis using very large volumes of normal saline along with diuretics,⁴⁸ achieving lithium clearance values of 39 mL/min (in patients with normal renal function).⁴⁹ However, other studies have suggested less than favorable outcomes with forced diuresis, including a reduction in lithium clearance.⁴³ Because of inconsistent results and the risk of electrolyte imbalances, forced diuresis is not recommended. On the other hand, volume resuscitation to replace fluid losses and to maintain adequate urine output is crucial to the treatment of lithium intoxication.

Decontamination

There is no known antidote for lithium, so particular attention should be paid to gastric decontamination. Although it has been demonstrated in *in vitro* studies that lithium does not bind well to activated charcoal,⁵⁰ charcoal should be given if co-ingestants are suspected. In patients with early presentation, consideration should be given to gastric lavage, especially for regular-release preparations. After ingestion of sustained-release preparations (e.g., Litho-Bid), whole bowel irrigation may be preferable. In a crossover study of healthy volunteers who were given GoLYTELY at 2 L/hr for 5 hours after lithium ingestion, there was a significant reduction in peak lithium concentrations by more than 50% and reduction in lithium absorption by 67%.⁵¹ Whole-bowel irrigation should also be considered after massive ingestion of regular-release products.

Limited evidence supports the use of sodium polystyrene sulfonate (SPS; Kayexalate) to bind lithium in the gut and to enhance elimination. Animal studies have demonstrated that the SPS resin effectively binds lithium and can reduce serum lithium concentrations even after IV lithium dosing.⁷ Studies in healthy human volunteers have shown small but statistically significant reductions in lithium absorption after treatment with SPS, without significant changes in serum sodium or potassium levels.^{52,53} However, the reductions were not large enough to likely affect the clinical course of an acute overdose.⁵² Furthermore, there is no consensus regarding optimal dosing or whether electrolyte alterations in a sick patient population could be more pronounced. At this time, SPS is not recommended for acute lithium ingestion.

Elimination

Besides hemodialysis, a variety of methods have been suggested or reported to enhance the elimination of lithium, including alkaline diuresis, IV theophylline, and dopamine. However, in addition to posing potential adverse effects, these alternative methods are not supported by clinical studies.

Lithium renal clearance can be estimated using the serum and urine lithium levels. Renal lithium clearance = urine flow rate (mL/min) × urine lithium (mEq/L) / serum lithium (mEq/L). The normal renal lithium clearance is estimated to be between 10 and 40 mL/min. Hansen and Amdisen, however, reported in their study of chronic lithium intoxicated patients that the lithium clearance of this group ranged from 0.9 to 18.4 mL/min.⁴³ Similar variable clearances for patients on chronic lithium therapy have been found in other studies.⁵⁴

Peritoneal dialysis has been shown to achieve lithium clearance rates of between 9 and 15 mL/min.^{23,49} This modality might be considered in patients who have poor renal function if hemodialysis facilities are unavailable (e.g., in remote areas). Otherwise, it should not be substituted for hemodialysis.

Because lithium has a small volume of distribution and minimal protein binding, hemodialysis is an appropriate method for lithium removal. Lithium clearances of 70 to 170 mL/min have been reported with hemodialysis. However, there is controversy about indications for hemodialysis. Removal of lithium from the plasma and extracellular fluid may have little effect on intracellular lithium concentrations, and toxic effects may persist even after serum levels fall. This is consistent with the clinical observation that serum lithium levels correlate poorly with signs and symptoms of toxicity. It could be argued that dialysis is most likely to be effective soon after an acute ingestion while the serum lithium level is markedly elevated and prior to intracellular redistribution. However, these patients generally experience less severe toxic effects,⁴⁵ and patients with levels as high as 10.6 or higher⁴⁰ may remain asymptomatic and recover with supportive measures alone.

Amdisen recommended that patients with impaired renal function or those who have taken an overdose and have persistent levels greater than 1.4 mEq/L should undergo hemodialysis.⁶ Jaeger and coworkers studied the kinetics of lithium in intoxicated patients and concluded that no rigid indication for hemodialysis can be set. They further stated that hemodialysis is not an emergency therapy but one that should be initiated only after observation of the patient as an inpatient and based on a combination of clinical and kinetic criteria.⁵⁴ Other authors have suggested that the rapid correction of lithium by hemodialysis might contribute to persistent neurologic toxicity similarly to rapid correction of hyponatremia.²⁸

Bailey and McGuigan in a prospective study recommended hemodialysis for patients with any of the following criteria: (1) severe toxicity, (2) alteration in level of consciousness, (3) cardiac toxicity, (4) creatinine greater than 2.3 mg/dL associated with an acute lithium level greater than 2.0 mEq/L or chronic level greater

than 1.5, or (5) creatinine greater than 1.7 mg/dL associated with a chronic level of 2.5 mEq/L or acute level of 4.0 mEq/L. Serum creatinine levels were obtained after several hours of hydration. The authors compared the outcomes for patients in whom dialysis was recommended but not performed to those of patients who actually received hemodialysis. Although fewer patients received dialysis than was recommended, there was no outcome difference between the two groups. They concluded that indications for hemodialysis should be based on clinical symptoms and reserved for the more severe cases.⁵⁵

Clearly, there is no consensus on precisely when to dialyze. Most agree that patients exhibiting signs and symptoms of severe lithium poisoning (seizures, coma, cardiac arrhythmias) or who have renal failure should undergo hemodialysis. In addition, dialysis should be considered in acute overdose patients with clinical deterioration and patients with chronic lithium toxicity whose serum levels are greater than 3.5 mEq/L. Patients with acute or acute-on-chronic overdose with elevated levels but who are asymptomatic or minimally symptomatic and have normal renal function should be treated with IV fluids and monitored closely for deterioration. There may be rebound (Fig. 30-2) in serum levels after dialysis, and the procedure should be repeated until the serum level 6 to 8 hours after dialysis is less than 1 mEq/L.

Several case reports have demonstrated success in adults and children⁵⁶ for treating lithium intoxication with the use of continuous renal replacement therapy (CRRT). This includes methods such as continuous venovenous hemodialysis (CVVHD), continuous arteriovenous hemodialysis (CAVHD), continuous venovenous hemodiafiltration (CVVHDF), and continuous arteriovenous hemodiafiltration (CAVHDF). The reported lithium clearance rates for CVVHD, CVVHDF, CAVHD, and CAVHDF are given in Table 30-4.⁵⁶⁻⁶⁰ While these clearances are less than for hemodialysis, the procedures require less specialized staff and facilities and can be done continuously for several hours or days, compared with typical dialysis runs of 2 to 3 hours at a time. In addition, CVVHD is pump-driven and therefore does not rely on the patient's arterial pressure to provide a pressure gradient. One particular case study documented success with CVVHD in a hemodynamically unstable lithium-intoxicated patient in whom hemodialysis had to be discontinued.⁵⁸

CRRT has the added advantage of ease of implementation and avoidance of rebound lithium levels (see Fig. 30-2). One author suggests that the combination of hemodialysis and CVVHD may have the potential to decrease length of hospital stay and health care costs.⁵⁶ CRRT procedures have been used for periods of 14 to 72 hours, with an average duration of 34.7 hours in one study.⁶⁰ It is not yet clear, however, whether CRRT will shorten the length of hospital stay or change outcome when compared with intermittent hemodialysis. There are no controlled studies to date comparing safety and efficacy of CRRT over other methods of therapy for routine treatment of lithium toxicity. Continuous renal

FIGURE 30-2 Serum lithium concentration after (A) high-volume continuous venovenous hemofiltration (HV-CVVH) vs. (B) intermittent hemodialysis (HD). Note the steady decline in lithium concentration during HV-CVVH in A in contrast with the rebound in lithium concentration after each run of hemodialysis in B. Although hemodialysis remains the gold standard for lithium elimination, other modes of continuous renal replacement therapy demonstrate promise. (Reproduced from Jaeger A, Sauder P, Kopferschmidt J, et al: When should dialysis be performed in lithium poisoning? A kinetic study in 14 cases of lithium poisoning. *J Toxicol Clin Toxicol* 1993;31:429-447, and van Bommel EF, Kalmeijer MD, Donssen H: Treatment of life-threatening lithium toxicity with high-volume continuous venovenous hemofiltration. *Am J Nephrol* 2000;20:408-411.)

replacement therapy may be considered in treating patients in facilities in which dialysis is not readily available or who are considered too unstable for immediate hemodialysis.

Disposition

All patients with symptoms of lithium intoxication should be admitted to the hospital for observation in a

TABLE 30-4 Approximate Clearance of Lithium Based on Different Methods*

METHOD OF LITHIUM CLEARANCE	APPROXIMATE CLEARANCE (mL/min)
Normal renal clearance in healthy patient	10–40 mL/min
Renal clearance of patients taking lithium chronically	0.9–18.4 mL/min
Peritoneal dialysis	9–15 mL/min
Hemodialysis	70–170 mL/min
CVVHD	23–54 mL/min
CVVHDF	28–62 mL/min
CAVHD	20.5 mL/min
CAVHDF	27–55 mL/min

*Approximate clearances are based on data from references 56 to 60. CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; CAVHD, continuous arteriovenous hemodialysis; CAVHDF, continuous arteriovenous hemodiafiltration.

monitored setting, even in the presence of normal serum lithium levels. Patients with moderate or severe symptoms should be admitted to an intensive care unit. For patients who are asymptomatic after an acute ingestion, serial levels should be obtained at 6-hour intervals until a downward trend has been established. Patients should not be discharged until they are asymptomatic and have a serum lithium level less than 1.5 mEq/L.

KURT C. KLEINSCHMIDT, MD

At a Glance...

- Chronic ethanol use is associated with many medical problems including osteoporosis, electrolyte abnormalities, polyneuropathy, endocrine disorders, dementia, alcoholic heart disease, cardiac dysrhythmias, liver dysfunction, and suppression of all hematopoietic elements.
- The elderly and children are more prone to experience ethanol's intoxicating effects.
- Benzodiazepines are the mainstay of therapy of alcohol withdrawal. Very large doses may be needed for severe withdrawal. Sympatholytic agents should not be used alone in severe withdrawal management.
- Delirium tremens is uncommon today. It manifests with significant autonomic hyperactivity and gross disorientation. Hyperthermia or seizures during delirium tremens is particularly associated with poor outcome.
- Wernicke's encephalopathy is difficult to diagnose, so all persons with alcoholism should receive thiamine during an evaluation.

INTRODUCTION

Ethanol is derived from fermentation of sugars in fruits, cereals, and vegetables. Valued for its medicinal and mood altering effects, ethanol has played a significant historical role in the medical, social, and religious rituals of humankind. While modern medical uses of ethanol are limited, it remains a popular social lubricant and is widely used in religious and social ceremonies. Ethanol is commonly abused by humans, resulting in significant medical and social morbidity. Its widespread availability also makes it a common cause of unintentional poisoning in children. In addition to alcoholic beverages, many household products such as food extracts, mouthwashes, and cough preparations contain ethanol, often in large amounts (Table 31-1).^{1,2}

Chronic alcohol-related problems are common. Approximately 8.2 million persons in the United States are dependent on alcohol. In a primary care practice, 15% of the patients had an "at-risk" pattern of alcohol use or an alcohol-related health problem.³ Chronic use of ethanol is associated with many medical problems including physical dependence and withdrawal, neuropsychiatric problems including Wernicke's encephalopathy, and significant effects on many body organs.

PHARMACOKINETICS

Ethanol is a clear, low-molecular-weight hydrocarbon that is highly soluble in water and lipids. Its volume of

distribution (0.6 L/kg) is similar to that of water. Ethanol does not bind proteins or tissues and does not affect the binding of other agents.⁴ Environmental and genetic factors influence its absorption, bioavailability, metabolism, and elimination.⁵ The significance of these factors is difficult to assess owing to great variations among individuals.

Ethanol is rapidly absorbed by passive diffusion across the lipid membranes of the stomach ($\approx 20\%$) and small intestine ($\approx 80\%$), reaching peak levels 20 to 60 minutes after ingestion.^{4,6} Various factors affect absorption (Table 31-2). Inter- and intraindividual differences in gastric emptying rate affect absorption.⁴ The time to maximum concentration can vary by as much as fourfold between subjects, and the maximum concentration itself can vary by twofold.⁴ The major factor decreasing the rate of gastric emptying, thus delaying ethanol absorption, is the presence of food.⁴ Decreased gastrointestinal motility also delays absorption.⁵ Activated charcoal binds ethanol poorly, minimally affecting its absorption.⁷

Ethanol is metabolized in a series of oxidative steps; initially to acetaldehyde and then to acetate. Three hepatic enzyme systems contribute to the initial metabolism to acetaldehyde: the microsomal cytochrome P-450 (CYP) isoenzyme CYP2E1, the cytosol-based enzyme alcohol dehydrogenase (ADH), and the hydrogen peroxide-dependent peroxisome catalase system (Fig. 31-1). The catalase system contributes minimally and is not discussed further.⁸

In the nonalcoholic person, 90% of the oxidation of ethanol to acetaldehyde is done by ADH. Multiple isoenzyme forms of ADH occur with variable frequency in different human populations. These ADH isoenzymes have different affinities for ethanol, resulting in variations in ethanol elimination rates among individuals and racial groups. The activity of ADH does not change with chronic ethanol consumption.⁹ However, liver ADH is degraded in the fasting state, which may result in as much as a 40% decrease in ADH activity.¹⁰

CYP2E1 (CYP2E1 is the specific isoenzyme) contributes less than 10% to the oxidation of ethanol in the

TABLE 31-1 Alcohol Content of Common Products and Medications

PRODUCT	ETHANOL CONTENT (%)
Aftershave lotions	15–80
Cold/allergy medications	5–16
Cough preparations	2–25
Glass cleaners	10
Mouthwashes	15–25
Perfumes/colognes	25–95

TABLE 31-2 Absorption and Metabolic Factors Affecting Blood Ethanol Concentrations

FACTOR	EFFECT ON BLOOD ETHANOL	REASON
Adiposity	↑	Relative ↓ in Vd
Age	↑ in elderly ↓ in those < 13 years of age	↓ Vd secondary to ↑ adipose/lean body mass ratio ↑ in metabolic rate
Chronic use	↓	If severe alcoholic liver disease present
Fasting state	↑	↑ in metabolic rate secondary to ↑ CYP2E1 oxidation ↑ Absorption secondary to faster gastric emptying and temporary ↓ in gastric ADH activity
Delayed gastric emptying	↓	Longer exposure to gastric ADH
Increased lung tidal volume	↓	↑ in elimination from breath
Medications	Variable	Often secondary to change in CYP2E1 activity
Sex	↑ in females	↑ in absorption secondary to ↓ gastric metabolism ↑ in adipose tissue ↓ in lean body weight
Cigarette smoking	↓	↑ in metabolic rate
Lean body weight (increased)	↓	Relative ↑ in Vd

↑, increase; ↓, decrease; ADH, alcohol dehydrogenase; Vd, volume of distribution.

moderate drinker. The K_m (the concentration of a substrate which yields half-maximal enzyme activity) of ADH for ethanol is much lower than that for CYP2E1. The contribution of CYP2E1 to the oxidation of ethanol increases as the blood ethanol concentration rises. The activity of CYP2E1 is significantly increased in chronic drinkers.⁸ Unlike ADH, which requires oxidized nicotinamide adenine dinucleotide (NAD⁺) and generates nicotinamide adenine dinucleotide reduced form (NADH), CYP2E1 requires the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and yields nicotinamide adenine dinucleotide phosphate, oxidized form (NADP⁺). Oxidation of ethanol by ADH results in an increased NADH/NAD⁺ ratio, creating an unfavorable “redox” state for oxidative metabolism, decreasing the oxidative capacity of the liver. Interestingly, the “revved up” CYP2E1 in chronic alcoholics creates excess NADP⁺, which improves the redox state of the liver and enhances ADH activity.⁸

The next step in ethanol metabolism is the oxidation of acetaldehyde to acetate, which also yields more NADH (Fig. 31-2). The reaction is catalyzed by various acetaldehyde dehydrogenase (ALDH) isoenzymes.

These isoenzymes are very efficient, having a K_m approximately 1000 times lower than that of ADH for ethanol.¹⁰ Fifty-percent of Japanese and Chinese persons have isoenzymes with decreased activity, resulting in increased levels of acetaldehyde after ingestion of ethanol.^{8,10} This may be the cause of the increased incidence of facial flushing, vasodilation, and tachycardia (acetaldehyde syndrome) noted in some Japanese after drinking.¹⁰ The increased acetaldehyde levels found in chronic alcoholics result from its increased production and are not due to inadequate ALDH activity.¹¹ Acetaldehyde itself is hepatotoxic by decreasing cellular capacity to repair DNA, increasing free radical-mediated lipid peroxidation, and augmenting hepatic collagen synthesis.¹²

Ethanol’s bioavailability, and thus blood ethanol concentration (BEC), is affected by first pass metabolism (FPM). FPM primarily results from liver ADH. However, the mucosa of the intestinal tract, particularly the stomach, also contains ADH. Stomach ADH can contribute up to 20% of the metabolism of ethanol.¹³

Metabolism is affected by other factors. Persons with chronic alcoholism and severe liver disease have decreased rates of ethanol metabolism that correlate with severity of hepatic damage. This mechanism may contribute to the loss of previously attained tolerance in some persons with chronic alcoholism.¹¹ Abnormalities of liver function tests are not associated with changes in BECs.¹⁴

Elimination involves multiple processes. Most ethanol is metabolized by the above-noted oxidative processes, resulting in carbon dioxide and water production. A small percentage of ethanol is eliminated unchanged in the breath. For example, lung volume affects levels, since ethanol is excreted unchanged in the breath. The contribution of this mechanism may be significant at high BECs.⁹

The elimination kinetics of ethanol are complex and not clearly defined. It was considered to be linear and to

FIGURE 31-2 Ethanol metabolism. CoA, coenzyme A; NAD⁺, nicotinamide adenine dinucleotide, oxidized form; NADH, nicotinamide adenine dinucleotide, reduced form.

follow zero order kinetics, that is, an absolute amount is eliminated per unit time. However, more recent work reflects that the kinetics are complicated. Elimination kinetics are difficult to evaluate because many enzyme systems with different K_m s are involved, different BEC ranges have been studied, and individual variability exists in the rates of ethanol elimination. One case report described a patient with a BEC of 1500 mg% whose ethanol elimination followed first order kinetics (an absolute percentage eliminated per unit time) down to 400 mg%.¹⁵ When BECs are high, the initial availability of free enzymes plus activation of CYP2E1 contributes to a rapid decline in ethanol that is most consistent with a first order process. The contribution of CYP2E1 decreases at moderate ethanol concentrations where the more linear decline reflects saturation of alcohol dehydrogenase. Ethanol elimination slows even further at low concentrations, a pattern consistent with the final phase of first order kinetics.

Because of ethanol's complex pharmacokinetics, BECs are variable and difficult to predict (see Table 31-2). Although the absolute dose of ethanol roughly correlates with the resulting BEC, it is not associated with the time to the peak level.⁶ The metabolism rate correlates directly with the degree of drinking done by individuals; however, there is much overlap between groups. Metabolism rates for nondrinkers are 12 to 24 mg%/hr and for persons with alcoholism 15 to 49 mg%/hr. Not all studies have demonstrated differences between chronic and intermittent drinkers.¹⁴ The only way to definitely know an individual's elimination rate is to obtain serial BECs. It is reasonable to assume a metabolic rate of 20 mg%/hr for unselected patients in an emergency department setting.¹⁴

SPECIAL POPULATIONS

The metabolism of ethanol is not significantly different in the elderly. However, age-related increases in adipose tissue and decreases in lean body mass result in decreased total body water. This results in higher BECs than those obtained by younger individuals ingesting equal amounts of ethanol.¹⁶ Cognitive impairment and dementia may also be worsened by chronic ethanol use.¹⁶ In addition, ethanol interacts with many medications commonly used by the elderly, including central nervous system (CNS) depressants, analgesics, anticoagulants, and antidiabetic agents.¹⁶

Childhood exposure to ethanol is uncommon, representing less than 1% of contacts with poison control centers (PCCs).¹⁷ Reports of pediatric deaths due to ethanol alone are rare. In 2002, exposures in children

aged 6 to 19 years were alcoholic beverages in 93%, whereas exposure in those younger than 6 years of age were not beverage related in 77%.¹⁷ Unlike many pediatric exposures, older children were involved with ethanol more than younger ones.¹⁷ Approximately 75% of the exposures reported to PCCs involve perfumes, colognes, and aftershave lotions; alcoholic beverages and mouthwashes make up 15% and 7% of the ingestions, respectively.² Most emergency department visits and hospital admissions result from drinking alcoholic beverages rather than nonbeverage items.¹⁷ Intentional exposure must always be considered and the appropriate child protection network initiated if this concern exists. While the pharmacokinetics are similar, children less than 13 years of age appear to metabolize ethanol faster than do adults with alcoholism.² Children have more severe effects at lower BECs than do adults, and fatal complications have been reported at less than 50 mg%.² Children commonly present with marked sleepiness or coma and may also have vomiting, ataxia, and seizures.² Ethanol-induced hypoglycemia occurs more frequently in children than in adults and has occurred with a BEC level as low 20 to 30 mg%.² Hypoglycemia is usually associated with ingestion of alcoholic beverages but does not appear to be dose dependent.² Seizures may occur and are often associated with hypoglycemia.² The etiology of hypoglycemia in children versus adults is not fully understood but may be related to smaller glycogen stores.²

An estimate of the potential BEC can be obtained by using the relationship between the volume of distribution (Vd), specific gravity of ethanol (SG), and volume ingested (A):

$$\text{BEC (mg/dL)} = \frac{A \text{ (mL)} \times \% \text{EtOH} \times \text{SG (0.80 g/mL)}}{(0.6 \text{ L/kg}) \times \text{body weight (kg)}}$$

For example, a concerned individual calls because a 20-kg toddler grabbed a half-ounce (15 mL) shot glass of 100-proof (50% ethanol) whiskey and drank it. The numerator determines the absolute amount of ethanol ingested (15 mL \times 0.50 \times 0.80 g/mL) and is divided by the volume in which it is distributed (0.6 L/kg \times 20 kg). After correcting for the units used, the expected BEC is 49 mg%. This is a potentially dangerous level in so young a child, and immediate evaluation in an emergency department would be appropriate. Conversely, the formula can be rearranged to determine the amount ingested once the BEC has been determined. This information may be used to verify the history when considering the possibility of a nonaccidental exposure.

Women attain higher BECs after ingesting equal amounts to men. Women generally have a smaller body mass but more fat, resulting in decreased total body

water and a decreased volume of distribution of ethanol.¹⁸ Women have decreased gastric ADH activity compared with men, also contributing to higher BECs.¹³

DRUG INTERACTIONS

Ethanol's complex pharmacology results in many potential drug interactions (Table 31-3). Because of cross-tolerance between ethanol and barbiturates, alcohol-dependent individuals who are abstaining from ethanol require relatively larger doses of barbiturates for induction of anesthesia.¹⁹ Conversely, barbiturate and benzodiazepine metabolism is inhibited in actively drinking individuals, since ethanol already occupies the microsomal CYP oxidizing system. Ethanol-associated CNS sedation is additive to that produced by benzodiazepines and other sedative-hypnotics such as chloral hydrate, ethchlorvynol, meprobamate, methylqualone, and glutethamide.¹⁹ Sedation associated with phenothiazines, antihistamines, and narcotics is also enhanced by ethanol.²⁰ The use of long-term β -blockers in persons with alcoholism may mask sympathomimetic symptoms associated with hypoglycemia or early withdrawal.²⁰ The significance of the interaction between the H_2 antagonists and ethanol is debated. All H_2 blockers except famotidine inhibit gastric alcohol dehydrogenase and have been associated with increased BECs.²¹

Disulfiram (Antabuse) irreversibly inhibits acetaldehyde dehydrogenase. If ethanol is ingested after pretreatment with disulfiram, a 5- to 10-fold increase in acetaldehyde develops within 15 minutes. Patients experience flushing and throbbing pains of the head and

neck, which are secondary to vasodilation. In addition, abdominal cramps, nausea, vomiting, chest pain, weakness, dizziness, dyspnea, hyperventilation, tachycardia, diaphoresis, and hypotension occur.^{19,20,22} Symptoms last 30 minutes to several hours. This reaction develops even up to 2 weeks after disulfiram exposure.²⁰ Toxicity can be precipitated by as few as 7 mL ethanol.²² Patients using disulfiram should be made aware of the presence of ethanol in over-the-counter products to prevent unexpected reactions.

Diethyldithiocarbamate, the major metabolite of disulfiram, chelates metals and thus inactivates metalloenzymes including ADH and dopamine β -hydroxylase (DBH). The increased BECs sometimes associated with disulfiram therapy have been attributed to ADH suppression. The sometimes intractable hypotension associated with disulfiram reactions may be secondary to DBH inhibition, which causes decreased nerve terminal norepinephrine production.²² Long-term users of disulfiram have an increased incidence of depression, which may be secondary to altered dopamine metabolism owing to suppression of central nervous system DBH.¹⁹ Although other medications have been associated with disulfiram-like reactions (see Table 31-3), their effects are generally inconsistent and mild.¹⁹ Management of patients with disulfiram reactions is generally supportive. However, hypotension secondary to vomiting and vasodilation can be severe and aggressive volume resuscitation may be needed. If vasopressor support is indicated, direct α agonists such as nor-epinephrine should be used, since dopamine's effect is blocked by disulfiram's inhibition of DBH. Antiemetics should be considered if vomiting is present.

TABLE 31-3 Medications That Interact with Ethanol

MEDICATIONS	MECHANISM OF INTERACTION	FINAL EFFECT
Acetaminophen Anesthetics (chloroform, halothane) Barbiturates Benzodiazepines Isoniazid Phenytoin Warfarin	Chronic ethanol use enhances CYP2E1 activity if (1) alcoholic is currently abstaining from drinking (2) alcoholic is currently drinking alcohol	Fulminant hepatic failure ↓ in medication levels ↑ in medication levels
Cimetidine Ranitidine	Inhibits gastric ADH, increasing ethanol bioavailability	↑ in blood ethanol concentration
Barbiturates Benzodiazepines Chloral hydrate	Synergistic with effects of ethanol	↑ in sedation ↑ in respiratory depression
Allopurinol	Synergistic with the ↑ in serum uric acid levels secondary to ethanol	↑ in gouty arthritis
Cephalosporins Chloramphenicol Griseofulvin Metronidazole Quinacrine Sulfonylurea oral hypoglycemics	Disulfiram-like reaction with inhibition of acetaldehyde dehydrogenase	Acetaldehyde syndrome

↑ increase; ↓ decrease; ADH, alcohol dehydrogenase.

The significance of the interaction between acetaminophen and ethanol in persons with chronic alcoholism is debated. Both acetaminophen and ethanol are metabolized by the CYP isoenzyme CYP2E1. Acetaminophen metabolism results in a small amount of the hepatotoxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI), which is eliminated by conjugation with glutathione. Hepatic injury, however, occurs when NAPQI production overwhelms the detoxification mechanism. Conditions that result in increased NAPQI production or in decreased glutathione detoxification can cause hepatotoxicity; patients with chronic alcoholism have these conditions. Ethanol use induces the CYP2E1 isoenzyme, resulting in increased NAPQI production. Chronic ethanol use and starvation decrease glutathione availability; further contributing to potential toxicity.^{23,24} One retrospective series describes patients with chronic alcoholism who have developed hepatotoxicity despite having minor overdoses or even after using less than 4 g/day.²³ Some authors have recommended that acetaminophen be used in decreased doses or not at all in patients with alcoholism.²⁵ However, a randomized, double-blind, prospective comparison of acetaminophen with placebo in 201 chronic alcoholics did not find increased transaminases with acetaminophen.²⁶

TOXICOLOGY

Acute Toxicity (Intoxication)

It is unusual for persons with alcoholism to present for acute care with intoxication as their only medical problem. In one urban emergency department (ED) series, only 26% of patients intoxicated with ethanol had intoxication as their sole problem.¹⁴ A different ED series found that 50% of 289 patients with positive ethanol screens had at least one other drug.²⁷ Fifty-three percent of 116 consecutive motor vehicle accident admissions to an urban trauma service had BECs greater than 100 mg%.²⁸

A toxic dose is considered to be 5 g/kg in an adult or 3 g/kg in a child. The ethanol content of popular beverages ranges from 3% to 6% in beers to as high as 90% in some distilled liquors. One ounce of whiskey (80 proof, or 40%), 12 ounces of beer, or 4 ounces of wine are approximately equipotent and will raise the BEC 25 mg% in the average adult. The majority of states in the United States use 0.08% (80 mg%) as the legal limit for ethanol.

Symptoms of intoxication begin with a perception of stimulation due to the suppression of central inhibitory mechanisms. However, as BEC rises, sedation, incoordination, ataxia, and impaired psychomotor performance appear.²⁹ Even higher levels can result in coma and death. While BECs typically correlate with symptoms in nondrinkers (Table 31-4),³⁰⁻³³ chronic drinkers require higher levels to reach similar states of intoxication. The degree of intoxication also correlates with the rate of rise of the BEC. Slower ethanol ingestion results in less intoxication.³⁰ Acute tolerance has been

TABLE 31-4 Signs and Symptoms of Intoxication and Blood Ethanol Concentrations in a Non-Alcohol-Dependent Population*

ETHANOL CONCENTRATION (MG%)	SIGNS AND SYMPTOMS
<25	Sense of warmth Sense of well-being Talkativeness Mild incoordination
25–50	Euphoria Clumsiness Decreased judgment and control
50–100	Decreased sensorium Worsened coordination, ataxia Decreased reflexes/increased reaction time Emotional lability
100–250	Cerebellar/vestibular dysfunction (ataxia, diplopia, slurred speech, visual impairment, nystagmus) Severe emotional lability, confusion, stupor Nausea, vomiting
250–400	Stupor or coma Little response to stimuli Incontinence Respiratory depression
>400	Respiratory paralysis Loss of protective reflexes Hypothermia Death

*Correlation between signs and symptoms and blood ethanol levels show wide variability among individuals.

demonstrated with a single large ingestion of ethanol. This manifests as a greater degree of intoxication at any BEC when the level is rising compared to when the level is falling.³⁰ Visual tracking of objects is decreased as much as 25% with a BEC of 80 mg%.³⁴ Coma is unusual when the BEC is below 200 mg%.³¹ The lethal level for 50% of the non-ethanol-dependent population is 450 mg%³¹ although individuals have survived BECs as large as 1500 mg%.¹⁵

DIAGNOSIS OF ACUTE INTOXICATION

The differential diagnosis is vast because it involves altered mentation or coma. Conditions that must routinely be considered include hypoglycemia, hypoxia, intracranial pathology, seizure, encephalopathy, uremia, cerebral infection, and shock. Many medications cause an alteration in mental status including sedative-hypnotics, opioids, antidepressants, and antipsychotics.

The patient's history and physical examination should guide the selection of ancillary laboratory data. The usefulness of routine measurement of the BEC in the emergency department is controversial. Its use is appropriate in a patient with an altered mental status. However, the BEC is less likely to affect management decisions in an intoxicated individual who is awake and alert. The disposition of intoxicated patients is a clinical decision and should not be based on BEC.

The BEC may be obtained by using various body fluids; however, venous blood and breath samples are most commonly used. BECs are *not* affected by the use of ethanol in the skin preparation, despite theoretical concerns.³⁵ The accuracy of the breath ethanol analyzer (BEA) depends on the constant equilibrium of ethanol in the blood to alveolar air at a ratio of 2100:1.⁴ BEA results are slightly lower than those from venous blood, especially at higher levels of ethanol, and may be affected by the patient's ability to cooperate.³⁶ BEA results are also consistently less than venous blood estimations in patients with poor pulmonary function, including the elderly.³⁷ Testing within 15 to 20 minutes of the last drink or if vomitus is in the mouth may cause small false elevations. Conversely, false negatives are rare.³⁶

MANAGEMENT OF ACUTE INTOXICATION

Other causes of altered mental status must be assessed depending on the clinical situation. Hypoglycemia should routinely be considered. The threshold to perform a head computed tomographic (CT) scan must be low. Because steady improvement occurs when mental status is depressed by ethanol, a head CT scan is indicated if a patient's sensorium does not improve during a period of observation.

Fluid administration is indicated, since the intoxicated patient is frequently volume depleted secondary to ethanol-induced diuresis, vomiting, and poor oral intake. However, IV fluids do not affect blood ethanol clearance.³⁸ Patients with alcoholism should also receive multivitamins, thiamine, and folate. The routine administration of glucose to sick alcoholic patients is rational because of the significant incidence of ketoacidosis and glycogen deficiency. Studies have not shown caffeine,³⁹ naloxone,⁴⁰ fructose,⁴¹ or flumazenil⁴² to hasten the reversal of intoxication. Gastric emptying is ineffective at decreasing BECs due to ethanol's rapid absorption. Charcoal should be considered in patients who may have ingested other toxins.

The timing of the disposition of an intoxicated patient is controversial. However, most would agree that patients should walk away from an acute care facility only when they actually can walk without difficulty and can demonstrate clear, appropriate thought processes. These points should be documented at the time of disposition.

Chronic Toxicity

NEUROPSYCHIATRIC EFFECTS OF CHRONIC INTOXICATION

In addition to the neuropsychiatric effects of acute intoxication, chronic ethanol use is associated with polyneuropathy, Wernicke's encephalopathy, Korsakoff's psychosis, cerebellar degeneration, dementia, and central pontine myelinolysis. Controversy exists over the etiology and management of these disorders and the relationship between them.

The most common chronic neurologic symptom in alcoholics is polyneuropathy. The axonal degeneration and demyelination likely results from both nutritional

deficiencies and direct toxic ethanol effects.³³ Common findings include painful dysesthesia, anesthesia, weakness, decreased pain and temperature sensation, and decreased touch and vibration sense.^{32,33} Disease progression is gradual, bilateral, and symmetric. The most common site of involvement is the distal legs.^{32,33} If severe, muscle atrophy occurs and the deep tendon reflexes are decreased. Abstinence may result in slow and incomplete recovery.³³

Wernicke's encephalopathy (WE) results from a deficiency of vitamin B₁ (thiamine) and is characterized by the classic triad of oculomotor abnormalities, ataxia, and global confusion. Thiamine is an enzyme cofactor in various metabolic pathways. Although WE is classically associated with alcoholism, thiamine deficiency may also occur in any nutritionally depleted state.^{32,33,43} Indeed, one autopsy series demonstrated that only 18% of cases occurred in persons with alcoholism.⁴³ Thiamine deficiency occurs in persons with alcoholism because of poor diet, reduced absorption and liver storage, and decreased conversion to its active form.^{33,43}

Glucose loading in thiamine-depleted individuals has been proposed to induce WE.⁴³ It is common for authors to recommend that thiamine be given *prior to* glucose in patients with altered mental status. The usual reference⁴⁴ cited in support describes four patients. None of these developed WE after a single, acute administration of glucose; however, all required hours of glucose administration. Thus, the specific order of administration of thiamine and glucose likely does not matter as long as they are given around the same time.⁴⁵

Only a small minority of thiamine-deficient patients develop WE. A low serum thiamine level has poor specificity for the diagnosis. The development of clinical disease in so few thiamine-deficient individuals reflects either a genetic contribution, unknown affecting variables, or underdiagnosis.⁴⁶ The diagnosis is usually established by the combination of clinical symptoms and magnetic resonance imaging revealing mammillary body shrinkage. On autopsy, findings include mammillary body shrinkage and petechial hemorrhages.^{33,37}

WE is likely more common than generally perceived, since the diagnosis is difficult to establish. Autopsy series have demonstrated cerebral and cerebellar neuropathologic changes specific for WE in 0.8% to 2.8% of the general population and in 12% of persons with alcoholism.⁴³ Reviews of premorbid patient symptoms from these series found stupor and coma to be the most common presentations, while WE was diagnosed in less than 20% of the patients.^{43,47}

Based on pathologic studies and chart reviews, WE presents with the classic triad in only 10% to 33% of the patients and up to 20% have none of the three.^{32,43} The onset occurs over several days to many weeks. The hallmark of WE is the extraocular movement abnormalities, with horizontal nystagmus noted in 85%, bilateral lateral rectus paralysis in 54%, and paresis of conjugate gaze in 44%.⁴⁸ The equilibrium loss is secondary to vestibular paresis and cerebellar dysfunction and typically produces ataxia of gait but not of the limbs.⁴⁸ The global confusional state consists of

apathy, poor concentration, spatial and temporal disorientation, and slow and irrational thinking. Most patients have a normal level of consciousness. Impairment of memory and ability to learn is present in a majority but is often difficult to demonstrate because of poor concentration skills.³⁰ Other manifestations include hypothermia and hypotension secondary to altered temperature regulation and decreased sympathetic outflow.⁴³ Wernicke's encephalopathy evolves over time, with mild, subclinical episodes progressing until the clinical triad is apparent.⁴³ The mortality for treated WE is 17% during the initial weeks after diagnosis, most of which is related to associated diseases including infections and cirrhosis.⁴⁸

WE is partially reversible with the administration of thiamine. It should be considered a medical emergency because of the associated morbidity and mortality. Thiamine absorption from the gastrointestinal tract is significantly poorer in thiamine-deficient patients than in healthy controls. In addition, ethanol loading decreases thiamine absorption by 50%.⁴⁹ It is recommended that patients with WE be hospitalized and receive 100 mg thiamine intravenously daily for at least 5 days.^{32,33} Ocular abnormalities generally reverse completely within hours to days except for a fine horizontal nystagmus on lateral gaze that persists in 60%.⁴⁸ Recovery from ataxia usually takes more than a month and is complete in only 33% of patients. Virtually all patients recover from the global confusion within 2 months, although most have persistent memory difficulties.⁴⁸

Abnormal thought processing is common in persons with chronic alcoholism. Neuropsychological impairment is present in 50% to 70% of detoxified persons with alcoholism.⁵⁰ Diagnoses that have been applied to these patients include both Korsakoff's psychosis (KP) and alcoholic dementia. Much overlap between dementia and KP exists and differentiation between the two is not clear. KP is classically described as an "abnormal mental state in which memory and learning are affected out of all proportion to other cognitive functions in an otherwise alert and responsive patient."⁴⁸ It is characterized by anterograde (events occurring now) and some retrograde (recent events) amnesia. Patients are alert, responsive, and can interact well socially but are apathetic and unaware of their disability.⁴⁸ The term *psychosis* is confusing, since patients with KP do not have the gross distortion of mental capacity typically associated with a psychosis.

The classic work of Victor reflected that 80% of those with WE will have KP evident once the global confusion of WE has cleared following thiamine treatment. He suggests that the memory impairment associated with WE is likely the beginning of KP—all primarily related to thiamine deficiency.⁴⁸ However, not all patients with KP will have had WE. In particular, patients with non-alcoholic WE uncommonly develop severe permanent memory disorders. This argues against WE and KP being the acute and chronic phases of the same thiamine deficiency.⁵⁰ KP may have a multifactorial etiology including a drinking lifestyle, multiple episodes of withdrawal, seizures, and repeated head injury.⁵⁰

Management of KP includes routine nursing care, proper diet, and abstinence from alcohol. The role of thiamine is not clear. Complete recovery from KP occurs over 1 to 3 months in 20% of afflicted patients, while 25% do not recover at all.⁴⁸

Alcoholic dementia has been used to describe cases in which amnesia occurs in conjunction with global intellectual decline.⁵⁰ It likely has multiple etiologies including a direct toxic effect of ethanol on the CNS. Cerebral atrophy is common. Some feel the dementia is a manifestation of KP.³³ Central pontine myelinolysis is also associated with alcoholism. It evolves over days to weeks and is associated with hyponatremia.³³ The pontine corticobulbar white fibers undergo demyelination, causing mental confusion, dysarthria, dysphagia, facial and neck weakness, dysfunctional tongue movements, and gaze palsies.^{32,33}

Alcoholic cerebellar degeneration affects chronic drinkers and is characterized by a gradual onset of ataxia that affects the trunk more than the limbs and the legs more than the arms.^{32,33} The symptoms and cerebellar abnormalities are similar to those found in WE, suggesting that these diseases may actually be parts of the same process.³³ While the gait ataxia is similar to that of WE, patients with cerebellar degeneration have more limb ataxia and dysarthria and much less nystagmus.³² Various causes have been proposed, including thiamine deficiency, electrolyte abnormalities, and direct toxicity from ethanol.³³ The disease stabilizes or improves with the cessation of drinking.³³

OTHER EFFECTS OF CHRONIC INTOXICATION

Ethanol alters many aspects of endocrine function including all levels of the hypothalamic-pituitary-adrenal axis, gonadal and carbohydrate activity, and mineral metabolism. Some of these effects may reverse with prolonged abstinence.⁵¹ Ethanol and its metabolites directly decrease testosterone production.⁵¹ Up to 50% of persons with alcoholism and cirrhosis have atrophic testes and many have gynecomastia. Women who drink moderately have more anovulatory cycles, and amenorrhea occurs more often in those with cirrhosis.⁵¹

Alcoholism is associated with osteoporosis in both men and women. Etiologies include ethanol's direct toxicity to osteoblasts, hypogonadism, decreased calcium intake, malabsorption, increased urinary calcium excretion, minimal exercise, and an altered parathormone response to hypocalcemia.⁵¹

Acute and chronic ethanol ingestion cause stimulation of the hypothalamic-pituitary-adrenal axis. Elevated adrenocorticotropic hormone and cortisol levels in some persons with alcoholism suggest Cushing's syndrome.^{31,51} These individuals have classic clinical stigmata such as central obesity and laboratory abnormalities including altered dexamethasone suppression tests.⁵¹ Glucocorticoid secretion returns to normal within a few weeks of abstinence.⁵¹

Ethanol alters fat and carbohydrate metabolism. Hepatic lipogenesis, peripheral fat mobilization, and hepatic uptake of circulating lipids are increased while hepatic lipoprotein release is decreased. The

FIGURE 31-3 Some effects of the increased NADH/NAD⁺ ratio.

altered NADH/NAD⁺ ratio impedes the function of the tricarboxylic acid cycle and slows fatty acid oxidation.¹² These actions cause triglycerides to accumulate in hepatocytes (steatosis) and increase serum triglycerides. Hypoglycemia results from nutrition-related glycogen depletion and decreased gluconeogenic activity resulting from the altered redox ratio.^{12,51,52}

Malnutrition leads to vitamin deficiency disorders such as pellagra, stomatitis, and scurvy. Thiamine deficiency is particularly common because its total body supply can be depleted within 33 days.⁴⁶ Electrolyte disorders include hypokalemia, hypophosphatemia, and hypomagnesemia. Hypokalemia is also caused by gastrointestinal losses and urinary excretion due to altered mineralocorticoid activity.^{52,53} Acid–base abnormalities occur in persons with alcoholism; however, ethanol itself does not cause an acidosis. The anion-gap acidosis sometimes seen in alcoholic patients results from a combination of keto acids and lactic acid. The increased NADH/NAD⁺ ratio favors lactate over pyruvate production (Fig. 31-3).^{52,54} Metabolic alkalosis secondary to vomiting and volume contraction may occur.⁵²

Alcoholic ketoacidosis (AKA) typically begins with abdominal pain (from gastric irritation, pancreatitis, hepatitis, etc.) and vomiting. Volume depletion occurs, and ethanol ingestion decreases as the patient becomes more ill. Comorbid conditions often cloud the typical clinical characteristics (Table 31-5). The stress-related catecholamine increase and resurgent gluconeogenesis (since the patient has stopped drinking) result in normal to mildly elevated serum glucose levels. Ketoacidosis results from acetyl CoA shunting to ketone production, increased lipolysis and free fatty acid (FFA) release, decreased peripheral tissue uptake and metabolism of ketones, and decreased urinary elimination of ketones (Fig. 31-4).⁵⁴ The primary keto acids are β-hydroxybutyrate and acetoacetate. In AKA, the increased NADH/NAD⁺ ratio favors β-hydroxybutyrate production (see Fig. 31-3).

The treatment of AKA includes volume resuscitation, thiamine and glucose supplementation, and management of associated disorders. Glucose administration causes endogenous insulin release, which suppresses FFA release and ketogenesis. Treatment of AKA results in a decreased NADH/NAD⁺ ratio, which decreases the β-hydroxybutyrate-to-acetoacetate ratio. Because the nitroprusside test for ketones measures only acetoacetate, this is paradoxically reflected by an increasingly positive nitroprusside test for ketones. Most urine dipsticks and in-laboratory tests for ketones are still based on nitroprusside color changes.

Acute ethanol ingestion causes dose-dependent suppression of pituitary antidiuretic hormone, resulting in its familiar diuretic effect. This causes free water loss

TABLE 31-5 Alcoholic Ketoacidosis Presentation Summary

SOURCE OF DATA	FINDINGS
History taking	Alcoholism Cessation or decrease of ethanol intake over prior 24–72 hours Fasted state Abdominal pain Vomiting
Physical examination	Consciousness Status consistent with volume depletion Tachycardia Tachypnea
Laboratory	Anion-gap metabolic acidosis pH may be acidemic, normal, or alkalemic Acidemia secondary to ketoacidosis Alkalosis secondary to tachypnea and vomiting Hypokalemia Hypophosphatemia Glucose level mildly elevated, normal, or low Serum and urinary ketones increased (elevation may be underestimated with the nitroprusside test because this test only measures acetoacetate, whereas β-hydroxybutyrate is the primary ketoacid)

without significant urinary electrolyte loss.⁵³ The effect of chronic ethanol intake on total body water is debatable. Ethanol-induced diuresis and periodic abdominal upset and vomiting may lead to dehydration in persons with chronic alcoholism. However, chronic ethanol use may cause a lowering of the pituitary osmole receptor set-point that increases antidiuretic hormone secretion, resulting in eventual volume overload.⁵³ Fluid supplementation of the patient with chronic alcoholism should be based on the clinical evaluation.

Cardiac abnormalities associated with ethanol use include alcoholic cardiomyopathy with congestive heart failure, dysrhythmias, hypertension, and coronary artery disease. The term *alcoholic heart disease* is replacing the term *alcoholic cardiomyopathy*, since cardiomyopathy technically is the primary disease of the cardiac muscle of unknown etiology. Alcoholic heart disease is affected by genetic predisposition and the amount and length of ethanol abuse.⁵⁵ Once alcoholic heart disease is present, the prognosis is poor unless patients abstain from further ethanol intake.⁵⁵ The postulated pathophysiology includes changes in the sarcolemma, the Na⁺/K⁺-activated ATPase pump, calcium homeostasis, and contractile proteins.⁵⁵ Changes in cardiac structure and function include four chamber dilatation, reduced left ventricular compliance and ejection fraction, mild endocardial and valve-leaflet scarring, and mural thrombi.⁵⁵

Chronic, heavy ethanol use increases both systolic and diastolic blood pressures.^{55,56} Conversely, acute ethanol ingestion causes decreased blood pressure that may be due to a combination of decreased vascular resistance and cardiac function.⁵⁷

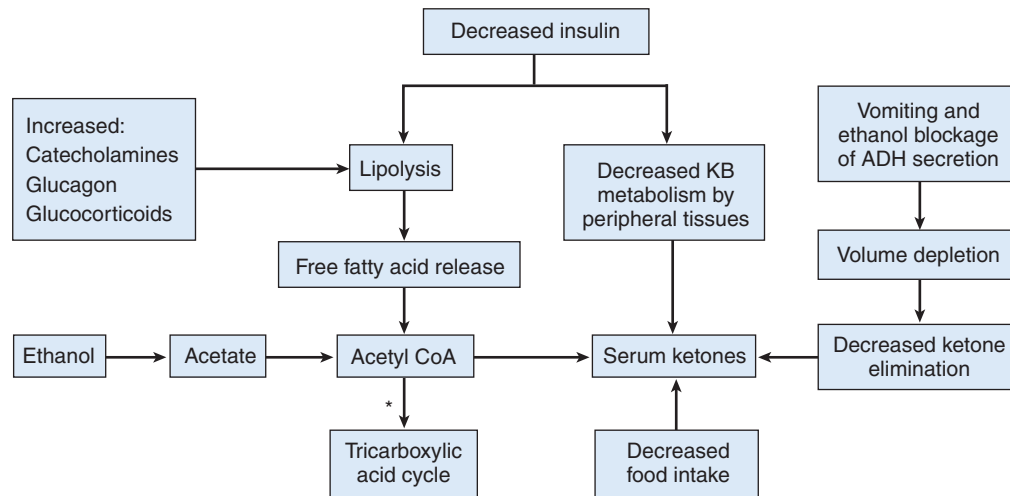

FIGURE 31-4 Factors causing ketonemia in alcoholic ketoacidosis. ADH, antidiuretic hormone. *The tricarboxylic acid cycle is significantly slowed because intermediates are used for gluconeogenesis.

The effect of ethanol on coronary atherosclerotic disease (CAD) and on stroke is biphasic. Regular light-to-moderate alcohol intake appears to provide protection against both CAD and ischemic stroke. This protective effect may be related to an increase in high-density lipoprotein and to a decrease in low-density lipoprotein, platelet aggregation, and fibrinolytic activity.⁵⁶⁻⁵⁹ Low doses of ethanol increase nitric oxide release, augmenting vasodilation. Conversely, heavy consumption increases the risk of CAD and both hemorrhagic and ischemic stroke.^{56,59} Excessive alcohol use increases atherosclerotic disease by increasing blood pressure, triglycerides, and insulin resistance and by altering coagulation.^{56,59}

Ethanol is associated with atrial and ventricular dysrhythmias. Ettinger and others described the “holiday heart syndrome” in persons with alcoholism without overt alcoholic heart disease who developed dysrhythmias. Atrial fibrillation and flutter are the most common signs; they clear with abstinence.⁶⁰ This relationship was supported by a review that found ethanol caused or contributed to 63% of admissions for atrial fibrillation. Eighty-nine percent of the ethanol-related cases converted to sinus rhythm within 24 hours of admission in contrast to only 42% of those with atrial fibrillation secondary to other etiologies.⁶¹

The effects of ethanol on the gastrointestinal tract include esophagitis, gastritis, peptic ulcer disease, malabsorption, gastrointestinal bleeding secondary to numerous causes, and liver and pancreatic diseases. Ethanol-associated liver disorders include fatty infiltration, alcoholic hepatitis, and fibrosis (cirrhosis). Fatty infiltration of the liver can start within days of the onset of heavy drinking. It is due primarily to triglyceride deposition, but dietary fat intake also contributes.¹⁸ Inflammation resulting from alcoholic hepatitis hastens the deposition of collagen. Inflammation associated with fatty infiltration results in the deposition of collagen, the primary protein of fibrous tissues, into liver lipocytes. The lipocytes eventually transform into collagen-

producing cells. Cirrhosis develops when collagen production outpaces its degradation.¹⁸

Ethanol’s induction of the CYP system increases the conversion of xenobiotic compounds such as anesthetics and industrial solvents to toxic metabolites. The system also activates carcinogens that may contribute to the increased incidence of upper alimentary and respiratory tract cancers in persons with alcoholism. Acetaldehyde accumulation is associated with impaired hepatic oxygen utilization, increased free radical production, lipid peroxidation, and fibrinogenesis.¹²

Ethanol abuse suppresses hematopoietic elements of the bone marrow through malnutrition-related vitamin deficiency and direct ethanol toxicity. Ethanol causes decreased bone marrow cellularity, vacuolization of marrow precursor cells, and a macrocytosis independent of folate deficiency. Chronic ethanol abuse causes thrombocytopenia that resolves with abstinence; however, its effect on platelet function is not clear.⁶² Ethanol also causes many types of anemia including iron and folate deficiency, hemolytic, and sideroblastic. Classic folate-dependent megaloblastic anemia occurs in 4% of ambulatory persons with alcoholism and generally affects those who imbibe hard liquor, since beer is actually a good folate source.⁶² Folate deficiency in persons with alcoholism is secondary to poor diet, malabsorption, disruption of the enterohepatic circulation, and a direct antifolate effect of ethanol.

Infection in alcoholics is associated with increased morbidity. Immunosuppression occurs with acute and chronic ethanol abuse. Acute ingestion causes decreased neutrophil delivery to infection sites and decreased adherence, whereas chronic abuse results in marrow suppression, decreased chemotaxis, and neutropenia. Neutrophil bactericidal and phagocyte activity are not affected by ethanol.⁶³ Abstinence results in the reversal of leukopenia within a few days.⁶² Ethanol is also associated with decreased pulmonary macrophage mobilization, bactericidal activity, and reticuloendothelial system clearance.⁶²

Addiction, Tolerance, Dependency, and Withdrawal in Chronic Intoxication

Various terms are associated with inappropriate use of addicting agents. The American Psychiatric Association uses the term *substance dependence* instead of drug addiction.²⁹ Substance dependence is a collection of physiologic, behavioral, and cognitive symptoms indicating that a person is continuing to use an agent despite having significant agent-related problems.²⁹ Tolerance and physical dependence reflect physiologic adaptation at a cellular level. Larger and larger doses of an agent are required to obtain the same effect and use of the agent is necessary to maintain the desired psychological effect or prevent symptoms of withdrawal. A withdrawal syndrome occurs in physically dependent individuals who reduce or cease their ethanol intake.²⁹ Physical dependence is not required for the diagnosis of substance dependence. Addictive drugs provide a “reward” by acting as positive reinforcers (producing euphoria) or as negative reinforcers (alleviating symptoms of withdrawal or dysphoria).²⁹ The brain system involved in the reward mechanism becomes hypersensitized to both the direct effects of the drug and associated environmental stimuli (cues) that are not directly attributable to the drug. The hypersensitization results in pathologic wanting, or craving, independent of symptoms of withdrawal. Substance abuse incorporates recurrent and significant adverse effects related to the use of an agent including the use of the agent in dangerous situations, failure to fulfill major role obligations, legal problems, and continued use despite all the attendant problems.²⁹

The pathophysiology of addiction is complex but interestingly is shared by different addicting agents. The center is the mesocorticolimbic dopamine systems that originate in the ventral tegmental area (VTA). Projections from the VTA go to limbic structures such as the nucleus accumbens, amygdala, and hippocampus and to the prefrontal cortex and anterior cingulate. These circuits affect reinforcement, memory, craving, and the emotional and motivational changes of the withdrawal syndrome. Addictive drugs provide a “reward” by stimulating release of dopamine from the VTA into the nucleus accumbens, causing euphoria and reinforcement of the behavior. Ethanol increases dopamine by activating the inhibitory neurotransmitter γ -aminobutyric acid (GABA) receptors or by inhibiting the stimulatory *N*-methyl-D-aspartate (NMDA) receptors. Chronic ethanol use enhances the function of NMDA receptors by modifying the subunits.²⁹ Opioid and serotonin receptors have a role in the reinforcing effects of ethanol.²⁹ Interestingly, during withdrawal, there is a decrease in dopamine levels in the nucleus accumbens.

The severity of withdrawal syndrome is related to three major factors: the degree of drug exposure, duration of exposure, and (of less clarity) the history of previous withdrawal episodes.⁶⁴ Persons with alcoholism with a longer history of recurrent withdrawal experience more severe withdrawal. This phenomenon has been referred to as “kindling.”^{64,65} “Reinstatement” is another

clinical entity that refers to the ever-shortening drinking bouts required before cycles of withdrawal.⁶⁵ This sensitization is likely related to hypofunction of the GABA receptors and enhanced function of the NMDA receptors.⁶⁴

PATHOPHYSIOLOGY OF INTOXICATION AND WITHDRAWAL

The complex cellular mechanisms of ethanol intoxication, tolerance, dependence, and withdrawal are not completely clear. Ethanol is a relatively weak sedative. Much greater concentrations of ethanol are required to induce an effect than are required of agents such as benzodiazepines or barbiturates. This likely reflects the absence of specific receptors for ethanol.³² Ethanol alters membrane fluidity, the function of membrane structures involved in signal transduction, binding of neurotransmitters, and regulation of gene expression.^{32,33} Selective sites of toxicity include the receptor complex of GABA, the areas regulating excitatory amino acids, calcium channels, the central adrenergic system, dopamine and adenosine receptors, and the hypothalamic-pituitary-adrenal axis.^{32,33}

GABA receptors are part of a large membrane protein complex that includes a GABA-activated chloride channel and closely linked benzodiazepine receptors whose effect is mediated by the same chloride channels.^{32,33} Ethanol causes neuronal inhibition by a direct effect on the chloride channel and indirectly by potentiating GABA.³² The physical proximity of these receptors may explain the cross-tolerance that occurs between ethanol and the benzodiazepines. Chronic ethanol use decreases the magnitude of GABA complex-mediated neuroinhibition, an effect that probably contributes to the development of tolerance.³² Decreased GABA-activated chloride channel flux during abstinence contributes to the CNS hyperexcitability of ethanol withdrawal.³² The sedating effect of benzodiazepines on patients with symptoms of ethanol withdrawal is likely due to activation of these same channels.

Calcium channels and their receptors also contribute to the cellular mechanisms of tolerance and withdrawal. A few days of ethanol use causes an increase in both calcium channel flux and binding site availability that persists for several hours after drinking has ceased. Calcium channel blockers decrease tremors, seizures, and death in ethanol-dependent rodents deprived of ethanol. Calcium channel blockers attenuate some of the sympathetic symptoms of withdrawal in humans; however, they do not prevent seizures or delirium tremens.³³

Ethanol affects the activity of excitatory amino acids, particularly NMDA, in certain areas of the brain.³³ Ethanol decreases NMDA-receptor-associated calcium channel flux and changes the cell's response to its activation. Of particular interest is ethanol's inhibition of NMDA receptors in the hippocampus, an area involved in learning and memory. This is a proposed mechanism of cognitive defects and “blackouts” associated with ethanol use.^{32,33}

Adrenergic activity affects withdrawal symptoms. The excitatory neurotransmitter norepinephrine (NE) is

released by presynaptic vesicles. It interacts with various receptors and is then sequestered into the presynaptic terminal. Within the hypothalamus, intersynaptic NE is taken up by extraneuronal cells (possibly astrocytes) and converted to epinephrine, which is then released back into the synapse. Phenylethanolamine-*N*-methyltransferase (PNMT) catalyzes this extraneuronal conversion of NE to epinephrine. Epinephrine activates presynaptic α_2 receptors, which inhibit NE release. Ethanol increases PNMT activity, leading to central adrenergic inhibition. Chronic ethanol ingestion leads to compensatory down-regulation of presynaptic α_2 receptors. Ethanol withdrawal is associated with decreased PNMT activity that results in less epinephrine being available to stimulate the previously down-regulated α_2 receptors. Since the α_2 receptors provide negative feedback to the presynaptic neurons, the resulting loss of negative inhibition yields increased sympathomimetic activity.⁶⁵ This pathophysiologic process explains the effect of the central α_2 agonist clonidine in decreasing the sympathomimetic activity associated with withdrawal. The stimulatory central adrenergic β receptors also appear to contribute to the withdrawal syndrome. Ethanol causes uncoupling between the β receptor proteins and their second messengers, which prevents the receptor down-regulation that typically occurs during sympathetic states. Increased adrenergic activity during withdrawal results in hyperstimulation of these receptors.⁶⁶ This mechanism may explain the effects of atenolol in management of the withdrawal syndrome. Excess dopaminergic states are associated with psychosis, hallucinosis, cravings, and the mechanisms of reward and reinforcement.³³ However, the roles of serotonin and dopamine in ethanol intoxication and withdrawal are not clearly defined.³³

Adenosine is also associated with physical dependence and tolerance.³³ While not a neurotransmitter itself, it modulates the effects of neurotransmitters. Acute ethanol ingestion inhibits intracellular transport of adenosine, leading to increased stimulation of extracellular membrane adenosine α_2 receptors. This stimulation of the α_2 receptors causes increased G protein-mediated adenylcyclase activity and increased intracellular adenosine 3',5'-cyclic phosphate (cyclic AMP). Chronic ethanol intake eventually causes an adaptive decrease in cyclic AMP production. Adapted cells require ethanol to maintain adequate cAMP production. The adenosine nucleoside transporter also loses its sensitivity to ethanol inhibition with chronic ethanol use. Protein kinase A activity, which requires cyclic AMP, is responsible for the decreased adenosine nucleoside transporter uptake. The decrease in available cyclic AMP associated with chronic ethanol ingestion eventually results in increased adenosine transporter activity. These membrane changes reflect "tolerance" at the cellular level.³³

WITHDRAWAL SYNDROMES

Into the 1950s, the cause of the clinical syndrome that we now refer to as "withdrawal" was hotly debated. It was unclear whether the syndrome was due to cessation of

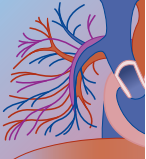

drinking, a direct toxic effect of ethanol, or nutritional deficiencies. Isbell and others settled the debate in 1953.⁶⁷ In their study, ethanol was given daily to 10 healthy, former opiate addicts in controlled conditions that provided adequate diets and vitamins but prevented the introduction of other agents. Upon cessation of drinking, four subjects who drank for up to 34 days all developed tremor, perspiration, gastrointestinal distress, and anorexia lasting 1 to 3 days. Three of these four drank for no more than 16 days, reflecting the little time needed to develop physical dependence. The six subjects who drank between 48 and 87 days developed vomiting, diarrhea, insomnia, hyperreflexia, and fever in addition to the above symptoms. Five also had hallucinations, two had seizures, and three developed delirium tremens.⁶⁷ Ethanol withdrawal developed even if the study participants did not become intoxicated as long as the amount of ethanol ingested remained large over time.⁶⁷

Symptoms of ethanol withdrawal range from mild anxiety and tremors to seizures, delirium tremens (DTs), and death. Symptoms start 6 to 8 hours after a significant drop in ethanol level. Sympathetic symptoms include tremors, tachycardia, hypertension, irritability, and/or hyperreflexia. Neuropsychiatric symptoms include anxiety, agitation, hyperalertness, easy startling, insomnia, craving for rest, self-preoccupation, inattention, and mild disorientation to time with no gross confusion.^{30,67} The absence of significant disorientation, confusion, and autonomic instability differentiates minor withdrawal from the more serious DTs. Tremors may be minimally noticeable (shaky inside) but worsen with activity or agitation and can become so coarse that the patient may not be able to talk, walk, or eat.³⁰ Symptoms often peak and begin to resolve within 24 hours but can last days to more than a week. Without treatment, the hyperalertness, shakiness, and insomnia can last as long as 10 to 14 days.³⁰ A mild symptom complex occurs in 70% to 80%, while 15% to 20% become moderately ill if treatment is not provided.⁶⁸

Hallucinations can occur in up to 25% of patients. Three quarters begin within 48 hours, but they may not occur until 6 to 8 days after the cessation of drinking.³⁰ Pure visual hallucinations are five times more frequent than auditory.³⁰ They may also rarely be tactile or olfactory. Other disorders of perception such as illusions are transient and rarely last longer than 3 days.³⁰

An unusual manifestation of ethanol withdrawal is "acute auditory hallucinosis," which occurred in 2% of patients in one series.³⁰ The patients did not have significant autonomic hyperactivity. The auditory hallucinations affected only chronic alcoholics, were usually threatening in nature, and lasted a few days to 2 weeks. Patients were oriented and appropriate during the hallucinatory events. Upon recovery, patients realized that the voices were imaginary but could vividly recall the events.³⁰

Alcoholic withdrawal seizures, or "rum fits," are generalized and tonic-clonic. Unlike idiopathic seizures, this is an adult-onset disease, with 94% beginning after the age of 30 years.⁶⁹ Electroencephalograms (EEGs) of patients with ethanol withdrawal seizures demonstrate diffuse

slowing that normalizes after the seizures have ceased. This is different from idiopathic seizure in patients whose baseline EEGs are abnormal.^{67,69} The frequency of withdrawal seizures in patients with concomitant idiopathic epilepsy is increased relative to those without epilepsy.³⁰ Three to 12 percent of untreated withdrawal patients have seizures, with 50% occurring 13 to 24 hours after cessation of drinking and 90% within 48 hours.^{30,69} Seizures occurring within 12 hours of the cessation of drinking often have other contributing factors including prior ethanol tapering or head trauma.^{30,69} Fifty-four percent of patients with alcohol withdrawal seizures have more than one seizure, all occurring within a few hours of each other.^{30,69} One third of patients who have seizures eventually develop DTs if not treated,^{30,69} while one third of those who have DTs will have had a seizure during the current withdrawal.⁷⁰ Seizures are unusual after the onset of DTs. Patients who have both withdrawal seizures and DTs typically have the seizures first. Delirium tremens begins during the postictal period in 25%, and most episodes begin within 3 days of the seizure.³⁰

While ethanol withdrawal can cause seizures, it is proposed that ethanol itself causes seizures. One retrospective series of 308 inner-city patients with new-onset seizures found that only 30% of the alcoholic patients had reduced or stopped their drinking during the 2 weeks prior to their seizures.⁷¹ It has been noted⁷² that even patients in the older, classic series^{30,69} had seizures outside the typical time frames or while still ingesting ethanol. It has been suggested that seizures in the setting of ethanol use should simply be referred to as “ethanol-related seizures.”⁷¹

Delirium tremens is an infrequent but potentially fatal syndrome. It can occur in individuals who have drunk steadily for as few as 48 days⁶⁷ and develops in approximately 5% of patients with untreated ethanol withdrawal.^{30,73} It typically begins 3 to 5 days after ethanol intake has decreased but can start within 24 hours or as late as 14 days.³⁰ Delirium tremens is marked by severe autonomic hyperactivity (hypertension, tachycardia, fever, tremors, diaphoresis, dilated pupils) and significant disorientation. Patients may demonstrate brief moments of insight and reality if their attention can be obtained. While 83% recover within 3 days, 10% can have relapses, with the entire process lasting up to a month.³⁰ Patients are typically amnesic for events during the delirium.³⁰

Prior to the 1950s, the mortality associated with DTs was as high as 50% but averaged 20% to 25%.⁷³ A 1950s series had a 15% mortality.³⁰ Mortality today is often quoted to be 5% to 15% in treated patients.⁶⁸ However, mortality has not been well studied since the benzodiazepines have become the mainstay of therapy. Mortality likely is relatively low in patients with DTs who have received adequate doses of benzodiazepines and appropriate nursing care. Death during DTs is usually related to patients' underlying medical conditions including pancreatitis, subarachnoid hemorrhage, gastrointestinal hemorrhage, infection, dehydration, seizure disorders, severe electrolyte abnormalities, cardiac rhythm disturbances, and liver disease.^{70,73} Hyperthermia or seizures in patients with DTs are particularly

associated with a poor outcome. In one series, seizures occurred in 31% of those who died versus 13% of survivors. Even more significant was that 51% of those with temperatures greater than 104° F died, compared with 8% of survivors.⁷⁰

Management of Withdrawal Syndrome

The treatment goals for individuals with the withdrawal syndrome are to prevent the progression of withdrawal to seizures or DTs, allay symptoms, treat underlying disorders, and prepare patients for long-term rehabilitation. Both pharmacologic and nonpharmacologic approaches have been used. Benzodiazepines are the mainstay of pharmacologic therapy. Nonpharmacologic approaches include reassurance, reality orientation, frequent monitoring of signs and symptoms, and general nursing care.⁷⁴ Nonpharmacologic therapy has been effective, but it has only been used on patients with mild withdrawal symptoms and without seizures or concomitant medical problems.^{74,75}

Patients in withdrawal should receive supplementary multivitamins, thiamine, glucose, and folate. Multivitamins are included because of malnutrition resulting from the “empty” ethanol calories. Thiamine is given by the oral, intramuscular, or intravenous routes. The safety of IV thiamine was demonstrated in a prospective series of 989 patients. Eleven had local irritation and only one developed mild generalized pruritis.⁷⁶ Dextrose is given because hypoglycemia is common owing to poor oral intake, glycogen depletion, and decreased carbohydrate production. Potassium, phosphate, and magnesium supplementation may also be beneficial, but there are no data to support this.

Patients with severe symptoms, altered mental status, or significant comorbid conditions should be hospitalized. Hayashida and others demonstrated that outpatient management was effective, safe, and less costly in a population with mild to moderate symptoms, no comorbid disease, and accessibility to daily follow-up.⁷⁷ Social issues including homelessness and social support must also be considered when making management decisions.

Benzodiazepines (BDZs) are cross-tolerant with ethanol and are the drugs of choice because of their sedative, anxiolytic, and anticonvulsive properties.⁷⁸ Their efficacy was established initially in two classic papers. Sereny and Kalant performed a five-armed, randomized, double-blind comparison of two doses of chlordiazepoxide, two doses of promazine, and placebo. Chlordiazepoxide improved study parameters more consistently than did promazine, and the latter was also associated with an increased progression to DTs.⁷⁹ Kaim and others compared chlordiazepoxide, chlorpromazine, hydroxyzine, thiamine, and placebo for the treatment of withdrawal. Chlordiazepoxide was clearly the best at preventing progression of withdrawal.⁸⁰ BDZs should be started at the onset of withdrawal symptoms, regardless of the blood ethanol concentration. Problems associated with the use of BDZs include excessive sedation and minor cardiovascular and respiratory depression.³¹ However, their safety profile is excellent.

No trials exist that compare oral to parenteral BDZs in patients with severe withdrawal, seizures, or DTs. However, most use intravenous BDZs because they can be better titrated to effect. Intramuscular administration of lorazepam is appropriate if intravenous access cannot initially be obtained.

The optimal choice of BDZ for the treatment of withdrawal is debated, especially with regard to the desirability of drug characteristics such as half-life, lipid solubility, the mechanism of metabolism and the presence of active metabolites, and abuse potential. An extensive meta-analysis found all BDZs to be equally effective in reducing signs and symptoms of withdrawal.⁸¹ However, the longer acting agents, with their active metabolites, may be more effective at preventing seizures during a fixed-dose taper owing to smoother withdrawal with fewer rebound symptoms.^{3,81} The potential for abuse is another consideration in BDZ choice. Faster acting agents such as lorazepam, diazepam, and alprazolam have a higher abuse potential than agents with a slower onset of action such as oxazepam or chlordiazepoxide.⁸² Oversedation is a concern, particularly with oral dosing. Agents with long half-lives or active metabolites may accumulate and cause extended periods of sedation.^{78,81} Interestingly, while oversedation is a concern, this author could not find any cases that reflected this has ever had any clinical significance in the alcohol withdrawal setting. Indeed, as noted above, the long-acting agents likely provide a “smoother” withdrawal with fewer symptom flares. This concept was supported by a comparison of diazepam and lorazepam that found the latter agent to be associated with significantly more anxiety, depression, and poorer performance on cognitive testing.⁸³ Severe liver dysfunction slows the metabolism of BDZs eliminated by oxidation (diazepam, chlordiazepoxide) more than those eliminated by glucuronidation alone (lorazepam oxazepam).^{78,84} It is possible that the metabolism of long-acting agents is decreased in the presence of cirrhosis, chronic active hepatitis, and old age, and half-lives are increased by concomitant administration of disulfiram, cimetidine, or ethanol.^{85,86} Such patients may become oversedated, especially with oral regimens, if dosing is not adjusted appropriately.^{78,84-86} The significance of lipophilicity is unclear. More lipophilic agents (midazolam > diazepam

> lorazepam) penetrate the CNS faster (of unclear clinical significance) but also undergo faster redistribution back out of the CNS (shortening the duration of a single injection).⁷⁸ Chlordiazepoxide continues to be one of the most commonly used agents for a fixed-dose taper. It was the first to enter the market (1960); is inexpensive; has long-acting metabolites that accumulate with multiple doses, enabling a smooth taper; and has a relatively low abuse potential. Comparisons among BDZs are shown in Table 31-6.

Few conclusions can be drawn from large reviews or meta-analyses. Three meta-analyses have reached similar conclusions: that BDZs are the agents of choice and the data are not clear as to the optimal BDZ.^{81,87,88} Bird and Makela conducted a literature review to determine whether lorazepam should be the agent of choice over the long-acting agents and concluded that no experimental evidence documented the clinical superiority of lorazepam.⁷⁸

Three treatment protocols with BDZs have been used. The most commonly used BDZ dosing method in the United States is a fixed-dose, 3- to 5-day taper of chlordiazepoxide.⁸⁹ A slower taper should be considered for the BDZs that only undergo glucuronidation—lorazepam and oxazepam.³¹ Tapering should be done by decreasing the dose and not by increasing the interval between doses.³¹

Another approach is the “loading dose technique,” which takes advantage of the sustained action of the long-acting agents. A high dose of a long-acting agent is given every 1 to 2 hours until the withdrawal symptoms clear or sedation occurs.^{90,91} For example, diazepam 20 mg orally has been used for each dose. Patients averaged four doses over 12 hours and then received no further medications. The long half-lives of diazepam’s active metabolites facilitate this approach, since therapeutic levels persist beyond 72 hours.⁹⁰ A pharmacokinetic study of the diazepam loading dose technique revealed that some patients did not reach maximum concentration until 90 minutes, reflecting that the dosing intervals should be at least 90 minutes long.⁹²

The third protocol is symptom-triggered therapy, in which patients receive medication only when symptoms exceed a threshold of severity, enabling individualized tapering regimens.⁸⁹ This approach uses an assessment

TABLE 31-6 Comparison of Benzodiazepines Used for the Treatment of Withdrawal

CHARACTERISTIC	CHLORDIAZEPOXIDE	DIAZEPAM	LORAZEPAM	OXAZEPAM
Routes	IV, IM*, PO	IV, IM*, PO	IV, IM, PO	PO
Initial dosing regimen	15–50 mg tid/qid	5–20 mg tid/qid	1–2 mg bid/qid	15–30 mg tid/qid
Liver metabolism	Oxidation	Oxidation	Glucuronidation	Glucuronidation
Active metabolites	Yes	Yes	No	No
Half-life (hr) [†]	(Long) Range: 6–30 Average: 10	(Long) Range: 20–70 Average: 33	(Intermediate) Range: 5–25 Average: 15	(Intermediate) Range: 5–20 Average: 8

IM, intramuscular; IV, intravenous; PO, oral; tab, tablet.

*IM absorption is erratic, and thus this route of delivery should be avoided if possible. Inject in the deltoid muscle if administration must be IM.

[†]Chlordiazepoxide’s and diazepam’s active metabolites have half-lives from 25 to 100 hr.

scale to establish severity. The most extensively studied scales are the Clinical Institute Withdrawal Assessment–Alcohol (CIWA-A) and the revised, shortened version of the same. The scales are reliable, reproducible, and valid. High scores predict increased likelihood of seizures or delirium.^{3,81} Symptom-triggered therapy decreases the total dose of BDZ and the duration of treatment.^{3,81,89} Unfortunately, studies of symptom-triggered therapy have been only in patients with mild to moderate withdrawal.^{81,86,89,93} Concerns over the approach include inducing drug-seeking behavior, undertreating patients, and causing “kindling” sensitization because too little treatment has been given.⁹³

For patients with severe withdrawal, very large doses of BDZs may be required. Reported doses include 2640 mg of diazepam over 48 hours⁹⁴ and 3600 mg of lorazepam over 3 days.⁹⁵ A common mistake in the management of patients with severe withdrawal is to not be aggressive enough with the use of BDZs. Use of the “usual” doses may be very inadequate.

Other sedative-hypnotic medications have been assessed. Barbiturates have been used extensively; however, there are few data to support them. They have a narrow safety margin, have abuse potential, and are very sedating. Barbitol, a long-acting oral barbiturate, decreases symptoms comparably to BDZs.⁸¹ Phenobarbital is supported by various uncontrolled trials. It has less abuse potential than other barbiturates, can be administered by multiple routes, and is inexpensive.⁹⁶ However, it has a greater risk of respiratory depression and a lower safety profile than BDZs.^{3,81} γ -Hydroxybutyrate (GHB) compared favorably with diazepam in a prospective series of 60 patients with mild to moderate withdrawal.⁹⁷ Propofol is reported to decrease the symptoms of DTs in patients who were refractory to benzodiazepines.^{95,98} A problem with these and other sedatives is that they have not clearly been shown to decrease the progression of withdrawal.

Anticonvulsant medications have long been used for ethanol withdrawal, with a main action of cross-tolerance with ethanol at the GABA_A receptors.^{3,96} Various open-label trials and anecdotal reports indicate that valproic acid is effective at reducing symptoms.⁹⁶ Gabapentin relieved withdrawal symptoms in a four-patient series.⁹⁹ Carbamazepine is the best studied of these agents. It is superior to placebo and at least equal to oxazepam, lorazepam, and barbitol for the suppression of mild to moderate alcohol withdrawal. Compared with lorazepam, it is associated with fewer protracted symptoms, less relapse during a 3-month follow-up, and fewer adverse events such as dizziness or incoordination.^{3,81,96} Like the nonbenzodiazepine sedative-hypnotics, the anticonvulsant medications have not been shown to prevent the progression of withdrawal in humans.

The neuroleptic phenothiazines and butyrophenones have no role in the management of withdrawal despite their ability to attenuate the signs and symptoms of withdrawal. They are less effective than BDZs in preventing delirium and have actually been associated with an increase in seizures compared with placebo.^{3,81} Neuroleptics can also modify the body’s ability to regulate hyperthermia and can cause hypotension.³¹

The sympatholytic centrally acting α_2 agonists and β blockers are also used. Their primary benefit is attenuation of hyperadrenergic symptoms such as tremor, tachycardia, and hypertension while permitting normal cognitive function.^{81,100,101} They usually are used in conjunction with other agents. They have not been shown to prevent seizures or progression to DTs.^{81,101} In seriously ill patients, the reduction of sympathetic symptoms masks the progression of DTs and the worsening of associated medical problems.^{100,101} β Blockers may be contraindicated for medical reasons including hypoglycemia, cardiomyopathy, and chronic obstructive pulmonary disease.¹⁰⁰

Alcohol-related seizures should be treated with BDZs. Intravenous lorazepam significantly decreased the frequency of recurrent seizures in one prospective, randomized series of 229 patients who presented following an alcohol withdrawal seizure.¹⁰² Phenytoin, valproic acid, carbamazepine, and primidone are not effective.¹⁰¹ In addition, except for phenytoin, these agents also cannot be rapidly loaded.

A Methanol

DAG JACOBSEN, MD, PHD ■ KNUT ERIK HOVDA, MD, PHD

At a Glance...

- Methanol or methyl alcohol is converted to the toxic metabolite formic acid, which causes acidosis and inhibits cell cytochromes.
- Clinical manifestations vary and are usually delayed for 12 to 24 hours: Visual disturbances, gastrointestinal symptoms, dyspnea, headache, and sometimes chest pain occur. In late stages, coma and respiratory arrest may be observed.
- Diagnosis is based on clinical signs, acid-base status, measurement of serum formate and/or direct serum methanol analyses, or calculation of the anion and osmolal gaps.
- Treatment consists of buffer, an antidote (either ethanol or fomepizole), folinic acid, and often hemodialysis.
- One should always consider multiple victims, especially if the source is contaminated alcohol.
- Permanent sequelae, such as impaired vision and brain damage, may develop if treatment is delayed.

Methanol (HCOOH, methyl alcohol, wood spirits) is a clear, colorless liquid at room temperature. It is a widely used commercial, industrial, and marine solvent and paint remover, as well as a solvent in paints, varnishes, shellacs, and photocopying fluid. It may be used as an antifreeze fluid and is commonly used in windshield-washing fluids. In addition, it can be formulated as a solid canned fuel (4%), along with ethanol and soap, or as a liquid fuel for heating small engines used in various hobbies. In the United Kingdom, methanol is adulterated with a purple dye to distinguish it from ethanol. However, its high industrial production and its use in laboratories, schools, and industrial processes account for the fact that large volumes may be obtained and contribute to epidemic outbreaks of methanol poisoning.

Methanol is also used as an adulterant to make ethyl alcohol unfit to drink when the latter is used for cleaning purposes. Because methanol can be purchased tax free and is considerably less expensive than normal alcoholic beverages, it is not surprising that chronic alcoholics may consume such compounds.¹ Methanol outbreaks are therefore most common in countries with high taxes on alcohol.² Methanol has no therapeutic properties and is considered to be only a toxicant.

TOXICOLOGY AND PHARMACOLOGY

The lethal dose of methanol is variably given as 30 to 240 mL, with 1 g/kg (1.2 mL/kg) as the best estimate.³

However, with aggressive treatment, survival may be achieved despite much higher intake. Because toxicity in methanol poisoning depends on the degree of metabolic acidosis, there is really no lethal or toxic concentration of methanol if its metabolism to formic acid is blocked. The minimum dose that can cause permanent visual defects is unknown, but most probably ingestion of more than 30 mL (adults) is necessary.

The main route of toxicity is ingestion, but toxicity may also occur after inhalation or skin absorption.^{4,5} Methanol is readily absorbed from the gastrointestinal (GI) tract after ingestion and reaches peak blood levels in 30 to 90 minutes. It is widely distributed in body tissues, with a volume of distribution of 0.6 to 0.7 L/kg.^{6,7} A small amount of methanol is found in the expired breath of normal persons, presumably due to endogenous metabolic production. The kidneys and lungs in untreated patients excrete less than 5% to 10% of unchanged methanol. The majority of methanol, therefore, is metabolized in the liver, by alcohol dehydrogenase to formaldehyde. Thereafter, formaldehyde is converted by the enzyme aldehyde dehydrogenase to formic acid, which is primarily responsible for the toxicity in methanol poisoning (Fig. 32A-1). This toxicity results from a combination of metabolic acidosis (H^+ production) and an intrinsic toxicity of the anion formate.⁷ The metabolism and hence elimination of formate depends on the folate pool in the liver.⁸ Primates have a small

FIGURE 32A-1 The metabolic pathways of methanol, ethylene glycol, and ethanol.

folate reserve and are the only species that accumulate formate and thus suffer from methanol toxicity.^{9,10} Other animals only develop acidosis and methanol toxicity if they are made folate deficient.¹¹ In our latest study,¹² the renal elimination of formate was unexpectedly high in nonacidotic patients. Based on experimental studies demonstrating that this renal elimination depends on pH, we have postulated that increasing acidosis may, by this mechanism, also contribute to the ensuing metabolic acidosis. Thus, metabolic acidosis may itself be a trigger for increasing accumulation of formate. If correct, this adds further importance to the correction of metabolic acidosis in these patients.

The elimination of methanol is usually of zero order because of saturation of alcohol dehydrogenase. Data on this elimination are limited, but elimination rates of 2.7 mmol/L/hr (8.5 mg/dL/hr)¹³ and 6.3 mmol/L/hr (20 mg/dL/hr)¹² have been reported. If ethanol metabolism is inhibited by antidote (ethanol or fomepizole) administration, methanol elimination is of first order with a half-life of 22 to 87 hours.¹² For unknown reasons, this half-life seems to increase with increasing serum methanol concentrations.^{12,14}

In the early stage of methanol poisoning, the toxic effects are due to the increasing metabolic acidosis caused by the production of formic acid. At this stage, there is a good correlation between the degree of metabolic acidosis reflected by the base deficit or the increase in anion gap, and the formate concentration.¹⁵ In late stages, as formate accumulates, the toxicity is mainly caused by acidosis and the histotoxic effects of formate, which inhibits mitochondrial respiration.¹⁶ The resulting lactate production increases acidosis and thereby

toxicity of formate, as more formate is protonated and thereby able to penetrate the blood-brain barrier.¹¹ Thus, a vicious hypoxic circle is initiated.¹⁷ In this late stage, the metabolic acidosis reflected by the increased anion gap usually is a combined formate and lactate acidosis.¹⁸

Why the eye is the primary target organ for methanol's toxic effects is unknown.^{19,20} In the late stages, specific lesions of the basal ganglia may develop.^{9,21} It is not known why this structure is particularly vulnerable in late stages of methanol toxicity. Although the mechanism of these lesions is not known, it is reasonable to believe that the histotoxic effect of formate in late stages, causing a so-called hypoxic circle, is a contributing factor (Fig. 32A-2).

Formate inhibits the enzyme cytochrome oxidase in the mitochondrial electron transport chain by binding to the ferric iron in the heme moiety of that enzyme. This inhibition occurs in the 5- to 30-millimolar range,¹⁶ which correlates with formate concentrations found in symptomatic patients^{17,18} and other primates.^{22,23} This inhibition of mitochondrial energy metabolism increases the production of reactive oxidative molecules and thus the likelihood of oxidative injury.²⁴ Formate also causes depletion of glutathione, which is the major endogenous molecule protecting against oxidative stress in the retina.²⁵ Because the retina is exposed to several sources of oxidative stress by virtue of its high intrinsic metabolic rate and its exposure to ambient radiation, retinal glutathione concentrations are relatively high compared with other organs.²⁶ Glutathione synthesis depends on mitochondrial respiration.²⁷ Experimental studies indicate that cones may be more sensitive than rods to long-term damage from methanol poisoning, possibly because of their greater number of mitochondria.²⁵

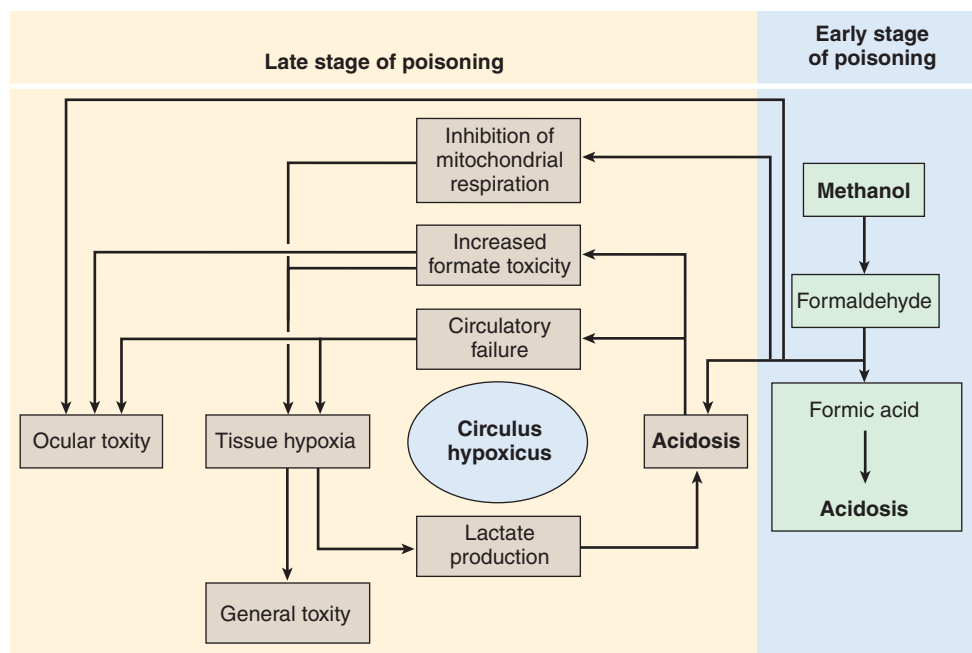

FIGURE 32A-2 Circulus hypoxicus; a proposed description of the toxic effects of methanol in humans. (Modified from Jacobsen D, McMartin KE: Methanol and ethylene glycol poisonings. Mechanism of toxicity, clinical course, diagnosis and treatment. *Med Toxicol* 1986;1[5]: 309-334.)

CLINICAL MANIFESTATIONS OF METHANOL INTOXICATION

Symptoms of methanol poisoning may be delayed for 12 to 24 hours, or even longer if ethanol is also ingested before, concomitantly, or just after methanol consumption. This characteristic latent period is thought to result from the slow metabolism of methanol to the principal toxic product, formic acid. In contrast to ethanol (or ethylene glycol), methanol does not cause significant central nervous system (CNS) depression and ethanol-like inebriation. Early clinical features are nausea, vomiting, and abdominal pain, but these are also seen in later stages.²⁸ A few cases may also present as acute abdomen, probably because of pancreatitis.^{9,29}

Clinical features of systemic toxicity are usually anorexia, headache, nausea, accompanied or followed by increasing hyperventilation as metabolic acidosis progresses.^{9,28} The first complaint may often be shortness of breath because of hyperventilation. Some patients may also have chest pain and may therefore be admitted acutely with the diagnosis of acute myocardial infarction. Visual symptoms (of all kinds, such as blind spots, blurred vision, or “snow fields”) may appear first, or with the symptoms above. Usually ocular symptoms precede objective signs, such as dilated pupils that are partially reactive or nonreactive to light and funduscopy showing optic disc hyperemia with blurring of the margins (pseudopapillitis).⁷

If treatment is not initiated at this early stage of poisoning, the patient may develop coma and respiratory and circulatory failure. Respiratory arrest is a dramatic complication associated with a mortality rate of 75%.²⁸ The toxic effect on the basal ganglia may not be evident in the acute stage because it is concealed by pronounced CNS depression. Survivors may later manifest a parkinsonian-like syndrome.^{7,9,21}

DIAGNOSIS

In the absence of an exposure history, methanol poisoning is difficult to diagnose, especially if ethanol is co-ingested and the latency period is prolonged. Therefore, methanol poisoning should be considered in every patient presenting with a metabolic acidosis of unknown origin.¹⁸ Methanol is usually determined by gas chromatography or radioimmunoassay techniques. Formate analyses are usually not available in the clinical setting, but a recent simple enzymatic method has proven to be both sensitive and specific and may therefore replace the need for more complicated gas chromatography.³⁰ Laboratory evaluation of suspected methanol poisoning should always include arterial blood gas analysis in addition to standard blood samples. If ethylene glycol poisoning is considered a differential diagnosis, urinalysis including microscopy should be performed in search of crystalluria (see Chapter 32B). The presence of crystals may suggest ethylene glycol, although their absence has no diagnostic value.

The standard physical examination should focus on vital signs (especially respiratory rate). Visual acuity and

funduscopy examinations should be performed. The objective signs of ocular toxicity of methanol include dilated pupils, which are partially reactive or nonreactive to light, and optic disc hyperemia with blurring of the disc margins (pseudopapillitis). The blurring of the disc margin may look like papillary edema, but there is no diopter difference between the fundus and the disc. Several days after the acute stage, this hyperemia turns into pallor, which is usually associated with blindness. A computed tomography scan or magnetic resonance scan of the brain may show necrosis of the putamen areas, a finding seen late in the course of methanol poisoning.^{9,21}

If the patient presents with a metabolic acidosis of unknown origin, especially if diabetic ketoacidosis and renal failure are ruled out, the anion and osmolal gaps should be calculated as a clue to the diagnosis. The accumulation of formate causes a metabolic acidosis with an increased anion gap.¹⁸ The “normal” range for the anion gap ($[Na^+ + K^+] - [Cl^- + HCO_3^-]$) in unselected acutely hospitalized patients is 12 ± 8 mmol/L (mean \pm 2 SD; reference range is then 4 to 20 mmol/L).³¹ In concentrations associated with toxicity, methanol also increases the serum osmolality, as do other alcohols. This effect can be demonstrated by calculating the difference between the measured osmolality (O_m) and the calculated osmolality (O_c):

$$\text{Osmolal gap (OG)} = O_c - O_m$$

The calculated osmolality is determined as follows:

$$\frac{1.86 \times Na + \text{glucose} + \text{urea}}{0.93}$$

where all concentrations are in mmol/L. To convert from SI units, divide glucose (mg/dL) by 18 and urea (BUN in mg/dL) by 2.8. Correct for co-ingested ethanol (mg/dL/4.6).

The reference range for the osmolal gap in unselected acutely admitted patients is 5 ± 14 mOsm/kg H₂O (mean \pm 2 SD).³¹ An osmolal gap above 19 (5 ± 2 SD) therefore indicates exogenous osmoles of some kind. Although the value of the osmolal gap has been questioned in recent years,³² as demonstrated by us in a recent epidemic, a decision level or cutoff value for the osmolal gap of 25 mOsm/kg H₂O works very well.¹⁸ Osmometry must be performed by the freezing point depression technique and not by the vapor pressure technique, because the latter does not detect the increased osmolality caused by volatile alcohols. The osmolal contribution from methanol and other alcohols is shown in Table 32A-1.

The relationships between the osmolal gap and methanol and between the anion gap and formate are presented in Figures 32A-3 and 32A-4. Note the good correlation for the patients studied. In the two patients with the highest anion gap (see Fig. 32A-4), there was a significant accumulation of lactate. Therefore, the increase of the anion gaps is slightly higher than the respective serum formate levels.

It must be noted that the magnitude of the increase in the osmolal and anion gap in methanol poisoning varies with time since ingestion, as illustrated in Figure 32A-5. In early stages, or if ethanol is co-ingested, only the osmolal gap is elevated, because the metabolism of methanol to

TABLE 32A-1 Molecular Mass of Alcohols and Their Contribution to the Osmolal Gap

ALCOHOL	MOLECULAR WEIGHT (DALTONS)	OSMOLAL CONTRIBUTION (mOsm/kg H ₂ O) per 100 mg/dL (*)	ANION GAP ELEVATED
Diethylene glycol	106	9	(+)
Ethanol	46	22	-

Isobutyl alcohol	74	14	-
Methanol	32	34	+
Propylene glycol	76	13	-

*A methanol concentration of 32 mmol/L (100 mg/dL) increases the osmolal gap by $32/0.93 = 34$ mOsm/kg H₂O. Divide by 0.93 because serum consists of 93% water.

**FIGURE 32A-3** S-methanol versus osmolal gap in 28 methanol-poisoned patients. Equation of correlation: $y = 1.03x + 12.71$, $R^2 = 0.94$. (From Hovda KE, Hunderi OH, Rudberg N, et al: Anion and osmolal gaps in the diagnosis of methanol poisoning: clinical study in 28 patients. Intensive Care Med 2004;30[9]:1842–1846.)

formate has not yet begun. In late stages of methanol poisoning, most of the methanol is metabolized to formate. At this stage the anion gap is elevated but the osmolal gap may be normal; formate detection may then be the only way to confirm the diagnosis.³⁰

If the diagnosis is based on the osmolal and anion gaps, it must be noted that elevated gaps also occur in ethylene glycol intoxication. Differentiating the two may be difficult, but the treatment is essentially the same. Hypocalcemia, seizures, and urine oxalate crystals indicate ethylene glycol poisoning; visual symptoms and/or optic

**FIGURE 32A-4** S-formate versus anion gap in eight methanol-poisoned patients. Equation of correlation: $y = 1.12x + 13.82$, $R^2 = 0.86$. (From Hovda KE, Hunderi OH, Rudberg N, et al: Anion and osmolal gaps in the diagnosis of methanol poisoning: clinical study in 28 patients. Intensive Care Med 2004;30[9]:1842–1846.)

disc hyperemia indicate methanol poisoning.²⁰ Differential diagnoses when both the gaps are elevated are few (Table 32A-2). A proposed algorithm for diagnosis and triage in suspected methanol poisoning is given in Figure 32A-6.

TREATMENT OF METHANOL INTOXICATION

General treatment measures include intensive supportive care and gastric decontamination. If the patient is seen soon (within 1 hour) after ingestion, which is rarely the case, gastric aspiration is recommended. Activated charcoal is probably of limited value because of limited binding.

Specific treatment of methanol poisoning includes intravenous (IV) sodium bicarbonate to combat the metabolic acidosis, antidotal therapy with ethanol or fomepizole to inhibit methanol metabolism to formate, and hemodialysis to remove methanol and formate and correct the metabolic acidosis. Folinic acid, 1 mg/kg IV up to 50 mg every 4 hours, may be of value in increasing the metabolism of formate.³³ If folinic acid is unavailable, folic acid, in the same dose, can be used.

Metabolic acidosis should be immediately and aggressively treated by infusing sodium bicarbonate,

aiming for a full correction of acidosis.³ As much as 400 to 600 mEq may be required during the first few hours. It is important to realize that bicarbonate treatment also decreases the amount of undissociated formic acid, resulting in less access of formate to the CNS, and thereby less toxicity.^{11,12,20} Hence, metabolic acidosis resulting from methanol poisoning, in contrast to most other causes of metabolic acidosis, should always be treated with bicarbonate.

Alkali treatment must be accompanied by administration of fomepizole or ethanol; otherwise, the acidosis becomes so-called bicarbonate resistant, because more formic acid will be produced from the metabolism of methanol. If a methanol level cannot readily be obtained and anion and osmolal gaps are difficult to interpret, ethanol or fomepizole therapy should be started in any patient with acidosis, symptoms, or a history of a potentially toxic alcohol ingestion. Antidotal treatment can be discontinued when the methanol level drops below about 6 mmol/L (20 mg/dL), provided that the acid-base status is normal and there are no complications.

The recommended therapeutic blood ethanol level is about 22 mmol/L (100 mg/dL). However, the amount of ethanol necessary to block methanol metabolism depends on the concomitant methanol level, because there is a dynamic competition for the enzyme alcohol dehydrogenase in the liver. If the blood methanol level is known, the molar ethanol concentrations should be at least one fourth of the molar methanol concentration.⁷

A blood ethanol level of 100 mg/dL may be achieved by giving a bolus dose of 600 mg/kg, followed by 66 to 154 mg/kg/hr IV or orally, with the higher maintenance dose for heavy drinkers. Mixing 50 mL of absolute ethanol with 450 mL isotonic glucose yields a 10% solution if a 10% ethanol solution for IV use is unavailable. With this solution, a bolus of 8 mL/kg (over 0.5 hour), followed by 1.5 mL/kg/hr, will produce the desired ethanol

TABLE 32A-2 Differential Diagnoses with Elevated Osmolal (>25) and/or Anion Gap (>20)

DIAGNOSIS	INCREASED OSMOLAL GAP	INCREASED ANION GAP
Methanol	Yes	Yes
Ethylene glycol	Yes	Yes
Isopropanol	Yes	No
Ethanol	Yes	No
Other alcohols	Yes	Rarely
Lactic acids	No	Yes
Ketoacidosis	Minimally	Yes
Acidosis in alcoholics	Minimally	Yes
Renal failure	No	Yes
Shock following trauma	Minimally	Yes

FIGURE 32A-6 “Hovdalgorithm” for diagnosis and triage in suspected methanol poisoning. (From Hovda KE, Hunderi OH, Rudberg N, et al: Anion and osmolal gaps in the diagnosis of methanol poisoning: clinical study in 28 patients. *Intensive Care Med* 2004;30[9]:1842–1846.)

concentration. The maintenance infusion should be increased or decreased according to frequently measured ethanol levels.

Monitoring the blood ethanol level is important, especially during hemodialysis, because this procedure also removes ethanol. As a rule of thumb, the maintenance dose of ethanol should be doubled during hemodialysis. If not, methanol metabolism can resume when the ethanol level drops, resulting in worsening toxicity despite hemodialysis.

Fomepizole (4-methylpyrazole; Antizol [Jazz Pharmaceuticals, Palo Alto, CA]) is commercially available from manufacturers in the United States and in Europe and has been approved for the treatment of methanol poisoning.^{9,14,34} While various dosing regimens have been proposed, we recommend a loading dose of fomepizole of 15 mg/kg IV, followed by doses of 10 mg/kg IV every 12 hours four times, thereafter 15 mg/kg every 12 hours. If hemodialysis is begun, fomepizole dosing frequency should be increased to every 4 hours. We generally recommend fomepizole over ethanol, like others.⁹ However, if diagnosis is uncertain (no serum methanol level available) and the osmolal gap is only a little elevated (less than 30 to 40 mOsm/kg H₂O), then ethanol may be preferable if no visual disturbances are present, because it is inexpensive.

Hemodialysis effectively removes methanol and formate and also counteracts metabolic acidosis.^{6,35} The only absolute indication for hemodialysis is visual impairment of any degree in a patient with metabolic acidosis or a detectable methanol level. Other indications usually mentioned are severe metabolic acidosis (particularly if unresponsive to bicarbonate and ethanol therapy), a blood methanol level above 15.6 mmol/L (50 mg/dL) (because of the very slow elimination of methanol during antidotal therapy), and ingestion of more than 1 g/kg of methanol. Following the approval of fomepizole for methanol poisoning, the situation has somewhat evolved. In most patients (i.e., those with no visual disturbances), dialysis is now only indicated to shorten the length of time on fomepizole treatment, since the methanol half-life is then 22 to 87 hours. In severe poisoning, however, with pronounced metabolic acidosis (base deficit greater than 20 mmol/L) and visual disturbances, in our opinion hemodialysis should be performed to remove formate and methanol.^{9,36} The role of dialysis in removing formate has been doubted,³⁷ but others have questioned the value of these data.³⁸

If hemodialysis is unavailable, the patient who needs it, or will probably need it, should be transferred to a facility with this capability. Alkali administration aimed at full correction of metabolic acidosis and antidotal therapy (preferably fomepizole, if available) should be given prior to transport.

There is no clear cutoff level for hemodialysis in methanol poisoning, because the presence of acidosis also must be considered. Hemodialysis is usually continued until the blood methanol level is below 6.3 mmol/L (20 mg/dL) and the acidosis is corrected. If methanol analyses are unavailable, hemodialysis should be continued for at least 8 hours or until the osmolal gap is normal in two samples 1 hour apart (possible osmolal

contribution from ethanol must be subtracted). This latter approach has been proven to save dialysis time and may be especially valuable in large outbreaks or in other circumstances where dialysis facilities are limited.³⁹ Serum formate concentration may also be used as a guide to hemodialysis.³³ Continuous venovenous hemodialysis and peritoneal dialysis may also remove methanol but not as effectively as hemodialysis.⁴⁰ Hemoperfusion is ineffective.

ADDENDUM

It should be emphasized that diagnosing and treatment of methanol poisoning is difficult. Because treatment is so effective but often is initiated too late, “time is vision” in this medical emergency. Consultation with a poison center or toxicologist is therefore strongly recommended if the physician is unfamiliar with the management of methanol poisoning. In addition, information on where to obtain methanol or formate levels may be provided.

The possibility of multiple victims should be considered when the source of methanol is unknown or is known to be contaminated ethanol. It should also be remembered that even if some patients are treated at a very late stage and brain circulation has stopped, the damage caused to the rest of the vital organs is often reversible upon standard supportive care. Organ donation has therefore often been performed in such patients.^{28,41}

B Ethylene Glycol

BRUNO MÉGARBANE, MD, PHD ■ STEPHEN W. BORRON, MD, MS ■ FRÉDÉRIC J. BAUD, MD

At a Glance...

- Ethylene glycol is a readily available and extremely toxic substance by ingestion.
- The hallmarks of intoxication are an increased osmolal gap early in the intoxication that steadily declines and an increased anion gap that increases as ethylene glycol is metabolized.
- When present, an increased osmolal gap should raise suspicion of ethylene glycol poisoning, but a normal osmolal gap does not rule out intoxication. Likewise, a normal anion gap early in the course of the poisoning does not rule out intoxication, as time is required for the formation of toxic acid metabolites.
- Ethylene glycol poisoning should be suspected in any case of altered mental status where the anion gap is increased. Laboratory interference may result in increased glycolic acid being reported as increased lactic acid, thus caution in interpretation is warranted.
- Fomepizole (4-methylpyrazole) is the antidote of choice for ethylene glycol poisoning. It should be administered without waiting for confirmation of poisoning.
- Ethanol can be administered orally or intravenously (IV) if fomepizole is not available, but blood concentrations must be carefully monitored, along with blood glucose and level of consciousness.
- Hemodialysis is often required, particularly in the case of significant acidosis and very high blood concentrations of ethylene glycol, and in the presence of renal insufficiency. Hemodialysis removes not only the toxic metabolites of ethylene glycol, but ethylene glycol itself, as well as the antidotes fomepizole and ethanol. Adjustments in antidotal dosing are required during dialysis.
- Consultation with a medical toxicologist is advised for defining ideal management.

Ethylene glycol poisoning is relatively uncommon, but still represents a significant threat in suicide or accidental poisonings, resulting in numerous deaths and serious sequelae. The American Association of Poison Control Center's Toxic Exposure Surveillance System reported 5081 exposures to ethylene glycol, with 16 deaths and 468 moderate and major outcomes in 2003.¹ Among these exposures, 71% occurred in adults older than 20 years, 16% in individuals 6 to 19 years, and 12% in children younger than 6 years. That 85% of exposures were unintentional (and presumably smaller) may explain the relatively low overall mortality. About 3% experienced life-threatening or significant symptoms or signs resulting in residual disability.

Ethylene glycol poisoning represents the most common poisoning among the toxic alcohols. Ethylene glycol (molecular weight 62.07 Daltons) is an odorless, colorless, volatile, slightly viscous, and sweet-tasting liquid, used in many chemical manufacturing processes (painting, plastics, safety explosives, synthetic fibers) (Table 32B-1). It is present in solvents and added to cosmetics and antifreeze solutions. Examples of uses include automobile antifreeze, hydraulic brake fluid (although diethylene and triethylene glycols are more commonly employed for this use), foam stabilizer, window cleaners, leather dyes, metal cleaners, degreasing agents, cellophane softening agent, printers' inks, stamp pad and ballpoint pen inks, synthetic waxes, and so on. Colorants, often fluorescent, are frequently added to automotive antifreeze products. Ethylene glycol is also used to de-ice airport runways and aircraft. Its evaporation rate is low (2.6 times smaller than ethanol), its boiling point is 197°C, and its pH is neutral. It is not miscible in hydrocarbons, but is easily miscible in water and low-molecular-weight aliphatic alcohols.

TOXICOKINETICS AND TOXICOLOGY

Ethylene glycol itself is nontoxic. Gastrointestinal absorption is rapid, with peak blood levels occurring

between 1 and 4 hours after ingestion. Percutaneous and pulmonary absorption is limited. No evidence of toxic accumulation was reported in volunteers, following inhalation exposures to concentrations up to 27 ppm for 4 weeks.² However, anecdotal skin irritation and iridocyclitis have been reported after accidental eye contact and cases of chronic poisoning with nystagmus and recurrent attacks of unconsciousness were described after exposure of factory workers to ethylene glycol vapors in 1950.³

The accepted lethal dose of ethylene glycol ingestion is 100 mL in a 70-kg adult, although methods used to determine it do not meet the usual scientific criteria. Moreover, death has been reported after ingestion of as little as 30 mL, while recovery with adequate medical intervention has occurred after ingestion of as much as 3000 mL.⁴ There are interspecies differences regarding preferential ethylene glycol metabolism to oxalate and relative susceptibility to poisonings. Humans, like monkeys, cats, and dogs, are highly susceptible, while rats, mice, guinea pigs, and rabbits are rather resistant.⁵

Following absorption, ethylene glycol is rapidly distributed throughout the body tissues, with a distribution volume of 0.5 to 0.8 L/kg.⁶ Ethylene glycol is successively oxidized by liver alcohol dehydrogenase (ADH) to glycolaldehyde and then by aldehyde dehydrogenase (AldDH) to glycolate (rapid step) and to glyoxylate (rate-limiting step) (Fig. 32B-1).⁷ Only a small part of glyoxylate is transformed into oxalate, which precipitates as calcium oxalate crystals in tissues and urine. Possible production of multiple other acids from glyoxalic acid have been described, including oxalomalic acid, γ -hydroxy- α -ketoglutaric acid, formic acid, glycine, benzoic acid, hypuric acid, and α -hydroxy- β -keto adipic acid; their respective roles in toxicity are controversial. Pyridoxine and thiamine are two cofactors in the metabolic pathways involving glyoxylate. However, they play only a small role in ethylene glycol detoxification. Liver metabolism is responsible for 80% of the absorbed dose of ethylene glycol. The remaining 20% undergoes glomerular filtration, passive tubular reabsorption, and urinary elimination. Ethylene glycol's renal clearance is about 27 mL/min, depending on renal function.⁸ There is limited elimination from the lungs due to ethylene glycol's high water solubility and low vapor pressure. The elimination half-life of ethylene glycol is about 3 hours, but markedly prolonged in the presence of an alcohol dehydrogenase competitor: 17 to 18 hours in the case of ethanol⁹ and 20 hours in the presence of fomepizole.¹⁰ Only 1% of the ingested dose appears as oxalic acid in urine. Ethylene glycol toxicokinetic parameters are given in the Table 32B-2.^{8,11-13}

Toxicity is related to the production of toxic metabolites. Accumulation in the blood of glycolate results in an anion gap metabolic acidosis. Glycolate accumulation correlates well with the anion gap and the decrease in serum bicarbonate concentration.¹⁴ On the other hand, glyoxylate and oxalate's contributions to the anion gap are limited.^{15,16} Two other factors, including lactate production and bicarbonate consumption, may

†Dependent on blood flow during hemodialysis.

account for worsening acidosis. Lactic acid is produced in response to nicotinamide-adenine dinucleotide (NAD) trapping that occurs during the breakdown of ethylene glycol and the by-products of glyoxalate metabolism, which inhibit the citric acid cycle and result in the conversion of pyruvate to lactate (see Fig. 32B-1). In addition, acidosis may be worsened by bicarbonate consumption due to glycine production, resulting from

glycolate (and to a lesser extent glyoxalate) recondensing under the activity of pyridoxal phosphate and glyoxalate transaminase enzymes.

Deposition of birefringent calcium oxalate crystals (see Fig. 32B-2) induces tissue destruction. Reversible oliguric or anuric acute renal failure is the primary injury due to oxalate crystal deposition in the proximal renal tubules,¹⁷ with evidence of interstitial nephritis, cortical focal hemorrhagic necrosis, and acute tubular necrosis.¹⁸ Damage is predominant in the proximal tubules, compared with distal ones, while glomeruli and basement membrane remain intact. A direct cytotoxic action of metabolites has also been proposed as a complementary mechanism of toxicity.¹⁹ This hypothesis is reinforced by the absence of correlation in pathologic findings between the extent of renal damage and the number of deposited crystals.²⁰ Although renal failure is usually reversible, persistent renal insufficiency has been reported. Initial central nervous system (CNS) depression is believed to be related to the glycol itself or the production of glycoaldehyde, whereas later in the course, persistent stupor or coma is probably the consequence of brain edema, hemorrhage, or metabolic encephalopathy.²¹ Hypocalcemia, for which the hypothesized mechanism is calcium chelation by oxalate, may contribute to the development of seizures, dysrhythmias, and negative inotropic effects. In fulminant forms, patients experience coma with seizure

activity, respiratory failure, cardiovascular collapse, pulmonary edema, and adult respiratory distress syndrome. Death may follow multiorgan failure. In these cases, autopsy reveals diffuse hemorrhage, inflammatory infiltration, and edema, in addition to the deposition of calcium oxalate crystals in kidneys, brain, pleura, lungs, pericardium, heart, pancreas, and spleen.²²

CLINICAL PRESENTATION

Presentation of ethylene glycol–poisoned patients is polymorphous, depending on the delay since ingestion, the ingested dose, the co-ingestion of ethanol, and the timing of medical intervention (Table 32B-3).²³ Early after ingestion, patients are usually asymptomatic or present only with hyperventilation due to metabolic acidosis (Kussmaul's respiration). In these patients, underestimation of poisoning severity may occur. In stark contrast, late presentation is responsible for life-threatening signs and symptoms, including coma, seizures, respiratory distress, and renal failure.²⁴ Ethylene glycol toxicity occurs in three classical theoretical stages, although the onset and progression of this condition are not always straightforward or predictable.^{25,26}

The first phase (called neurologic) occurs within 30 minutes to 12 hours after ingestion. Patients appear inebriated and euphoric, but without the characteristic alcohol smell. Nausea, vomiting, and hematemesis are possible, reflecting ethylene glycol gastrointestinal direct irritation. It is not uncommon, however, to observe an

initial latent period, reflecting the time required for the toxic metabolites to accumulate. Rapidly, the most severely intoxicated patients may develop coma, myoclonic seizures, nystagmus, ataxia, ocular external muscle paralysis, CNS depression, and meningismus. Loss of light reflexes and papilledema have been reported but are more frequent in relation to methanol poisoning. Sustained hypocalcemia is responsible for muscle spasms and hyperreflexia. Cranial computed tomography scans are usually normal, despite the neurologic symptoms. However, various radiologic abnormalities have been reported, including diffuse cerebral edema, intraparenchymal hemorrhage or petechiae, and reversible hypodense areas localized in various brain, brainstem, and cerebellum territories.

The second phase (called cardiopulmonary) starts between 12 and 24 hours after the ingestion. Patients present with tachycardia, mild hypertension, pulmonary edema, adult respiratory distress syndrome, and congestive heart failure. These presentations are believed to be due to calcium oxalate crystal deposition within the vascular tree, the myocardium, and the lung parenchyma. Hypoxia may be related to aspiration pneumonia or CNS depression. Dysrhythmias with QTc interval prolongation may be the consequence of profound hypocalcemia.

The third phase (called renal) begins between 24 and 72 hours after the ingestion. Patients present with flank pain and tenderness, oliguria, and acute renal failure. Bone marrow suppression has been reported, but hepatic damage is usually minimal. Calcium oxalate or hippurate crystals are present in the urine.

Delayed symptoms are possible in the most severe cases: persistent renal insufficiency requiring prolonged hemodialysis, as well as delayed cranial nerve deficits (5 to 20 days after ingestion)^{27,28} involving cranial nerves II, V, VII, VIII, IX, X, and XII that are related to calcium oxalate crystal deposition–associated local infiltration, which may be observed on magnetic resonance imaging. All these injuries slowly resolve, but last as long as several months, particularly after severe encephalopathy or profound acidemia with reported arterial pH as low as 6.46.^{29,30} Ultimately, recovery of renal function is usually complete. However, exceptional cases requiring chronic hemodialysis or renal transplantation have been reported.

LABORATORY DIAGNOSIS OF ETHYLENE GLYCOL POISONING

Ethylene glycol poisoning should be strongly suspected in patients exposed to presumed ethylene glycol–containing products, patients inebriated without the smell of alcohol, patients presenting with metabolic acidosis and elevated anion gap unexplained by an increased plasma lactate concentration, and finally, patients presenting with acute renal failure or multiorgan failure of unexplained origin.³¹ Caution is advised in interpreting plasma lactate values, as glycolate has been shown to cause interference in laboratory analysis of lactate.^{32,33} The evolving laboratory profile reflects ethylene glycol metabolism, organic acid

TABLE 32B-3 Ethylene Glycol Poisoning

MAJOR SYMPTOMS AND SIGNS	LABORATORY FINDINGS
Early	
Inebriation, drowsiness Coma, ataxia, CNS depression	Elevated osmolal gap Detectable ethylene glycol
Vomiting, nausea	
Delayed	
Dyspnea, hyperventilation, tachypnea Kussmaul's respiration	Acidosis with elevated anion gap Detectable ethylene glycol and metabolites
Coma, seizure, cerebral edema	Elevation of serum creatinine
Tetany, muscle paralysis, myoclonus	Elevation of blood urea nitrogen
Tachycardia, hypertension, dysrhythmias, myocarditis	Hypocalcemia
Acute renal failure	Elevation of creatine phosphokinase
Respiratory distress, noncardiogenic pulmonary edema	Hematuria, proteinuria, leukocyturia
Multiorgan failure	Calcium oxalate crystals in urine
Very Delayed (rare)	
Persistent renal insufficiency Cranial nerves deficiencies (including bilateral facial paralysis and ophthalmoplegia)	

accumulation, and medical intervention timing. The combination of an osmolal gap and an anion gap is strongly suggestive of ethylene glycol poisoning, but is not specific.⁷ At a given time after ingestion, the concentrations of remaining ethylene glycol and the accumulated acid metabolites affect the magnitude of the osmolal and anion gap, respectively.

Osmolal gap is the difference between the measured osmolality (by the freezing point depression method) and the calculated one, based on sodium, blood urea nitrogen (BUN), and glucose concentrations: $(1.86 [\text{Na}^+] + [\text{BUN}] + [\text{glucose}]) / 0.93$, in SI units. If values are reported in mg/dL, the BUN should be divided by 2.8 and the blood glucose by 18. Note that vapor pressure methods may underestimate the contribution of volatile alcohols like ethylene glycol. An elevated osmolal gap (normal values 10 to 15 mOsm/kg H₂O) corresponds to the presence of ethylene glycol in blood, with an increase of 2 mOsm/kg H₂O for every 0.1 g/L (1.6 mmol/L) of ethylene glycol. Other alcohols and ketones may of course contribute to the osmolal gap (Table 32B-4). Normal osmolal gap may be encountered very early (before significant absorption) or very late in the course of poisoning, when ethylene glycol is completely metabolized.³⁴ Contribution of metabolites to the osmolal gap is reduced, explaining its transient elevation due to ethylene glycol's short half-life. However, persistent high osmolal gap with low ethylene glycol level has been reported and attributed to plasma glycolate.³⁵ A normal osmolal gap does not rule out poisoning.

Anion gap (normal values 12 to 16 mmol/L) is the difference between measured cations and anions in plasma and is calculated as follows: $([\text{Na}^+] + [\text{K}^+]) - ([\text{HCO}_3^-] + [\text{Cl}^-])$. Significant acidosis is produced with the production of ethylene glycol metabolites. Glycolic acid, which accounts for approximately 96% of the anion gap, significantly correlates with the decline in serum bicarbonate concentration and the elevation in anion gap.^{7,35} Other toxicants, including methanol-derived formate, may be responsible for increased anion gap. Differential diagnoses exist, with endogenous organic acid accounting for the anion gap: diabetic, alcoholic, or starvation-related ketoacidosis (with accumulation of acetone, acetoacetate, and β -hydroxybutyrate), circulatory hepatic failure (with elevation of lactate), renal failure (with accumulation of phosphates, sulfates, and nitrogen acid compounds), and critical illness.²³ Thus, specificity

of the diagnosis value of anion gap is increased in the absence of hypotension, diabetes, seizures, and alcoholism. Consistently, ethanol co-ingestion delays the appearance of anion gap, also reducing the symptoms of intoxication. Simultaneous ingestion of bromide (not distinguished from chloride on electrolyte analysis) may also mask the anion gap.³⁶

Other laboratory features of ethylene glycol poisoning include elevation of serum creatinine and BUN concentrations, rhabdomyolysis (elevation of serum creatine phosphokinase concentration), hypocalcemia, hyperkalemia (in the case of acute renal failure), and nonspecific leukocytosis (see Table 32B-3). If lumbar tap is performed, high cerebrospinal fluid protein, neutrophils or monocytes, red blood cells, or xanthochromia may be observed. The presence of either monohydrate (whewellite) or dihydrate (weddelite) calcium oxalate crystals in the urine is characteristic of ethylene glycol renal injury (Fig. 32B-2). These crystals appear 4 to 8 hours after ingestion and may persist for up to 10 days in the presence of renal failure. Identification of the nature of these crystals requires polarized light microscopy and repeated urinalysis. Crystals are birefringent, variegated and pleomorphic, octahedral, or tent shaped for dihydrate forms, and they are prism or needle shaped for monohydrate forms. Other forms of calcium oxalate include dumbbell, ovoid, and elliptical crystals. Other clinical settings may include calcium oxalate crystals, like primary hyperoxaluria, or oxalate-rich dietary excess foods. However, detection of calcium oxalate crystalluria, particularly the monohydrate forms, supports the diagnosis of ethylene glycol poisoning.³¹ In addition to crystals, microscopic hematuria, proteinuria, leukocyturia, and urine with low specific gravity may be observed. The absence of crystals does not exclude the diagnosis of ethylene glycol exposure.

Definitive diagnosis is assessed by the measurement of plasma ethylene glycol concentration. Early after ingestion, the plasma ethylene glycol concentration is elevated in relation to the ingested amount. On the other hand, late in the course, low plasma ethylene glycol concentrations are observed, contrasting with the severity of the clinical presentation. In fact, severity of poisoning better correlates with reduced bicarbonate level, elevated anion gap, and elevated glycolic acid than with serum ethylene glycol concentration. The method of choice for measuring ethylene glycol concentration is gas chromatography with flame ionization detection.³¹ Commonly, ethylene glycol is analyzed as the boronic ester derivative by using packed or capillary columns. Underivatized ethylene glycol is difficult to analyze due to the poor detection limit of flame ionization detectors. However, direct injection of ethylene glycol on a wide-bore capillary column has been described, with the advantage of eliminating the derivatization step and extending the analytical life of the column. Thus, in practice, separate dedicated columns are preferred, rendering this technique reserved for specialized laboratories of toxicology. Propanediol and butanediol are used as appropriate internal standards. Consequently, some IV medication solvents containing propylene glycol (diazepam, phenytoin) may produce false-positive

TABLE 32B-4 Molecular Weight and Contribution of Various Alcohols and Ketones to the Osmolal Gap

NAME OF THE COMPOUND	MOLECULAR WEIGHT (DALTONS)	OSMOLAL GAP (mOsm/kg H ₂ O) AT 1 g/L CONCENTRATION

results. Confirmation by mass spectrometry is thus required, especially in ketotic patients.³⁷ Enzymatic screening assays based on ethylene glycol oxidation using *Enterobacter aerogenes* glycerol dehydrogenase have been described.³⁸ The produced NADH is measured by spectrophotometer. Cross-reactions are possible with glycerol and glycoaldehyde, the short half-lives of which make them unlikely to interfere with the assay. However, their use in critically ill patients may be limited due to several glycerol-containing IV medications. Consistently reliable screening tests can eliminate ethylene glycol as a cause of increased anion gap metabolic acidosis in a comatose patient, preventing the patient from receiving invasive and inappropriate treatments.

POISONING MANAGEMENT

Recommended management of ethylene glycol poisonings includes (1) supportive care; (2) infusion of sodium bicarbonate to correct metabolic acidosis, to increase renal elimination of glycolate, and to inhibit precipitation of calcium oxalate crystals; (3) antidotes, such as a competitive ADH substrate (ethanol) or inhibitor (fomepizole) to block ADH metabolism of the toxic alcohol; and (4) intermittent dialysis to remove the toxic alcohol and its toxic metabolites.^{7,23}

Usual supportive treatments include correction of life-threatening signs, dehydration, acid-base, and fluid imbalances. Particular attention should be directed to adapt fluid load to diuresis in the case of acute renal failure. Treatment of seizures is standard: benzodiazepines (diazepam or lorazepam), phenobarbital, and (perhaps) phenytoin. Gastric lavage is useful only within the first hour after ingestion because of the very rapid

gastrointestinal absorption of ethylene glycol. Activated charcoal is not useful because ethylene glycol is not adsorbed. Hemoperfusion is not recommended because of column saturation and the absence of correction of acid-base disturbances. Hypocalcemia should be corrected with IV calcium only in case of symptoms related to low levels of calcium (tetany, muscle paralysis, or seizures). Two cofactors of ethylene glycol metabolism may be administered: pyridoxine (500 mg IV every 6 hours over 2 days) to stimulate glyoxalate to glycine metabolism and thiamine (100 mg IV every 6 hours over 2 days) to enhance transformation of glyoxalate to α -OH- β -keto adipate.

ANTIDOTES

Fomepizole

Fomepizole (4-methylpyrazole, 4MP) [Antizol, Orphan Medical, Minnetonka, MN, in the United States, and Fomepizole, Opi & Isotec, France, in Europe) is a potent inhibitor of ADH, with limited toxicity in animals and humans, that prevents the metabolism of ethylene glycol or methanol into their toxic metabolites. Fomepizole was approved by the U.S. Food and Drug Administration in 1997 for the treatment of ethylene glycol poisoning. It has been successfully used in France since 1981 in several cases of ethylene glycol poisoning.³⁹⁻⁴¹ No lethality or significant morbidity occurred if patients were treated before significant toxic metabolism of ethylene glycol had occurred, and all such patients recovered from their poisoning. A recent multicenter prospective clinical trial performed in the United States confirmed the efficacy of fomepizole in the treatment of ethylene glycol intoxication.¹⁰ There was clinical improvement

with rapid resolution of acidosis and an absence of any new symptoms of poisoning after the initiation of therapy. Renal injury was prevented if fomepizole was administered early in the course of ethylene glycol intoxication. Treatment with fomepizole resulted in alteration of the toxicokinetics of ethylene glycol, with a prolongation of its first-order elimination (to 19.7 ± 1.3 hours) and a reduction in glycolate formation.¹⁰

Fomepizole pharmacokinetics have been largely studied. Although mostly used by the IV route, fomepizole is rapidly and almost completely absorbed orally. In fact, the three initial cases of ethylene glycol poisoning were treated with fomepizole by the oral route.⁴⁰ Thereafter, 4 of 11 cases of ethylene poisonings in the series reported by Borron and colleagues received this antidote orally.⁴¹ When intravenously administered, fomepizole is typically infused in 100 mL of 0.9% sodium chloride or 5% dextrose over 30 minutes. Fomepizole's volume of distribution has been reported to be in the range of 0.6 to 1.0 L/kg. Its plasma protein binding is low. Fomepizole has three metabolites: 4-hydroxymethylpyrazole, the only active metabolite with approximately one third of the potency of the parent compound, 4-carboxypyrazole, and a glucuronide metabolite.⁴² Fomepizole is virtually entirely eliminated by saturable hepatic metabolism, with a Michaelis constant (K_m) of 6 $\mu\text{mol/L}$, a concentration always markedly exceeded during therapeutic use.⁴³ Fomepizole is a competitive inhibitor of ADH with an *in vitro* inhibitory constant for human ADH of 0.2 $\mu\text{mol/L}$.⁴⁴ Its affinity for ADH is 500- to 8000-fold greater than that of ethanol. A plasma concentration of 10 $\mu\text{mol/L}$ was shown in experimental studies to be sufficient to inhibit formate accumulation in the methanol-poisoned monkey.⁴² Thus, this plasma concentration of fomepizole was considered to be sufficient in prospective human trials of this antidote. In the Methylpyrazole for Toxic Alcohols (META) studies in the United States, complete inhibition was reached in each reported case.¹⁰ Plasma fomepizole concentrations using the prescribed dosing regimen exceeded the target concentration of 10 $\mu\text{mol/L}$. At therapeutic concentrations, elimination is characterized by dose-dependent, nonlinear, zero-order kinetics, with a rate of 4 to 15 mmol/L/hr.^{43,45}

While fomepizole blocks ADH activity, repeated doses induce cytochrome P-450, and particularly cytochrome P-450 2E1, resulting in an increase in its own elimination rate. Initial studies with human volunteers demonstrated that fomepizole has the ability to induce its own metabolism after 48 hours of treatment.⁴³ Thus, an increase of up to 15 mg/kg in patients treated over 48 hours is currently recommended by North American authors and was incorporated into practice guidelines developed by the American Academy of Clinical Toxicology to account for its enhanced metabolism.²³ This dosing protocol has been validated in the U.S. META study.¹⁰ However, it is noteworthy that fomepizole is expensive and a dosage regimen using the minimal effective cumulative dose remains to be determined. The French dosing regimen consists of a loading dose of 15 mg/kg followed by 10 mg/kg every 12 hours until the

alcohol concentration is <0.2 g/L (3.2 mmol/L) or becomes undetectable. Borron and colleagues reported a series of ethylene glycol poisonings treated with tapering doses of fomepizole.⁴¹ In the French experience, no failure was noted in any patient who was treated without a dose increase, except in one case. In this severely poisoned patient (initial ethylene glycol concentration 4.2 g/L [67.6 mmol/L], peaking at 6.4 g/L [101.9 mmol/L] 4 hours later), anion gap decreased following the administration of a 6.4 mg/kg loading dose of fomepizole.⁴⁶ However, the beneficial effect was reported to be transient and dose dependent, requiring further maintenance doses of 11.3, 4.8, and 2.4 mg/kg, and the patient ultimately recovered without sequelae. This early treatment failure was likely due to an inadequate initial dose rather than failure to up-regulate the dose for induced fomepizole metabolism. Based on this clinical experience, a different dosage regimen is recommended in Europe (Table 32B-5).

During concomitant hemodialysis, fomepizole is extracted with a mean extraction coefficient of $49.6 \pm 42.5\%$, a mean hemodialysis clearance of 99 ± 33 mL/min, and a mean hourly extracorporeal extraction of $83 \pm 31\%$.^{47,48} Although not systematically validated, two different schemes were proposed to compensate for fomepizole loss in the dialysate. The U.S. manufacturer recommends a reduction in the dosing interval from 12 to 4 hours, while European researchers have proposed a continuous IV infusion of 1 to 1.5 mg/kg/hr for the entire duration of the hemodialysis session following the initial loading dose.^{47,48} Since the duration of hemodialysis depends on the initial plasma ethylene glycol concentration to be lowered below the toxic range, the continuous infusion protocol appears better adapted, rather than a shortening of the dosing interval. Moreover, this regimen appears simpler and sufficient to maintain fomepizole at or above the minimally effective concentrations (greater than 10 $\mu\text{mol/L}$). However, the dosage of fomepizole during continuous venovenous hemodiafiltration or continuous arteriovenous hemodialysis and the pharmacokinetics in patients with liver disease or liver failure are not known.

In patients with normal renal function throughout the course of the poisoning, the renal clearance of ethylene glycol is consistently reported to be about 20 mL/min (see Table 32B-2).²³ In relation to ADH blockade, fomepizole administration results in first-order elimination of ethylene glycol with a prolonged half-life to 20 hours.^{10,49} Thus, the antidotal regimen (dose and duration) blocks the metabolism of the toxic alcohol, resulting in its retention in the body for a longer time.

The usual contraindications of fomepizole administration are previously known allergy to pyrazole derivatives (such as phenylbutazone) and pregnancy, due to the lack of data on safety in these cases. The randomized, placebo-controlled, double-blinded studies in human volunteers⁴⁸ as well as the various clinical trials in poisoned patients¹⁰ indicated that fomepizole is well tolerated at doses used therapeutically, although headaches (12%), nausea (11%), dizziness (7%), and irritation at the injection site were reported. Other

adverse reactions included rash, lymphangitis, vomiting, diarrhea, abdominal pain, tachycardia, hypotension, vertigo, slurred speech, inebriation, fever, mild transient eosinophilia, and slight increases in hepatic transaminases. None required the discontinuation of therapy. Drug interactions are possible with the ones modifying cytochrome P-450 activity, such as phenytoin, carbamazepine, cimetidine, or ketoconazole. Reciprocal metabolic interaction also exists between ethanol and fomepizole. In rats, the concurrent administration of ethanol with a 1 mmol/kg dose of fomepizole markedly increased the duration of fomepizole elimination.⁵¹ The concomitant acute administration of ethanol decreased by about 50% the concentration of 4-hydroxymethylpyrazole. Similarly, in rats chronically fed diets containing fomepizole and/or ethanol, plasma fomepizole levels were higher with concomitant ethanol administration, suggesting that ethanol delays fomepizole metabolism. In human volunteers, using double-blind crossover designs, therapeutic doses of fomepizole (10 to 20 mg/kg) caused a 40% reduction in the rate of elimination of ethanol (0.5 to 0.7 g/kg). Ethanol was demonstrated to inhibit fomepizole metabolism, consequently increasing its blood concentrations.⁴³ Thus, the previous intake or administration of ethanol before fomepizole therapy does not decrease the efficiency of the antidotal therapy. However, the clinical relevance of the effect of fomepizole on ethanol elimination remains to be determined. Although not formally studied in children, there have been several pediatric cases reported where the drug appears to be efficacious and without severe side effects,⁵²⁻⁵⁴ other than nystagmus.⁵⁵

However, unlike ethanol, therapeutic concentrations are reliably achieved with the proposed dosing regimens, and no severe central nervous system or significant liver toxicity or hypoglycemia occurred in fomepizole-treated patients. To reduce ethanol therapy side effects, appropriate monitoring and IV glucose intake in a controlled environment such as an intensive care unit (ICU) are necessary. Monitoring of therapeutic conc-

entrations of fomepizole does not appear to be necessary in patients with normal hepatic function. Therefore, considering its demonstrated clinical efficacy and safety, fomepizole should be recommended as a first-line antidotal treatment in poisoned patients. In the case of exposure to a toxic alcohol or diagnosis of a metabolic acidosis with elevated anion gap unexplained by a concomitant increase in serum lactate concentration, a loading dose of fomepizole should be administered while awaiting measurement of the toxic alcohol concentrations, which will permit a definitive diagnosis. Indications to begin empiric treatment for ethylene glycol poisoning are summarized in Box 32B-1.

Ethanol

Ethyl alcohol is an ADH competitive substrate blocking ethylene glycol liver metabolism when plasma ethanol

BOX 32B-1 INDICATIONS TO START EMPIRIC TREATMENT FOR ETHYLENE GLYCOL POISONING, PREFERRING FOMEPIZOLE ADMINISTRATION (LOADING DOSE: 15 mg/kg) IF AVAILABLE

History of ethylene glycol ingestion (accidental, suicidal, criminal or as alcohol substitute)
Intoxication associating decreased level of consciousness, ataxia, slurred speech, and/or focal neurologic examination in an inebriated patient without the odor of ethanol or with the absence of ethanol in blood
Unexplained metabolic acidosis, with anion gap (> 16mmol/L) and/or osmolar gap (> 15mOsmol/kg)
Calcium oxalate crystals in urine or urine that fluoresces under the Wood's lamp
Ethylene glycol concentration > 0.2 g/L

From Barceloux DG, Krenzelok EO, Olson K, Watson W: American Academy of Clinical Toxicology practice guidelines on the treatment of ethylene glycol poisoning. *J Toxicol Clin Toxicol* 1999;37:537–560.

levels of 1 to 1.5 g/L are maintained. ADH is 50% inhibited for an ethanol concentration of 0.02 g/L and more than 90% for 0.5 g/L. However, ethylene glycol concentrations of greater than or equal to 3.26 g/L (5.26 mmol/L) are required to saturate the enzyme by 50%.⁵⁶ Ethanol may be administered orally or given as an IV infusion of 10% ethanol diluted in 5% dextrose. The IV route is possible in comatose patients and does not induce gastrointestinal upset. The oral route has the advantage of being simple and rapid, with various forms and concentrations readily available. However, first-pass liver metabolism reduces ethanol bioavailability. Thus, in chronic alcoholics or in case of hepatic enzyme induction, higher doses of ethanol may be required than in abstinent patients.

During ethanol administration, ethylene glycol's elimination half-life is prolonged to 17 hours but is only 2.5 hours in association with hemodialysis. The recommended ethanol regimen in ethylene glycol poisoning management is a loading dose of 0.6 to 0.7 g/kg of 50% ethanol, followed by a maintenance dose of 110 mg/kg/hr of 20% ethanol, or greater, if large amounts of ethylene glycol were ingested. The ethanol should be diluted to 10% if given IV (Table 32B-6). This median dose may vary between 66 mg/kg/hr (for nondrinkers) to 154 mg/kg/hr (for alcoholics). Ethanol therapy should be continued until plasma ethylene glycol concentration is less than 0.2 g/L or undetectable.²³ Plasma ethanol concentrations should be closely monitored, every 1 to 2 hours. During hemodialysis, ethanol should be administered at a rate of 230 mg/kg/hr to maintain blood ethanol levels between 1.0 and 1.5 g/L. Ninety-five percent ethanol can be added to the dialysate bath to reach concentrations of 1.0 g/L, allowing easier ethanol blood level stabilization.⁵⁷ Adverse effects are numerous, limiting indications of ethanol to centers where fomepizole is unavailable: inebriation, obtundation, CNS depression (with the risk of need for intubation), pancreatitis, hypoglycemia in

children, and local phlebitis requiring infusions by central venous access. That said, a recent study demonstrated a low rate of clinically important adverse effects related to ethanol used as an antidote to treat methanol poisoning in children.⁵⁸ Despite wide variation in ethanol levels, but with appropriate monitoring and IV glucose intake in a controlled environment such as a pediatric intensive care unit, ethanol therapy does not carry as many risks as generally believed.

HEMODIALYSIS

Hemodialysis is considered to be an integral part of the treatment of patients receiving ethanol or fomepizole therapy to expedite removal of the alcohol and thus reduce the duration of antidote treatment. Hemodialysis clearance of toxicant depends on molecular size, charge, distribution, and protein- or lipid-binding status. Ethylene glycol is efficiently cleared by dialysis (see Table 32B-2). The traditional end-point of dialysis is a plasma concentration of less than 0.2 g/L or undetectable, with disappearance of acid-base imbalance and correction of the anion and osmolar gap.²³ More recently, a simple method to estimate the required dialysis time was validated in 13 ethylene glycol- and 5 methanol-poisoned patients.^{59,60} The required dialysis time (RDT) to reach a 5 mmol/L toxin concentration target was obtained by the following formula: $RDT (h) = [-V \cdot \ln (5/A)] / 0.06k$, where V (L) is Watson's estimate of total body water, A is the initial toxin concentration in mmol/L, and k (mL/min) is 80% of the manufacturer-specified dialyzer urea clearance. In these studies, there was no difference between the predicted hemodialysis duration and that actually carried out based on hourly concentration sampling.

Hemodialysis has usually been recommended in cases of confirmed ethylene glycol poisoning, severe or refractory metabolic acidosis, and deteriorating vital signs, and in the onset of acute renal failure (Box 32B-2). A serum ethylene glycol concentration above 50 mg/dL was a well-recognized indication, even though not all investigators agree.⁶¹ In the U.S. META study, 17 of 19 ethylene glycol-poisoned patients treated with fomepizole were hemodialyzed.¹⁰ Among them, 18 survived, whereas only 1 died secondary to a myocardial infarction. All the patients in whom renal injury developed (9 of

TABLE 32B-6 Therapeutic Doses of Ethanol in Ethylene Glycol Poisoning, According to the Patient Status and Equivalence Between the Different Ethanol Presentations

	ABSOLUTE ETHANOL	VOLUME (43% ORAL SOLUTION)	VOLUME (10% IV SOLUTION)

BOX 32B-2 REVISED RECOMMENDATIONS FOR HEMODIALYSIS IN ETHYLENE GLYCOL

Arterial pH < 7.10
 Drop in arterial pH > 0.05 resulting in a pH outside the normal range despite bicarbonate infusion
 Inability to maintain arterial pH > 7.3 despite bicarbonate therapy
 Decrease in bicarbonate concentration > 5 mmol/L despite bicarbonate therapy
 Rise in serum creatinine by > 90 mmol/L
 Recently released: Initial plasma ethylene glycol concentration ≥ 50 mg/dL

Data from references 23 and 61.

19, 46%), had a plasma glycolate concentration on admission of greater than 98 mg/dL. Renal elimination and hemodialysis are the only significant routes of ethylene glycol elimination, as long as fomepizole concentrations are maintained well above 10 $\mu\text{mol/L}$.⁴⁹ Hemodialysis effectively clears glycolate, with an elimination rate of $170 \pm 23 \text{ mmol/L/min}$ and a half-time of $155 \pm 474 \text{ minutes}$, compared with the spontaneous elimination rate of $1.8 \pm 0.67 \text{ mL/L/min}$ and half-time of $625 \pm 474 \text{ min}$.¹⁶

In a retrospective study, Borron and colleagues demonstrated the lack of requirement of systematic dialysis in the management of ethylene glycol poisoning treated with fomepizole.⁴¹ Among 38 patients treated for suspicion of ethylene glycol exposure, 11 patients had ethylene glycol concentrations of greater than 0.2 g/L. Among these, 21% presented in coma, 34% in metabolic acidosis, and 11% with an initial plasma creatinine of greater than 110 $\mu\text{mol/L}$ (1.2 mg/dL). Hemodialysis was performed in only 3 of these 11 patients, 2 with renal insufficiency and acidosis and 1 with a very high ethylene glycol concentration (134 mmol/L, or 837.5 mg/dL), but with normal renal function. Among the 7 patients with normal renal function treated with fomepizole, no subsequent deterioration was noted. Among all the 38 patients, only 1 died within a few hours after his admission, with severe multiorgan failure, whose onset started before fomepizole administration. Patients who were dialyzed were significantly more acidotic (arterial pH 7.11 vs. 7.31) than those who were not. Patients treated with fomepizole prior to the onset of significant acidosis did not require hemodialysis. Since this study, new insights have been developed with regard to hemodialysis criteria. An absolute concentration above 0.5 g/dL is no longer considered to be an independent criterion for hemodialysis in patients treated with fomepizole.⁴⁹ The use of hemodialysis should be based on the presence of renal insufficiency or severe metabolic acidosis rather than unsupported criteria of serum concentrations greater than 0.5 g/L alone.⁶² The recommended criteria are now the existence of a significant metabolic acidosis (pH < 7.25), renal failure, or electrolyte imbalances unresponsive to conventional therapy and deteriorating vital signs despite intensive supportive care.²³ Before fomepizole availability, repeated hemodialysis had been recommended in case of redistribution of ethylene glycol within 12 hours after its cessation.⁶³ Initial serum glycolic acid concentration appears to be a good indicator for hemodialysis. However, it is not readily available in the majority of hospitals. An initial glycolic acid level higher than 10 mmol/L predicts acute renal failure, with a sensitivity of 100%, a specificity of 94%, and an efficiency of 98%.⁶⁴ In a retrospective study including 41 ethylene glycol-poisoned patients, these researchers demonstrated that a glycolic acid concentration higher than 8 mmol/L is a criterion for the initiation of hemodialysis. On the contrary, ethylene glycol concentration was not predictive of acute renal failure or central nervous system toxicity, while an anion gap of greater than 20 mmol/L or pH of less than 7.30 predicts acute renal failure. There was no need to dialyze, regardless of ethylene glycol level, if the glycolic

acid level was less than or equal to 8 mmol/L in patients receiving antidotal treatment.⁶⁴

CRITICAL ANALYSIS OF ETHYLENE GLYCOL TREATMENT

Although ethanol and hemodialysis constituted the recommended therapy for many years, it is unlikely that applying principles of evidence-based medicine would justify such recommendations now, given the significant experience with fomepizole and dialysis.⁶² While it would have been desirable in the U.S. prospective trial¹⁰ to have a comparison group with the standard of practice (ethanol plus hemodialysis), this was not done for a variety of reasons. Nonetheless, until demonstration that ethanol therapy results in equivalent efficacy and outcomes, it is difficult not to recommend fomepizole. To date, there has been no randomized comparative study regarding efficacy and cost effectiveness among hemodialysis + ethanol versus hemodialysis + fomepizole or fomepizole alone. There are frequent references to the minimal cost of parenteral ethanol in comparison with the relatively high cost of fomepizole. Such comparisons generally ignore the critical issue of laboratory costs for monitoring serum ethanol and blood glucose, the increased nursing care required for patients maintained in a state of ethanol intoxication, and the requirement for intensive care (which may not be necessary in patients receiving fomepizole in the absence of extant toxicity). Considering the high cost of fomepizole (about \$1000 per gram), smaller hospital centers that only occasionally see ethylene glycol poisoning might prefer to continue to stock inexpensive and readily available parenteral ethanol rather than fomepizole.⁶⁵ However, it should be kept in mind that the suggested shelf life of fomepizole is 3 years and that, in some cases, the manufacturer will replace it at no charge after this period, rendering it economical even for smaller emergency departments to have this antidote in their armamentarium.

Why is it worthwhile to confirm that fomepizole may obviate hemodialysis under certain conditions? First, there is a significant downside to the use of hemodialysis: it is not universally available, rendering it difficult to obtain in case of epidemic poisonings. It represents an invasive technique with risks of adverse effects, such as hemorrhage, catheter infections, and metabolic disorders (hypophosphatemia). Moreover, hemodialysis of poisoned patients often requires hospitalization in an ICU. If significant toxicity and hemodialysis can be avoided by the early administration of fomepizole, ICU admissions may be limited to a relatively brief (24-hour) period of observation (Fig. 32B-3). There are also advantages to the use of fomepizole in comparison with ethanol: fomepizole is a more potent ADH inhibitor (and not a substrate), with a wider therapeutic index, a longer duration of action, easier dosing, and more predictable kinetics. There is no need for blood fomepizole concentration monitoring, treatments are well tolerated, and there are no similar data to prove ethanol efficacy. Use of ethanol, in our estimation, should now be limited to settings where fomepizole is

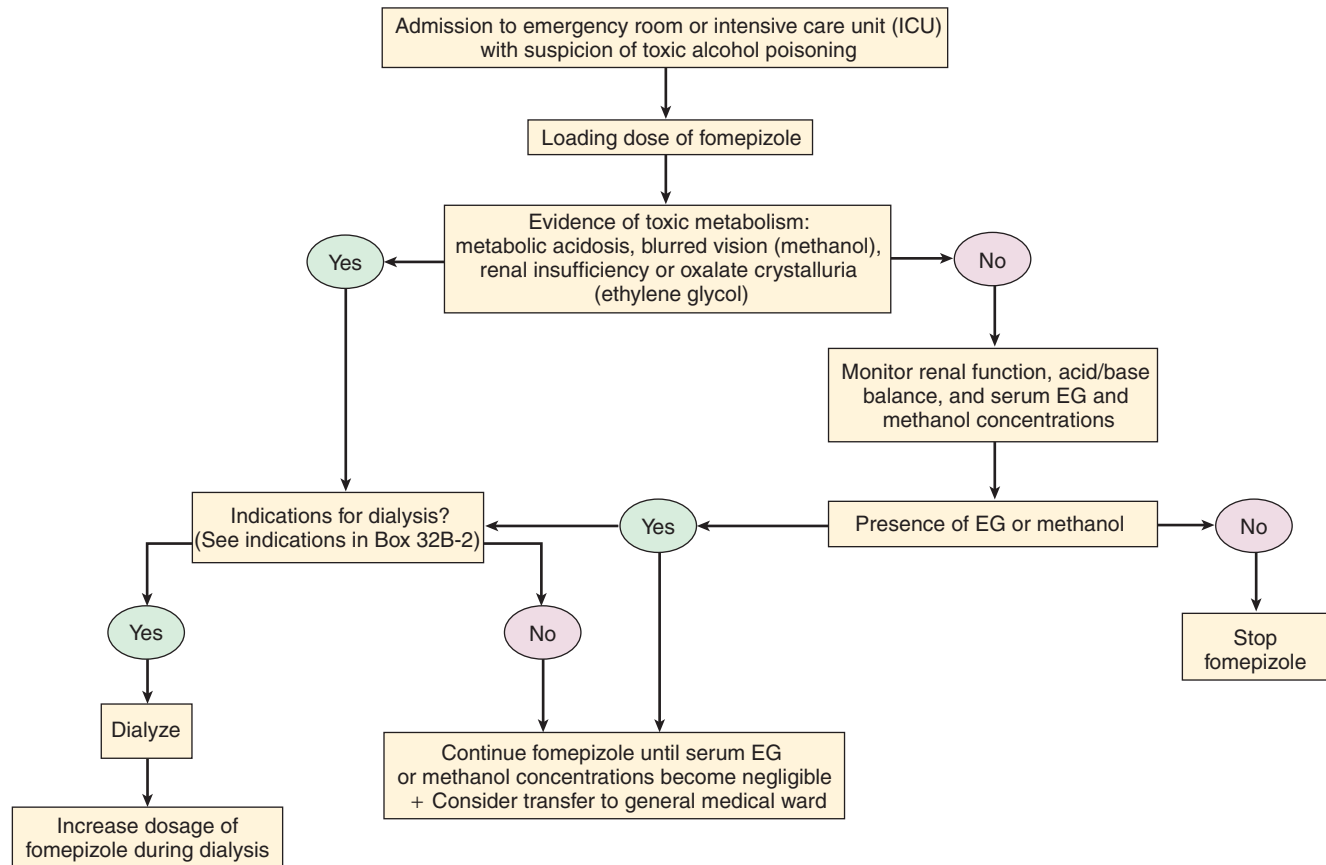

FIGURE 32B-3 Proposed algorithm for treatment of ethylene glycol- and methanol-poisoned patients. This algorithm is based on series and case reports and has not been validated prospectively. (Adapted from Megarbane B, Borron SW, Baud FJ: Current recommendations for treatment of severe toxic alcohol poisonings. *Intensive Care Med* 2005;31:189–195.)

unavailable or in patients for whom fomepizole is contraindicated. Given its safety, especially in patients who may subsequently be found not to be poisoned with toxic alcohols, fomepizole is of value in emergency medicine because it permits a margin of diagnostic error. In selected exposed patients, fomepizole may obviate the need for hemodialysis. However, the risks and benefits of fomepizole must be weighed against those of hemodialysis. Accelerated blood clearance by an adequate single hemodialysis session provides for a shorter hospital stay and fewer required doses of ADH inhibitors.⁶⁶

C Other Toxic Alcohols

MARCO L. SIVILOTTI, MD, MSc

At a Glance...

- These alcohols range considerably in their degree of toxicity.
- Multiple routes of exposure are possible, which in turn affect the degree of toxicity.
- Poisoning with certain alcohols may produce early central nervous system depression and elevation of serum osmolality followed by a delayed-onset metabolic acidosis and renal failure.
- Fomepizole or ethanol are potential antidotes in selected cases.
- Isopropanol poisoning results in ketosis (acetonemia and acetonuria) without significant metabolic acidosis, and can almost always be managed supportively in a manner analogous to ethanol intoxication.

Although ethanol, methanol, and ethylene glycol account for the vast majority of toxicity from alcohols encountered in clinical practice, other members of this chemical class can also be harmful to human health. An alcohol is any compound with a hydroxyl (-OH) group attached to a carbon chain. The chemical structures of commonly encountered alcohols are shown in Table 32C-1. Since their toxicities vary considerably, they will be discussed individually.

ISOPROPANOL

Isopropanol (2-propanol, isopropyl alcohol) is widely used as a solvent, rubefacient, and sterilizing agent and is found in many skin lotions, mouthwashes, rubbing alcohols, and cleaning fluids. Being readily available and less expensive than ethanol, it is often abused as an ethanol substitute. The IDLH (immediate danger to life and health) workplace standard according to the

National Institute of Occupational Safety and Health is 2000 ppm.

Isopropanol is rapidly absorbed after oral ingestion into a volume of distribution of 0.7 L/kg. Peak serum concentrations occur from 30 to 120 minutes after ingestion, whereas peak concentrations of its metabolite, acetone, do not occur until 4 hours after ingestion.¹ Inhalation and dermal application can also result in substantial absorption and subsequent toxicity.²⁻⁵ Isopropanol is metabolized primarily by alcohol dehydrogenase (ADH) in the liver (80%). A smaller fraction is eliminated unchanged by the kidneys. The serum elimination half-life is 2.5 to 16.2 hours, and increases substantially when ethanol or fomepizole are also present.⁶⁻¹² Because isopropanol is a secondary alcohol (the hydroxyl group is attached to a carbon atom bonded to two other carbon atoms), oxidation yields a ketone (acetone), which cannot be further oxidized to an organic acid.¹³ Acetone is slowly eliminated by the lungs and kidneys with a half-life ranging from 7.6 to 26 hours.^{7,14,15} As a result, the biochemical hallmark of isopropanol metabolism is the presence of a substantial ketonemia and ketonuria without acidemia.

Clinically, isopropanol ingestion resembles acute ethanol poisoning. Central nervous system (CNS) depression develops rapidly, and has generally reached its nadir within a few hours of the ingestion. Animal data suggest that the CNS depressant effects of isopropanol are two to three times more potent than ethanol, whereas its metabolite, acetone, has CNS depressant effects equivalent to ethanol.¹⁶ CNS depression can range from mild lethargy with slurred speech and ataxia to deep coma with areflexia. The fruity breath odor of ketones may be appreciated on physical examination. Other clinical findings include hemorrhagic gastritis, vomiting, abdominal pain, hemorrhagic tracheobron-

TABLE 32C-1 Chemical Structure and Molecular Weight of Selected Alcohols

	CHEMICAL STRUCTURE	MOLECULAR WEIGHT (DALTONS)
Methanol	CH ₃ OH	32
Ethanol	CH ₃ -CH ₂ OH	46
Isopropanol	CH ₃ -CHOH-CH ₃	60
Benzyl alcohol	(C ₆ H ₅)-CH ₂ OH	108
Ethylene glycol	CH ₂ OH-CH ₂ OH	62
Propylene glycol	CH ₂ OH-CHOH-CH ₃	76
Polyethylene glycols	CH ₂ OH-CH ₂ -O-(CH ₂ -CH ₂ -O) _n H	
Diethylene glycol	n = 1	106
Triethylene glycol	n = 2	150
PEG-400	n = 8-9	~400
PEG-3350	n = 68-84	~3350
Ethylene glycol ethers (cellosolves)	CH ₃ -(CH ₂) _n -O-CH ₂ -CH ₂ OH, n = 0	
Ethylene glycol monomethyl ether	n = 0	76
Ethylene glycol monoethyl ether	n = 1	90
Ethylene glycol monobutyl ether	n = 3	118

chitis, tachycardia, muscle weakness, and pulmonary aspiration. Rarely, massive ingestion results in hypotension from vasodilatation and negative cardiac inotropic effects, and respiratory arrest. The duration of CNS depression may be prolonged due to the added CNS depressant effects and slower rate of elimination of the acetone metabolite.

Serum isopropanol concentrations can be measured by gas chromatography, and may be reported on an “alcohol screen” in addition to methanol and ethanol (but not necessarily ethylene glycol). Serum concentrations of at least 50 to 100 mg/dL (8 to 17 mmol/L) result in intoxication, and of at least 150 mg/dL (25 mmol/L) result in coma, although tolerance can diminish these effects. Cardiovascular depression is generally seen at concentrations above 450 mg/dL (75 mmol/L). Because treatment is largely supportive and determined by clinical findings, serum isopropanol concentrations usually add little information beyond identifying and quantifying the exposure. Small concentrations of isopropanol may be detectable in the serum of patients with alcoholic, starvation, and diabetic ketoacidosis due to acetone reduction back to isopropanol.^{17,18} In one study, 15% of patients with diabetic ketoacidosis had detectable serum concentrations of isopropanol, ranging as high as 30 mg/dL.¹⁷ Breath analysis for ethanol by infrared absorption may detect isopropanol as an interferent.¹⁹ Some enzymatic assays may misrepresent isopropanol as ethanol.

In general, the presence or absence of an osmol gap is neither sensitive nor specific and cannot be used to rule in or out a toxic alcohol ingestion (see Chapter 3). Both isopropanol and acetone will increase serum osmolality. For each 1 mg/dL of either isopropanol (molecular weight 60 daltons) or acetone (58 daltons) in the serum, the serum osmolality will increase by about 0.17 mOsm/kg. Therefore, either isopropanol or acetone contribute approximately 10 mOsm/kg at a combined concentration of 60 mg/dL (10 mmol/L), and the osmolal gap multiplied by 6 approximates the summed serum concentrations of isopropanol and acetone in mg/dL. Thus, when history, physical examination, and initial laboratory data suggest poisoning with isopropanol and conclusive measurement of this alcohol is not immediately available, the osmolal gap can be used to quantify and follow the exposure with good sensitivity, since the metabolite, acetone, is both osmotically active and uncharged.

Acetone is detectable in the serum within 30 minutes, and in the urine within 3 hours after isopropyl alcohol ingestion.¹ Conversely, the absence of serum acetone effectively rules out isopropanol ingestion, unless ethanol is also present. Acetone can interfere with serum creatinine assays,²⁰⁻²² and persists after isopropanol is undetectable. Other laboratory findings associated with isopropanol poisoning include rhabdomyolysis, hemolytic anemia, and renal tubular acidosis.

Patient management closely parallels acute ethanol ingestion. Gastrointestinal decontamination is rarely indicated due to the delay that usually occurs between ingestion and hospital presentation. Large doses of

activated charcoal have been shown to adsorb both isopropanol and acetone *in vitro*.²³ Administration of such large doses of activated charcoal, however, is impractical in the care of poisoned patients. Thus, in circumstances where a patient can be treated immediately after a massive ingestion, small nasogastric tube aspiration is the only decontamination necessary. Supportive care must emphasize airway protection and ensure adequate tissue oxygenation. Careful monitoring and frequent reassessment are essential. As with ethanol, the pharmacokinetics are such that peak CNS effects typically occur by the time of hospital presentation. If symptoms have not developed within 2 hours after reported ingestion, they will not develop, and patients can be cleared for discharge.²⁴ Unlike ethanol, however, the duration of CNS depression may be prolonged. Regardless, serial observation should demonstrate an improving level of consciousness with time. Indeed, a deterioration should lead the clinician to investigate alternate causes of the depressed level of consciousness. Similarly, the presence of a metabolic acidosis demands a careful evaluation of alternate diagnoses, including alcoholic ketoacidosis (see Chapter 6) and inadequate tissue perfusion following massive ingestion.

Inhibition of ADH using either fomepizole or ethanol is not indicated and would only serve to prolong toxic effects.^{12,13} Hemodialysis, while effective at removing both isopropanol and acetone, is not necessary for the vast majority of patients. Hemodialysis should be reserved for the rare patient with severe hemodynamic compromise despite fluid resuscitation.^{25,26}

THE HIGHER ALCOHOLS

The higher saturated aliphatic alcohols may also have some toxicity. The higher liquid alcohols are butyl, amyl, ethyl, hexyl, and so on, and the solid fatty alcohols include lauryl, myristyl, cetyl, and stearyl. The liquid alcohols are used as solvents, and the solid fatty alcohols are used in cosmetics. The term *fusel alcohol* is used to describe the higher-order alcohols produced by natural fermentation, and are present in beer and other alcoholic beverages at concentrations as high as 2200 ppm.²⁷ In general, the CNS potency of an alcohol increases with increasing carbon chain length.¹⁶ The order of increasing toxicity by single oral doses is as follows: ethanol, isopropanol, *n*-propanol, *sec*-butyl, *n*-butyl, *tert*-butyl, isobutyl, and amyl alcohol. *n*-Butyl alcohol vapors have produced conjunctivitis and keratitis. Although skin irritation is common with the liquid alcohols, percutaneous absorption does not seem to occur. Vapor inhalation may produce pulmonary injury. The amyl alcohols are more potent, and ingestion or rectal instillation of about 30 mL has proved lethal in human adults. Glycosuria and methemoglobinemia may result from ingestion of isoamyl alcohol.

The primary alcohols, such as ethanol, *n*-propanol, *n*-butyl, and isobutyl alcohol, are oxidized to aldehydes and carboxylic acids. Therefore, significant metabolic acidosis may result from their ingestion. The secondary

alcohols, such as isopropanol and *sec*-butyl alcohol, are converted to ketones, which may also cause CNS depression. The tertiary alcohols such as *tert*-butyl alcohol are metabolized slowly and incompletely, and excreted in the urine as glucuronides.

Very few cases of human toxicity have been described. In general, the major clinical effects are in the CNS, particularly with vaporizing compounds, and include headache, muscle weakness, giddiness, ataxia, confusion, delirium, and coma. If these agents are ingested, GI effects predominate and consist of vomiting and diarrhea. The odor of the alcohol may be noted. Fusel alcohols may contribute to both the flavor and side effects (“hangover”) of certain alcoholic beverages. Death from higher alcohols is mainly due to respiratory failure but may also result from cardiac arrhythmias.

BENZYL ALCOHOL

Benzyl alcohol (α -hydroxytoluene) is an aromatic alcohol used as an antimicrobial preservative at concentrations ranging from 0.9% to 2.0% in many multidose medication vials and parenteral solutions. It is readily oxidized *in vivo* to benzoic acid, and conjugated with glycine to form hippuric acid. Neonates have reduced capacity to metabolize benzoic acid, and toxicity may result from bioaccumulation of benzyl alcohol and benzoic acid with repetitive dosing. Neonates inadvertently given 100 to 240 mg/kg/day of benzyl alcohol (mostly in bacteriostatic catheter flush solutions) developed a syndrome of CNS depression, severe metabolic acidosis, gasping respiration, thrombocytopenia, hepatorenal failure, seizures, intracranial hemorrhage, bradycardia, skin breakdown, cardiovascular collapse, and death, termed the “gasping baby syndrome.”²⁸ The evidence for causation rests on the original case-control description, elevated concentrations of serum and urine metabolites, and the disappearance of the syndrome with the removal of bacteriostatic solutions from the nursery.^{28,29} A reduction in kernicterus, intracranial hemorrhage, neurologic deficit, and perhaps mortality has also been associated with elimination of benzyl alcohol solutions in neonates.³⁰⁻³² The daily dose of benzyl alcohol should not exceed 5 mg/kg body weight.³³ Some common parenteral medications formulated with benzyl alcohol include amiodarone, atracurium, atropine sulfate, bacteriostatic water and saline for injection, bumetanide, chlordiazepoxide, diazepam, furosemide, glycopyrrolate, heparin, hydroxyzine, metoclopramide, midazolam, lorazepam, pancuronium, physostigmine, procainamide, prochlorperazine, succinylcholine, and trimethoprim-sulfamethoxazole.

PROPYLENE GLYCOL

Propylene glycol (1,2-propanediol; PG) is a clear, colorless, odorless, sweet-tasting liquid that is widely used as a solvent and antimicrobial preservative. PG is considerably less toxic than ethylene glycol,³⁴ and thus commonly used as the main ingredient in many “ethylene

glycol-free” antifreeze, de-icing and heat-exchanger solutions. Being generally recognized as safe by the U.S. Food and Drug Administration, it is routinely used as a solvent in pharmaceutical preparations, and as a humectant and preservative in food products. Deaths are rare following exposure to PG. Nevertheless, the relatively high concentration of PG in intravenous formulations of phenytoin (40%), diazepam (40%), chlordiazepoxide (20%), etomidate (35%), phenobarbital (70%), pentobarbital (40%), and lorazepam (80%) can result in toxicity during rapid or prolonged infusion of high doses of these medications. PG is also present in parenteral preparations of esmolol, digoxin, multivitamins, nitroglycerin, and trimethoprim-sulfamethoxazole. Toxicity following dermal exposure is possible, particularly in infants and burn patients.^{35,36} The use of silver sulfadiazine cream has produced serum hyperosmolality, hypoglycemia, seizures, and CNS depression from transdermal absorption of PG.³⁶⁻³⁸ The oral median lethal dose (LD₅₀) is 20 g/kg or greater in rodents.³⁴ The daily dose should not exceed 25 mg/kg.³⁹

Similar to other alcohols and glycols, PG is rapidly absorbed from the gastrointestinal tract with peak serum levels after 1 to 2 hours, and distributes into a volume of 0.6 L/kg. The terminal hydroxyl group of PG is readily oxidized via ADH to form lactic acid (2-hydroxypropanoic acid), which subsequently can be converted to pyruvate and enter the Krebs’s cycle. Up to half of the parent glycol is excreted unchanged in the kidneys. The serum elimination half-life in adults is 2.3 ± 0.7 hours, but becomes saturated above 50 mg/dL, and can be up to 17 hours (or zero-order 13.5 mg/dL/hr) in neonates.^{36,40,41} With chronic dosing of racemic PG, D-lactate accumulates in cats.⁴² The significance of chirality is not known in human exposures. In an adult patient treated with continuous ethanol infusion and ethanol: PG serum concentrations of 1:2 mol/mol, zero-order elimination of 13 mg/dL/hr was observed across PG concentrations ranging from 300 to 500 mg/dL.⁴³ PG concentrations greater than 17.7 mg/dL are required to increase the lactate concentration and increase the anion gap.⁴⁴ PG concentrations of 76 mg/dL will increase the serum osmolality by about 10 mOsm/kg.⁴⁵ PG can be detected by gas chromatography. PG is a potential interferent when testing for ethylene glycol, so mass spectrometry should be used to confirm glycol identity.⁴⁶⁻⁴⁸

High doses result in abrupt cardiovascular depression, cardiac conduction abnormalities including QRS widening and bradycardia, lactic acidosis, hyperosmolality, CNS depression and seizures, hypoglycemia, deafness, and thrombophlebitis, as described in various case reports.⁴⁹⁻⁵³ Bradycardia is vagally mediated, as evidenced by pretreatment with atropine or vagotomy in animals.⁵⁴ Most toxic effects from PG are attributed to the parent glycol rather than its metabolites, suggesting that ADH inhibitor therapy is of limited benefit.⁵⁵ Hemodialysis has been used in critically ill patients.^{56,57} The role of fomepizole is unknown.⁵⁵ Continuous venovenous hemofiltration with dialysis removes PG more slowly, and one patient receiving up to 9 g PG hourly developed toxicity despite simultaneous venovenous hemofiltration.⁵⁸

DIETHYLENE GLYCOL

Diethylene glycol (2,2'-dihydroxydiethyl ether, ethylene diglycol, 2,2'-oxydiethanol, 3-oxapentane-1,5-diol) is a viscous, sweet-tasting hydroscopic liquid. It is used as a plasticizer, antifreeze, lubricant, and liquid fuel (e.g., Sterno Wick Chafing Fuel, Des Plaines, IL). Its solubility in both organic and aqueous solutions has resulted in its occasional incorporation into pharmaceutical elixirs, with tragic results. The use of diethylene glycol to dissolve the early sulfa drug sulfanilamide by the Messengill company in 1937 resulted in 105 deaths, and triggered a national outcry.⁵⁹ This tragedy led to the federal Food, Drug and Cosmetic Act in 1938, which initiated the close regulation of the safety of medicinals by the Food and Drug Administration. Unfortunately, outbreaks continue to occur in developing countries following the inadvertent substitution of diethylene glycol for PG or glycerin in elixirs usually intended for children, with mortality rates of 40% to 100%.⁶⁰⁻⁶⁴ (Table 32C-2) The oral LD₅₀ ranges from 4.9 g/kg (rabbits) to 28.2 g/kg (mice), but is only 1.1 to 2.2 g/kg in mice when given intravenously. A human infant fatality has been reported following ingestion of 3.6 g.

After ingestion, diethylene glycol is rapidly absorbed, and 40% to 70% is excreted unchanged in the urine. The remainder is oxidized to 2-hydroxyethoxy acetic acid by ADH and aldehyde dehydrogenase, which may esterify under physiologic conditions to the cyclic lactone *p*-dioxanone, a nonacid.^{65,66} The parent ether link is stable in vivo, accounting for the absence of ethylene glycol, glycolate, and glyoxalate in animal toxicity studies, and the inconsistent observation of oxalate in human cases.⁶⁵⁻⁶⁸ Lactic acid accounts for a substantial portion of the metabolic acidosis.⁶⁹ Pyrazole and ethanol both reduce but do not eliminate the toxicity in animal models,⁶⁹ suggesting that the parent compound is also toxic.

Nephrotoxicity (tubular necrosis) is the prominent feature in animal poisoning studies. Other findings include CNS depression and hemorrhage, metabolic acidosis, and fatty liver. In poisoned humans, characteristic findings include delayed-onset renal failure with

vacuolar nephropathy and acute tubular necrosis, and centrilobular hepatic necrosis following single or subacute ingestion of about 1 g/kg. In the Haiti outbreak, the maximum possible median toxic dose was 1.5 g/kg (95% confidence interval 0.25 to 4.9 g/kg).⁶² In serious poisonings, headache, dizziness, CNS depression, anorexia, nausea, vomiting, diarrhea, and abdominal pain are commonly seen within 24 hours after ingestion. Unlike poisoning with ethylene glycol, the metabolic acidosis is not as prominent until renal toxicity is advanced. Laboratory findings include elevated serum osmolality, hypoglycemia, elevated blood urea nitrogen and creatinine, anion gap metabolic acidosis, elevated liver function test results, and an abnormal urinalysis result with cells and casts. In addition to hepatorenal failure, other late findings include cerebral and pulmonary edema, encephalopathy progressing to coma, facial nerve paralysis, demyelinating neuropathy, seizures, hypertension, adrenal cortical hemorrhage, and pancreatitis.

Although there is little reported experience in humans, both early dialysis and the inhibition of ADH is recommended for all symptomatic diethylene glycol exposures, especially patients with acidemia or renal insufficiency.^{67,70} Using fomepizole to inhibit ADH is rational,⁷¹ and has been used empirically in human cases.^{69,70} The toxicity of the parent compound suggests that fomepizole without hemodialysis is unwise. In addition to dialysis and ADH inhibition, the need for intensive care to multiple patients with multiorgan failure may overwhelm a health care system in the context of an outbreak.^{62,64}

POLYETHYLENE GLYCOLS

Triethylene glycol is the next higher molecular weight polymer after diethylene glycol in the series of polyethylene glycols. This series consists of subunits of ethylene glycol joined by an ether link. As the number of subunits increases, the polyethylene glycols are typically a mixture of varying chain lengths and are described by a number (e.g., PEG-3350). This number denotes the average molecular weight of the mixture.

TABLE 32C-2 Diethylene Glycol (DEG) Poisoning Outbreaks

YEAR	COUNTRY	SOURCE (% DEG)	AGES	FATALITIES IDENTIFIED	REFERENCES
1937	USA	Sulfonilamide (72%)	30% children	105 of 353	59
1969	South Africa	Sedatives	Children	7	103
1985	Spain	Topical silver Sulfadiazine		5	104
1985	Netherlands	Wine	Adults		105
1986	India	Glycerin (18.5%)	Adults	14	106
1990	Nigeria	Acetaminophen	Children	47	63
1990–1992	Bangladesh	Acetaminophen	Children	236	60
1992	Argentina	Propolis		7	68
1995/1996	Haiti	Acetaminophen (14%)	Children	101 of 109	61, 62
1998	India	Cough syrup (17.5%)	Children	33 of 36	64

These compounds are liquids at room temperatures until the molecular weight exceeds 1000 daltons, after which they become solids and are termed carbowaxes. The toxicity also decreases substantially with increasing molecular weight. The higher polyethylene glycols are commonly used as excipients in medications and ointments. Intravenous lorazepam contains nearly 20% PEG-400, and burn ointments may contain over 99% PEG-300. PEG-3350 combined with an electrolyte solution (PEG-ELS) is used as a bowel evacuant for whole bowel irrigation (e.g., Go-Lytely [Braintree Laboratories, Braintree, MA] and CoLyte [Schwarz Pharma, Milwaukee, WI]).

Only lower-molecular-weight polyethylene glycols are absorbed in significant quantities after ingestion. These compounds can be metabolized via ADH to mono- and diacid metabolites,⁷² but the majority is excreted unchanged in the urine. The ether link appears to be stable in vivo (see earlier section on Diethylene Glycol), and toxic amounts of ethylene glycol are not generated. In animals, 10 g/kg of polyethylene glycols over a wide range of molecular weights are well tolerated after single intravenous administration.

Although uncommon, toxicity associated with polyethylene glycols includes CNS depression, serum hyperosmolality, anion gap metabolic acidosis, and renal failure. Triethylene glycol has been reported to cause acute toxicity after ingestion in humans.⁷³ In this case report, intentional ingestion of nearly pure triethylene glycol resulted in coma and profound anion gap metabolic acidosis (initial arterial pH 7.03, anion gap 30 mmol/L, lactate 2 mmol/L, osmol gap 7) within 90 minutes of ingestion. In another case report, an intentional ingestion of brake fluid containing both diethylene glycol (10%) and triethylene glycol (55% vol/vol) resulted in coma, clonus, and anion gap acidosis (pH 7.34, anion gap 28 mmol/L, lactate 12 mmol/L, osmol gap 31) at least 2 hours after ingestion.⁶⁹ The third report of toxicity following intentional ingestion involved the liquid contents of a lava light (18% PEG-200) by a 65-year-old man who presented with confusion, nystagmus, renal failure, and acidosis (anion gap 15, creatinine 5.7 $\mu\text{g/dL}$). Burn patients absorb PEG-300 from creams applied topically and eliminate acid metabolites in urine,⁷² perhaps resulting in toxicity.⁷⁴ For instance, serum hyperosmolality, anion gap metabolic acidosis, and acute tubular necrosis have been described in this patient population and may be attributed to PEG percutaneous absorption.⁷⁴ One case of hyperosmolar metabolic acidosis in a patient administered 1.7 g lorazepam intravenously (18% PEG-400, 80% PG) was attributed to the 150 mL of polyethylene glycol excipient,⁵⁷ but the coadministered 704 g of PG are a more plausible explanation.⁵⁵ The relative safety of PEG-3350 is illustrated by a case report of a 2-year-old child treated with 3 L/kg of whole bowel irrigation over 5 days without adverse effects.⁷⁵

Treatment with ADH blockade using either fomepizole or ethanol appears to be appropriate for symptomatic ingestions of low-molecular-weight polyethylene glycols.^{69,73} The role of hemodialysis is not defined, but should be

instituted for persistent metabolic acidosis or renal insufficiency. The acute oral toxicity of the higher-molecular-weight polyethylene glycols is minimal.

GLYCOL ETHERS

The glycol ethers, or cellosolves, are a family of organic compounds in which at least one alkyl hydrocarbon is joined by an ether link to a diol such as ethylene glycol. Thus, the basic structure is $\text{R1-O}-(\text{CH}_2)_x\text{-O-R2}$. The most common glycol ether, accounting for about half of the annual production in North America, is ethylene glycol *n*-butyl ether (EGBE), in which $\text{R1} = \text{CH}_3(\text{CH}_2)_3-$ (i.e., *n*-butyl), $x = 2$ (ethylene glycol), and $\text{R2} = \text{H}$. Replacing R1 with methyl results in ethylene glycol methyl ether (EGME). Other commonly encountered glycol ethers are listed in Table 32C-3.

Since the glycol ethers combine the solubility properties of both alcohols and ethers, they are miscible in a wide range of aqueous and organic solutions, and have numerous household and industrial applications. The first reports of human toxicity appeared in the 1930s following the introduction of EGME into the manufacture of stiffened shirt collars. Workers producing “fused collar” shirts developed toxic encephalopathy and bone marrow toxicity following chronic pulmonary and dermal exposure.⁷⁶ Today, various glycol ethers are found as the primary component of automotive brake fluids, as well as in fuel injector and carburetor cleaners, degreasing agents, stain removers, carpet and fabric cleaners, inks and ink removers, leather dyes, shoe polish, leather conditioners, and many window and surface cleaning products. Their coating properties lead to their use in lacquers, paints, varnishes, and surface preparation agents. They are used extensively in the semiconductor industry, as well as the plastics, rubber, photography, and printing industries.

Although the first human fatality attributed to intentional ingestion of a glycol ether was reported over 50 years ago,⁷⁷ there are very few published case reports of toxicity following acute use. This is in contrast with their prevalence in the household environment. For the years of 1998 to 2000, the American Association of Poison Control Centers Toxic Exposure Surveillance System shows over 26,000 human exposures (54% age younger than 6 years) to products containing any glycol other than ethylene glycol, out of a total of 6.6 million cases reported to U.S. poison control centers. Of these, 64 (0.2%) resulted in major toxicity, and 2 deaths are listed, both in adults, presumably following intentional ingestion with suicidal intent. Indeed, toxicity was not observed in a retrospective poison control center study of 24 young children following accidental ingestion of a mouthful of products containing less than 10% glycol ethers.⁷⁸

Following oral ingestion, absorption of low-molecular-weight glycol ethers such as EGME and EGBE is rapid, and comparable with ethanol.⁷⁹ Pulmonary absorption is also possible, particularly of the more volatile agents. Thus, methyl derivatives such as EGME (vapor pressure

TABLE 32C-3 Glycol Ethers

NAME	ABBREVIATION	CAS NO.	SYNONYMS	STRUCTURE

9.7 mm Hg at 25° C) are more hazardous than EGBE (vapor pressure 0.9 mm Hg). The diethylene and dipropylene glycol ethers have vapor pressures ranging from about 0.4 to 0.004 mm Hg under ambient conditions, reducing the risk for exposure, and triethylene glycol ethers or higher are essentially nontoxic via the pulmonary route.⁸⁰ The glycol ethers readily diffuse across intact skin in inverse proportion to molecular weight. EGME diffuses across human skin more quickly than ethanol, then in decreasing order propylene glycol methyl ether (PGME), ethylene glycol ethyl ether (EGEE), dimethylene glycol methyl ether (DEGME), diethylene glycol ethyl ether, and EGBE.⁸¹ Both the pulmonary and dermal routes of exposure can lead to toxicity in the occupational setting.⁸² Once absorbed, the volume of distribution for EGBE has been estimated at 0.7 L/kg.⁸³

The monoalkyl ethers are predominantly metabolized to alkoxyacetic acid by hepatic ADH and aldehyde dehydrogenase.⁸⁰ For example, EGME is oxidized to methoxyacetic acid and EGBE to butoxyacetic acid (BAA). This metabolism is inhibited in animals by pyrazole (a fomepizole analog) or relatively low concentrations of ethanol. *O*-dealkylation to ethylene glycol and a monoalcohol plays a minor role in mammals. The alkoxyacetic acid and its glycine conjugate are the major urinary metabolites recovered.⁸³ Only trivial amounts of the parent compound are eliminated in feces or breath. Despite reports of moderate increases in oxaluria in two case reports,^{84,85} the absence of detectable ethylene glycol, methanol, and tissue calcium oxalate crystals in most other published reports demonstrates that the toxicity of EGME and EGBE is not due to the release of ethylene glycol.^{77,79,85,86} Two other case reports may represent ethylene glycol ingestions.^{87,88} In contrast to all

the ethylene glycol monoalkyl ethers and β-PGME, ADH oxidizes secondary alcohols such as α-PGME more slowly, and *O*-dealkylation presumably via CYP450 can produce substantial quantities of PG.⁸⁰

Because of the paucity of published reports of acute toxicity following oral ingestion, careful scrutiny of these case reports is justified, as summarized in Table 32C-4. Analogous to most other toxic alcohols, the acid metabolites appear to be more potent toxins than the parent glycol ether. Rapid onset coma may occur within 1 hour of ingestion,⁷⁹ but an anion gap metabolic acidosis follows several hours later if ADH metabolism is not inhibited.^{79,84-86} Mild to moderate hemolysis has been observed in humans following large ingestions of EGBE,^{79,84,89,90} but not after inhalational exposure or with other glycol ethers. Animal models demonstrate that BAA is the proximate hemolytic agent.⁹¹ Human erythrocytes appear to be resistant to hemolysis in vitro.⁹² Other reported toxic effects following glycol ether ingestion are hypotension requiring pressors, mild renal dysfunction with proteinuria, lactic acidosis, and less commonly disseminated intravascular coagulopathy, acute lung injury, hepatic dysfunction, and hypochloremic metabolic acidosis.

Chronic exposure can result in bone marrow suppression, encephalopathy, developmental toxicity, and subfertility. The neurologic effects range from personality changes to amnesia, headache, and lethargy, with tremor, clonus, ataxia, and dysarthria. Both erythroid and myeloid hypoplasia have been described on the bone marrow aspirates of workers exposed to higher concentrations of EGME, but not following low level exposures to EGBE.^{93,94} Several epidemiologic studies have reported an association between decreased fertility in female workers and exposure to EGME, EGBE (and

The table summarizes published reports of serious glycol ether ingestion. AG, anion gap (mM); CPR, external chest compressions; creat, serum creatinine; DIC, disseminated intravascular coagulation; HD, hemodialysis; N, normal; OG, osmolal gap; PTA, prior to hospital arrival; RR, respiratory rate.

their acetate derivatives which are deesterified in vivo to the parent glycol ether), and other ethylene and PG ethers used in photolithography during semiconductor fabrication.⁹⁵⁻⁹⁷ EGME, EGEE, and perhaps higher glycol ethers are teratogenic.⁹⁸⁻¹⁰⁰

The diagnosis of acute exposure to glycol ether depends on a reliable history, since laboratory testing for the parent glycol ether or its acid metabolite is generally

not possible within a clinically relevant turnaround time. CNS depression should be present on physical examination following significant poisoning. The presence of an anion gap metabolic acidosis, with or without a concurrent lactic acidosis, is an indirect marker of exposure and metabolism, but is not specific. The osmolal gap is usually normal despite severe symptoms.^{79,90,101,102} In fact, in one patient with rapid onset coma, the serum

concentration of EGBE was 3 mmol/L, and would therefore not be expected to increase the osmol gap appreciably.

Treatment must therefore be predicated upon clinical effects such as mental status, acid-base status, and other readily apparent end-organ effects. Many of the patients in case reports were treated with ADH blockade or delayed hemodialysis, or both. Fomepizole was used in one instance.⁸⁶ There are insufficient data on which to base a firm recommendation at this time. The use of an ADH inhibitor is based on the premise that the acid metabolite is the more toxic species, and is justified only if substantial amounts of the parent glycol ether remain at the time of initiation of therapy. It is difficult to interpret the human toxicokinetics of the parent glycol ether, because the reported methodologies for quantifying EGBE appear to yield inconsistent results. From these imprecise published estimates, it would appear that the glycol ether is absorbed and cleared rapidly from the serum. The available data also suggest that full-dose ethanol therapy can result in hemodynamic compromise and a hyperchloremic metabolic acidosis.¹⁰¹ The use of hemodialysis is recommended to correct refractory metabolic acidosis and to remove the glycol ether metabolites. Here again, the literature is unsatisfactory. The only report of serial serum BAA levels suggests that hemodialysis does not increase BAA elimination substantively.⁸⁹ This observation is at odds with the low molecular weight and volume of distribution of BAA, and should be confirmed prior to reconsidering the role of hemodialysis.

Pending better information, it seems prudent to recommend fomepizole or low-dose ethanol for symptomatic patients who present shortly after an intentional ingestion of a product known to contain nontrivial concentrations of glycol ethers. Hemodialysis should be offered to patients with a metabolic acidosis not responsive to fluids and sodium bicarbonate. Accidental sips of solutions with less than 10% glycol ether can be managed with home observation if the patient remains asymptomatic.⁷⁸

At a Glance...

- Opioids elicit the same overall physiologic effects as morphine but may demonstrate conspicuous differences following an overdose.
- The classic “opioid toxidrome” (mental status depression, respiratory depression, miosis, and decreased bowel motility) may not be apparent following a mixed overdose.
- Purity and adulterants play a considerable role in the outcome and complications of heroin use.
- Inhalation of heated heroin vapors may result in a progressive spongiform leukoencephalopathy.
- Acute lung injury may occur following opioid overdose or naloxone therapy.
- Higher doses of naloxone may be required to antagonize the effects of high-potency opioids (e.g., fentanyl and its analogs, methadone, pentazocine, propoxyphene, and diphenoxylate).
- Naloxone has a short half-life, and the effects of most opioids will significantly outlast several doses of naloxone.
- Judicious use of naloxone infusion may obviate the need for endotracheal intubation.

HISTORY AND INTRODUCTION

Opium, one of the oldest known pharmacologic agents, is derived from the poppy *Papaver somniferum*. The Sumerians first reported the psychotherapeutic benefits of juice from immature poppy heads about 4000 BC. Opium solutions contained morphine, codeine, and numerous other related alkaloids. In 1806, morphine was isolated from opium by Sertürner. Other alkaloids were later isolated, including codeine in 1832 by Robiquet and papaverine in 1848 by Merck. Morphine was soon recognized to be as addictive as opium. Attempts were made to increase morphine’s antinociceptive and antidiarrheal properties while decreasing tolerance and dependence. The result was Dreser’s synthesis of diacetylmorphine (heroin) in 1898.

The existence of specific opioid receptors was definitively established in 1973 by Snyder and colleagues in the United States and Terenius and colleagues in Sweden. In 1975, Kosterlitz and Hughes identified two endogenous pentapeptides with morphine-like activity—the leu-enkephalin and the met-enkephalin—opening the door to the characterization of additional endogenous ligands. Work continues on opioid receptors with the aim of improving our understanding of their biopharmacology and manipulating the beneficial effects of opioids, while reducing their undesirable consequences.

The term *opiate* specifically refers to all naturally occurring alkaloids derived from opium, including

morphine, 6-mono-acetyl-morphine, codeine, codethyline, and pholcodine. In contrast, the term *opioid* refers to all drugs, natural or synthetic, with morphine-like actions or actions mediated through binding to opioid receptors. This chapter focuses on the clinical issues concerning the acute and chronic toxicology of opioids and appropriate treatment relevant to current clinical practice.

EPIDEMIOLOGY

The dangers of opioid overdose have been recognized for as long as the use of opium itself. Overdose from illicit opioid use has increased in many countries over the past decade,¹ as has the illicit production, transportation, and consumption of opioids, especially heroin. Higher production, increasing purity, and lower prices have considerably contributed to the worldwide expansion of opioid use. Higher heroin purity enables users to smoke or snort rather than inject it, contributing to widespread popularity, illustrated by a recently reported epidemic of heroin use.² Changes in the route of opioid administration over time may occur in relation to opioid tolerance or drug purity increase. Heroin vapor inhalation produced by heating heroin on aluminum foil is increasingly common. The majority of drug users currently entering treatment programs are noninjectors. There is a trend toward multidrug use, with attendant drug-drug interactions and the risk of polyintoxication.

In 2004, the Substance Abuse and Mental Health Services Administration (SAMHSA) and the Drug Abuse Warning Network (DAWN) estimated that 19.1 million Americans ages 12 or older (about 7.9% of the population) were current illicit drug users.³ However, the prevalence of heroin use remains low in the general population when compared with alcohol, tobacco, or cannabis. Typically, less than 2% of the adult population has ever used heroin, and less than 1% is dependent on heroin. An estimated 300,000 persons in the United States suffer from heroin dependence or abuse (Fig. 33-1), and 118,000 persons have used heroin for the first time within the past 12 months with an average age of initiation at 24 years. The number of injectors has been estimated to be about 5.3 million worldwide, which appears to be constant. For 2003, the American Association of Poison Control Centers (AAPCC) reported 22,600 opioid overdoses among the 270,000 exposures to analgesics (around 8%), which resulted in 213 of 656 deaths (around 35%) attributed to this pharmacological class.⁴

The SAMHSA reported 709,000 hospital facility visits in 2004 related to illicit drug use, versus 638,484 in 2001

FIGURE 33-1 Comparative incidence of dependence or abuse of specific substances among past users of substances in the United States in 2004. (Courtesy of the Substance Abuse and Mental Health Services Administration, <http://www.icpsr.umich.edu/SAMHDA>.)

and 323,100 in 1978.³ This increase does not necessarily reflect an elevation in the number of heroin users, but rather a greater number of individuals seeking help. Emergency department admissions for opioid overdose were estimated in the United States at 93,000 per year in 2002 versus 72,000 in 1995. In contrast, heroin use is decreasing in western Europe, with a rise in the mean age, presumably in relation to the widespread introduction of opioid maintenance treatment programs and to the development of dependence on other illicit drugs (cannabis, cocaine, and amphetamines). In France, for example, traditional opiate use has decreased since 1996, when both prescribed and diverted buprenorphine appeared on the scene.⁵ In other countries, various locally produced opioids are used, including “home-back” in Australia and New Zealand, prepared with codeine and other opiates; “kompot” in Poland, made from poppy straw; and “black water opium” in Vietnam.

Opioids represent the most lethal illicit drug, with most of the fatalities occurring in young males, resulting in 33,662 potential years of life lost and 42 years of life lost per death.⁶ A dependent heroin injector has a 20 to 30 times greater estimated risk for premature death than a similar-aged non-drug-using person. In 1995, opioid overdose deaths accounted for 76% of all deaths due to illicit drug use and 9% of deaths among young adults 15 to 44 years of age in Australia.² In Glasgow, nearly a third of all deaths among young adults 15 to 35 years of age were related to opioids.⁷ However, after a rise in the second half of the 1980s, the number of overdose deaths has generally stabilized or declined in the majority of Western countries.^{1,5} Nearly two thirds of all long-term heroin users have self-overdosed on heroin at least once.⁸

Mortality for opioid users in maintenance treatment is reduced (about four times), in comparison to opioid users involved in opioid-related emergencies.⁹ Substi-

tution therapy with methadone, levomethadyl acetate, or buprenorphine may result in a substantial reduction in consumption of illicit opiate and psychoactive substances.¹⁰⁻¹² However, deaths have been attributed to maintenance treatment as well, in relation to their overdose or misuse. Deaths have been reported in relation to buprenorphine “overdose.”¹³⁻¹⁶ Forensic studies concluded that these deaths were due to asphyxia, with the underlying cause attributed to misuse and/or coadministration of psychotropic substances. Buprenorphine is injected by some users, despite the labeling for sublingual use.¹⁷⁻¹⁹ However, despite an estimated 90,000 patients treated with high-dose buprenorphine (8 to 16 mg/day) in France since 1996, the number of significant reported side effects has been limited.^{5,20} Interestingly, it appears that a strict limitation on the number of patients per prescribing physician for buprenorphine substitution programs has been associated with very limited abuse of the product since its launch in the United States in 2002.²¹ Similarly, most lethal methadone intoxications are due to diverted or illegal methadone, in association with medications or other illicit drugs.^{22,23} Recent increases in methadone prescription under strict medical control have not increased the number of lethal methadone intoxications but may have contributed to a large decrease in overall drug intoxication deaths.²⁴

PHARMACOLOGY

The Various Opioid Molecules

Morphine is still obtained from opium or extracted from poppy straw. A number of natural alkaloids are derived from *Papaver somniferum*, including phenanthrenes (morphine, codeine, and thebaine) and benzylisoquinolines (papaverine, noscapine). Codeine is methylmorphine. Thebaine, the precursor of several compounds such as oxycodone and naloxone, differs from morphine in the methylation of its two hydroxyl groups and the presence of double bonds in the ring. Heroin is a diacetylmorphine, in the 3 and 6 positions. Hydromorphone, oxymorphone, hydrocodone, and oxycodone are also made by modifying the morphine molecule. Synthetic opioids can be structurally divided into five classes: morphinans, phenylpiperidines, benzomorphanes, methadones, and propionanilides. Levorphanol is the only commercially available opioid agonist from the morphinan series. The phenylpiperidine family includes meperidine, diphenoxylate, loperamide, fentanyl, sufentanil, alfentanil, and remifentanil. Methadone and propoxyphene are structurally related opioids. Some partial opioid antagonists are clinically used, including pentazocine (a benzomorphan derivative), nalbuphine (structurally related to naloxone and oxymorphone), buprenorphine (a semisynthetic opioid derived from thebaine), and meptazinol. Minor changes in the chemical structure may convert an agonist into an antagonist opioid, like nalorphine (derived from morphine) or naloxone and naltrexone (both derived

from oxymorphone). These substitutions are critical in determining agonist or antagonist properties, as well as their interactions with the various opioid receptors.

A simple classification scheme including all opioids, whether clinically used or not, distinguishes natural exogenous opioids, synthetic opioids, and endogenous opioids.

THE EXOGENOUS NATURAL OPIOIDS

This class includes opiates derived from *Papaver somniferum*, like morphine, as well as other animal-derived peptides, like deltorphins, extracted from the skin of South American frogs belonging to the *Phyllomedusa* genus and characterized by a high affinity to δ receptors.

THE SYNTHETIC OPIOIDS

This group may be subdivided into nonpeptide and peptide-like molecules. The first subgroup includes morphine derivatives, like heroin, buprenorphine, methadone, and etorphine (Fig. 33-2), as well as some δ selective agonists.

THE ENDOGENOUS OPIOIDS

Endogenous opioids are naturally occurring peptides with various types of opioid activity. They are produced after the cleavage of high-molecular-weight precursors. This group includes endorphins, enkephalins, and dynorphins or neoendorphins. They are found at various sites and in differing quantities throughout the central and peripheral nervous system. Complex interactions with multiple opioid receptors result in modulation of the response to painful stimuli. More recently, two tetrapeptides have been described and dubbed “endomorphins” due to their high affinity to μ opioid receptors, making them good candidates as endogenous ligands of these receptors.²⁵

FIGURE 33-2 Chemical structures of the main opiate/opioid molecules.

PHARMACODYNAMICS

The clinically used opioids exert a common activity profile, mainly through μ opioid receptors. The central analgesic action of opioids is the most important property used in therapeutics.²⁶ These antinociceptive effects are mediated through spinal and supraspinal opioid receptors. Analgesia occurs without loss of consciousness. Given to patients in pain, opioids reduce the pain, while drowsiness commonly occurs and euphoria may be experienced. Given to normal pain-free subjects, opioids may induce nausea, vomiting, drowsiness, apathy, or lessened physical activity.

Mood alterations including euphoria, tranquility, and rewarding properties may follow opioid administration. Their mechanism is still not clearly understood but seems mediated by dopaminergic pathways, independently from those involved in physical dependence and analgesia. Pinpoint miosis is a near pathognomonic consequence of opioids on the parasympathetic innervation of pupils. The cough reflex is depressed through a direct action on the cough center in the medulla. This antitussive action represents the target effect of some opioid agents. Nausea and vomiting are caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla.

Opioids may be responsible for respiratory depression, mainly by a direct effect on the brainstem respiratory centers. Opioids may also depress the pontine and medullary centers involved in regulation of respiratory rhythmicity. With usual opioid doses, in the absence of underlying pulmonary or neurologic diseases, clinically significant respiratory depression is rare, unless other psychotropic or sedative medications are concomitantly used. Respiratory depression increases with the dose and is the incriminated mechanism of death following opioid overdose. All phases of respiration may be depressed, including respiratory rate and tidal and minute volumes. Following an intravenous (IV) injection of morphine, maximal respiratory depression is obtained within 5 to 10 minutes. High doses of certain opioids (fentanyl, alfentanil, remifentanyl, and sufentanyl) may produce acute muscular rigidity, involving the trunk and the chest wall, sometimes compromising respiration. The mechanism for this is still debated and may involve basal ganglia dopamine receptor blockade, α_2 -adrenergic or δ opioid receptor stimulation. In patients undergoing anesthesia, muscle rigidity may necessitate the administration of neuromuscular blocking agents to facilitate mechanical ventilation.

Endocrine effects have also been reported, including the inhibition of gonadotropin-releasing hormone and corticotropin-releasing factor production, inducing a diminution in concentrations of luteinizing hormone, follicle-stimulating hormone, adrenocorticotropic hormone, and β -endorphin circulating. Antidiuretic hormone release is also reduced. Opioids increase the muscular tonus of the gastrointestinal (GI) tract and diminish peristaltic contractions. They also diminish biliary, pancreatic, and intestinal secretions, but increase anal sphincter tone. Intestinal resting tone is increased and

spasms may result. All these effects induce desiccation of the feces, leading to constipation and the therapeutic use of some opioid compounds as antidiarrheic substances. Opioids also increase bladder external sphincter tone, resulting in urinary retention, sometimes requiring bladder catheterization.

Opioid-related cardiovascular side effects are well known: mild reduction in blood pressure, risk for orthostatic hypotension, or, uncommonly, bradycardia. Only propoxyphene is associated with significant cardiovascular toxicity due to sodium channel blockade. Opioids also induce peripheral vasodilatation at therapeutic doses. The skin of the face, neck, and upper thorax may flush due to histamine liberation. The immune system also may be considered a potential therapeutic target of opioids, including central immunomodulatory activity or direct effects on immune cells. This latter effect is related to an activation of δ opioid receptors expressed on peripheral blood cells. Met-enkephalin and β -endorphin may stimulate the chemotactic properties of neutrophils, monocytes, or lymphocytes. In contrast, morphine reduces the activity of natural killer lymphocytes and neutrophil activity. The latter immunosuppressive effects appear to be mediated through μ receptors.²⁷

Prolonged treatment with opioids may induce a tolerance to their effect, characterized by the loss of their effectiveness and the necessity to increase doses to obtain the same effects. Dependence on opioids is responsible for the appearance of withdrawal when the opioid therapy is abruptly stopped. Addiction results from an altered behavior with the compulsive use of opioids and an overwhelming need for their procurement and use. The molecular mechanisms of dependence and tolerance appear very complex, involving opioid and *N*-methyl-D-aspartate receptors. These pathways are physiologic responses to opioid treatments and may be distinct from those involved in addiction.

Morphine, tramadol, meperidine, fentanyl, and related opioids are used primarily for their analgesic properties. Codeine is used widely for its antitussive action. Given their dynamic and kinetic properties, methadone (with a long half-life) and buprenorphine (with partial μ agonist activity) are used as maintenance therapies in heroin abusers. Naloxone, the therapeutic antagonist of reference, is used to reverse neurologic and respiratory depression induced by acute opioid poisoning.

OPIOID RECEPTORS

The International Union on Receptor Nomenclature has recently recommended a nomenclature change from the historical Greek alphabet to one similar to other neurotransmitter systems, the receptors δ , κ , and μ , becoming OP_1 , OP_2 , and OP_3 , respectively.²⁸

1. *The μ opioid receptors (OP_3)*. The μ receptors were the first opioid binding sites described, in relation to morphine agonist activity and high affinity.²⁹ Morphine has a 50-times higher affinity for μ receptors in comparison with other opioids. Fentanyl

and other piperidyl agonists also have good affinity and selectivity for μ receptors (Table 33-1).

Naloxone is the only clinically used opioid receptor antagonist, with a higher affinity for the μ than for the other receptors.³⁰ Other antagonists also have good selectivity for μ receptors (Fig. 33-3).

μ Receptors are further classified into μ_1 and μ_2 subclasses (Table 33-2). The μ_1 receptors found in the periaqueductal gray matter, the nucleus raphe magnus, and the locus caeruleus are postulated to have supraspinal analgesic properties. The μ_1 receptors are responsible for almost all opioid analgesic properties, and to some extent, their side effects. The μ_2 receptors, characterized by a lower affinity for opioids than μ_1 , are responsible for the untoward side effects of opioids, including respiratory depression, delayed GI motility (nausea, vomiting, and constipation), urinary retention, bradycardia, miosis, euphoria, and physical dependence.

2. *The κ receptors (OP_2)*. The κ agonists produce analgesia that is unaffected by tolerance or antagonists to μ receptors (see Table 33-2). The κ_1 receptors appear to be concentrated in the spinal cord, whereas κ_2 and κ_3 receptors appear to predominate in the supraspinal region. They may even outnumber μ receptors in that region. Untoward effects of κ stimulation include respiratory depression (less than μ), miosis, dysphoria, and psychotomimetic effects.
3. *The δ receptors (OP_1)*. The δ receptors mediate spinal analgesia, specifically via thermal nociception. Both enkephalins and β -dynorphin bind to this class. The δ receptors also have a cortical distribution and may have a role interacting with centrally located μ receptors. Untoward side effects include respiratory depression via decreased respiratory rate.²⁹

All these opioid receptors have now been cloned and sequenced. They each consist of seven transmembrane segments (Fig. 33-4). The molecular conformations of the opioid receptors play an important role in their activity.^{31,32} All the opioid receptors belong to the G-protein-binding superfamily, with significant sequence homology between their transmembrane regions. However, important differences exist within their intracellular and extracellular segments, determining the differences in their binding properties (Table 33-3). Different mechanisms of cellular transduction are now described, depending not on the receptor type but on its localization. The G-protein structure contains three subunits (α , β , γ), from which the $\beta\gamma$ subunit is liberated on the binding of the α subunit to guanosine triphosphate. The $\beta\gamma$ is then able to activate various effector systems, including phospholipase C, adenylate cyclase, other channels, or transport proteins (Fig. 33-5). The main postsynaptic signal transduction mechanism is based on the inhibition of the adenylate cyclase, mediated by inhibitory G proteins (G_i), associated with μ , κ , and δ opioid receptors.^{33,34} Opening of potassium channels may result from opioid receptor stimulation, yielding membrane hyperpolarization and neuronal excitability reduction.^{35,36} On the presynaptic membrane, the opioid receptor activation is associated with a closure

of N-type calcium channels, resulting in a reduction of intracellular calcium concentration at the end of the synapse and leading to the blockage of presynaptic vesicle fusion with the terminal membrane and the reduction in neurotransmitter release.³⁷

PHARMACOKINETICS

Opioids are available in numerous formulations, allowing various routes of administration, including oral, parenteral, transdermal (fentanyl), transmucosal (morphine

κ_3	Nalorphin		Supraspinal analgesia

*Leverphanol and etorphin are nonspecific agonists of the three opioid receptor types, whereas naloxone and naltrexone are nonselective antagonists of these three receptor types.

and hydromorphone), epidural, intrathecal, intranasal, and even intrapulmonary (by smoking) administration. In opioid overdoses, dosage, duration, and route of administration may influence symptoms and their duration. Thus, considering opioid pharmacokinetic properties is useful in understanding their toxicologic

consequences and choosing the best methods of treatment.

Variable reduction in bioavailability results from first pass metabolism when absorbed through the GI tract. Morphine bioavailability by the oral route is only 25%, in contrast to codeine at 60%. Buprenorphine undergoes

A

B

extensive first pass metabolism after oral administration, making the sublingual route mandatory for a bioavailability of 50%.³⁸

Protein binding and any interaction that alters it also play a vital role in pharmacodynamics. The range of protein-bound opioid varies from a low of 7% for

codeine to greater than 90% for methadone and buprenorphine. Depression in albumin and other serum proteins (α - or β -globulin) resulting in decreased binding may produce higher levels of free opioid with possible opioid toxicity. Changes in serum pH may also alter protein binding of opiates. Transport system

proteins, such as P-glycoproteins, may also influence tissue distribution. Crossing the blood-brain barrier is dependent on lipid solubility and polarity and influences clinical effects. Heroin (diacetylmorphine) enters the brain more readily than both of its metabolites, 6-monoacetylmorphine (6-MAM) and morphine, explaining its greater addictive potential.

Opioids generally undergo hepatic metabolism with some form of conjugation, hydrolysis, oxidation, or dealkylation. Some of the resulting metabolites have been implicated in the activity or recognized toxic side effects of various opioids. Examples of this include the metabolism of codeine to morphine, morphine to the more active morphine-6-glucuronide, buprenorphine to norbuprenorphine, meperidine to the potentially neurotoxic normeperidine, and propoxyphene to the potentially cardiotoxic norpropoxyphene. Figure 33-6 illustrates the metabolism of buprenorphine, which undergoes extensive cytochrome P-450 3A4-mediated *N*-dealkylation to norbuprenorphine and then glucuronidation.³⁹ Cytochrome genotype appears to be an important parameter in opioid efficacy or toxicity. Small doses of codeine, which is bioactivated into morphine by cytochrome P-450 2D6, may be responsible for life-threatening intoxication in patients with allele patterns inducing ultrarapid metabolism, in combination with inhibition of cytochrome P-450 3A4 activity and a transient reduction in renal function.⁴⁰

Excretion of opiates occurs primarily via the renal route, with about 90% of the opioid metabolites eventually being excreted in the urine, usually via glomerular filtration. A small amount may end up in the GI tract via enterohepatic circulation. The urinary detection of opioids or metabolites is a routinely used diagnostic test. The presence of 6-MAM in the urine is a reliable marker of recent heroin consumption, because humans cannot acetylate morphine but only deacetylate heroin. Renal failure leads to toxic effects via accumulated drug or active metabolites (morphine-6-

glucuronide or normeperidine). Hepatic dysfunction results in delayed liver metabolism of certain opioids (meperidine, pentazocine, and propoxyphene), leading to accumulation and development of central nervous system (CNS) or respiratory depression.

Drug interactions may occur at various sites affecting the absorption, metabolism (induction of hepatic enzymes), and elimination of opioids (competition for renal excretion) contributing to the potentiation or reduction of their effects. Acceleration of metabolism in the liver, which results from phenytoin induction, may result in diminished activity (methadone) or an increase in potentially toxic metabolites (normeperidine). The discontinuation of an interacting drug may play just as important a role as the addition of one in changing the bioavailability and activity of opioids. These interactions may lead to the onset of overdose or withdrawal symptoms. Interaction between buprenorphine and benzodiazepines, which is suspected to be one of the mechanisms of buprenorphine-related toxicity or fatality,⁴¹ has been attributed to a pharmacodynamic mechanism.⁴²

TOXICOLOGY

In general, a drug classified as an opiate or opioid elicits the same overall physiologic effects as morphine, the prototype of this group. However, there are conspicuous differences among these agents, which will be specifically addressed. Varying degrees of the classic “opiate toxidrome” (i.e., mental status depression, respiratory depression, miosis, and decreased bowel motility) may manifest in patients administered opioids.

Central Nervous System Effects

A dose of 5 to 10 mg of morphine usually produces analgesia without altering mood or mental status in a patient. Sometimes dysphoria rather than euphoria may

FIGURE 33-5 Regulation of the different cellular effectors by the opioid receptors MAPK (mitogen-activated protein kinases), AC (adenylate cyclase), PLC (phospholipase C), IP3 (inositol 1,4,5 triphosphate), and PIP2 (phosphatidylinositol 4,5 biphosphate).

FIGURE 33-6 Liver metabolism of buprenorphine (Bup), as demonstrated *in vitro*, using liver microsomes. Various cytochromes P-450 (CYP) are involved, resulting in the production of a predominant active metabolite, the norbuprenorphine (Norbup). Other metabolites (M1 to M5) are also produced, but their role and importance *in vivo* are unknown. (From Chang Y, Moody DE, McCance-Katz EF: Novel metabolites of buprenorphine detected in human liver microsomes and human urine. *Drug Metab Dispos* 2006;34(3):440–448.

manifest, resulting in mild anxiety or a fear reaction. Nausea is frequently reported, whereas vomiting is occasionally observed. The clinical effects of morphine are accentuated with increasing doses (e.g., analgesia is stronger, lethargy and drowsiness progress to sleepiness and coma). Slurred speech and significant motor incoordination are usually absent.

Morphine and most of its congeners cause pupillary constriction. This effect is predominantly a central effect and is accentuated following an overdose. Not all patients taking opioids present with miosis. Patients taking meperidine or propoxyphene regularly maintain normal pupillary size, and patients taking pentazocine may not develop miosis.⁴³ Mydriasis may occur in severely poisoned patients secondary to hypoxic or anoxic brain injury. Combination drug use such as cocaine and heroin (“speedball”), scopolamine-adulterated heroin, and Lomotil (diphenoxylate hydrochloride and atropine sulfate; Pfizer, New York, NY) or the presence of adulterants may produce variable pupil size depending on the relative contribution by each agent.

Cerebral circulation does not appear to be altered by therapeutic doses of morphine, unless respiratory depression and carbon dioxide retention result in cerebral vasodilation.⁴⁴ Seizures are rare adverse drug events associated with most therapeutic opioid dosing. In an acute opioid overdose, seizures are most likely to be caused by hypoxia. Morphine-induced seizures have only been reported in neonates,⁴⁵ and seizures should be anticipated in patients with meperidine, propoxyphene, or tramadol toxicity.

Respiratory Effects

Respiratory failure is the most serious consequence from opioid overdose. Opioids reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors in the respiratory centers to an increase in carbon dioxide tension (P_{aCO_2}) and depress the ventilatory response to hypoxia.⁴⁶ The combined diminution in hypercapnic and hypoxic drive leaves virtually no stimulus to breathe, and apnea ensues. Even small doses of morphine depress respiration by directly affecting the brainstem respiratory centers. Morphine-induced respiratory depression initially relates more closely to changes in tidal volume and a reduction of respiratory rate with escalating doses.^{30,44} The peak respiratory depressant effect is usually noted within 7 minutes of IV morphine administration, and may be delayed for up to 30 minutes if the drug is administered intramuscularly. Normal carbon dioxide sensitivity usually returns within 2 to 3 hours, while minute volume may remain below normal for up to 5 hours following a therapeutic dose.⁴⁷

Cardiovascular Effects

Therapeutic opioid doses cause arteriolar and venous dilation and may result in a mild decrease in blood pressure.⁴⁸ This change in blood pressure is clinically insignificant while the patient is supine, but significant orthostatic changes are common.⁴⁹ Hypotension appears to be mediated by histamine release⁵⁰ and may be related to the nonspecific ability of certain opioids to activate mast cell

G protein,⁵¹ which induces degranulation of histamine-containing vesicles. The combination of H_1 and H_2 antagonists appears to be effective in ameliorating the hemodynamic effects of opioids.⁵² Not all opioids are equivalent in their ability to release histamine. In one study, meperidine produced the most, and fentanyl the least, hypotension and elevation of plasma histamine levels.⁵³

Bradycardia is unusual, but a reduction in heart rate is common as a result of the associated reduction in CNS stimulation. Myocardial damage (necrotizing angitis) in opiate overdose associated with prolonged hypoxic coma may be mediated by cellular components released during rhabdomyolysis, direct toxic effects, or hypersensitivity to the opioids or adulterants.⁵⁴

Gastrointestinal Effects

Therapeutic use of opioids, morphine in particular, produces significant nausea and vomiting.⁵⁵ It is mediated through agonism at dopamine-2 receptor subtypes within the chemoreceptor trigger zone of the medulla. Opioid-induced constipation is an adverse drug event of both the therapeutic and recreational use of opioids. It is mediated by μ_2 receptors within the smooth muscle of the intestinal wall. Morphine and related drugs may cause a delay in the passage of gastric contents through the pylorus up to 12 hours and marked decrease in intestinal peristalsis.

SPECIFIC OPIOIDS

Heroin

Heroin has two to five times the analgesic potency of morphine, with similar effects on the CNS.⁵⁶ Virtually all street heroin in the United States is produced in clandestine laboratories and is adulterated prior to distribution. The purity of street heroin is between 5% and 90%, and is usually less than 50%.⁵⁷ Adulterants may include noscapine, caffeine, procaine, various sugars, phenobarbital, methaqualone, quinine, and acetaminophen in combination with caffeine.^{58,59} Heroin is generally bought by the “bag” (25 mg) or quarter gram and may also be mixed with other drugs of abuse (e.g., “speed ball”). Purity and adulterants may play a considerable role in the outcome and complications of heroin use. Interindividual variation in sensitivity and tolerance makes correlation of serum heroin levels with clinical symptoms difficult.

Heroin is available as either a hydrochloride salt or a base, with the base being the prevalent form in most regions of the world. The hydrochloride salt form is typically a white or beige powder and is highly water soluble, which allows simple IV administration. Heroin base is often brown or black in color, and “black tar heroin” is one designation referring to an impure form available in the United States. Heroin base is virtually insoluble in water, and requires heating until it liquefies prior to IV administration. This process involves heating the powder in a spoon or bottle cap until it is dissolved, passing the heroin through cotton or a cigarette filter

into a syringe, and boiling the cotton or filters to extract additional drug. The filtered heroin and the extract are injected IV or subcutaneously (“skin popping”). Some drug users may become acutely ill with a benign febrile, leukocytic syndrome following an IV injection. This condition is known as “cotton fever,” and its etiology has been attributed to bacteremia following injection of *Enterobacter agglomerans* that has colonized in the cotton or cigarette filters.⁶⁰

Heroin may also be taken intranasally (snorted) and by inhalation of heated vapors. Inhalation of heated vapors is known as “chasing the dragon,” “Chinesing,” or “Chinese blowing,” and involves placing heroin base on aluminum foil, heating it from below with a flame, and inhaling the thick white pyrolysate through a straw. The bioavailability of heroin administered by this route is comparable with that of heroin administered by other routes, and the clinical and toxicological effects are dose dependent.^{61,62}

Physiologically, the effects of heroin are identical to those described for morphine.^{63,64} The plasma half-life of heroin is 5 to 15 minutes. Heroin is initially deacetylated in the liver and plasma and then is renally excreted as a conjugate, with small amounts of morphine, diacetylmorphine, and 6-MAM.⁶⁵ The initial heroin rush is probably due to its high lipid solubility and rapid penetration into the CNS.⁵⁶ The majority of its lasting effects are attributable to its metabolites 6-MAM and morphine.⁴⁹ Fatal overdoses with heroin have been reported with serum morphine concentrations of 0.1 to 1.8 $\mu\text{g}/\text{mL}$.⁶⁶

Acute lung injury (noncardiogenic pulmonary edema) as a complication of heroin overdose was first described by William Osler during an autopsy.⁶⁷ Its presentation and clinical course following nonfatal heroin overdoses were first described in 1953,⁶⁸ and later in case series and reports.⁶⁹ Patients with acute lung injury may present early on in their course; within 2 hours of parenteral heroin use and up to 4 hours following intranasal heroin use.^{66,69,70} Typically, the patient awakens from an opioid coma, either spontaneously or following an opioid antagonist, and over the subsequent several minutes to hours develops hypoxemia and pulmonary rales. Classic frothy, pink sputum is occasionally observed in the patient’s airway. Acute lung injury was reported in 48% of hospitalized heroin overdose patients⁷¹ and was noted in 50% to 90% of heroin overdose patients at postmortem examinations, many of whom died in a prehospital setting.^{72,73} Postmortem studies of patients who succumbed to heroin-induced acute lung injury showed no gross cardiac pathology.⁷⁴ The mechanism for acute lung injury may be multifactorial and includes profound hypoxemia, hypersensitivity reactions, immune complex deposition in the alveolar capillary membrane, histamine-induced capillary leakage, neurogenic sympathetic discharge, and transient lymphatic pumping irregularities.^{70-72,75-79}

A consequence of “chasing the dragon” is a progressive spongiform leukoencephalopathy and was first reported from the Netherlands.⁸⁰ The initial symptoms include pronounced motor restlessness (e.g., compulsion to move), apathy, bradyphrenia, soft (pseudobulbar)

speech, disturbed cerebellar speech, and ataxia. After 2 to 4 weeks some patients developed rapid worsening of the cerebellar symptoms (e.g., gait disturbance). Hyperactive deep tendon reflexes and pathologic reflexes with hypertonic hemiplegia or tetraplegia developed. Some patients developed tremor of the head and shoulders, and others developed myoclonic jerks or choreoathetoid movements. In most cases palmomental, snout, and oculomandibular reflexes became evident. Patients who did not deteriorate remained stable with subsequent partial improvement. Within the next 2 to 4 weeks some patients further progressed in their clinical course and developed stretching spasms, profuse perspiration, central pyrexia, and blindness. The spastic paresis became hypotonic and resulted in areflexia. Some patients developed akinetic mutism. All patients who had progress to this stage died, most because of respiratory difficulties. The mortality rate was 25%. Survivors have stabilized with severe deficits or shown modest degrees of improvement.^{81,82}

Heroin toxicity may be associated with cardiac conduction abnormalities and dysrhythmias,⁸³⁻⁸⁵ which may be the result of metabolic derangements associated with hypoxia, a direct effect of heroin or its metabolites or of adulterants.^{54,86,87} Quinine-adulterated heroin has been associated with dysrhythmias,^{88,89} amblyopia,⁹⁰ and thrombocytopenia.⁹¹ Patients exposed to heroin that has been adulterated with scopolamine may present in acute anticholinergic crisis.⁹² Surreptitious addition of cocaine to heroin may cause significant myocardial ischemia or infarction.⁹³ Other reported adulterants include thallium,⁹⁴ lead,⁹⁵ amphetamines,⁹⁶ chloroquine,⁹⁷ and strychnine.⁹⁸

Codeine

Codeine (methylnorphine) is available as a sole ingredient and in combination with aspirin or acetaminophen. Codeine is rapidly absorbed by the oral route, producing a peak plasma level within 1 hour of a therapeutic dose.⁹⁹ Ten percent of codeine is metabolized to morphine.¹⁰⁰ Both codeine and morphine appear in the urine within 24 to 72 hours, with only morphine being detected in the urine at 96 hours.⁹⁹ The effect of codeine on the CNS is comparable but less pronounced than that of morphine. An IV codeine phosphate dose of 750 to 900 mg produces symptoms similar to those seen with acute heroin overdose.¹⁰¹ Fatal ingestions with codeine alone are rare. The estimated lethal dose in a nonabuser is 800 mg, with a serum codeine concentration of 0.14 to 4.8 mg/dL.^{102,103}

Fentanyl

Fentanyl is a synthetic opioid with rapid onset of action and short duration of action, and has a potency 100 times that of morphine. It is highly lipid soluble and has a volume of distribution of 60 to 300 L.¹⁰⁴ Legitimate fentanyl use is limited to anesthesia and conscious sedation, and it has been abused mostly by medical and paramedical personnel because of limited access since it was first introduced. Numerous fentanyl analogs (e.g., α -

methylfentanyl [“China White”], 3-methylfentanyl, α -methyl-acetyl-fentanyl, α -methyl-fentanyl acrylate, and benzyl fentanyl) have been illicitly synthesized and distributed on the street as heroin substitutes.¹⁰⁵⁻¹⁰⁹ They can be 200 to 6000 times more potent than morphine. Toxic effects may be experienced with very small amounts. Typically, the patients present comatose and apneic. In such cases, unsuspecting users administer their usual “dose” of heroin, which surreptitiously contains variable amounts of an illicit fentanyl analog. A number of “heroin-related” deaths have been attributed to these agents secondary to marked increased potency compared with heroin.¹⁰⁶⁻¹⁰⁸

Rapid IV injection of certain high-potency opioids (e.g., fentanyl) may result in acute muscular rigidity primarily involving the trunk, and may impair chest wall movement and exacerbate hypoventilation. Similar effects contribute to lethality during epidemics of fentanyl-adulterated heroin.¹⁰⁷ Although motor activity resembling seizures has been associated with fentanyl use,¹¹⁰⁻¹¹² simultaneous electroencephalogram recording during fentanyl induction of general anesthesia did not show epileptiform activity.¹¹³⁻¹¹⁶ This suggests a myoclonic rather than epileptic nature of the observed muscle activity.¹¹⁵

Fentanyl is available as a patch; a transdermal delivery system establishes a depot of drug in the upper skin layers, where it is available for systemic absorption. After removal of the patch, drug absorption from the dermal reservoir continues and the effective fentanyl half-life is 17 hours, versus 2 to 4 hours associated with the IV route (Duragesic [fentanyl], Janssen Pharmaceutica, Piscataway, NJ). The availability of a transdermal fentanyl delivery system provides a widening pool of individuals with access. Prescribed transdermal fentanyl patches can be sold or stolen. Disabling myoclonus has been reported after several days of fentanyl therapy by the transdermal delivery system.¹¹⁷ Misuse and abuse of the fentanyl patch has been reported in the form of simultaneous application of multiple patches, ingestion, inhalation, and IV injection of the transdermal fentanyl patch contents, which has resulted in respiratory arrest and death.¹¹⁸⁻¹²⁴

Meperidine

Meperidine is a synthetic opioid and is chemically different from the traditional opiates. Although considered to possess strong analgesic properties when given by the parenteral route, it is less than half as effective if given by the oral route.¹²⁵ It appears to be a common drug of abuse among medical personnel, with few reports of meperidine poisoning or fatalities.¹²⁶⁻¹²⁸ Meperidine is metabolized in the liver primarily by *N*-demethylation to normeperidine, an active metabolite with half the analgesic and euphoric potency of meperidine, and twice the neurotoxic properties.^{129,130} Excretion is primarily through the kidneys as conjugated metabolites.¹³¹ Meperidine and normeperidine may be detected in either urine or serum.¹³¹ Meperidine toxicity

has been attributed to the accumulation of normeperidine in patients with renal impairment, which has an elimination half-life of 14 to 24 hours.¹³²⁻¹³⁴ However, when meperidine is used in large doses and at frequent dosing intervals, seizures may occur in patients with normal renal function.¹³⁵⁻¹³⁸

Meperidine also interacts with serotonin receptors by blocking presynaptic reuptake of serotonin. A potentially fatal form of serotonin syndrome may occur in patients on monoamine oxidase inhibitors (MAOIs) and is treated with meperidine.¹³⁹

Meperidine is the prototype for a series of homologs that are used as heroin substitutes. In a process to synthesize a meperidine analog, 1-methyl-4-phenyl-propionoxypiperidine (MPPP), as a heroin substitute, a clandestine drug laboratory inadvertently introduced 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) by incorrect heating of the synthetic mixture. When MPTP is introduced into the body, monoamine oxidase-B in glial cells metabolizes MPTP to MPP⁺, which selectively destroys dopamine-containing cells in the substantia nigra by inhibiting mitochondrial oxidative phosphorylation.^{140,141} MPTP contaminant led to an epidemic of severe parkinsonism among IV drug abusers (“frozen addicts”) within days of repeated injections.¹⁴²⁻¹⁴⁴

Diphenoxylate and Loperamide

Diphenoxylate is structurally similar to meperidine, with limited absorption from the GI tract that contributes to its strong local constipating effects, and is used in the management of diarrhea. Diphenoxylate (2.5 mg) is formulated with 0.025 mg of atropine sulfate (Lomotil). In therapeutic doses, the drug has no significant CNS effects. However, the standard adult formulation may result in significant systemic absorption and toxicity in children. One half tablet of Lomotil has been reported to cause serious toxicity in children.¹⁴⁵⁻¹⁴⁷ Signs and symptoms arising from a toxic ingestion may be delayed, prolonged, or recurrent.¹⁴⁷ This is related to the delayed gastric emptying effects inherent to both opioids and anticholinergics, and more important, the accumulation of the hepatic metabolite difenoxin, which is a significantly more potent opioid than diphenoxylate and possesses a longer serum half-life.^{148,149}

Loperamide, an over-the-counter antidiarrheal agent, is another meperidine analog with limited absorption from the GI tract, and appears to have a high safety profile.¹⁵⁰

Methadone

Methadone is a synthetic opioid commonly used in the treatment of chronic pain or detoxification, or as a maintenance substitute for opioid addiction, and is also sold on the streets.^{151,152} Methadone is well absorbed from the GI tract, resulting in a peak plasma level within 2 to 4 hours, with peak effect occurring within 2 hours.¹⁵³ It has an average half-life of 25 hours and may be

as long as 52 hours during long-term maintenance therapy.¹⁵⁴ Methadone and its inactive metabolite, an *N*-demethylated pyrrolidine, may be detected in either urine or plasma.¹⁵⁵ Its analgesic, sedative, euphoric, and respiratory depressive effects are comparable with those seen with analogous doses of morphine.^{156,157} In a nontolerant person, a 40- to 50-mg dose may produce coma and respiratory depression.^{155,158} Rapid escalation of methadone doses have been associated with choreo-athetoid movements and may be due to enhanced striatal dopamine release.¹⁵⁹ Unintentional pediatric poisoning with fatal consequences has occurred in situations in which parents on methadone maintenance treatment had improperly stored their methadone at home.¹⁶⁰ A protracted clinical course is expected following an overdose. There is a possible association between patients on very high doses of methadone and having torsades de pointes, particularly in a setting of additional dysrhythmia risk factors (e.g., hypokalemia).¹⁶¹ In these patients the mean daily methadone dose was 397 ± 283 mg and their mean QTc interval was 615 ± 77 msec.

Buprenorphine

Buprenorphine is a semisynthetic, highly lipophilic opioid, with 25 to 50 times more potent analgesic activity than morphine.¹⁶² Sublingual buprenorphine is well absorbed, with 60% to 70% of the bioavailability of the IV route. Buprenorphine is mainly metabolized in the liver by CYP3A4 to an active dealkylated metabolite, norbuprenorphine. There is no direct relation of buprenorphine's clinical effects with plasma concentrations.

Buprenorphine is a partial μ receptor agonist and a weak κ receptor antagonist, with ceiling effects. Dose-effect relationships, both in animals and humans, suggest a plateau of respiratory effects.¹⁶³ Buprenorphine shows a very slow dissociation from opioid receptors, and consequently, has a long duration of action. These pharmacologic properties appear to be of utmost importance regarding its safety for use in substitution treatment. They confer a low level of physical dependence and mild withdrawal symptoms on cessation after prolonged administration. Although respiratory depression can be prevented by prior administration of naloxone, buprenorphine is weakly antagonized by naloxone given after buprenorphine.¹⁶⁴

Buprenorphine 8 to 16 mg/day has been used in France as a maintenance treatment for opioid-dependent patients since 1996. In 2002, buprenorphine was approved by the Food and Drug Administration for the treatment of opioid addiction in certified physicians' offices. A mixture of buprenorphine and naloxone named Suboxone (Reckitt Benckiser Healthcare, Ltd., Hull, UK) is also available, designed to discourage IV use. Since the advent of office-based availability, buprenorphine has been successfully used for opioid detoxification, with a good safety profile.^{10,11} In France, the introduction of high-dose buprenorphine coincided with a decrease in opiate/opioid poisoning mortality

rates.⁵ In the United States, restricted conditions for drug prescription (no more than 30 patients per qualifying certified physician) have resulted in little abuse since its launch.²¹

As with other opioids, buprenorphine intoxication includes coma, respiratory depression, and pinpoint pupils. Several deaths have been associated with buprenorphine misuse or psychotropic drug coingestion, including benzodiazepines.¹⁴ However, forensic determination of the exact role of buprenorphine in the death process appears difficult, because other factors may be involved (and potentially unknown), including substitution modality and concomitant intake of other drugs.²⁰ Moreover, the exact mechanism of interaction between buprenorphine and benzodiazepines (often implicated in buprenorphine deaths) is unknown.¹⁶⁵ The clinical role of drugs that interact with CYP3A4 and that may modify production of norbuprenorphine (an active metabolite with more potent respiratory depressant effects) is unknown.

Propoxyphene

Propoxyphene is structurally related to methadone, and toxicity has resulted in significant morbidity and mortality.¹⁶⁶⁻¹⁶⁸ It is available alone or in combination with aspirin or acetaminophen. Oral administration is followed by rapid absorption, with peak serum levels occurring within 1 hour.¹⁶⁹ The plasma half-lives of propoxyphene and its main active hepatic metabolite norpropoxyphene are 6 to 12 hours and 37 hours, respectively. Norpropoxyphene is also the primary metabolite excreted in the urine and is believed to play a role in the prolonged clinical course following an overdose.^{170,171} Prominent cardiovascular effects may occur with propoxyphene toxicity and manifest by wide-complex dysrhythmias and negative contractility through sodium channel antagonism similar to that of type IA antidysrhythmic agents. Propoxyphene appears to be responsible for both CNS (e.g., respiratory depression and seizures) and cardiac toxicity (e.g., QRS prolongation, negative inotropy, and dysrhythmias), whereas norpropoxyphene contributed only to the cardiotoxicity.¹⁷²

The clinical course following an overdose may be severe and rapidly progressive, with cardiac dysrhythmias, circulatory collapse, seizures, and respiratory arrest developing within 1 hour.¹⁷³⁻¹⁷⁸ Propoxyphene toxicity may result in focal and generalized seizures.^{176,178} The minimum toxic dose reported is 10 mg/kg, and 20 mg/kg is considered potentially fatal,¹⁷⁹ but tolerance develops with chronic use. Doses of 1000 to 2000 mg may be ingested or injected with minimal signs of intoxication in chronic propoxyphene abusers and heroin addicts.^{178,180-182} Blood levels in fatal overdose cases range from 0.1 to 2.5 mg/dL.^{167,168}

Pentazocine

Pentazocine is a synthetic analgesic class with both agonist and weak antagonist activity at the opioid

receptors.¹⁸³ The physiologic effects of pentazocine are similar to morphine, and with one third of its analgesic potency.¹⁸³ When administered by the oral route, peak plasma pentazocine levels occur within 1 hour.¹⁸⁴ Pentazocine is extensively metabolized in the liver,^{183,184} with the parent compound and metabolites detectable in either urine or plasma.¹⁸³ Anxiety, dysphoria, and hallucinations may be more common with pentazocine than with other opiate derivatives.¹⁸³

Pentazocine (Talwin, Sandoz, Princeton, NJ) is associated with a fairly specific scenario of parenteral abuse when used in combination with the antihistamine tripeleminamine (Pyribenzamine, Novartis, Basel, Switzerland), a blue capsule. This combination forms a street product known as “T’s and blues” and, once solubilized and injected, was used as a heroin substitute that was previously popular among addicts because of its heroin-like “rush” and lower cost.¹⁸⁵⁻¹⁸⁷ Newer combination street products, such as pentazocine with methylphenidate, have been reported.¹⁸⁸ Acute toxicity results in the typical opiate intoxication syndrome, as well as dyspnea, hyperirritability, hypertension, and seizures. It is believed that these effects may be directly related to the tripeleminamine dose.^{186,189,190}

In an effort to curtail IV pentazocine abuse, the oral preparation was reformulated to contain 0.5 mg of naloxone (Talwin-NX, Sandoz, Princeton, NJ).¹⁹¹ The naloxone component is inactivated when taken orally, and avoids withdrawal symptoms. However, when Talwin-NX is parenterally administered, pentazocine’s effects are antagonized by naloxone, which causes withdrawal in opiate-dependent individuals. Because pentazocine’s duration of action exceeds that of naloxone, delayed respiratory depression may occur.

Dextromethorphan

Dextromethorphan, an analog of codeine and the optical isomer of levorphanol (a potent opioid analgesic), is found in a large number of nonprescription cough and cold remedies. Within the therapeutic dose, dextromethorphan lacks analgesic, euphoriant, and physical dependence properties.¹⁹² Dextromethorphan is formulated as the hydrobromide salt. It is available as a single ingredient or in combination with decongestants (sympathomimetics) and antihistamines. Dextromethorphan is well absorbed from the GI tract, with peak plasma levels occurring 2.5 and 6 hours after ingestion of regular and sustained-release preparations, respectively. The therapeutic effect lasts 3 to 6 hours, with a corresponding plasma half-life of 2 to 4 hours. The predominant antitussive effect is attributed to the active metabolite dextrorphan.¹⁹³

Over-the-counter access appears to be the primary reason for its popularity in abuse, although its abuse pattern seems to be self-limiting due to adverse drug events, such as lethargy, somnambulism, and ataxia, after a few weeks of abuse.¹⁹⁴ Dextromethorphan abuse appears to be associated with a psychological rather than a physiologic dependence syndrome.¹⁹² Recreation dextromethorphan abusers report increased perceptual awareness, altered time perception, euphoria, and visual

hallucinations.¹⁹⁴⁻¹⁹⁶ Long-term dextromethorphan use may result in bromide toxicity.¹⁹⁷ Since dextromethorphan frequently appears in combination products, the contribution of these co-ingestants should be considered in assessing overdose or abuse cases.

Dextromethorphan blocks presynaptic serotonin reuptake and may elicit the serotonin syndrome in patients on MAOI therapy.^{198,199} Interaction between dextrorphan and the “ σ receptor” produces a phencyclidine-like dysphoria.²⁰⁰ The metabolism of dextromethorphan to dextrorphan is dependent on CYP2D6 activity, an enzyme with a significant genetic polymorphism. Patients who express extensive metabolizer polymorphism appear to experience more drug-related psychoactive effects, whereas patients with poor metabolizers experience more adverse effects related to the parent compound.²⁰¹ Occasionally, a patient may experience choreoathetoid or dystonia-like movements while on dextromethorphan.²⁰²

Tramadol

Tramadol is structurally similar to morphine and has both opioid and nonopioid mechanisms responsible for its clinical effects. It is a centrally acting analgesic with moderate affinity for μ opioid receptors. However, the metabolite *O*-demethyl tramadol appears to have a higher affinity than the parent compound for the same receptors. In therapeutic doses, tramadol does not appear to produce significant respiratory depression or have significant cardiovascular effects. Most of the analgesic effects are attributed to the nonopioid properties of the drug. Tramadol may exert its analgesic effect by blocking the reuptake of biogenic amines (e.g., norepinephrine and serotonin) at synapses in the descending neural pathways, which inhibits pain responses in the spinal cord.²⁰³ Serotonin syndrome may develop in patients concurrently taking tramadol and serotonin reuptake inhibitor medication.^{204,205} Seizures may occur during therapeutic dosing.²⁰⁶

BODY PACKERS

The transportation of illicit drugs by internal concealment is an important means of international smuggling, with accounts of body packing worldwide. Body packers are sometimes called “mules,” “swallowers,” “internal carriers,” or “couriers.” These are people who transport large numbers of meticulously prepared illicit drug packets in their GI tracts across borders with the intent to sell or receive compensation for transporting the drug. Typically, the packets contain either concentrated cocaine or heroin. If one of these packets ruptures, the amount of drug released may cause life-threatening toxicity.^{207,208}

CLINICAL MANIFESTATIONS

Mental status depression, respiratory depression, miosis, and decreased bowel motility are the hallmarks of opiate intoxication, with the magnitude and duration of toxicity

dependent on the dose and individual degree of tolerance. The clinical effects of an overdose with any one of the agents in this class are similar. However, as discussed, there are important differences between certain drugs. Overdoses resulting in toxicity often have a prolonged clinical course, partially due to an opioid-induced decrease in GI motility and prolonged half-life of the drug or its active metabolites.

Miosis is considered a consistent finding in opioid poisoning, with the exception of meperidine, propoxyphene, petazocin, dextromethorphan use, in case of a mixed overdose with an anticholinergic or sympathomimetic drug, or when severe acidemia, hypoxemia, hypotension, or a CNS structural disorder is present.

Patients presenting with CNS depression following an opioid overdose represent the most seriously intoxicated patients. However, codeine, meperidine, and dextromethorphan intoxications are remarkable for CNS hyperirritability, resulting in a mixed syndrome of stupor and delirium. In addition, patients with meperidine toxicity may also have tachypnea, dysphoric and hallucinogenic episodes, tremors, muscular twitching, and spasticity,^{126,132,133,135} whereas patients with dextromethorphan toxicity may also manifest restlessness and clonus.^{196,209-212}

Acute lung injury after heroin overdose may not be unique. It has been reported with overdoses of opioids that include methadone, propoxyphene, codeine, buprenorphine, and nalbuphine.^{76,102,103,189,213-222} Acute lung injury may not develop until 24 hours following methadone overdose.^{70,71,223,224}

Patients with heroin-induced acute lung injury typically have normal capillary wedge pressures and elevated pulmonary arterial pressures.^{224,225} In contrast, elevated systemic, pulmonary arterial, and pulmonary capillary wedge pressures and total systemic vascular resistance are seen with pentazocine intoxication.²²⁶ These effects are believed to result from transient endogenous catecholamine release.²²⁷ Signs and symptoms of heroin-induced acute lung injury usually resolve within 24 to 36 hours.^{69,228,229} Persistent pulmonary symptoms beyond 24 to 48 hours may indicate aspiration or bacterial pneumonitis, with atelectasis, fibrosis, bronchiectasis, granulomatous disease, or pneumomediastinum.²³⁰

Adulterants in street drugs are potential pulmonary toxicants.²³¹ The injection of adulterants such as talc (magnesium trisilicate) has produced granulomatosis in small pulmonary arteries, resulting in pulmonary thrombosis, pulmonary hypertension, and acute cor pulmonale.^{189,190,230,232} Other potential pulmonary complications associated with IV opioid use include pulmonary arteritis, septic emboli, lung abscess, bacterial pneumonia, aspiration pneumonitis, pulmonary edema, and respiratory arrest.

Seizures and focal neurologic signs are usually absent following opiate intoxication²³³ unless precipitated by severe hypoxia, dysrhythmia and hypotension, an intracranial process (e.g., brain abscess and subarachnoid hemorrhage), hypersensitive immune vascular injury or vasculitis, proconvulsive adulterants, meperidine, propoxyphene, pentazocine (T's and blues), or tramadol use.^{176,178,186,234-242} Normeperidine neurotoxicity may manifest as delirium, tremor, myoclonus, or seizures.

Meperidine- and propoxyphene-related seizures may be more frequent in chronic drug abusers with renal dysfunction.

Hypotension may occur following opiate overdose, although pentazocine intoxication may result in hypertension.¹⁸⁶ Heroin and propoxyphene toxicity may be associated with nonspecific ST-segment and T-wave changes, first-degree atrioventricular block, atrial fibrillation, prolonged QTc intervals, and ventricular dysrhythmias.^{83-85,173-175} Cardiovascular findings may be exacerbated by electrolyte abnormalities, metabolic derangements associated with hypoxia, or adulterants (e.g., quinine) in street drugs.

The anticholinergic and opioid effects may be significantly delayed, prolonged, or recurrent following a Lomotil overdose.^{147,243} The relevance of delayed toxicity is highlighted by a patient with an asymptomatic presentation 8 hours postingestion who was observed for several hours and discharged. This patient returned to the emergency department 18 hours postingestion with severe atropinism.²⁴³ Toxicity may manifest as a biphasic clinical syndrome, and patients may manifest anticholinergic toxicity (CNS excitement, hypertension, fever, flushed dry skin) before, during, or after opioid effects. However, opioid effects (CNS and respiratory depression with miosis) may predominate or occur without any signs of atropinism. Cardiopulmonary arrest has been reported to occur 12 hours after Lomotil ingestion.²⁴⁴

Patients presenting after a tramadol overdose may exhibit lethargy, nausea, tachycardia, agitation, seizures, coma, hypertension, and respiratory depression.²⁴⁰ Tramadol-associated seizures are brief, and significant respiratory depression is uncommon.

Interaction between meperidine and MAOIs, dextromethorphan and MAOIs, and tramadol and selective serotonin reuptake inhibitors may result in the serotonin syndrome.²⁴⁵⁻²⁴⁶ Patients with severe serotonin syndrome exhibit rapid onset of altered mental status, muscle rigidity, hyperthermia, autonomic dysfunction, coma, seizures, and death.

Rhabdomyolysis, hyperkalemia, myoglobinuria, and renal failure may complicate the clinical course of an acute opioid overdose or opioid dependence.^{86,247,248} Rhabdomyolysis has been reported following IV, inhalational, and intranasal heroin abuse.²⁴⁹ Acute renal failure may be due to direct insult by the abused substance, adulterants in the street drugs, and prolonged coma.^{86,247,248} Chronic parental drug use may result in glomerulonephritis and renal amyloidosis and has been associated with concurrent bacterial infections.²⁵⁰⁻²⁵³

Body packers are typically asymptomatic, but are at risk for delayed and prolonged toxicity from packet rupture.²⁵⁴ Symptomatic patients will exhibit the typical signs and symptoms of opiate intoxication. Body packers may also present with or develop signs and symptoms of intestinal obstruction, and occasionally intestinal perforation and peritonitis.²⁵⁵

Clandestine laboratories have produced exceedingly potent and toxic drugs as new manufacturing methods have been developed to circumvent the use of controlled or unavailable precursor compounds. As government

authorities stringently regulate these products and their precursors, new drugs and methods are designed to take their place.¹⁰⁵ Since these drugs may contain a wide variety of active ingredients, adulterants, and contaminants, the clinical syndromes seen in the abuser may be only partly related to the opioid component.

DIAGNOSIS

Laboratory Studies

Laboratory studies such as complete blood count, serum electrolytes, blood urea nitrogen, creatinine, creatine phosphokinase, urinalysis, arterial blood gas, electrocardiography, imaging studies, and lumbar puncture should be obtained as clinically indicated. Laboratory investigations should also include infections associated with IV drug abuse (e.g., endocarditis, aspergillosis, bacterial meningitis, cutaneous abscess, mycotic aneurism, intracranial abscess, epidural abscess, transverse myelitis, viral hepatitis, wound botulism, tetanus, osteomyelitis, and acquired immunodeficiency syndrome).

MANAGEMENT

Opioid toxicity should be part of the differential diagnosis in all comatose patients. However, the classic “opioid toxidrome” may not be apparent following a mixed overdose. Respiratory support is paramount in the management of patients with opioid toxicity; and the patient should be managed according to current advanced cardiac life support guidelines. Priorities include assessment and establishment of effective ventilation and oxygenation, followed by ensuring adequate hemodynamic support. Initial support with a bag-valve-mask (BVM) device is appropriate, along with 100% oxygen supplementation. Oral or nasal airway placement may be helpful, and caution is advised with their use given the potential for vomiting and/or aspiration. A suction apparatus should be available for immediate use at the patient’s bedside. Ventilatory support can usually be safely provided with a BVM device while awaiting the reversal of respiratory depression by an opioid antagonist. Endotracheal intubation is indicated in severely compromised patients in whom there is a real risk for aspiration or in patients who do not satisfactorily respond to opioid antagonists.

GI decontamination should be considered after vital signs have been stabilized. Opioids may cause decreased GI motility, and this suggests there may be some benefit to GI decontamination several hours postingestion. Gastric lavage may be of benefit in patients who are critically ill, do not respond to naloxone, are suspect of polypharmacy overdose, or have overdosed on Lomotil; retrieval of Lomotil pills as late as 27 hours postingestion has been reported.¹⁴⁷ In the obtunded patient, endotracheal intubation should be performed prior to the placement of the orogastric tube to minimize the risk of aspiration. Early administration of activated charcoal has been advocated as the sole GI decontamination procedure. Although the clinical benefits of multiple

oral doses of activated charcoal remain to be established, it has potential benefit because of the prolonged absorption phase typically encountered with opioid overdoses. Patients should be closely monitored for the presence of bowel sounds and passing of charcoal-laden stool. Repeat charcoal doses should not be used in the absence of active bowel sounds or in the presence of an ileus. Ipecac-induced emesis in patients with opioid overdose is not recommended given the potential for rapid deterioration and the risk for aspiration.

Naloxone is a pure competitive opioid antagonist at the μ , κ , and δ receptors, and has a greater affinity for the μ receptor than for the κ or δ receptors. It can reverse the analgesia, respiratory depression, miosis, hyporeflexia, and cardiovascular effects of opiate toxicity^{256,257} and is effective in terminating opioid-induced vomiting. The goal of naloxone therapy is to reestablish adequate spontaneous ventilation and maintain adequate airway reflexes without precipitating an acute withdrawal syndrome.²⁵⁸ Naloxone is relatively contraindicated in the pregnant patient, in whom precipitation of acute narcotic withdrawal may induce premature labor or miscarriage. However, this does not preclude judicious naloxone use in pregnant patients with severe respiratory depression. A judicious starting dose for IV naloxone may be 0.05 to 0.1 mg if the patient is possibly opioid dependent. Otherwise, an initial 2-mg dose can be administered. The recommended pediatric naloxone dose is 0.1 mg/kg, up to 2 mg. For high-potency opioids (e.g., fentanyl and its analogs) or opioids with a greater affinity for the κ or δ receptor (e.g., pentazocine, propoxyphene) a larger than usual dose of naloxone may be needed to successfully antagonize the opioid effects.²⁵⁹ Repeat IV naloxone boluses up to 10 to 20 mg should be considered if there is a history of opioid exposure, a strong clinical suspicion based on presenting signs and symptoms, or a partial response to the initial naloxone dose. Submental, intranasal, intralingual, endotracheal, intraosseous, intramuscular, and subcutaneous routes of naloxone administration are acceptable alternatives when vascular access is not readily available.²⁶⁰⁻²⁶⁴ However, intramuscular and subcutaneous injections are less desirable in the emergent situation. Repeat naloxone boluses may be required every 20 to 60 minutes because of its short elimination half-life (60 to 90 minutes) compared with that of most opioids.²⁶⁵ A continuous naloxone infusion may be considered in patients who have a positive response and require repeated bolus doses because of recurrent respiratory depression.²⁶⁶⁻²⁶⁸ A therapeutic naloxone infusion may be made up by multiplying the effective naloxone bolus dose by 6.6, adding that quantity to 1000 mL normal saline, and infusing the solution at 100 mL/hr. The infusion is titrated to maintain adequate spontaneous ventilation without precipitating acute opioid withdrawal and is empirically continued for 12 to 24 hours. The patient should be admitted to an intensive care setting where the patient will be frequently assessed during this time. After discontinuing the naloxone therapy, the patient should be carefully observed for 2 to 4 hours for recurrent respiratory depression. In the event of acute iatrogenic opioid withdrawal, allow the

effect of naloxone to abate and avoid administering additional opioids.

Clinical experience has demonstrated naloxone to be an extremely safe drug. It has been administered at a bolus dose of 5.4 mg/kg followed by infusion at 4 mg/kg/hr for 23 hours in the treatment of acute spinal cord injury.²⁶⁹ Although naloxone is ordinarily a safe drug, there have been reports ascribing acute lung injury,^{222,270-275} hypertension, cardiac dysrhythmias, and death to naloxone therapy.²⁷⁶⁻²⁷⁹ Typically, the patient has a depressed consciousness and respiration. After naloxone administration, the patient awakens and over minutes to hours is noted to become hypoxic with an adequate respiratory rate and to develop pulmonary edema. Pink, frothy sputum may be evident in the nasopharyngeal area. Acute naloxone-induced withdrawal has been associated with massive CNS sympathetic discharge, which may be a precipitating factor in the development of “neurogenic” pulmonary edema.²⁸⁰⁻²⁸² It appears that the pulmonary injury is at the alveolar-capillary membrane, resulting in manifestations consistent with acute respiratory distress syndrome.^{77,218} Abrupt heroin withdrawal precipitated by naloxone may contribute to the development of acute lung injury. However, it cannot be the only effect. Naloxone does not appear to directly alter the vascular permeability of the lung.²⁸³ Pulmonary edema was reported in 50% to 90% of the autopsies performed on heroin overdose patients, many of whom were declared dead in the prehospital setting and never received naloxone.^{72,73} In addition, opioid antagonist was unavailable when the initial cases of pulmonary edema were reported. A mechanical effect in which negative intrathoracic pressure generated by attempted inspiration against a closed glottis creates a large pressure gradient across the alveolar membrane and draws fluid into the alveolar space may be responsible for the observed association between naloxone administration and acute lung injury, similar to ventilator-associated pulmonary edema (Müller maneuver) prior to the advent of demand ventilators and neuromuscular blockers.²⁸⁴ Opioid poisoning may result in glottic laxity, prevent adequate air entry during inspiration, and may be especially prominent at the time of naloxone administration. This may result in breathing being reinstated prior to the return of adequate upper airway function.

Naloxone is effective in reversing diphenoxylate (Lomotil)-induced opioid toxicity, but recurrence of respiratory and CNS depression is common.²⁴³ All patients with significant diphenoxylate overdose should be admitted for monitored observation in the hospital for at least 24 hours.¹⁴⁷ Naloxone has been reported to reverse, though inconsistently, the CNS effects of ethanol, benzodiazepines, clonidine, chlorpromazine, and valproic acid following an overdose.²⁸⁵⁻²⁸⁸

Naloxone administration may “unmask” cocaine toxicity in patients using “speedballs”²⁸⁹ or anticholinergic toxicity in patients using heroin and scopolamine.²⁹⁰

Hypotension may respond to naloxone therapy, but may require fluid resuscitation and vasopressors. Overzealous fluid resuscitation should be avoided because of the risk for pulmonary edema. Cardiac

dysrhythmias should be managed according to current advanced cardiac life support guidelines. Sodium bicarbonate may be useful in treating cardiotoxicity from drugs with “quinidine-like effects” (type IA antidysrhythmics) that impair sodium channel functioning, manifested by widened QRS complexes, dysrhythmias, and hypotension. Sodium bicarbonate has been reported to be effective in narrowing the QRS complex in the setting of propoxyphene-induced wide complex dysrhythmias.²⁹¹ Sodium bicarbonate (1 to 2 mEq/kg) may be administered as an IV bolus over a period of 1 to 2 minutes. Greater amounts may be required to treat unstable ventricular dysrhythmias. Sodium bicarbonate boluses can then be repeated as needed with the end point of stabilizing or narrowing the QRS interval. Excessive alkalemia (pH greater than 7.55) and hypernatremia should be avoided.

Management of seizures should follow current treatment guidelines and should include benzodiazepines or barbiturates. Adjunct naloxone therapy may be effective in propoxyphene-²⁹² but not meperidine- or tramadol-related seizures. Experimental evidence suggests naloxone may potentiate normeperidine-induced seizures by inhibiting an anticonvulsant effect of meperidine.²⁹³ Naloxone appears to potentiate the anticonvulsant effects of benzodiazepines and barbiturates, and may antagonize the effects of phenytoin.²⁹⁴ Seizure has been reported immediately following naloxone administration for tramadol overdose.^{240,295} The tramadol package insert cautions against naloxone use in overdose situations.

The management of serotonin syndrome is primarily supportive. Sedation, paralysis, intubation and ventilation, anticonvulsants, antihypertensives, and aggressive rapid cooling may all be necessary. There has been some success with nonspecific serotonin antagonist cyproheptadine (4 to 8 mg every 8 hours orally).²⁹⁶

The occurrence of acute lung injury appears to be clinically unpredictable,^{70,71,76,297} and it has been suggested that a man in his late thirties who is a relatively inexperienced heroin user and has a Glasgow Coma Scale score of 4 to 5, has a respiratory rate of 6, and requires naloxone to maintain his respiratory drive in the prehospital setting would have a high likelihood of developing acute lung injury.²⁹⁸ It has been recommended to observe all patients for at least 24 hours following emergence from an opioid overdose. However, some clinicians suggest that 4 hours patient observation may be sufficient following a pure IV heroin or short-acting opioid overdose.^{69,299} An even shorter observation of at least 1 hour in an emergency department has been investigated and may be acceptable, and remains to be validated.³⁰⁰ This study suggests that patients with presumed opioid overdose can be safely discharged 1 hour after naloxone administration if they (1) can mobilize as usual, (2) have oxygen saturation on room air greater than 92%, (3) have a respiratory rate between 10 and 20 breaths per minute, (4) have a temperature between 35.0° C and 37.5° C, (5) have a heart rate between 50 and 100 beats per minute, and (6) have a Glasgow Coma Scale score of 15.

The management of acute lung injury should include adequate ventilation, oxygenation, and positive-pressure

ventilation as needed. Inotropic and chronotropic agents and preload- and afterload-reducing agents appear to be of little value. In one case series, the majority of patients only required supplemental oxygen, and 33% of patients required mechanical ventilation.⁶⁹

Asymptomatic body packers may be managed conservatively by the prograde route provided the condition of packaging does not appear to be compromised. Some clinicians suggest whole bowel irrigation with polyethylene glycol electrolyte lavage solution based on retrospective case series and case reports.^{207,301-303} A proposed method, based on more than 100 cases of cocaine body packers, together with more than 10 years' experience, suggests a safe and efficient method for the medical management of asymptomatic body packers. This same method may be applied to heroin body packers and involves the oral administration of a water-soluble contrast solution followed by serial abdominal radiographs (Box 33-1).^{304,305}

Body packers who develop opiate toxicity can often be managed with continuous naloxone infusion, activated charcoal, and whole bowel irrigation. Surgical intervention is indicated for patients with intestinal obstruction or perforation, and may be indicated when packets fail to progress through the GI tract after conservative management. Endoscopic retrieval of a few packets that are retained in the stomach may be considered, and should be performed by an experienced endoscopist.

Pruritis is a common opioid adverse drug event. It may be localized or general and range from mild to severe. Antihistamines are usually ineffective, but naloxone has frequently been found to offer relief. Ondansetron has been reported to provide relief in refractory cases.³⁰⁷

Treatment of spongiform leukoencephalopathy is supportive, and antioxidant therapy with coenzyme Q (30 mg four times daily), vitamin E (2000 mg daily), and vitamin C (2000 mg daily) has been advocated.³¹⁰

Constipation may be ameliorated by oral naloxone. Enteral naloxone is poorly absorbed, and opioid with-

drawal symptoms are usually not evident when the oral dose of naloxone does not exceed hepatic glucuronidase capacity.³⁰⁸ Methylnal-trexone is a quaternary ammonium molecule and is unable to cross the blood-brain barrier. It antagonizes the effects of opioids on the GI tract without precipitating opioid withdrawal.³⁰⁹

Forced diuresis and manipulation of urine pH have not been demonstrated to be of clinical benefit in opioid overdose. Hemodialysis may be indicated in patients with compromised renal function and are toxic from opioids or its metabolites (e.g., normeperidine) that depend on renal elimination.³¹⁰

OTHER OPIOID ANTAGONISTS

Nalmefene is effective for the reversal of opioid-induced CNS effects and may be administered orally or intravenously. Its half-life and dose-dependent duration of action are 4 to 8 hours following IV administration.^{311,312} The initial adult dose is 0.5 mg for those who are not opioid dependent and 0.1 mg for those suspected of having opioid dependency. If there is an incomplete response or no response, additional doses can be given at 2- to 5-minute intervals. A total dose of 1.5 mg may be necessary to exclude the possibility of opioid poisoning. Nalmefene has proven safety and efficacy in the management of meperidine-induced sedation and opiate overdose in the emergency department.³¹³⁻³¹⁵ The principal advantage over naloxone is its considerably longer duration of antagonistic action, which translates into fewer complications arising from fluctuations in the level of consciousness, reduced incidence of re sedation, better long-term control of longer-acting opiate ingestions, and fewer indications for naloxone infusions. Withdrawal syndrome precipitated by the use of nalmefene would also be prolonged.

Naltrexone is a potent, long-acting, pure opiate antagonist that is effective orally. Its use is primarily limited as adjunctive therapy for opioid detoxification. Naltrexone may induce a withdrawal syndrome lasting up to 72 hours.

DISPOSITION

The minimum observation period following a patient's emergence from an opioid overdose remains to be determined. Data seem to suggest that observation for 1 to 4 hours may be sufficient following a pure IV heroin or short-acting opioid overdose.^{69,299,300} Factors that favor extended observation or hospital admission include exposure to agents with long half-lives (e.g., methadone, L- α -acetylmethadol, propoxyphene, diphenoxylate, and buprenorphine); agents whose toxicity may be delayed, prolonged, or recurrent (e.g., diphenoxylate); large amounts of ingestant or co-ingestant; low tolerance to opioids (as compared to that of the chronic abuser); respiratory or cardiovascular instability; and comorbid conditions. Although administering an opioid antagonist can have a temporizing effect, overdose on an opioid with a long half-life (e.g., methadone) will significantly

BOX 33-1

MANAGEMENT OF ASYMPTOMATIC BODY PACKERS

Abdominal radiographs with oral contrast:

1. Administer an oral dose of water-soluble contrast (e.g., Gastrografin): 1 mL/kg.
2. Perform abdominal radiographs (supine and upright) at least 5 hours after oral contrast administration.
3. If radiographs are positive, administer an oral dose of 100 mL mineral oil twice daily.
4. Perform daily abdominal radiographs and after a spontaneous bowel movement.
5. All bowel movements are checked for drug packets.
6. The patient may be discharged after passage of two packet-free bowel movements and negative abdominal radiographs.

Patients are permitted to feed normally and vascular access should be maintained.

outlast several doses of naloxone and may require a continuous naloxone infusion or the use of nalmefene. Because of the potential for delayed onset and recurrent respiratory and CNS depression following naloxone therapy, it is recommended to observe patients for at least 24 hours. Patients who are on high-dose methadone therapy and have a prolonged QTc interval on ECG should be admitted to an intensive care unit because of its association with torsades de pointes and risk for sudden death.¹⁶¹

ACKNOWLEDGMENT

At a Glance...

- All sedative-hypnotics are not the same.
- Central nervous system depression is their main effect.
- Additive CNS effects occur with other CNS depressants.
- There is no specific antidote for any of the sedative-hypnotics.
- Plasma concentrations of these agents do not assist in management.
- Hemodialysis does not help in clinical management.

INTRODUCTION AND HISTORY

Sedative-hypnotic is a term that describes different medications that sedate or calm a person or induce drowsiness and sleep. The substances covered in this chapter are all chemically different from benzodiazepines and barbiturates (see Chapters 35 and 36). This chapter will focus on the multiple, diverse sedative-hypnotic drugs that are not structurally similar (Fig. 34-1).

Sedatives and hypnotics were among the earliest medications to be introduced into medical practice. Chloral hydrate was synthesized in 1832 and first used clinically starting in 1869. Deaths from this agent were reported as early as 1890.¹ Chloral hydrate, urethane, and paraldehyde were used prior to the introduction of barbital in 1903 and phenobarbital in 1912. As the physical dependence, withdrawal, and abuse potential of these agents began to be appreciated, a search was made for sedative-hypnotics that minimized these risks. Chlorpromazine, the first phenothiazine, was introduced in the early 1950s, and meprobamate, a bis-carbamate ester, was introduced in 1955. Other sedative-hypnotics were introduced during this time period that were presumed to have more selectivity and less abuse potential, including glutethimide, methyprylon (piperidine-diones), chlormezanone, ethinamate (urethane derivative), ethchlorvynol, and methaqualone (quinazolines and their derivatives).²⁻⁵

FIGURE 34-1 Chemical structures of sedative-hypnotics described in this chapter. (All structures drawn and identified using ChemIDplus, accessed at <http://chem.sis.nlm.nih.gov/chemidplus/>.)

Because of the high abuse potential, tolerance, and acute toxicity of the early sedatives and hypnotics, their use was eventually discontinued. Ethinamate, chlormezanone, methpyrlyon, paraldehyde, and methaqualone were withdrawn in the 1980s and 1990s. These agents had dependence and abstinence syndromes at least equal to those of the barbiturates, and intoxication was more difficult to manage. During the 1980s to 1990s, selective benzodiazepine receptor agonists were identified and synthesized, including zolpidem, zaleplon, zopiclone (not available in the United States), and alpidem. Zopiclone was first introduced in France in 1987. It was the first cyclopyrrolone hypnotic and was chemically unrelated to other existing sedatives. Ultimately, zolpidem and zaleplon were marketed in the United States. Alpidem was not marketed in the United States due to inconsistent results during clinical trials and was withdrawn from the French market in 1993 due to reports of hepatic toxicity.^{6,7}

Sedative-hypnotics are used worldwide, but overall use has steadily decreased since the 1980s. Over the years, barbiturate and benzodiazepine use has increased, replacing the older sedative-hypnotics. In the United States, American Association of Poison Control Centers (AAPCC) data show that exposures to sedative-hypnotics (nonbarbiturates and nonbenzodiazepines) decreased from 2000 to 2003 (Fig. 34-2). Exposures to chloral hydrate, however, remain steady, with approximately 220 toxic exposures reported per year. Fewer than five deaths per year from these agents were reported to U.S. poison centers from 2000 to 2003 (Fig. 34-3).⁸

In Australia, the ratio of female-to-male overdoses was 1.5 to 1. Most overdoses were from the barbiturate or benzodiazepine class, with a small percentage in the "other" class, but specific agents were not described.⁹ Chloral hydrate was noted in 0.3% of admissions and 3.5% of deaths from self-poisoning between 1987 and 1992.¹⁰ Chloral hydrate was 4.5 times as likely (odds ratio [OR] 4.5, confidence interval 2–10, 95%) to be used for self-poisoning and had a high likelihood of death (OR

58.1) between 1989 and 1992. In London, 3.1% of overdoses were with sedative-hypnotics, excluding benzodiazepines and barbiturates, during 1984 to 1988. The female-to-male ratio was 1.3:1 for all overdoses.^{11,12}

Chlormethiazole was the most popular medication for ethanol withdrawal in Great Britain during the mid-1980s, but its use was discontinued secondary to drug interactions. The drug exhibits cross-tolerance with ethanol, and with long-term use alcoholics readily transferred dependence and often used it while continuing to drink, resulting in a significantly increased mortality rate. There were 95.7 deaths per million prescriptions for this drug, which was twice that of chloral hydrate. By comparison, the newer less toxic alternatives zolpidem and zopiclone resulted in approximately 2 deaths per million prescriptions each.^{4,5}

During the late 1960s and early 1970s, 22% of overdose fatalities were due to glutethimide. Mortality approaches 20% after glutethimide-only overdoses and 17% in mixed ingestions, and is greater than any other drug in the sedative-hypnotic group.¹³

Meprobamate was the second most commonly prescribed sedative in the United States after barbiturates during this same time period, and was available in combination dosage forms containing anticholinergics, conjugated estrogens, antianginal agents, and antidepressants.^{14,15} In France, mortality from meprobamate overdose was approximately 2.6%.¹⁶ Until 1992, the drug was sold over the counter in some European countries, including Belgium. Moving it to prescription status decreased the number of meprobamate poisoning cases requiring admission from 120 to 18 per year.¹⁷

STRUCTURE AND STRUCTURE-ACTIVITY RELATIONSHIPS

The exact mechanism of action is unknown or unclear for many sedative-hypnotics. Some affect the γ -aminobutyric acid (GABA) chloride channel but differently from

FIGURE 34-2 Human exposures to selected sedative-hypnotics, 2000–2003, United States. (Data from WebTESS, American Association of Poison Control Centers, <http://webtess.aapcc.org>, accessed June 2004.)

FIGURE 34-3 Human deaths attributed to selected sedative-hypnotics, 2000–2003, United States. (Data from WebTESS, American Association of Poison Control Centers, <http://webtess.aapcc.org>, accessed June 2004.)

benzodiazepines and barbiturates. The primary metabolite of chloral hydrate is trichloroethanol (TCE), which seems to produce the main sedative-hypnotic effect. TCE affects the GABA_A receptor–ion channel complex similar to other sedative-hypnotic agents by altering chloride currents and decreasing excitability of neurons, but only when GABA is present. In addition, TCE inhibits ion currents activated by excitatory amino acids. This combined effect leads to central nervous system (CNS) sedation.¹⁸ TCE also sensitizes the myocardium to endogenous catecholamines and may induce arrhythmias, similar to other halogenated hydrocarbons.^{19–21}

Chlormethiazole similarly affects GABA_A-evoked currents in a dose-dependent fashion. It modulates the GABA receptor via a site separate from that of the benzodiazepines. At low doses it potentiates GABA-evoked responses; at high doses it directly activates the GABA receptor. Chlormethiazole prolongs the GABA channel burst duration similar to that of the barbiturates. In addition, chlormethiazole potentiates glycine-evoked currents. This potentially explains its efficacy in treating status epilepticus resistant to therapy with benzodiazepines or barbiturates.²² It does not seem to have any direct interaction with the *N*-methyl-D-aspartate receptor.⁴

Meprobamate potentiates GABA at the GABA_A receptors and also activates the chloride channel in the absence of GABA.²³

Zaleplon, zolpidem, and zopiclone are selective GABA_A benzodiazepine receptor agonists (type 1 omega-1).^{7,24} It is unknown at this time how this receptor site mediates pharmacologic activities.^{25–27}

The mechanisms of action for ethchlorvynol, glutethimide, and methyprylon are unknown. Glutethimide has an active metabolite, 4-hydroxy-2-ethyl-2-phenylglutarimide.

SPECIFIC DRUGS

The pharmacology and toxicology of the different sedative-hypnotics will be considered individually for

similar agents. The diagnosis and treatment sections consider all drugs together due to the similar diagnostic approach and management of all of these agents.

General Comments on Pharmacology and Pharmacokinetics

Absorption varies greatly between the sedative-hypnotic agents; some have significant first pass clearance. Due to their high lipid solubility, many of these agents can be described by a two- or even three-compartment model of distribution and eventual elimination. The initial plasma elimination reflects partitioning into fat stores, and the later slow elimination reflects gradual release from fat stores back into the plasma. All are extensively metabolized in the liver along complex multiple pathways and all are enzyme inducers. Specific pathways of metabolism have not been fully elucidated. Many agents have at least one active metabolite.^{1,7,14,15,24,28,29}

The pharmacokinetic parameters of selected agents are summarized in Table 34-1. It is noteworthy that with the exception of the newer agents, zaleplon and zolpidem, data from various studies with the older agents are inconsistent. See Table 34-2 for a summary of important drug interactions.

General Comments on Toxicology

The sedative-hypnotics generally produce drowsiness and sedation, hence their classification. Overdose of these agents is associated with sedation, dizziness, hypothermia, and hypotension that can progress to coma and respiratory depression. Patients may vomit and aspirate, leading to pneumonia or even death. In all of these patients, respiratory depression may lead to hypoxia, which could result in devastating neurologic injury if not recognized and treated. There are a few exceptions to this general picture, and there are a few additional findings with specific agents, which are described under the individual agents.

Adverse Effects

Physical dependence and cross-tolerance exists between many of these agents, and withdrawal symptoms have been reported after chronic use and abuse. Maternal administration has resulted in respiratory depression or withdrawal in neonates exposed for many of these agents, including chlormethiazole and ethchlorvynol.^{30,31}

Chloral Hydrate/Trichloroethanol

PHARMACOLOGY AND PHARMACOKINETICS

See Table 34-1.

SPECIAL POPULATIONS

For chloral hydrate, toxicity has been particularly pronounced in neonates due to accumulation and persistence of TCE for several days after chloral hydrate has been discontinued. Because TCE competes with bilirubin for protein binding sites and metabolic (glucuronidation)

TABLE 34-1 Pharmacokinetic Parameters of Selected Agents

	HALF-LIFE (hr)	Vd	RENAL EXCRETION	METABOLISM	PROTEIN BINDING %	BIOAVAILABILITY	PEAK (hr)
Chloral hydrate (<i>Noctec</i>)	Rapid reduction to TCE TCE 7–11, Avg 8		Less than 10% parent compound	Liver extensive Metabolized to trichloroethanol active metabolite and trichloroacetic acid	70%–80%		0.3–1
Chlormethiazole (investigational in USA)	2.6–8.9	0.28 L/kg	0.1–5%	Hepatic 70%–80% 2 inactive metabolites	56%–64%	10%–15% increase in liver disease	0.5
Chlormezanone (<i>Trancopal</i>) (TEN reactions led to discontinuation in 1996)	19–24	1.2 L/kg	40% less than 3% unchanged	Stomach-hydrolyzed Liver: hydrolysis and oxidation with nonglucuronide conjugation	48%–64%		1–2
Ethchlorvynol (<i>Placidyl</i>)	10–25	4 L/kg	Less than 10%				
Ethinamate (discontinued 1990 in USA)	1.9–2.5		36%	Extensive hydroxylation and glucuronidation			0.5–1.0
Glutethimide (<i>Doriden</i>)	Parent 11.6–13.5	1.6 L/kg	Less than 2% unchanged	2–3 active metabolites	47%–59%		1–6
Meprobamate (<i>Equanil, Miltown</i>)	9–11	0.5–0.8 L/kg	10%–20%	90% liver to inactive metabolites	0–30%		2–3
Methaqualone (<i>Mandrax</i>) (discontinued in 1983 in USA)	10–43 Avg 16		Feces 1%–4%	Site of metabolism to phenolic derivatives unknown	Parent highly protein bound	67%–99%	1–2
Methyprylon (<i>Noludar</i>) (discontinued by Roche in 1988)	9.2	0.97 L/kg	3% unchanged 60% metabolites	2 identified P-450 enzyme system, some dose dependency	38%	Assumed at least 90%	2
Paraldehyde (removed from U.S. market)	7.4	1.73 L/kg	0% unchanged	Liver: 70%–80% to acetaldehyde 30% exhaled via lungs		Well absorbed IM PO:93% PR:80%	
Zaleplon (<i>Sonata</i>)	1	1.4 L/kg	Less than 1% active, 71% inactive	CYP3A4 4 inactive metabolites	60%	30% first pass effect	1.1
Zopiclone	3.5–6	1.5 L/kg	4–5% parent Extensive metabolites	Extensive:1 active (<i>N</i> -oxide) 1: <i>N</i> -desmethyl (inactive)	45%	80%	1–1.5
Zolpidem (<i>Ambien</i>)	1.2–4	0.54 L/kg	Less than 1% active, 79%–96% inactive	Extensive No active metabolites	89%–92%	70%	1.6–2

IM, intramuscularly; PO, orally; PR, rectally; TCE, trichloroethanol; TEN, toxic epidermal necrolysis; Vd, volume of distribution.

systems, resulting in both impaired transport and elimination, it should be used with caution in neonates. There have been reports of indirect hyperbilirubinemia, apnea, and difficulty in weaning neonates from mechanical ventilation after chloral hydrate therapy.³²

DRUG INTERACTIONS

The prototypical drug interaction for this class of medications has been the interaction between chloral hydrate and ethanol. Chloral hydrate is rapidly converted to TCE.²¹ TCE successfully competes with ethanol for the dehydrogenase enzymes that metabolize ethanol, thereby decreasing elimination of ethanol. Ethanol stimulates NADH production and therefore increases the rate of chloral hydrate reduction to TCE by liver

alcohol dehydrogenase. This dual mechanism results in an increased production of TCE and decreased elimination of ethanol that is the basis for the toxicity of the “Mickey Finn.”³³ Other interactions with chloral hydrate are based on its ability to induce microsomal enzymes and displace other agents such as furosemide and warfarin from plasma protein binding sites.^{1,20} Chloral hydrate increases myocardial sensitivity to catecholamines, with the potential for inducing recalcitrant and fatal dysrhythmias when these agents are used. See section on Management below.²¹

TOXICOLOGY: MANIFESTATIONS

For chloral hydrate, cardiac toxicity is a hallmark of severe overdose, manifested by atrial and ventricular

**TABLE 34-2** Summary of Important Drug Interactions

SEDATIVE	INTERACTING MEDICATION	MECHANISM	RESULT	
Chloral hydrate	Ethanol	Competition for alcohol dehydrogenase system	Accumulation of trichloroethanol and elevated ethanol levels	
	Furosemide	Displacement of furosemide from protein binding sites	Cardiovascular toxicity	
	Warfarin	Displacement of warfarin from protein binding sites	Increased risk of bleeding	
Chlormethiazole	Cimetidine	Decreased metabolism	50% increase in half-life	
	Ethchlorvynol	Microsomal enzyme induction	Decreased prothrombin time	
	Glutethimide	Microsomal enzyme induction	Decreased prothrombin time	
	Meprobamate	Ethanol	Variable; increased sedation	
	Zaleplon	Cimetidine	Enzyme inhibition	Increased plasma concentration of zaleplon by 85%
Zolpidem	Rifampin	Enzyme induction	Decreased C _{pm} and AUC by 80% and increased clearance fivefold	
	Ritonavir	Decreased metabolism	Increased serum concentrations	
	Rifampin	Induction of CYP3A4	Decreased serum concentrations	
	(*both phenytoin and carbamazepine could potentially interact as well)			
	Ketoconazole	Inhibition of metabolism	Decreased clearance by 40%–65%	
Zopiclone	Sertraline, venlafaxine, bupropion, desipramine, fluoxetine	Unknown	Hallucinations	
	Oral contraceptives	Increased clearance	Decreased half-life of zolpidem	
	Cigarette smoking	Increased clearance	Decreased half-life	
	Erythromycin	Decreased plasma clearance or increased oral bioavailability	Increased plasma concentrations and AUC	
	Rifampin	Induction of CYP3A4	Decreased plasma concentrations of zopiclone	
(*both phenytoin and carbamazepine could potentially interact as well)				

AUC, area under the curve; C_{pm}, maximum plasma concentration of the drug.

dysrhythmias, including unifocal and multifocal ventricular premature contractions, bigeminy, torsades de pointes, ventricular fibrillation, and asystole.^{1,19-21} When ethanol and chloral hydrate are ingested together (a Mickey Finn), the CNS depressant actions of both are enhanced, leading to the so-called “knock-out drop” effect, or rapid, decreased level of consciousness; some persons also experience vasodilation, tachycardia, facial flushing, headache, and hypotension.³³

Chlormethiazole

PHARMACOLOGY AND PHARMACOKINETICS

Chlormethiazole exhibits a 10-fold increase in bioavailability if co-ingested with alcohol and in patients with cirrhosis, presumably from an impaired first pass effect. Low serum albumin in alcoholics leads to decreased protein binding, allowing for an increased free drug serum concentration. This may account for the high death rate in alcoholics who continue to drink while taking chlormethiazole.¹²

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵

TOXICOLOGY: MANIFESTATIONS

The coma associated with chlormethiazole overdose may be prolonged and has been reported to last from 40 to 92 hours. Victims also have increased salivation and

bronchial secretions.³⁴ A direct effect on thermoregulatory centers contributes to significant hypothermia. The addition of alcohol to chlormethiazole leads to a deep coma, severe respiratory depression, and increased mortality.⁵

Chlormezanone

PHARMACOLOGY AND PHARMACOKINETICS

Chlormezanone is rapidly absorbed and metabolized into at least six compounds, which are excreted in the urine. In one series of eight elderly patients, oral absorption of chlormezanone was delayed but not reduced, and the half-life was prolonged to 54 hours. The volume of distribution calculated from these data was approximately 85 L, which is consistent with other agents of this class. The half-life following an overdose without evidence of shock has been estimated at 29 to 35 hours.³⁵ Chlormezanone is similar to baclofen in chemical structure, and its metabolite exerts a similar muscle relaxant effect.³⁶

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵

TOXICOLOGY: MANIFESTATIONS

Chlormezanone overdose signs and symptoms are similar to those of other sedatives; metabolic acidosis has also been noted. In addition, drug-induced hepatitis may

occur, with abrupt elevation of liver enzymes, prolonged prothrombin time, elevated bilirubin, and hypoglycemia. Diffuse hydropic degeneration and necrosis of hepatocytes with pericentral vein congestion are noted on liver biopsy.³⁷⁻³⁹ Central anticholinergic syndrome has been reported in chlormezanone overdose both as a result of single agent ingestion and in combination with ofloxacin and diphenhydramine.⁴⁰

ADVERSE EFFECTS

Even with the recommended dose of chlormezanone, a hypersensitivity reaction can result in a transient hepatitis, which is associated with eosinophilia, cholestasis, and mild periportal infiltration. A fixed skin eruption may also occur at normal doses.³⁷⁻³⁹

Ethchlorvynol

PHARMACOLOGY AND PHARMACOKINETICS

Ethchlorvynol is rapidly absorbed after oral administration. It is highly lipophilic, and concentrates in adipose tissue and the CNS.⁴¹ Because of this high lipid solubility, it exhibits a biphasic elimination, with a secondary plasma peak occurring between 7 and 14 hours postingestion, reflecting gradual elimination from extensive body stores. This may explain the large variation in the duration of coma reported after large ingestions (50 to 300 hours). Ethchlorvynol is metabolized by hepatic glucuronidation and/or hydroxylation. Some of the volatile oil is eliminated via the lung. It is unknown whether the parent compound or the metabolite of the drug is responsible for the pungent breath odor that is noticed in intoxicated patients. Ethchlorvynol may accumulate in circulating and developing blood cells; severe pancytopenia has been reported.⁴²

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵ Ethchlorvynol is a microsomal enzyme inducer that enhances the metabolism of warfarin, decreasing its effectiveness.⁴³

TOXICOLOGY: MANIFESTATIONS

Ethchlorvynol overdose presents with the typical symptoms, but bradycardia rather than tachycardia may be present. A distinctive pungent aromatic odor may be noted on the breath. There is a direct relationship between the dose and the duration and level of coma, but no such relationship exists between dose and the occurrence or level of hypothermia. Interestingly, however, the level of coma does not change appreciably after hemodialysis and a reduction in the ethchlorvynol level. Deep prolonged coma may last from 10 to 288 hours, with a mean of 119 hours. Deep tendon reflexes are usually absent, and there may be loss of the corneal and pupillary light reflexes. The prolonged coma places victims at risk for complications such as gram-negative pneumonia, pressure ischemia and neuropathy, thrombophlebitis, and thromboembolism. Pressure necrosis similar to that reported for barbiturates,

glutethimide, opiates, and carbon monoxide has been noted.⁴⁴ An autopsy performed on one patient who had severe multisystem disease revealed bilateral bronchopneumonia, pulmonary embolism, thrombophlebitis of the ovarian vein, renal infarct, focal hepatic necrosis, acute cystitis, marked cerebral edema, and passive congestion of viscera.⁴⁵ Intravenous injection, and possibly oral ingestion, of ethchlorvynol may lead to noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema appears to be mediated by cyclooxygenase products since it can be blunted by the prior administration of nonsteroidal anti-inflammatory agents.^{46,47} After intravenous injection, patients experience a mintlike taste, marked shortness of breath, and nonproductive cough; physical findings include diffuse end-inspiratory rales and a normal cardiac examination. Other findings include hypoxemia, respiratory acidosis, bilateral alveolar infiltrates on chest x-ray without cardiomegaly, and a normal electrocardiogram.^{48,49}

Glutethimide

PHARMACOLOGY AND PHARMACOKINETICS

Absorption of glutethimide is slow and erratic due to its poor solubility. The absorption is hastened and increased with concurrent ethanol ingestion.¹³ The apparent volume of distribution for glutethimide is greater than that of body water.²⁸ Due to its high lipid solubility, 80% of the parenterally administered drug appears to be sequestered in the gastrointestinal tract, adipose tissue, and the central nervous system. Less than 2% is found in the blood.⁵⁰ The majority of the metabolites undergo enterohepatic circulation in animals, with slow urinary excretion. At least one metabolite, 4-hydroxy-2-ethyl-2-phenylglutarimide (4-HG), contributes to toxicity.⁵¹ In mice, 4-HG is approximately twice as potent as the parent compound in producing death.^{41,52} The drug is 90% conjugated in the liver as two glucuronides with delayed excretion. As with other highly lipophilic agents, it is eliminated following a biphasic elimination curve. Further complicating elimination is the racemic nature of the drug, with each enantiomer being metabolized differently.⁴¹

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵ Glutethimide is a microsomal enzyme inducer that enhances the metabolism of warfarin, decreasing its effectiveness.⁴³ Glutethimide potentiates codeine's sedative effect, with increased risk for death when both are taken together.⁵³

TOXICOLOGY: MANIFESTATIONS

Intoxication with glutethimide results in a prolonged coma with variations in coma depth and sudden apnea, but little correlation between blood levels and the patient's clinical condition.⁵³ Cerebral edema and seizures appear to be more common than with other sedative-hypnotics. Acute renal failure is rare but has been reported.¹³ Anticholinergic activity of glutethimide

probably contributes to reduced gastric motility and delayed gastrointestinal transit, urinary retention, mydriasis, and some of the hallucinations and delusions reported in acute ingestions of the drug.⁵⁴ In the 1970s, there were reports of neonatal withdrawal from glutethimide. Infants born to mothers addicted to glutethimide responded well initially, then had recurrence of symptoms about 5 days later, including overactivity, restlessness, tremors, hyper-reflexia, hypotonus, vasomotor instability, incessant crying, and general irritability. The infants usually responded to treatment with benzodiazepines, phenobarbital, and morphine/methadone/opioid over 6 to 7 weeks.⁵⁵

Meprobamate

PHARMACOLOGY AND PHARMACOKINETICS

Meprobamate has a low solubility in water, is resistant to gastric and intestinal juices, and decreases gastric motility; bezoar formation is more likely than with other sedative-hypnotics. The metabolism of meprobamate is induced by ethanol.¹⁵ Meprobamate has characteristics of a drug whose elimination might be increased by hemoperfusion, including a low intrinsic clearance, a relatively low volume of distribution, and charcoal adsorption.⁵⁶ Carisoprodol is a muscle relaxant (half-life of 100 minutes) that is converted to meprobamate (half-life of 11.3 hours).^{57,58}

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵

TOXICOLOGY: MANIFESTATIONS

Meprobamate intoxication may be difficult to distinguish from other sedatives, but some differences may be noted. Fluctuating coma and seizures may occur, although the drug has been reported to have anticonvulsant activities. Cardiac dysrhythmias include both tachycardia and bradycardia; hypotension can be profound and protracted, and is attributed to direct action on the CNS vasomotor center. Pulmonary edema has been reported, as has bullous skin lesions. Meprobamate deaths have been attributable to shock, pulmonary edema, or complications such as pneumonia or sepsis. Carisoprodol overdose presents with the same clinical picture.^{16,57,58}

Methaqualone

PHARMACOLOGY AND PHARMACOKINETICS

See Table 34-1.

TOXICOLOGY: MANIFESTATIONS

Methaqualone is no longer available either as a single drug or in combination with diphenhydramine (Mandrax) in the United States or United Kingdom; however, some is available on the black market and is used to adulterate heroin. Patients presenting with a methaqualone overdose exhibit a range of neurologic symptoms, including lethargy to coma, slurred speech, and gait disturbance. Sensorimotor abnormalities

include hyperacusis, blurred vision, ophthalmoplegia, hallucinations, and paresthesias. Increased muscular tone and rigidity, hyper-reflexia, clonus, myoclonus, and seizures may occur, leading to rhabdomyolysis and hyperthermia. In general, hypotension and respiratory depression occur less frequently with methaqualone than with other drugs in this class, but can be exacerbated by co-ingestion of additional depressants or ethanol. Markedly increased tracheobronchial secretions and salivation are also seen in intoxication. One case of unilateral pulmonary edema has been reported. Retinal hemorrhages, purpura, and gastrointestinal hemorrhages can occur. Studies in animal models noted that the drug inhibits adenosine diphosphate (ADP) and decreases both collagen- and ADP-induced platelet aggregation.⁵⁹ Many of these findings may be related to or exacerbated by diphenhydramine combined with methaqualone in a preparation available earlier.⁵⁹⁻⁶²

Methyprylon

PHARMACOLOGY AND PHARMACOKINETICS

Methyprylon is structurally and pharmacologically related to glutethimide, but is more water soluble and therefore has nearly complete gastrointestinal absorption. Its distribution and elimination are generally described as a two-compartment model. Hepatic metabolism is via the P-450 dehydrogenase system, with production of at least four metabolites. A second oxidative pathway has also been identified with multiple metabolites. The elimination half-lives of methyprylon reported in the literature vary greatly (4 to 50 hours).⁶³

DRUG INTERACTIONS

Ethanol and imipramine produce additive clinical effects.²⁵

TOXICOLOGY: MANIFESTATIONS

Patients with methyprylon overdose may demonstrate inconsistent findings. Various studies have reported cases with no hypotension, moderate to severe hypotension that was recurrent, no decrease in peripheral reflexes except in mixed ingestions, hyperreflexia and seizure activity, hyperreflexia and areflexia, pinpoint, sluggish pupils, or fixed and dilated pupils. The one fatal case in the literature was deeply comatose, cyanotic, and hypotensive, and presented approximately 18 hours post-ingestion. Other cases that presented earlier, but with equally severe initial findings recovered with supportive treatment or supportive treatment plus hemodialysis.⁶³⁻⁷⁰

Zaleplon, Zolpidem, and Zopiclone

PHARMACOLOGY AND PHARMACOKINETICS

The kinetics of zaleplon, zolpidem, and zopiclone have been characterized to a greater extent than the preceding agents. Neither zaleplon nor zolpidem appear to exhibit dose-dependent kinetics within the therapeutic range. Zaleplon has a more rapid elimination than zolpidem.⁷ Zolpidem has a rapid absorption, rapid distribution into the CNS, and rapid onset of activity.⁷¹

Zolpidem is metabolized in the liver by four different P-450 pathways. Sixty-one percent of the drug is metabolized through the 3A4 enzyme system, 22% through 2C9, 14% through 1A2, and less than 3% through the combined 2D6 and 2C19 pathways.⁷² Because it is less lipophilic than other similar agents, it is cleared from the CNS more rapidly.⁶

Zopiclone has a high bioavailability, which suggests absence of a significant first pass effect. Thirteen metabolites through seven pathways have been identified. A low volume of distribution, confirmed by autopsy results, indicates that the agent has no particular preferential distribution into solid organs.⁷³ The drug's elimination follows a two-compartment model.⁷⁴ The half-life of its primary active metabolite is approximately equal to the half-life of the parent drug. The half-life of zopiclone is longer in patients with cirrhosis and in elderly patients, so the dosage should be reduced by half in these patients. The half-life of the drug is also prolonged in patients with renal disease, but the changes are slight and probably not clinically significant.^{25,75,76}

SPECIAL POPULATIONS

Zopiclone dosage should be reduced by half in elderly patients and those with severe liver insufficiency.⁷⁵

DRUG INTERACTIONS

Ethanol and imipramine appear to have no effect on the kinetics or pharmacodynamics of zopiclone.²⁵ Rifampin has been shown to enhance the metabolism of zaleplon, zolpidem, and zopiclone due to its potent induction of cytochrome P-450, resulting in decreased maximum peak concentration, reduction of the area under the curve (AUC), and increased total clearance. This potential effect also exists for other inducers of the cytochrome isoenzymes, such as phenytoin and carbamazepine.⁷⁷⁻⁷⁹ Zaleplon appears to have no significant pharmacokinetic drug interactions with digoxin, ibuprofen, warfarin, imipramine, or paroxetine; however, additive psychomotor effects have been reported when it is combined with imipramine, paroxetine, or thioridazine. Cimetidine increases the plasma concentration of zaleplon by 85%.^{77,80-83} Erythromycin has been shown to increase the AUC and peak concentrations of zopiclone, but the differences are not likely to be of clinical significance.⁸⁴ Ranitidine did not increase drowsiness when used in patients receiving a single dose of zopiclone as a preoperative medication.⁸⁵ No pharmacokinetic interactions have been observed between digoxin, warfarin, or ranitidine and zolpidem.^{86,87} The half-life of zolpidem is reduced by smoking and oral contraceptive use; this is not likely to be clinically significant.⁸⁸ There is an increase in peak serum concentration and a decrease in time to peak concentration of zolpidem in patients who also take sertraline, but this is also unlikely to be of routine clinical significance.⁸⁹ Ketoconazole decreases the clearance of zolpidem by approximately 40%; itraconazole and fluconazole produce only small changes in the drug's elimination kinetics. Ritonavir also reduces the clearance of zolpidem.^{72,90} Decreased psychomotor performance has been observed with the

combination of chlorpromazine and zolpidem, but no pharmacokinetic interaction was found with single-dose administration.⁸⁷ There is an increased risk for hallucinations with concurrent use of zolpidem and select antidepressants, including bupropion, fluoxetine, sertraline, venlafaxine, and desipramine. The mechanism of this interaction has not been established.⁹¹

TOXICOLOGY: MANIFESTATIONS

Two cases of zaleplon overdose have been reported, and both patients recovered uneventfully. Zolpidem overdose usually presents with a mild clinical picture, including drowsiness and vomiting. Some patients experience gait abnormalities, blurred vision, mydriasis, visual hallucinations, and memory impairment. More severe symptoms are consistent with multiple-drug overdose, including respiratory depression or failure and hypotension.⁹²⁻⁹⁷ Fatalities have occurred with zolpidem taken with co-ingestants such as morphine, hydrocodone, meprobamate, lidocaine, and carisoprodol.^{93,97,98}

ADVERSE EFFECTS

Withdrawal symptoms after chronic use have been reported with zopiclone and zolpidem but are not generally life threatening. Hallucinations and sensory distortion may occur with therapeutic doses of zolpidem. Amnesic psychotic reactions and agitation with disorganization of thoughts may occur.^{6,97,99-101}

DIAGNOSIS

Laboratory Testing

A toxicology screen may confirm the presence of these agents, but will generally not be helpful in establishing the level of toxicity and planning treatment; severity of toxicity is generally a clinical diagnosis. General laboratory testing should include a complete blood count, serum electrolytes, blood urea nitrogen (BUN), creatinine, liver enzymes, and arterial blood gas. Pulse oximetry should be monitored.

Therapeutic serum chlormezanone levels are normally 4 to 6 mg/L, with levels greater than 50 mg/L considered toxic. Ethchlorvynol levels are directly proportional to the amount ingested, but they do not correlate with clinical symptoms.⁴⁵

Meprobamate levels of 3 to 10 mg/dL are associated with mild to moderate signs of toxicity, 10 to 20 mg/dL with deeper coma, and greater than 20 mg/dL with severe toxicity and increased fatality rate. Rising levels may indicate continued absorption, which would suggest the formation of concretions in the gastrointestinal tract.

Methaqualone levels of 2 to 5 µg/dL are generally considered to be in the toxic range.⁶² Multiple complications have been associated with methaqualone, and therefore baseline laboratory evaluation should include a complete blood count, liver enzymes, coagulation studies, platelet count, serum creatine phosphokinase (CPK), BUN, creatinine, and electrolytes. Coagulation abnormalities, with prolonged prothrombin and partial

thromboplastin times, inhibition of platelet aggregation, and decreases in factors V and VII may lead to bleeding problems. Rhabdomyolysis and hyperthermia may affect renal function.^{59,62} Methypyrlyon levels of greater than 3.0 mg/dL are associated with coma, and levels less than 3.0 mg/dL are generally associated with somnolence. Other symptoms do not demonstrate a correlation between dose and severity.^{63,70} Most laboratory values are not affected in methypyrlyon overdose, although slight transient elevations of liver enzymes have been noted.^{65,68}

Other Diagnostic Testing

Additional testing, such as electrocardiography (ECG) and chest radiography should be performed as indicated in specific clinical situations. Chloral hydrate is radiopaque and may be seen on radiography.¹⁰² Methaqualone ECG abnormalities are reversible and include right bundle branch block and nonspecific T wave abnormalities.^{59,62}

On examination, a pear-like odor to the breath may be noted in chloral hydrate overdose, and a pungent, vinyl-like odor may be associated with ethchlorvynol overdose.

Differential Diagnosis

The differential diagnosis of these agents typically includes other CNS depressant drugs, CNS lesions, other endocrine or infectious processes, and fluid and electrolyte abnormalities. Organophosphate poisoning is included in the differential diagnosis of methaqualone overdose because of the copious secretions associated with this agent.

MANAGEMENT

Supportive Measures

The standard “ABCs” approach is appropriate in cases of sedative-hypnotic overdose. For comatose patients, the main goal is supporting the airway, ventilation, and cardiovascular system. Vital signs must be monitored frequently, including respirations, pulse, blood pressure, and temperature. Unresponsive patients should be intubated to protect the airway and to ensure adequate respirations and ventilation. Ventilation/oxygenation should be monitored with pulse oximetry and arterial blood gas, making adjustments in fraction of inspired oxygen (FIO₂) or rate of ventilation as indicated. Aggressive management of the respiratory status decreases the risk factors for cardiac arrest. Hypotension may be treated with isotonic fluid boluses; vasopressors and inotropes should be used as indicated. Cardiac dysrhythmias should be treated according to advanced cardiac life support (ACLS) protocols with the exception of chloral hydrate (see Specific Treatment). Seizures may be treated with benzodiazepines. Normal body temperature should be maintained; warming blankets

may be sufficient, but use of warmed IV fluids, radiant warming, and other methods may also be required. This is especially important if the patient is hypothermic and develops cardiac dysrhythmias; patients may not respond to usual ACLS protocols during hypothermia. One must anticipate the sequelae of coma and immobilization. The overall incidence and severity of pneumonia is directly proportional to the duration of coma; gram-negative organisms are frequently the cause of pneumonia in these patients. Patients may develop pressure ischemia and neuropathy from prolonged immobilization; such patients should be repositioned frequently. Victims are also at risk for thrombophlebitis and thromboembolism.

Decontamination

Gastric lavage should be considered in patients presenting with mixed ingestions or a potentially lethal ingestion of a single drug if they present within 1 to 2 hours of ingestion. Activated charcoal 1 g/kg may decrease absorption and should be administered. Multiple-dose activated charcoal has been advocated for meprobamate and glutethimide ingestions to prevent ongoing absorption from concretions and delayed motility and to interrupt enterohepatic circulation; however, its efficacy in these ingestions is unproved. Gastric lavage, multiple-dose activated charcoal, and whole bowel irrigation should be considered with meprobamate because of the tendency toward bezoar formation. Recovery of a bezoar weighing only 25 g could be clinically significant because the minimum lethal dose is approximately 20 g. However, it is important to evaluate whether ileus is present before instituting these measures.^{56,103-105}

Laboratory Monitoring

Arterial blood gases and pH provide information about ventilation and acid–base status. Mixed respiratory and metabolic acidosis may be seen due to hypoventilation, immobilization, hypotension, and hypothermia.

Monitoring for complications related to prolonged coma and immobilization should be considered.⁴⁵ One should monitor for rhabdomyolysis and hyperthermia in cases of myoclonus and seizures, including serum CPK, creatinine, BUN, and electrolytes. Special attention should be focused on maintaining renal function. One should monitor liver enzymes, platelet count, and coagulation times after methaqualone ingestion.⁶²

Antidote

There are no specific antidotes currently available for sedative-hypnotic overdoses. Flumazenil has been reported to reverse the effects of chloral hydrate, but there are concerns that it may also precipitate seizures in chloral hydrate overdose, so it should be used with caution, if at all.¹⁰⁵ Flumazenil may reverse CNS depression from severe zolpidem toxicity and zaleplon overdose.¹⁰⁶

Specific Treatment

Chloral hydrate and trichloroethanol sensitize the myocardium to endogenous catecholamines. Naloxone and flumazenil may precipitate ventricular dysrhythmias. Ventricular dysrhythmias associated with chloral hydrate overdose may be treated with β blockers: propranolol (adults 1.0 to 2.0 mg IV bolus followed by 1.0 to 2.0 mg/hr infusion, children 0.01 to 0.1 mg/kg, maximum 1 mg) or esmolol (adults 500 μ g/kg IV slow bolus over 2 minutes followed by 25 to 100 μ g/kg/min, children 100 to 500 μ g/kg given over 1 minute, followed by infusion of 25 to 100 μ g/kg/min, titrated to dysrhythmias cessation). Torsades de points may be treated with IV magnesium or overdrive pacing.

Platelets, fresh frozen plasma, and vitamin K should be administered for uncontrolled bleeding after methaqualone ingestion.⁶²

Elimination Enhancement

In general, there is no convincing evidence to support the use of hemodialysis or hemoperfusion in the treatment of sedative-hypnotic overdose. Historically, these methods have been attempted for severe chloral hydrate (TCE) poisoning or inadequate response to supportive care, but clinical improvement has not correlated with reduced levels of drug.¹⁰⁷ There is no evidence to support the use of hemodialysis or hemoperfusion in treating chlormethiazole, glutethimide, or chlormezanone overdoses.^{108,109} The use of forced diuresis, hemodialysis, peritoneal dialysis, and hemoperfusion in accelerating the removal of ethchlorvynol remains somewhat controversial. Although these modalities have been shown to reduce the half-life of ethchlorvynol, they have not been shown to shorten the duration of coma, or to reduce morbidity or mortality.^{45,110} Hemodialysis and hemoperfusion can enhance the elimination of meprobamate, but these invasive methods are rarely indicated when aggressive decontamination and supportive measures are used.¹⁰³ Hemodialysis and hemoperfusion do not alter the clinical outcome of methaqualone overdose, but do increase clearance.¹¹¹ Although dialysis has been used in cases of severe methyprylon overdoses, reports of clinical improvement and elimination of the active drug have been inconsistent. Most cases can be managed with supportive care. Osmotic diuresis has also been used, but there is little evidence that this is helpful.^{63,65,68,70} There is no experience with hemodialysis for zaleplon or zopiclone overdose. Zolpidem is not dialyzable.⁷⁶

Disposition

Symptomatic patients should be admitted and monitored for 24 hours, or until symptoms resolve; asymptomatic patients for 2 to 6 hours. Patients who are comatose, hypotensive, hypothermic, or show signs of cardiac instability should be admitted to the intensive care unit for supportive care and close monitoring. It may take a day or up to a week to stabilize the patient, depending on

level of coma, respiratory compromise, and development of complications. The patient may be discharged to home or psychiatric care when he or she is stable.

The prolonged deep coma and severe respiratory depression associated with ethchlorvynol overdose may last up to 17 days. Patients who improve initially should be observed for at least 24 hours due to the biphasic distribution of ethchlorvynol.⁴⁵

Patients who have ingested significant amounts of chloral hydrate should be admitted for observation and their cardiac status monitored for at least 24 hours. Asymptomatic patients with suspected ingestions should be monitored for 6 to 8 hours. Because of the gastric irritation and vomiting associated with chloral hydrate overdose, the patient should be followed for later development of esophageal stricture.²⁰

Asymptomatic patients should be monitored for 6 to 8 hours after meprobamate or glutethimide ingestion. Patients with mild symptoms should be observed for 12 to 24 hours; those with more severe symptoms require longer observation and support due to the biphasic recurrence of toxic symptoms after an initial resolution.^{51,109}

Infants born to mothers who have received chlormethiazole should be monitored for 36 to 48 hours for development of respiratory depression or apnea.³⁰ Neonatal withdrawal symptoms may persist for up to 45 days in infants born to mothers addicted to glutethimide.⁶⁷

SUSAN E. FARRELL, MD ■ TANIA M. FATOVICH, MD

At a Glance...

- Benzodiazepines are widely prescribed and used for sedative, hypnotic, amnestic, anxiolytic, anticonvulsant, and muscle relaxant properties.
- Benzodiazepines are relatively safe in isolated overdose but may be dangerous when co-ingested with other agents.
- Laboratory testing is of limited value in overdose.
- Treatment of overdose is primarily supportive.
- Flumazenil, a competitive antagonist at the γ -aminobutyric acid A receptor, will reverse the toxic effects of benzodiazepines but should be used with caution in benzodiazepine poisoning.
- Patients with benzodiazepine overdose that remain asymptomatic after 4 to 6 hours of observation are medically safe for psychiatric evaluation and disposition.

INTRODUCTION AND RELEVANT HISTORY

The first commercially marketed benzodiazepine, chlordiazepoxide, was accidentally synthesized in 1955 by Roche Laboratories in Nutley, New Jersey. The scope of its pharmacologic properties and clinical applications, however, were not appreciated until 1957, when it was noted to possess effective sedative, hypnotic, and anticonvulsant properties.¹ Subsequent to its clinical release as Librium (Roche Pharmaceuticals of Hoffman-La Roche, Inc., Nutley, NJ) in 1960, chlordiazepoxide spawned an era of widespread benzodiazepine use that still persists today. Diazepam, perhaps the best known and most commercially successful of all the benzodiazepines, was synthesized in 1959 and marketed as Valium (Roche Pharmaceuticals of Hoffman-La Roche, Inc. Nutley, NJ) in 1963. Since the early 1960s, more than 3000 benzodiazepines have been developed, more than 120 have been tested for biologic activity, and approximately 50 different benzodiazepines are currently marketed worldwide. Fourteen benzodiazepines are currently available for clinical use in the United States. They are classified as schedule IV drugs by the Food and Drug Administration (FDA). These agents and a few related compounds available outside the United States are listed in Table 35-1.

Benzodiazepines have various sedative, hypnotic, amnestic, anxiolytic, anticonvulsant, and muscle relaxant properties. All benzodiazepines are effective in the treatment of anxiety and insomnia. However, individual drugs are approved by the FDA and marketed for specific indications on the basis of their clinical and pharmacologic characteristics. For example, alprazolam may have significant antidepressant activity in addition to its sedative properties. Benzodiazepines such as alprazolam

and clonazepam have gained use in the treatment of social phobias and panic disorders,^{2,3} and clonazepam and lorazepam may be effective in place of, or in combination with, a neuroleptic and lithium for the treatment of acute mania in bipolar disorder.⁴ Reports also describe the efficacy of benzodiazepines for the initial treatment of catatonia⁵⁻⁸ and neuroleptic-induced akathisia and dystonias.⁹ In addition, short-acting benzodiazepines such as temazepam and triazolam have found new uses in the prevention and treatment of jet lag.^{10,11} Their action is presumed to be through the readjustment of sleep patterns and body temperature, and they shorten the time to resynchronize activity rhythms when used in conjunction with regular exercise. In the past several years, certain benzodiazepines have also been reported to be of benefit in the treatment of pain syndromes,¹² by both decreasing situational anxiety in the setting of acute pain and relieving muscle tension related to some chronic musculoskeletal pain syndromes. Finally, benzodiazepines are also increasingly used in the treatment of cancer patients for the relief of anticipatory anxiety and nausea, insomnia, chemotherapy-induced emesis, neuralgias, and psychiatric disorders secondary to high-dose steroids.¹³

Since their introduction, the benzodiazepines have enjoyed a meteoric rise in popularity and have largely replaced other sedative-hypnotics. Their extraordinary acceptance in clinical medicine has been based on their safety, efficacy, minimal side effects, relatively low addiction potential, and the medical and public demand for sedative and anxiolytic agents. In 1979, the U.S. National Household survey reported that 11% of the adult population in the United States had taken an anxiolytic on one or more occasions in the previous year.¹⁴ Benzodiazepine use peaked in the late 1970s and mid-1980s. Since that time, the annual prevalence of benzodiazepine use in the United States has declined, from a prevalence of 13% in 1981 to 8.3% in 1990.¹⁵ Similar declining rates in benzodiazepine prescriptions have been reported in Australia, Great Britain, and Canada. This decline has largely been attributed to widespread negative publicity and concern about potential misuse, abuse, and long-term side effects, particularly dependence and withdrawal.

Benzodiazepine prescriptions vary by age. In a recent nationwide U.S. survey, 5% of children were prescribed benzodiazepines, a rate that has remained stable from 1987 to 1996.¹⁶ Data from a Canadian study of benzodiazepine prescriptions dispensed for the elderly demonstrated rates that decreased from 25.1% in 1993 to 22.5% in 1998. Prescription rates, however, were still significantly higher for older patients: approximately 20% for those 65 to 69 years of age, and approximately 30% for those at least 85 years of age.¹⁷

TABLE 35-1 Benzodiazepines Available in the United States

GENERIC NAME	TRADE NAME	YEAR OF INTRODUCTION	RECOMMENDED ADULT DOSE*	AVAILABLE DOSAGE FORMS	FDA-APPROVED INDICATIONS	RATE OF ORAL ABSORPTION
Alprazolam	Xanax	1981	Oral: 0.75–4 mg/day divided tid	0.25-, 0.5-, 1-mg tablets	Anxiety Anxious depression	Intermediate
Chlordiazepoxide	Librium	1960	Oral: 15–100 mg/day divided tid to qid	5-, 10-, 25-mg tablets or capsules	Alcohol withdrawal Anxiety Preoperative sedation	Intermediate
Clonazepam	Klonopin	1974	Oral: 7.5–20 mg/day divided tid	0.5-, 1-, 2-mg tablets	Seizure disorder	Intermediate
Clorazepate	Tranxene	1972	Oral: 7.5–60 mg/day divided qd to qid	2.75-, 7.5-, 15-mg capsules	Anxiety Alcohol withdrawal	Rapid
Diazepam	Valium	1963	Oral: 6–40 mg/day divided qd to qid IV: 0.1 mg/kg per dose	2-, 5-, 10-mg tablets	Anxiety/insomnia Alcohol withdrawal Muscle spasm/seizures Preoperative sedation	Rapid
Flurazepam	Dalmane	1970	Oral: 15–30 mg/day hs	15-, 30-mg capsules	Insomnia	Rapid
Halazepam	Paxipam	1981	Oral: 80–160 mg/day divided tid to qid	20-, 40-mg capsules	Anxiety	Intermediate to slow
Lorazepam	Ativan	1977	Oral: 1–10 mg/day divided bid to tid IM: 0.5 mg/kg IV: 0.05 mg/kg	0.5-, 1-, 2-mg tablets	Anxiety/insomnia Anxious depression Preoperative sedation	Intermediate
Midazolam	Versed	1986	Oral: not available IM: 0.07–0.08 mg/kg IV: Begin 1–2.5 mg, titrate to effect; 0.05 mg/kg total		Preoperative sedation Anesthesia induction Conscious sedation	Rapid [†]
Oxazepam	Serax	1963	Oral: 30–120 mg/day divided tid to qid	10-, 15-, 30-mg capsules 15-mg tablets	Anxiety Alcohol withdrawal Anxious depression	Slow
Prazepam	Centrax	1977	Oral: 20–60 mg/day divided bid	5-, 10-mg capsules 10-mg tablets	Anxiety	Ultraslow
Temazepam	Restoril	1981	Oral: 15–30 mg qhs	15-, 30-mg capsules	Insomnia	Slow
Triazolam	Halcion	1983	Oral: 0.125–0.5 mg qhs	0.125-, 0.25-, 0.5-mg capsules	Insomnia	Intermediate

IM, intramuscularly; IV, intravenously.
 *Maximum dose not established.
 †Oral form of midazolam is not yet commercially available, but may administer parenteral formulation orally at 0.3 to 0.7 mg/kg (typically in children).

Because of their widespread availability, benzodiazepines are also among the most frequently misused drugs. Dependence and abuse by the general population, however, are minor when compared to those of alcohol, cocaine, or opiates. As a class, benzodiazepines are not powerful euphorians and are therefore not frequently abused as a primary agent. Secondary drug abuse is common, however, usually in the form of self-medication, to decrease the adverse side effects of stimulants or hallucinogens, to ameliorate the

unpleasant symptoms of withdrawal from more highly addictive substances, or to substitute for the drug of primary dependence when it is not available.

Benzodiazepines are often used by intravenous drug abusers. This combination of intravenous drug use and benzodiazepine abuse has been correlated with increased incidence of needle sharing, polydrug use, psychosocial dysfunction, depression, anxiety, and poor health.¹⁸ The U.S. Treatment Outcome prospective study reported that 73% of heroin abusers also used benzodi-

azepines on their entry into treatment.¹⁸ A 1999 study found a similarly high prevalence of benzodiazepine abuse among patients entering a methadone treatment clinic, with lifetime and current prevalences of 66.3% and 50.8%, respectively.¹⁹

In an attempt to limit such widespread availability and the incidence of misuse and abuse, various laws regulating the prescribing of benzodiazepines have been enacted, with mixed results.²⁰ For example, in 1989, the State of New York enacted a regulation that required prescriptions for benzodiazepines to be written in triplicate, with mandatory reporting of prescriptions to the New York State Department of Health. The purpose of the regulation was to decrease improper prescribing practices, to restrict overall use of benzodiazepines, and to help eliminate fraud and illegal misdirection of the drugs. As a result of this regulation, benzodiazepine prescriptions decreased by 2 million, but were accompanied by a concurrent increase in the use of other anxiolytics.^{21,22} The number of elderly patients using benzodiazepines was reduced by 33%, and the number of prescriptions written was reduced by 45%.²³ Weintraub compared the use of benzodiazepine alternatives in New York to prescribing practices in other unlegislated areas, and concluded that “an undesirable increase has occurred in the prescribing of less acceptable medications.”²⁴ Other unintended consequences of this legislation included an increase in patient visits to an urban psychiatric emergency department for a recurrence of previously controlled psychiatric symptoms or acute benzodiazepine withdrawal. Sales of distilled spirits also increased during the first 4 months after the law was implemented. Similar findings have been reported in European studies.²⁵

A more recent study reported another unintended effect of the New York ruling. A marked decrease in new benzodiazepine prescriptions was found among patients discharged from the hospital after cardiac- or cancer-related admissions, 72.5% and 69.4%, respectively.²⁰ Over the past decade, six states have enacted legislation to restrict benzodiazepine prescribing.

Although benzodiazepines have a low likelihood for producing fatal central nervous system (CNS) depression and are, thus, remarkably safe as compared with older sedative-hypnotics, their potential for addiction and abuse is still well-recognized and a matter of medical and legal controversy.

STRUCTURE AND STRUCTURE-ACTIVITY RELATIONSHIPS

All benzodiazepines are organic bases composed of a benzene ring fused to a seven-membered diazepine ring²⁶ (Figs. 35-1 and 35-2). All of the important benzodiazepines have a 5-aryl substituent and various substitutions at the R1 and R4 positions of the diazepine ring. The aryl ring at position R5 confers greater potency of the molecule. Specific benzodiazepine agonists vary in the substitutions at the R1, R2, R3, R4, R7, and R2' positions. Substitution of a keto group at R5 and a methyl group at R4 creates the benzodiazepine antagonist flumazenil. Despite the myriad benzodiazepine

FIGURE 35-1 The general chemical structure of benzodiazepines.

FIGURE 35-2 The four most prescribed benzodiazepines in the United States.

compounds available, all derivatives can be expected to have similar qualitative pharmacologic and clinical effects when adjusted for differences in potency. Variations in the pharmacokinetics of an individual drug's onset, duration of action, and metabolism make it more suitable for certain indications.

PHARMACOLOGY

Benzodiazepines produce their sedative, hypnotic, anxiolytic, and anticonvulsant effects through their ability to potentiate the activity of γ -aminobutyric acid (GABA), the major inhibitory neurotransmitter in the CNS. GABA is involved in sleep induction, control of neuronal excitation and epileptic potentials, anxiety, memory, hypnosis, and modulation of the hypothalamic-pituitary axis. GABA is found in high concentrations in the basal ganglia, hippocampus, cerebellum, hypothalamus, and substantia gelatinosa of the dorsal horn of the spinal cord.²⁷

Three types of GABA receptors have been defined. GABA_A is a hetero-oligomeric chloride channel composed of five subunits of various types, which is modulated by chemicals such as benzodiazepines,

barbiturates, ethanol, and steroids. GABA_B is a seven trans-membrane receptor coupled to G proteins, which activate the second messenger system of phospholipase C and adenylate cyclase, leading to the opening of calcium and potassium channels. It is also a hetero-oligomeric receptor, composed of subunits R1a, R1b, and R2. Baclofen is an agonist at the GABA_B receptor. GABA_C is an ionotropic chloride channel, similar to GABA_A. In fact, GABA_C receptors may actually be homomeric GABA_A receptors, composed entirely of one subunit type, unlike GABA_A. Although both GABA_A and GABA_C are chloride channels, they are architecturally, pharmacologically, biochemically, and physiologically different. Benzodiazepines do not modulate GABA_C.²⁸

GABA_A receptors are made up of five subunits. To date, eight subunit families and 18 subunit types have been identified: α_{1-6} , β_{1-3} , γ_{1-3} , δ , ϵ , π , θ , ρ_{1-3} . Nearly all GABA_A receptors in the brain are composed of a combination of α , β , and γ subunits. This structural diversity of the GABA_A receptor accounts for the variations in its channel functioning and affinity for GABA and its related receptor ligands, such as benzodiazepines, localization in the brain, and pharmacology. This compares to the GABA_C receptor, which is composed of only ρ subunits and is located primarily in the retina and neuroendocrine cells in the gut.^{29,30}

The molecular structure of the GABA_A receptor and the activity of benzodiazepines are intimately related. Although the theoretically possible combination of GABA_A subunits is greater than 500,000, the most prevalent receptor combinations in the brain contain α_1 , α_2 , α_3 , and α_5 subunits, any β subunit type, and γ_2 . The combination of $\alpha_1\beta_2\gamma_2$ is especially prevalent. These subunits are encoded as a cluster on chromosome 5 of the genome, such that their expression is regulated in a coherent manner.³¹

Benzodiazepine recognition sites, termed *benzodiazepine receptor (BZ) types I and II*, are located on the GABA_A receptor. Because these sites are also binding sites for nonbenzodiazepine ligands, they have been termed w_1 and w_2 receptors. A "peripheral type" benzodiazepine receptor, or "P" site, has also been identified in most peripheral tissues and glial cells in the brain. It is unrelated to central benzodiazepine receptors, but may be involved in the modulation of central benzodiazepine effects, the synthesis of neurosteroids, and steroid hormones in peripheral glands.³²⁻³⁴ Benzodiazepine receptor ligands can act as agonists, antagonists, or inverse agonists at the GABA_A receptor. In other words, binding of these ligands may increase, decrease, or block the effects of GABA at GABA_A receptors, respectively.

Recent studies now show that the ω_1 and ω_2 receptors actually correspond to the interface of the α subunits and the γ_2 subunit on the GABA_A receptor complex.³⁵ Specifically, ω_1 receptors correspond to the interface at the α_1 subunit, and ω_2 receptors correspond to the interface at the α_2 , α_3 , or α_5 subunit on GABA_A.³⁶ This interface is the active binding site for benzodiazepines, which bind at the α subunit. After benzodiazepine binding, a conformational change, mediated through the γ_2 subunit, occurs at the β subunit, enhancing the

binding of GABA at the β subunit. The chloride ion channel opens, hyperpolarizing the cell, and limiting excitatory impulses. Benzodiazepines potentiate GABA effects by increasing the frequency of channel opening (Fig. 35-3). They are positive modulators of the GABA receptor. In the absence of GABA, however, benzodiazepines have no direct effect on GABA_A receptor function; benzodiazepine effects depend on the presynaptic release of GABA.

Although classic benzodiazepines act at all $\alpha\gamma_2$ interfaces of the GABA_A receptor complex, animal studies, which target individual subunit formation through genetic single point mutations and knockouts, have elucidated the important relationship between the pharmacologic effects of benzodiazepine agonists and the subunit composition of individual GABA_A receptors.^{29,37} For example, GABA_A receptors, which contain α_1 subunits, mediate the sedative and amnestic effects produced by benzodiazepines. The anticonvulsant effects of these drugs are also partially mediated by α_1 -containing receptors. Anxiolysis and muscle tone are mediated through α_2 -containing GABA_A receptors, which comprise only 15% of all GABA_A receptors, but are particularly dense in the amygdala and the dorsal horn cells of the spinal cord.

GABA_A receptors, which are the active binding sites of benzodiazepines, are extremely heterogeneous receptor complexes. It is this complexity that accounts for the variety of effects of GABA_A-related modulators. Classic benzodiazepines act at all GABA_A receptors, accounting for their many side effects. The creation of drugs that act at specific receptor subunits will allow for selective therapeutic effects devoid of the side effects, which are common to the benzodiazepines. For example, zopiclone, zolpidem, alpidem, and zaleplon, nonbenzodiazepine sedatives, preferentially bind to α_1 GABA_A receptors, accounting for their therapeutic efficacy as hypnotics.^{29,37} Future research into the development of subtype-selective drugs with specific activity mediated at specific GABA_A receptor subunits is certain to enhance the therapy of many neuropsychiatric disorders, which involve GABA regulation.

Endogenous benzodiazepine-like substances, diazepam-binding inhibitors, have been recently isolated. Although the actual source of diazepam-binding inhibitors is controversial, research into their role in neuroendocrine function,³⁴ panic disorder,³⁸ anxiety,³⁹ memory and learning,⁴⁰ and hepatic encephalopathy,^{41,42} may further elucidate the normal regulatory functions of GABA.

PHARMACOKINETICS

Although some benzodiazepines form water-soluble salts at acidic pH, at physiologic pH all are moderately to highly lipid-soluble molecules that are rapidly and completely absorbed from the proximal small bowel (see Tables 35-1 and 35-2). Significant differences in lipid solubility affect the rate of gastrointestinal absorption and subsequent distribution. Highly lipophilic benzodiazepines, such as diazepam and flurazepam, are rapidly

FIGURE 35-3 Benzodiazepine receptors and the GABAergic synapse. Central nervous system neurotransmission occurs via a complex circuitry consisting of multiple connections, pathways, feedback mechanisms, and inhibitory/disinhibitory neurons, all under the control of neurotransmitters and neuroinhibitors. The body's most important neuroinhibitor, γ -aminobutyric acid (GABA), is synthesized in nerve endings of presynaptic GABAergic neurons from glutamate, under the influence of the enzyme glutamic acid decarboxylase. GABA is stored in synaptic vesicles located in presynaptic nerve endings and is released into the synapse to function as a neuroinhibitor. GABA activity is terminated by diffusion out of the synapse or reuptake into presynaptic nerve endings. Specific GABA receptors have been identified on the subsynaptic membrane of postsynaptic neurons. GABA receptors are adjacent to and coupled with chloride ion channels in such a way that activation of a GABA receptor "opens" the associated channel, increasing chloride ion influx. The end result is hyperpolarization of the cell membrane and decreased neuronal excitability. The activity of GABA or its functional relationship to GABA receptors may be related to GABA modulin, an endogenous peptide located in synaptic membranes. The benzodiazepine receptor is located on a subunit of the benzodiazepine-GABA pharmacophore, spatially adjacent to the GABA receptor. Binding of benzodiazepines to the benzodiazepine receptor subunit induces a change in the receptor complex, which facilitates GABA binding to the GABA receptor subunit, increasing the frequency of chloride ion channel opening. Benzodiazepine antagonists competitively block specific benzodiazepine receptor sites and either block the benzodiazepine binding or displace already bound drug, thereby offsetting any benzodiazepine-enhanced GABAergic transmission. GABA, γ -aminobutyric acid; BZD, benzodiazepine; ABZD, benzodiazepine antagonist.

TABLE 35-2 Absorption Rates of Orally Administered Benzodiazepines

	TIME OF PEAK PLASMA CONCENTRATION
Rapid	<1.2 hr
Desmethyldiazepam (from clorazepate [Tranxene])	
Diazepam (Valium)	
Flurazepam (Dalmane)	
Midazolam* (Versed)	
Intermediate	1.2–2.0 hr
Alprazolam (Xanax)	
Chlordiazepoxide (Librium)	
Clonazepam (Klonopin)	
Flunitrazepam (Rohypnol)	
Halazepam (Paxipam)	
Lorazepam (Ativan)	
Triazolam (Halcion)	
Slow	2.0–3.0 hr
Oxazepam (Serax)	
Temazepam (Restoril)	
Ultraslow	>3.0 hr
Desmethyldiazepam (from prazepam [Centrax])	
Diazepam CR (slow release)	

*Oral form midazolam not yet commercially available.

absorbed, and less lipophilic compounds, such as oxazepam and temazepam, are more slowly absorbed.^{26,43}

The rate of oral absorption is influenced by other factors, such as the co-ingestion of ethanol⁴⁴ (enhanced absorption), or co-ingestion of food or antacids⁴⁵ (slowed). Depending on the drug preparation and the presence of co-ingestants, the time from ingestion to appearance of the drug in the systemic circulation is approximately 10 to 20 minutes. In general, the time to maximal serum concentration (T_{max}) is inversely related to the maximal serum concentration (C_{max}) and may be influenced by the aforementioned factors.⁴⁶

Certain benzodiazepines, such as clorazepate, flurazepam, and prazepam, do not reach the systemic circulation in clinically significant amounts. Clorazepate is rapidly decarboxylated in the acidic environment of the stomach to its active metabolite, *N*-desmethyldiazepam (nordiazepam), which is then absorbed completely. Flurazepam and prazepam undergo first pass metabolism in the liver and reach the systemic circulation only as metabolites.

Benzodiazepine absorption from intramuscular injection is variable. Lorazepam and midazolam are the only benzodiazepines rapidly and completely absorbed after intramuscular administration. Chlordiazepoxide absorption is particularly slow and erratic; plasma concentration may not peak for 6 to 12 hours. Diazepam is inconsistently absorbed after intramuscular administration. Serum levels of diazepam and chlordiazepoxide are more rapidly achieved by the oral route than by intramuscular administration.

After absorption, benzodiazepines are highly protein bound, ranging from 70% to 99%. Protein binding is greatest with highly lipid-soluble drugs (e.g., diazepam 99% bound) and least with more water-soluble agents (e.g., alprazolam 70% bound). Only unbound drug is available to cross the blood-brain barrier and interact with CNS receptors. Drug concentrations in the cerebrospinal fluid are generally 2% to 4% of plasma levels, roughly equivalent to the concentration of free drug in the plasma. Alterations in protein binding affect the amount of free drug available to the CNS at sites of action, and the subsequent clinical effects.

All benzodiazepines distribute widely and rapidly to highly perfused organs. Their volume of distribution ranges from 0.3 to 5.5 L/kg, and tissue concentrations within the brain, liver, and spleen typically exceed that of the serum. Because penetration into the CNS is rapid, the onset of clinical effects is limited more by the rate of systemic absorption of individual compounds than by their rate of distribution.

After initial distribution within the central compartment, benzodiazepines slowly redistribute to less perfused tissues, such as adipose and muscle. The rate of initial distribution and redistribution, and thus onset and offset of clinical effect, correlates with the individual drug lipophilicity.

Benzodiazepine activity is terminated by at least three mechanisms. Two of these are pharmacokinetic, and the third is a function of alterations of the GABA(A)/benzodiazepine recognition site. The rate of redistribution of drug from the central compartment to the peripheral compartment is the most important determinant of the duration of clinical effect. The second mechanism responsible for the duration of action is hepatic metabolism and renal excretion. The third mechanism is acute tolerance that occurs at the level of the receptor.

The duration of action of benzodiazepines is a function of the CNS elimination half-life, which correlates with drug lipophilicity. During single-dose administration, the most lipophilic benzodiazepines have the shortest duration of action due to their rapid and extensive redistribution. They have the longest calculated plasma half-lives after redistribution because they remain in clinically inactive peripheral storage compartments (fat, muscle) for prolonged periods. In contrast, drugs that are less lipophilic have a longer duration of action, but a shorter plasma half-life due to slower redistribution from the CNS. This is illustrated by comparing the clinical anticonvulsant activity of lorazepam and diazepam. Lorazepam, a drug of relatively low lipophilicity, has more prolonged anticonvulsant activity than the highly lipophilic diazepam. The benzodiazepine midazolam is extremely lipophilic and rapidly metabolized in the liver. It has an extremely rapid onset but short duration of action due to both rapid redistribution and hepatic metabolism. Benzodiazepines may be classified into four different groups based on plasma elimination half-lives of the parent in combination with its active metabolites (see Tables 35-1 and 35-3).

TABLE 35-3 Classification of Benzodiazepines According to Plasma Half-Life

Short	HALF-LIFE
Flurazepam (Dalmane)	1–4 hr
Midazolam (Versed)	2–5 hr
Triazolam (Halcion)	2–6 hr
Intermediate	
Alprazolam (Xanax)	6–20 hr
Chlordiazepoxide (Librium)	5–20 hr
Halazepam (Paxipam)	10–20 hr
Lorazepam (Ativan)	10–20 hr
Oxazepam (Serax)	5–15 hr
Temazepam (Restoril)	5–20 hr
Estazolam (Prosem)	10–20 hr
Long	
Flunitrazepam (Rohypnol)	20–50 hr
Clonazepam (Klonopin)	20–30 hr
Diazepam (Valium)	20–70 hr
Nitrazepam (Mogadon)	17–50 hr
Very Long	
Clorazepate [†] (Tranxene)	30–200 hr
Desalkylflurazepam*	45–300 hr
Desmethyldiazepam*	30–200 hr
Prazepam [†] (Centrax)	30–200 hr

*Active metabolite of primary benzodiazepine compounds.

[†]Prodrug or drug precursor that does not reach the system circulation in clinically significant amounts. Compounds are metabolized in the gastrointestinal tract or liver before systemic absorption and appear in the serum as desmethyldiazepam.

During prolonged administration, the plasma half-life is a more reliable predictor of clinical response (intensity and duration) to the highly lipophilic agents. Repeated doses of lipid-soluble benzodiazepines cause the eventual saturation of peripheral fat stores during redistribution. As they become saturated, the concentration gradient from plasma to peripheral lipid compartment decreases, increasing the drug concentration and duration of action at CNS receptor sites. In addition, the lipid stores act as a depot for the drug and its active metabolites, resulting in prolonged release of drug and persistence of drug effects.⁴⁵ Benzodiazepines with longer elimination half-lives have a greater potential for accumulation after multiple doses and are more likely to exhibit prolonged “washout” periods after termination of multiple-dose therapy. In contrast, these agents are less likely to be associated with rebound side effects upon termination of treatment.⁴⁶

Hepatic biotransformation via phase I oxidation or phase II conjugation accounts for virtually all benzodiazepine metabolism and clearance in humans. Oxidative metabolism occurs primarily at the cytochrome families CYP3A, CYP2D, and CYP2C.⁴⁷ These drugs undergo aliphatic hydroxylation or *N*-demethylation to pharmacologically active intermediates, and/or conjugation to inactive glucuronides, sulfates, and acetylated compounds; these inactive compounds are subsequently renally excreted (Fig. 35-4).

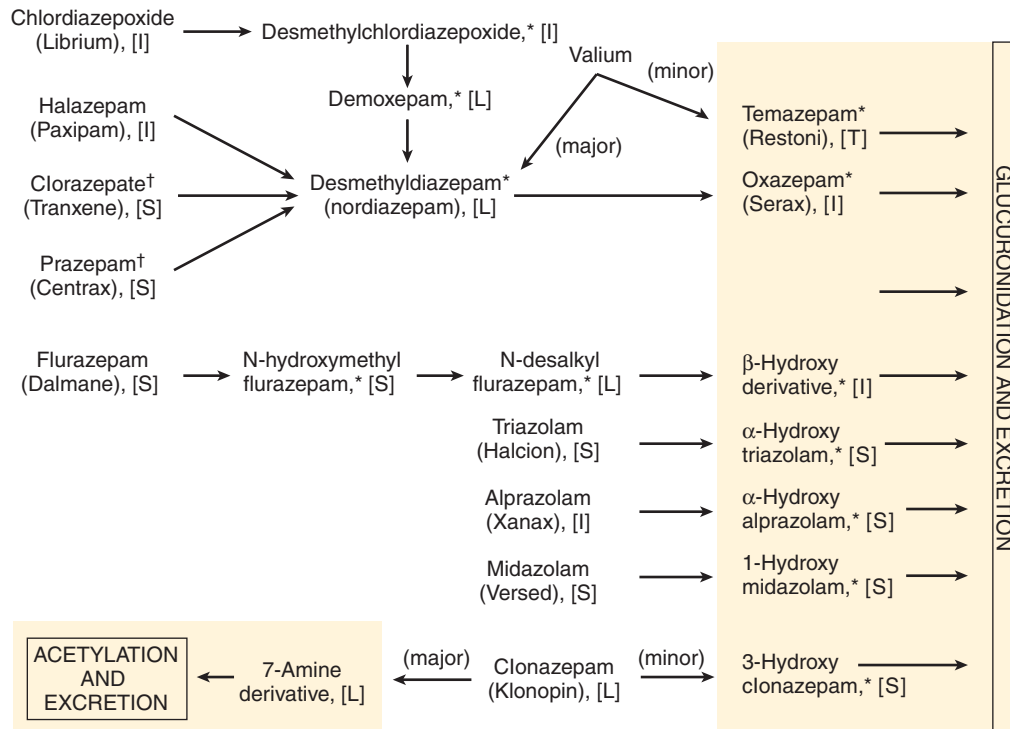

FIGURE 35-4 Major metabolic pathways of benzodiazepines approved for use in the United States. [S], conversion half-life of less than 6 hours; [I], conversion half-life of 6 to 20 hours; [L], conversion half-life of greater than 20 hours; *, active metabolite; †, prodrug or drug precursor, which does not reach the systemic circulation in clinically significant amounts. Shaded areas denote processes that proceed via phase II metabolism.

Several benzodiazepines are biotransformed to active metabolites, which possess half-lives that far exceed those of the parent compound. In such instances, persistent clinical effects are a consequence of the metabolite, its blood concentration, lipophilicity, and affinity for the GABA_A/benzodiazepine receptor complex. For example, flurazepam has a plasma half-life of 1 to 4 hours, but its pharmacologically active metabolite, desalkylflurazepam, has a serum half-life of 45 to 300 hours. Due to biotransformation to active metabolites with slow elimination, the duration of action of most benzodiazepines often bears little resemblance to the elimination half-life of the administered (parent) drug. For those agents that are biotransformed to inactive metabolites (e.g., lorazepam and oxazepam) or active metabolites that are subsequently rapidly eliminated (e.g., temazepam and triazolam), the duration of action will be more closely correlated with their clinical duration of action. Elimination of benzodiazepine metabolites usually occurs via renal clearance.

Tolerance can develop rapidly to nearly all of the clinical effects of benzodiazepines, although the effect on anxiolytic properties is limited. Several studies have been performed to evaluate the mechanism of tolerance. Mice made tolerant to lorazepam exhibited decreased benzodiazepine-receptor binding and GABA_A function, consistent with down-regulation of the receptor. Subsequent discontinuation of lorazepam was accompanied by increased motor activity, receptor binding, and function, consistent with up-regulation. Lorazepam-tolerant mice

also had markedly reduced levels of messenger RNA for some subunits of the GABA_A/benzodiazepine receptor.⁴⁸ Tolerance to chronic lorazepam was attenuated in mice, and the down-regulation of the GABA_A receptor reversed when the benzodiazepine antagonist flumazenil was administered concomitantly with lorazepam.⁴⁹ Tolerance is likely due to acute uncoupling of the benzodiazepine effect at the GABA receptor, as well as changes in gene expression for certain subunits of the GABA receptor, particularly the α_1 and γ_2 subunits, in conjunction with up-regulation of genes encoding less common subunits, such as α_4 and α_5 .^{31,33}

The incidence of tolerance is unclear. In one retrospective study of 191 patients that received long-term benzodiazepine therapy, 92% had not needed to increase their dose of benzodiazepine, despite drug treatment for a mean of 5.6 years.⁵⁰ Conversely, the development of tolerance to these medications has limited their long-term utility as sedatives and anticonvulsants. Interventions to prevent or reduce tolerance are under study and consist of intermittent dosing, tapering schedules, use of benzodiazepine antagonists, or coadministration of anticonvulsants.⁴⁹

Special Populations

GERIATRICS

The clinical responses of elderly patients to benzodiazepines are altered as a result of age-related changes in both pharmacokinetics and pharmacodynamics. Aging is

associated with an increased volume of distribution, increased plasma half-life, and decreased hepatic clearance of some benzodiazepines. Advanced age is associated with diminished hepatic oxidative metabolism, serum protein-binding (i.e., hypoalbuminemia), and glomerular filtration, all of which place the elderly at increased risk for complications due to benzodiazepine accumulation. At the receptor level, positron emission tomography has not demonstrated a diminution in benzodiazepine-binding potentials in elderly persons.⁵¹ However, elderly men experienced increased sensitivity to the sedative, hypnotic, and psychomotor effects of alprazolam when compared with younger men, despite similar serum benzodiazepine concentrations.⁵² The increased sensitivity to benzodiazepines may be due to a combination of age-related changes in the rate of acute tolerance, higher concentrations of drug in the brain due to altered blood-brain barrier permeability, enhanced benzodiazepine receptor binding, increased receptor functionality, or less homeostatic reserve to compensate for drug effect. Short-acting agents, which undergo less hepatic biotransformation, have few active metabolites, and have less capacity for bioaccumulation are the benzodiazepines of choice in this population.

HEPATIC AND RENAL IMPAIRMENT

Because benzodiazepines are primarily metabolized by the liver, their pharmacokinetics may be altered in patients with cirrhosis.^{45,46,53} In general, agents that undergo phase I biotransformation may accumulate in cirrhotic patients due to increased volumes of distribution, decreased protein binding, prolonged half-life, and decreased oxidative clearance.⁴⁵ Dose adjustment is usually unnecessary for agents, which are biotransformed by phase II glucuronidation alone. Elimination of benzodiazepine metabolites occurs via renal clearance. Patients with renal insufficiency may be at risk for the accumulation of active metabolites.

PREGNANCY

Benzodiazepines readily cross the placenta and may accumulate in the fetus, with serum concentrations that exceed those achieved in the mother. High doses of benzodiazepines administered during the immediate prepartum period may produce a floppy baby syndrome in newborn infants. This syndrome may be attributed to the persistence of long-acting benzodiazepine metabolites in neonatal serum.^{54,55} The incidence may decrease when benzodiazepines, which undergo only phase II metabolism, are administered.⁵⁶

Most benzodiazepines are categorized as class D in pregnancy by the FDA, indicating that these drugs have caused or are expected to cause an increased incidence of human fetal malformations with maternal use. The teratogenic potential of benzodiazepines is unknown, and categorization comes from early human data that are inconsistent.

Fetal benzodiazepine dependence occurs, and subsequent withdrawal may be delayed up to 10 days postpartum due to diminished neonatal benzodiazepine clearance.⁵⁷ Benzodiazepines and their metabolites are

excreted in breast milk in clinically significant amounts⁵⁸ and may sedate a nursing neonate. Because the metabolic capability of neonates is immature,⁵⁹ benzodiazepines metabolized by phase I pathways may persist for extended periods. Breast-feeding should be avoided if benzodiazepines are to be administered to lactating women.

OTHER

There are ethnic-associated differences in the metabolism of certain benzodiazepines. For instance, East Asian populations exhibit slower phase I activity of the P-450 oxidative enzyme system (particularly the CYP2C family) and may be more sensitive to the clinical effects of benzodiazepines.^{47,60} Gender-specific sensitivity to benzodiazepine effects has been reported in association with concomitantly administered progesterone in postmenopausal women.⁶¹ This is likely a pharmacodynamic effect, because progesterone and its metabolites are steroid hormones, which modulate activity at the GABA(A) receptor. Finally, obese patients may have an increased sensitivity to benzodiazepine effects associated with multiple doses.⁶²

Drug Interactions

Benzodiazepine drug interactions can be pharmacodynamic or pharmacokinetic; they may be associated with effects at the GABA_A/benzodiazepine recognition site or associated with benzodiazepine absorption and hepatic metabolism.

Benzodiazepines potentiate the CNS-depressant effects of ethanol and numerous other drugs. Many of these interactions occur at the GABA_A receptor, where ethanol, barbiturates, propofol, some general anesthetics, and other sedative-hypnotics (e.g., meprobamate, zaleplon, zolpidem, and zopiclone) also have binding sites and act as positive GABA modulators. Methylxanthines and some antibiotics diminish benzodiazepine-induced sedation.

Since phase I biotransformation is a primary metabolic pathway for many benzodiazepines (e.g., diazepam, alprazolam, and temazepam), drugs that induce or inhibit the function of the P-450 CYP3A4 and CYP2D or 2C enzyme families can enhance or diminish the normal metabolism of benzodiazepines. The result may be shortened elimination half-life and reduced efficacy, or prolonged duration of action and oversedation.^{47,63} Phase II conjugation reactions are effected to a lesser degree, inhibited by probenecid and induced by oral contraceptive agents.⁴⁷ These alterations in conjugative enzyme function will not produce significant clinical effects as related to benzodiazepines.

Certain drugs also inhibit renal tubular secretion of benzodiazepine metabolites. Probenecid inhibits the tubular secretion of organic bases, and has been shown to decrease the renal clearance of *N*-desmethyladinazolam, the active metabolite of adinazolam.⁶⁴ The coadministration of probenecid with adinazolam was associated with a decrease in psychomotor skill performance in healthy volunteers, and was presumed to be secondary to *N*-desmethyladinazolam accumulation.

TOXICOLOGY

Clinical Manifestations

ACUTE

The acute clinical manifestations of benzodiazepines are mainly those of CNS depression. Patients with a pure benzodiazepine overdose display mild to moderate sedation, often with dysarthria and ataxia, without serious neurologic, cardiovascular, or respiratory impairment.

CHRONIC

The long-term effects of benzodiazepines on the GABA_A receptor and GABA physiology are not known. Research into the neurochemical effects of chronic benzodiazepine use indicates the possibility of subtle and delayed effects on cognitive function and memory acquisition. The reversibility of these effects is unclear. In one study of long-term benzodiazepine users who were detoxified from benzodiazepines, some cognitive defects persisted for up to 6 months.

Adverse Effects

Therapeutic doses of benzodiazepines cause various degrees of sedation, drowsiness, lightheadedness, lethargy, and lassitude in virtually all patients, especially when therapy is initiated. Dysarthria, ataxia, motor incoordination, impairment of cognition, and amnesia may also occur. Uncommonly, fatigue, headache, blurred vision, vertigo, nausea and vomiting, diarrhea, arthralgias, chest pain, and incontinence have been reported. The frequency and severity of side effects increase with age.

Uncommon side effects of rapid intravenous benzodiazepine administration include respiratory arrest, cardiac arrest, hypotension, and phlebitis at the site of injection. Severe adverse reactions are more common in the elderly, patients with severe cardiopulmonary disease, and those taking cardiorespiratory depressant medications. Other extremely rare side effects reported after benzodiazepine overdose include neuromuscular blockade; hematologic, renal, and hepatic toxicity; acute rhabdomyolysis; anaphylaxis; dermatitis; and acute respiratory distress syndrome. Postoperative exposure to benzodiazepines may increase the risk for delirium in recovering surgical patients.

Long- and short-acting benzodiazepines have different side effect profiles.⁶⁵ Long-acting benzodiazepines are associated with residual sedation and daytime drowsiness and may cause greater respiratory depression in patients with pulmonary disease. In addition, long- and intermediate-acting benzodiazepines are considered to have reinforcing properties that may lead to their persistent use and potential for abuse.⁶⁵ In comparison, short-acting benzodiazepines (those used as hypnotics) are more commonly associated with daytime anxiety and rebound insomnia upon discontinuation.

The anxiolytic benzodiazepines have been reported to unmask bizarre, uninhibited behavior in some patients, as well as hostility, rage, paranoia, and depression. These reactions occur more frequently in elderly patients or

those with overt or latent psychoses and organic brain syndrome. Such disinhibition or dyscontrol reactions are quite rare and usually are related to the patient's preexisting expectations and pretreatment level of aggression and hostility.⁶⁶

Rates of benzodiazepine usage increase with age, and elderly patients thus account for a disproportionately large percentage of benzodiazepine prescriptions. In addition, the elderly are more likely to be long-term users of these drugs. These facts, in combination with age-related differences in benzodiazepine pharmacokinetics and pharmacodynamics, place this population at greater risk for adverse side effects, namely, excess sedation, falls, and cognitive impairment.

Multiple studies demonstrate adverse effects suffered by elderly benzodiazepine users.⁶⁷⁻⁶⁹ Chronic use and higher-than-recommended dosages are associated with an increased risk for accelerated decline in physical performance in community-dwelling elderly women.⁷⁰ In one review of 11 epidemiologic studies, at least a 50% increase in the risk for hip fracture secondary to falls was associated with benzodiazepine use, especially during the initiation of therapy and at higher doses.⁷¹ After adjustment for covariates, the risk for hip fracture was also increased with benzodiazepine dosage regimens greater than or equal to 3 mg/day of diazepam equivalents, during initiation (first 2 weeks) of benzodiazepine therapy, and continuous benzodiazepine use for greater than 1 month.⁷² Short-acting benzodiazepines were not found to be safer than long-acting agents in these studies.

Benzodiazepines, particularly long-acting agents, are the drug class most commonly associated with cognitive impairment in elderly people, often producing confusion, forgetfulness, slowing of thought processes, and loss of the ability to care for oneself.⁷³ In a 4-year longitudinal study, chronic elderly benzodiazepine users had a greater risk for cognitive decline, independent of age, sex, education, ethanol, and other psychotropic drug use.⁷⁴ A subgroup of elderly patients with neurodegenerative processes, such as dementia, may be at greater risk for cognitive impairment.^{69,75} Although a recent study notes the difficulty of quantifying benzodiazepine exposure in relation to adverse events,⁷⁶ and outcomes of cognitive studies depend on the battery of tests applied to the study patients, it is still prudent to be cautious when using benzodiazepines in the elderly. Low doses should be administered for brief periods, and patients should be closely monitored for the development of side effects. If excess sedation, confusion, agitation, or other signs of cognitive impairment develop in an elderly patient taking benzodiazepines, the drug should be discontinued immediately pending further clinical investigation. The benzodiazepine effect may be overlooked by family and physicians and wrongly attributed to senility or a worsening of an underlying disease process.

Benzodiazepine use in pregnancy may be associated with teratogenic effects and fetal loss. A syndrome of benzodiazepine embryopathy was reported in the 1980s, consisting of growth retardation, dysmorphic features, and CNS dysfunction, after oxazepam exposure.⁴⁵ These

findings may be linked to potential benzodiazepine-induced regulation of GABA_A subunit expression in the embryo. For example, mice, which lack β_3 subunits, have an associated cleft palate. A recent review of the teratogenicity of benzodiazepines concluded that current data are insufficient to make informed decisions regarding benzodiazepine use in pregnancy, but suggest that diazepam and chlordiazepoxide, but not alprazolam, are safe.⁷⁷ These drugs, however, are still categorized as pregnancy class D by the FDA.

In an animal model, fetal exposure to benzodiazepines alters function and stressor-induced responsiveness of the GABA_A receptor in the brains of the exposed adult animals. It is hypothesized that the GABA receptor has a developmental role in integrated stress responses, in addition to developmental changes in non-neural systems. Research is ongoing into the effect of prenatal exposure to benzodiazepines on the development of both the neurologic and immunologic systems. Central GABA_A receptors and “peripheral” benzodiazepine receptors may interact with exogenous benzodiazepines in a way that adversely affects fetal development of these systems.

Fetal benzodiazepine dependence and subsequent neonatal withdrawal can occur. The syndrome resembles neonatal narcotic withdrawal; symptoms include hyper-tonicity, irritability, tremors, hyperreflexia, tachypnea, and weight loss.⁵⁷ Benzodiazepine administration to ill neonates may be associated with an increased risk for respiratory depression and hypotension.⁷⁸

Early animal data suggested that benzodiazepine use may influence the risk for selected cancers. However, no association between the use of these drugs and the incidence of cancers, including breast, large bowel, malignant melanoma, lung, endometrium, or ovarian, has been proven.^{79,80}

Acute Overdose

Numerous clinical reports support the relatively benign nature and uncomplicated course of benzodiazepine overdose.^{44,81,82} In contrast to older sedative-hypnotic drugs, benzodiazepines have a high therapeutic index. Deaths attributable to benzodiazepines taken alone are extremely rare,^{1,81,82} and often involve short-acting benzodiazepines.⁸³ For instance, death has been associated with isolated ingestions of flunitrazepam, flurazepam, nitrazepam, and triazolam.

CNS depression is the hallmark of benzodiazepine overdose. Patients become acutely drowsy, stuporous, and ataxic, or may present in low-grade coma without focal neurologic abnormalities. These patients can generally be aroused from this state with verbal or painful stimulation. In one series of 38 patients with pure benzodiazepine overdose, 16 were awake and none were more symptomatic than grade 0 coma (asleep but arousable).⁸⁴ In a series of 93 cases of diazepam overdose, patients required only supportive therapy, and no patient who ingested benzodiazepines alone required hospital admission.⁸⁴ Occasionally, patients may manifest mild hypothermia, bradycardia, and hypotension.

Profound and significant coma, hypotension, respiratory depression, or hypothermia is extremely uncommon in oral overdose, unless other drugs have also been ingested. Although prolonged deep coma, cyclic coma, and focal neurologic signs⁸⁵ have been reported with benzodiazepine overdose, such clinical scenarios are distinctly unusual. Most acutely poisoned patients become easily arousable or awaken within 12 to 36 hours. The duration of coma, however, may be prolonged in elderly and nonhabituated patients. After recovery of consciousness, it is typical for overdosed patients to feel dizzy, depressed, and apathetic for an extended period of time. Recovery may also be prolonged for those who develop complications (e.g., aspiration pneumonia).

When they do occur, deaths are almost always due to benzodiazepines taken in combination with other drugs. The risk for toxicity is substantially increased when co-ingested with other CNS depressants.⁸² In this series, the combination of benzodiazepines and barbiturates was noted to be particularly dangerous, and 50% of these overdose patients required mechanical ventilation. Ethanol, identified as a co-ingestant in 38% of benzodiazepine overdoses,⁴⁴ also enhances the CNS toxicity of benzodiazepines.⁸⁶ These clinical outcomes are predictable, based on the synergistic effects of these drugs at the GABA_A/benzodiazepine receptor complex.

DIAGNOSIS

Laboratory Testing

Qualitative urine screening for the presence of parent benzodiazepines or their metabolites provides rapid, useful information in the evaluation of patients with an unknown cause of CNS depression. Qualitative screening techniques, however, are fallible and should not be used in isolation to make clinical treatment decisions. Most laboratories perform initial screens for benzodiazepines with diagnostic immunoassays, the results of which are confirmed by gas or high-pressure liquid chromatography and/or mass spectrometry. Quantitative plasma measurements are not available in most hospitals, and provide no significant therapeutic direction to the treating physician.^{81,84,87,88} Plasma concentrations of benzodiazepines correlate very poorly with the severity of toxic effects (e.g., degree of CNS depression) or mortality.

Various urine immunoassay screens are available and are standardized against the detection of a single benzodiazepine compound, usually oxazepam. Other structurally similar benzodiazepines are subsequently detected through immunologic cross-reactivity with the compound that is used as the standard. The concentration of benzodiazepine metabolites in urine can vary by several orders of magnitude, depending on the ingested drug, drug dose, and time of sample collection relative to dosing. Therefore, the sensitivity for detecting any individual benzodiazepine may vary significantly.

Laboratory detection of benzodiazepines depends on the particular toxicologic screen used. For example, the

enzyme-multiplied immunoassay technique (EMIT) screen cross-reacts with chlordiazepoxide, clonazepam, demoxepam, desalkylflurazepam, desmethyldiazepam, flurazepam, lorazepam, oxazepam, prazepam, and temazepam.⁸⁹ However, several of these compounds are inconsistently detected unless they are present in extremely high concentrations. Enzymatic hydrolysis may improve the yield of EMIT screens.⁹⁰ Triazolobenzodiazepine derivatives, such as alprazolam or triazolam,⁹¹ may be particularly difficult to detect in small but clinically significant ingestions because they possess poor immunologic cross-reactivity with oxazepam. The radioimmunoassay screening test, Abuscreen (Roche Diagnostic Systems, Inc., Somerville, NJ), identifies alprazolam, chlordiazepoxide, demoxepam, clorazepate, diazepam, temazepam, desmethyldiazepam, desalkylflurazepam, halazepam, lorazepam, midazolam, and prazepam but does not detect clonazepam or flurazepam.⁹²

Various urine screens have been compared in their ability to accurately detect benzodiazepines.^{93,94} The metabolites that most commonly produce false-negative results were lorazepam and 7-aminoclonazepam. None of the screens were able to detect α -hydroxytriazolam or α -hydroxyalprazolam. Although some urine screens have sensitivities of 90% to 98%, as compared with gas chromatography/mass spectrophotometry, the range in sensitivities is 80% to 100%.⁹⁵ In summary, the cross-reactivity lists quoted by screen manufacturers may be incomplete, and it is important to realize that some commonly used screens may produce negative results despite a clinically significant benzodiazepine ingestion. In addition, positive screens for benzodiazepines may not correlate with clinical toxicity and may reflect the presence of an inactive metabolite (e.g., *N*-desmethyldiazepam) that cross-reacts with the screen.

False-positive benzodiazepine screens have been reported in the urine of patients using the nonsteroidal anti-inflammatory agent oxaprozin.^{96,97} Its urinary metabolite is probably responsible for these results. Similar false-positive results have been reported for etodolac, naproxen sodium, fenoprofen calcium, and tolmetin sodium.⁹⁴ False-positive screens have also been reported in the presence of sertraline.^{98,99} In this era of drug screening for legal and management decisions in the workplace, it is important to be aware of the limitations of some screening technologies.

Although some research toxicology laboratories have the capacity to measure quantitative benzodiazepine levels, their measurement is not useful in the management of acute overdose. Therapeutic diazepam levels range between 0.5 and 2.0 $\mu\text{g}/\text{mL}$, while levels of 5 to 20 $\mu\text{g}/\text{mL}$ are generally regarded as toxic. Yet, many patients with “toxic” levels may exhibit no or only mild clinical toxicity. Quantitative measurement of serum benzodiazepines and their metabolites may be useful for differentiating acute from chronic ingestions or for medicolegal or forensic cases.

Other sources of tissue used for benzodiazepine detection include hair^{100,101} and oral fluids.⁹⁵ Both sources may yield false-negative results and lack the sensitivity to be used as screening tests. Forensic studies

have also examined benzodiazepine detection in post-mortem samples of bile and bone, with fairly good yield.^{102,103}

Other Diagnostic Testing

Other diagnostic testing should be performed as necessary to identify or exclude coexisting conditions, which may also require treatment. Such testing often includes, but is not limited to, computed tomography of the head, laboratory testing for ethanol and other toxicants for which qualitative or quantitative testing may be beneficial, measurements of serum electrolytes and glucose, as well as electroencephalography for sub-clinical status epilepticus. Arterial blood gas analysis and capnography may be performed to assess the adequacy of respiration in those patients with CNS depression.

Differential Diagnosis

Patients with a pure benzodiazepine overdose display mild to moderate sedation, often with dysarthria and ataxia, without serious focal neurologic, cardiovascular, or respiratory derangement. There are no specific diagnostic clinical features unique to benzodiazepine overdose. Toxicity from benzodiazepines produces signs and symptoms that are similar to many toxicologic and nontoxicologic entities. The CNS depressant effects may be similar to effects produced by alcohols, antiepileptics, antipsychotics, barbiturates, carbon monoxide and other gases, lithium, opiates, other sedative-hypnotics, and skeletal muscle relaxants. CNS infection, traumatic head injury, cerebrovascular accidents, and metabolic disturbances should be considered and ruled out with appropriate testing.

MANAGEMENT

Supportive Measures and Laboratory Testing

Treatment for benzodiazepine overdose is primarily supportive. Patients with significant CNS or respiratory depression should have their airways protected, breathing assisted, and cardiovascular support provided supportive as necessary. All patients should have continuous cardiac monitoring, an intravenous line established, and electrocardiography performed. Supplemental oxygen, continuous pulse oximetry, and parenteral thiamine, dextrose (or rapid fingerstick glucose determination), and naloxone should be considered for patients with altered mental status or seizures. Semi-comatose patients should be placed in the left lateral, head-down position to minimize the risk for aspiration. Frequent vital sign and neurologic evaluations are necessary. Routine laboratory analysis should include a complete blood count and measurement of electrolytes, blood urea nitrogen, creatinine, glucose concentrations, and pregnancy testing for women of childbearing age. Serum acetaminophen and

salicylate concentrations should be performed for all intentional overdose patients. Co-ingestion of other toxic substances, concurrent trauma, or other underlying medical conditions significantly alter the diagnostic and therapeutic approach. Urine screening may confirm the presence of benzodiazepines or their metabolites. Negative screening does not rule out the presence of certain benzodiazepines, as mentioned above.

Decontamination and Enhanced Elimination Techniques

Single-dose administration of activated charcoal (1 g/kg orally or by nasogastric tube) is the preferred method of gastrointestinal decontamination and may be beneficial if administered within 1 hour of drug ingestion. Orogastric lavage is not recommended for isolated benzodiazepine overdose since the risk for death is very low in this patient population. The clinical benefit of activated charcoal administration beyond 1 hour following benzodiazepine ingestion is likely low.

Antidotes

Flumazenil (Romazicon [Roche Pharmaceuticals of Hoffman-La Roche, Inc., Nutley, NJ]) was synthesized in 1979 and is the benzodiazepine antagonist available in the United States. It is a 1,4-imidazobenzodiazepine, a derivative of the antibiotic anthramycin,¹⁰⁴ which contains a diazepine ring that binds at the benzodiazepine receptor complex (Fig. 35-5).

Flumazenil is administered intravenously. It has also been studied as a potential reversal agent after subcutaneous,¹⁰⁵ sublingual, intramuscular, rectal,¹⁰⁶ submucosal,¹⁰⁷ intranasal,¹⁰⁸ and endotracheal administration.¹⁰⁹ Orally administered flumazenil has been studied in the treatment of epilepsy¹¹⁰⁻¹¹² and hepatic encephalopathy.¹¹³

Flumazenil has a volume of distribution of 1.1 L/kg, is 40% to 50% protein bound, and is highly lipid soluble.¹⁰⁴ It has a distribution half-life of 5 minutes and rapidly crosses the blood-brain barrier to reverse benzodiazepine-induced sedation within 1 to 2 minutes after intravenous administration. The mean half-life of flumazenil is 57 minutes; therefore, re-sedation may occur within 1 to 2 hours after administration, requiring subsequent doses. Flumazenil is hepatically metabolized by conjugation, and the metabolite is renally excreted. In oral dosage form, flumazenil is rapidly absorbed but has low bioavailability secondary to significant first pass metabolism in the liver.

The dose of flumazenil is 0.2 IV per dose, to a total of 3 mg, in adults and 0.01 mg/kg IV per dose, to a total of

0.05 mg/kg or 1 mg, in children. A continuous infusion of flumazenil has been used in both children¹¹⁴ and adults.¹¹⁵ The adult dose of flumazenil is 0.2 mg intravenously over 30 seconds, followed by 0.3 and 0.5 mg at 1-minute intervals to a maximum dose of 3 mg. Alternatively, flumazenil may be administered in 0.2-mg aliquots intravenously every 30 to 60 seconds until a dose of 3 mg is reached. Flumazenil rapidly reverses the sedative, anxiolytic, anticonvulsant, ataxic, anesthetic, and muscle relaxant effects of benzodiazepines in animals and humans.¹¹⁶ It restores an electroencephalogram to the baseline waking state in patients who have been administered benzodiazepines,^{117,118} and is an effective antidote for benzodiazepine overdose.¹¹⁹

Patients with benzodiazepine-induced coma respond dramatically within 1 to 5 minutes after flumazenil administration.^{120,121} A number of benzodiazepine effects have been reversed by flumazenil, which include respiratory depression,¹²² midazolam-induced laryngospasm,¹²³ first-degree atrioventricular block in alprazolam overdose,¹²⁴ lorazepam-induced acute delirium,¹²⁵ and midazolam-associated myoclonic movements in full-term newborns.¹²⁶

Incomplete or partial antagonism of benzodiazepine-induced sedation has been reported¹²¹ but may be secondary to co-ingestion of other sedative-hypnotics or concomitant medical causes of depressed consciousness. In addition, residual memory deficits may persist. Finally, orally administered flumazenil may only partially reverse the effects of benzodiazepines.¹²⁷

Flumazenil acts as an antagonist, competitively removing both positive and negative GABA modulators from the benzodiazepine recognition site. It binds at the same α_2 interface on the GABA(A) complex where benzodiazepines bind and interacts with amino acid residues that are not associated with benzodiazepine binding. At high doses, it is reported to have agonist-like anticonvulsant activity. However, it is also reported to have weak inverse agonist properties.¹²⁸ Based on its mechanism of action, flumazenil has been used to reverse sedation in cases of hepatic encephalopathy.¹²⁹ Anecdotal reports also describe partial reversal of ethanol- and carbamazepine-induced CNS depression.

When administered to normal volunteers, flumazenil has produced dizziness, facial erythema, anxiety, and headache. Symptoms are often mild and disappear within several minutes. Flumazenil has been shown to further increase intracranial pressure when administered to head-injured patients with elevated intracranial pressure. Reports of ventricular dysrhythmias have been associated with its administration.¹¹⁴ Additionally, flumazenil has been noted to precipitate seizures in epileptic patients who take benzodiazepines for seizure control and in patients who have co-ingested drugs that lower the seizure threshold.^{130,131} Older case series demonstrated an increased risk for seizures after flumazenil administration to patients who had ingested cyclic antidepressants. A more recent study, however, did not show such serious complications occurring in this setting. The lack of seizure precipitation in this latter study may have been due to slow incremental flumazenil dosing or smaller total doses of the antagonist.¹³² Flumazenil has

FIGURE 35-5 The chemical structure of flumazenil (Ro 15-1788), a specific benzodiazepine antagonist.

also precipitated acute benzodiazepine withdrawal and seizures in dependent persons. For these reasons, the role of flumazenil in patients who present with suspected benzodiazepine overdose and CNS depression or undifferentiated drug coma is controversial.

Flumazenil has been used in the pediatric population for both reversal of sedation and for empiric treatment in the unconscious patient. Pediatric case reports of flumazenil-associated seizures have also been reported,¹³³ one in the setting of iatrogenic apnea induced by diazepam and treated with flumazenil after an infant presented with febrile seizures.¹³⁴ The Flumazenil Pediatric Study Group suggests flumazenil dosing of 0.01 mg/kg infusion (max 0.2 mg) each minute to a maximum of 0.05 mg/kg (or 1 mg) for reversal of sedation.¹³⁵

As mentioned, flumazenil has the potential to precipitate withdrawal symptoms in benzodiazepine-dependent individuals.¹³⁶ In animal studies, the severity of withdrawal depends on the specific benzodiazepine used, the dose and duration of treatment, and the dose of flumazenil administered.¹³⁷ Abrupt withdrawal symptoms are usually more severe when induced by flumazenil administration.

Although the potential toxicity of benzodiazepines is relatively low and aggressive therapy for pure overdose is rarely required, flumazenil offers several important potential uses in clinical medicine. Its use can help to confirm a suspected diagnosis of benzodiazepine overdose and obviate the need for other diagnostic testing (e.g., cranial computed tomography and lumbar puncture). Flumazenil may reverse overdose of zolpidem and zopiclone, and may be indicated for benzodiazepine-associated respiratory depression, particularly if intubation and mechanical ventilation would otherwise be indicated. Flumazenil may be useful postoperatively to reverse the effects of preoperative sedation or to reverse iatrogenic overdose when benzodiazepines are used for conscious sedation. Flumazenil may be used in select circumstances with experienced practitioners in these settings. The use of flumazenil for undifferentiated coma, even when administered slowly, is dangerous and not recommended. Despite its potential usefulness, flumazenil should not become “routine” antidote in the treatment of coma secondary to overdose.

Elimination

There are no practical ways to significantly enhance the elimination of benzodiazepines. Forced diuresis is of no value. Extracorporeal removal techniques are not recommended as part of treatment for benzodiazepine poisoning since these agents have large volumes of distribution and high plasma protein binding.

Disposition

Most patients with isolated benzodiazepine overdose develop minimal to mild toxicity and are medically safe after an observation period of 4 to 6 hours in the emergency department. Patients who are able to safely ambulate after observation may be discharged

after appropriate psychiatric consultation. Patients who develop more significant CNS depression or have continued evidence of mild toxicity at 6 hours should be admitted to a monitored bed for continued observation.

Barbiturates

RICHARD LYNTON, MD

At a Glance...

- The barbiturates are a family of sedative-hypnotics. Their clinical use has fallen dramatically over the past 3 decades as benzodiazepines and other safer sedative-hypnotics have been created.
- Barbiturates are associated with significant morbidity and mortality, the result of their ability to produce profound central nervous system and myocardial depression.
- There are nine barbiturates in clinical use, each having a unique pharmacokinetic profile.
- Barbiturate use is associated with a number of significant drug interactions.
- Tolerance and dependence with barbiturates can lead to significant addiction as well as an abstinence syndrome (withdrawal) with acute discontinuation.
- Barbiturate overdose produces a syndrome of central nervous system depression; severe intoxication may lead to hemodynamic instability. Other manifestations, for example, skin changes ("barb blisters"), are less common.
- Treatment of barbiturate overdose begins with supportive care that includes airway and blood pressure support
- The elimination of phenobarbital can be enhanced through three measures: multiple-dose activated charcoal, urine alkalinization, and hemodialysis. Hemodialysis and other extracorporeal drug removal techniques are generally reserved for patients with severe phenobarbital toxicity (serum concentration > 100 µg/L). These elimination techniques are not effective with other barbiturates.

Over the past 30 years, barbiturates as a class have slowly been replaced by safer sedative-hypnotics such as benzodiazepines. Their role to toxicologists as drugs in overdose settings are therefore significantly less, as shown in cumulative data from poison centers in North America (Fig. 36-1). Barbiturate overdose now results in less morbidity and mortality when compared with more commonly used benzodiazepines. However, barbiturates continue to be important in sedation, anesthesia, and seizure control, and as an adjunct in headache treatment. With such widespread use, the barbiturates continue to have overdose potential.

HISTORY

In 1864, research assistant Adolph von Baeyer in Ghent, Belgium, produced barbituric acid, a cyclic diureide, from the condensation of malonic acid and urea.¹ Barbituric acid itself does not possess any central nervous system (CNS) properties. The hypnotic and CNS-depressant effects of its congeners were discovered after various substitutions were made to it.

In 1903, Fisher and von Mehring introduced diethylbarbituric acid or barbital as the first barbiturate to enter medicine, under the trade name Veronal. In 1912, phenobarbital, under the trade name Luminal, was independently and simultaneously brought to medicine by Loewe, Juliusburger, and Impens.¹⁻³

In the mid-20th century, barbiturates became the most popular class of sedative-hypnotics. During this time they also became popular substances of abuse, along with other sedative-hypnotics of that era; collectively these agents were known as "downers." Sold on the street with such names as "red devils," barbiturates were taken either alone or with ethanol to produce a pleasurable feeling of intoxication. The death of actress Marilyn Monroe was attributed to barbiturates; an empty bottle of Nembutal was found at her side. As safer sedative-hypnotics for those with insomnia or other sleep disturbances were created, use of barbiturates declined quickly; they are rarely used for these purposes any longer. Finally, among advocates of euthanasia and suicide, barbiturates remain one of the most commonly recommended drugs.

PHARMACOLOGY AND PHARMACOKINETICS

Table 36-1 shows the general formula of barbituric acid and where the substitutions occur that give each chemical its characteristics. Most barbiturates carry oxygen at carbon position 2 on the ring and hence are called oxybarbiturates. Barbiturates where sulfur replaces oxygen are called thiobarbiturates; of these, only thiopental is currently in use in the United States.

FIGURE 36-1 Toxic Exposure Surveillance System (TESS) Data. (Data from references 65 through 69.)

TABLE 36-1 Barbiturate Classification

GENERAL FORMULA AND SUBSTITUTED DERIVATIVES

BARBITURATE	TRADE NAME	pKa	DURATION OF ACTION (hr)	PLASMA HALF-LIFE (hr)	R _{5a}	R _{5b}	R ₃
Short-Acting Barbiturates							
ULTRASHORT							
Thiopental	Pentothal	7.6	0.3	6–46	Ethyl	1-Methylbutyl	H
Methohexital	Brevital	7.9	0.3		Allyl	1-Methyl-2-pentynyl	CH ₃
SHORT							
Pentobarbital	Nembutal	7.96	3.0	21–42	Ethyl	1-Methylbutyl	H
Secobarbital	Seconal	7.90	3.0	20–28	Allyl	1-Methylbutyl	H
INTERMEDIATE							
Amobarbital	Amytal	7.75	3–6	15–40	Ethyl	Isopentyl	H
Butobarbital	Butisol	7.74	3–6	34–42	Ethyl	sec-Butyl	H
Long-Acting Barbiturates							
Barbital	Veronal	7.74	6–12	48	Ethyl	Ethyl	H
Mephobarbital	Mebaral	8.5	6–12	48–52	Ethyl	Phenyl	CH ₃
Phenobarbital	Luminal	7.24	6–12	48–144	Ethyl	Phenyl	H
Primidone	Mysoline	—	6–12	6–22	Ethyl	Phenyl	H

*S= Substitution for O= in thiopental, H₂ substitution for O= in primidone.

Lipid solubility is important in barbiturate pharmacokinetics. In general, increased lipid solubility decreases drug latency of onset and duration of action, and increases metabolic degradation rate and hypnotic potency. Methylation of one or both of the nitrogens increases drug affinity for lipids and hence decreases duration of action; methohexital is an example of such a drug. Other methylated barbiturates are demethylated in the body, producing long-acting compounds; mephobarbital conversion to phenobarbital is such an example. Sulfur in general makes thiobarbiturates more lipid soluble than oxybarbiturates; this explains thiopental's rapid onset and short duration. The anticonvulsant activity of barbiturates is produced by discrete moieties such as a phenyl group at carbon 5 or alkyl groups on both nitrogen atoms.^{1,4}

Barbiturates are well absorbed orally as sodium salts. Other routes of administration include rectal (particularly in children) and intravenous.

Barbiturates distribute throughout all body compartments, including the blood-brain barrier, and can cross the placenta, depending on their lipid solubility, protein binding, and extent of ionization.

Barbiturates are metabolized by either oxidation at carbon 5, n-dealkylation, cleavage of the barbituric acid

ring, or desulfuration as in the case of thiobarbiturates. Of these, oxidation is the most important, yielding polar compounds that appear in urine as free compounds or glucuronide conjugates. Barbital, because of its low lipid solubility, is one of the few barbiturates that rely almost exclusively on renal elimination for removal of drug from the body.¹

Primidone is unique in that it is oxidized to phenobarbital and phenylethylmalonamide, the latter having no anticonvulsant activity.⁵ In neonates the half-life of phenobarbital is very long (45 to 409 hours) but decreases with age. Primidone conversion to its active metabolites generally does not occur with neonates.⁶

THERAPEUTIC USES OF BARBITURATES

Table 36-2 displays some of the currently used barbiturates and their indications. Barbiturates continue to play an important role in seizure treatment. Phenobarbital is used as maintenance therapy for patients with seizure disorders. It is useful for both generalized tonic-clonic seizures and simple partial seizures. Several, including phenobarbital and pentobarbital, are useful for treating status epilepticus in the intensive care unit

**TABLE 36-2** Common Barbiturates and Their Uses

BARBITURATE	SCHEDULE	INDICATION	PREPARATIONS
Thiopental	III	Anesthetic Pediatric sedation ICP management Status epilepticus	250, 400, and 500 mg injectable 1, 2.5, 5 g injectable
Methohexital	IV	Anesthetic	500 mg, 2.5 g, 5 g injectable
Secobarbital	II	Insomnia Status epilepticus	100 mg capsule
Amobarbital	II	Insomnia Narcoanalysis Schizophrenia aid	500 mg injectable 50 mg capsules
Butobarbital	II (secobarbital/phenobarbital combination)	Sedation, anxiety	30 mg/5 mL elixir 30 and 50 mg tablets
Mephobarbital	III IV	Sedation Seizure prophylaxis	32, 50 and 100 mg tablets
Pentobarbital	II III (suppositories)	Insomnia Status epilepticus Barbiturate withdrawal Coma induction	18.2 mg/5 mL elixir 50, 100 mg capsules 50 mg/mL injectable 30, 60, 120, 200 mg suppositories
Phenobarbital	IV	Seizure prophylaxis Barbiturate withdrawal Sedation, anxiety	20 mg/5 mL elixir 15, 16, 30, 32, 60 65, and 100 mg tablets 30, 60, 65, and 130 mg/mL
Primidone		Psychomotor seizure prophylaxis Refractory tonic-clonic seizures	

ICP, intracranial pressure.

where a “barbiturate coma” can be employed in attempts to treat refractory seizures. Pentobarbital as a second-tier agent for the treatment of refractory intracranial hypertension is also commonly used.^{7,8} However, a recent Cochrane review found no evidence of improved outcome when barbiturates were used to treat increased intracranial pressure in severely head-injured patients.⁹

Several over-the-counter (OTC) and prescription medications contain barbiturates (e.g., butalbital in combination with acetaminophen, codeine, aspirin, or caffeine) that are used to treat migraine headaches. Barbiturates are also used to treat insomnia and anxiety states; as hypnotics, they are also used to provide general anesthesia as in the case of thiopental and methohexital.

Less well known uses for barbiturates include primidone for the treatment of essential hand tremor¹⁰ and phenobarbital for cyclic vomiting,¹¹ to prevent and treat hyperbilirubinemia in neonates,¹² or as an intervention for chronic anovulation.¹³ There is anecdotal evidence that pentobarbital may be useful for treating γ -hydroxybutyrate (GHB) and γ -butyrolactone withdrawal.^{14,15}

Phenobarbital, thiopental, and methohexital have all been useful for sedation and immobilization in young children and can be given by different routes. Barbiturate use is contraindicated in patients with porphyrias.¹⁶

TOLERANCE, ABUSE, AND DEPENDENCE

The abuse potential of barbiturates results from pharmacologic characteristics such as rapid onset and lipid solubility that facilitates entry across the blood-brain

barrier. Barbiturates bind to γ -aminobutyric acid A [$GABA_A$] through an ionotropic or ligand gated mechanism that mediates fast synaptic transmission, causing a conformational change in the $GABA_A$ channel and an influx of chloride that goes on to activate proteins essential in producing CNS-depressant effects.¹⁷ In the presence of a depressant such as a barbiturate, stimulatory effects will increase neurologically to keep the body in homeostasis. Over time, if that drug becomes unavailable due to abrupt cessation in use, unfavorable neuroexcitation symptoms predominate, such as tremors, anxiety, insomnia, tachycardia, hypertension, and even seizures. These symptoms usually resolve once the drug is reintroduced, creating an environment for dependence potential.

Tolerance also manifests because of pharmacokinetic and pharmacodynamic properties of barbiturates. Because they are microsomal inducers, enhanced metabolism and resulting decreased drug at the site of action can produce tolerance within days. A reduced response in the face of unchanged or higher drug concentration through cellular adaptive changes can develop over weeks to months.¹⁸

Patients who use medications with butalbital for treatment of migraines are particularly at risk for abuse. Care should be taken when treating these patients and in consideration of withdrawal from the medication. There is anecdotal evidence that withdrawal seizures, personality changes, and psychotic behavior can occur.¹⁹ A syndrome of a rebound headache commonly occurs in these patients, which worsens as the dose of butalbital is increased to prevent headache induction. This syndrome has been treated with a long-acting barbiturate such

as phenobarbital. Patients generally require inpatient monitoring until they are symptom free.^{20,21} There is an ongoing debate whether butalbital should be removed from the U.S. formulary, given its relative lack of therapeutic value.^{22,23}

DRUG INTERACTIONS AND ADVERSE DRUG REACTIONS

One of the potential common drug interactions with barbiturates occurs when they are given in conjunction with other sedative-hypnotics. Benzodiazepines, alcohol, anesthetics such as propofol and etomidate, glutethimide, and zolpidem, to name a few, all can have a synergistic effect with serious consequences if dosage adjustments are not made.

Certain herbs used in conjunction with phenobarbital appear to lower seizure threshold. These include thujone-containing herbs such as wormwood and sage, and gamolenic acid-containing herbs such as evening primrose oil and borage.²⁴ Table 36-3 lists some important drug-herb interactions.

Anticonvulsant hypersensitivity syndrome (AHS) is a rare life-threatening adverse drug reaction seen with phenobarbital and primidone use. The syndrome usually occurs 1 to 8 weeks after initiation of the drug and may present with fever, cervical adenopathy, pharyngitis, skin findings ranging from skin eruption to Stevens-Johnson syndrome, and systemic injury. There is anecdotal evidence suggesting that severe cases of AHS may respond to steroids and immunoglobulin therapy.^{25,26} Other findings seen with barbiturate hypersensitivity include urticaria, erythema multiforme, leukocytoclastic vasculitis, bullous eruption, and fixed drug eruptions.²⁷ At therapeutic doses, barbiturates have also been implicated in toxic epidermal necrolysis, and when abused by injection through skin-popping, tender erythematous plaques can lead to deep ulcers caused by the alkalinity of barbiturates.²⁸

Tubular interstitial nephritis has been seen with phenobarbital therapy.²⁹ Barbiturates are known to cause

the syndrome of inappropriate antidiuretic hormone as well.³⁰

Barbiturates have been implicated in cytochrome P-450 interactions. Phenobarbital is known to be a potent inducer of CYP1A2, 2A6, 2C8, 2C9, 2C19, and 3A4. Phenobarbital is also a known substrate for CYP2E1; it may be a substrate for CYP2C9 and 2C19 as well. Vulnerable populations such as children, pregnant women, the elderly, and patients with genetic polymorphisms can be adversely affected. Care must also be taken when using phenobarbital as an anticonvulsant in combination with other anticonvulsants.³¹ Phenobarbital increases oral contraceptive, warfarin, theophylline, and corticosteroid metabolism. Valproate is known to increase serum phenobarbital concentrations by inhibiting p-hydroxylation and n-glucosidation, significantly reducing its clearance.³²

Primidone and phenobarbital are known to cause hypocalcemia; however, primidone has been shown to shorten the QT interval.³³ Thiopental has been implicated in treatment-resistant hypokalemia, with severe rebound hyperkalemia occurring in patients treated with barbiturate coma for traumatic brain injury and subarachnoid hemorrhage.³⁴

There are also data implicating them in gingival hyperplasia³⁵ and various embryonic malformations in mothers receiving long-standing therapy for epilepsy³⁶; this may result from folate antagonism.³⁷ Adverse drug reactions can occur in infants whose mothers are breast-feeding while taking phenobarbital or primidone. Although no clear consensus exists for recommendations to this specific subpopulation of anticonvulsant users, lactation should be regarded as potentially unsafe, and such mothers should observe infants for sedation or poor suckling.³⁸ To those who must be maintained on antiseizure medication such as phenobarbital, monthly levels are recommended.³⁹

Primidone has been implicated in the development of rare cases of hyperammonemia.⁴⁰ Another rare reported effect includes shoulder-hand syndrome.^{41,42}

Phenobarbital and primidone have also been implicated in the development of bone disorders. Patients

TABLE 36-3 Common Herbs and Their Potential Barbiturate Interactions

HERB	USE	EFFECT ON BARBITURATE
Kava	Relaxation beverage Uterine relaxation	Synergistic CNS depression in animal studies
Valerian	Anxiety, insomnia	Increased CNS depression
St. John's Wort	Depression	Decreased efficacy of barbiturates
Cayenne	Food additive Local irritant (mace)	Increased or decreased effect of barbiturates
Passion flower	Nervous restlessness, insomnia	Increased CNS depression
<i>Tylophora indica</i>	Treat asthma	Increased sedation
Eucalyptus	Rubefacient URI treatment	Decreased sedative and depressant effects
Catnip	Treat muscle spasms, asthma, newborn colic, sedative	Increased CNS depression and psychomotor retardation
Calamus	Sedative, pain relief, vasodilator	Increased sedation, potentiates the hypnotic effect of barbiturates

CNS, central nervous system; URI, upper respiratory infection.

taking these medications chronically demonstrate a drop in bone mineral density. Although low 25-hydroxyvitamin levels have been noted, the exact etiology of osteopenia is unclear. At-risk patients include postmenopausal women, older men, children, and institutionalized patients.^{43,44}

CLINICAL PRESENTATION OF BARBITURATE OVERDOSE

Barbiturates are sedatives and as such their physiologic effects are depressive. The differential diagnosis of barbiturate overdose includes other drugs and toxins that produce CNS and cardiovascular depression, such as other sedative-hypnotics, toxic alcohols, cellular asphyxiants, and other psychotropic agents. Medical conditions such as hypoglycemia must always be ruled out in any patient presenting with an altered level of consciousness.

Manifestations of acute barbiturate toxicity can be divided into (1) mild intoxication (victims are somnolent but arousable with slurred speech, unsteady gait, and nystagmus); (2) moderate intoxication (victims have depressed level of consciousness, decreased deep tendon reflexes, and slowed respirations), and (3) severe intoxication (victims are unresponsive to painful stimuli; respiratory, cardiovascular, and neurologic collapse occur).⁴⁵

Four grades of coma from barbiturate overdose are shown in Table 36-4.⁴⁶

Cardiovascular effects most commonly include hypotension, but cardiovascular collapse and cardiac arrest are also possible. In severe overdoses, respiratory depression and apnea may occur. Hypothermia is commonly seen after barbiturate overdose.⁴⁷⁻⁴⁹ Along with clonidine, guanfacine, GHB and its congeners, and narcotics, barbiturates are among the few drugs associated with significant hypothermia. Barbiturate overdose victims can also present with renal failure due to acute tubular necrosis. Several case reports describe massive crystalluria from primidone overdose^{50,51}; however, this has also been seen during maintenance therapy.⁵²

TABLE 36-4 Stages of Coma in Barbiturate Overdose

GRADE	FEATURES
I	Patient is comatose, the patient withdraws from painful stimuli, and the reflexes are intact.
II	Patient is comatose and fails to respond to painful stimuli, but the reflexes are intact and the vital signs are stable.
III	Patient is comatose and fails to respond to painful stimuli, deep tendon reflexes are absent, but vital signs are stable.
IV	Patient is comatose and fails to respond to painful stimuli, deep tendon reflexes are absent, and vital signs are unstable, with respiratory and cardiovascular depression.

Muscle necrosis and calcification associated with acute renal failure have also been described.⁵³

Barbiturate blisters, also known as coma blisters, although not specific for barbiturate overdose, have been seen. They are noted in patients profoundly poisoned with associated neurologic sequelae such as loss of consciousness, hence the latter name. They typically appear as blanchable erythematous patches at pressure points of normal skin within 24 hours of coma. A biopsy of the lesion shows intraepidermal or subepidermal blisters with characteristic necrosis of sweat glands. Over the next 2 to 3 days these patches become blisters or erosions, but they usually heal spontaneously over 1 to 2 weeks²⁸ (Fig. 36-2).

EVALUATION AND MANAGEMENT

As with most drug overdoses, the mainstay of treatment and good outcome is attention to supportive care principles. Since respiratory and CNS depression are the most common findings, attention to the airway and prevention of hypoxia are of the utmost importance.

FIGURE 36-2 Coma blisters. (From Bologna J, Jorizzo JL, Rapini RP [eds]: *Dermatology*, Vol 1. St. Louis, Mosby, 2003.)

Given the risk for cardiovascular compromise and hypothermia, attention should be directed to vital signs as soon as possible. Also, ruling out hypoglycemia is essential; missing this diagnosis can have grave consequences.

Activated charcoal should be given in a dose of 50 to 60 g (1 g/kg in children). For patients who have a compromised airway, endotracheal intubation is advised prior to giving charcoal. With very large overdoses, antecedent gastric lavage may be considered; however, it should be performed cautiously, given the morbidity associated with this procedure.

Laboratory evaluation should include basic electrolytes and glucose. Screening assays employing semi-quantitative immunoassays of serum and urine are readily available. Serum barbiturate levels can be useful in gauging the clinical course or therapy. In patients who have taken primidone, it is important to measure serum concentrations of phenobarbital, its active metabolite.

The therapeutic range for phenobarbital is generally considered 15 to 40 µg/mL. Toxic effects from phenobarbital can be seen at 50 µg/mL.⁵⁴ Parenthetically, cross-reaction among various barbiturates and nonbarbiturates have been reported, requiring special consideration of a false-positive result.^{55,56}

Urine alkalinization is of theoretical value in the treatment of phenobarbital overdose but not overdose of other barbiturates. According to the theory of ion trapping, phenobarbital, as a weak acid, will be poorly reabsorbed by the renal tubules if it can be ionized in the milieu of an alkaline urine. The administration of sodium bicarbonate is therefore typically recommended to produce such an alkaline environment. However, having a pKa of 7.4, phenobarbital is difficult to ionize without producing profound changes in urine pH; such alkalinization is rarely achieved in clinical practice without the unwanted effects of metabolic alkalosis or hypernatremia. Given the risks versus benefits, routine urinary alkalinization in barbiturate overdose is no longer recommended.⁵⁷

Multiple-dose activated charcoal (MDAC) has been shown to be more effective in decreasing phenobarbital half-life, increasing its total body clearance in adults and neonates.⁵⁷⁻⁶⁰ Working by the principle of “gastro-intestinal dialysis,” MDAC reduces the elimination half-life of phenobarbital by more than 50%; this effect occurs even when the drug has been administered intravenously. However, while MDAC greatly accelerates phenobarbital elimination, its clinical value in the treatment of phenobarbital overdose has been questioned. In a seminal study by Pond and colleagues, MDAC, while greatly reducing the elimination half-life of phenobarbital in a cohort of severely poisoned patients, was ineffective in reducing length of intensive care unit stay and other measures of therapeutic benefit.⁶¹ In a more recent study of 30 patients equally divided into three groups who received MDAC only, urine alkalinization alone, or both, clinical parameters, including the duration of assisted ventilation, intubation, and coma, were all appreciably reduced the greatest in the group that only received MDAC.⁶²

Extracorporeal removal by hemodialysis or hemoperfusion is also effective in removing the barbiturates, although they are reserved for the most severe cases. Hemoperfusion is thought to be more effective in barbiturate clearance; however, it has a high rate of adverse effects, is less available than hemodialysis, and, in the era of the high-flux hemodialysis apparatus, does not produce substantially greater clearance rates.⁶³ As a result, hemodialysis has become the extracorporeal treatment of choice for severe phenobarbital overdose. It is important to note that while phenobarbital is readily removed by hemodialysis, other barbiturates are not. Exchange transfusion has been reported to be useful in an underweight newborn with phenobarbital intoxication.⁶⁴

Indications for hemodialysis after phenobarbital have not been clearly established. Prevailing recommendations call for the procedure in all patients with serum phenobarbital concentrations of 100 µg/mL or greater. This recommendation is based on the clinical observation that as serum phenobarbital concentrations reach and exceed this range, victims are more likely to develop signs of life-threatening intoxication, including severe hypotension and, in the face of fluid support, pulmonary edema. Unfortunately, victims with serum phenobarbital concentrations in this range are often too hypotensive to become ideal hemodialysis candidates. Given the ease and efficacy of hemodialysis in patients with severe barbiturate overdose, its early use should always be considered.

All patients with a barbiturate overdose will need to be admitted. Disposition will depend on clinical affects. Patients with severe mental status depression will need intensive care unit admission, possible intubation with mechanical ventilation, and close monitoring. Less poisoned patients must also be watched closely, in an inpatient setting. In all intentional overdose patients, disposition should include a psychiatric evaluation.

MATTHEW D. SZTAJNKRYCER, MD, PHD

At a Glance...

- The skeletal muscle relaxants comprise a structurally and pharmacologically heterogeneous group of compounds, all of which are purported to decrease skeletal muscle tone.
- Central nervous system depression is the predominant finding in acute toxicity.
- Cardiac conduction abnormalities and dysrhythmias are rare, with the exception of orphenadrine.
- Management is primarily supportive, focusing on central nervous system and cardiopulmonary support.

Muscle tone reflects a complex interplay among the central nervous system, spinal cord, and musculoskeletal system. Skeletal muscle relaxants comprise a structurally and pharmacologically heterogeneous group of compounds, all of which are purported to decrease skeletal muscle tone. Mechanistically, this may occur at the level of the central nervous system, spinal cord, or musculoskeletal system. These agents are prescribed for acute post-traumatic muscle spasm (e.g., acute lumbar strain) or the management of spasticity associated with chronic neuropathologic processes (e.g., multiple sclerosis, cerebral palsy, spinal cord injury). Dantrolene is also used in the treatment of severe muscle hypertonia due to malignant hyperthermia, neuroleptic malignant syndrome (NMS), and tetanus.

Significant abuse potential exists for several of these agents.^{1,2} Carisoprodol has additionally been used to modify the effects of other abused drugs, including benzodiazepines, alcohol, and cocaine.³

In addition to the benzodiazepines (see Chapter 35), 10 skeletal muscle relaxants have clinical and toxicologic significance (Table 37-1). An 11th agent, chlormezanone, was voluntarily recalled from worldwide markets in 1996 due to severe hypersensitivity reactions.

According to the American Association of Poison Control Centers, 21,793 exposures were reported in 2003. Of these, 4084 resulted in moderate toxicity, 1024 resulted in major toxicity, and 59 resulted in death. A total of 2490 exposures occurred in children 5 years old or younger, and 14,019 occurred in patients over the age of 19.

STRUCTURE

Baclofen (Lioresal, para-chlorophenyl- γ -aminobutyric acid; Novartis, East Hanover, NJ) differs from GABA (γ -aminobutyric acid) solely due to the presence of an additional phenylchloride group. Carisoprodol (Rela

[Schering-Plough, Kenilworth, NJ], Soma [Wallace, Somerset, NJ], n-isopropyl-meprobamate) is structurally similar to the sedative-hypnotic agent meprobamate (see Chapter 34). Cyclobenzaprine (Flexeril, McNeil, Chattanooga, TN) is a tricyclic amine, structurally related to amitriptyline (see Chapter 27), while orphenadrine (Norflex, 3M Pharmaceuticals, St. Paul, MN) is structurally related to diphenhydramine (see Chapter 39). Dantrolene (Dantrium, Procter & Gamble, Cincinnati, OH) and metaxalone (Skelaxin, Mallinckrodt, Hazelwood, MO) are structurally related to phenytoin (see Chapter 40), while tizanidine (Zanaflex, Acorda Therapeutics, Hawthorn, NY) is an imidazoline derivative similar to clonidine (see Chapter 62). Chlorzoxazone (Parafon Forte, Ortho-McNeil Pharmaceutical, Raritan, NJ), methocarbamol (Robaxin, Wyeth-Ayerst, Collegeville, PA), and the chemically related chlorphenesin (Maolate, Upjohn, Pfizer, Inc., New York, NY) are unrelated to other agents.

PHARMACOLOGY

With the exception of dantrolene, the skeletal muscle relaxants act centrally, in part through central nervous system (CNS) modulation of interneurons, modifying pain perception without affecting pain threshold.⁴

Baclofen, a GABA_B agonist, acts predominantly at presynaptic sites, as well as by decreasing spinal γ motor neuron activity.⁵ Carisoprodol acts pharmacologically through its primary metabolite meprobamate, increasing chloride ion flux through the GABA_A receptor complex. At high concentrations, meprobamate is capable of blocking *N*-methyl-D-aspartate (NMDA)-receptor mediated calcium currents.⁶ Cyclobenzaprine possesses antimuscarinic, antihistaminic, and sedative properties with (in contrast to the tricyclic antidepressants) only weak inhibition of presynaptic norepinephrine and serotonin reuptake. Skeletal muscle activity is attributed to brainstem-mediated inhibition of α and γ motor neurons.⁷ Although orphenadrine demonstrates peripheral antimuscarinic properties, NMDA receptor blockade, and sodium channel blockade, its skeletal muscle relaxant properties appear to be centrally mediated.⁸ Orphenadrine-mediated dopamine release may be partly responsible for its abuse potential.⁹ Tizanidine, a centrally acting α_2 agonist, is believed to reduce spasticity by increasing presynaptic inhibition of motor neurons.¹⁰ Dantrolene is unique among the muscle relaxants, acting directly on skeletal muscle. It functions by inhibiting calcium release from the sarcoplasmic reticulum, decreasing the force of skeletal muscle contraction without affecting cardiac or smooth muscle.¹¹

TABLE 37-1 Selected Pharmacologic Properties of Muscle Relaxants

AGENT	Vd (L/kg)	TIME TO PEAK LEVEL (hr)	ELIMINATION	METABOLITES	SPECIAL POPULATIONS	DRUG INTERACTIONS
Baclofen	1.3	2	2-6	Deaminated metabolites	Renal insufficiency	NSAIDs Levodopa
Carisoprodol	1	1-4	1.5-6	Meprobamate, hydroxycarisoprodol Hydroxymeprobamate	Renal insufficiency, hepatic insufficiency

Cyclobenzaprine	6	4-6	24-72	Glucuronide conjugate Cyclobenzaprine-N-oxide Norcyclobenzaprine, bis-10, 11-dihydroxy-nortriptyline 3-hydroxy-cyclobenzaprine 5-hydroxy-dantrolene		
Dantrolene	0.54 (pediatric)	4-8	8-10		Liver insufficiency Women Age > 35 years Amyotrophic lateral sclerosis	Calcium channel antagonists Vecuronium Theophylline
Metaxalone Methocarbamol	1-2	3.3-4.3 1	2.4-9.2 1.2-2.2	3-(2-hydroxyphenoxy)-1, 2-propanediol-1-carbamate 3-(4-hydroxy-2-methoxyphenoxy)- 1,2-propanediol-1-carbamate N-monodemethyl orphenadrine Orphenadrine-N-oxide O-methylbenzhydrol conjugate O-methylbenzhydroxyacetic acid conjugate Metabolite 3 (DS-200-717) Metabolite 4 (DS-201-341)	Porphyria	
Orphenadrine	Large	2-4	14			
Tizanidine	2.4	1.5	2.1-4.1		Renal insufficiency, hepatic insufficiency	Oral contraceptives, phenytoin

Vd, volume of distribution.

PHARMACOKINETICS

The heterogeneous nature of the muscle relaxants results in a wide range of pharmacokinetic properties (see Table 37-1). Baclofen is rapidly and completely absorbed from the gastrointestinal tract with therapeutic dosing. Absorption is both decreased and prolonged as ingested dose increases. Although penetration of the blood-brain barrier is limited at therapeutic doses, baclofen demonstrates central effects at higher doses.¹² Carisoprodol is rapidly absorbed after ingestion.¹³ Cyclobenzaprine is slowly but completely absorbed after ingestion, while 70% of an ingested dantrolene dose is absorbed. Orphenadrine is readily absorbed after ingestion, demonstrating 100% bioavailability. Peak orphenadrine plasma levels may be delayed in overdose.¹⁴

Metabolism of the muscle relaxants is primarily hepatic, and elimination is primarily renal. Less than 1% of ingested carisoprodol and chlorzoxazone are eliminated unchanged in the urine, while 85% of baclofen is excreted unchanged. After extensive first pass hepatic metabolism, 50% of an ingested cyclobenzaprine dose is excreted in the urine. Substantial enterohepatic recirculation occurs, with 15% excreted in the bile unchanged.¹⁵ Orphenadrine and tizanidine also demonstrate significant enterohepatic recirculation. The elimination half-life of cyclobenzaprine is 1 to 3 days, substantially longer than that of the other muscle relaxants. Approximately 60% of an ingested orphenadrine dose is excreted in the urine, with up to 30% excreted unchanged in the setting of urinary acidification.

Selected At-Risk Patient Populations

With the exception of cyclobenzaprine, safety in pregnancy is uncertain (category C). Cyclobenzaprine is presumed safe in pregnancy (category B). Carisoprodol is concentrated in breast milk and is considered unsafe in lactation. Methocarbamol is considered safe in lactation, and the safety of the remaining agents is unknown. Baclofen and tizanidine should be used cautiously in patients with renal insufficiency.¹⁶ Tizanidine and dantrolene are contraindicated in the setting of liver disease. Dantrolene should also be used cautiously in women and individuals over the age of 35 due to an increased risk for idiosyncratic hepatotoxicity (see Adverse Effects with Therapeutic Use), and in patients with amyotrophic lateral sclerosis due to potential worsening of neuromuscular weakness.¹⁷ Orphenadrine and carisoprodol are associated with acute porphyria and are contraindicated in patients with porphyria.

Adverse Drug Interactions

All skeletal muscle relaxants have the potential for adverse drug interactions with other CNS depressants. Concomitant baclofen and levodopa administration has resulted in hallucinations and worsening of parkinsonian symptoms.¹⁸ Chlorzoxazone metabolism is decreased with concomitant disulfiram administration

and in slow acetylators on isoniazid.^{19,20} Due to structural similarities with the tricyclic antidepressants, potential adverse interactions have been suggested for cyclobenzaprine and guanethidine or tramadol. Animal studies have demonstrated potentially lethal interactions between dantrolene and verapamil or theophylline.^{21,22} In the former, dantrolene administration to verapamil-pretreated swine resulted in profound myocardial depression, hyperkalemia (8.0 ± 0.7 mEq/L), and cardiac arrest preceded by complete heart block in 50% of the experimental group. In the latter, rat studies demonstrated increased theophylline mortality from concomitant therapeutic dantrolene doses in the absence of increased seizure frequency. Dantrolene prolonged neuromuscular blockade in a patient receiving vecuronium.²³ Oral contraceptive use has been associated with decreased tizanidine clearance, while tizanidine use is associated with decreased phenytoin clearance.²⁴

TOXICOLOGY

Adverse Effects with Therapeutic Use

Numerous adverse effects have been associated with therapeutic use of the muscle relaxants (Table 37-2). CNS depression has been noted with all the agents, although it is less commonly associated with dantrolene. Additional CNS findings associated with baclofen therapy include movement disorders, memory impairment, muscle weakness, flapping tremor, nystagmus, diplopia, and dysarthria. Increased seizure activity, including status epilepticus, has been observed in patients with preexisting seizure disorders. Chlorzoxazone use is associated with opisthotonus and torticollis, while visual blurring and sensorineural hearing loss have been described with therapeutic use of intravenous and oral dantrolene, respectively. Neuropsychiatric effects, including mania, depression, psychosis, confusion, and amnesia, have been described with all skeletal muscle relaxants.

Cardiovascular complaints associated with baclofen administration include palpitations, flushing, bradycardia, hypotension, and hypertension. Facial flushing and orthostatic hypotension have been reported with carisoprodol use. Cyclobenzaprine, methocarbamol, and chlorphenesin are associated with hypotension, palpitations, and syncope. Although possessing only 2% to 10% of clonidine's antihypertensive potency, mild hypotension, symptomatic orthostatic hypotension, and syncope have been described with tizanidine use. Pericarditis, pleural effusions, and pleural fibrosis have been described with chronic therapeutic dantrolene use.²⁵

Gastrointestinal complaints typically include nausea, vomiting, abdominal pain, and diarrhea or constipation. Idiosyncratic, potentially fatal hepatotoxicity is associated with chronic chlorzoxazone and dantrolene use. Onset of chlorzoxazone-associated hepatotoxicity is variable, typically occurring within weeks of initiation of therapy, but occasionally occurring after 5 or more months. Although reversible, centrilobular hepatotoxicity

TABLE 37-2 Clinical Toxicity of the Muscle Relaxants

AGENT	CHRONIC EXPOSURE	ACUTE INTOXICATION
Baclofen	Neuropsychiatric dysfunction, GI upset, urinary retention, morbilliform rash, palpitations, physical dependence	Coma, respiratory depression, seizures, hypothermia
Carisoprodol	Sedation, nausea, vomiting, orthostatic hypotension, allergic reactions, physical dependence	Coma, nystagmus, seizures, cardiovascular instability
Chlorphenesin	CNS depression, neuropsychiatric dysfunction, allergic reactions	CNS depression
Chlorzoxazone	CNS depression, amnesia, parasthesias, opisthotonus, torticollis, urticaria, nausea/vomiting, idiosyncratic hepatitis	Coma, GI distress, hypotonia, hypotension
Cyclobenzaprine	CNS depression, antimuscarinic syndrome, hypotension, palpitations, syncope	Antimuscarinic syndrome, coma
Dantrolene	CNS depression, neuropsychiatric dysfunction, idiosyncratic hepatotoxicity, pericarditis, pleural effusions, muscle weakness	Severe muscle weakness, CNS depression, hypotension
Metaxalone	CNS depression, neuropsychiatric dysfunction, syncope	CNS depression, nephrotoxicity, seizures, muscular rigidity
Methocarbamol	CNS depression, neuropsychiatric dysfunction, syncope, hypotension, hypersensitivity reactions	CNS depression, seizures
Orphenadrine	Antimuscarinic syndrome	Antimuscarinic syndrome, coma, seizures, cardiac conduction abnormalities, ventricular dysrhythmias, hypoglycemia, pulmonary hemorrhage
Tizanidine	CNS depression, syncope, urinary retention, orthostatic hypotension	Coma, hypotonia, miosis, bradycardia, apnea, hypothermia

CNS, central nervous system; GI, gastrointestinal.

city has recurred upon rechallenge to chlorzoxazone.²⁶ Risk factors for fatal hepatic necrosis after dantrolene use include age greater than 30 years, chronic use greater than 2 months, female gender, doses greater than 300 mg/day, high bilirubin levels, and concomitant illness.^{27,28}

Urinary retention has been associated with baclofen, cyclobenzaprine, orphenadrine, and tizanidine. Dantrolene and baclofen use is associated with acneiform and morbilliform rashes, respectively. Cyclobenzaprine and orphenadrine are associated with central and peripheral antimuscarinic symptoms. Profound muscle weakness can occur with dantrolene use, resulting in diminished protective airway reflexes.²⁹ Severe allergic reactions have been reported with carisoprodol and chlorphenesin, associated with the additives sodium metabisulfite and tartrazine, respectively.

Acute Intoxication

Severe baclofen poisoning is characterized by coma, respiratory depression, bradycardia, and hypotension. Other CNS findings include hyporeflexia and encephalopathy.^{30,31} Seizure activity has been observed after oral and intrathecal overdose, including generalized tonic-clonic activity, focal motor seizures, and status epilepticus. Two of eight patients in a case series of recreational abuse and 5 patients in a series of 12 overdoses developed seizures.^{31,32} Seizure activity is believed secondary to the inhibitory effects of baclofen at presynaptic GABA_B receptors and resultant inhibition of presynaptic GABA release, and may be delayed as long as 12 hours after acute ingestion. Cardiovascular findings are typically limited to bradycardia and hypotension, although cardiac conduction disturbances including first-

and second-degree AV block and QTc prolongation have rarely been reported in overdose. Mechanical ventilation was required in 10 of 12 patients after acute baclofen overdose in one case series.³¹ Accidental intrathecal bolus administration of 10 mg resulted in coma and respiratory arrest within 80 minutes.³³ Mild hypothermia is common in overdose. Minimum adult oral lethal doses in case reports range from 1000 to 2500 mg, while acute ingestions of 300 to 970 mg have resulted in severe poisoning. In overdose, elimination half-life increases to 8.6 hours, with one report suggesting an elimination half-life of 34.5 hours.³⁴

Acute carisoprodol toxicity presents similarly to meprobamate, with potentially abrupt onset of coma, cardiovascular instability, and death. Coma may persist for several days, and cerebral and pulmonary edema have been noted in severe overdose. Sixteen of 50 patients in a case series of meprobamate intoxications required mechanical ventilation.³⁵ Hypotension is likely multifactorial, related to CNS depression, direct effects on the CNS vasomotor center, and myocardial depression.³⁶ Ingestion of 700 mg by a toddler was associated with severe toxicity, and ingestion of 3.5 g by a 5-year-old resulted in death.^{37,38}

Antimuscarinic findings predominate in acute cyclobenzaprine poisoning. CNS findings range from agitated delirium to coma. Symptoms typically occur within 4 hours of ingestion, although they may be delayed up to 12 hours. In one case series, sinus tachycardia occurred in one third of patients and CNS depression in 54%.³⁹ Three percent of patients required mechanical ventilation. Despite chemical similarity to the tricyclic antidepressants, impaired cardiac conduction, ventricular dysrhythmias, and seizures have only rarely been reported. Less than 1% of patients manifested

dysrhythmias other than sinus tachycardia, none of which were life threatening. While one case report suggested a minimum lethal adult dose of 100 mg, a case series suggested that adult ingestions of less than 100 mg were asymptomatic, and no deaths were reported after ingestions of up to 1000 mg.^{39,40}

Severe orphenadrine intoxication is associated with respiratory and CNS depression, ranging from lethargy to coma. Antimuscarinic findings are noted in overdose, including mydriasis and sinus tachycardia, and may predominate in milder toxicity. Unlike cyclobenzaprine, orphenadrine poisoning is associated with seizures (including status epilepticus), cardiac conduction abnormalities, ventricular dysrhythmias, and cardiac arrest.⁴¹⁻⁴³ Life-threatening symptoms may appear precipitously, necessitating prompt, aggressive management. Additional manifestations of severe toxicity include hypoglycemia (especially in children), hypokalemia, hypothermia, pulmonary hemorrhage, and disseminated intravascular coagulation (DIC).⁴⁴ A 3-year-old child died after ingestion of 400 mg of orphenadrine, and a 23-month-old child developed severe toxicity after ingestion of 300 mg.^{42,43}

Acute tizanidine toxicity presents similarly to clonidine, with decreased level of consciousness, hypotonia, hyporeflexia, hypotension, bradycardia, miosis, respiratory depression, apnea, and hypothermia (see Chapter 62). A 3-year retrospective review of 45 cases demonstrated lethargy in 38 patients (84%), bradycardia in 14 (31%), hypotension in 8 (18%), agitation in 7 (16%), and coma in 2 (4%).⁴⁵ The minimum adult ingested doses associated with hypotension and coma were 28 and 120 mg, respectively.

In acute overdose, chlorzoxazone toxicity presents as varying degrees of CNS depression, gastrointestinal distress, and hypotonia. Coma, flaccidity, hyporeflexia, and subsequent secondary respiratory failure have been described. With the exception of hypotension, cardiovascular toxicity has not been described. Acute dantrolene overdose is not well described in the literature.^{46,47} Severe muscle weakness may occur, with CNS depression occurring less frequently. Hypotension has been reported. Metaxalone overdose manifests predominantly as CNS depression, ranging from sedation to coma. Seizures may rarely occur, as may nephrotoxicity, and elevated hepatic transaminases. In one case report, severe muscular rigidity with subsequent prolonged weakness required placement in an extended care facility.⁴⁸ Findings in acute methocarbamol and chlorphenesin overdose are similar to metaxalone, with CNS depression and rare seizures noted. Cardiotoxicity is extremely rare in isolated ingestions.

Withdrawal

Chronic carisoprodol use is associated with tolerance, dependence, and a withdrawal syndrome, attributed to the metabolite meprobamate.⁴⁹ Symptoms are analogous to those seen with withdrawal from other sedative-hypnotic agents, with death reported after sudden withdrawal.⁵⁰ After long-term baclofen use, a withdrawal syn-

drome has been described, manifesting as hallucinations, agitated delirium, and seizures, typically within 12 to 96 hours of discontinuation.^{51,52} Withdrawal may last as long as 8 days. This syndrome is particularly severe after abrupt discontinuation of intrathecal infusion, manifesting as an NMS-like syndrome. Severe dysautonomia, spasticity and rigidity, marked hyperthermia (43°C), tachycardia, rhabdomyolysis, agitated delirium, seizures, and DIC have been reported. In one case, an infant born to a paraplegic mother receiving chronic baclofen therapy developed status epilepticus resistant to multiple anti-epileptic agents 7 days postdelivery. The seizures abated within 30 minutes of receiving baclofen.⁵³

DIAGNOSIS

Diagnosis of skeletal muscle relaxant poisoning is based on history and clinical examination. Although analytic laboratory monitoring methods exist to confirm exposure to these agents, they are not routinely available, nor do specific levels correlate with outcome. Baclofen may be detected in serum using either high-performance liquid chromatography or gas chromatography/mass spectrometry technology. Therapeutic serum concentrations range from 80 to 395 ng/mL. Postmortem levels of 17 µg/mL have been reported 12 hours after ingestion.⁵⁴ Cyclobenzaprine has been reported to cross-react with the Syva EMIT (Dade-Behring, Deerfield, IL) technique and Abbott Adx tricyclic antidepressant (TCA) immunoassay (Abbott Laboratories, North Chicago, IL), and migrates similarly to amitriptyline on the Toxilab thin layer chromatography (TLC) system (Varian, Inc., Palo Alto, CA).⁵⁵ Therapeutic blood concentrations range from 10 to 40 ng/mL, with postmortem levels of 260 to 300 ng/mL reported.^{55,56} Therapeutic blood levels of orphenadrine are less than 0.2 µg/mL, while moderate effects have been described at levels of 5.1 µg/mL and severe effects at 12.3 µg/mL. Postmortem levels have ranged from 7 to 33 µg/mL.^{42,57} Therapeutic serum levels for carisoprodol range from 4 to 7 mg/L, while coma has been reported with a serum level of 13.4 mg/L 19 hours after ingestion, and death has been reported with a level of 36 mg/L 4.5 hours after ingestion.⁵⁸

No specific laboratory analyses are routinely indicated, and clinical investigations are directed toward identification of end-organ toxicity. Creatine phosphokinase, electrolytes, and urine output should be monitored in patients with prolonged seizures or coma. Serum glucose should be rapidly determined in patients presenting with altered mental status. Coagulation studies and hepatic transaminase levels are indicated in orphenadrine intoxication, while hepatic and renal studies are indicated in metaxalone toxicity. Acetaminophen levels may be indicated in patients presenting after acute intentional ingestion. Electrocardiographic monitoring should be considered to detect the presence of conduction abnormalities and dysrhythmias. Computed tomography of the head and electroencephalographic assessment may be indicated to evaluate altered mental status, prolonged coma, and status epilepticus.

BOX 37-1

DIFFERENTIAL DIAGNOSIS OF MUSCLE RELAXANT INTOXICATION

Antidepressants
 Antihistamines
 Antiepileptic agents
 Barbiturates
 Benzodiazepines
 Buspirone
 Carbon monoxide
 Cyanide
 Ethanol
 Ethylene glycol
 γ -hydroxybutyrate (GHB)
 Ketamine
 Lithium
 Hydrogen sulfide
 Imidazolines
 Isoniazid
 Isopropanol
 Organophosphate and carbamate pesticides
 Phencyclidine
 Sedative-hypnotic agents
 Solvents
 Zolpidem

Differential Diagnosis

Signs and symptoms of skeletal muscle relaxant poisoning are nonspecific, reflecting the CNS depressant effects of the agents (Box 37-1). The differential diagnosis for cyclobenzaprine and orphenadrine also includes sympathomimetic agents, antihistamines, antipsychotic agents, antispasmodic agents, cyclic antidepressants, and antimuscarinic plants and preparations. Toxicologic causes of altered mental status and seizures include cyanide, carbon monoxide, organophosphates and carbamates, bupropion, camphor, isoniazid, lithium, meperidine, propoxyphene, phencyclidine, oral hypoglycemics, phenothiazines, venlafaxine, and cyclic antidepressants. Toxicologic causes of cardiac conduction abnormalities include antidysrhythmics, antidepressants, antihistamines, antimuscarinic agents, β -adrenergic antagonists, propoxyphene, phenothiazines, and cocaine. The differential diagnosis for tizanidine intoxication includes opiates and opioids, clonidine and imidazolines, organophosphates and carbamates, and olanzapine.

MANAGEMENT

Management of skeletal muscle relaxant toxicity is primarily supportive, focusing on respiratory, CNS, and cardiovascular monitoring and support.

Given the potential for profound CNS and respiratory depression, early aggressive airway management is paramount in patient management. Cardiovascular toxicity predominantly presents as hypotension, bradycardia, or

tachycardia. Hypotension should initially be treated with intravenous crystalloid boluses, provided no contraindication exists. Inotropic support is indicated for patients failing to respond to fluid boluses. Atropine is the first-line agent for symptomatic bradycardia. Cardiac dysrhythmias are treated according to standard guidelines, except as noted below. Benzodiazepines are first-line agents for patients with psychomotor agitation or seizures. Benzodiazepine-resistant seizures may be treated with barbiturates. Administration of oral or intrathecal baclofen may be required for seizures associated with baclofen withdrawal.⁵³ Core body temperature should be monitored due to the potential for hypothermia (baclofen) or hyperthermia (agitation, seizures, antimuscarinic syndrome, or sedative-hypnotic withdrawal syndrome).

Activated charcoal administration may be considered for patients presenting within 1 hour from time of ingestion, in accordance with the published guidelines of the American Academy of Clinical Toxicology and European Association of Poisons Centres and Clinical Toxicologists. Agents with delayed gastric emptying secondary to anticholinergic properties may benefit from activated charcoal beyond this time frame, although data are sparse. Whole bowel irrigation may be considered after ingestion of sustained-release preparations. Hemodialysis is not beneficial in the management of skeletal muscle relaxant toxicity.

Agent-Specific Management Strategies

Physostigmine has reversed baclofen-induced coma and orphenadrine-associated CNS toxicity, but is not universally effective, and has been associated with cardiac arrest⁵⁹⁻⁶² (Table 37-3). As a result, physostigmine use is limited to severe toxicity unresponsive to meticulous supportive care. Although flumazenil has successfully reversed coma and stupor in chlorzoxazone and carisoprodol intoxications, respectively, routine use cannot be recommended due to concern of flumazenil-induced seizures.^{63,64} Given similarities to clonidine, naloxone may have a role in the management of tizanidine-associated CNS depression, bradycardia, and hypotension.⁶⁵ Cyproheptadine has been used in the management of intrathecal baclofen withdrawal.⁶⁶

Atropine appears beneficial in the management of baclofen-associated bradycardia and hypotension.⁶⁷ QRS prolongation associated with orphenadrine and cyclobenzaprine toxicity is initially managed with sodium bicarbonate, analogous to tricyclic antidepressant toxicity (see Chapter 27). Ventricular dysrhythmias unresponsive to sodium bicarbonate therapy are treated with lidocaine. Physostigmine has reversed orphenadrine-associated ventricular tachycardia.⁶⁸ Quinidine, disopyramide, and procainamide are contraindicated due to their effects on sodium channels.

Multidose activated charcoal may be beneficial in the management of cyclobenzaprine and orphenadrine, which demonstrate enterohepatic recirculation, although outcome data are lacking. Hemoperfusion may be of benefit in carisoprodol toxicity, due to its

**TABLE 37-3** Specialized Treatment Recommendation for Muscle Relaxant Toxicity

ANTIDOTAL AGENT	MUSCLE RELAXANT	INDICATION	DOSE
Atropine	Baclofen Tizanidine	Bradycardia and hypotension	Adult: 0.5–1 mg IV every 5 min (maximum dose 3 mg) Pediatrics: 0.02 mg/kg every 5 min minimum 0.1 mg, maximum dose 1 mg in children, 2 mg in adolescents
Physostigmine	Baclofen Cyclobenzaprine Orphenadrine	Severe antimuscarinic syndrome	Adult: 1–2 mg IV over 5 min (may repeat once) Pediatrics: 0.02 mg/kg IV (maximum dose 0.5 mg)
Flumazenil	Carisoprodol Chlorzoxazone	CNS depression	Adult: 0.2 mg IV over 30 s every 1 min (maximum dose 5 mg) Pediatrics: 0.01 mg/kg IV over 30 s every 1 min (maximum dose 1 mg)
Naloxone	Tizanidine	CNS depression	Adult: 0.4–2 mg IV (maximum dose 10 mg) Pediatrics ≤ 20 kg: 0.01 mg/kg, then 0.1 mg/kg if needed Pediatrics > 20 kg: 0.4–2 mg IV (maximum dose 10 mg)
Cyprohepatidine	Baclofen	Withdrawal	Adult: 4–8 mg PO every 1–4 hr until therapeutic response (maximum dose 32 mg/day) Pediatrics: 0.25 mg/kg/day PO divided every 6 hr (maximum dose 12 mg/day)

CNS, central nervous system; IV, intravenously; PO, orally.

ability to effectively remove the primary metabolite, meprobamate.⁶⁹ Brisk diuresis may increase the elimination of baclofen, which is predominantly excreted in an unchanged form.

Patient Disposition

Asymptomatic or mildly symptomatic patients presenting after ingestion of a non-sustained-release preparation may be medically cleared after a 6-hour observation period. In the case of cyclobenzaprine and orphenadrine, an observation period of 6 to 12 hours has been suggested. Due to the potential for CNS and respiratory depression, significantly intoxicated patients should be admitted to a monitored setting. Hemodynamically unstable patients require continuous cardiopulmonary monitoring in an intensive care setting. Patients may be medically cleared for hospital discharge after signs and symptoms of toxicity have resolved.

At a Glance...

- The toxic effects of antipsychotic agents are often an amplification of their pharmacologic effects; overdose findings can be predicted by knowledge of relative receptor binding affinities.
- The presence of central nervous system or respiratory depression, miosis, sinus tachycardia, anticholinergic findings, and extrapyramidal signs should suggest antipsychotic agent poisoning.
- Clinical effects occur within 1 to 4 hours following antipsychotic agent overdose.
- Timely supportive care should ensure a good outcome for the vast majority of patients with antipsychotic poisoning.
- The optimal treatment of neuroleptic malignant syndrome requires prompt recognition, immediate withdrawal of antipsychotic agents, and the provision of good supportive care.

INTRODUCTION AND RELEVANT HISTORY

Prior to 1952, drug therapy for schizophrenia was ineffective and often involved the nonspecific use of sedative-hypnotics (e.g., barbiturates) to calm patients during periods of agitation. The discovery of the traditional antipsychotics (e.g., chlorpromazine and haloperidol) in the early 1950s revolutionized the treatment of schizophrenia. These agents provided specific and effective therapy for the positive signs and symptoms (e.g., delusions, disorganized behavior, hallucinations) of psychosis. Subsequent to their introduction, however, it was realized that traditional agents were associated with disabling extrapyramidal motor and neuroendocrine (e.g., hyperprolactinemia) side effects, and were dangerous in overdose (significant cardiac and neurotoxicity). In addition, it became apparent that these agents were not effective for the negative signs and symptoms (e.g., alogia, avolition, and social withdrawal) and neurocognitive deficits of schizophrenia. This led to the development of second-generation or atypical antipsychotic agents in the 1990s. Atypical agents produce minimal extrapyramidal side effects (EPS) at clinically effective antipsychotic doses and are effective for the negative signs and symptoms and neurocognitive deficits of schizophrenia. Atypical agents, however, are also associated with a variety of adverse effects (e.g., glucose intolerance, weight gain, prolonged QTc interval) that limit efficacy and patient compliance. In 2002, further advance in drug therapy for schizophrenia was marked by the release of the third-generation antipsychotic aripiprazole. It is anticipated that this novel antipsychotic and the class it represents will provide

equal or greater antipsychotic efficacy combined with a lower incidence and severity of side effects.

Terminology

The term *antipsychotic* is somewhat of a misnomer because these agents are often used for purposes other than treating psychoses: They are also used as pre-anesthetics and for the treatment of the manic phase of bipolar disorder, agitated behavior, drug-induced hallucinations, nausea and vomiting, migraine and tension headaches, hiccups, pruritus, Tourette's syndrome, and various extrapyramidal movement disorders (e.g., tics, chorea, and hemiballismus).¹ Historically, this class of agents was termed *major tranquilizers* due to their ability to calm agitated patients. To think of these agents as simple sedatives, however, is overly simplistic. Until recently, the term *neuroleptic* was synonymous with and preferred to antipsychotic, because all traditional antipsychotics produce EPS at therapeutic doses. The introduction of agents that produce minimal EPS, or atypical antipsychotics, has allowed separation of antipsychotic from neuroleptic effects, and prevents the ready interchange of terms. Consequently, the term *antipsychotic* is more commonly used.

Epidemiology

Toxicity from the antipsychotic drugs may be dose related and occur following unintentional or intentional overdose, or may be idiosyncratic and occur as unanticipated adverse effects during therapeutic administration. Dose-related toxicity will vary according to agent, patient age and habituation, and comorbid conditions. Toxic effects are often an overextension of an agent's pharmacologic effects.¹ Because of a large toxic-to-therapeutic ratio, fatalities rarely occur. Death, when it occurs, is usually a consequence of polysubstance overdose. The agents with the greatest individual toxicity or highest fatal toxicity index (most deaths caused per prescription written) are the low-potency traditional agents, such as chlorpromazine, loxapine, mesoridazine, and thioridazine.²⁻⁴ These agents, however, are now implicated in fewer deaths from antipsychotic agents in the United States due to their lower frequency of usage. In 2004, there were 42,833 antipsychotic agent exposures reported to U.S. poison centers, of which 38,315 (89%) were due to atypical antipsychotics and 4518 (11%) were due to phenothiazines.⁵ Major toxicity and death occurred in 5.5% and 0.2% of atypical agent exposures and 4.1% and 0.4% of phenothiazine exposures, respectively.⁵ While antipsychotic drugs often have a wide margin of safety, these drugs are commonly used, have a

large number of adverse effects, and can produce significant toxicity in the nonhabituated host or those at the extremes of age.

CLASSIFICATION AND STRUCTURE-ACTIVITY RELATIONSHIPS

Antipsychotics can be classified by structure, pharmacologic profile, and whether they are typical (traditional or conventional) or atypical (novel, second and third generation). Classification by structure is challenging since antipsychotics are a structurally diverse group of heterocyclic compounds. Currently more than 50 neuroleptics are available worldwide, with numerous others in various stages of development.¹ Chemical classes include benzamide, benzepine, butyrophenone (phenylbutylpiperidine), diphenylbutylpiperidine, indole, phenothiazine, quinolinone, rauwolfia alkaloid, and thioxanthene derivatives (Table 38-1).¹ The phenothiazines and thioxanthenes are traditional tricyclic antipsychotic agents for which structure predicts function. These agents have two benzene rings linked by a sulfur atom and either a nitrogen (phenothiazines) or carbon (thioxanthenes) atom double bonded to the side chain at position 10 of the central ring (Fig. 38-1).¹ The presence of an electron-withdrawing group at position 2 increases antipsychotic efficacy and potency. Phenothiazines and thioxanthenes are subdivided into three groups (aliphatic, piperidine, and piperazine), based on the side chain substitution at position 10 on the central ring (see Fig. 38-1). The nature of the substitution influences pharmacologic activity. The aliphatic and piperidine subclasses have a higher antipsychotic potency and incidence of EPS, but a lower incidence of sedation, hypotension, and anticholinergic effects than do the piperazine class.¹ In general, the antihistaminergic and anticholinergic properties of the phenothiazines and thioxanthenes are derived from the presence of a tertiary amino group in the side chain connected by two or three carbons to position 10 of the central ring (see Fig. 38-1 and Chapter 39).¹ Aside from the phenothiazine and thioxanthene classes, structure-activity relationships have not been well characterized for most antipsychotics. Therefore, classification based on chemical structure has limited clinical utility for most agents.

A more clinically useful method of antipsychotic agent classification is to identify agents by their relative receptor-binding profiles (Table 38-2). Because clinical toxicity of antipsychotics results from exaggerated pharmacologic activity, knowledge of the agent's binding affinity at various receptors allows one to predict adverse effects in both therapeutic and overdose situations.⁶⁻⁸

The most commonly used method of classifying antipsychotics is to identify them as typical or atypical. This classification is clinically based. Agents are considered atypical if they (1) produce minimal EPS at clinically effective antipsychotic doses; (2) have a low propensity to cause tardive dyskinesia (TD) with long-term treatment; and (3) are effective for treating both the positive and negative signs and symptoms of schizophrenia.⁶⁻¹⁰ Interestingly, this clinically determined classification

system is rooted in receptor binding. Drug atypia is defined by unique, relative receptor-binding profiles (see Pharmacology section). In the preclinical area, knowledge of an agent's relative receptor-binding affinities can be used to predict whether it will be atypical or typical.

PHARMACOLOGY

All antipsychotic agents bind and block presynaptic (autoreceptors) and postsynaptic D₂ receptors in the central nervous system (CNS).¹ Initially, this receptor antagonism stimulates increased presynaptic production and release of dopamine. With continued antipsychotic treatment, however, depolarization inactivation occurs at the synapse, and decreased production and release occurs simultaneous with continued postsynaptic receptor blockade. Partial receptor agonists and agents with lower receptor affinity (e.g., atypical agents) are less likely to lead to depolarization inactivation at the synapse.

Antipsychotic agents block D₂-subtype receptors in nigrostriatal (basal ganglia), tuberoinfundibular (hypothalamus to pituitary), mesocortical, and mesolimbic pathways of the brain.^{1,6,8,9} These agents also antagonize D₂ receptors in the medulla oblongata and the anterior hypothalamus. Blockade of the D₂ receptors in the area postrema (chemotactic trigger zone) is responsible for the antiemetic activity of antipsychotics. Antipsychotic efficacy is mediated by a drug's ability to block mesocortical and mesolimbic D₂ receptors; all antipsychotics share this property.^{1,6,8,9} For most neuroleptics, there is a strong correlation between the affinity (potency) at D₂ receptors and daily dose necessary to treat the positive symptoms of schizophrenia (see Tables 38-1 and 38-2).^{1,8,11} Based on in vivo studies utilizing positron emission tomography, the therapeutic effects of neuroleptics correlate with 70% or greater D₂ receptor occupancy in the mesolimbic pathway.¹²

Antagonism of the D₂ receptors in other brain regions, however, accounts for many of the undesired side effects of antipsychotics. For example, antagonism of the D₂ receptors in the tuberoinfundibular pathway in the pituitary gland causes hyperprolactinemia, which can result in galactorrhea, gynecomastia, menstrual changes, and sexual dysfunction.¹⁶ Antagonism of the nigrostriatal D₂ receptors produces EPS (e.g., acute dystonia, parkinsonism, akathisia). Agents with higher D₂ receptor affinity (e.g., fluphenazine, haloperidol, and thiothixene) have a high likelihood for producing EPS.⁶ In contrast, agents with minimal D₂ receptor affinity (i.e., clozapine, quetiapine) or those that selectively inhibit the limbic D₂ receptors over the nigrostriatal D₂ receptors (e.g., sulpiride, remoxipride) are less likely to produce EPS.^{6,7,10} Unfortunately, for most traditional antipsychotics, basal ganglia D₂ receptor blockade occurs in the same dose range necessary for limbic D₂ blockage.¹² This produces a high incidence of EPS at therapeutic doses for traditional antipsychotics.^{1,6}

Regulation of core body temperature involves dopamine. D₂ receptor blockade by antipsychotics in the anterior hypothalamus (preoptic area) can alter the core temperature set point, block thermosensitive neuronal

**TABLE 38-1** Classification and Dosing of Antipsychotic Agents

STRUCTURAL CLASS	GENERIC NAME (TRADE NAME)	DAILY DOSE RANGE (mg)
Typical Agents		
Butyrophenone (phenylbutylpiperidine)	Droperidol (Inapsine)	1.25–30
	Haloperidol (Haldol)	1–30
	<i>Other: benperidol, bromperidol, melperone, pipamperone, trifluoperidol</i>	
Diphenylbutylpiperidine	Pimozide (Orap)	1–20
	<i>Other: fluspirilene, penfluridol</i>	
Indole	Molindone (Moban)	15–225
	<i>Other: oxypertine</i>	
Phenothiazine Aliphatic	Chlorpromazine (Thorazine)	25–2000
	Promazine (Sparine)	50–1000
	Promethazine (Phenergan)	25–150
	Triflupromazine (Vesprin)	5–90
Piperazine	Acetophenazine (Tindal)	40–400
	Fluphenazine (Prolixin)	0.5–30
	Perphenazine (Trilafon)	4–64
	Prochlorperazine (Compazine)	10–150
	Trifluoperazine (Stelazine)	2–40
	Thiethylperazine (Torecan)	10–30
Piperidine	Mesoridazine (Serentil)	30–400
	Thioridazine (Mellaril, Millazine)	20–800
	<i>Other: diethazine, ethopropazine, levomepromazine, perazine, pipotiazine thiopropazate, thioproperazine, pericyazine</i>	
Thioxanthene	Chlorprothixene (Taractan)	30–600
	Clopenthixol	—
	Flupenthixol	4
	Thiothixene (Navane)	6–60
	Zuclopenthixol (Cisordinal, Clopixol)	10–50
Atypical Agents		
Benzamides	Amisulpiride	100–1200
	Raclopride	5–8
	Remoxipride	150–600
	Sulpiride	100–1600
	Sultopride	100–1200
	<i>Other: epidepride, eticlopride, levosulpiride, nemonapride, tiapride</i>	
Benzepine	Clozapine (Clozaril, Leponex)	150–900
	Loxapine (Loxitane)	20–250
	Olanzapine (Zyprexa)	5–20
	Quetiapine (Seroquel)	300–600
	Zotepine	100–300
	<i>Other: butaclamol, fluperlapine, clothiapine, metiapine, savoxepine</i>	
Indole	Risperidone (Risperdal)	2–16
	Sertindole (Serlect)	12–24
	Ziprasidone (Zeldox)	40–160
	<i>Other: iloperidone</i>	
Quinolinone	Aripiprazole (Abilify, Abitat)	10–30

inputs, and inhibit centrally mediated thermoregulatory responses.¹ Thus, either hypothermia or hyperthermia can occur from antipsychotic therapy. D₂ receptor antagonism in the hypothalamus and the nigrostriatum mediates the neuroleptic malignant syndrome (NMS), a fulminant hyperthermic adverse reaction associated with antipsychotic therapy. Decreased tolerance to heat and fatal heat stroke have been described in patients who

take phenothiazines.⁹ Antipsychotics have also been used successfully to treat hyperthermia associated with cocaine and amphetamines.¹⁰⁻¹²

In addition to their D₂ receptor antagonism, most antipsychotics are competitive antagonists at a wide variety of other neuroreceptors. Since the D₂ receptor binding affinity determines the daily (therapeutic) dose, the relative binding affinity at other neuroreceptor

FIGURE 38-1 Phenothiazine structure.

sites compared with that at D_2 receptors predicts the likelihood of producing clinical effects from other neuroreceptors (see Table 38-2).^{6,13} Knowledge of relative binding affinities can be used to predict clinical effects at both therapeutic doses and overdoses.^{6,13} For instance, high relative antagonism at the H_1 -histamine receptor (e.g., aliphatic and piperidine phenothiazines, clozapine, loxapine, olanzapine, and quetiapine) results in sedation, hypotension, and appetite stimulation.^{1,6,13,14} Significant blockade of the M_1 -muscarinic receptor (e.g., aliphatic and piperidine phenothiazines, clozapine, and olanzapine) produces anticholinergic effects (e.g., agitation, hallucinations, delirium, blurred vision, dry skin

and mucous membranes, hyperpyrexia, ileus, mydriasis, tachycardia, and urinary retention). Sialorrhea, a feature unique to clozapine, is likely mediated by its partial agonism at M_1 and M_4 receptors.⁶ Significant antagonism of the α_1 -adrenergic receptor (e.g., aliphatic and piperidine phenothiazines, clozapine, risperidone, ziprasidone, olanzapine, and sertindole) results in orthostatic hypotension, reflex tachycardia, nasal congestion, and miosis.¹ Blockade of the α_2 -adrenergic receptor by certain agents (e.g., clozapine and risperidone) may produce sympathomimetic effects (e.g., tachycardia). The ability of certain agents (e.g., loxapine, clozapine) to block neuronal reuptake of norepinephrine and antagonize $GABA_A$ receptors partly accounts for the high prevalence of seizures with these drugs. High relative binding affinities at M_1 and $5-HT_{1A}$ - and $5-HT_{2A}$ -serotonin receptors are inversely related to the likelihood of producing EPS.^{1,13,15,16}

Although drug atypia is defined clinically, it also appears to be determined by one or more of several different pharmacologic mechanisms. Atypical agents belong to one of four distinct receptor-binding groups: (1) D_2 and D_3 receptor antagonists (e.g., amisulpiride, remoxipride, raclopride, sulpiride); (2) D_2 , α_1 , and 5-

TABLE 38-2 Relative Neuroreceptor Affinities for Antipsychotics*

*Relative neuroreceptor affinity is the neuroreceptor affinity at receptor X/dopamine D_2 receptor affinity.

[†]Binding affinity (potency) at D_2 receptor correlates inversely with the daily dose of antipsychotic agent.

[‡]High binding affinity but partial agonist at receptor.

0, minimal to none; 1+, low; 2+, moderate; 3+, high; 4+, very high. NE, norepinephrine.

Data from references 1, 6–8, 57, 58, and 181.

HT_{2A} receptor antagonists (e.g., ziprasidone, sertindole, risperidone), also known as the serotonin-dopamine antagonists; (3) broad-spectrum, multireceptor antagonists (e.g., clozapine, olanzapine, quetiapine); and (4) D₂ and 5-HT_{1A} receptor partial agonists (e.g., aripiprazole), also known as dopamine and serotonin system stabilizers.⁷ Characteristics associated with drug atypia include low D₂ receptor potency (high milligram drug dosing); low D₂ receptor occupancy (less than 70%) in the mesolimbic and nigrostriatal areas at therapeutic doses; partial agonist activity at D₂ receptors; high affinities for M₁, D₁, D₃, α₂, 5-HT_{1A}, and 5-HT_{2A} receptors relative to the D₂ receptor; multiple neuroreceptor antagonism; and a low likelihood of raising serum prolactin concentrations.^{6-8,10,12,14,16}

CNS serotonin antagonism is now recognized as an important mechanism of antipsychotic action and minimizing the likelihood of EPS.^{1,14-18} Normally, serotonergic fibers inhibit dopamine release in the nigrostriatum and prefrontal cortex. Thus, blockade of the 5-HT_{2A} receptors in the CNS increases dopamine release in the striatum and prefrontal cortex. Antipsychotics that have high relative 5-HT_{2A} receptor antagonism (5-HT_{2A}/D₂ binding ratio greater than 1) (e.g., amperozide, clozapine, risperidone, sertindole, ziprasidone) have enhanced efficacy for treating the negative signs and symptoms of schizophrenia and provide a lower EPS liability.¹⁶⁻¹⁸ Agents with partial agonist activity at 5-HT_{1A} autoreceptors (e.g., ziprasidone, aripiprazole) have similar beneficial effects.

Pathophysiology

CARDIAC EFFECTS

The aliphatic and piperidine phenothiazines (e.g., chlorpromazine, thioridazine, and mesoridazine) have direct negative inotropic and quinidine-like (type IA) antiarrhythmic effects on cardiac myocytes.¹ These agents block voltage-gated fast sodium channels; blockade is enhanced at less negative membrane potentials and faster heart rates.^{1,19} Thus, conduction disturbances will be augmented for drugs that also produce tachycardia (e.g., those with anticholinergic properties) or tissue acidemia (e.g., as a result of drug-associated seizure or shock). In addition, certain antipsychotic agents antagonize delayed-rectifier, voltage-gated potassium channels (encoded by the HERG gene) responsible for membrane repolarization during phase 3 of the action potential.^{1,20,21} Potassium channel antagonism is concentration, voltage, and reverse frequency dependent; block is augmented at higher drug tissue concentrations, less negative membrane potentials, and slower heart rates.^{20,21} Potassium channel blockade may induce early after depolarization and triggered ventricular activity (e.g., torsades de pointes [TdP]). Some neuroleptics, (e.g., haloperidol, mesoridazine, pimozide, and thioridazine) are also calcium channel antagonists.²² The cardiac channel effects of antipsychotics produce a depressed rate of phase 0 depolarization, decreased amplitude and duration of phase 2, and prolongation of phase 3. In addition, early after-depolarizations that result from the

blockade of the rectifying potassium channels can trigger ventricular arrhythmias (e.g., TdP).

CARDIOVASCULAR

Hypotension results from α₁-adrenergic antagonism and loss of peripheral vasomotor tone, α₂-adrenergic antagonism and loss of central vasomotor tone, and direct membrane-depressant cardiac effects. Membrane-depressant effects result in impaired cardiac conduction and contractility.¹ Cardiovascular effects are dose related. Tachycardia occurs as a vasomotor reflex to hypotension or from anticholinergic drug effects.

SEIZURES

All antipsychotic agents appear to lower the seizure threshold and produce dose-related electroencephalographic (EEG) abnormalities that are similar to discharge patterns observed in epileptic patients.^{1,23-27} The degree of EEG changes and incidence of seizures are greatest with certain agents (e.g., clozapine, loxapine, and aliphatic and piperidine phenothiazines).^{1,23-29} The mechanisms of seizure production are not well elucidated but appear to involve GABA_A receptor antagonism, norepinephrine reuptake inhibition, and disrupted ionic flow through neuronal membrane channels.

EXTRAPYRAMIDAL SIDE EFFECTS

All EPS result from D₂ receptor blockade by antipsychotics in basal ganglia nuclei.^{1,6,14,30,31} This leads to a disruption of neurotransmission in numerous basal ganglia and thalamocortical pathways critical for coordinated movement. These pathways utilize acetylcholine, serotonin, glutamate, γ-aminobutyric acid (GABA), and various neuropeptides for communication.^{16,17,32} Drug-induced parkinsonism is a result of decreased nigrostriatal dopaminergic activity with resultant striatal cholinergic excess.^{1,6,30,31} Akathisia is likely produced by D₂ receptor blockade in mesocortical pathways.^{1,6,30,31} The pathophysiology of acute dystonic reactions (ADRs) is still unknown. One attractive theory posits that dystonia is the manifestation of an acute compensatory response to nigrostriatal D₂ receptor blockade produced by antipsychotics. The acute administration of antipsychotics provokes increased dopamine synthesis and release from nigrostriatal neurons and postsynaptic receptor up-regulation.^{30,31,33,34} As brain concentrations of the neuroleptic decline hours to days after a dose, a state of dopamine excess develops and hyperkinesia or dystonia results. TD is likely secondary to an increased number and up-regulated dopamine receptor as a compensatory response to chronic D₂ receptor blockade by antipsychotics in the nigrostriatum.^{1,6,30,31,33,34} TD signifies a state of dopaminergic supersensitivity and cholinergic underactivity in the basal ganglia.

NMS appears to involve dopaminergic hypoactivity in the CNS. Blockade of D₂ receptors in the striatum and hypothalamus results in muscular rigidity (similar to parkinsonism) and altered thermoregulation, respectively.³⁵⁻³⁷ Fever occurs largely from increased heat production from muscular rigidity but is also due to impaired heat dissipation and an altered set point of

core temperature in the hypothalamus.^{1,35-37} Blockade of D₂ receptors in the mesolimbic and mesocortical regions produces altered mentation. Blockade of D₂ receptors in peripheral sympathetic nerve terminals and the vasculature may cause autonomic disturbances.^{38,39} The pathophysiology of NMS may involve iron. Iron is a positive modulator of dopamine receptor activity, and low serum iron levels often displayed in those with NMS may lead to a decreased number of dopamine receptors in the brain.^{40,41}

PHARMACOKINETICS

Although most classes of antipsychotics have similar pharmacokinetics, there is substantial interindividual variability. Following oral administration, absorption is generally rapid and nearly complete. Because of extensive first-pass hepatic and intestinal metabolism, however, bioavailability is erratic and unpredictable (range 10% to 70%).^{1,42,43} Peak plasma concentrations occur within 1 to 6 hours after oral administration. Intramuscular (IM) administration increases bioavailability by a factor of 4 to 10.¹ Peak plasma concentrations occur within 30 to 60 minutes after IM administration of immediate-release preparations but are delayed up to 24 hours following IM administration of depot preparations.^{1,42,43} Following an oral overdose, absorption occurs more rapidly but peak plasma concentrations are delayed; clinical effects may occur earlier and last longer. The depot (sustained-release) injectable preparations are created by esterifying the hydroxyl group of the antipsychotic with a long-chain fatty acid (e.g., enanthate or decanoate) and dissolving it in a sesame oil vehicle.¹

Most antipsychotics are highly protein bound (75% to 99%) and lipophilic. These drugs have large volumes of distribution (usual range 10 to 40 L/kg) and tend to accumulate in brain and other tissues.^{1,42,43} Removal of these agents by hemodialysis or hemoperfusion is impossible.

Antipsychotic agents are largely and extensively eliminated by hepatic metabolism. Less than 1% of an ingested dose is excreted unchanged by the kidney. Hepatic metabolism occurs via flavin-containing monooxygenase or cytochrome P-450 mixed-function oxidase systems or by hydroxylation, sulfoxidation, *N*-dealkylation, and conjugation.^{42,43} Hepatic metabolites are not easily measured but often remain pharmacologically active and will extend the parent drug's effects after therapeutic doses or overdose. Thus, there is often a poor correlation between serum concentration and clinical effects.⁴²⁻⁴⁴ Metabolites are variably excreted in the urine and stool after conjugation and enterohepatic circulation, respectively. Elimination half-lives of most antipsychotic agents range from 20 to 40 hours after oral dosing. Depot IM preparations have elimination half-lives of 7 to 21 days.^{1,42} With newer sustained-release preparations (e.g., Risperdal Consta, Janssen, LP, Titusville, NJ), steady-state plasma concentrations are maintained for 4 to 6 weeks after the last IM injection.⁴⁵

Risperdal Contra contains an aqueous suspension of risperidone mixed with a biodegradable copolymer. The pharmacokinetic profile of common neuroleptic drugs is presented in Table 38-3.

Special Populations

PREGNANCY AND BREAST-FEEDING

Due to their high lipophilicity, most antipsychotics readily enter the fetal circulation across the placenta and are readily secreted into breast milk.¹ Data that establish the safety of antipsychotics during pregnancy are lacking, and these drugs are thus considered pregnancy class C; their use in pregnant women is warranted only if the benefits to the mother justify the potential risks to the fetus. While most manufacturers recommend against the use of antipsychotics during breast feeding, toxic effects and impaired development have not been demonstrated to date in infants who have been breast-fed by women regularly taking antipsychotics.⁴⁶

RENAL IMPAIRMENT

Most of the antipsychotics are metabolized almost exclusively in the liver before excretion and are not significantly affected by alterations in renal function. Risperidone and the benzamide derivatives (e.g., sulpiride and remoxipride), however, require dosage alterations for patients in renal failure because large amounts of these drugs are excreted unchanged by the kidneys.⁴³

HEPATIC IMPAIRMENT

Patients with advanced hepatic disease (e.g., cirrhosis) and conditions that impair hepatic blood flow (e.g., congestive heart failure) have diminished clearance of antipsychotic agents. Thus, dose reduction is recommended for this group of patients during chronic therapy.⁴³ The presence of hepatic disease, however, is unlikely to affect clinical outcome following acute overdose in this group of patients.

AGE

Infants and geriatric patients have reduced capacity to metabolize and eliminate antipsychotic agents, whereas children tend to metabolize these drugs more rapidly than adults.¹ In general, however, elderly and pediatric patients are more sensitive to the effects of neuroleptics than are young adults. Thus, patients at the extremes of age have a greater tendency to develop anticholinergic stigmata, EPS, sedation, confusion, and postural hypotension. The safety and efficacy of many antipsychotics have not been adequately studied in pediatric patients.

GENETIC POLYMORPHISMS

There is large interindividual variation in the hepatic biotransformation of antipsychotic agents, which largely reflects CYP enzyme polymorphisms. For instance, 5% to 10% of white individuals are CYP2D6 "poor metabolizers," which may result in certain antipsychotic drug concentrations (e.g., risperidone, haloperidol, thioridazine) that are up to 10-fold higher than those in

**TABLE 38-3** Pharmacokinetics of Various Antipsychotics

ANTIPSYCHOTIC AGENT	TIME TO PEAK AFTER ORAL DOSING (hr)	ELIMINATION HALF-LIFE (hr)	PROTEIN BINDING (%)	Vd (L/KG)	ROUTE OF METABOLISM	ACTIVE METABOLITE
Typical Agents

NA, data not available.
Pharmacokinetic data obtained from references 1, 8, 10, 42–44, and 182.

“normal” CYP2D6 individuals.^{47,48} Dose adjustment for these patients is unknown. Theoretically, these patients are at greater risk for adverse drug interactions.

Drug Interactions

The coadministration of antipsychotics with other drugs has the potential for numerous clinically significant pharmacodynamic and pharmacokinetic interactions.⁴⁹ The CNS and respiratory depressant effects of neuroleptics are potentiated when co-ingested with alcohols, antihistamines, opiates, other psychotropics, and sedative-hypnotics. Fatal cardiopulmonary arrest has occurred when therapeutic doses of clozapine have been taken with lorazepam.⁵⁰ Exaggerated anticholinergic effects could occur when certain antipsychotics are coadministered with tricyclic antidepressants, antihistamines, antiparkinson agents, and some skeletal muscle relaxants (e.g., cyclobenzaprine). Hypotension could occur when antipsychotics with α_1 -adrenergic antagonist effects are co-ingested with antihypertensives with similar properties (e.g., prazosin, hydralazine). QT prolongation may occur when cardioactive agents are coadministered with certain antipsychotics (e.g., droperidol,

haloperidol, thioridazine). The combination of lithium and neuroleptic agents can produce a syndrome similar to NMS.^{51,52}

Since many neuroleptics are metabolized by the CYP2D6, CYP1A2, and CYP3A4 enzymes, their clearance can be significantly altered when coadministered with inhibitors or inducers of these enzymes (see Table 38-3). A thorough knowledge of the neuroleptic's unique receptor-binding profile and hepatic metabolism will facilitate recognition and treatment of clinically significant drug interactions.

TOXICOLOGY

Clinical Manifestations Following Overdose

Isolated antipsychotic agent overdose is rarely fatal; most patients who overdose on these agents will remain asymptomatic or develop only mild toxicity.⁵ Ingested doses that produce acute toxicity and lethality are highly variable; many patients have survived ingestions reported to be lethal in others.⁵³ Toxicity largely depends on age,

habituation, and comorbid illness of the patient, agent identity, and time to treatment. Tolerance develops to the sedative effects of antipsychotics over a period of days to weeks.¹ Thus, nonhabituated adults and young children (rarely prescribed these agents) are more sensitive to the toxic effects of antipsychotics than those who have ingested the drug chronically. The ingestion of a single tablet of chlorpromazine, clozapine, loxapine, mesoridazine, olanzapine, quetiapine, or thioridazine may cause CNS and respiratory depression in young children.⁵³⁻⁵⁸ Multireceptor, low-potency agents (e.g., clozapine, loxapine, chlorpromazine, thioridazine, and mesoridazine) are more toxic than more selective, high-potency agents (e.g., fluphenazine, haloperidol).¹⁻⁵ When death occurs, it usually results from respiratory arrest (prior to medical intervention), arrhythmias, or aspiration-induced respiratory failure.²

Clinical effects begin within 30 to 90 minutes and peak within 2 to 6 hours of ingestion. Delayed onset and peak toxicity are possible after ingestion of drugs that slow gastrointestinal motility (e.g., anticholinergic drugs). Resolution of serious toxicity usually occurs by 24 to 48 hours. The toxic effects are similar in adults and children.

CNS depression is the most common finding following overdose.^{3,54-64} CNS effects range from lethargy, slurred speech, ataxia, and confusion in mild intoxication, to mild coma with respiratory depression in moderate intoxication, to deep coma with apnea and loss of brainstem and deep tendon reflexes in severe intoxication. Paradoxical agitation and delirium may occur with mixed overdoses and those involving antipsychotic agents with anticholinergic properties (e.g., chlorpromazine, clozapine, mesoridazine, olanzapine, and thioridazine). Respiratory depression that necessitates endotracheal intubation is uncommon but occurs with greater frequency in children, polydrug overdoses, and sedating, multireceptor, low-potency antipsychotics (e.g., aliphatic and piperidine phenothiazines, clozapine, olanzapine, and quetiapine). Apnea and sudden infant death syndrome have been associated with the use of antipsychotic agents.⁶⁵ Pulmonary edema can rarely occur.⁶⁶

Seizures are uncommon in overdose, reported in about 1% of patients in large series.^{3,57} Seizures, however, appear to occur with greater frequency after ingestion of chlorpromazine, clozapine, loxapine, mesoridazine, and thioridazine. A seizure incidence of 60% and 10% have been reported following loxapine and clozapine overdose, respectively.^{28,57,60} Loxapine-induced seizures can be recurrent and severe, resulting in rhabdomyolysis, myoglobinuria, and acute renal failure.²⁸

Anticholinergic manifestations (peripheral and central) are frequent following overdoses of thioridazine, mesoridazine, chlorpromazine, clozapine, and olanzapine. These effects include dry, flushed skin; dry mucous membranes; mydriasis; sinus tachycardia; decreased bowel sounds; urinary retention; myoclonic jerking and tremulousness; hyperthermia; agitation; delirium; and coma. Both hyperthermia and hypothermia have been described following antipsychotic overdose. Neuro-

muscular hyperactivity, seizures, the inability to sweat, and cutaneous vasodilation at high ambient temperature increase the likelihood of drug-associated hyperthermia. Coma, hypotension, suppressed shivering capability, and cutaneous vasodilation at low ambient temperatures increase the likelihood of drug-associated hypothermia. Miosis or mydriasis may occur with antipsychotic overdose. Miosis is more likely to occur in seriously poisoned patients with both atypical and typical agents; it has been described in 75% of adults and 72% of children after phenothiazine overdose.^{57,60,61,63,67}

The most common cardiovascular manifestations of antipsychotic overdose are sinus tachycardia and orthostatic hypotension.^{57,59,60,63} Other cardiovascular effects occur uncommonly and include hypertension, sinus bradycardia, conduction abnormalities, and supraventricular and ventricular tachyarrhythmias. Electrocardiographic (ECG) abnormalities include prolongation of the PR, QRS, and QT intervals, non-specific ST-T wave changes, depressed ST segments, T wave abnormalities (widening, flattening, notching, and inversion), increased U wave amplitude, rightward shift of the terminal 40 milliseconds of the QRS (i.e., the presence of R in aVR), atrioventricular, bundle branch, fascicular, and intraventricular blocks, and supraventricular and ventricular arrhythmias.^{3,68-72} Other than sinus tachycardia, repolarization abnormalities are the earliest and most common ECG abnormalities.⁶⁸⁻⁷² Serious cardiotoxicity is more common with the aliphatic and piperidine phenothiazines and less common with atypical agents.^{3,57} TdP ventricular tachycardia has been reported after overdose of droperidol, haloperidol, mesoridazine, pimozide, and thioridazine.⁷²⁻⁷⁷ Cardiovascular and ECG abnormalities should be apparent within several hours of an acute overdose.

Although EPS are often idiosyncratic reactions that follow therapeutic neuroleptic doses, these effects may also be dose related, and have occurred following overdose with many neuroleptics.^{54,59,64} EPS can be the presenting manifestation in a child following accidental neuroleptic poisoning.^{54,64,78}

Adverse Effects

All antipsychotics, typical or atypical, are associated with numerous adverse effects. Adverse effects may be idiosyncratic or dose related, can occur early or late in the course of therapy, and are often the result of receptor antagonism.¹ Neurologic and cardiovascular side effects occur most commonly.

EXTRAPYRAMIDAL SIDE EFFECTS

EPS are a group of sustained movement disorders that can occur in approximately 30% of patients treated with antipsychotic agents and often lead to medication non-compliance in those with psychosis.^{1,79} All antipsychotics can produce EPS, but the incidence is significantly reduced for newer generation, atypical agents. The incidence of EPS is similar to that with placebo during chronic therapy with clozapine, olanzapine, quetiapine, ziprasidone, and aripiprazole.^{14,34,79-81} There are six EPS

syndromes. They can be divided into the reversible syndromes that occur within hours to days (e.g., acute dystonia, akathisia) or days to weeks (e.g., parkinsonism, NMS) and the potentially irreversible syndromes that occur after months to years of therapy (e.g., TD, focal perioral tremor).¹

Acute dystonia is a hyperkinetic movement disorder characterized by intermittent, uncoordinated, spasmodic, or sustained involuntary contractions of muscles of the face, tongue, neck, trunk, and extremities. Clinical manifestations include facial grimacing, trismus, blepharospasm, oculogyric crisis, tongue protrusion, buccolingual crisis, retrocollis, torticollis, opisthotonus, abnormal postures and gait, tortipelvis, and respiratory difficulty. ADRs, although distressing to patients, are rarely life threatening. Pharyngeal and laryngeal muscle spasm has produced respiratory distress and asphyxia.⁸²

ADRs usually occur soon after initiation of antipsychotic therapy or after an increase in dose. Fifty percent occur within 48 hours and 90% within the first 5 days of treatment.^{83,84} The peak incidence occurs when antipsychotic concentrations are declining in the serum. In one study of pediatric patients, ADRs occurred 5 to 50 hours (mean 23 hours) after the first therapeutic dose and 1 to 20 hours (mean 5 hours) after single accidental ingestion of phenothiazines.⁸⁵ The incidence of ADRs varies according to the agent's identity, dose, route of administration, and duration of therapy, and the presence of individual risk factors. The incidence is lowest with agents that have low D_2 receptor potency and/or high relative potency at $5-HT_2$, $5-HT_{1A}$, M_1 , α_2 , or D_4 receptors (atypical agents). Incidence rates of 25%, 16%, 8.3%, 3.5%, and less than 1% have been described for IM fluphenazine decanoate, haloperidol, thiothixene, chlorpromazine, and atypical agents, respectively.^{33,83,84} Individual risk factors include male gender, young age (peak range 5 to 45 years), a family history or personal history of ADRs, or a recent history of cocaine or alcohol use.^{33,83,84,86,87}

Akathisia is a condition of subjective unease and motor restlessness that occurs within minutes to days of initiation or increase of antipsychotic drug dosing.^{14,81} It is usually observed within the first 3 months of treatment.¹ Akathisia may be misinterpreted as anxiety or agitation related to an underlying psychiatric condition. Akathisia is characterized by the inability to sit still and the overwhelming need to continuously move the legs or get up and walk or pace. Patients are frequently anxious, agitated, or unable to concentrate. About 30% of patients ingesting traditional agents develop akathisia.^{1,8,10,14,81} The incidence is less with atypical agents, with an incidence range of 5% to 15%.^{88,89} Akathisia is more likely to occur with the use of higher-potency D_2 antagonists, larger doses, rapid dose escalation, and parenteral antipsychotic administration.^{14,81,88}

Parkinsonism is a reversible, intermediate-stage EPS that typically occurs gradually over days to weeks and is evident by 2 to 3 months of therapy.¹ Parkinsonism is characterized by muscle rigidity (cogwheel type), bradykinesia or akinesia, mask facies, shuffling gait, tremor (e.g., pill rolling), and cognitive impairment.

Antipsychotic-induced parkinsonism occurs in 13% of patients who take antipsychotic agents chronically.^{6,14} Antipsychotic-induced parkinsonism occurs in all age groups but occurs with greater frequency in the elderly. Other risk factors for its occurrence include female sex, the presence of organic brain injury, use of high-potency agents, and long duration of therapy.^{1,6,14,81} The rabbit syndrome is an uncommon reversible late-onset EPS characterized by perioral lip tremor. It usually occurs after months or years of antipsychotic treatment and is considered a variant of parkinsonism.¹

TD is a hyperkinetic, late-onset EPS that typically occurs after 2 years of antipsychotic therapy and only rarely before 6 months.^{1,14,81} It is characterized by involuntary, painless, stereotyped, repetitive movements of orofacial structures and, occasionally, the trunk and arms. These movements include chewing; tongue protrusion; lip smacking, sucking, and pursing; facial grimacing; grunting; rapid eye blinking; and occasionally choreoathetosis of the trunk and limbs. TD is associated with all antipsychotic agents, but the incidence is significantly lower with atypical agents, particularly clozapine. TD develops in 15% to 25% of patients on long-term antipsychotic therapy. An annual incidence of 3% to 5% is described with traditional antipsychotics, whereas atypical agents have an annual incidence of less than 2%.⁹⁰ TD occurs in patients of all ages (including children) but occurs more commonly in women older than 50 years.⁹¹ TD is frequently elicited in patients who have their drug discontinued or dose lowered after years of therapy.^{1,91}

NMS is an uncommon but potentially fatal idiosyncratic complication of antipsychotic drug therapy. NMS is often considered an extreme, severe form of EPS⁹²⁻⁹⁵ (see also Chapter 10A). NMS usually occurs early in the course of treatment or soon after a change in dose but may appear at any time during therapy. It is estimated that NMS occurs in 2 out of every 1000 patients treated with neuroleptics.⁹⁵ While NMS has been associated with all antipsychotic agents, most cases have been secondary to the high-potency agents haloperidol and fluphenazine, particularly their depot formulations. NMS is not a result of overdose and usually occurs with antipsychotic serum concentrations in the therapeutic range. Potential risk factors for development of NMS include rapid initiation of antipsychotic therapy; use of high-potency agents and depot preparations; dehydration; severe patient agitation or catatonia; requirement of restraints or patient seclusion; preexisting organic brain disease, mental retardation, or affective disorder; a history of NMS or electroconvulsive therapy (ECT); poorly controlled EPS; and concomitant use of predisposing drugs, namely lithium, anticholinergic agents, and antiparkinson agents.⁹²⁻⁹⁸ NMS occurs more commonly in men (2:1 male:female ratio), with a mean age of 40 years.⁹²⁻⁹⁸

NMS typically develops over a period of 24 to 72 hours and is commonly characterized by the tetrad of altered consciousness, fever (temperature greater than 38° C), muscular rigidity, and autonomic dysfunction.⁹²⁻⁹⁸ Altered mental status includes lethargy, agitation, mutism,

stupor, and coma. Muscular rigidity is lead pipe and cogwheel type, similar to parkinsonism.¹ Autonomic dysfunction includes fever, tachycardia, tachypnea, hypertension or hypotension, diaphoresis, sialorrhea, pallor, flushing, urinary incontinence, and cardiac arrhythmias. Other common findings include EPS (e.g., tremor, bradykinesia, akinesia, festinating gait, chorea, dystonia, dysphagia, dysarthria, aphonia), mutism, seizures, abnormal reflexes, dyspnea, and hypoxemia. Laboratory abnormalities include elevated serum creatine phosphokinase (greater than three times normal) in up to 97% of cases, leukocytosis, elevated levels of hepatic transaminases, hyper- or hyponatremia, metabolic acidosis, myoglobinuria, elevated serum blood urea nitrogen and creatinine, and decreased serum iron levels.^{40,41,92-99} Medical complications of NMS include rhabdomyolysis, myoglobinuric renal failure, aspiration pneumonitis, pulmonary edema, pulmonary embolism, respiratory failure, sepsis, coagulopathy, disseminated intravascular coagulation, seizures, myocardial infarction, cardiac arrhythmias, peripheral neuropathy, necrotizing enterocolitis, and periarticular ossification.⁹²⁻⁹⁹

The presence of fever and muscle rigidity is usually required for diagnosis, but their absence has been associated with certain NMS variants. NMS is best considered a heterogeneous syndrome with variable signs, symptoms, and severity.⁹³⁻⁹⁵ Most cases of NMS seem to follow a sequence of development. Mental status changes and muscular rigidity precede autonomic dysfunction and fever in over 80% of cases.¹⁰⁰ Early recognition of confusion, catatonia, or worsening EPS may facilitate timely treatment and halt progression to the fulminant syndrome.¹⁰⁰

Once antipsychotics are discontinued, the signs and symptoms of NMS resolve over a period of 1 to 61 days, with a mean duration of approximately 10 days.⁹⁴⁻⁹⁷ The clinical course is nearly twice as long in patients who have received IM depot preparations.⁹⁴⁻⁹⁷ NMS was initially characterized as malignant due to its frequent fatal outcome. Mortality rate, once estimated to range from 17% to 28%, now ranges from 0 to 11.6%.⁹²⁻¹⁰²

SEIZURES

Seizures are usually generalized and major motor type. Risk factors for seizures include a history of organic brain disease, epilepsy, drug-associated seizures, or ECT, an abnormal baseline EEG, polypharmacy, initiation of antipsychotic therapy, rapid dose titration and/or use of large antipsychotic doses, and the use of certain antipsychotic agents.²³⁻²⁹ Seizures occur most commonly with chlorpromazine, clozapine, and loxapine; the risk is dose dependent with these agents.^{25,28,29,57} A 0.5% incidence of seizures has been reported with low to moderate doses of chlorpromazine (30 to 900 mg/day) and 9% incidence with daily doses greater than 1 g.²³ A seizure incidence of 1.8% has been reported with moderate doses of clozapine (300 to 600 mg/day), whereas those taking greater than 600 mg/day have an incidence of 4.4%.^{24,27,29} Seizures are unlikely to occur during therapeutic dosing with other antipsychotics;

the incidence is comparable with that of placebo (less than 1%).²⁴

CARDIOVASCULAR

Although repolarization abnormalities (e.g., prolongation of the QT interval) and arrhythmias are dose dependent and have been reported most frequently with antipsychotic overdose, these findings can also occur with therapeutic doses of these agents. QT prolongation has been associated with therapeutic dosing and overdose of aliphatic and piperidine phenothiazines, droperidol, haloperidol, loxapine, pimozide, quetiapine, risperidone, sertindole, and ziprasidone.^{3,28,68-77,103-117} The U.S. manufacturer of sertindole (Abbott Laboratories, North Chicago, IL) withdrew its new drug application for consideration by the Food and Drug Administration (FDA) due to concern that therapeutic dosing would be associated with TdP and sudden death. The rare association of ventricular arrhythmia (e.g., TdP) with therapeutic doses of droperidol (typically large doses) caused the FDA to issue a "black box" warning to U.S. health care practitioners in December 2001.¹¹⁵ Sudden unexplained death has been described in otherwise healthy patients taking therapeutic doses of many antipsychotic drugs.^{104,115-117} These deaths are presumed to be the result of malignant ventricular arrhythmias (e.g., TdP).^{116,117} In one series of sudden death from antipsychotics, more than half were associated with thioridazine.¹⁰⁴

Myocarditis and cardiomyopathy have rarely been associated with the therapeutic use of antipsychotic agents. Ten cases of myocarditis, some with eosinophilic cellular infiltrates, have been described in association with clozapine; this adverse effect is rare, idiosyncratic, often occurs within 1 to 2 weeks of starting therapy, is likely the result of acute hypersensitivity, and may be fatal.^{118,119}

METABOLIC

Recently, the therapeutic use of the benzepines (e.g., clozapine, olanzapine, and quetiapine) and aripiprazole has been associated with an increased risk for developing type 2 diabetes mellitus or diabetic ketoacidosis (DKA).¹²⁰⁻¹²⁴ Numerous cases of fatal DKA or hyperglycemic hyperosmolar nonketotic coma have been reported in patients taking either clozapine or olanzapine.¹²⁵⁻¹²⁹ African Americans appear to be affected disproportionately as compared with other races.¹³⁰ Hypertriglyceridemia has also been reported in patients taking olanzapine, clozapine, and quetiapine.¹³¹⁻¹³⁴ Nonalcoholic steatohepatitis has been associated with the therapeutic use of olanzapine and risperidone, and pancreatitis has been associated with the use of clozapine.^{135,136} Asymptomatic elevations of hepatic transaminases (both cholestatic and hepatic pattern) have been reported with most neuroleptics.¹³⁷⁻¹³⁹ These elevations are usually idiosyncratic, self-limiting, and typically occur during the first 3 months of therapy. Most atypical antipsychotics produce increased appetite and weight gain; these side effects occur most commonly

with benzepine agents and are likely associated with the increased risk for acquired diabetes mellitus.^{1,14,57} Priapism, allergic dermatitis, photosensitivity, cholestatic jaundice, and pigmentation of the skin, cornea, lens, and retina have been associated with therapeutic phenothiazine use.¹

HEMATOLOGIC TOXICITY

Agranulocytosis (absolute neutrophil count of less than 500 per cubic millimeter) is a life-threatening idiosyncratic reaction that can rarely occur with phenothiazine and clozapine therapy. Agranulocytosis occurs in approximately 1 in 10,000 patients taking chlorpromazine and 1 in 100 patients taking clozapine.¹⁴⁰⁻¹⁴³ Early recognition (by regular white blood cell monitoring) and treatment (use of granulocyte colony-stimulating factor [G-CSF]) of clozapine-associated agranulocytosis has reduced its mortality to 3% to 4%.¹³⁰ Prompt treatment with the use of G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) has reduced the duration of granulocytopenia from a mean of 16 days to 8 days.¹⁴⁴ Agranulocytosis has also been reported with the use of olanzapine, quetiapine, and risperidone.¹⁴⁵⁻¹⁴⁷ Clozapine has been associated with an increased risk for thromboembolic disease.¹⁴⁸

DIAGNOSIS

The diagnosis of antipsychotic poisoning is based on a positive history of ingestion, suggestive physical findings, and supporting evidence from the ECG, laboratory, and other adjunctive tests. Physical findings that suggest antipsychotic agent toxicity include CNS and/or respiratory depression, anticholinergic stigmata, miosis, hypotension, and EPS. The presence of sinus tachycardia and/or repolarization abnormalities on ECG supports a history of antipsychotic agent poisoning. Phenothiazines and butyrophenones are radiopaque and often visible on abdominal radiographs. The use of abdominal radiography as a diagnostic aid is not recommended, however, since a normal radiograph does not rule out significant ingestion of these or other antipsychotic agents. Similarly, although the Forrest, ferric chloride, and Phenistix colorimetric urine tests can be positive in the setting of phenothiazine ingestion, the tests are both insensitive and nonspecific.¹⁴⁹ Thus, they should not be used to confirm or rule out ingestion of either phenothiazine or nonphenothiazine antipsychotics.

Comprehensive screening of urine (using gas chromatography and mass spectrometry) may be used to qualitatively confirm the presence of most antipsychotics. Comprehensive testing, however, is not routinely available at most hospitals, and results are often delayed beyond 4 to 6 hours. In addition, comprehensive tests have other limitations. False-negative results may occur with newer atypical agents or if testing is performed too early or late following exposure. For instance, a false-negative screen is likely to occur for a patient who

presents with EPS more than 24 hours after ingestion of a single antipsychotic tablet. Quantitative drug concentrations can also be performed for most antipsychotic agents (usually from the drug manufacturer). Serum drug concentrations, however, will not guide therapy; they do not correlate well with clinical toxicity and are not readily available. It should be recognized that certain antipsychotics (e.g., chlorpromazine, mesoridazine, quetiapine, and thioridazine) will often produce false-positive results for tricyclic antidepressants on many commercial immunoassay screens for drugs of abuse.¹⁵⁰

The diagnosis of NMS is clinical and based on a positive history of antipsychotic exposure and suggestive physical findings. The adoption and use of standardized criteria to make the diagnosis is recommended (Box 38-1).^{35,95,151,152} Fever and muscular rigidity should be present to make the diagnosis of NMS, and the diagnosis should not be made before other medical illnesses (e.g., CNS infection) have been excluded.

Differential Diagnosis

Toxicity from antipsychotic agents produces signs and symptoms that are similar to many toxicologic and nontoxicologic entities. The CNS and cardiovascular manifestations of antipsychotic overdose may be similar to effects produced by alcohols, antiarrhythmics, anticholinergics, antiepileptics, antihistamines, barbiturates, cyclic antidepressants, lithium, opiates, sedative-hypnotics, and skeletal muscle relaxants. Toxicity from chlorpromazine, loxapine, mesoridazine and thioridazine can be clinically indistinguishable from that of cyclic antidepressants. CNS infection, traumatic head injury, cerebrovascular accidents, and metabolic disturbances should be considered and ruled out with appropriate testing. ADRs must be differentiated from anticholinergic, antiepileptic, and strychnine poisoning, CNS or oropharyngeal infections, hypocalcemia, hypomagnesemia, temporomandibular joint dislocations, cerebrovascular accidents, and conversion disorders. Akathisia may be mistaken for acute anxiety or agitation associated with underlying psychosis.¹ NMS must be differentiated from the anticholinergic, serotonin, and sedative-hypnotic withdrawal syndromes; poisoning by hallucinogens, lithium, monoamine oxidase inhibitors, strychnine, and sympathomimetics; and intracranial hemorrhage, thyrotoxicosis, heat stroke, pheochromocytoma, malignant hyperthermia, and lethal catatonia.

Malignant hyperthermia should not be confused with NMS. Malignant hyperthermia is a rare, inherited disorder of skeletal muscle calcium metabolism. Exposure to certain anesthetic agents (e.g., succinylcholine, halothane) or stress precipitates enhanced release and impaired reuptake of calcium from the sarcoplasmic reticulum in skeletal muscle cells. The result is excessive excitation-contraction coupling and a syndrome of muscle rigidity and fever that may appear clinically similar to NMS. Unlike NMS, malignant hyperthermia is associated with general anesthesia and not antipsychotics.

BOX 38-1 USEFUL DIAGNOSTIC CRITERIA FOR NEUROLEPTIC MALIGNANT SYNDROME (NMS)**Criterion 1***

- A. Treatment with neuroleptic agents within 7 days of symptom onset (2–4 weeks for depot agents)
- B. Fever > 38° C
- C. Muscle rigidity
- D. Five of the following:
1. Change in mental status
 2. Tachycardia
 3. Hypertension or hypotension
 4. Tachypnea or hypoxia
 5. Diaphoresis or sialorrhea
 6. Tremor
 7. Incontinence
 8. Increased CPK or myoglobinuria
 9. Leukocytosis
 10. Metabolic acidosis

CPK, creatine phosphokinase.

*Data from reference 95.

† Data from reference 152.

‡ Data from reference 151.

Criterion 2†

- A. Major:
1. Fever
 2. Rigidity
 3. Elevated CPK concentration
- B. Minor:
1. Tachycardia
 2. Abnormal arterial blood pressure
 3. Tachypnea
 4. Altered mental status
 5. Diaphoresis
 6. Leukocytosis
- C. The presence of all three major criteria, or two major and three minor criteria indicate a high likelihood of NMS
- D. Symptoms are supported by an appropriate clinical history

Criterion 3‡

- A. Development of muscle rigidity and fever associated with the use of neuroleptics
- B. At least two of the following:
Change in level of consciousness
Mutism
Tachycardia
Hypertension or labile blood pressure
Diaphoresis
Dysphagia
Tremor
Incontinence
Leukocytosis
Laboratory evidence of muscle injury (e.g., elevated CPK)
- C. Symptoms in A and B are not due to another substance or to a neurologic or general medical condition
- D. Symptoms in A and B are not better accounted for by a mental disorder

MANAGEMENT**Overdose****OVERVIEW**

Treatment for antipsychotic agent poisoning is mainly supportive.⁵⁸ Patients with significant CNS or respiratory depression should have their airway protected, breathing assisted, and cardiovascular support provided as necessary. All patients should have continuous cardiac monitoring, an intravenous (IV) line established, and an ECG performed. Supplemental oxygen, continuous pulse oximetry, and parenteral thiamine, dextrose (or rapid fingerstick glucose determination), and naloxone should be considered for patients with altered mental status or seizures. Semicomatose patients should be placed in the left lateral, head-down position to minimize the risk for aspiration. Frequent vital sign and neurologic evaluations are necessary. Routine laboratory analysis should include a complete blood count and measure-

ment of electrolytes, blood urea nitrogen, creatinine, glucose concentrations, and pregnancy testing for women of childbearing age. Serum acetaminophen and salicylate concentrations should be performed for all intentional overdose patients. For patients with seizures or hyperthermia, laboratory evaluation should also include an arterial blood gas, urinalysis, and measurement of serum creatine phosphokinase, calcium, and magnesium concentrations. A complete blood count should also be obtained on any patient who presents with a fever while taking clozapine or chlorpromazine.

SEIZURES

Seizures are often self-limited and may not require specific treatment. If prolonged or recurrent, seizures should be treated with benzodiazepines (e.g., lorazepam 0.05 to 0.1 mg/kg IV). Barbiturates (e.g., phenobarbital 10 to 20 mg/kg IV) are reserved for seizures refractory to benzodiazepine therapy. Pentobarbital coma may rarely be necessary for patients with status epilepticus

associated with certain antipsychotics (e.g., loxapine). The efficacy and safety of phenytoin treatment for antipsychotic-associated seizures is unknown. Measurements of blood glucose concentration and core temperature are imperative for those with seizures.

CARDIOVASCULAR

Hypotension is treated initially by placing the patient in the Trendelenberg position and administering IV crystalloid boluses (10 to 40 mL/kg). α -Adrenergic agonists (e.g., norepinephrine, phenylephrine) are the preferred vasopressors for treatment of refractory hypotension. Dopamine, an indirect-acting vasopressor, may be ineffective and is not recommended as a first-line agent for hypotension. Central venous, peripheral arterial, or pulmonary arterial catheter monitoring is recommended for patients requiring prolonged vasopressor therapy. Intraventricular conduction delay (e.g., prolonged QRS on ECG) and ventricular arrhythmias should be treated with sodium bicarbonate (1 to 2 mEq/kg IV bolus followed by intermittent boluses or continuous infusion).¹⁵³ Lidocaine (1 to 1.5 mg/kg IV) is an acceptable alternative or second-line agent for ventricular arrhythmias.¹⁵⁴ Types Ia (e.g., quinidine, procainamide), Ic (e.g., propafenone), II, III (e.g., amiodarone), and IV antiarrhythmic agents should be avoided in patients with cardiac conduction disturbances and/or ventricular arrhythmias. Their use may potentiate such cardiotoxicity.¹⁵⁴ TdP ventricular tachycardia should be treated in the standard fashion (e.g., IV magnesium and/or lidocaine, overdrive pacing with isoproterenol or electrical pacing, correction of electrolyte disturbances).¹⁵⁵⁻¹⁵⁸ Sinus tachycardia associated with antipsychotic poisoning does not require specific treatment.

ANTICHOLINERGIC SYNDROME

Physostigmine may be used to control agitation and reverse delirium in patients with the anticholinergic syndrome (ACS) from certain antipsychotics (see Chapter 39). It has been used successfully for patients with ACS associated with chlorpromazine, clozapine, olanzapine, and thioridazine.^{57,60,159,160} Physostigmine is safe provided that the ECG does not demonstrate cardiac conduction disturbances (e.g., prolonged PR or QRS intervals).¹⁵⁹ Physostigmine should be given slowly IV (0.02 mg/kg in children, or 2 mg in adults) over 3 minutes. Because the clinical duration of action of physostigmine is short (20 to 90 minutes) compared with that of antipsychotic agents, resolution of the anticholinergic stigmata after physostigmine administration should not alter patient disposition. Agitation associated with the ACS from antipsychotics may also be treated with benzodiazepines.

DECONTAMINATION AND ENHANCED ELIMINATION

Gastrointestinal decontamination should be initiated rapidly after patient stabilization. Single-dose administration of activated charcoal (1 g/kg orally or by nasogastric tube) is the preferred method of gastrointestinal

decontamination. Orogastric lavage is not routinely recommended since the risk for death following acute neuroleptic overdose is very low. If performed, gastric lavage should be followed by the administration of activated charcoal. Due to slowed gut motility and delayed drug absorption produced by the anticholinergic effects of many antipsychotics, activated charcoal administration is still recommended when patients present several hours after an overdose. The clinical benefit of this recommendation, however, is likely minimal. Forced emesis, use of cathartics, whole bowel irrigation, and multiple-dose activated charcoal are not recommended for antipsychotic poisoning due to their low likelihood to provide clinical benefit. Extracorporeal removal techniques are not recommended as part of treatment for antipsychotic poisoning since these agents have large volumes of distribution and high plasma protein binding.

Extrapyramidal Side Effects

ADRS

Treatment of ADRs may rarely require supplemental oxygen and assisted ventilation for patients with respiratory difficulty from laryngeal and pharyngeal dystonia. The usual treatment is parenteral administration of either diphenhydramine (1 mg/kg IV or IM) or benztropine (1 to 2 mg IV or IM in adults, or 0.02 to 0.05 mg/kg in pediatric patients). ADRs typically respond within 5 to 10 minutes of IV anticholinergic administration, but repeat dosing may be necessary for its complete resolution. If dystonia does not respond to anticholinergic therapy, diazepam (0.1 mg/kg IV) or lorazepam (0.05 to 1.0 mg/kg IV) may be effective. Following parenteral therapy, an oral anticholinergic agent should be administered for the next 48 to 72 hours to prevent dystonia recurrence.¹⁶¹

AKATHISIA

No treatment for akathisia is uniformly effective.⁸⁸ Anticholinergic drugs significantly reduce the incidence of akathisia when administered prior to or concomitant with antipsychotic agents.¹⁶² Although recommended as first-line treatment for established akathisia, anticholinergic therapy often fails to provide consistent and adequate symptom relief.^{81,163} Alternatively, benzodiazepines may provide effective symptom relief.⁸⁸ Patients who develop akathisia but require chronic antipsychotic treatment may benefit from reduction of the antipsychotic dose, substitution with another atypical agent, administration of propranolol (10 mg orally three times per day), clonidine (0.1 mg orally three times per day), cyproheptadine (16 mg/day), anticholinergic agents (e.g., benztropine or diphenhydramine), or benzodiazepines (e.g., diazepam).^{88,164-167}

PARKINSONISM

Drug-induced parkinsonism may be minimized by using low doses of traditional antipsychotics, changing to an atypical agent, or adding either an anticholinergic agent (e.g., benztropine or diphenhydramine) or one that enhances dopaminergic activity (e.g., amantadine).⁸¹

TARDIVE DYSKINESIA

Once tardive dyskinesia (TD) develops, it is difficult to treat and may be irreversible. The best treatment is to minimize its risk for occurrence.¹⁶⁸ Antipsychotic drugs should be administered at the lowest possible effective doses, and periodic reevaluation should be performed to determine the continued need for antipsychotic therapy and evaluate for the earliest signs of TD.^{81,168} Because TD is a progressively irreversible disorder, early detection and prompt antipsychotic withdrawal will increase the likelihood of complete recovery. Atypical agents should preferentially be used for long-term therapy since they have a lower propensity for producing TD. Anticholinergic agents will exacerbate TD and should not be used.¹ While higher doses of antipsychotic agents will temporarily relieve the symptoms of TD, this treatment is discouraged because it will further enhance dopamine receptor dysfunction and lead to worsening dyskinesia.^{1,81,168}

NEUROLEPTIC MALIGNANT SYNDROME

Successful treatment of neuroleptic malignant syndrome (NMS) requires prompt recognition, immediate withdrawal of antipsychotic and NMS-potentiating drugs (e.g., lithium or anticholinergics), exclusion of other medical conditions that could simulate or complicate NMS, and the provision of good supportive care. Good supportive care necessitates the provision of adequate ventilation and oxygenation, rehydration, aggressive temperature reduction, nutritional support, low-dose heparin to prevent thromboembolic disease, antibiotics to treat concurrent infection, and treatment of cardiopulmonary, metabolic, and renal complications.⁹⁹ Gastrointestinal decontamination is not necessary since NMS is associated with therapeutic dosing of antipsychotic agents. Empirical antibiotic administration is prudent due to the difficulty in differentiating NMS from a systemic infectious process and the high incidence of concurrent infection. Prophylactic intubation should be strongly considered for patients with excessive sialorrhea, swallowing dysfunction, coma, hypoxia, acidosis, or muscular rigidity associated with their hyperthermia.

The role of specific pharmacotherapies for NMS is controversial since most data on individual agent efficacy comes from retrospective studies and case reports. Although each therapy has been reported effective anecdotally in the management of NMS, none has been consistently beneficial or clearly superior to supportive care alone.^{94,95,99,169} Specific treatment measures include dantrolene, nondepolarizing neuromuscular paralysis, benzodiazepines, bromocriptine, amantadine, levodopa/carbidopa, nifedipine, nitroprusside, and ECT.

Anticholinergic agents are not recommended for treatment of NMS; they are considered ineffective and may worsen hyperthermia.^{37,94,95} One retrospective study in children and adolescents with NMS, however, noted a reduction in the duration of illness associated with the use of anticholinergic agents.⁹⁷

Dantrolene is a hydantoin derivative that inhibits the release of ionized calcium from the sarcoplasmic reticulum. It causes direct muscle relaxation by

uncoupling excitation-contraction in the skeletal muscle. It is used to control NMS-associated rigidity and hyperthermia. It can be administered orally or intravenously. While the initial dosing is 1 to 2.5 mg/kg every 6 hours, doses up to 10 mg/kg/day are considered safe.^{94,95,170,171} Dantrolene should be continued until the signs and symptoms of NMS resolve.

Bromocriptine, a dopamine receptor agonist, is given orally three times daily (2.5 to 10 mg/dose).^{94,95,99} Amantadine, which enhances presynaptic dopamine release, is given orally two times per day (100 to 200 mg per dose).^{94,95,99} Levodopa/carbidopa, which increases presynaptic dopamine stores, is given orally three to four times daily (25/250 mg per dose). Dopamine agonists are given alone or in conjunction with dantrolene or other muscle relaxants. For both dantrolene and dopamine agonist therapy, it is recommended that treatment be tapered over a period of days.^{92,172} Signs of NMS have returned when pharmacotherapies have been abruptly discontinued.¹⁷³

In one retrospective analysis of 67 cases of NMS, dantrolene or bromocriptine reduced mean times to improvement and complete resolution of toxicity as compared with supportive care alone.¹⁷⁴ Mean response time to clinical improvement was 1.0 day for bromocriptine, 1.7 days for dantrolene, and 6.8 days for supportive care alone. Mean time to complete resolution was 9.0 days for dantrolene, 9.8 days for bromocriptine, and 15.8 days for supportive care alone. A prospective nonrandomized study of 20 patients with NMS, however, demonstrated a more prolonged illness and greater complication rates with bromocriptine or dantrolene treatment as compared with supportive care alone.¹⁷⁵ The mean duration of illness was 9.9 days for patients receiving bromocriptine/dantrolene versus 6.8 days for patients receiving supportive care. In retrospective analyses, dopamine agonists have been reported to reduce NMS mortality rates significantly, from 21% to 9.2%.^{176,177} The addition of dantrolene to bromocriptine treatment does not offer additional survival advantage.

ECT has been employed successfully for NMS. In one review of 29 patients, a positive response occurred in 83% of patients.¹⁷⁸ Some suggest that the mortality rate of NMS patients treated with ECT is lower than that of patients treated supportively.¹⁷⁸ ECT should be reserved for severely affected patients since this therapy has been associated with cardiac arrhythmias, cerebral edema, and death.⁹⁵

Prompt reduction of NMS-associated muscle rigidity and hyperthermia can be expected to minimize the risk for rhabdomyolysis, renal failure, pneumonia, respiratory failure, disseminated intravascular coagulation, and cardiovascular collapse. These complications are responsible for most NMS-associated deaths, and, thus, their prevention is paramount. Since NMS-associated hyperthermia occurs primarily from muscular rigidity, rapid peripheral muscle relaxation is imperative. Dantrolene and bromocriptine take a day or more to achieve fever reduction. Nondepolarizing neuromuscular paralysis will provide rapid, predictable, and effective resolution of rigidity and fever and should be the first-

line treatment for patients who have severe hyperthermia (e.g., core temperature greater than or equal to 40° C). Pancuronium administration has been effective for the rapid control of fever and rigidity in patients with severe NMS.¹⁷⁹

For patients with less severe NMS, a logical first approach to the management of fever and rigidity is the administration of benzodiazepines (e.g., diazepam 0.1 to 0.4 mg/kg or lorazepam 0.05 to 0.1 mg/kg IV) coupled with antipyretics, evaporative cooling, ice packs, and cooled IV fluids.¹⁸⁰ The addition of dopamine agonist therapy and dantrolene may be helpful. If muscle rigidity persists and core temperature reaches 40° C despite these therapies, neuromuscular paralysis with a nondepolarizing paralytic agent is recommended. The level of intervention depends on the severity of illness.

Disposition

Most patients with pure neuroleptic overdose develop only mild toxicity and are medically safe for psychiatric evaluation and disposition after an observation period of 4 to 6 hours in the emergency department. Patients who have continued evidence of mild toxicity (e.g., sinus tachycardia, mild CNS depression, QTc prolongation) at 6 hours should be admitted to a monitored bed for continued observation. Patients with evidence of moderate or severe toxicity at any time (e.g., significant CNS and/or respiratory depression, cardiac arrhythmias or conduction disturbances, acidosis, prolonged hypotension, seizures, ACS) should be admitted to the intensive care unit for supportive care. Due to its significant associated morbidity, all patients suspected of having NMS should be admitted initially to the intensive care unit.

At a Glance...

- Anticholinergic and sedating antihistamine agent poisoning is common and should be included in the differential diagnosis of any patient with an altered mental status and sinus tachycardia, particularly those with agitated delirium.
- The diagnosis of the anticholinergic syndrome is based on the clinical examination; the absence of patient sweating is a key physical finding.
- The majority of patients with anticholinergic poisoning have a good outcome with supportive care.
- Treatment with physostigmine is indicated for select patients with agitated delirium and the absence of conduction disturbances on the electrocardiogram.

INTRODUCTION AND RELEVANT HISTORY

Anticholinergic drugs and plants have a distinct place in world history. Marc Anthony's military troops were neutralized and defeated after ingesting hallucinogenic anticholinergic plants. In 1676, a witness wrote of British soldiers' antics after they had consumed salad containing *Datura stramonium*. His account is a vivid description of anticholinergic poisoning¹:

. . . some of them eat plentiful of it [James-town weed], the Effect of which was a very pleasant Comedy; for they turn'd natural Fools upon it for several Days: One would blow up a Feather in the Air: another wou'd dart Straws at it with much Fury; and another stark naked was sitting up in a Corner, like a Monkey, grinning and making Mows at them; a Fourth would fondly kiss, and paw his Companions, and sneer in their faces . . . and after Eleven Days return'd to themselves again, not remembering any thing that had pass'd.

In the world of crime, scopolamine has been "truth serum," "date-rape drug," and "knockout drops" for great detective novels. In the real world, it has produced temporary psychosis so that victims could be robbed. Analgesia for broken bones and cure for the common cold are only a few of the historical uses of anticholinergic drugs. These drugs continue to contribute to modern medicine.

Today, many classes of prescription and over-the-counter medications have anticholinergic properties. Anticholinergic effects are the desired therapeutic actions for some medications but may occur as unintended or exaggerated adverse drug effects for others. In addition to medications, a number of plants and mush-

rooms contain anticholinergic alkaloids. Some may be ingested deliberately for their mind-altering effects. Others may be added to illicit drugs to enhance the drug experience but produce inadvertent effects. For instance, scopolamine-tainted heroin^{2,3} and atropine-adulterated cocaine⁴ has led to hospitalizations for anticholinergic poisoning. Anticholinergic toxicity has also been associated with the use of herbal supplements.⁵ Antihistamines are a diverse group of medications, most with potent anticholinergic effects and numerous other pharmacologic activities.

The clinical syndrome of anticholinergic poisoning is one of the most common and readily recognized toxidromes. The ability to identify the signs and symptoms of this syndrome and differentiate it from other drug intoxications and medical illnesses is a basic skill that is necessary for all health care practitioners that care for poisoned patients.

CLASSIFICATION AND STRUCTURE**Anticholinergics**

Anticholinergic (antimuscarinic) agents may be classified by their source (natural, semisynthetic, or synthetic) or structure (tertiary amine or quaternary ammonium compounds). The naturally occurring agents, atropine (*d,l*-hyoscyamine) and scopolamine (*l*-hyoscyne), are tropane alkaloids of the belladonna (family Solanaceae) plants.⁶ Specifically, atropine and scopolamine are esters of tropic acid (aromatic acid) and tropine and scopine (organic bases), respectively (Fig. 39-1). Semisynthetic derivatives are created by the addition of a different organic base to tropic acid or a methyl group to the base's nitrogen. Synthetic derivatives have a wide variety of structures but maintain the ester bond in close proximity to a nitrogen to preserve anticholinergic activity. In general, anticholinergic activity requires the presence of a tertiary or quaternary amino group linked by two or three carbons to an ester, ether, or nitrogen and one or more aromatic rings (see Fig. 39-1). Embedded in each anticholinergic compound is a portion that resembles the structure of acetylcholine, which allows for competitive binding at muscarinic receptors. The most potent antimuscarinic agents have an ester and -OH group in close proximity to the amino group.

Antimuscarinic compounds contain a tertiary amine or quaternary ammonium structure. The tertiary amines are readily absorbed from the gastrointestinal (GI) tract and freely cross the blood-brain barrier (BBB). Quaternary ammonium compounds, however, have a charge on their nitrogen and are, thus, not well absorbed from the GI tract and penetrate the BBB poorly. Quaternary deriv-

FIGURE 39-1 Structures of some anticholinergic agents.

atives, however, have more potency at both muscarinic and nicotinic receptors. The charge, like that of acetylcholine, enables greater attraction to the anionic active site of target receptors.

Antihistamines

H₁-receptor antagonists are typically divided into six structural classes. They include ethanolamines (diphenhydramine), ethylenediamines (pyrilamine), alkylamines (chlorpheniramine), piperazines (hydroxyzine), phenothiazines (promethazine), and piperidines (loratadine, acrivastine, cetirizine, and fexofenadine). Although potent antihistamines, doxepin (a dibenzoxepine) and other tricyclic antidepressants (TCAs) are classified by their other drug effects and considered separately (see Chapter 27). Except for the novel class of piperidines, all first-generation agents readily cross the BBB and are often referred to as *sedating antihistamines*.

First-generation H₁-receptor antagonists have a tertiary amino group connected by two or three carbons to a nitrogen or ether link and then two to three aromatic rings (Fig. 39-2).⁷ Like histamine, antihistamines have a β-aminoethyl side chain. Unlike histamine, antihistamines have substitutions on their amino group and more than a single aromatic ring. As shown in Figures 39-1 and 39-2, sedating antihistamines possess the structural characteristics necessary to bind and competitively antagonize muscarinic receptors (tertiary amine linked by an ethyl group to an aromatic ring). This large overlap of structure accounts for a large overlap in pharmacologic and toxic effects and is why these agents are considered together.

Agents That Produce the Anticholinergic Syndrome

Both pharmaceutical agents and plants may cause significant anticholinergic toxicity (Box 39-1). For many medications, such as the GI antispasmodics or the local

mydriatics, the anticholinergic properties produce the desired therapeutic effect for the drug. Hence, many of the primary pharmacologic effects are not considered toxic. The desired therapeutic effects of other medications (e.g., antipsychotics and antiparkinsonian drugs), however, are not the anticholinergic manifestations. Thus, mydriasis, constipation, tachycardia, and dry mouth are frequently considered adverse effects. The more potent the anticholinergic binding relative to other drug effects, the more likely the antimuscarinic side effects will occur with therapeutic drug dosing.

Combining medications with anticholinergic properties produces synergistic effects.⁸⁻¹⁰ For example, when antiparkinsonian medications are administered in combination with phenothiazines to prevent the occurrence of undesirable extrapyramidal reactions, this greatly increases the incidence of toxic confusional states.¹¹ Small changes in the dose of either drug may precipitate the central anticholinergic syndrome in a previously unaffected individual.¹² Many over-the-counter medications have anticholinergic properties and can precipitate the anticholinergic syndrome when ingested by an unknowing layperson who is already prescribed an agent with antimuscarinic activity. For example, the combined use of oral diphenhydramine with topical application of Caladryl lotion (calamine lotion and diphenhydramine [Parke-Davis, Morris Plains, NJ]) has produced central anticholinergic toxicity in children.¹³⁻¹⁵

An unusual form of toxicity involves the use of transdermal scopolamine patches.¹⁶ Several cases of the central anticholinergic syndrome have been reported in adults and children using the patches for treatment of motion sickness. Accidental instillation of the drug into the eyes has occurred after manipulation of the patch. This has resulted in a unilateral fixed dilated pupil or bilateral fixed dilated pupils without focal neurologic changes.^{17,18} This finding is also known as the “cornpicker’s pupil” and has been described in cornfield workers who have unintentionally rubbed pulverized jimsonweed in their eyes during harvesting.¹⁹ An additional

FIGURE 39-2 Structures of some H₁-histamine antagonists.

BOX 39-1 EXAMPLES OF AGENTS WITH ANTICHOLINERGIC PROPERTIES

Plants and Mushrooms

Atropa belladonna (Deadly nightshade)
Datura stramonium (Jimsonweed)
Mandragora officinarum (Mandrake)
Hyoscyamine niger (Henbane)
Amanita muscaria (Fly agaric)
Amanita pantherina (Panther)

Belladonna Alkaloids and Related Synthetic Compounds

Atropine
 Scopolamine
 Glycopyrrolate (Robinul)

Antispasmodics

Clidinium bromide (Librax)
 Dicyclomine (Bentyl)
 Propantheline bromide (Pro-Banthine)
 Methantheline bromide (Banthine)
 Flavoxate (Urispas)
 Oxybutynin (Ditropan)

Antiparkinsonism Medications

Benztropine mesylate (Cogentin)
 Biperiden (Akineton)
 Trihexyphenidyl (Artane)

Local Mydriatics

Cyclopentolate (Cyclogyl)
 Homatropine (Isopto Homatropine)
 Tropicamide (Mydracil)

Muscle Relaxants

Cyclobenzaprine (Flexeril)
 Orphenadrine (Norflex)

Antihistamines

Brompheniramine (Dimetane)
 Chlorpheniramine (Ornade, Chlor-Trimeton)
 Cyclizine (Marezine)
 Dimenhydrinate (Dramamine)
 Diphenhydramine (Benadryl, Caladryl)
 Hydroxyzine (Atarax)
 Meclizine (Antivert)

Antipsychotics

Chlorpromazine (Thorazine)
 Clozapine (Clozaril)
 Loxapine (Loxitane)
 Mesoridazine (Serentil)
 Olanzapine (Zyprexa)
 Thioridazine (Mallaril)

Over-the-Counter Sleep Aids

Diphenhydramine (Benadryl)
 Doxylamine (Unisom)

Cyclic Antidepressants

Amitriptyline (Elavil)
 Clomipramine (Anafranil)
 Doxepin (Sinequan)
 Imipramine (Tofranil)

Others

Amantadine (Symmetrel)
 Carbamazepine (Tegretol)
 Cyproheptadine (Periactin)
 Ipratropium (Atrovent)

method of systemic anticholinergic toxicity involves the absorption of ophthalmologic agents or nasal decongestants through the conjunctiva, nasal mucosa, or GI tract.^{20,21}

Scopolamine eyedrops have allegedly been used deliberately to disorient subsequent victims of theft.²² The victim is often found naked, disoriented, hallucinating, and amnesic to the events before hospital-

ization. Scopolamine was believed to have been placed in a beverage ingested by the victim.²³ Many toxicologic laboratories do not routinely screen for scopolamine; therefore, these patients had negative results on toxicologic screens.

Both anticholinergic pharmaceuticals and plants may be abused. Central anticholinergic effects of intentional ingestion may produce euphoria and hallucinogenic effects.²⁴ It has been proposed that a physiologic dependence and the development of withdrawal symptoms exist when the agent is withheld.²⁴ Among the most frequently reported anticholinergic drugs abused are the antiparkinsonian agents trihexyphenidyl and benztropine mesylate.²⁵ These drugs have potent dopamine reuptake inhibition. The resulting dopamine excess is a proposed mechanism for craving of many abused drugs.^{25,26} Drug seekers may feign extrapyramidal symptoms to receive additional anticholinergic agents.^{24,27-30}

Many types of plants contain alkaloids that produce anticholinergic stigmata in humans. Most of these are found in the family Solanaceae, which include the genera *Atropa*, *Datura*, *Hyoscyamus*, *Lycium*, and *Solanum*. The principal alkaloids found in these plants include solanine, atropine (a racemic mixture of *d*- and *l*-hyoscyamine, of which only the levorotatory isomer is pharmacologically active), and scopolamine (*l*-hyoscine). The mushrooms *Amanita muscaria* and *Amanita pantherina* have rarely been reported to cause anticholinergic or cholinergic toxicity. Anticholinergic effects can be severe but are rarely the prominent finding with poisoning by these mushrooms (see Chapter 23).³¹ The alkaloid content of each species and each plant varies greatly and depends on many parameters such as the time of year, the available moisture, and the temperature. For this reason, it is very difficult to determine predicted toxicity in relation to the amount and the origin of the plant material. Recreational abusers of anticholinergic mushrooms and *D. stramonium* (jimsonweed) are unable to titrate the dose of ingested substance because of this tremendous biologic variability and, therefore, are prone to severe anticholinergic poisoning.

PHARMACOLOGY

Anticholinergics

Acetylcholine is an endogenous neurotransmitter found in various synaptic sites and neuroeffector junctions (e.g., secretory glands and smooth and cardiac muscle) in the central and peripheral nervous systems.⁶ The actions of acetylcholine are mediated by muscarinic and nicotinic cholinergic receptors. Muscarinic receptor sites are in the brain (e.g., cerebral cortex, thalamus, hippocampus, reticular activating system), postganglionic parasympathetic nervous system, and select postganglionic sympathetic nervous system sites (e.g., sweat glands). Nicotinic receptors are located at the skeletal muscle motor end plate and spinal cord and autonomic ganglia.³² There are five subtypes of muscarinic receptors (M_{1-5}) and all are transmembrane proteins that interact

with G proteins.³² Acetylcholine binds to and activates muscarinic receptors, and the result is stimulation or inhibition of cellular function. Nicotinic receptors are ligand-gated cation channels in autonomic ganglia and postsynaptic membranes. Their activation results in increased permeability to sodium and calcium ions, depolarization, and excitation. Nicotinic receptor activation is responsible for enhanced autonomic neurotransmission and skeletal muscle contraction. Acetylcholine is inactivated when metabolized at the synaptic cleft by the enzyme acetylcholinesterase.

Anticholinergic drugs block acetylcholine's action by competitively binding to and blocking muscarinic receptors. Receptor blockade and clinical effects are dose dependent. Clinical effects, however, are nonuniform since there is variable sensitivity of the neuroeffector organ sites to blockade by muscarinic receptor antagonists.⁶ Differential sensitivity is largely from the variable parasympathetic tone of each organ system but is also influenced by the effects of other neuronal inputs and the ability of the drug to reach the end organ. In general, small doses of anticholinergic drugs decrease secretions of the sweat, bronchial, and salivary glands. Larger doses produce mydriasis, cycloplegia, and increased heart rate from blockade of the sphincter muscle of the iris, ciliary muscle of the lens, and vagus nerve innervation to the heart, respectively. Even larger doses cause urinary retention and ileus from depressed bladder tone and GI motility, respectively. These classic peripheral anticholinergic effects are caused by blocking postganglionic cholinergic nerves and predominate in most cases of acute poisoning.³³ Cholinergic neurons are spread widely through the cerebral cortex and subcortical areas.³² Because of this ubiquitous distribution, they likely have a role in regulation and modulation of other neurotransmitters.³⁴ Central cholinergic pathways are important to memory, wake-sleep cycle, alertness, and orientation and for fine-tuning motor movements. *Central anticholinergic syndrome* refers to an acute psychosis or delirium resulting from inhibition of central cholinergic transmission. The degree of central anticholinergic activity is related to a medication's ability to cross the BBB.

Muscarinic antagonists are highly selective for muscarinic over nicotinic sites. Thus, the nicotinic receptors at autonomic ganglia and the motor end plates are unaffected by drugs that block muscarinic receptors.

Antihistamines

Histamine is a mediator of the allergic response, a regulator of gastric acid secretion, and a central nervous system (CNS) neurotransmitter.³⁵ Four distinct receptors have been identified (H_1 , H_2 , H_3 , H_4). Stimulation of H_1 receptors constricts bronchioles, dilates peripheral vasculature, increases vascular permeability, and triggers proinflammatory effects through B cells, T cells, monocytes, and lymphocytes.³⁶ H_1 receptors have also been detected in the brain, GI tract, and genitourinary tract. H_2 receptors are primarily regulators of gastric acid secretion but are also present in the brain, lymphoid

cells, and uterus. In the CNS, histamine (H_1 and H_2) modulates activities such as arousal, thermoregulation, and neuroendocrine and vegetative functions that are controlled by the neocortex, hypothalamus, and hippocampus.³⁵ H_3 receptors are expressed in the brain and the bronchial smooth muscle and are presynaptic regulators of synthesis and release of histamine into the synapse. The recently characterized H_4 receptor is expressed on mononuclear cells, neutrophils, eosinophils, mast cells, and resting cluster of differentiation CD_4 T lymphocytes.

The antihistamines are reversible competitive inhibitors of H_1 -histamine receptors.³⁵ Except for the newer, second-generation piperidines, all first-generation agents readily cross the BBB and produce both CNS excitation and depression. All H_1 antagonists inhibit both the early vasodilatory effects and later vasoconstrictive effects of histamine. In addition, these agents block histamine-mediated increases in capillary permeability, pruritus, and salivary, lacrimal, and other exocrine secretions. First-generation antihistamines (but not second-generation agents) are also competitive antagonists at both central and peripheral muscarinic receptors and produce clinical effects that are often clinically indistinguishable from those of other anticholinergic drugs. Therapeutic antimuscarinic effects are likely responsible for the prevention of motion

sickness with these agents. In addition, antihistamines alter cortical neurons and block fast-sodium channels. These effects cause CNS symptoms, local anesthetic effects, and cardiac conduction abnormalities.^{37,38} Diphenhydramine and orphenadrine have been associated with QRS prolongation following overdose.³⁸ Promethazine and other phenothiazines have α_1 -adrenergic blocking effects, which may result in hypotension. The piperidines block the outward potassium rectifier current of cardiac cells, and may result in QTc prolongation and torsades de pointes-type cardiac dysrhythmias. Some H_1 antagonists affect serotonin receptors. Specifically, cyproheptadine is a competitive antagonist at 5-HT₁- and 5-HT₂-serotonin receptors.³⁹

PHARMACOKINETICS

Relevant pharmacokinetic parameters for the anticholinergic and antihistaminergic agents are listed in Table 39-1. Clinical toxicity is usually evident within 1 to 4 hours after ingestion of these agents, but the severity and duration of toxic effects are highly variable. The pharmacokinetic parameters of these agents may change significantly after overdose. Anticholinergic agents decrease gut motility and may produce delayed, erratic, and prolonged absorption with excessive doses.

TABLE 39-1 Pharmacokinetic Parameters of Common Anticholinergic and Antihistaminergic Compounds*

GENERIC NAME (TRADE NAME)	ROUTES OF ADMINISTRATION AND THERAPEUTIC DOSING FOR ADULTS	TIME TO PEAK AFTER ORAL DOSING (hr)	ELIMINATION HALF-LIFE (hr)	PROTEIN BINDING (%)	Vd (L/kg)	ROUTE OF METABOLISM	ACTIVE METABOLITE

Pharmacokinetic data obtained from references 94 and 95.

SPECIAL POPULATIONS: PREGNANCY AND LACTATION

Most anticholinergic and antihistaminergic drugs are categorized as Class B or C by the U.S. Food and Drug Administration. Although largely unknown, most agents are likely secreted into breast milk as suggested by their large volumes of distribution.

DIPHENHYDRAMINE

There is one case-control study in which there was a slight statistical association between cleft palate and diphenhydramine exposure in the first trimester. Other than this single study, the vast majority of animal and human data support the safe usage of diphenhydramine in pregnancy. Diphenhydramine is excreted into human breast milk, and the manufacturer concludes that the drug is contraindicated in nursing mothers.⁴⁰

CIMETIDINE

Although the use of cimetidine in pregnancy has not been associated with congenital malformations, multiple animal studies and one human study of nonpregnant patients suggest an antiandrogen effect in the form of decreased prostate, seminal vesicle, and testes size and decreased human libido. Cimetidine is excreted into breast milk, but the effect on the infant is unknown.⁴⁰

ATROPINE

Atropine readily crosses the placenta. No fetal or neonatal adverse effects were noted in two human studies in which atropine was used to reduce gastric secretions before cesarean section. The largest study of fetal exposure to atropine demonstrated no associated congenital anomalies. Another smaller study, however, demonstrated a possible association of atropine exposure to neonatal limb reduction, but other factors could have contributed as well.⁴⁰

TOXICOLOGY

Clinical Manifestations

Although anticholinergic agents often have activity at sites other than muscarinic receptors, the major clinical toxicity from these agents is the anticholinergic syndrome. Manifestations are divided into peripheral and central antimuscarinic effects (Box 39-2). Peripheral manifestations include (1) thirst, dry mucous membranes and hot, dry skin from inhibition of secretions from salivary glands, bronchioles, and sweat glands; (2) skin flushing from dilation of cutaneous blood vessels, especially those of the face; (3) hyperpyrexia from the inability to sweat and neuromuscular hyper-reactivity; (4) mydriasis, poor pupillary light response, and blurred vision from pupillary sphincter and ciliary muscle paralysis; (5) tachycardia from vagolytic effects; (6) urinary retention from inhibition of ureter and bladder contraction; and (7) decreased bowel sounds from inhibition of gastric emptying and GI motility. Sinus

BOX 39-2

SYMPTOMS/SIGNS OF ANTICHOLINERGIC TOXICITY

Peripheral (Muscarinic Blockade)

- Tachycardia
- Dry, flushed skin
- Dry mucous membranes
- Dilated pupils
- Hyperpyrexia
- Urinary retention
- Decreased bowel sounds
- Hypertension
- Hypotension (late finding)

Central Anticholinergic Syndrome

- Confusion
- Disorientation
- Loss of short-term memory
- Ataxia
- Psychomotor agitation
- Picking and grasping movements
- Extrapyramidal reactions
- Visual/auditory hallucinations
- Frank psychosis
- Coma
- Seizures
- Respiratory failure
- Cardiovascular collapse

tachycardia is one of the earliest and most reliable signs of muscarinic receptor blockade.⁴¹ Thus, the absence of tachycardia early after anticholinergic poisoning suggests inaccurate history or co-ingestion of a cardiotoxic agent. The urinary bladder may be palpable from bladder atony, and impaired bowel motility may produce an ileus and delayed and prolonged drug absorption. This latter effect may result in prolonged symptoms secondary to protracted drug absorption.

Anticholinergic delirium, or the central anticholinergic syndrome, is characterized by patient hyperactivity; tremulousness; disorientation; short-term memory impairment; agitation; delirium; visual and auditory hallucinosis; slurred, nonsensical, or incoherent speech; meaningless motor activity such as repetitive picking at bed clothes or grabbing at nonexistent objects; removal of clothing; seizures; and coma.^{8-10,42-44}

In overdose, both central and peripheral anticholinergic signs are commonly present. Indeed, the famous mnemonic, “Mad as a hatter, red as a beet, dry as a bone, blind as a bat, and hot as a hare” describes the syndrome well. The central anticholinergic syndrome may occasionally occur without evidence of peripheral signs.⁴⁵⁻⁴⁸ Although one study reported that “isolated” central anticholinergic signs and symptoms were present in 17% of their patients with the anticholinergic syndrome, dry skin was preserved in those with central sign predominance.⁴⁹ Thus, “isolated” central anticholinergic syndrome will likely have at least some peripheral signs of poisoning present and should be more appropriately termed *central predominance* anticholinergic syndrome.

Central predominance anticholinergic syndrome seems more likely to occur in the very young and old, those with underlying organic brain syndrome, those with exaggerated antimuscarinic responses to therapeutic doses, and late following an acute overdose (when peripheral effects have decreased in intensity).¹⁰

Anticholinergic agents may produce seizures following both therapeutic and excessive doses. Seizures are more commonly dose related and, thus, occur more frequently in overdose. Anticholinergic-induced seizures are usually short lived and require no specific therapy. However, large overdoses of diphenhydramine, pyrilamine, hydroxyzine, orphenadrine, cyclic antidepressants, and carbamazepine have caused prolonged or repeated seizures.

The mechanism of anticholinergic-induced seizures remains unclear. The majority of seizures related to anticholinergic toxicity seem to be associated with medications having other toxic manifestations rather than purely anticholinergic drugs. Seizures have been reported with antihistamine, cyclic antidepressant, phenothiazine, and carbamazepine poisonings but are infrequently reported in jimsonweed abusers and atropine-poisoned infants. Interestingly, researchers have suggested that histamine may have a role as a natural anticonvulsant. Positron emission tomography has demonstrated possible H₁ receptors' coalescence around epileptogenic foci in brain, and this may inhibit generalization of epileptic discharges in the brain.⁵⁰ Histamine and its precursor, histidine, seem to act as anticonvulsants in the mammalian brain by their actions on presynaptic H₃ receptors and postsynaptic H₁ receptors.⁵¹⁻⁵⁴ H₁ antagonists have been shown to decrease the seizure threshold in rats and mice by heat and electrical stimuli to the brain, respectively.^{52,53} Similarly, antihistamines increase electroencephalographic abnormalities and are suspected of producing seizures in epileptic patients. Retrospective data have suggested that phenothiazines, a class of antihistamine, decrease the seizure threshold.^{55,56} Doxepin and other cyclic antidepressants are potent histamine blockers that frequently cause seizures when taken in serious overdoses. In addition, seizure activity from some medications with anticholinergic activity is due to interactions at γ -aminobutyric acid (GABA) receptors (cyclic antidepressants) or adenosine receptors (carbamazepine).

Sinus tachycardia is the most common arrhythmia in anticholinergic poisoning and occurs by blocking vagal effects on M₂-muscarinic receptors on the sinoatrial node pacemaker.⁶ Sinus tachycardia is most prevalent in young, healthy adults who normally have high resting vagal tone.⁶ Tachycardia may not be as evident in the very young and old. Some anticholinergic agents cause life-threatening cardiac arrhythmias by mechanisms other than muscarinic blockade. Medications with anticholinergic effects and the potential to cause quinidine-like conduction abnormalities include cyclic antidepressants, phenothiazines, diphenhydramine, chlorpheniramine, orphenadrine, pyrilamine, and class IA antiarrhythmics.³⁸ These drugs have sodium channel-blocking properties that not only slow conduction but also

decrease myocardial contractility. Phenothiazines also block rectifying potassium channels and may prolong the QT interval and cause torsades de pointes or other ventricular dysrhythmias.

Rhabdomyolysis is an occasional complication of anticholinergic poisoning, particularly for patients that have psychomotor agitation.⁵⁷ Drug-induced rhabdomyolysis from anticholinergic poisoning is due to excess energy use or inadequate oxygen and nutrient delivery to the muscle, which causes myocyte breakdown. Patients at greatest risk are those who have repetitive or prolonged seizures, coma, compartment syndrome, hyperthermia, or severe agitation requiring restraint.

Death from anticholinergic or antihistamine poisoning is most often from cardiac arrhythmia and is frequently associated with seizures. Death is not likely to occur from antimuscarinic receptor antagonism but rather the sodium and potassium channel-blocking effects of these drugs.⁵⁸

Diagnosis

The diagnosis of anticholinergic or sedating antihistamine poisoning is based on a positive history of ingestion and physical findings consistent with the anticholinergic syndrome. When a history of ingestion is not available from the patient due to delirium or obtundation, patient belongings and the exposure environment should be searched for clues to diagnosis. Any knowledge of a patient's past medical history, particularly a list of medications, may greatly assist diagnosis. Any history obtainable from friends or relatives about abuse of drugs or hallucinogenic plants (particularly jimsonweed and mushrooms) may be of value. A history of recent travel and the use of scopolamine patches should be sought.

In a mixed ingestion, the physical findings may be variable and make the diagnosis more challenging. Electrocardiographic (ECG), laboratory, and other adjunctive tests are not often helpful to confirm or refute the diagnosis of anticholinergic poisoning. An ECG often demonstrates sinus tachycardia alone. The presence of repolarization abnormalities (e.g., nonspecific ST-T changes, QT prolongation) is consistent with certain agents (e.g., diphenhydramine). As with many poisonings, a toxicology screen has limited value. Agents that produce anticholinergic toxicity are not often part of a routine immunoassay screen.²³ Comprehensive qualitative screening techniques (e.g., gas chromatography/mass spectrometry) and quantitative assays are not readily available and do not routinely guide treatment. These tests may be useful for confirmation of the presence of a drug after treatment has been initiated. Toxicology screens are more useful to identify other causes of altered mental status or to identify unsuspected co-ingestions (e.g., acetaminophen).

As stated, the diagnosis and treatment of the anticholinergic syndrome is guided by the clinical examination. This cause of delirium can be missed if the physician fails to recognize associated peripheral signs or inappropriately dismisses the diagnosis because common

peripheral anticholinergic signs (e.g., sinus tachycardia and mydriasis) are absent. Anticholinergic delirium has been misdiagnosed as dementia or psychotic depression in elderly patients and varicella encephalitis in children.^{45,47}

DIFFERENTIAL DIAGNOSIS OF ANTICHOLINERGIC POISONING

The constellation of symptoms that identify the anticholinergic syndrome can be mimicked, in part, by many other toxins and medical conditions (Box 39-3). Distinguishing it from adrenergic excess (sympathomimetic poisoning, thyrotoxicosis, or pheochromocytoma) can be difficult. The pupillary, cardiovascular, and CNS effects of sympathomimetic poisons are similar to those produced by anticholinergic poisoning. Sweating frequently accompanies adrenergic stimulation, whereas dry skin and mucous membranes are characteristic of anticholinergic poisoning. Paranoid hallucinations and violent behavior often accompany adrenergic-induced

hallucinations, whereas anticholinergic poisoning causes mumbling speech, picking at sheets, and disorientation. Urinary retention may also be helpful in distinguishing anticholinergic from sympathomimetic poisoning. The anticholinergic syndrome has similarities to the autonomic dysfunction and altered mental status that occurs with ethanol or sedative-hypnotic withdrawal, serotonin syndrome, neuroleptic malignant syndrome, or a disulfiram reaction. The absence of sweat with the anticholinergic syndrome is a key differentiating feature from these other drug-associated syndromes. Chronic salicylate poisoning can appear similar to anticholinergic poisoning because patients often present with altered mental status, tachycardia, and fever. Medical conditions can also mimic the anticholinergic syndrome. Hypoxia or hypoglycemia causes delirium, agitation, or CNS depression. Dry, hot skin and altered sensorium due to heat stroke, dehydration, or sepsis can be mistaken for anticholinergic toxicity. Central anticholinergic effects in the absence of peripheral signs can be similar to those caused by some hallucinogenic substances, steroid-induced psychosis, vascular or infectious CNS disease, sepsis, or psychiatric illnesses.

BOX 39-3 TOXINS AND MEDICAL CONDITIONS EASILY CONFUSED WITH THE ANTICHOLINERGIC SYNDROME

Toxins

Adrenergic poisons

- Amphetamines
- Caffeine
- Cocaine
- Methylphenidate
- Pseudoephedrine
- Theophylline

Autonomic dysfunction

- Disulfiram reactions
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Withdrawal from ethanol or benzodiazepines

Central hallucinogen poisoning

- Lysergic acid diethylamide
- Mescaline
- Phencyclidine
- Psilocybin mushrooms

Lithium poisoning

- Salicylate poisoning
- Steroid-induced psychosis

Medical Conditions

Adrenergic excess

- Pheochromocytoma
- Thyrotoxicosis

Central nervous system infection

- Cerebral vasculitis

Dehydration

- Heat stroke

Hypoglycemia

- Hypoxia

Psychiatric illnesses

- Sepsis

TREATMENT OF ANTICHOLINERGIC TOXICITY

General Management

The majority of patients poisoned by anticholinergic agents are adequately treated with supportive care and observation.

Anticholinergics inhibit GI motility and can cause prolonged, erratic, or delayed drug absorption. After a large overdose of benztropine, a patient demonstrated erratic absorption and repeated worsening of anticholinergic symptoms over 9 days.⁵⁹ Because of slowed GI absorption, gastric emptying procedures may be useful even when patients present many hours after toxicant ingestion. Administration of charcoal is effective for preventing further drug absorption. Repeated doses of activated charcoal may play a role in preventing continued absorption, although the development of ileus limits its use. There is no role for enhanced elimination techniques (e.g., hemodialysis or hemoperfusion) with anticholinergic agents and antihistamines due to their large volumes of distribution and high protein binding (see Table 39-1).

A search for and removal of a transdermal patch should be initiated in all patients with altered mental status that could be attributed to the anticholinergic syndrome.

Treatment of Agitation

Anticholinergic-induced delirium ranges from mild confusion to severe agitation and possibly violence. Controlling agitation is necessary for adequate patient assessment and to prevent rhabdomyolysis, hyperthermia, and physical injury. Physical and chemical re-

straints are indicated for the treatment of severe agitation. Benzodiazepines may be tried initially to control patient agitation, but they are often ineffective when anticholinergic-associated agitation is severe.⁶⁰ Adjuvantive therapy with haloperidol or other neuroleptics is not recommended to control agitation since these agents can impair thermoregulation. Provided no contraindications for its use exist (see Antidote Therapy), physostigmine has been shown to be both safe and effective for the treatment of agitated delirium in the setting of known or suspected anticholinergic syndrome.⁴⁹ As compared with benzodiazepine therapy, physostigmine treats patient delirium better, controls patient agitation more effectively, may decrease the need for mechanical ventilation, and shortens the course of neurologic morbidity.⁴⁹ When the diagnosis is initially suspected but uncertain, physostigmine may obviate the need for further testing (e.g., head computed tomography and lumbar puncture) upon resolution of delirium.⁴⁹

Treatment of Seizures

Although the mechanism of seizures is not well understood for this class of agents, drug-associated seizures are generally best treated with benzodiazepines (e.g., diazepam or lorazepam) followed by barbiturates (e.g., phenobarbital) when necessary. Data from case reports suggest that physostigmine may be effective for seizure termination, but clinical experience is limited and efficacy not well established.^{61,62} The administration of physostigmine for seizures from this class of agents is not recommended, particularly since seizures are a known major adverse effect from physostigmine.

Treatment of Rhabdomyolysis

Agitation and excessive neuronal stimulation increase the risk of rhabdomyolysis. Controlling agitation and seizures is important to prevent rhabdomyolysis. Serial measurements of creatine phosphokinase in blood and determination of occult blood positivity in the urine will help identify those at risk for developing acute renal failure from rhabdomyolysis. Ensuring adequate urine output with intravenous (IV) fluids is the mainstay of treatment for preventing acute tubular necrosis.⁵⁷ The efficacy of mannitol and urine alkalization has not been established for the routine treatment of rhabdomyolysis.⁶³

Treatment of Cardiovascular Toxicity

Sinus tachycardia is the most common toxic cardiovascular effect from anticholinergic poisoning but rarely requires intervention. A large number of drugs with anticholinergic effects cause QRS prolongation and dysrhythmias by blocking fast-sodium channels (type 1a activity).⁶⁴⁻⁶⁶ IV sodium bicarbonate improves impaired conduction from fast-sodium channel blockers such as cyclic antidepressants, diphenhydramine, and orphenadrine.^{38,67} Rarely, myocardial pump failure occurs with large overdoses. Case reports have demonstrated that

refractory shock can occur despite aggressive medical intervention. Patients with such profound cardiovascular toxicity have been successfully resuscitated after cardiac bypass or intra-aortic balloon pump procedures.⁶⁸

Antidote Therapy

Although its use is controversial, physostigmine is a well-recognized antidote that can be used to treat the anticholinergic syndrome. Physostigmine, a naturally occurring alkaloid obtained from the West African vine *Physostigma venosum*, is a reversible, carbamate cholinesterase inhibitor.⁶ After a single dose of physostigmine, the action of acetylcholine is potentiated at postganglionic parasympathetic and central cholinergic neuroreceptors, and the competitive blockade by anticholinergic agents is reversed by mass action. As a tertiary amine, physostigmine readily crosses the BBB and is capable of reversing central anticholinergic effects (e.g., agitation, hallucinations, delirium, and coma).⁶⁹⁻⁷³ Peripherally, physostigmine may reverse the tachycardia, mydriasis, ileus, and urinary retention that occur secondary to muscarinic blockade.

Physostigmine is a nonspecific analeptic. Its administration results in cholinergic modulation of other CNS neurotransmitter pathways by poorly understood mechanisms. The sedating effects of drugs without anticholinergic activity have responded to physostigmine administration through nonspecific arousal.⁷³ Because of this, physostigmine was employed as part of a “coma cocktail” in the 1970s and often administered to patients with undifferentiated drug-induced coma. When used for this indication, physostigmine was neither consistently effective nor safe. Physostigmine resulted in an unacceptable high incidence of side effects (e.g., seizures, cholinergic crisis, bradyarrhythmias, and asystole), particularly when used for TCA poisoning.⁶⁰

In one clinical series, 2 of 21 patients who received physostigmine had seizures after its administration, and 2 developed cholinergic symptoms (hypersalivation in 1 patient, bradycardia and hypotension in the other). The author of this series concluded that physostigmine has “little part to play in routine management” because patients with anticholinergic symptoms usually fare well with supportive therapy alone.⁷⁴ In another clinical series of 26 patients (of which 17 had ingested a TCA), seizures occurred in 3 (12%) patients and bradycardia in 1 patient given physostigmine.⁷⁵ In a recent retrospective chart review of 39 adults who were administered physostigmine for the anticholinergic syndrome, 1 (2.6%) developed a brief seizure. However, this individual had presented after a 1- to 2-minute seizure, so it is impossible to say that physostigmine caused the seizure.⁷⁶ In a retrospective study that compared treatment of physostigmine with benzodiazepines in a group of 52 patients with anticholinergic delirium, physostigmine was more effective for the control of agitation and reversing delirium.⁴⁹ One case report described a patient poisoned by *D. stramonium* (jimsonweed), who developed atrial fibrillation and a short run of ventricular tachycardia 45 minutes after administration of physostigmine.⁷⁷ In an

additional case report, an 85-year-old man developed ventricular ectopy 30 minutes after receiving 1 mg of physostigmine.⁷⁸

AU: Unclear what you mean by 'dangerous for use'. Do you mean for any use?

Physostigmine is no longer indicated in the treatment of cyclic antidepressant poisoning, and evidence strongly suggests that it is dangerous for use.^{74,75,79,80} A series of 41 patients taking intentional overdoses of maprotiline showed that 6 of 7 patients treated with physostigmine developed seizures.⁷⁴ The investigators concluded that the use of physostigmine should be abandoned in overdoses of maprotiline and other cyclic antidepressants. The danger of physostigmine administration is further illustrated in another cases series of two patients with acute severe TCA poisoning. The administration of physostigmine was temporally associated with the occurrence of bradycardia.⁸⁰ The potential risks associated with physostigmine are greater than the benefits gained from its use in cyclic antidepressant toxicity.

There is a long history of clinical use of physostigmine as an antidote. It is apparent that when used inappropriately (e.g., nondifferentiated drug-induced coma, known or suspected TCA poisoning, rapid IV administration), it is associated with an unacceptably high incidence of side effects. Conversely, when used appropriately, it is both safe and effective and the preferred treatment for the anticholinergic syndrome. The use of physostigmine is indicated for the treatment of patient agitation and delirium in known or suspected anticholinergic syndrome, particularly when patients are dangerous to themselves or others. Although efficacy is not well-established, physostigmine may also be appropriate for narrow complex supraventricular arrhythmias in the setting of the anticholinergic syndrome that result in hemodynamic instability (hypotension, myocardial ischemia, or congestive heart failure) when other attempts to control heart rate have failed or are believed to be too risky in a particular patient. Neostigmine, a quaternary cholinesterase inhibitor that does not cross the BBB, may play a selective role for severe ileus or intestinal pseudo-obstruction associated with anticholinergic drugs.⁸¹ Absolute contraindications for the use of physostigmine include any evidence of cardiac conduction disturbances on ECG (e.g., prolonged PR or QRS intervals) or known or suspected acute cyclic antidepressant poisoning. Although physostigmine has been previously recommended for the treatment of ventricular tachyarrhythmias and seizures associated with the anticholinergic syndrome, these should be considered relative, if not absolute, contraindications for use of this antidote. Conversely, although contraindications for the use of physostigmine have historically included the presence of patient asthma, ischemic heart disease, peripheral vascular disease, and mechanical obstruction of the GI or urogenital tract, these contraindications are theoretical, unsubstantiated, and no longer considered true.^{6,82}

The suggested doses of physostigmine are as follows:
For children: a dose of 0.02 mg/kg slowly IV over 3 to 5 minutes.

For adults: 1 to 2 mg slowly IV; may be repeated every 10 minutes until cessation of the life-threatening

condition. Schneck has recommended an IV infusion of 2 mg in 100 mL of normal saline infused over 10 minutes to avoid adverse effects from too rapid administration.³⁴

In one study of adults, the mean initial dose necessary to treat agitated delirium associated with the anticholinergic syndrome was 2.2 mg (range, 0.5 to 6 mg) with a mean initial response time of approximately 11 minutes.⁴⁹ The duration of action is usually 20 to 60 minutes, and recurrence of anticholinergic symptoms may require repeated doses. In this same study, relapse of symptoms occurred in 78% of patients with a mean relapse time of 100 minutes.⁴⁹ Adverse effects are more likely after repeated doses. Cholinergic excess due to physostigmine use is not often life threatening. It has been suggested that atropine should be available and given in half the dose of physostigmine should severe cholinergic toxicity develop.⁷⁰ The use of glycopyrrolate, a pure peripheral anticholinergic agent, has been proposed as an alternative to atropine to treat the cholinergic toxicity of physostigmine.

Whenever physostigmine is used, it should (1) be given very slowly (over 3 to 10 minutes) IV; (2) not be given merely to "wake the patient up"; (3) be used only in a setting where advanced life support is available; (4) be used only when central and peripheral anticholinergic findings are present; (5) be used only in the absence of cardiac conduction abnormalities suggesting sodium channel blockade; and (6) always be preceded and followed by proper supportive care.

SPECIAL CONSIDERATIONS FOR ANTIHISTAMINE AND ANTICHOLINERGIC TOXICITY

Nonsedating Piperidine Antihistamines

Acrivastine, cetirizine, fexofenadine, desloratadine, and loratadine are currently marketed in the United States as nonsedating piperidine antihistamines. In therapeutic doses, their lack of CNS effects is secondary to an inability to cross the BBB.³⁹ Acrivastine, the active metabolite of triprolidine, was given to humans for 1 week at 100 times the recommended dose without cardiovascular effects.⁸³ Cetirizine, the carboxylated metabolite of hydroxyzine, lacked cardiovascular toxicity and sedation in overdose.⁸⁴ Fexofenadine, the metabolite of terfenadine, has a safety profile similar to placebo with no significant drug interactions, cardiotoxicity, or sedation.⁸⁵ In vitro, loratadine significantly inhibited the potassium rectifier current.⁸⁶ Loratadine, when given with nefazodone, resulted in significantly increased QT interval in humans.⁸⁷ Desloratadine, the active metabolite of loratadine, does not seem to effect the potassium rectifier current.^{88,89} This finding was likely from the inhibition of the CYP3A4-mediated metabolism of loratadine, leading to increased concentrations.

From a historical perspective, terfenadine and astemizole were withdrawn from the market in the late 1990s because of the high incidence of ventricular dys-

rhythmias. Terfenadine and astemizole inhibit the delayed potassium rectifier current and thus slow repolarization.⁹⁰ Accumulation of these drugs in the serum as occurred with overdose or impaired metabolism from coadministration of CYP3A4 inhibitors, was manifested clinically as prolongation of the QT interval and torsades de pointes. Agents that inhibit CYP3A4 metabolism of terfenadine include erythromycin, clarithromycin, ketoconazole, fluconazole, itraconazole, and grapefruit juice. Underlying liver disease in the absence of P-450 inhibitors can also cause cardiac toxic effects.

H₂ Receptor Blockers

The H₂ blockers are competitive antagonists at H₂ receptors and block gastric acid secretion. These agents are used to treat peptic acid diseases and include cimetidine, ranitidine, famotidine, and nizatidine. They are highly selective receptor antagonists and do not block H₁ receptors or have antimuscarinic activity. Blocking central H₂ receptors alters neurotransmitter function and causes delirium, confusion, agitation, and seizures. Confusion is more likely to occur in elderly patients and those who have elevated blood concentrations of these agents after acute deterioration of renal and hepatic function.⁹¹ Only cimetidine causes significant inhibition of hepatic microsomal mixed-function oxidases that may impair metabolism of other drugs.

Acute overdose of the specific H₂ receptor antagonists typically causes only minor toxic effects such as drowsiness and mild bradycardia.⁹² More serious effects such as hypotension or bradycardia are likely to occur with IV overdoses and not with ingestion of the drug. Other effects rarely reported include hypersensitivity hepatitis, bone marrow suppression, and renal failure with long-term therapeutic doses.

Chemical Weapons

Anticholinergic chemicals have been used both as an agent and an antidote in chemical warfare. 3-Quinuclidinyl benzylate (QNB) was first developed for the treatment of GI illness but later turned over to the U.S. Army because of the multiple cases of delirium at very low doses. QNB is a competitive antagonist at the muscarinic receptors in the central and peripheral nervous systems. The reader is referred to Chapter 105E for a detailed discussion of this agent.

Atropine is a component, along with pralidoxime, of the Mark I kits developed as an antidote for nerve agent poisoning. There are multiple cases of anticholinergic poisoning from unjustified injections in the Scud missile attacks on Israel in 1991. There were 208 unjustified injections of atropine accounting for 47% of all the injuries during this 8-day barrage of surface-to-surface missiles⁹³ (see Chapter 105A).

DISPOSITION

Clinical toxicity is usually evident within 1 to 4 hours after ingestion, but the severity and duration of toxic

effects are highly variable. The potential for prolonged toxin absorption and, thus, prolonged toxicity from anticholinergic agents must be considered when determining patient disposition. Patient discharge or medical clearance is reserved for patients who do not develop toxic effects or who develop mild toxic effects initially that resolve during a 6-hour period of observation (provided that GI ileus and significant co-ingestants with delayed toxicity are not present). No patient should be discharged without suicide assessment, substance abuse counseling, or poison prevention counseling.

Those patients who manifest mild toxicity (e.g., ataxia, lethargy, mild agitation, sinus tachycardia, repolarization abnormalities on ECG) should be admitted to a monitored bed for continued observation. Patients with moderate to severe toxicity (e.g., significant CNS depression or agitation, respiratory depression, hypotension, seizures, acid–base disturbances, nonsinus arrhythmias, and cardiac conduction disturbances) should be admitted to an intensive care unit for aggressive supportive care. In addition, patients who are given large doses of benzodiazepines for the control of agitation require intensive care unit observation. Patients whose agitation and delirium resolve following the administration of physostigmine still require hospital admission due to the short duration of antidotal activity and, consequently, high incidence of recrudescence toxicity. When the appropriate disposition of a patient is in question, consultation with a medical toxicologist or poison control center is recommended.

40 *Anticonvulsants*

DONNA SEGER, MD

At a Glance...

- Many anticonvulsants are used to treat nonconvulsive disorders such as mood disorders.
- Drugs that are hepatically metabolized via the cytochrome system interact with other drugs metabolized via the same system.
- Data on overdose is minimal for most newer anticonvulsants. Unless otherwise stated, treatment is supportive.
- Gastrointestinal decontamination recommendations supported by the American Academy of Clinical Toxicology/European Association of Poison Control Centres and Clinical Toxicologists are as follows:
 - Gastric lavage may be considered if the patient is obtunded within an hour of ingestion.
 - Whole-bowel irrigation may be considered when tablets are sustained release or enteric coated.

Prior to 1993, the only drugs available to treat epilepsy—phenobarbital, primidone, phenytoin, carbamazepine, and valproate—caused significant side effects. Many patients taking these drugs still had refractory seizures. Since 1993, eight new anticonvulsants with better side effect profiles and less hepatic enzyme induction have been approved. However, they are more expensive than the traditional drugs and may not be more cost effective.¹

EPILEPSY AND DRUG DEVELOPMENT

Epilepsy is a chronic neurologic condition in which the patient suffers recurrent, unprovoked seizures.² Seizures, a paroxysmal transient disturbance of brain function, affect 1% of the world's population. Side effects of anticonvulsants (ACs) and the 25% of the epileptic population who are not seizure-free have driven the development of new ACs that are less toxic and more efficacious.³

Choice of Drug

The ideal AC has the following pharmacokinetic characteristics: rapid absorption after oral ingestion, high bioavailability, rapid achievement of steady-state concentrations, minimal protein binding, linear kinetics, long elimination half-life that allows twice a day dosing, minimal hepatic metabolism, primary renal excretion, and constant interpatient pharmacokinetics. The ideal drug is also effective for a wide range of seizure

types, causes few adverse effects, and interacts with few drugs.⁴

Sudden Unexpected Death

Sudden unexpected death (SUD) is increased in patients with epilepsy and reflects population rates, not drug effect. Mechanism and role of AC in SUD are unknown and may depend on the unique circumstances.⁵

Teratogenicity

Major malformation, growth retardation, and hypoplasia of the midface and fingers is called anticonvulsant embryopathy. The incidence of embryopathy correlates with exposure to the anticonvulsant drug.⁶ Its incidence is not increased in infants whose mother had epilepsy but did not take anticonvulsant drugs during pregnancy.

Anticonvulsant Hypersensitivity Syndrome

Anticonvulsant hypersensitivity syndrome (AHS), a rare, life-threatening syndrome consisting of rash and internal organ (most frequently liver) involvement, occurs within 8 weeks of initiation of an AC and is not related to dose or serum concentration of the drug. AHS occurs in one in 1000 to 10,000 exposures and is most frequently caused by the aromatic AC (phenobarbital, phenytoin, carbamazepine). Its cause is unknown. Treatment is discontinuation of the anticonvulsant and aggressive supportive care. The syndrome is associated with substantial morbidity and mortality, including fulminant hepatic failure and death.⁷

PHENOBARBITAL

Pharmacology

Phenobarbital (PB) inhibits seizures by potentiating synaptic inhibition through two separate actions on the γ -aminobutyric acid (GABA_A) receptor—that is, enhanced effects of GABA-evoked chloride currents, and direct activation of the receptor at supratherapeutic concentrations.⁸

Pharmacokinetics

PB is slowly absorbed, with peak concentrations occurring several hours after a single dose. It is 40% to 60% bound to plasma proteins. Up to 23% of the dose is eliminated unchanged by pH-dependent renal excretion. The remainder of the drug is metabolized primarily by hepatic CYP2C9.⁸

Toxicology

ACUTE TOXICITY (OVERDOSE)

Central nervous system (CNS) depression is caused by the effects of the drug on the reticular activating system and the cerebellum. Vasodilation, decreased sympathetic output, and negative inotropic cardiac effects cause hypotension. Decreased consciousness, respiratory depression, hypotension, and hypothermia follow overdose. Less severe toxicity is manifest by slurred speech, ataxia, nystagmus, and confusion. The patient may appear intoxicated. Pupils may be constricted or dilated. Brainstem and deep tendon reflexes are usually depressed or absent. Bullous skin lesions may also be seen.⁹ Owing to PBs rapid CNS redistribution, patients may become more alert despite persistently elevated serum drug concentrations. Fatalities result from cardiorespiratory arrest or (direct) myocardial depression.

CHRONIC TOXICITY

Sedation and impaired cognition occurs in both children and adults.⁹

ADVERSE EFFECTS

Children manifest altered sleep, fussiness, irritability, and hyperactivity.

Diagnosis

The relationship between plasma concentration and adverse effects depends on the development of tolerance. Side effects usually disappear with continued use even when serum concentrations are supratherapeutic. The usual therapeutic serum concentration is 15 to 40 µg/mL. Concentrations greater than 60 µg/mL are associated with significant toxicity in the nontolerant individual.⁹

Management

Administration of multiple-dose activated charcoal (MDAC) and urinary alkalinization to a pH of 7.5 to 8.0 increases elimination of the parent compound. Although both MDAC and urinary alkalinization decrease elimination half-life, treatment with these modalities may neither shorten the clinical course nor change outcome. Hemoperfusion and hemodialysis increase clearance of the drug, although they are rarely needed for this overdose.^{10,11} A serum PB concentration of greater than 100 to 125 µg/mL is an indication for extracorporeal drug removal.

PHENYTOIN

Pharmacology

Phenytoin (PHT) causes voltage-frequency and use-dependent block of sodium channels, inhibits calcium channels, and stimulates the Na⁺/K⁺-ATPase pump.¹²

Pharmacokinetics

Limited phenytoin solubility (i.e., dissolution rate decreases with increasing dose) causes prolonged absorption and delays peak serum concentrations, which have been reported to occur days after ingestion of a large dose. After a 400-mg dose, peak serum concentrations occur in 8 hours. The drug is 90% protein bound with a volume of distribution of 0.6 to 0.7 L/kg. Half-life is 20 to 30 hours. Metabolism is hepatic. Inactive metabolites and 5% of the parent drug are renally excreted.^{13,14}

Metabolism is dose dependent. At therapeutic serum concentrations, elimination is first order (i.e., rate of drug metabolism increases as the concentration of the drug increases). In the upper therapeutic and toxic serum concentrations, the hydroxylation reaction reaches maximum velocity and elimination is zero order (i.e., rate of metabolism is constant).¹³⁻¹⁵

Absorption from bone is rapid following intraosseous administration. Pharmacokinetics approximate those following intravenous administration.¹⁶

Toxicology

ACUTE TOXICITY (OVERDOSE)

Initial cerebellar symptoms (nystagmus, ataxia, and drowsiness) are followed by basal ganglia signs (movement disorders) as serum concentrations exceed 20 mg/L. At higher concentrations, the CNS becomes depressed, ultimately producing coma. PHT overdose does not cause cardiac toxicity. The occurrence of paradoxical seizures following overdose has not been confirmed. Treatment is supportive.¹⁷

CHRONIC TOXICITY

Chronic PHT toxicity may occur during therapeutic ingestion owing to (1) small increases in maintenance doses that saturate enzyme systems, leading to zero order kinetics; (2) decrease in protein binding of the drug (e.g., addition of another drug); or (3) drug-induced alteration in hepatic metabolism.

Although head computed tomography (CT) may demonstrate cerebellar atrophy and cerebellar tissue loss in patients chronically receiving phenytoin, seizures can cause the same changes.¹⁸

ADVERSE EFFECTS

Adverse effects of PHT usually occur when serum concentrations are greater than 15 mg/L. Gingival hyperplasia and folic acid deficiency are among the most common and are dose related. Rash, acne, lupus-like syndrome, Stevens-Johnson syndrome, thyroid function inhibition, hirsutism, hypertrichosis, benign intracranial hypertension (pseudotumor cerebri), carbohydrate intolerance, peripheral neuropathy, osteomalacia, and altered vitamin D metabolism (increased alkaline phosphatase) may occur. The most serious adverse effect is a hypersensitivity syndrome manifested by fever, rash, lymphadenopathy, hepatitis, and eosinophilia. Death

typically occurs from fulminant hepatic failure. Elevated liver enzymes should be monitored closely to distinguish transient enzyme elevation from progression to hepatic failure.¹⁹

Diagnosis

Symptoms correlate with free rather than total phenytoin concentrations; free concentrations are usually not available. Therapeutic serum concentrations (10 to 20 mg/L) equate with a free PHT concentration of 1.0 to 2.0 mg/L. Symptoms of toxicity occur when free PHT concentrations are greater than 5 mg/L.²⁰

Management

Treatment of acute overdose and chronic PHT toxicity is supportive. The drug's prolonged elimination half-life may cause prolonged symptoms. The main concern in patients with PHT toxicity is ataxia causing a fall and resultant injury. The patient must be in the appropriate setting for observation.¹⁷

Intravenous Phenytoin

PHT is administered intravenously when a therapeutic concentration is needed as rapidly as possible (e.g., subtherapeutic concentrations following a seizure). Propylene glycol is necessary to maintain solubility and stability of parenteral PHT, but it can cause hypotension and bradycardia if administered too rapidly. In concentrations of 6 to 10 mg/L of normal saline (NS), PHT maintains solubility for about 1 hour. Oral loading results in delayed therapeutic concentrations, since limited PHT absorption (with a large dose) prolongs the time needed to reach therapeutic concentration.²¹

An IV dose of 15 to 18 mg/kg produces therapeutic serum concentrations lasting 12 to 24 hours. Distribution to the brain is rapid, and anticonvulsant activity begins within 3 to 5 minutes after IV infusion. If serum concentration of phenytoin is known, each 100 mg of IV phenytoin will increase serum concentration approximating 1.2 mg/L.²¹

Rapid IV administration of the drug (because of propylene glycol) and high PHT solution concentrations can cause cardiovascular toxicity. A PHT concentration of 4 to 10 mg/mL NS can be safely administered at a rate of 50 mg/min in patients younger than 50 years of age, and a concentration of 4 mg/mL NS (1 g phenytoin in 250 mL NS) at a rate of 25 mg/min in patients less than 50 years of age. Patients should be on a cardiac monitor. A constant infusion pump should monitor intravenous piggyback delivery. PHT should not be administered to patients with marked bradycardia, second- or third-degree heart block, active severe arteriosclerotic heart disease (ASHD), or hypotension. Fatalities have occurred in elderly patients with ASHD and in younger patients when the IV delivery rate or phenytoin concentration was greater than recommended.^{23,24}

If the total dose administered is greater than 1 g, ataxia, dizziness, and confusion may occur despite appropriate administration rate and concentration. The infusion should be stopped if systemic side effects occur.²³

Solvent alkalinity may cause burning and aching of the arm if infused into a small vein and buffering capacity of the blood is exceeded. Decreasing the rate or concentration may alleviate the symptoms. Soft tissue and vascular injury have occurred in elderly women with cardiovascular disease. A 20-gauge IV catheter and administration rate less than 25 mg/min may decrease the risk of injuries.²⁵

FOSPHENYTOIN

Pharmacology

Fosphenytoin (FOS) is a disodium phosphate ester prodrug of PHT that is water-soluble and therefore does not require propylene glycol. Phosphatases present in the liver, red blood cells, and other tissues remove the phosphate molecule and convert FOS to active PHT in 8.4 minutes following intravenous administration.²⁶

Pharmacokinetics

Maximal serum concentration is reached within 10 to 20 minutes of starting the infusion. Therapeutic PHT concentrations (10 to 20 mg/mL) occur within 10 minutes of infusions administered at a rate of 100 mg/min and within 30 minutes of infusions administered at less than 100 mg/min.²⁷

ADVERSE EFFECTS

Nystagmus, headache, ataxia, and somnolence are the most frequent symptoms. Paresthesias and perineal and generalized pruritus have been reported in 30% to 60% of patients.

Diagnosis

Determination of FOS concentrations is of no value, since the drug is not clinically active. However, serum PHT levels are useful in guiding therapy.

Intravenous PHT vs. Intravenous FOS

FOS may be administered more rapidly than PHT. However, owing to the need for observation and other medical issues in patients who have just had a seizure, emergency department (ED) time is not decreased by administration of FOS. The adverse effect profile of FOS is different from that of PHT but not necessarily better. A significant number of people suffer perineal pruritus. FOS is more expensive than PHT. Cost analysis does not justify administration of FOS over PHT.^{28,29}

CARBAMAZEPINE

Pharmacology

Carbamazepine (CBMZ) inhibits sodium channels, interferes with release of glutamate (and possibly other neurotransmitters), and inhibits muscarinic and nicotinic acetylcholine receptors, *N*-methyl-D-aspartate (NMDA) receptors, and CNS adenosine receptors.³⁰

Pharmacokinetics

CBMZ is an iminostilbene derivative that is chemically and structurally similar to imipramine, yet shares few of its pharmacologic properties. Absorption is slow, and peak serum concentrations usually occur within 4 to 8 hours but may be as late as 12 hours after ingestion.^{31,32} A serum therapeutic concentration is 4 to 12 µg/mL.

The drug is 75% protein bound and has a volume of distribution of 0.79 to 1.19 L/kg. It is metabolized by liver cytochrome P4503A4 to an active metabolite (10,11-epoxide) with a half-life of 10 to 20 hours. The epoxide concentration is 10% to 15% of the parent compound in adults and 20% in children. The epoxide may be responsible for the neurotoxicity of the drug. Because CMBZ induces its own metabolism, its half-life after an isolated single dose (35 hours) is much longer than the half-life of the drug at steady state (10 to 20 hours). Autoinduction takes about a month. Elimination of the parent compound follows zero order kinetics, and 3% of the parent compound is excreted unchanged in the urine. The epoxide is metabolized to inactive compounds, which are excreted in the urine.^{32,33}

Toxicology

ACUTE TOXICITY (OVERDOSE)

Delayed and erratic absorption due to CMBZ's anticholinergic properties and low water solubility can cause delayed clinical deterioration and a cyclic clinical course. Peak serum concentrations may occur 72 hours after ingestion of immediate-release (IR) and 96 hours after ingestion of controlled-release (CR) formulations. Half-life may be prolonged (39 hours) after an isolated ingestion or shorter when chronic therapeutic ingestion has induced metabolism.^{31,32}

Symptoms of toxicity include coma, respiratory failure, ataxia, nystagmus, mydriasis, ileus, hypertonicity, increased deep tendon reflexes, movement disorders, and anticholinergic toxidrome. Seizures are more likely to occur in patients with high serum drug concentrations and an underlying seizure disorder. Left ventricular dysfunction with heart failure has been reported. Complete heart block (without hemodynamic compromise) has been reported in children. Cardiac arrhythmias are rarely seen. Laboratory abnormalities include hyponatremia, hyperglycemia, and transient elevation of serum liver enzymes.³⁴⁻³⁸

CHRONIC TOXICITY

CBMZ-induced bradycardia (including complete heart block) may occur in elderly patients with a defective conduction system or sick sinus syndrome. Benign cardiac conduction disturbances have been found in up to 57% of patients with CBMZ toxicity. Patients over 50 years of age should have an electrocardiogram (ECG) performed prior to initiation of CBMZ therapy.^{37,38}

ADVERSE EFFECTS

Adverse effects occur in 25% of patients ingesting CBMZ. A mild transient leukopenia that may occur during the first month of treatment is unrelated to aplastic anemia, which occurs in 1 in 575,000 patients taking CBMZ. Hematologic monitoring is recommended. Discontinuation of the drug is not required for the mild liver enzyme elevation that occurs in up to 10% of patients taking CBMZ.

Diagnosis

Although serum CBMZ concentrations do not accurately correlate with the clinical severity of the poisoning, serum concentrations greater than 40 mg/L are associated with an increased risk of serious complications such as coma, seizures, respiratory failure, and cardiac conduction defects. Serum concentrations greater than 60 to 80 mg/mL may be associated with a fatal outcome. The seriousness of toxicity should be judged by the clinical status of the patient, not by the serum CBMZ concentration.^{37,38}

Because of its ringed structure, CBMZ can cause a false-positive tricyclic antidepressant (TCA) result on the urine drug screen (UDS). Both CBMZ and carbamazepine 10,11-epoxide are measured by the standard enzyme multiplied immunoassay test (EMIT). A ratio of parent compound to epoxide greater than 2.5 is suggestive of continuing gastrointestinal (GI) absorption.³⁹

Management

Gastric lavage may be considered if the patient is obtunded within 1 hour of ingestion of CBMZ. Prolonged absorption is possible. MDAC may decrease half-life but may not decrease time to recovery or change outcome. The benefit:risk ratio of MDAC administration in a sleepy patient or a patient who may require intubation must be assessed in each case. Similarly, although charcoal hemoperfusion (CHP) decreases the half-life of both CBMZ and the epoxide, the efficacy of charcoal hemoperfusion has not been compared with administration of multiple doses of activated charcoal or supportive care. If extracorporeal removal is considered in a life-threatening overdose, hemodialysis usually is the treatment of choice, since CHP cartridges are not readily available.⁴⁰⁻⁴²

VALPROATE

Pharmacology

Valproate (VPA) has a number of indirect actions on the GABAergic system, causing increased GABA concentration. VPA reduces release of γ -hydroxybutyrate (an eliptogenic amino acid) and blocks cell firing induced by NMDA glutamate receptors. In rat brain sections, VPA increases brain endogenous opioid. Active metabolites may add to the drug's antiepileptic actions.⁴³⁻⁴⁶

Pharmacokinetics

VPA is a simple eight-carbon, branch-chained fatty acid. It is rapidly and completely absorbed, with peak serum concentrations occurring 1 to 4 hours after ingestion. The drug is extensively metabolized in the liver by glucuronic acid conjugation and mitochondrial β -oxidation, which may be inhibited by long-term or high-dose VPA therapy. VPA enters the mitochondria by a transport system that uses L-carnitine as a cofactor. Cytosolic ω -oxidation plays a smaller role in metabolism. Protein binding is determined by serum concentration with 90% of the drug protein bound at concentrations of 40 $\mu\text{g}/\text{mL}$. Concentrations greater than 150 $\mu\text{g}/\text{mL}$ saturate protein binding sites, and less than 70% of the drug is protein bound. VPA has a small volume of distribution (0.13 to 0.23 L/kg) The half-life of VPA is 8 to 21 hours but may be up to 42 hours after overdose. In therapeutic concentrations and following overdose, elimination kinetics of the parent compound appear to be first order. Less than 3% of the drug is excreted unchanged in urine and feces.^{47,48}

Toxicology

ACUTE TOXICITY (OVERDOSE)

If the enteric-coated or CR formulation has been ingested, peak serum concentration may be delayed for 12 to 16 hours. Patients who have ingested these formulations cannot be medically cleared until the clinical picture and serum concentration are assessed at the end of this time period.⁴⁹

CNS depression, ranging from drowsiness to coma, is the most frequent sign following overdose. Serum concentrations greater than 850 $\mu\text{g}/\text{mL}$ uniformly cause coma. Respiratory depression, hypotension, hypoglycemia, hypocalcemia, hypernatremia, hypophosphatemia, and anion-gap metabolic acidosis may persist for days. Serum aminotransferases, ammonia, amylase, and lactate may be elevated. Pancreatitis may occur. Thrombocytopenia, the most common hematologic toxicity, may be clinically significant and severe.⁴⁹

VPA increases renal ammonia production and blocks hepatic ammonia metabolism. Resultant hyperammonemia may increase intracellular osmolarity, which promotes influx of water into the cell and causes cerebral edema. Hyperammonemia (in the absence of liver failure) and cerebral edema have been reported following VPA overdose. Whether increased ammonia is

the cause of cerebral edema and the resultant increased intracranial pressure is unknown.⁵⁰

CHRONIC TOXICITY

Increased serum liver enzymes and bilirubin occur in up to 60% of patients with therapeutic VPA serum concentrations. Liver enzymes normalize with dose reduction or discontinuation of the drug.

Hepatic failure, histologically evident as microvesicular steatosis, occurs in 1 in 20,000 patients. VPA-induced hepatotoxicity may be either intrinsic (reversible, reproducible, and dose dependent) and benign, occurring in 44% of patients, or idiosyncratic (unpredictable, not dose dependent, long latent period) and fatal. Children less than 3 years of age who are receiving multiple antiepileptic agents and have additional medical problems are at highest risk for fatal hepatotoxicity (incidence of 1 in 500). Liver enzymes and ammonia should be checked in children therapeutically ingesting VPA who demonstrate somnolence, lethargy, or even coma.⁵¹

Asymptomatic hyperammonemia without hepatic damage occurs in 20% of patients taking this drug. The origin of the ammonia is hepatic, a result of impaired urea cycle function and inability to metabolize nitrogen loads. The mechanism of this impairment is unknown. Carnitine deficiency may play a role in impaired urea production.⁵⁰

Thirty-six cases of VPA-associated pancreatitis, including nine deaths, have been reported. Patients receiving multiple anticonvulsants may be at highest risk for developing pancreatitis. The cause of the pancreatitis is unknown. Abdominal pain, lethargy, or coma may be the presenting symptoms. Thrombocytopenia, usually transient despite continuing the drug, has rarely induced bone marrow toxicity.⁵²

ADVERSE EFFECTS

Fifteen percent of patients experience GI side effects such as anorexia, nausea, and diarrhea. CNS effects of sedation, ataxia, and tremor also occur.

Diagnosis

Serum concentration does not correlate well with either seizure control or toxicity. Therapeutic concentrations are 50 to 100 $\mu\text{g}/\text{mL}$. The incidence of adverse side effects increases at concentrations greater than 120 $\mu\text{g}/\text{mL}$.

EMIT will yield higher values of serum VPA than will the gas-liquid chromatographic assay, requiring consistent analytic methodology. VPA is eliminated partly as ketone bodies and may cause a false-positive test result for ketones in the urine.

Management

Administration of high-dose naloxone has been reported to reverse VPA-induced CNS depression, possibly by reversal of VPA-induced release of endogenous opioids or reversal of VPA blockade of GABA uptake.⁵³

Because of delayed peak serum concentrations, serial concentrations should be obtained. Whole-bowel irrigation may be considered if the patient ingests Depakote or an extended-release preparation and presents within 5 hours of ingestion. Serum ammonia concentrations should be obtained in all patients with an altered level of consciousness. Serum glucose, calcium, phosphate, and platelets must be monitored.⁵⁴

β -Oxidation, the primary metabolic pathway, may be decreased following overdose. Hypocarnitinemia, which inhibits β -oxidation, may occur following long-term VPA therapy. The clinical relevance of hypocarnitinemia in patients with seizures on chronic VPA therapy or in overdose patients is unknown. L-Carnitine has been administered to overdose patients in an attempt to increase VPA metabolism via β -oxidation. L-Carnitine causes few adverse side effects. However, its administration is experimental.⁵⁵

Hemoperfusion (HP) and hemodiafiltration without HP have been performed to treat severe VPA overdose. Although the significant protein binding should not make it amenable to dialysis, the hypothesis is that unbound (free) drug is markedly increased in overdose. None of the extracorporeal means of detoxification have been compared with supportive care to determine whether these measures improve outcome.⁵⁶

FELBAMATE

Introduction

Shortly after U.S. Food and Drug Administration (FDA) approval, it became apparent that felbamate was not well tolerated owing to GI complaints, insomnia, weight loss, dizziness, fatigue, ataxia, and lethargy. Felbamate-induced aplastic anemia (with an incidence 100 times higher than in the general population) and hepatic failure caused many physicians to discontinue the drug. Unfortunately, acute withdrawal of felbamate precipitated status epilepticus in some patients, causing some fatalities.^{57,58}

Currently, felbamate is recommended only when other treatment regimens have failed. It remains on the market with a black box warning for aplastic anemia and hepatic failure and is not considered a first-line anticonvulsant.¹

Pharmacology

Felbamate decreases the sodium current, enhances inhibitory actions of GABA, and blocks NMDA and α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. There is no effect on benzodiazepine receptors or GABA receptor binding.^{1,59}

Pharmacokinetics

Felbamate is a dicarbamate derivative structurally related to meprobamate. The drug is 90% bioavailable after ingestion. Time to peak plasma level is 1 to 4 hours.

Volume of distribution is 0.75 L/kg. It is 25% bound to plasma protein, and elimination half-life is 20 hours. Forty to fifty percent is excreted unchanged in the urine.⁵⁹

Toxicology

ACUTE TOXICITY (OVERDOSE)

Somnolence and GI symptoms may occur. Following overdose of felbamate and VPA, massive felbamate crystalluria and acute renal failure occurred. Crystalluria may have been caused by felbamate alone or in combination with VPA.⁶⁰

CHRONIC TOXICITY

Fatal hepatitis and aplastic anemia are potential life-threatening effects.

ADVERSE EFFECTS

Weight gain, weakness, malaise, influenza-like symptoms, palpitations, tachycardia, agitation, psychological disturbance, aggressive reaction, pruritus, and Stevens-Johnson syndrome have been reported.

Diagnosis

Liver enzymes and white blood counts must be monitored when felbamate is taken. Although there is no recommended therapeutic range for felbamate, plasma concentrations as high as 140 μ g/mL have been tolerated without significant adverse effects.⁶¹ Acute overdose is treated with supportive care; there is no means of enhancing the drug's removal.

GABAPENTIN

Pharmacology

Structurally related to GABA, gabapentin does not bind to GABA receptors but is thought to enhance the release or actions of GABA. Unlike GABA, gabapentin readily crosses the blood-brain barrier. Gabapentin inhibits voltage-dependent sodium currents.¹²

Pharmacokinetics

Bioavailability is dose-dependent owing to facilitated transport during absorption by the L-amino acid transporter. The transport system becomes saturated at higher doses, limiting absorption. (The drug is presumed to be transported across the blood-brain barrier in the same way.) Oral bioavailability is 60% after a 300 mg dose and decreases to 35% when the dosage is 1600 mg three times a day. It is neither metabolized (and therefore does not induce hepatic enzymes) nor bound to plasma proteins. Gabapentin half-life is 5 to 7 hours. Kinetics are linear. Since gabapentin is eliminated by the kidneys, its renal clearance is dependent on creatinine clearance; the dose should be adjusted in patients with renal impairment.⁶²

Toxicology

ACUTE TOXICITY (OVERDOSE)

Serious toxicity has not been reported after gabapentin overdose, probably because of its limited bioavailability.⁶³

ADVERSE REACTIONS

Side effects of dizziness, somnolence, fatigue, ataxia, headache, tremor, diplopia, nausea and vomiting, and rhinitis are usually transient and disappear with prolonged therapy.⁶⁴

CARCINOGENICITY

While the drug was being developed, preclinical studies temporarily ended owing to increased incidence of pancreatic acinar cell tumors in male Wistar rats fed high doses of gabapentin. The tumors did not occur in female rats, mice, or monkeys. Human pancreatic cancer tends to be ductal. The relevance of the tumors in animals to human carcinogenesis is unknown.⁶⁴

Diagnosis

In adults receiving 900 to 1800 mg/day, plasma concentrations range from 2.7 to 4.1 $\mu\text{g/mL}$ following a single dose and from 4.0 to 8.5 $\mu\text{g/mL}$ following multiple doses.

Management

The treatment of gabapentin overdose is supportive. There is no established role for forced diuresis to enhance its urinary elimination.

LAMOTRIGINE

Pharmacology

Lamotrigine (LTG) stabilizes presynaptic neuronal membranes by blocking voltage-dependent sodium channels and thereby preventing the release of excitatory amino acids, especially glutamate and aspartate. Although LTG is a weak inhibitor of dihydrofolate reductase, antifolate drugs have not been shown to possess anticonvulsant activity.⁶⁵

Pharmacokinetics

The drug is well absorbed; bioavailability is 98%. Its half-life is 22 to 36 hours. Being 55% protein bound, LTG is metabolized by hepatic glucuronidation, which is a target for enzyme inducers and inhibitors. Not surprisingly, metabolism of LTG is markedly increased by inducing drugs. Less than 10% is excreted unchanged.⁶⁵

DRUG INTERACTIONS

Hepatic drug enzyme inducers such as carbamazepine, phenytoin, and phenobarbital reduce the half-life of LTG by 15 hours. Sodium valproate reduces the clearance of LTG by 21% and increases its half-life to 59

hours. LTG does not induce or inhibit hepatic enzymes. LTG increases symptoms when added to carbamazepine through pharmacodynamic rather than pharmacokinetic interactions.⁶⁶

Toxicology

ACUTE TOXICITY (OVERDOSE)

Serious toxicity has not been reported in adults. In a single case report, ataxia and rotational nystagmus were described. An analysis of serum concentrations suggests the elimination pharmacokinetics are first order. Seizures and coma have been reported in children ingesting LTG; all recovered without sequelae.^{67,68}

ADVERSE REACTIONS

Hypersensitivity reactions evidenced by multiorgan dysfunction and hepatic abnormalities, with and without the presence of a rash, have been reported. All patients who developed LTG-associated hypersensitivity syndrome were concomitantly taking ACs. Supratherapeutic dosing of LTG has also been associated with hypersensitivity reaction.⁶⁸

Rashes, including Stevens-Johnson syndrome, toxic epidermal necrolysis, and hypersensitivity reaction occur in up to 25% of children less than 16 years of age and 0.3% (3/1000) of adults. Rarely, death has occurred. Rash usually occurs within 2 to 8 weeks of initiation of the drug, but isolated cases occurring after prolonged treatment (6 months) have been reported. Risk factors include coadministering VPA and exceeding the recommended initial doses of LTG or escalating the dose. LTG should be discontinued at the first sign of a rash. Other reported side effects are headache, nausea, vomiting, dizziness, diplopia, ataxia, and tremor.⁶⁹

Diagnosis

At therapeutic doses, trough plasma concentrations are 2 to 4 mg/L. Maximum reported concentration following overdose is 35.8 mg/L. Serum concentrations are of no clinical value following overdose.⁶⁷

Treatment of overdose is supportive.

TOPIRAMATE

Pharmacology

Topiramate, a sulfamate-substituted monosaccharide, is structurally distinct from other ACs. Topiramate causes a state-dependent blockade of sodium channels and potentiates GABA-mediated neuroinhibition by acting at a unique modulatory site. It enhances GABA-mediated chloride influx into neurons (similarly to diazepam), increasing the frequency at which GABA activates GABA_A receptors. The drug itself does not interact with GABA_A binding sites or BZDP binding sites on GABA_A. Topiramate also causes blockade of glutamate-mediated neuroexcitation. It is a weak carbonic anhydrase inhibitor.⁷⁰

Pharmacokinetics

Topiramate is rapidly and completely absorbed from the GI tract and is minimally protein bound (9% to 17%) but extensively bound to erythrocytes until the binding sites are saturated. The drug's half-life is 19 to 23 hours. Hepatic metabolism is minimal, and there are no active metabolites. The drug is primarily (70%) excreted in the urine.⁷⁰

Toxicology

ACUTE TOXICITY (OVERDOSE)

Coma, status epilepticus, and hyperchloremic metabolic acidosis have been reported following acute overdose.⁷¹

ADVERSE EFFECTS

CNS side effects (sedation) and cognitive side effects (trouble concentrating and finding words, decreased attention span) are worse with rapid titration of topiramate. Weight loss, ataxia, dizziness, nystagmus, tremor, and fatigue may occur. Since the drug is a carbonic anhydrase inhibitor, exchange of hydrogen ion for sodium ion and reabsorption of bicarbonate is decreased at the proximal renal tubule. Metabolic acidosis can therefore develop. Carbonic anhydrase inhibitors also decrease urinary citrate. Both decreased urinary citrate and acidosis increase the chance of calcium phosphate stones.^{72,73}

Treatment of topiramate overdose is supportive; there are no antidotes.

TIAGABINE

Pharmacology

Tiagabine (TGB) prolongs the action of GABA by selectively inhibiting GABA transporters in the glia and neurons. TGB does not affect voltage-gated sodium or calcium channels.⁷⁴

Pharmacokinetics

TGB is oxidized via the cytochrome P-450 system but does not affect hepatic enzyme function and therefore does not affect other drug metabolism. Its half-life is 5 to 8 hours although it may be decreased to 3 hours by inducing drugs.^{1,75}

Toxicology

ACUTE TOXICITY (OVERDOSE)

TGB overdose may precipitate seizures and non-convulsive status.⁷⁶

ADVERSE REACTIONS

Side effects associated with therapeutic use include dizziness, headache, asthenia, and tremor. Visual field defects (VFDs) have been reported. Whether VFDs are

completely reversible when the drug is discontinued is unclear.⁷⁷

Diagnosis

Therapeutic monitoring of plasma concentration is not recommended, since there is no clinical correlation between plasma concentrations and clinical course. Treatment of TGB overdose is supportive.

VIGABATRIN (VGB)

Introduction

Early experiments revealed that brain microvacuoles developed in some animal species taking vigabatrin (VGB). An extensive clinical monitoring program since 1982 throughout the United States and Europe has not revealed evidence of VGB-related CNS vacuolation in humans.⁷⁸

Pharmacology

VGB is a structural analog of GABA and an irreversible inhibitor of GABA transaminase, the enzyme primarily responsible for GABA catabolism. VGB also reduces GABA reuptake activity. Both mechanisms increase brain GABA concentrations.

Pharmacokinetics

The bioavailability of VGB is 90%, and volume of distribution is 0.8L/kg. The drug is not protein bound, has negligible hepatic metabolism, and is primarily cleared by the kidneys. Its half-life is 5 to 7 hours. The pharmacologic half-life is much longer than the elimination half-life, with the duration of action being 5 to 7 days.⁷⁹

Toxicology

ACUTE TOXICITY (OVERDOSE)

Symptoms following overdose include drowsiness, decreased level of consciousness, and coma. Respiratory depression, bradycardia, hypotension, agitation, irritability, confusion, and abnormal behavior have also been reported.⁸⁰

ADVERSE REACTIONS

Mood and behavior changes such as depression, psychosis, and acute encephalopathy may occur. Sedation, fatigue, headache, and weight gain are usually mild and short lasting.

Diagnosis

There is no correlation between plasma concentration and seizure control or adverse effects. Treatment of overdose is supportive.

LEVETIRACETAM

Pharmacology

Levetiracetam is structurally unrelated to other antiepileptic drugs. It does not affect the GABA system, nor does it block sodium or calcium channels. In vitro, the drug binds to brain cell membranes in reversible, saturable, and stereoselective fashion.⁸¹

Pharmacokinetics

Levetiracetam is rapidly and completely absorbed, and peak plasma concentrations occur in an hour. Minimal protein binding and lack of hepatic metabolism prevent drug interactions. Sixty-six percent is excreted unchanged in the urine, of which 27% is excreted as inactive metabolites. The drug's volume of distribution is 0.5 to 0.7 L/kg. Its half-life in adults is 6 to 8 hours; in the elderly, 10 to 12 hours; and in children, 6 hours. Because it is primarily renally excreted, dosage adjustments are necessary for patients with renal impairment.^{81,82}

Toxicology

ACUTE TOXICITY (OVERDOSE)

Levetiracetam may cause CNS and respiratory depression. Recovery is rapid with supportive care. Elimination kinetics are first order following overdose. Treatment of overdose is supportive.⁸³

ZONISAMIDE

Pharmacology

Zonisamide (ZNS) is a sulfonamide. The drug blocks sodium channels and T-type calcium channels and is a weak carbonic anhydrase inhibitor.^{82,84}

Pharmacokinetics

Peak plasma concentrations are achieved in 2.4 to 3.6 hours after ingestion. Japanese studies have reported linear pharmacokinetics, whereas U.S. studies have reported nonlinear pharmacokinetics with first order clearance. CYP3A4 is the isoenzyme that metabolizes the drug. The drug's elimination half-life is 63 hours. The drug is excreted in the urine as unchanged drug, as an acetylation product, and as the glucuronide of a metabolite.⁸⁴

Toxicology

CHRONIC TOXICITY

Carbonic anhydrase inhibitors decrease urinary citrate, an inhibitor of stone formation. Whether ZNS increases the risk of nephrolithiasis is unknown.

In 2001, oligohydrosis and hyperthermia were reported in 38 patients in Japan and 2 patients in the

United States. Pediatric patients may be at increased risk for this dangerous adverse effect.⁸⁵

ZNS may contribute to psychosis during polytherapy. The incidence of psychotic episodes in epileptic patients taking ZNS is higher than the prevalence of epileptic psychosis in those not receiving the drug.⁸⁶

SIDE EFFECTS

Drowsiness (24%), ataxia (13%), anorexia, dizziness, forgetfulness, slowness of thought, and irritability are usually mild and transient.

OXCARBAZEPINE

Pharmacology

Oxcarbazepine (OXZ) is the 10-keto analog of carbamazepine. Similarly to CBMZ, oxcarbazepine blocks voltage-sensitive sodium channels, causing stabilization of hyperexcited neural membranes, inhibition of repetitive neuronal firing, and inhibition of the spread of discharges. The drug also increases potassium conductance, decreases glutaminergic transmission, and modulates the calcium channel.⁸⁷

Pharmacokinetics

OXZ is well absorbed; its absorption is not affected by food. Peak serum concentrations occur 4 to 6 hours after ingestion. It is rapidly metabolized in the liver to an active, nontoxic metabolite, which is widely distributed in the brain and lipophilic tissues and is responsible for the pharmacologic action of the drug. Metabolite half-life is 8 to 10 hours and is not affected by other ACs. Compared with CBMZ, OXZ has fewer side effects owing to lack of toxicity of the metabolite. OXZ is 38% bound to plasma protein. Since the active drug is excreted by the kidneys, the dose may need to be reduced in patients with renal impairment.⁸⁸

Toxicology

ADVERSE EFFECTS

Duration and frequency of side effects are less than for CBMZ. Side effects include fatigue, headache, dizziness, ataxia, and nausea. Skin rash occurs in up to 10% of patients and is the main reason for discontinuation of the drug. OXZ may be administered to patients who have developed a rash while taking carbamazepine. Cross-reactivity is about 25%. Clinically insignificant hyponatremia occurs in 20% of patients.⁸⁹

DRUG INTERACTIONS

An advantage of OXZ is that it causes few drug interactions. If OXZ is substituted for carbamazepine, deinduction can occur.

JOÃO DELGADO, MD

At a Glance...

- Marijuana is the most commonly used illicit drug in the United States.
- Marijuana intoxication is self-limited and typically produces mild symptoms.
- There is no specific antidote—treatment of intoxication is supportive.

INTRODUCTION AND RELEVANT HISTORY

Marijuana is by far the most extensively used illicit drug in the United States. The hemp plant, *Cannabis sativa*, from which it is prepared, has been used for centuries not only for its psychoactive resin but also for hemp fiber and rope. The cannabinoid Δ^9 -tetrahydrocannabinol (THC) is the principal psychoactive constituent and is found in highest concentration in the leaves and the flowering tops of the plant. In addition, the plant contains hundreds of other chemicals, including several cannabinoids. Marijuana and its synthetic analogs (e.g., dronabinol) have also been used medicinally to treat a variety of chronic conditions.

The term *marijuana* refers to dried, tobacco-like preparations of the leaves, stems, and flowers. The THC content of marijuana is variable and may range from 0.4% to 20%, depending on cultivation techniques. The average THC content of confiscated marijuana has increased over the past two decades from under 2% in the late 1970s to 7.79% in 2005.¹ A typical marijuana cigarette contains 500 to 1000 mg of plant material, which is equivalent to approximately 25 to 50 mg of THC. Hashish is the resin extracted from the tops of the flowering plants and has a THC concentration that may exceed 10%. Hash oil is an organic solvent extract of cannabis that may have a THC concentration of 20% or higher.

The modern phase of therapeutic cannabis use began in 1842, when O'Shaughnessy reported on its effectiveness as an analgesic and anticonvulsant.² Cannabis was subsequently touted as a treatment for psychiatric illnesses, insomnia, poor appetite, opium addiction, chronic alcoholism, delirium tremens, and a wide variety of painful disorders. However, as synthetic analgesics and sedatives became available, the medical use of cannabis faded. The Marijuana Tax Act of 1937 officially eliminated it from medical practice in the United States.

Current therapeutic uses of cannabinoids include alleviating chemotherapy-induced nausea and vomiting and attenuation of anorexia and nausea associated with AIDS. In general, enthusiasm for the medicinal use of marijuana has been tempered by inconsistent clinical

trial results, modest therapeutic effectiveness, the adverse health consequences of delivery by smoking, undesirable side effects, and the superiority of already marketed drugs. Those advocating the use of marijuana for medicinal purposes argue that THC is delivered more effectively in smoke than in oral preparations, that marijuana is less expensive than synthetic THC, and that marijuana produces few if any harmful side effects.

The most common form of marijuana use in the United States is in cigarettes. Generally, smoke is inhaled deeply and held in the lungs for 15 to 30 seconds, which results in rapid intoxication or "high." Other psychoactive substances, such as phencyclidine or cocaine, may be mixed with marijuana and then smoked. Ingestion is the second most common means of intoxication and is typically accomplished by baking marijuana inside cookies or brownies. In contrast to inhalation, the effects after ingestion occur more gradually and the level of intoxication is not as readily controlled as with inhalation. Illicit intravenous injection of crude marijuana plant extracts remains an unusual practice. The gummy consistency of the plant resin and its poor water solubility limit its use via this route.

EPIDEMIOLOGY

The National Institute on Drug Abuse (NIDA) funds an ongoing national research and reporting program called the Monitoring the Future Study, in which secondary school students, college students, and young adults are surveyed annually about drug use.³ This study has consistently shown that alcohol is the most frequently used substance in all subgroups, and marijuana is the most frequently used illicit substance. The most recent data show that nearly one half of 12th graders have used marijuana at least once and that 22% are current users.⁴ Another large national survey indicates that 37% of the U.S. population (83 million people) has used marijuana at least once and 14.6 million are currently using marijuana.⁵ Such widespread use has significant public health implications. For example, workers who smoke marijuana frequently have higher rates of absenteeism and miss more days of work due to illness than nonsmokers.⁶ Perhaps more concerning is marijuana's role as a "gateway" drug, meaning that marijuana users are more likely to move on to other more harmful drugs, such as cocaine, heroin, and amphetamines.⁷

STRUCTURE

Cannabinoids are aryl-substituted monoterpenes unique to the genus *Cannabis*. *C. sativa* contains over 60 cannabi-

FIGURE 41-1 Chemical structure of 1-*trans*- Δ^9 -tetrahydrocannabinol.

noids, the most pharmacologically potent of which is THC (Fig. 41-1).

PHARMACOLOGY AND PATHOPHYSIOLOGY

THC produces numerous pharmacologic and behavioral effects through its action on the CB₁ cannabinoid receptor. This receptor is a member of a large family of receptors that are coupled to G proteins and modulate adenylate cyclase.⁸ CB₁ receptors are distributed primarily in axons and nerve terminals. Their presynaptic localization suggests a modulatory role on neurotransmitter release. In fact, THC is known to inhibit the release of a variety of neurotransmitters, including acetylcholine, dopamine, γ -aminobutyric acid, L-glutamate, serotonin, and norepinephrine.⁹ A number of arachidonic acid derivatives have been shown to serve as endogenous CB₁ ligands. These derivatives include arachidonolyl-glycerol (Ara-G1) and anandamide.^{10,11} The establishment of a cannabinoid receptor and several endogenous ligands with biosynthetic and degradative pathways suggests the possible presence of a distinct neurochemical system. A peripheral cannabinoid receptor, designated CB₂, has been identified in macrophages but its role remains unknown.¹²

The highest density of cannabinoid receptors is found in the cerebral cortex, particularly the frontal areas, cerebellum, basal ganglia, hypothalamus, and hippocampus.⁹ This distribution explains the prominent effects of THC on memory, cognition, and motor function. Scarce levels of CB₁ receptors in the brainstem regions are thought to account for the low lethality of cannabinoids. Binding has also been found in the B-lymphocyte-rich areas, including the marginal zone of the spleen, the nodular corona of Peyer's patches, and the cortex of lymph nodes.¹³

Pharmacologic effects begin rapidly and generally peak within 30 minutes of smoking a marijuana cigarette. Behavioral and physiologic effects generally return to baseline levels 4 to 6 hours after smoking. However, impairment of various performance measures related to complex tasks, such as driving a car or flying an airplane, has been demonstrated immediately after marijuana use and persisting for as long as 24 hours.^{14,15} Marijuana is classified as a schedule I controlled substance ("no currently accepted medical use") by the U.S. Drug Enforcement Administration, whereas pharmaceutical THC is classified as a schedule III controlled substance.

The THC analogs dronabinol, levonantradol, nabilone, and nabilonol have been used to treat chemotherapy-

induced nausea and vomiting.¹⁶ A systematic review of the medical literature determined that cannabinoids appear to be more effective than conventional antiemetics in treating mild to moderate nausea but were associated with significant side effects that limited their usefulness.¹⁷ The development of 5-HT₃ receptor antagonists, such as granisetron and ondansetron, has further limited the use of THC for this indication. Dronabinol is approved by the Food and Drug Administration for chemotherapy-associated nausea and vomiting refractory to conventional antiemetics. The recommended dose is 5 to 15 mg/m². Dronabinol is also approved for appetite stimulation in patients with AIDS wasting syndrome.¹⁸ The typical starting dose for appetite stimulation is 2.5 mg twice a day. Dronabinol is marketed under the trade name Marinol (Solvay Pharmaceuticals, Inc., Marietta, GA).

Although THC has analgesic properties, it is no more effective than codeine and produces considerable side effects in the effective analgesic dose range.¹⁹ Marijuana, THC, and several synthetic derivatives have been shown to lower intraocular pressure in patients with glaucoma but are not widely used for this indication.²⁰ A topical preparation of marijuana intended for the treatment of glaucoma is marketed as Canasol in Jamaica (Medi-Grace Ltd., Kingston, Jamaica).²¹ Extensive animal studies have shown that THC is capable of producing both proconvulsant and anticonvulsant effects. Cannabidiol, in particular, showed some promise as an anticonvulsant in animal studies.²² However, its efficacy was not sufficient to warrant clinical use in humans. Recently, there has been an interest in using *Cannabis* for tremor and spasticity associated with multiple sclerosis. Clinical trials have not shown improvement in objective measures of tremor or spasticity despite the perception by participants of an improvement of their symptoms.^{23,24}

PHARMACOKINETICS

THC is readily absorbed when marijuana is smoked, with peak serum concentrations obtained within 10 to 20 minutes. Peak clinical effects occur within 30 minutes of smoking.²⁵ Heavy marijuana smokers absorb THC more efficiently (23% to 27% bioavailability) than light smokers (10% to 14% bioavailability).²⁶ Although oral ingestion of marijuana produces similar pharmacologic effects, THC is absorbed more slowly and erratically than when smoked. Oral bioavailability is only 6% to 10% because of extensive first pass metabolism. Peak plasma THC concentrations occur 1 to 3 hours after ingestion and are much lower than those achieved by smoking.

THC is highly protein bound (97% to 99%) and lipophilic, with an apparent volume of distribution of 4 to 14 L/kg.²⁵ THC is metabolized first to hydroxylated metabolites, followed by conversion to carboxylic acids. The metabolites are subsequently excreted as conjugates. The initial hydroxylated metabolites of THC (i.e., 11-hydroxy-THC and 8- β -hydroxy-THC) are active but do not achieve appreciable plasma concentrations and are not likely to contribute to the acute behavioral

effects of marijuana.²⁵ Approximately 15% and 50% of THC is excreted in urine and feces, respectively, over several days.²⁷ The urinary elimination half-life of THC averages 5 days in heavy users of marijuana as compared with 20 to 57 hours for infrequent users.^{25,28} The primary urinary metabolite is conjugated 11-*nor*-9-carboxy- Δ^9 -THC, which has a urinary elimination half-life of 3 days in heavy users.²⁹ Only trace amounts of THC are excreted in urine unchanged.

Blood concentrations of THC peak before behavioral effects and do not correlate well with pharmacologic effects.³⁰ Peak behavioral effects lag behind the time of peak plasma THC levels by 10 to 30 minutes for smoking and 1 to 3 hours for ingestion; significant effects may last for 4 to 8 hours.^{25,31,32} In clinical settings, blood and urine levels of THC and metabolites are only useful for determining whether or not an individual has used marijuana and not in determining degree of resulting impairment.

TOXICOLOGY

Overall, toxicity arising from cannabinoid use is mild. Even when large doses are used, the effects are not usually prolonged or life threatening. Exceptions to this rule are ingestions involving small children, who may become severely obtunded after ingesting hashish or marijuana, and individuals who experience severe allergic reactions to *Cannabis*, both of which are rare occurrences.^{33,34}

Psychological and Neurologic Effects

Marijuana's effects on central nervous system functions such as behavior, cognition, perception, and performance are its most important physiologic effects. Individuals who consume low to moderate quantities generally report a feeling of well-being and pleasant relaxation, euphoria, a dreamlike state, alteration of time and space perception, and a heightening of their senses. Smoking a large quantity of marijuana can produce a range of effects including mild anxiety, paranoid behavior, acute psychosis, problems in dealing with reality, and obsessional thought content characterized by delusions, hallucinations, illusions, and bizarre behavior. These adverse effects sometimes occur in inexperienced users even after low doses.

Cognitive functioning, such as speaking, problem solving, and memory recall, are affected by marijuana use.³⁵ Marijuana's interference with short-term memory is thought to be a major cause of poor cognitive performance during marijuana intoxication. Information learned while intoxicated is less well recalled than in a sober state.

Impairment of complex motor functions also occurs in intoxicated individuals.³⁵ Some parameters that affect driving performance continue to be impaired even several hours after a marijuana user no longer feels high. Epidemiologic data suggest that drivers who recently used *Cannabis* are approximately three to seven times

more likely to have caused a crash than sober drivers.³⁶ This impairment is exacerbated by the common combination of marijuana with alcohol.

Adverse psychological reactions to marijuana use occur relatively frequently.³⁷ The exaggeration of the more usual marijuana response, in which an individual loses perspective (i.e., the realization that what he or she is experiencing is a transient drug-induced distortion of reality), may produce anxiety. This reaction appears to occur primarily in inexperienced users, although unexpectedly higher doses of the drug can cause such a response even in experienced users. Symptoms usually resolve in a few hours as the immediate effects of acute intoxication recede. Typically, only authoritative assurance and limiting sensory input are required.

Uncommon cannabinoid-induced symptoms may include severe panic and anxiety states, paranoia, depression, personality changes, confusional states, and psychoses, which are indistinguishable from primary psychiatric syndromes unless the drug-induced etiology is known. Whether marijuana use can precipitate permanent psychiatric illness in individuals who have no underlying predisposition remains controversial. Marijuana has also been linked to transient ischemic attacks and strokes, but definitive evidence of a causative role is lacking.^{38,39} There is no convincing evidence that cannabinoids are neurotoxic to humans.⁴⁰

Respiratory Effects

Inhalation of marijuana smoke is associated with rhinitis, pharyngitis, laryngitis, cough, hoarseness, and bronchitis, which are symptoms commonly reported by tobacco smokers as well. Interestingly, marijuana smoke also produces bronchodilatation in both normal and asthmatic patients. Prolonged marijuana use is associated with chronic bronchitis and changes in respiratory tract cells.⁴¹ In contrast to tobacco smoke, which affects primarily the smaller airways and the alveoli, marijuana smoke is associated with large airways disease.^{42,43} Longitudinal data suggest an additive effect of marijuana plus tobacco with respect to symptom prevalence. Uncommon adverse effects include pneumothorax and pneumomediastinum from the Valsalva maneuver that marijuana users frequently employ in an attempt to increase THC absorption by the lung; partial upper airway obstruction from marijuana smoke-induced uvulitis; and pulmonary aspergillosis.⁴⁴⁻⁴⁶

As with tobacco smoke, marijuana smoke has a high content of particulate matter, or tar. Compared to tobacco smoke, marijuana smoke contains threefold more tar and results in fivefold higher carbon monoxide concentrations.⁴⁷ No large-scale epidemiologic studies have been carried out to determine if there is a relationship between smoking marijuana and the incidence of lung cancer. Nevertheless, there is good reason for concern about the possibility that lung cancer might result from prolonged use. Several reports have noted a higher-than-expected incidence of head and neck squamous cell carcinoma.⁴⁸ Like tobacco smoke residuals, so-called tar *Cannabis* residuals, when applied to the skin

of experimental animals, produce tumors. Analysis of marijuana smoke has also revealed high concentrations of carcinogenic hydrocarbons.

Cardiovascular Effects

Dose-related sinus tachycardia is the most common cardiovascular effect observed after the administration of THC, regardless of route.⁴⁹ Orthostatic hypotension may occur with higher doses. Electrocardiographic changes in intoxicated individuals include nonspecific ST-T changes as well as occasional premature ventricular contractions. One report implicated marijuana use in causing atrial fibrillation.⁵⁰ The cardiovascular effects are caused primarily by stimulation of the autonomic nervous system with involvement of both the parasympathetic and sympathetic pathways. These effects are not likely to have serious consequences in young, healthy adults but may be significant in patients with preexisting cardiovascular disease. For example, one study found that the risk of having a myocardial infarction increases fourfold in the hour following marijuana use.⁵¹ No long-term cardiovascular effects have been described to date.

Reproductive Effects

No definitive evidence shows that marijuana use alters reproductive function in either gender to such an extent that reproduction is compromised. Changes in sex hormone levels after heavy marijuana use have been described, but these effects have not been consistently demonstrated. For example, one study found depressed testosterone levels in heavy marijuana users but another found no difference in levels of testosterone, luteinizing hormone, follicle-stimulating hormone, prolactin, or cortisol.^{52,53} Even when lower testosterone levels have been noted, the levels have been within normal limits. Whether long-term use of marijuana might result in persistently depressed levels of serum testosterone is unknown.

An increased incidence of gynecomastia and elevated estrogen levels have been noted in some men who use marijuana chronically. Studies of the semen of male long-term users found abnormalities in count, motility, and structural characteristics of the sperm examined.^{54,55} In men with already marginal fertility, decreased fertility might well result, although definitive evidence of this has not emerged. Marijuana use does not appear to affect the ovulatory cycle in women.⁵⁶

Pregnancy and Fetal Development

In laboratory animals, exposure to high doses of THC results in an increased number of stillbirths and decreased litter size.⁵⁷ Malformations in offspring have also been described, but these occur only when dams received very high doses of THC during the initial stages of organogenesis. Many of these studies conducted with high doses of THC more likely reflect maternal toxicity rather than direct effects on embryonic and fetal development.⁵⁸

The effects of maternal marijuana use on fetal development and the outcome of pregnancy are difficult to study in humans because these effects are confounded by alcohol and drug use, smoking, nutritional status, and socioeconomic status. A reduction in birth weight of infants born to women who used marijuana during pregnancy has been noted in some studies but not in others.⁵⁹ In general, marijuana users are more likely than nonusers to have had an unplanned pregnancy, premature labor, and abruptio placentae, and their children are more likely to have lower birth weight and congenital features compatible with fetal alcohol syndrome or other major malformations.⁶⁰⁻⁶² Because women who smoke marijuana frequently smoke tobacco, drink alcohol, and abuse other drugs, it is difficult to isolate a marijuana effect. The long-term consequences of prenatal marijuana exposure are not clear. Some alterations in language skills are observed at 2 years of age, and verbal ability and memory were different between marijuana-exposed and nonexposed 4-year-olds.^{63,64} However, these differences were not observed in 5- and 6-year-olds.

Immune System

The presence of a unique subpopulation of cannabinoid receptors in macrophages suggests that cannabinoids are capable of affecting the immune system. Although there has been concern that cannabinoids could contribute to immunosuppression, particularly in already compromised individuals, convincing evidence is lacking in humans.^{65,66} Marijuana smoke has been shown to alter numerous immune parameters in vitro. Described changes in macrophages include suppression of superoxide production, altered morphology, diminished phagocytic and spreading ability, increased interleukin-1 production, suppression of extrinsic antiviral activity, and alteration of tumor necrosis factor levels.⁶⁷⁻⁷³ Studies examining cellular and humoral responses have produced inconsistent results, with some showing differences in immunoglobulin production and alteration in CD4 to CD8 ratios, while others have not been able to demonstrate differences.^{74,75} Perhaps most concerning is the observation that cannabinoids may decrease host resistance to infection. While these effects are unlikely to affect normal hosts, they may be significant in compromised hosts.

Tolerance and Dependence

The development of tolerance to the effects of marijuana is well established.⁷⁶ Marijuana dependence, defined as experiencing physical symptoms (such as irritability, restlessness, sleep disturbance, nausea, and diarrhea) on cessation of use may occur in settings of heavy use.⁷⁷ It is estimated that more than 200,000 individuals in the United States seek treatment for marijuana dependence each year.⁷⁸ The gradual release of accumulated THC from fat stores creates a “tapered dose” effect and is thought to account for the relatively mild manifestations of marijuana withdrawal.

EFFECTS OF MARIJUANA IN COMBINATION WITH ALCOHOL AND OTHER DRUGS

Marijuana is most commonly used along with ethanol. Several studies have reported that concomitant marijuana and ethanol use produces either additive or supra-additive effects on psychomotor performance.^{79,80} One study, however, reported that marijuana attenuates plasma ethanol levels, with a resultant decrease in the duration of subjective effects for both agents.⁸¹ Concomitant use of intranasal cocaine and marijuana smoke enhances the tachycardia observed with marijuana alone. The duration of the effects of marijuana and cocaine are unaltered when both drugs were given together; however, marijuana pretreatment reduces the time required for the onset of cocaine effects and decreases the duration of negative cocaine effects. Moreover, marijuana pretreatment increases cocaine levels almost twofold.⁸² These observations are thought to occur because marijuana-induced dilation attenuates the vasoconstrictive properties of cocaine, enhancing the absorption of the latter. Simultaneous use of marijuana and amphetamines increases the intensity and duration of a subjective high.

DIAGNOSIS

The clinical features of acute marijuana intoxication are nondescript. Conjunctival hyperemia, nasopharyngeal irritation, tachycardia, and difficulty with short-term memory with its attendant effects on fluency of speech and performance of complex tasks, may be noted. Acute anxiety reactions as well as an acute toxic psychosis with hallucinations, delusions, illusions, and agitation are primarily observed in inexperienced individuals or in those who take large doses. Symptoms, even when severe, generally subside within 4 to 6 hours. In individuals with underlying schizophrenia, marijuana may exacerbate existing symptoms or precipitate a relapse.³⁷ Urine immunoassay is the easiest way to confirm marijuana use. Although a marijuana-induced toxic psychosis that lasted days has been described, symptoms that persist beyond a few hours after marijuana use are more likely to indicate the presence of a cointoxicant or an underlying psychiatric disorder.

Laboratory Testing

The typical means of detecting marijuana use is through measurement of the THC metabolite 11-*nor*- Δ^9 -THC carboxylic acid in urine using an immunoassay screen. Common cutoff limits for commercially available kits are 20, 50, and 100 ng/mL. When the results from the initial screen are confirmed by gas chromatography/mass spectrometry, the results are extremely reliable, with sensitivity and specificity approaching 100%. Therapeutic use of synthetic THC may result in a positive urine screen.

The length of time that marijuana metabolites can be detected in urine depends on the cutoff limit, the amount absorbed, and the frequency of use. Using a urine screen with a 50 ng/mL cutoff, THC may be detected for 1 to 3 days after acute marijuana use. Lower detection cutoffs permit detection for as long as a week or more.⁸³ Heavy users may have detectable cannabinoids in urine for weeks following last use. The reason for this is that THC accumulates in fat stores and upon cessation gradually redistributes back to blood and is then eliminated. Obese individuals who have large lipid stores of THC and lose weight rapidly may have detectable THC in their urine despite a prolonged period of abstinence.

A number of purported methods to defeat urinary assays have been described. These include dilution, bleach, lemon juice, potassium nitrite, niacin, salt, tetrahydrozoline, and vinegar. Marijuana use may be distinguished from dronabinol use by measuring urinary Δ^9 -tetrahydrocannabinivirin, which is a THC analog found only in plant material.⁸⁴

Passive inhalation of marijuana smoke may lead to low concentrations of THC and the 11-carboxy metabolite in both serum (up to 20 ng/mL) and urine (up to 40 ng/mL).⁸⁵ However, this requires such an intense exposure to ambient marijuana smoke that it would be unlikely to occur outside research settings. Passive exposure to marijuana smoke ordinarily does not trigger a positive immunoassay nor does it produce psychotomimetic effects.^{25,86} A group of rock concert attendees who were in an area where marijuana was smoked did not have detectable THC metabolites using a radioimmunoassay with a detection limit of 50 ng/mL.⁸⁷ Ingestion of hemp seed oil and other hemp seed food products has resulted in positive urine screens.⁸⁸

Antenatal exposure to cannabinoids may be documented by testing urine as soon as possible after birth. When routine urine testing is negative but clinical suspicion remains high, meconium may be tested for *Cannabis* and other illicit substances. In fact, meconium is more sensitive than urine or hair testing in determining antenatal exposure to cannabinoids and may indicate exposure as remote as the second trimester.⁸⁹ Methods for meconium analysis for the presence of THC have been described.⁹⁰

Federal regulations require that workers employed in certain transportation-related occupations, such as aviation, mass transit, railroads, and trucking, undergo drug and alcohol testing. The Department of Transportation develops and publishes the rules that govern the testing of these transportation workers. The Department of Transportation cutoff concentration for THC is 50 ng/mL for initial screening and 15 ng/mL for confirmatory testing.

MANAGEMENT

Treatment of marijuana intoxication is supportive. Anxiety associated with inexperience or excessive doses can generally be managed with a quiet, protective environment, reassurance, and mild sedation with

benzodiazepines, if needed. Patients who experience psychotic symptoms should be treated with antipsychotic medications. Activated charcoal may help prevent the absorption of THC after ingestion but data are not available on its effectiveness. Because THC toxicity is rarely life threatening, gastric emptying is not recommended. Patients who present with anxiety or a toxic psychosis may be discharged when their symptoms have abated. Admission is almost never required.

Elimination

THC is not amenable to enhanced elimination techniques due to high protein binding and a large volume of distribution.

Prevention and Addiction Treatment

No prevention model has been successful on a broad scale. Although recent data suggest that the prevalence of marijuana use in school-aged children may be declining, it is unknown which public health measures or policies, if any, are responsible for this decline.⁴ The standard treatment modality for marijuana use has been psychotherapy similar to that of a 12-step Alcoholics Anonymous model. This approach, coupled with urine monitoring, can be effective in terminating marijuana use. However, as with most other drugs of abuse, relapse is common.

R. STEVEN THARRATT, MD, MPVM

At a Glance...

- Cocaine is the most frequent cause of emergency department visits and death associated with illicit drug use in the United States.
- The major routes of administration of cocaine are sniffing, injecting, and smoking (free-base or “crack” cocaine).
- Local anesthetic effects and the blockade of catecholamine and serotonin uptake define cocaine’s principal mechanisms of action.
- Toxicity is manifested primarily by behavioral alterations, hyperthermia, seizures, and cardiac abnormalities. Less commonly, gastrointestinal, liver, kidney, muscle, renal, and pulmonary damage have been reported.
- Treatment is primarily supportive in nature.

INTRODUCTION AND RELEVANT HISTORY

Cocaine continues to be a significant drug of abuse in the United States, as well as in many other parts of the world. It is often associated with drug-related emergency department (ED) visits, intensive care unit (ICU) admissions, and death.¹⁻³ Cocaine is frequently detected on drug screens performed on reckless or impaired drivers⁴ and trauma patients that present to EDs.^{5,6} Although the central nervous and cardiovascular systems are most commonly affected by cocaine, the drug can have toxic manifestations in nearly every organ system. Due to the prevalence and medical significance of cocaine toxicity, health care providers must be knowledgeable of and alert for cocaine toxicity.

Cocaine, an alkaloid that is derived from the leaves of *Erythroxylum coca*, has an interesting history that interfaces with the history of medicine and drug abuse. The first recorded medicinal uses were reported by Spanish physicians in 1596.⁷ Cocaine was first isolated from coca leaves in 1859 by Albert Nieman, a graduate student at the University of Göttingen.⁸ By 1863, Angelo Mariani was marketing a wine in France that was fortified with about 6 mg per ounce of the cocaine alkaloid extract.⁸ In the United States, the Parke-Davis Company was selling a fluid extract containing 0.5 mg/mL of a crude cocaine by 1880.⁸ By 1884, Sigmund Freud had proposed that cocaine be used for the treatment of depression, cachexia, and asthma and also as a local anesthetic.⁹ That same year, cocaine was also first used in eye surgery, a field that was revolutionized by the discovery of this drug. William Steward Halsted, the father of modern American surgery, first used cocaine in regional nerve blocks also in 1884. Unfortunately, Halsted,

like Freud, became heavily dependent on cocaine.⁹ In 1885, the Georgia pharmacist John Styth Pemberton registered the cocaine-containing “French Wine Cola” in the United States; later, he renamed the product Coca-Cola.^{3,8} Coca-Cola was initially a mixture of extracts from the cocaine-containing coca leaf and the caffeine-containing African kola nut. The soft drink was first introduced in 1892 as a brain tonic for elderly people who were easily tired; it was also marketed as a cure for all nervous afflictions.³

By 1893, fatalities from the use of cocaine had been reported. In 1895, a series of six fatalities was reported in the *Lancet*.^{6,10} In 1909, more than 10 tons of cocaine was imported into the United States without legal restraint. Multiple over-the-counter medical products and elixirs containing various amounts of cocaine were created. A product for nasal application called Dr. Tucker’s Asthma Specific contained 420 mg of cocaine per ounce.⁸ The passage of the Harrison Narcotics Act of 1914 finally banned nonprescription use of cocaine-containing products. Subsequently, a significant reduction in the use of cocaine occurred in the United States. Although amphetamines surpassed cocaine as the most prevalent stimulant of abuse in the 1950s, the use of cocaine surged again in the 1970s. Cocaine currently remains the most commonly abused stimulant and illicit drug of abuse.^{1,9,11} The Controlled Substances Act of 1970 prohibited the manufacture, distribution, and possession of cocaine in the United States, except for increasingly limited medical uses.⁹ It has since been designated as a schedule II drug by the U.S. Drug Enforcement Agency (DEA). By the 1980s, chunks of an alkaloidal cocaine called “crack” had become widely available. Cocaine is still used medicinally as a local anesthetic. Topical application of the hydrochloride (1%, 4%, or 10% solution) to the eyes or upper respiratory tract mucosa provides local anesthesia and vasoconstriction with a single agent.¹²

EPIDEMIOLOGY

Cocaine use and dependence remains an epidemic in the United States. The widespread availability of a highly pure, relatively inexpensive, easy-to-use, and highly addictive formulation crack cocaine has ensured the continued American addiction to this illicit drug.^{13,14} In 1999, it was estimated that 25 million Americans had used cocaine at least once, 3.7 million used it within the past year, and 1.5 million were current regular users.^{1,14} Each year, the number of new users steadily increases, with 900,000 new users estimated in 2000.¹⁵ The prevalence of cocaine use is greatest in Americans 18

to 25 years of age. Approximately 11% of Americans older than 12 years have used cocaine, with 7% of adults between 18 and 34 years of age having used it within the previous year.³ According to the Drug Abuse Warning Network, cocaine continues to be the most frequent cause of ED visits associated with illicit drug use in the United States; it accounted for 30% of all such ED visits in 2002 (approximately 200,000 ED visits).¹ In addition, from 1995 to 2002, cocaine-related ED visits have increased by 33%.¹

Death after cocaine use is one of the five leading causes of death in the 15- to 44-year-old age group.¹⁶ Between 1990 and 1992, as many as 26.7% of all deaths in New York City were associated with the presence of cocaine or a cocaine metabolite in the blood or urine.¹⁶ More than 30% of these deaths were attributed to cocaine directly, and 65% involved traumatic injuries associated with cocaine.¹⁶ Cocaine overdose appears from surveys of users to be less associated with crack cocaine smoking than with intravenous use.¹⁷ Accidental overdose deaths have slightly decreased from its peak between 1993 and 1995 in New York.¹⁸ Regardless, cocaine alone or in combination with alcohol and/or an opiate was determined to be the cause of death in 69.5% of these cases.¹⁸ In a study of intravenous drug users in San Francisco, the use of heroin and cocaine together ("speedballs") was frequently associated with overdose.¹⁹ A survey of cocaine users in Brazil noted that 20% had experienced one or more episodes of overdose.²⁰ In Tennessee in 1993, more than 25% of reckless drivers who did not smell of alcohol were found to be intoxicated with cocaine alone or in combination with marijuana.⁴ Again, both the direct effects of cocaine and related trauma contribute to the high rate of cocaine-associated deaths.^{3,6,16} In 2001, cocaine was the most frequent cause of drug-related deaths reported to medical examiners in the United States.^{2,14}

Cocaine remains a major drug of abuse, with the majority coming into the United States from South and Central America.²¹ The DEA noted that in 2002, federal drug seizures of cocaine in Florida alone amounted to 26,258 kg.²¹ Acute and chronic cocaine toxicity represents a major challenge to the clinician. Cocaine's ability to cause significant multiorgan system dysfunction contributes to this challenge. Preventive care and new carefully tested approaches to therapy can help reduce the incidence and improve the outcome of patients with this modern affliction.

STRUCTURE/STRUCTURE-ACTIVITY RELATIONSHIPS

Cocaine is a naturally occurring drug; it is the principal active alkaloid that is derived from the leaves of the shrub *Erythroxylum coca*, found in South and Central America, India, and Java, and also from *Erythroxylum novogranatense*, found in South America. Coca leaves may be chewed or ingested as a tea (*mate de coca*).³ This is how the ancient Incas used and native South Americans still

currently use cocaine. Each coca leaf contains 0.1% to 0.9% cocaine by weight.^{3,22} A partly purified product, cocaine sulfate (also known as *pasta*, *basuco*, *basa*, *pitillo*, and *paste*) is made when coca leaves are mixed with water and dilute sulfuric acid. Coca paste is commonly mixed with tobacco and smoked in South America.^{3,22} Coca paste is often further refined to cocaine hydrochloride (an odorless, white, crystalline powder) by repetitive mixings with various solvents (e.g., kerosene, methyl alcohol, and sulfuric acid). Refined cocaine hydrochloride powder is 30% to 40% pure.^{3,22}

Cocaine hydrochloride is freely soluble in water and can be injected intravenously or readily absorbed across all mucous membranes. Alternatively, the free base of cocaine can be made by dissolving the hydrochloride salt in a solvent and separating and drying the precipitate. Cocaine free base is not water soluble and, thus, cannot be injected intravenously or readily absorbed across mucosal surfaces.^{3,13,22} Cocaine base, however, is lipophilic and rapidly absorbed across the alveolar-capillary and blood-brain barrier.

Free-basing is a process of converting cocaine hydrochloride back to cocaine base for smoking. Traditionally, free base was made by dissolving the hydrochloride salt in water, adding ammonia to remove the hydrochloride, adding ether to solubilize the base, and then letting the ether evaporate from the base.^{3,13} An alternative form of cocaine free base, crack is made by dissolving the hydrochloride salt in water, adding sodium bicarbonate (baking soda) to remove the hydrochloride, heating the mixture until the water evaporates, and cooling the free base into a soft mass that subsequently dries into a hard rock.^{3,13} Cocaine free base has a relatively low melting point as compared with the hydrochloride form (98°C versus 197°C) and is stable to pyrolysis.^{3,14} Thus, the free base can be heated, vaporized, and inhaled (smoked). The base is commonly smoked in a glass or regular pipe or mixed with tobacco or marijuana in cigarette form. If the ether is not fully evaporated from the free base prior to smoking, airway burns are a possibility.¹³ The hydrochloride form of cocaine breaks down with pyrolysis.⁹ The term *crack* comes from the popping sound that occurs when the rock is smoked.^{3,13,14} Due to ease of production, relative inexpense, ease of use, and rapid onset of effects after use, crack has become a very popular means of cocaine abuse.^{13,19} It also appears to be the most potent and addictive form of cocaine.^{13,14} Crack and free-base cocaine are 85% to 90% pure, whereas cocaine hydrochloride preparations are often adulterated with one or more of several compounds (e.g., sucrose, mannitol, lactose, quinine, caffeine, amphetamine, phencyclidine, talc, procaine, lidocaine, or strychnine).²³

The stimulant cocaine (benzoylmethylecgonine, C₁₇H₂₁NO₄) is an ester of benzoic acid and the amino alcohol base methylecgonine (Fig. 42-1).¹² Its molecular weight is 303.4. In its natural form, cocaine is a weak base with a pKa of 8.6.²⁴ The ester structure of cocaine predicts rapid hydrolysis by esterases and a short duration of action. Its structure is similar to other ester-type local anesthetics.¹²

FIGURE 42-1 The chemical structure of the alkaloid cocaine hydrochloride.

PHARMACOLOGY

Cocaine produces its clinical effects predominantly from reuptake blockade and enhanced presynaptic release of catecholamines (e.g., norepinephrine and dopamine) and serotonin from central and peripheral nerve terminals.^{3,24} Reuptake blockade of norepinephrine in the sympathetic nervous system innervation to the adrenal gland results in postsynaptic medullary release of catecholamines (predominantly epinephrine) and systemic sympathetic effects.²⁵ Reuptake inhibition of dopamine in the central nervous system (CNS) produces stimulation of both D₁- and D₂-dopamine receptors in mesocortical, mesolimbic (e.g., nucleus accumbens), and basal ganglia areas of the brain; this accounts for the euphoric, psychostimulatory, and motor effects from cocaine.^{12,26} Cocaine also enhances release of the excitatory amino acids glutamate and aspartate in the limbic system, which adds to its psychostimulatory effects.^{27,28} Reuptake inhibition with repetitive cocaine use leads to accelerated catabolism and depletion of presynaptic catecholamines and serotonin. In addition, compensatory processes work to down-regulate the overstimulated neuronal pathways. Cocaine craving and movement disorders (e.g., parkinsonism) likely occur from depletion of dopaminergic stores or a down-regulated dopamine pathway.¹²

Cocaine also causes marked local anesthetic effects from the blockade of membrane sodium channels (see Chapter 63).^{11,12,24} Sodium channel blockade is concentration, frequency, pH, and voltage dependent; block is greater at higher frequencies of stimulation, lower pH, and more positive membrane potentials.¹² Vasoconstrictive effects of cocaine will increase local drug concentration and membrane effects.¹² Cocaine may also inhibit potassium channels and sodium-calcium exchange mechanisms in some cellular membranes.²⁹

PHARMACOKINETICS

Cocaine is readily absorbed across all mucous membranes.^{3,12,14} The onset of action and peak effects depend on the dose and route of absorption. Mucosal and oral administration of cocaine result in a slower absorption, slower onset of action, later peak effect, and longer duration of action than the inhalation and intravenous routes.¹⁴ Although absorption is rapid after ingestion, the oral bioavailability of both the hydrochloride and

free-base forms are only 30% to 40%.³ After nasal insufflations of cocaine, the onset of effects occurs within 1 to 5 minutes.^{3,14} Constriction of nasal vessels inhibits and prolongs drug absorption, such that the duration of effects are extended, peak levels are blunted, and dose-dependent toxicity is reduced.^{13,30} When cocaine is snorted, chewed, or ingested, peak levels and effects occur within 30 to 120 minutes.^{3,24,30} The inhalation route produces a more rapid increase in plasma and brain cocaine levels and more intense euphoria than the nasal and oral routes; the cardiovascular effects are similar to those produced by an equivalent intravenous dose of cocaine.²² When inhaled and injected intravenously, the onset of action occurs within seconds, and peak effects occur within 3 to 5 minutes. The duration of effects typically lasts 5 to 15 minutes after inhalation and 20 to 60 minutes after intravenous use of cocaine.^{12,14,30} The rapid decrease in plasma and brain cocaine concentrations that follow an initial surge (i.e., brief duration of euphoria) probably accounts for the desire to reuse within 10 to 30 minutes of inhalant (crack) use.¹²

Although dependent on dose and route of administration, peak cocaine blood concentrations of 200 to 600 mg/mL are seen with typical doses (0.2 to 2 mg/kg or 10 to 140 mg).^{24,30} Peak blood concentrations of several thousand milligrams per milliliter have been reported in intoxicated patients.^{24,30} Blood cocaine concentrations averaged 4600 mg/mL in one study of 37 cocaine-related fatalities.³¹

Cocaine has a volume of distribution of 2 to 3 L/kg.^{24,30} About 35% to 45% of cocaine is rapidly metabolized by nonenzymatic hydrolysis to benzoylecgonine. Another 32% to 49% of cocaine is metabolized to ecgonine methyl ester by enzymatic hydrolysis with hepatic and plasma esterases (e.g., pseudocholinesterase). A small amount of the benzoylecgonine is metabolized on to ecgonine in a 24-hour period. Although these metabolites tend not to be very active, a small percentage of cocaine, particularly after toxic exposure, undergoes hepatic microsomal oxidative metabolism (*N*-demethylation) to norcocaine, a potentially active metabolite, and then to *N*-hydroxynorcocaine, a metabolite potentially toxic to the liver.^{24,30} Endogenous (genetic) loss or induced (e.g., by organophosphate pesticide exposure) loss of cholinesterase activity in a patient may result in a delay in metabolism of cocaine and may increase the toxic risk of a given exposure. Blood or plasma samples must be frozen, or fluoride or cholinesterase inhibitors must be added to samples, to prevent cocaine from being hydrolyzed to ecgonine methyl ester by serum cholinesterases.

The serum half-life of cocaine is approximately 30 to 90 minutes. The fact that only 1% to 9% of cocaine appears in the urine unchanged (dependent on urine pH) makes the analysis of the major cocaine metabolites benzoylecgonine and ecgonine more useful for diagnostic and forensic purposes. Benzoylecgonine and ecgonine have serum half-lives of approximately 4 to 6 hours and 3 to 4 hours, respectively.^{12,24,30}

Intravenous use of cocaine alone or in combination with heroin, benzodiazepines, or other sedative-hypnotics

is commonly seen. As previously noted, the intravenous use of heroin in combination with cocaine is called “speedballing” and is thought to be responsible for 12% to 15% of toxic cocaine episodes managed in EDs in the United States.¹ The combined use of ethanol and cocaine facilitates the formation of cocaethylene.³² This potent cocaine metabolite has a half-life of approximately 2 hours. Animal studies and human epidemiologic studies suggest that cocaethylene is more toxic to the brain and heart than cocaine or its usual metabolites.³³ The risk of sudden death is 21.5-fold greater with the combined use of ethanol and cocaine than with cocaine use alone.³³ The exact contribution of cocaethylene to this increased toxicity in humans is controversial.³⁴ In a randomized, double-blind trial, daily oral cocaine treatment at doses without subjective effects or signs of toxicity significantly decreased physiologic responses to intravenous cocaine.³⁵ Whether this is a form of tachyphylaxis is not clear.

TOXICOLOGY

The toxicity of cocaine comes from the extension of its pharmacology and mechanisms of action. Acute toxicity is frequently noted from CNS and sympathetic nervous system overstimulation. Toxic cardiac manifestations are likely from cocaine’s effect on sodium and potassium exchange channels along with its catecholaminergic effects.

In addition to acute toxic effects, binge use depletes central and peripheral nervous system catecholamines and serotonin, resulting in depression and potential reduced vascular tone. Cocaine withdrawal may represent an extension of this type of depleted state. The toxicity associated with cocaine abuse often results in ED and ICU admissions.

CLINICAL MANIFESTATIONS

Cocaine is capable of inducing toxicities in many organ systems. Both acute and chronic abnormalities have been reported with cocaine exposures. Studies have not established the exact prevalence or incidence of the toxicities, which are summarized in Table 42-1.

Cardiovascular

Cocaine use and abuse is frequently associated with a wide array of cardiovascular complications.^{14,36,37} Acute and chronic cardiovascular toxicity results from an exaggeration of both β - and α -adrenergic receptor stimulation, augmented myocardial cellular calcium influx and elevation of cytosolic free calcium concentrations, and increased secondary messenger (e.g., phospholipase C, inositol triphosphate) activation.³⁷

Chest pain is the most frequent presenting complaint of patients who have used cocaine and is responsible for approximately 16% of cocaine admissions to EDs.^{5,14,38-41} Although most of cocaine-associated chest pain is

noncardiac in origin, ruling out myocardial ischemia is the principal concern when such patients present to the ED.^{14,41} This is because acute myocardial infarction (MI) is the most frequently reported cardiac consequence of cocaine abuse.^{41,42} Prospective studies have shown that approximately 6% of patients with cocaine-associated chest pain that present to the ED have an MI by enzyme analysis.^{41,43} The risk for MI is increased 24-fold in the hour following use of cocaine.^{14,44} Cocaine-associated MI is not route, dose, or duration dependent; it occurs following all routes of administration, with a wide range of doses, and occurs in both first-time and long-term users.^{14,41} Cocaine-associated MI cannot be distinguished from noncardiac chest pain on the basis of chest pain location, quality, duration, associated symptoms, or the presence of traditional risk factors for atherosclerosis.^{14,41,43} A recent retrospective study of patients with cocaine-associated chest pain found that a 9- to 12-hour period of ED observation without evidence of ischemic or cardiac complications predicted a very low risk for death or MI for a 30-day period after ED discharge.⁴⁵

Several mechanisms may lead to cocaine-induced MI.⁴⁶ These include increased myocardial oxygen demand in the setting of limited myocardial oxygen supply, coronary artery vasoconstriction, enhanced platelet aggregation, in situ coronary artery thrombosis formation, left ventricular hypertrophy, and accelerated atherosclerosis.^{14,37,41,46} Increased oxygen demand is created by cocaine-induced tachycardia, enhanced contractility, and increased blood pressure (enhanced afterload). Decreased oxygen supply is the result of coronary vasoconstriction, which is greatest in diseased coronary artery segments.⁴⁷ Cocaine-induced coronary artery vasoconstriction is mediated by α -adrenergic stimulation, as evidenced by its reversal after administration of the α -adrenergic receptor antagonist phentolamine and exacerbation with β -adrenergic antagonist therapy.^{48,49} Cocaine potentiates vasoconstriction by stimulating release of endothelin and thromboxane (vasoconstrictors) and impairing release of nitric oxide and prostacyclin (vasodilators) from endothelial cells.^{50,51} Coronary artery spasm leading to MI has been widely reported in cocaine users.³⁸ Both epicardial and microvascular cardiac flow is impaired by cocaine.⁵² Enhanced platelet activity occurs from α -adrenergic-mediated increases in platelet aggregation and increased releases of thromboxane and adenosine diphosphate.^{53,54} In situ thrombosis formation may occur from cocaine-induced vasoconstriction and resultant disruption in the endothelial surface (i.e., plaque rupture).⁵⁵ In addition, concentrations of antithrombin III and protein C are decreased and concentrations of tissue plasminogen activator inhibitor are increased after cocaine use.^{3,56} Cocaine may promote atherosclerosis by enhancing endothelial cell permeability to low-density lipoprotein and enhancing endothelial cell expression of adhesion molecules and leukocyte migration to their surface.^{14,57,58}

Most patients with cocaine-associated MI are young (mean age 38 years), nonwhite (72%) tobacco smokers (91%). They have a history of cocaine use within the past

**TABLE 42-1** Major Noninfectious Medical Complications Associated with Cocaine Use

COMPLICATION	FREQUENCY AND MAGNITUDE OF EVENTS*	COMPLICATION	FREQUENCY AND MAGNITUDE OF EVENTS*
Respiratory		Cardiac

*Estimated.

+, rarely reported; ++, commonly reported; +++, frequently seen with chronic use or overdose.

24 hours (88%), have a history of repeated use of cocaine (mean duration of use of 5 years), and do not have other traditional risk factors for atherosclerosis.^{37,14,41,43,44} Q-wave and non-Q-wave infarctions are seen with equal frequency.¹⁴ Although most patients have the onset of pain within an hour of cocaine use, MI has been reported several days after use.⁴²⁻⁴⁴ MI has also been associated with therapeutic doses and use of cocaine and in the setting of cocaine withdrawal.^{41,42} Angiographic studies of these patients have demonstrated both atherosclerotic and normal coronary arteries with about equal frequency.^{13,14,59} Left ventricular hypertrophy, hypertension, and coronary atherosclerosis are thought to occur as a result of chronic cocaine use. Accelerated atherosclerosis is found in animals that are administered cocaine chronically and in 40% of autopsies of young patients who used cocaine regularly.^{3,60}

Early cardiovascular complications occur in up to 36% of patients with cocaine-associated MI.^{14,41,60} Ventricular arrhythmias occur in 4% to 17%, congestive heart failure in 5% to 7%, and death in less than 2%.^{14,60} Most complications (90%) occur within 12 hours of hospital arrival, and death is extremely unlikely for those patients who are alive on hospital arrival.^{41,60}

The cardiovascular toxicity of cocaine is potentiated by concomitant cigarette smoking or use of alcohol. Similar to cocaine, cigarette smoking produces coronary vasoconstriction by an α -adrenergic mechanism.⁶¹ Simultaneous use of cocaine and cigarettes produces synergistic increases in blood pressure, heart rate, and coronary vasoconstriction.^{41,61} When cocaine is used concomitantly with alcohol, the heart rate increase is greater than when each drug is used alone.⁶² Patients who die of a combined overdose of cocaine and ethanol

have lower blood cocaine concentrations than those who die from cocaine alone.^{14,63} The hepatic transesterification product cocaethylene is considered to be largely responsible for the synergistic toxicity that occurs when cocaine and ethanol are used in close proximity.⁶⁴ Animal models have demonstrated that cocaethylene is more lethal than cocaine.^{14,65} Cocaethylene increases myocardial oxygen demand by producing hypertension and increased vascular resistance; it does not have direct effects on coronary blood flow.⁶⁶

A number of clinical reports have described left ventricular hypertrophy, systolic dysfunction, dilated cardiomyopathy and myocarditis from long-term use of cocaine. Myocardial hypertrophy is frequently discovered at autopsy in patients who die from cocaine toxicity.⁶⁷ Seven percent of long-term abusers of cocaine demonstrate left ventricular systolic dysfunction by radionuclide ventriculography.^{14,68} Numerous mechanisms may explain cocaine-associated cardiomyopathy. Repetitive elevations of plasma catecholamines as occur with repetitive cocaine use may produce subendocardial contraction band necrosis, mononuclear cell myocardial infiltration, myocytolysis, myocarditis, and resultant fibrosis.⁶⁹ These effects may be reversible with discontinuation of cocaine use. Alternatively, cocaine-induced cardiomyopathy may be the result of repetitive episodes of ischemia or infarction, long-standing hypertension, an immune-mediated or hypersensitivity reaction to cocaine, altered myocyte collagen production, or from the toxic effects of cocaine adulterants or contaminants, including heavy metals such as manganese.^{14,37}

Because of cocaine's local anesthetic properties and its effects on catecholamines, it is not surprising that both cardiac conduction disturbances and arrhythmias are common in patients who abuse cocaine. Although sinus bradycardia, complete heart block, and bundle branch block have been described, supraventricular and ventricular tachyarrhythmias occur most commonly.^{14,37} At low doses, sinus bradycardia and ectopic rhythms may occur.⁷⁰ At high doses, cocaine produces direct sodium and potassium channel blockade, prolonged QRS and QTc intervals and ST-T wave changes on electrocardiograms (ECGs), and resultant intraventricular conduction delays and reentrant ventricular dysrhythmias (e.g., ventricular tachycardia and torsades de pointes).^{14,29,37,70} Enhanced sympathetic stimulation will increase myocardial intracellular calcium concentrations, enhance automaticity, produce afterdepolarizations, and possibly lead to ectopic rhythms (e.g., tachyarrhythmias).^{14,37} Cardiac conduction abnormalities and arrhythmias occur most commonly in the context of myocardial ischemia, profound metabolic acidosis, seizures, hypoxia, or hypotension.^{14,37,71} These latter effects minimally play a potentiating role and may often be the primary cause of cardiac toxicity from cocaine.

Acute aortic dissection and rupture and papillary muscle rupture have been associated with cocaine use in otherwise healthy patients.⁷² Endocarditis is a frequent complication of intravenous drug use, and thus is seen in the patient abusing intravenous cocaine.⁷³

Central Nervous System

Neurologic complaints occur in 17% to 42% of patients with cocaine-related medical problems necessitating ED treatment in the United States.^{3,5,39,40} Altered mental status, anxiety, paranoid behavior, dizziness, headaches, paresthesias, tremors, seizures, strokes, transient ischemic attacks, and coma represent the majority of these neurologic complaints.⁷⁴ Cocaine-associated strokes may be ischemic or hemorrhagic. The mechanisms of cerebrovascular accidents are multifactorial and include cerebral vasoconstriction, thrombosis, vasculitis, and loss of vasomotor autoregulation in the setting of acute hypertension, and embolism of particulate matter.^{3,74-77} Increased activity of platelets and other mediators of thrombosis potentiate the likelihood of an ischemic stroke. Cocaine-induced agitated delirium may result from disrupted dopaminergic function and is often associated with fulminant hyperthermia, rhabdomyolysis, and sudden death.⁷⁸

Seizures are a very common manifestation of cocaine toxicity and have been reported in up to 9% of ED patients with cocaine toxicity.³⁹ Drug-induced seizures are frequently caused by stimulants. Cocaine-induced seizures accounted for the increase in all drug-induced seizure cases from 4% in 1981 to 23% in 1988.⁷⁹ Although not fully elucidated, the mechanism of cocaine-induced seizures involves interaction of the drug with voltage-dependent sodium channels and numerous neurotransmitter systems. It appears that 5-HT₂-serotonergic, D₁-dopaminergic, α_1 - and α_2 -adrenergic, GABA_A, and glutamatergic receptors are all involved in cocaine-induced seizures.⁸⁰ Human and animal data suggest that cocaine-induced seizures are usually generalized, single seizures without long-lasting neurologic consequences.^{81,82} The majority of cocaine-related seizures are associated with intravenous injection or inhalation of cocaine. In one study, Pascual-Leone and colleagues found that when habitual cocaine abuse was associated with seizures, computed tomography and electroencephalography frequently showed diffuse brain atrophy and diffuse slowing, respectively.⁸¹ Multiple or focal seizures are often seen with acute intracerebral complications (e.g., hemorrhage) or with the toxic manifestations of other medications.⁸¹ Recurrent generalized seizures have been reported in children after mucosal application of the topical anesthetic tetracaine-adrenaline-cocaine. Seizures may be a major determinant of cocaine lethality.⁸³ This justifies aggressive immediate treatment of sustained cocaine-induced seizures with the correction of seizure-associated metabolic acidosis and hypoxemia. Repetitive or prolonged seizures attributed to the use of cocaine indicate the need for further diagnostic workup that includes computed tomography of the brain and, possibly, lumbar puncture.

Cerebral vasculitis, headaches, toxic encephalopathies, transient ischemic events, migraine-like events, and a wide array of extrapyramidal side effects (e.g., acute dystonic reactions, Tourette's syndrome, akathisia, choreoathetosis, tardive dyskinesia) have been reported

with both acute and chronic use of cocaine.^{3,13,84,85} Choreoathetoid movements associated with crack use have been termed “crack dancing.”⁸⁵ Extrapyramidal movement disorders occur from dopamine disturbances in the basal ganglia; choreoathetosis is from an overabundance of dopamine, and acute dystonia from dopamine deficiency. As expected, cerebral hemorrhage, cerebral infarction, and cerebral vasculitis are associated with significant morbidity and mortality among cocaine users. Kaku and Lowenstein reported that 34% of patients between the ages of 15 and 44 years with a diagnosis of ischemic or hemorrhagic stroke had associated drug abuse. Cocaine and amphetamines accounted for the largest percentage of cases.⁸⁶ Psychological dependence and a cocaine withdrawal or abstinence syndrome have been reported.^{12,24} The cocaine abstinence syndrome has been described as having three phases.²⁴ The first phase is a “crash” that lasts up to 4 days and is characterized by dysphoria, depression, irritability, anxiety, and insomnia followed by hypersomnolence, exhaustion, and drug craving. The second phase lasts from 1 to 10 weeks and is characterized by anergia, anxiety, listlessness, and drug craving. The third phase, which has been called the “extinction phase,” may last indefinitely and is associated with normalization of mood and actions but also episodic drug craving that is often triggered by environmental cues.²⁴ Acute psychiatric disturbances, including agitation, anxiety, depression, psychosis, paranoia, and suicidal ideation have been widely reported in cocaine users.⁸⁷ The cocaine “washed out” syndrome is similar to the “crash” associated with the abstinence syndrome and occurs soon after a several day binge of cocaine.¹² Patients are lethargic with normal vital signs and sleep deeply for a period of 24 to 48 hours. The syndrome is considered to result from an acute depletion of catecholamines that follows a several day binge of cocaine.

Pulmonary

Cocaine can produce a wide range of pulmonary complications (see Table 42-1).^{88,89} Cocaine-induced pulmonary disturbances occur in up to 25% of users and often result in ED and ICU admissions.^{3,90} Primary respiratory depression or reduced respiratory drive has been associated with toxic cocaine exposures. This has occurred both in conjunction with and independent of cardiac arrhythmias and seizure-induced cardiovascular collapse.

Cocaine smoking is associated with significant barotrauma and may result in pneumothorax, pneumomediastinum, pneumopericardium, and subcutaneous air.^{3,89} The self-application of a Valsalva maneuver (to increase positive airway or intrapleural pressures) by cocaine smokers seeking enhancement of its euphoric effects may precipitate barotraumatic complications. High positive airway pressures can also be generated by an “assistant” who blows back into the cocaine pipe being used. Thermal injury from smoking cocaine may also contribute to the development of barotrauma.

Noncardiogenic pulmonary edema is associated with cocaine use.^{88,89,91} Although pulmonary edema may be cardiogenic and occur secondary to acute or chronic left ventricular failure from increased vascular resistance, the majority of cases appear to be caused by a noncardiogenic “capillary leak” syndrome.⁹² Both neurogenic and non-neurogenic mechanisms for cocaine-induced noncardiogenic pulmonary edema can be postulated. Cocaine may directly injure pulmonary endothelium and increase local capillary permeability.⁹¹

Exacerbation of reversible airway diseases, including asthma, has been reported in association with the use of cocaine. These exacerbations may be the consequences of heat or of exposure to the impurities in cocaine, since its catecholamine effects would not be expected to produce airway bronchospasm.^{23,88,89} An increase in bronchial hyperactivity has been seen in patients who inhaled “rebujo” (vaporized heroin and cocaine on aluminum foil compound) compared with controls using lung function tests before and after methacholine challenge.⁹³

Dyspnea is a frequent presenting complaint of patients with cocaine-induced toxicity, occurring in 3% to 22% of cases in various series.^{3,5,39,40} Hemoptysis, bronchitis, and expectoration of carbonaceous sputum are frequent complaints of cocaine users in the ED. An increased incidence of pulmonary hypertension, pulmonary infarction, pulmonary hemorrhage, and pulmonary foreign body granulomas have been reported in cocaine users.^{3,89} Bronchiolitis obliterans and organizing pneumonia (BOOP) associated with fever and dyspnea may also occur.^{88,89,94} Loss of a functional alveolocapillary interface as measured by a reduction in carbon monoxide diffusion capacity has been observed in studies of frequent cocaine users.⁸⁸ The interpretation of this finding is complicated by other pulmonary exposures to tobacco and marijuana in the population studied. Other studies have suggested that the reduction can be attributed to tobacco use alone.⁹⁵

A specific syndrome known as “crack lung” is a hypersensitivity pneumonitis associated with the smoking of cocaine; it is characterized by fever, chest pain, dyspnea, wheezing, hemoptysis, productive cough, and diffuse interstitial and alveolar infiltrates.^{3,89,96} Clinically inapparent alveolar hemorrhage has been demonstrated to occur frequently in crack cocaine users.⁹⁷ Again, whether these manifestations of pulmonary toxicities are related to cocaine exposure itself, to the inhalation of superheated adulterants, or to exposure to combustion products is unknown.

Hyperthermia

The majority of cocaine deaths are associated with drug-induced hyperthermia.⁹⁸⁻¹⁰⁰ Cocaine may produce hyperthermia from increased heat production (e.g., psychomotor agitation, neuromuscular hyperactivity, seizures), impaired heat dissipation (e.g., cutaneous vasoconstriction), and altered thermoregulation (e.g., hypothalamic dysfunction). Although psychomotor

agitation and seizures are the principal etiologies of hyperthermia, temperature elevations from cocaine have been reported in their absence.^{59,60,101,102} Altered thermoregulation may be the result of an altered core temperature set point from D₂-dopamine or 5-HT₂-serotonin receptor agonism effects in the hypothalamus.^{60,102} In general, the duration and severity of hyperthermia from drug-associated heatstroke are correlated closely with mortality.⁹⁸ Patient dehydration and high ambient temperature will increase the lethal effects of cocaine and other drugs. Interestingly, in one study, it was shown that mortality from cocaine in New York City increased at higher ambient temperatures.¹⁰³ Like exertional heatstroke, hyperthermia from cocaine toxicity may precipitate a cascade of complications that includes agitated delirium, coma, seizures, cerebral edema, rhabdomyolysis, acute renal failure, hepatocellular necrosis, disseminated intravascular coagulation, metabolic acidosis, and cardiovascular collapse.^{98,101,102,104} Rectal temperatures as high as 45.6° C (104° F to 114.1° F) have been reported.¹⁰²

Rhabdomyolysis and Renal Failure

Similar to the vascular beds of other organ systems, cocaine produces vasoconstriction as well as thrombosis of both large and small skeletal muscle and renal vessels; ischemia and cell death may ensue with the amount of tissue injury dependent on the size of the occluded vessel.^{3,105} Cocaine-associated rhabdomyolysis may result from ischemia, seizures, and trauma.^{101,104} Approximately one third of patients with cocaine-associated rhabdomyolysis develop acute renal failure.¹⁰¹ Renal failure usually occurs from acute tubular necrosis, either from direct cocaine-induced renal cortical vasoconstriction or from rhabdomyolysis with myoglobinuria and renal tubular obstruction. The presence of profound hypotension, hyperpyrexia, and marked elevations of serum creatine kinase levels at admission are useful for predicting renal failure.¹⁰¹ Cocaine-induced rhabdomyolysis is often associated with seizures, coma, hypotension, arrhythmia, or cardiac arrest. In one series, six of seven patients who developed cocaine-induced rhabdomyolysis, disseminated intravascular coagulation, and renal failure died.¹⁰¹ The systemic release of tissue thromboplastin from local ischemic injury may partly precipitate disseminated intravascular coagulation.^{3,101} Chest wall, skeletal muscle rhabdomyolysis is felt to account for the majority of cocaine-associated chest pain and is often mistaken for myocardial ischemia.^{3,14,41}

Head and Neck

Although rarely life-threatening, head and neck complications of cocaine toxicity are not uncommon. An ophthalmologic condition called “crack eye” has been described; it is characterized by pain, photophobia, lacrimation, chemosis, and hyperemia in association with corneal epithelial defects. In addition, microbial keratitis may complicate the syndrome of crack eye, leading to potential long-term corneal alterations.¹⁰⁶ Central retinal

artery occlusion and blindness have been associated with cocaine use.¹⁰⁷

Chronic sinusitis as a result of cocaine abuse, including osteolytic sinusitis and secondary bilateral optic nerve involvement, has been described.¹⁰⁸ Midline granulomas and loss of olfaction have also been reported with cocaine use. Acute epiglottitis has followed crack cocaine inhalation. It is not known whether epiglottitis is a direct effect of cocaine or is induced by the inhalation of hot gases. Cocaine-induced dental erosions and gingival necrosis have been reported.¹⁰⁹ A perforated nasal septum is commonly noted with chronic nasal inhalation of cocaine. At least one case of the pulmonary aspiration of a fragment of nasal septum has been described.⁸⁸

Gastrointestinal

Gastrointestinal (GI) tract ischemic injury may occur when cocaine is used by all routes of administration.³ The fear of GI tract injury is heightened when “body stuffers” (people who ingest a relatively small amount of loosely wrapped drugs to avoid arrest) or “body packers” or “mules” (people who ingest large amounts of well-wrapped drugs to smuggle them across borders) ingest the drug. Cocaine ingestion has been associated with bowel obstruction, ischemia, necrosis, and perforation.¹¹⁰⁻¹¹² Although it commonly occurs in the small bowel, obstruction and perforation may occur in the esophagus.¹¹³ Ischemia and perforation occur in the small or large bowel and are usually focal and segmental.³ Patients with cocaine-induced bowel ischemia will often manifest constant pain in the midabdomen and may have associated low-grade fever and leukocytosis.^{3,114} Symptomatic body stuffers or body packers may present with a seizure, vomiting, abdominal pain, an adrenergic crisis, or cardiac arrest.^{115,116} Acute pyloric and GI perforations have been reported after prolonged crack cocaine smoking.¹¹¹ The intense vasoconstriction from stimulation of α -adrenergic receptors in the mesenteric vasculature is believed to contribute to focal tissue ischemia and perforation. Thermal injury of the esophagus has been reported after smoking free-base cocaine.¹¹² Nontraumatic splenic infarction, hemorrhage, and hematomas have been reported from cocaine use.^{3,117}

Pregnancy

Significant alteration in menstrual cycle function, including amenorrhea and infertility, have been noted with cocaine abuse.¹¹⁸ If the female cocaine user becomes pregnant, increased risk for placental abruption exists.¹¹⁹ Cocaine causes uterine contractions, decreased uterine blood flow, and constriction of placental blood flow.^{3,120} As a result, premature rupture of membranes, spontaneous abortion, pregnancy-induced hypertension, intrauterine growth retardation, precipitous delivery, and fetal death have been associated with cocaine use.¹¹⁹ A meta-analysis suggests that increased congenital malformations of the limbs, the GI tract, and the cardiovascular and neurologic systems occur in children of cocaine users.¹²¹ Congenital urinary tract anomalies

and bilateral cleft lip may be associated with maternal cocaine use.^{119,121,122} Abnormal ventilatory patterns and increased incidence of sudden infant death syndrome have been reported with maternal cocaine use.^{123,124}

Other neurobehavioral abnormalities in the neonate, including tremulousness and an increased startle reflex (“crack baby” behavior), have been noted after maternal cocaine use.^{119,124} Infants born to women who were heavy cocaine users during pregnancy demonstrate altered “executive” functioning at 9.5 to 12.5 months of age.¹²⁴ Brain dopamine and serotonin concentrations and pathways are abnormal at birth in rats that have significant prenatal exposure to cocaine. These neurotransmitter concentrations return to normal as the rat ages.¹²⁵ The duration and long-term implications of these neurobehavioral abnormalities are unknown. Both cocaine and cocaethylene are found in breast milk and may be transferred to breast-fed infants.¹²⁶

Urologic Effects

Several cases of impotence and priapism from acute cocaine use have been reported. Intranasal, intra-urethral, and topical application (to the glans penis) of cocaine have all been reported to cause priapism.¹²⁷ The risk for priapism is greater when cocaine is used in combination with trazodone.¹²⁸

Hepatic

Oxidative processes centered around the tropane nitrogen are responsible for about 10% of cocaine metabolism, using the cytochrome P-450 enzyme system within the liver.^{30,129} This minor pathway appears to be responsible for hepatic toxicity. It produces norcocaine, norcocaine nitroxide, hydrogen peroxide, and superoxide radicals.^{129,130} These products are thought to reduce hepatocyte nicotinamide-adenine dinucleotide phosphate (NADPH) and glutathione levels.¹²⁹

The formation of lipid peroxidation and the resultant superoxide or hydroxyl radical injury are believed to lead to the intrinsic hepatotoxicity seen with cocaine abuse.¹²⁹ A case of fulminant liver failure that recovered after snorting large doses of cocaine has been reported with centrilobular necrosis.¹³¹ Agents that deplete NADPH and intracellular glutathione (e.g., acetaminophen) can enhance the risk for cocaine hepatotoxicity. Human cocaine hepatotoxicity is seen most frequently as necrosis in zone 3 of the liver that corresponds to the cytochrome P-450 distribution.^{129,130} Although many case reports of cocaine-induced hepatotoxicity exist and hepatocyte tissue cultures confirm intrinsic toxicity, the clinical incidence of cocaine hepatotoxicity is unknown, but is probably low. The explanation for the low frequency of hepatitis secondary to cocaine toxicity is as yet unknown, and the determination of its exact incidence is complicated by the high prevalence of viral and alcohol-induced liver disease in this patient population. Most instances of toxic hepatitis (manifested as hepatic transaminitis) attributed to cocaine will occur in the setting of fulminant hyperthermia and multiorgan dysfunction.

Hematologic

The association of disseminated intravascular coagulation, rhabdomyolysis, and renal failure has been discussed.¹⁰¹ Severe destructive thrombocytopenia unrelated to retroviral infection has been reported in a small series of both intravenous and inhalation cocaine users.¹³² Cocaine-associated thrombocytopenia has been described and has a clinical course similar to that of immunopathic thrombocytopenic purpura. In one series, five of six patients with thrombocytopenia responded favorably to corticosteroids. The sixth patient had a partial response to corticosteroids and a complete response to splenectomy.¹³² Whether this thrombocytopenia reflects a direct or an indirect immunologic stimulus from cocaine or a contaminant is not known. In addition, increased platelet aggregation is believed to contribute to thrombocytopenia in some cocaine users.

In a study of 19 patients presenting to an ED with acute cocaine use, hemoglobin and hematocrit levels were significantly elevated, but no evidence of erythrocytosis was seen. Male patients presenting with chest pain were more likely than females to demonstrate these effects.¹³³

Endocrine

Thyroid function tests are not significantly different from normal values in heavy users of cocaine. Hyperprolactinemia with resultant galactorrhea has been described in chronic cocaine abusers. Higher peak and trough levels of prolactin-releasing factor have also been reported in male cocaine users with hyperprolactinemia.¹¹⁸ In one study, prolactin levels remained elevated for 4 weeks in men and women during hospitalization for cocaine withdrawal.⁶⁹ The persistent elevation of prolactin was attributed to cocaine-induced derangement in the dopaminergic neural regulatory systems. In this same study, levels of plasma luteinizing hormone, testosterone, and cortisol were found to be within the normal range. Chronic cocaine use also alters plasma growth hormone levels, dexamethasone suppression of cortisol, and thyroid-stimulating hormone response to thyroid-releasing hormone.¹³⁴ Many of these neuroendocrine abnormalities are augmented when cocaine abuse is combined with ethyl alcohol.¹³⁵ The clinical importance of these findings is unclear, but they may account for the impotence and gynecomastia reported in men who chronically abuse cocaine.

DIAGNOSIS

The diagnosis of cocaine toxicity is based on a suggestive history, physical findings consistent with the known toxicity of cocaine (e.g., sympathomimetic effects), and laboratory testing that confirms the presence of cocaine. The physical examination may need to include a thorough cavity search (e.g., vaginal and rectal examinations) when body packing or body stuffing is suspected.

Laboratory Testing

If the history of use is clear and symptoms or signs of intoxication are mild, laboratory testing is often unnecessary. If patients have moderate to severe toxic effects, routine laboratory investigations should include a complete blood count; measurements of electrolytes, blood urea nitrogen, creatinine, glucose, creatine phosphokinase (CPK), or troponin T or I; and a urinalysis. The diagnosis of acute MI in the setting of cocaine-associated chest pain is most accurately made with serial measurements of troponin T or I.⁴¹ Troponin measurements are more specific than CPK-MB measurements; the latter can be falsely elevated with concomitant cocaine-associated rhabdomyolysis.^{14,41,136} Patients with agitated delirium, seizures, hyperthermia, or severe rhabdomyolysis should have liver function tests, calcium, phosphate, and coagulation (e.g., prothrombin time, international normalized ratio, disseminated intravascular coagulation [DIC] screen) parameters measured. Arterial blood gas analysis and lactate concentrations may be helpful for patients with significant toxicity.

Analysis of both blood and urine for cocaine and its metabolites can be readily and routinely performed at most hospitals. Testing of saliva, hair, meconium, gastric aspirates, and breast milk can also be performed, if necessary. An enzyme-linked immunoassay directed against benzoylecgonine is useful for the rapid, qualitative screening of samples for cocaine and its metabolites. This method usually detects benzoylecgonine in body fluids at or above a concentration of 300 ng/mL.³⁰ False-positive results are rare. Other screening tests include thin-layer and high-pressure liquid chromatography. Gas chromatography followed by mass spectrometry (GC-MS) of urine or blood represents one of the most sensitive and specific assays available for identifying cocaine and its metabolites and can be used to confirm the presence of cocaine in a body fluid specimen. Quantification of cocaine and its major metabolites in saliva using GC-MS have been reported.¹³⁷ Typically, cocaine metabolites will be detected in the urine for 48 to 72 hours after cocaine use. Rarely, heavy use may allow metabolite detection for up to 22 days.^{138,139} Quantification of cocaine and its metabolites from body fluids is generally not recommended because no correlation has been found between cocaine or metabolite levels and the severity of clinical effects and mortality.^{85,140} Cocaine concentrations in tissues of patients who die from cocaine intoxication vary greatly, depending on the dose, route of administration, period of survival, and manner of storage of specimens prior to analysis.³⁰

Other Laboratory Testing

A chest radiograph and ECG should be performed on all patients with chest pain, cardiopulmonary complaints, or moderate to severe toxicity from cocaine. Arrhythmias, conduction disturbances, and repolarization abnormalities (e.g., prolonged QRS and QTc intervals) can be readily identified on the ECG. The ability to detect acute MI on the ECG, however, is significantly more limited.

The ECG is abnormal in 56% to 84% of patients with cocaine-associated chest pain, yet its sensitivity and positive predictive value for detecting acute MI are only 36% and 18%, respectively.^{41,43,141,142} Up to 43% of patients with cocaine-associated chest pain that are determined subsequently not to have an MI meet ECG criteria for thrombolytic therapy.^{41,43,141}

A normal ECG has greater diagnostic utility for those with cocaine-associated chest pain. The specificity and negative predictive value of the ECG for ruling out acute MI are 90% and 96%, respectively.¹⁴¹ A normal ECG in a patient with cocaine-associated chest pain, however, cannot be used to rule out MI.⁴³

Chest radiography is used to facilitate diagnosis of pneumothorax, pneumopericardium, pneumomediastinum, pneumonia, "crack lung," pulmonary edema, or pulmonary hemorrhage or infarct. Abdominal plain films may be useful as a screening tool to detect the presence of foreign bodies in a suspected body packer. Plain abdominal radiography has a sensitivity of 85% to 90%.^{115,143} In contrast, plain abdominal radiography is not useful or recommended to detect the presence of drug packets in a "body stuffer."¹⁴⁴ Contrast-enhanced computed tomography (CT) or barium-enhanced radiography are recommended when plain radiography is negative and clinical suspicion for ingested or retained packets is high.¹¹⁵ The incidence of false-positive and -negative results with contrast-enhanced radiography has been reported to be 4%.¹⁴⁵ Head CT imaging should be performed for patients with recurrent seizures, headache, or altered mental status associated with cocaine to rule out intracerebral hemorrhage. Lumbar puncture may be necessary to rule out subarachnoid hemorrhage. Chest and abdominal CT imaging with oral and intravenous contrast may be necessary for patients with significant chest, back, and abdominal pain to evaluate for the presence of a vascular catastrophe (e.g., aortic dissection) or pulmonary, renal, or GI tract hemorrhage, ischemia, or infarct.

Differential Diagnosis

Cocaine may produce effects similar to those of other toxicants, such as sympathomimetic drugs (e.g., amphetamines, methylxanthines, nicotine, ephedrine, β - and α -adrenergic agonists, monoamine oxidase inhibitors), central hallucinogens (e.g., tryptamine derivatives, phenylpiperidine, lysergic acid diethylamide, hallucinogenic amphetamines), drug withdrawal states (e.g., alcohol and sedative-hypnotic withdrawal), metabolic poisons (e.g., salicylates, dinitrophenol), psychotropics (e.g., cyclic antidepressants, lithium, antipsychotics, amantadine), membrane-active drugs (e.g., local anesthetics and antiarrhythmics), and certain drug-associated syndromes (e.g., malignant hyperthermia, serotonin syndrome, and neuroleptic malignant syndrome). Certain medical emergencies may present in a similar manner, such as endocrinologic disorders (e.g., pheochromocytoma, thyrotoxicosis, hypoglycemia), infections (e.g., meningococcal meningitis, sepsis, tetanus), neuropsychiatric disorders (e.g., paranoid schizophrenia, bipolar disorder, intra-

cerebral hemorrhage, head trauma, status epilepticus), and environmental disorders (e.g., exertional and non-exertional heatstroke).

MANAGEMENT

Table 42-2 outlines an algorithm for the general approach to patients with suspected cocaine toxicity. Prospective human studies evaluating different treatment options for such patients are lacking. Thus, recommendations are based on the findings from animal studies and small series of human poisonings with cocaine. The initial management strategy is to institute airway, breathing, and circulatory support as necessary. Supplemental oxygen, vascular access, and continuous cardiac and respiratory monitoring should be provided rapidly. All patients with altered mental status and seizures should have their serum glucose checked or be given dextrose infusion for possible neuroglycopenia. A critical component to successful management is to obtain a core (i.e., rectal) temperature early and treat hyperthermia promptly. Aggressive control of seizures and psychomotor agitation are equally important, particularly since these manifestations often precipitate cocaine-associated hyperthermia. After initial supportive care has been provided, subsequent treatment will depend on the signs, symptoms, and organ system(s) affected. Early GI decontamination should be strongly considered for patients who have ingested cocaine. Activated charcoal with or without a cathartic is administered (1 g/kg body weight) initially; other GI decontamination modalities (e.g., whole bowel irrigation) are also recommended for body stuffers and packers.^{115,146} Specific measures for each complication are discussed below. Even patients with cocaine-induced brain death have been successfully stabilized so that organs can be harvested for transplantation.¹⁴⁷

Given the relatively large volume of distribution and short elimination half-life, enhanced elimination techniques (e.g., urine acidification, hemodialysis) are unlikely to improve the clearance of cocaine and are also not necessary. These approaches have not been formally studied in humans. No specific antidotes exist. However, efforts to develop immunologic ways to bind or neutralize cocaine with antibodies, FAB fragments, vaccines, and specific dopamine receptor antagonists are ongoing and would have potential utility in treating both acute toxicity and drug addiction.^{148,149}

Cardiovascular Toxicity

As a result of the relatively short half-life of cocaine and its metabolites, supportive care with minimal pharmacologic intervention is usually adequate for most patients with acute cocaine-related cardiovascular toxicity.

Hypertension and sinus tachycardia usually respond to sedation alone. Nonspecific sympatholysis with benzodiazepines is recommended as first-line treatment.^{14,41,150-152} When hypertension and tachycardia do not respond to sedation and are associated with end-organ dysfunction

(e.g., myocardial ischemia, confusion, headache, congestive heart failure), treatment with nitroprusside, calcium channel blockers (e.g., verapamil), or nonselective α -adrenergic agents (e.g., phentolamine) are recommended.^{14,41,48,151,152} The use of a β -adrenergic antagonist therapy alone is generally contraindicated for treatment of cocaine toxicity. These agents may result in unopposed α -adrenergic stimulation and worsened end-organ toxicity (e.g., increased coronary vasospasm, worsening hypertension).^{14,41,49,151,152}

Patients with cocaine toxicity may present with palpitations and supraventricular tachycardia. Treatment of the patient with no evidence of coronary artery disease includes observation, sedation with benzodiazepines, and the occasional judicious use of calcium channel blockers (e.g., verapamil or diltiazem) for heart rate control.¹⁵³ Adenosine may be used but its efficacy is questionable due to the transient nature of its effects as compared with the sympathomimetic effects of cocaine. Synchronized cardioversion may be necessary for unstable patients with arrhythmias. The use of β -adrenergic antagonists is contraindicated in these patients for the reasons stated above. Although the data are controversial, the use of labetalol is usually not recommended since it is largely a β -adrenergic antagonist (β - to α -effect of 6 to 1).^{14,41,151,152,154,155}

Ventricular arrhythmias are best treated with lidocaine, sodium bicarbonate, and nonspecific sedation with benzodiazepines.^{14,41,151,152} The correction of hypoxia and metabolic and electrolyte abnormalities are critically important. Sodium bicarbonate (1-2 mEq/kg intravenous boluses) administration is recommended as a first-line treatment for ventricular or wide-complex arrhythmias immediately after cocaine use, when the fast sodium-channel (type I) blocking effects of cocaine are most likely to be operative.^{14,41,151,152} Sodium bicarbonate has been shown to reverse cocaine-induced QRS complex prolongation in animal studies and human case reports.^{71,156,157} Lidocaine is recommended as first-line treatment when ventricular arrhythmias are attributed to cocaine-induced myocardial ischemia.^{14,41,151,157,158} Although lidocaine itself is a fast-sodium channel blocker, lidocaine competitively antagonizes the sodium channel-blocking activity of cocaine.¹⁵⁷ Unlike cocaine, which has slow on-off sodium channel-binding kinetics, lidocaine has rapid on-off binding kinetics at the sodium channel.¹⁵⁷ Lidocaine does not prolong action potential duration or the QRS interval, and its presence could partly reverse the prolongation that occurs in the presence of toxic concentrations of cocaine. Based on most animal and human clinical data, lidocaine is likely safe and effective for use in cocaine poisoning.^{157,158}

Intravascular volume replacement, diuretics, cardiotoxic and inotropic agents, and careful vasopressor support have all been utilized in cocaine-induced cardiomyopathy with congestive heart failure.¹⁴ Monitoring of central venous or pulmonary artery wedge pressure may be necessary for titration of these agents. Short-term use of intra-aortic balloon pumps also has been reported to augment cardiac function during transient myocardial dysfunction. General supportive care is important in

MILD COCAINE TOXICITY	SEVERE COCAINE TOXICITY	EVALUATE FOR OTHER AGENTS
↓ β-Adrenergic blockers (e.g., esmolol, metoprolol) may be contraindicated (see text) Nitrates (e.g., nitroglycerin) Sedation (e.g., diazepam)		
↓ CNS, central nervous system; PEEP, positive end-expiratory pressure; IV, intravenous.		

maintaining cardiovascular function during cocaine-induced cardiac toxicities. Discontinuation of cocaine use appears to be the most prudent way of reversing or limiting the progression of cocaine-induced chronic cardiomyopathy.

Myocardial Ischemia

Recommendations are based on two recent reviews of cocaine-induced myocardial ischemia and the recently revised consensus guidelines on emergency cardiovascular care from the American Heart Association in collaboration with the International Liaison Committee on Resuscitation.^{14,41,151,152} Patients with suspected cocaine-induced myocardial ischemia or MI should be treated initially with oxygen, parenteral benzodiazepines, aspirin, and nitrates. Both benzodiazepines and nitroglycerin have been shown to improve hemodynamics (reduce rate-pressure product) and resolve chest pain in patients with cocaine-associated chest pain and suspected myocardial ischemia.^{41,150,159} As previously noted, use of β-adrenergic antagonists is contraindicated because they may result in unopposed α-adrenergic effects and exacerbate coronary vasoconstriction associated with cocaine.^{14,41,49,151,152,154} The specific use of labetalol, although not recommended, cannot be considered an absolute contraindication based on the scientific data available to date.^{151,152} In humans undergoing cardiac catheterization and given intranasal cocaine, labetalol reversed cocaine-induced increases in mean arterial pressure but had no effect on cocaine-induced vasoconstriction of coronary arteries.¹⁵⁵ The use of calcium channel blockers (specifically, verapamil), the α-blocker phentolamine, and heparin therapy are considered second-line therapies for cocaine-induced coronary ischemia.^{41,151-153} Both verapamil and phentolamine have been shown to reverse coronary artery vasoconstriction in human volunteers given intranasal cocaine immediately prior to cardiac catheterization.^{48,153}

If medical management does not eliminate cocaine-induced myocardial ischemia, primary percutaneous intervention (diagnostic and therapeutic cardiac catheterization) is recommended over rapid reperfusion with thrombolytic therapy.^{14,41} The increased risk for cerebrovascular hemorrhage with cocaine-induced toxicity

requires that the use of thrombolytics in this patient population be carried out with extreme care.^{14,41} Thrombolytic therapy has not been proven safe or effective in patients with cocaine-associated MI.¹⁶⁰ In addition, it is usually difficult to base treatment decisions in this patient population on ECG criteria for an MI, which are both insensitive and nonspecific. In general, the mortality of cocaine-induced MI patients that make it to the hospital alive is less than 2%.^{14,41} The morbidity and mortality are likely to be increased with the use of thrombolytic therapy. Major intracerebral hemorrhage has been reported in more than 5% of published cases of cocaine-induced MI treated with thrombolytic therapy. Thrombolysis should only be considered when the diagnosis of cocaine-induced MI is firm and cardiac catheterization is not available. As mentioned, the use of lidocaine is recommended for ventricular arrhythmias felt secondary to myocardial ischemia. In review of the use of lidocaine in 29 patients with cocaine-associated MIs, no enhanced cocaine toxicity was seen.¹⁵⁸

Central Nervous System Toxicity

Sedation with benzodiazepines (e.g., diazepam) is the first-line treatment for CNS agitation associated with cocaine; large doses may be necessary.^{99,100,161} Although controversial, the adjunctive use of neuroleptics (e.g., droperidol, haloperidol, or ziprasidone) may be effective for the control CNS agitation produced by cocaine.

Successful treatment of cocaine-induced hyperthermia requires early recognition, rapid cooling, and aggressive supportive care.^{98-100,102} Cooling methods include rehydration with cooled intravenous fluids; cool water mist and fans (evaporative and convective cooling); ice packs; ice water baths; and ice water, gastric, peritoneal, rectal, or bladder lavage. Since cocaine-induced hyperthermia is predominantly secondary to increased muscle activity, prompt peripheral muscle relaxation is essential to minimize morbidity and mortality. Sedation with benzodiazepines may be tried initially for mild cases of hyperthermia. Nondepolarizing neuromuscular paralysis (e.g., pancuronium), however, which provides rapid, predictable, and effective termination of motor hyperactivity, should be instituted for severe or refractory hyperthermia.^{98,100,102} When canines given intravenous

lethal doses of cocaine are ventilated and pretreated with pancuronium, hyperthermia, metabolic acidosis, and mortality can be prevented.⁹⁹

Seizures associated with cocaine are generally best treated with benzodiazepines (e.g., lorazepam) followed by barbiturates (e.g., phenobarbital, pentobarbital), if necessary. The efficacy and safety of phenytoin has not been established. Animal studies suggest that other antiepileptics (e.g., felbamate and gabapentin) may also be effective for cocaine-induced seizures.¹⁶²

Treatment for other neurologic complications of cocaine abuse is supportive. Subarachnoid hemorrhage and intracerebral bleeding may be associated with an underlying cerebral saccular aneurysm or vascular malformation and may require neurosurgical intervention. Transient ischemic attacks and ischemic cerebrovascular accidents are treated symptomatically and may require empiric therapy with aspirin and heparin. The use of thrombolytic therapy for acute ischemic strokes associated with cocaine has not been studied and is theoretically dangerous. Migraine-like headaches produced by cocaine have been reported to improve with ergotamine treatment. However, there is theoretical concern about the use of another vasospastic agent such as ergotamine in view of the vasospastic side effects of cocaine itself. The use of serotonergic agonists (e.g., triptans) for cocaine-induced migraine headaches has not been reported.

Pulmonary Complications

The management of pulmonary complications associated with cocaine use is supportive.⁸⁹ Supplemental oxygen, bronchodilator therapy, steroids, and mechanical support may be necessary for cocaine-induced bronchospasm. Oxygen, diuretics, and intubation with or without positive end-expiratory pressure (PEEP) have been used successfully and may be necessary for patients with cocaine-induced pulmonary edema.⁸⁹ In addition to PEEP, the lengthening of inspiratory time intervals can also increase the functional residual capacity and may also enhance oxygenation. Empiric treatment with corticosteroids for BOOP and eosinophilic pulmonary syndromes is recommended, but efficacy has been variable.^{88,89} Patients with pneumomediastinum or pneumopericardium should be admitted and observed for the subsequent development of a pneumothorax.⁸⁹ Chest tube placement is necessary for patients with large pneumothoraces or those who do not resolve or worsen with high-flow oxygen. It is important to inform patients that barotraumatic complications may recur with repeated use of crack cocaine.⁸⁹

Rhabdomyolysis and Renal Failure

Treatment of cocaine-induced rhabdomyolysis and renal failure is supportive. Aggressive rehydration is recommended to correct hypovolemia and prevent myoglobin precipitation in the renal tubules. Isotonic normal saline is recommended initially to establish and maintain a

urine flow of at least 2 mL/kg/hr. Careful monitoring of electrolytes (e.g., phosphate, calcium, potassium) is necessary. Although not proven effective, most experts recommend the administration of bicarbonate-rich fluids to alkalinize the urine (urine pH > 7) and prevent myoglobin precipitation in the renal tubules. Hemodialysis may be necessary for acute renal failure.

Body Stuffers and Packers

Whole bowel irrigation, endoscopy, surgery, cathartics, and repeat doses of activated charcoal have been used to treat patients who have ingested packets of cocaine.^{115,143,145,146,163-165} In a series of 34 body stuffers in Chicago, 74% remained asymptomatic, 18% had mild symptoms, 4% had moderate symptoms, and 4% had severe symptoms leading to death. Abdominal radiography, decontamination, and benzodiazepines appeared to be useful.¹⁶⁶ In another series of patients, approximately 3% of patients that ingested cocaine packets required surgical removal for obstruction or toxic effects.¹⁶⁷

Asymptomatic body packers and stuffers may be treated conservatively with simple observation in an ICU until spontaneous passage of the packets has occurred.^{115,116,167} Alternatively, GI tract decontamination with activated charcoal (to bind any cocaine that may leak out of the packets) coupled with whole bowel irrigation may be performed to enhance passage of the packets (see Chapter 2B). Whole bowel irrigation should be continued until complete clearance of the drug packets has occurred from the GI tract. Abdominal imaging with contrast and the passage of several packet-free stools is used to confirm passage of all cocaine packets.^{115,145} Symptomatic body stuffers should be treated similarly to other symptomatic cocaine-intoxicated patients. In addition, GI tract decontamination with activated charcoal is important for these patients to limit further cocaine absorption.^{115,146} Symptomatic body packers, either from mechanical bowel obstruction or perforation or from cocaine poisoning, require immediate surgical removal of drug packets.^{115,116} Although endoscopy has been used to remove cocaine packets from the stomach or proximal small bowel, operative removal is still recommended due to the risk for packet rupture during endoscopic removal.¹¹⁵

DISPOSITION

The level (intensive care or floor) and duration of medical care are dependent on the severity and duration of toxicity. If signs and symptoms of toxicity are mild to moderate and resolve after a 4- to 6-hour observation period in the ED, patients may be medically discharged. Patients with altered mental status, persistent abnormal vital signs, nonsinus rhythms, or significant end-organ toxicity (e.g., rhabdomyolysis) should be admitted for further care and observation. Patients with cocaine-associated chest pain who are not at high risk for acute coronary syndrome may be admitted to a 9- to 12-hour chest pain observation unit.⁴⁵ These patients may

subsequently be discharged with close follow-up if they “rule out” for MI by troponin testing and cardiovascular complications do not occur during their 12-hour observation.⁴⁵ Body packers and stuffers usually require ICU admission for observation and treatment.¹¹⁵ After clinical toxicity has resolved, referral for psychiatric follow-up care may be needed, as may serologic testing for viral hepatitis and human immunodeficiency virus. Evaluation for complications attendant to intravenous drug abuse (e.g., endocarditis, sexually transmitted diseases, etc.) should also be considered.¹⁶⁸

43 *Dissociative Agents: Phencyclidine, Ketamine, and Dextromethorphan*

IVAN E. LIANG, MD ■ EDWARD W. BOYER, MD, PHD

At a Glance...

- Phencyclidine, ketamine, and dextromethorphan are structurally related chemicals referred to as dissociative agents.
- The dissociative agents produce their psychotomimetic effects by antagonizing *N*-methyl-*D*-aspartate receptors in the central nervous system.
- Clinical effects of overdose include euphoria, a trance-like state, nystagmus, and, occasionally, violent behavior; hyperthermia, rhabdomyolysis, metabolic acidosis, and cardiovascular collapse may ensue. Coma and seizures may occur in severe overdose.
- Patients are often anesthetized and may be unaware of serious injuries.
- All of the dissociative agents may produce a positive urine toxicology screen for phencyclidine.
- Treatment for dissociative agent overdose is supportive. Benzodiazepines or haloperidol are preferred agents for chemical restraint.

Phencyclidine (phenylcyclohexyl piperidine, or PCP), ketamine [2-(*O*-chlorophenyl)-2-methylamino cyclohexanone], and dextromethorphan [(+)-3-methoxy-17-methyl-9a,13a,14a-morphinan] (Fig. 43-1) are structurally related chemicals that are abused for their dissociative properties. Because these drugs are often used in club settings, the prevalence of their use may have increased dramatically over the past decade. Intoxication with these agents produces a syndrome of sympathetic activation, central nervous system depression, and hallucinations.

EPIDEMIOLOGY

Accurate estimation of the abuse prevalence of phencyclidine, ketamine, and dextromethorphan is difficult. Because these substances are frequently taken in conjunction with other drugs, individuals suffering the effects of multiple drug use may present with a confusing clinical picture that prevents clinicians from accurately identifying the substances used. Nonetheless, the Drug Abuse Warning Network (DAWN) in 2003 identified a dramatic increase in the use of phencyclidine in several metropolitan areas. Data from the American Association of Poison Control Centers' Toxic Exposure Surveillance System (TESS) in 2002 identified 918 phencyclidine exposures with 6 deaths.¹ The DAWN data also observed significant increases in ketamine reports that were likely related to its abuse in party settings such as in raves and circuit parties. In 2002, TESS reported 342 ketamine exposures. Similarly, dextromethorphan was identified by DAWN as having a significantly increased prevalence of abuse. Data from TESS suggest that abuse or misuse of

the drug by adolescents between ages 13 and 19 has increased more than 300% over a 3-year period.² Dextromethorphan abuse has been observed in children as young as 11.³

Dissociative agents are widely available in pill, powder, and injectable form. Phencyclidine is more commonly sold as a powder, but has been recently reported as an additive to marijuana cigarettes in metropolitan areas. Ketamine is difficult to synthesize; therefore, it is diverted from pharmaceutical or veterinary sources in injectable or powdered formulations.⁴ Abused dextromethorphan is commonly diverted from over-the-counter cough and cold products that are widely available in stores.⁴ Even individuals not intending to take dissociative agents may inadvertently receive them since ketamine and dextromethorphan are commonly used as adulterants in tablets purportedly containing methylenedioxymethamphetamine (MDMA, or "Ecstasy").⁵⁻⁷

NEUROPHARMACOLOGY

Phencyclidine, ketamine, and dextromethorphan exert their psychotomimetic effects by antagonizing with high affinity the *N*-methyl-*D*-aspartate (NMDA) receptors in limbic and cortical structures, inhibiting the release of excitatory amino acid neurotransmitters.^{8,9} Dissociative drugs bind to the Ca²⁺ cation channel of the NMDA receptor to modulate glutamate neurotransmission, the end result of which is the production of specific neurobehavioral findings such as dissociative, "out-of-body" experiences.^{7,9} When used for licit purposes such as procedural sedation, these experiences are known as "emergence reactions." NMDA receptor antagonism may selectively interrupt association pathways of the brain before producing somesthetic sensory blockade, and may also selectively depress the thalamoneocortical system before depressing the reticular activating and limbic systems. Dissociative agents also produce dose-dependent reuptake blockade of norepinephrine, dopamine, and serotonin, which contributes to the psychomotor, sympathomimetic, and psychotomimetic effects associated with these agents.⁹ In recreational doses, PCP,

Phencyclidine (PCP) Ketamine Dextromethorphan
FIGURE 43-1 Chemical structure of dissociative agents.

ketamine, and dextromethorphan (large via its active metabolite, dextrorphan) bind with high affinity to nonopiate σ receptors, which may contribute to their antinoceptive and sedative activities. As a nonanalgesic opiate, dextromethorphan produces antitussive activity by selectively binding to δ receptors without exhibiting classic opiate effects that occur from binding to μ and κ opiate receptors. In high doses, PCP and ketamine also bind to opioid and nicotine and muscarinic acetylcholine receptors.

PHENCYCLIDINE

Phencyclidine (PCP, “angel dust,” “PeaCe Pill”) was originally marketed in 1957 as a preinduction anesthetic agent that was not associated with cardiorespiratory depression.¹⁰ Many patients in their postoperative course, however, developed extreme agitation and dysphoria.¹⁰ Phencyclidine therefore was removed from the marketplace, although it was reintroduced as the veterinary product Senylan (Parke-Davis, Detroit, MI). Phencyclidine emerged as a hallucinogen in the 1960s but did not reach full popularity until the 1970s.^{11,12} It was classified as a schedule I substance in 1978, and its use declined during the 1980s.¹³ Over the past 5 years, however, increasing numbers of PCP abusers appear to smoke the drug with another substance such as marijuana.¹⁴⁻¹⁷

Pharmacology

Phencyclidine is a highly lipophilic, water-soluble weak base. It is rapidly absorbed following oral, intranasal, intramuscular, intravenous, pulmonary, or rectal administration. Absorption is minimal in the stomach, but occurs rapidly in the duodenum and jejunum.^{15,16} Onset of effects occurs within 30 to 60 minutes when ingested, but may be as rapid as 2 minutes after smoking.¹⁵ Acute toxicity often persists for 4 to 6 hours, and generally resolves within 48 hours.¹⁶ At oral doses of between 5 and 10 mg, toxic psychoses and violent behavior are described.¹⁸ Oral doses greater than 10 mg are associated with schizophreniform reactions, although the dose-response relationship is incompletely defined.¹⁸

Phencyclidine distributes widely in tissues.^{16,18} It possesses an unusual enterogastric circulation in which significant amounts of the drug are actively secreted into the stomach and then reabsorbed in the small intestine.¹⁵ The concentration of PCP in gastric fluid may be 50 times higher than in the serum.¹⁵ The concentration in the brain may be up to nine times that of the serum.^{15,16} The slightly acidic milieu of the cerebrospinal fluid (CSF) induces ion trapping of the compound, an effect that explains the prolonged neurologic effects of the drug.¹⁶

The apparent volume of distribution of phencyclidine is 6.3 L/kg, and the drug is 78% protein bound.¹⁵ The large volume of distribution and lipophilicity contribute to PCP’s persistence in the body and its long duration of action. Phencyclidine is hepatically metabolized in a

stepwise manner, first by oxidative hydroxylation to an inactive metabolite that undergoes glucuronidation. This water-soluble derivative is the major metabolite that is renally eliminated. Significant first pass metabolism occurs after ingestion, an effect that is not observed following pulmonary or parenteral administration.¹⁵ More than 90% of users excrete metabolites in the urine for up to 7 days after exposure, while chronic abusers do so for up to 4 weeks after last use.¹⁹ Ten percent of an ingested dose is excreted unchanged in the urine.

Clinical Effects

No therapeutic indications are described for PCP, although NMDA antagonists may have theoretical utility in preventing neuronal injury following cerebral hypoxic/ischemic insult.^{20,21}

Phencyclidine exhibits a broad variety of clinical effects, some of which are unpredictable but which are generally dose related.²¹ Violent behavior, rotatory nystagmus, hypertension, anesthesia, and analgesia are the most characteristic signs of intoxication.^{21,22} At elevated doses, PCP will produce a dissociative condition characterized by a catatonic, trancelike state but may include a sense of euphoria, omnipotence, tremendous strength, and sexual prowess.²³ Seizures are described at high doses, and coma may occur, persisting for up to 10 days.²² Lower doses of phencyclidine will produce ataxia, slurred speech, profuse diaphoresis, and neuromuscular rigidity.²¹ The most common causes of death from PCP overdose involve trauma or occur as the sequela of physical restraint of severely agitated patients, with attendant hypothermia, rhabdomyolysis, metabolic acidosis, and cardiovascular collapse.²⁴

The neurologic examination may reveal horizontal, vertical, or rotatory nystagmus, a prominent finding that occurs in over half of all intoxicated patients.^{21,22} Pupils may be miotic and reactive, and reflexes are briskly hyperactive. Increased muscle strength is commonplace, and several attendants may be required to restrain agitated patients. Patients are anesthetic and are often unaware of injuries, a quality that results from the dissociative effects of the drug.²²

Prominent psychiatric effects of phencyclidine include violent, aggressive behavior that, when combined with a sense of tremendous strength, is troublesome for caretakers.²¹ Patients may also demonstrate mania, but catatonia and visual hallucinations are common.²⁵ Physiologic dependence on PCP in the absence of clear physiologic symptoms is described, as is an abstinence syndrome characterized by depression, anxiety, and irritability.²⁶ Long-term PCP abuse is associated with diminished abstract thought and incidental memory.²⁶

A temperature greater than 38.8°C (101.8°F) was identified in 2.6% of patient in one series of PCP intoxications.²² Hyperthermia in PCP overdose may arise from isometric muscle contraction and may portend significant morbidity.²⁷ Elevations in serum transamines, rhabdomyolysis, clotting abnormalities, hepatic injury, and renal failure probably arise as a consequence of poorly treated hyperthermia and muscle trauma.

Diagnosis

The diagnosis of phencyclidine poisoning can be inferred from history and physical examination findings, and is confirmed by laboratory testing. Rotatory nystagmus is an important clinical clue to establishing the diagnosis.^{21,22} Because PCP is lipophilic and may be detected in the urine for up to 4 weeks, urine is the preferred specimen for detection.¹⁹ If present, PCP should elicit a positive result on qualitative urine toxicologic screen. Quantitative measurement of phencyclidine in plasma is not recommended because clinical signs and symptoms do not correlate well with plasma concentrations.

Patients in whom phencyclidine intoxication is suspected should have electrolytes, blood urea nitrogen, creatinine, transaminases, coagulation times, glucose, and serum creatine phosphokinase concentrations measured. Hyperthermic patients deserve measurement of arterial pH. Clinicians should remain vigilant for electrolyte disturbances, metabolic acidosis, and renal failure.

KETAMINE

Initially developed as a veterinary anesthetic, ketamine is structurally similar to PCP (see Fig. 43-1). Ketamine is often diverted from veterinary or pharmaceutical sources and is sold either in powdered or liquid form or as an adulterant in club drug (“Ecstasy”) pills.

Pharmacology

The pharmacology of ketamine is similar to that of phencyclidine. Ketamine can be administered via oral, intranasal, intramuscular, intravenous, and rectal routes.²⁸ Ketamine is a weakly basic amino compound (pKa of 7.5) with close structural similarity to phencyclidine.²⁸ It is commercially available as 1:1 racemic mixtures of the S(+) and R(-) enantiomers of the hydrochloride salt. Ketamine undergoes rapid absorption via all routes and distributes within 7 to 10 minutes of intravenous administration into highly perfused tissues such as the brain, heart, and lungs. Concentrations in these organs may be four to five times greater than corresponding plasma levels. Ketamine then undergoes a second redistribution into muscle and, eventually, adipose with a distribution half-life of approximately 10 to 15 minutes.^{8,28-30} Ketamine and its metabolites are moderately protein bound in the serum 60%, 50%, and 69% for ketamine, norketamine, and dehydronorketamine, respectively, in human serum.³¹ Volumes of distribution of ketamine have been reported ranging from 2 to 5 L/kg.²⁹

Ketamine undergoes significant first-pass metabolism via hepatic *N*-demethylation by CYP2D6 to produce norketamine, a compound with one third the activity of the parent compound.^{28,32,33} This metabolite is subsequently hydroxylated and conjugated to water-soluble compounds that undergo renal elimination. Approximately 90% of an administered ketamine dose is eliminated as the conjugated hydroxyl metabolite; about

4% is excreted unchanged. Interestingly, the elimination half-life is approximately 2.5 to 3 hours in adults, but only 1 to 2 hours in children.^{29,33}

The onset of effects depends on the method of administration. In general, anesthetic or therapeutic doses of ketamine are between 1 and 2 mg/kg (approximately 1 mg for a 70-kg patient) for intravenous administration; the dose of ketamine used for recreational purposes is somewhat lower.²⁹ Recreational doses begin at approximately 25 mg and are titrated upward to clinical effect. One method of titration, for example, involves insufflating approximately 25-mg “bumps” of ketamine until the user can no longer feel his or her legs. Clinical effects often resolve within 10 minutes of intraparenteral dosing, but may persist for up to 90 minutes after oral administration.³²

Clinical Effects

Recommended doses of 1 to 2 mg/kg intravenously, up to 4 mg/kg intramuscularly, and 7 mg/kg orally will produce anesthesia and analgesia accompanied by catalepsy with minimal purposeful response to noxious stimuli. The eyes often remain open, with a slow nystagmic gaze; corneal and light responses often remain normal.³⁴ Hypertonic and occasionally purposeful movements may be intermittently noted.³⁴ Subanesthetic doses will produce a spectrum of symptoms, but will often interfere with normal cognition and appropriate responses to environment.³⁴

Ketamine evokes a number of physiologic responses besides anesthesia.^{28,30} The drug increases sympathetic outflow and effect that can be blunted by sedation with benzodiazepines.^{28,30} Ketamine produces elevated cerebrospinal fluid and intraocular pressures, although this effect may be abolished by maintenance of normocapnia and/or benzodiazepine administration.²⁸ The salivary and tracheal-bronchial secretions that accompany ketamine administration are due to the drug’s cholinergic characteristics.²⁸ Despite these secretions, ketamine has been associated with decreases in airway resistance and bronchospasm.²⁸ Respiratory failure from massive doses of ketamine has been described, although this finding occurred in multiple drug use.²⁸

Hallucinations that occur as ketamine anesthesia decreases are described as “emergence reactions” and are the reason for which the drug is diverted to illicit use.^{7,35} Drug users frequently describe cosmic, religious, or near death experiences, visualization of psychedelic colors, and out-of-body experiences that can be characterized as ranging from pleasurable to nightmarish.⁷ During the episode, patients may be mildly agitated, sympathomimetic, or frankly psychotic and delirious. Incidence of emergence reactions is low among children, but has been reported to be as high as 30% in adults.³⁵

Diagnosis

Establishing the diagnosis of ketamine intoxication requires the recognition of subtle physical examination findings. When used illicitly, ketamine does not, in general,

produce the extreme agitation of phencyclidine.³⁵ Instead, intoxicated patients may demonstrate a distinctive, plodding gait as the legs dissociate from the remainder of the body.⁷ Patients may lose fine motor control and experience nausea and vomiting with movement. They may deliver pronouncements that are confusing to sober observers.⁷ In addition to the acute dissociative effects, ketamine is associated with dystonia, paranoia, and rhabdomyolysis.³⁵ This latter finding occurs almost exclusively in patients who receive physical restraints without chemical sedation.

Dependence on ketamine has been described. The chronic effects of ketamine abuse include poor concentration, inhibited learning capabilities, and decreased memory. Ketamine users have described “flashbacks” up to several months after use of the drug.⁷ In addition, habitual users describe tolerance to established doses of ketamine, which can be explained by the ability of ketamine to induce the expression of cytochrome P-450 enzyme subtypes.²⁸

The diagnosis of ketamine intoxication may be confused by the observation that ketamine produces a false-positive result on qualitative urine assays for phencyclidine.³⁶

DEXTROMETHORPHAN

The easy availability of dextromethorphan in over-the-counter preparations contributes to its increasing abuse by younger adults. Data from the TESS database suggest that abuse or misuse of the drug has increased more than 300% over a 3-year period in adolescents between the ages of 13 and 19.² Abused dextromethorphan products are sometimes known by users as “Triple C” from the three Cs whose imprint is used to identify some products that are preferred for abuse, but gelcap formulations of dextromethorphan are also called “Skittles” or “Red Hots” because of the similarity in appearance between the drug and the popular candies.^{37,38} Unwitting users may not recognize that some over-the-counter dextromethorphan formulations may contain acetaminophen or anticholinergic agents, which cause their own toxicity.

Pharmacology

Dextromethorphan is available in oral formulation; it is well absorbed following ingestion with maximum serum concentrations at 2.5 hours.³⁹ The major metabolite of dextromethorphan, dextrorphan, achieves peak plasma concentrations at 1.6 to 1.7 hours following ingestion.⁴⁰ The volume of distribution of dextromethorphan in humans is not firmly established, but is thought to be large (5.0 to 6.7 L/kg).²⁹ Dextromethorphan and its metabolites undergo renal elimination, with less than 0.1% of the drug being eliminated in the feces.²⁹ The half-life of the parent compound is approximately 2 to 4 hours in individuals with normal metabolism.

Dextromethorphan is metabolized by cytochrome CYP2D6. In humans, CYP2D6 is a genetically polymorphic enzyme responsible for metabolizing numerous

substances.⁴¹ Rapid metabolizers—those individuals with extensive CYP2D6 activity and, hence, increased rates of dextromethorphan metabolism—constitute about 85% of the U.S. population. Dextromethorphan undergoes 3-demethylation to dextrorphan and, to a lesser extent, *N*-demethylation to 3-methoxymorphinan.^{40,41} Both of these metabolites are further demethylated to 3-hydroxymorphinan. Dextrorphan is the active metabolite that produces neurobehavioral effects, while dextromethorphan does not exhibit the same actions. Dextromethorphan is therefore a prodrug, and the metabolic conversion of dextromethorphan to dextrorphan is an important determinant of the abuse potential of dextromethorphan in an individual. Experienced dextromethorphan users describe tachyphylaxis to the drug, but whether this effect is from alterations in cytochrome function or other effects is not known.

Clinical Effects

The dose of ingested dextromethorphan determines the neurobehavioral outcome. Recreational users of dextromethorphan describe several intensities of effect from the drug, known as “plateaus.”⁴² The first plateau is a mild stimulant effect similar to that of methylenedioxymphetamine. The second plateau is described as similar to a combination of concurrent ethanol and marijuana intoxication, although some users describe hallucinations as occurring at this stage.⁴³ The third level is a dissociative, “out-of-body” state like that produced by a low recreational dose of ketamine, and the fourth plateau is a fully dissociative condition similar to that produced by ketamine intoxication.⁴² Neurobehavioral effects begin within 30 to 60 minutes of ingestion and persist for approximately 6 hours.

To produce nominal effects from dextromethorphan—the first plateau—online drug encyclopedias such as Erowid (www.erowid.org) describe a dose of between 100 and 200 mg (1.5–2.5 mg/kg). The second plateau may be achieved with 200 to 400 mg (2.5–7.5 mg/kg), and the third plateau can be achieved with 300 to 600 mg (7.5–15 mg/kg) of the drug. An ingested dose of 600 to 1500 (>15 mg/kg) mg of dextromethorphan may produce a full-blown dissociative state. These doses depend on several factors, such as an individual’s CYP2D6 subtype and body weight as well as the degree of tolerance to dextromethorphan.

The clinical presentation of dextromethorphan intoxication therefore depends on the ingested dose. Minimally intoxicated persons may develop tachycardia, hypertension, vomiting, mydriasis, diaphoresis, nystagmus, euphoria, loss of motor coordination, and giggling or laughing.⁴² In addition to the above findings, persons with moderate intoxication may demonstrate hallucinations and a distinctive, plodding ataxic gait that has been compared to “zombie-like” walking.⁴³ Severely intoxicated individuals in a dissociated state may be agitated or somnolent.^{38,42,44,45} Extremely agitated patients may develop hyperthermia and metabolic acidosis.

Experienced dextromethorphan users describe a rapidly developing and persistent tolerance to the drug.⁴² Dependence on dextromethorphan is rarely described.⁴⁶⁻⁴⁸

Although dextromethorphan is not thought to have addictive properties, susceptible individuals may develop craving and habitual use of the drug.^{44,49} An abstinence syndrome may be associated with cessation of dextromethorphan abuse that is characterized by dysphoria and intense cravings.^{46,48,50,51} Toxic psychosis and cognitive deterioration may arise from chronic use of the drug.^{46,50,51}

Toxicity in the setting of dextromethorphan abuse can arise from additional sources. Over-the-counter cough formulations frequently contain, in addition to dextromethorphan, other pharmaceutical agents such as chlorpheniramine, acetaminophen, or pseudoephedrine.⁵² Chlorpheniramine is an H₁ receptor antagonist. Consequently, individuals who have abused chlorpheniramine-containing dextromethorphan formulations may also exhibit anticholinergic signs and symptoms, such as tachycardia; warm, dry, flushed skin; dry mucosa; mydriasis; agitated delirium; urinary retention; and gastrointestinal dysmotility (see Chapter 39). Severe chlorpheniramine intoxication has also been associated with seizure activity, rhabdomyolysis, and hyperthermia.³⁸ Pseudoephedrine intoxication may mimic that of chlorpheniramine except that patients may exhibit diaphoresis. In contrast, overdose of acetaminophen, an antipyretic and analgesic that is a component of over 100 cough and cold preparations, produces delayed hepatic injury and, potentially, death. Lastly, because dextromethorphan is produced as the crystalline hydrobromide salt, bromism is a rare consequence that has been identified in heavy chronic abusers of dextromethorphan.⁵³

Drug interactions exist between dextromethorphan and other substances, the best characterized of which is serotonin syndrome. Dextromethorphan and its active metabolite, dextrorphan, block reuptake of serotonin in central nerve terminals. This condition typically occurs from the interaction between dextromethorphan and selective serotonin reuptake inhibitors or monoamine oxidase inhibitors, but concurrent administration of antibiotics (e.g., linezolid), opiate analgesics (e.g., meperidine and tramadol), or drugs of abuse (e.g., Syrian rue) could precipitate the condition.⁵⁴ Patients with serotonin syndrome may demonstrate the clinical triad of mental status changes, autonomic instability, and muscular hypertonicity⁵⁵ (see Chapters 10A and 29).

Diagnosis

The diagnosis of dextromethorphan intoxication relies on epidemiologic, historical, and physical examination findings. Younger adolescents may be at increased risk for dextromethorphan abuse.⁵⁶ In addition, data from the National Institute on Drug Abuse's Community Epidemiology Working Group and other sources suggests that pharmaceutical abuse may be more prevalent among females.⁵⁷⁻⁵⁹ On history, patients may report the abuse of dextromethorphan-containing products. The diagnosis of dextromethorphan intoxication is otherwise made on clinical grounds, with attention directed to signs and symptoms of dissociative use: tachycardia, hypertension, diaphoresis, ataxia, nystagmus, and, potentially, hallucinations, but clinicians should remain

aware that specific findings depend on the degree to which individuals are intoxicated. The differential diagnosis of dextromethorphan intoxication includes other potentially serious toxidromes. Patients with ataxia, nystagmus, and mental status changes may suffer from ketamine or phencyclidine abuse, lithium intoxication, phenytoin or carbamazepine poisoning, serotonin syndrome, Wernicke-Korsakoff syndrome, and sedative-hypnotic, including ethanol, abstinence syndromes.⁴⁸

Although dextromethorphan does not produce true positive results on toxic screens or cross-react with the opiate portion of the screen, the molecule may produce false-positive results on qualitative urine assays for phencyclidine.^{60,61}

TREATMENT
